HP-5890 Series II gas chromatograph (GC) with appropriate column and 4.0 mm-i.d. × 6.3-mm-o.d. × 78.5-mm Restek uniliner coupled in-line to a VG 70-250SEQ mass spectrometer (Micromass UK) with EI/CI ion source and oscilloscope

1. Vent the VG 70-250SEQ mass spectrometer to atmospheric pressure. Install the ion source (EI/CI source) and the appropriate GC-column.
2. Evacuate the air and bring the mass spectrometer under vacuum and set the instrumental parameters as follows:

GC (HP-5890 Series II) conditions:	
Carrier gas:	99.999% helium, head pressure of 10 psi
Injector temperature:	290°C
Oven temperature:	200°C
Injection mode:	Direct (splitless)
Liner:	4.0-mm-i.d. × 6.3-mm-o.d. × 78.5-mm
MS conditions:	
Methane pressure:	4×10^{-5} mbar (as read by the pirani gauge)
Source temp:	250°C
Slit:	CI
CI mode:	Negative
Emission current (EC):	0.2–1 mA
Electron energy (EE):	50–150 eV
GC transfer-line temp:	300°C
Septum reservoir temp:	150°C
Septum transfer-line temp:	175°C

3. Introduce 1 µl perflurokerosine (PFK) or perfluorotributylamine (FC43) to the septum inlet.
4. Tune the mass spectrometer at a mass resolving power (RP) of 1000 for a particular ion from PFK or FC43, choosing the tuning ion closer to the monitoring masses of the analyte and the internal standard (IS). Adjust the emission current (EC), electric energy (EE), and lenses to give the highest intensity of the tuning ion displayed on the oscilloscope in the front console.
5. Close the source slit until the ion intensity is decreased to 10% of that in step 4.
6. Close the collector (analyzer) slit until the ion intensity is further decreased 50% of that in step 5.
7. Retune the mass spectrometer for the same ion at RP 10,000.

   After this tuning at RP 10,000 the peak width is 10% and the ion signal ~5% from the original signal (step 4) at RP 1000.

8. Set the instrumental parameters (Tables 3.9.3 to 3.9.5) for each adduct and calibrate the instrument using appropriate reference compound (PFK or FC43).
9. Set the multiplier voltage to 9.

   This can vary from 7 to 10 depending on the concentration of the adduct in the biological sample. The ion abundance (peak area from the ion chromatogram) should not exceed saturation level (1×10^9).

10. Adjust the needle valve until the lock mass from the reference compound is ~5 to 10 V as measured from the console (oscilloscope).
11. Finally inject 2 µl of the sample in toluene to be analyzed by GC/ECNCI/HRMS. Measure the area of the analyte and the internal standard in the ion chromatograms and calculate the concentration of the adduct using the corresponding calibration curve.

Table 3.9.3 Selected Ion Monitoring Experiment and GC Program for εGua[a]

Channel	Mass	Dwell time (msec)	Delay time (msec)
Lock (PFK)	354.9792	50	20
PFK	354.9792	20	20
εGua	354.0413	50	20
$^{13}C_4$,$^{15}N_2$ εGua (IS)	360.0489	50	20

[a]Results are for 30-m × 0.32-mm × 0.1-mm-thickness DB-5^{MS} fused silica capillary column (J & W Scientific). Column temperature program: held 30 sec at 100°C (initial), increasing 20°C/min to 290°C, held 3 min, increasing 50°C/min to 300°C, and held 2 min.

Table 3.9.4 Selected Ion Monitoring Experiment and GC Program for 7-HEG[a]

Channel	Mass	Dwell time (msec)	Delay time (msec)
Lock (FC43)	556.9695	50	20
Check (FC43)	556.9695	20	20
7-HEG	555.0515	50	20
$^{13}C_4$-7-HEG (IS)	559.0649	50	20

[a]Results are for 15-m × 0.32-mm × 0.1-mm-thickness DB-5^{MS} fused silica capillary column (J & W Scientific). Column temperature program: held 1 min at 70°C after injection, raised at 20°C/min to 290°C, and held 3 min.

Table 3.9.5 Selected Ion Monitoring Experiment and GC Program for 7-HPG[a]

Channel	Mass	Dwell time (msec)	Delay time (msec)
Lock (FC43)	575.9679	50	20
Check (FC43)	575.9679	20	20
7-HPG	569.0671	50	20
$^{13}C_4$-7-HPG (IS)	573.0807	50	20

[a]Results are for 15-m × 0.32-mm; 0.1-mm-thickness DB-5^{MS} fused silica capillary column (J & W Scientific). Column temperature program: held 1 min at 70°C after injection, raised 20°C/min to 290°C, and held 3 min.

QUANTIFYING DNA ADDUCTS: LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY (LC/MS)

LC/MS methods are extremely popular for quantitation of biological compounds since they provide the specificity of a mass spectrometric method without requiring labor-intensive and time-consuming sample preparation procedures. Besides the simplified sample preparation procedures, these techniques also have the advantage of employing mild conditions; thus the possibility of sample degradation and formation of artifacts or false positives is minimized. With a continuous decrease in the cost of mass spectrometers, these powerful tools are becoming widely available for routine quantitative analysis of

biological compounds. A typical LC/MS setup uses an HPLC unit coupled to a mass spectrometer using an atmospheric pressure ionization interface—electrospray ionization and atmospheric pressure chemical ionization interfaces being the most common choices. The type of mass spectrometer to use is dictated by the need for sensitivity and specificity. Triple quadrupole mass spectrometers are the best choices since they can provide the sensitivity given by quadrupole mass analyzers and the specificity afforded through use of selected reaction monitoring as mode of detection. A mass spectrometer with single quadrupole or an ion trap mass analyzer could be sufficient, depending on the requirement.

BASIC PROTOCOL 7

Quantification of N7-Guanine Adducts by LC/ESI/IDMS/MS

The authors' laboratory has been using LC/ESI/MS/MS for quantification of mainly N7 guanine adducts (Tretyakova et al., 1998; Koc et al., 1999). Quantification of DNA adducts by LC/MS typically involves hydrolysis of DNA to cleave the adducts from DNA, enrichment of the adducts over unmodified DNA bases, desalting, and quantification by LC/MS. The enrichment step is very critical since unmodified bases may cause sensitivity loss due to signal suppression in ESI ionization. The type of enrichment method that needs to be employed depends on the method of DNA hydrolysis.

Materials

DNA sample
Isotopically labeled internal standard (e.g., $^{13}C_4$-N7-HEG)
100% methanol
SPE reversed-phase cartridge, preferably polar endcapped (e.g., ODS-AQ, Waters Chromatography or Aquasil, Keystone Scientific)
Calf thymus DNA

22-G needles
95° and ~60°C water baths
Centricon 30 filters
Autosampler vial with 250-µl insert
Mass spectrometer with electrospray ionization source and the capability to conduct selected reaction monitoring (e.g., Thermoquest TSQ 7000, Micromass Quattro II)

Perform neutral thermal hydrolysis

N7-Guanine adducts can be removed from the DNA fairly selectively by heating the DNA 30 min at 95°C, leaving most (>95%) of the unmodified bases on the DNA backbone.

1. Shear DNA sample by passing through a 22-G needle five to six times.
2. Transfer 0.1 to 1.0 mg sheared DNA into a microcentrifuge tube, spike with several hundred femtomoles isotopically labeled internal standard, and vortex.
3. Subject the solution to neutral thermal hydrolysis by incubating tubes 30 min in a 95°C water bath. Vortex the tubes two or three times during heating.
4. Cool the tubes on ice and transfer the contents of the tubes into Centricon 30 filters that have been washed with 2 ml water to remove glycerol present in these filters.
5. Centrifuge the Centricon filters at 5000 × *g*, 4°C, until all of the solution is filtered.

   The time needed to filter the sample will vary depending on the volume and DNA concentration.

6. Because some of the sample will be left on the membrane, add ~200 µl water and centrifuge again 5 min at 5000 × *g*, 4°C, to filter more of the solution.

   After the Centricon 30 filtration, DNA backbone will be left on the membrane while N7 adducts will be in the filtrate. DNA backbone can be recovered from the filter by reversing the filter, adding ~100 µl water, and centrifuging into a clean tube.

Desalt the sample

7. Run 5 ml of 100% methanol to regenerate the SPE reversed-phase cartridge. Then equilibrate with ~10 ml water.
8. Load the hydrolysate onto the reversed-phase cartridge by gravity.

   Salts present in the hydrolysate may suppress response in electrospray ionization; therefore, the salts should be removed from the sample before LC/MS analysis. This is typically done with solid-phase extraction cartridges. Alternatively, one can perform the desalting procedure on-line using column switching techniques or by simply diverting the early LC effluent to waste instead of the mass spectrometer.

9. Wash loaded cartridge three times with 1 ml water each.
10. Elute the adducts with 5 ml of 100% methanol into a clean culture tube.
11. Evaporate to dryness (i.e., remove methanol) in a SpeedVac evaporator.
12. Dissolve the contents in ~100 µl water by mild heating in a ~60°C water bath and vortexing
13. Transfer the sample into an autosampler vial with a 250-µl insert and store up to 2 years at −70°C until LC/MS analysis.

Perform LC/ESI/MS/MS analysis

14. Calibrate the mass spectrometer according to manufacturer's procedure.

    For this step, a mass spectrometer equipped with an electrospray ionization source and the capability to conduct selected reaction monitoring (SRM) experiments is used. Triple quadrupole mass spectrometers such as TSQ 7000 (Thermoquest) or Quattro II (Micromass) are most widely used for this purpose.

15. Develop an LC method on a reversed-phase column that enables separation of adducts of interest from possible interferences, mostly normal bases.
16. Using the mobile phase and flow rate used for chromatographic separation, optimize the ESI conditions (e.g., nitrogen flow rate, spray and lens voltages) for maximum sensitivity for the protonated molecular ion.
17. Optimize the collision gas pressure and collision energy to get an efficient dissociation to produce product ion (protonated guanine in this case).
18. Prepare calibration curve standards with calf thymus DNA and run them through the sample preparation procedure as if they were samples.

    A calibration curve is generated and the amount of DNA and internal standard in the calibration standards should be the same as samples.

Analyze samples

19. Prior to running a batch of samples, analyze a low-level calibration standard to make sure that sensitivity is satisfactory for the samples.
20. If satisfied with the sensitivity, inject the sample.

21. Inject standards or quality to control samples after 5 to 10 injections to monitor the instrument performance.

See Koc et al. (1999) for an example method.

QUANTIFYING DNA ADDUCTS: ^{32}P-POSTLABELING

The ^{32}P-postlabeling assay is an ultrasensitive method to detect covalently modified DNA. This technique was developed by Randerath et al. (1981) and has since undergone several refinements to enhance its sensitivity and specificity. Analysis involves enzymatic digestion of DNA to nucleotides, selective 5′-end labeling of chemically-modified nucleotides using [^{32}P]ATP, separation by TLC or HPLC to resolve DNA adducts, and detection of adducts by measuring radioactivity. ^{32}P-postlabeling has been applied to detect structurally diverse DNA adducts but is particularly useful to detect DNA modified by bulky aromatic compounds, such as polycyclic aromatic hydrocarbons (Gupta and Earley, 1988; Randerath and Randerath, 1994). Under optimal conditions, this method can achieve a level of detection as low as 1 adduct per 1×10^{10} nucleotides using 10 µg DNA.

BASIC PROTOCOL 8

^{32}P-Postlabeling Analysis of DNA Adducts

Each DNA adduct generally requires separate method development. The described method should be used as an initial approach. Different methods for adduct enrichment, as well as different chromatography conditions, may be required depending on the DNA adduct.

Materials

100% and 50% methanol
DNA sample
Hydrolysis buffer (see recipe)
0.24 U/µl micrococcal nuclease (Sigma-Aldrich): aliquot and freeze up to 1 year at −80°C
2 mg/ml spleen phosphodiesterase (Sigma-Aldrich), aliquot and freeze up to 1 year at −80°C
0.3 mM $ZnCl_2$
0.25 M sodium acetate, pH 5
5 mg/ml nuclease P1 (Sigma-Aldrich): aliquot and freeze up to 1 year at −80°C
0.5 M Tris base
Kinase buffer (see recipe)
30 U/µl polynucleotide kinase (United States Biochemical): store up to 1 year at −20°C
160 mCi/ml [γ-^{32}P]ATP (7000 Ci/mmol; ICN)
100 mM Bicine, pH 9.6
20 U/µl apyrase (Sigma-Aldrich): aliquot and freeze up to 1 year at −80°C
1 M and 1.7 M NaH_2PO_4, pH 6.0 (*APPENDIX 2A*)
5.3 M lithium formate/8.5 M urea, pH 3.5
1.2 M LiCl/0.5 M Tris·Cl (pH 8.0; *APPENDIX 2A*)/8.5 M urea
0.25 M LiCl
HPLC-grade H_2O

13 × 20–cm PEI cellulose TLC plates, flexible
5 × 20–cm Whatman 17 wick
Blow dryer
2.5-cm Whatman no. 1 filter paper wick
Phosphorescent pen

Incubator or heating block
X-ray film cassette
Darkroom
Liquid scintillation counter

CAUTION: When working with radioactivity, use appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out experiments and dispose of wastes in appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*). All work with radioactivity must be performed using acrylic shielding and monitored using a Geiger counter.

1. Place 100% methanol, 50% methanol, and water in trays, using a sufficient volume to cover 13 × 20–cm flexible PEI cellulose TLC plates. Prepare plates by gently washing plates 5 min per solvent sequentially. Air dry TLC plates.
2. Place 5 µg DNA sample in a microcentrifuge tube and evaporate using a Speedvac evaporator. Add 4 µl water, 2 µl hydrolysis buffer, 2 µl of 0.24 U/µl micrococcal nuclease, and 2 µl of 2 mg/ml spleen phosphodiesterase. Incubate at 37°C for 3.5 hr.

   For greater amounts of DNA, adjust the amounts of enzymes appropriately.
3. Remove 2 µl of the digest.

   This aliquot will be used in step 16 for analysis of total nucleotides.
4. To the remaining DNA digest mixture, add 1.5 µl of 0.3 mM $ZnCl_2$, 3 µl of 0.25 M sodium acetate, pH 5, and 1.5 µl of 5 mg/ml nuclease P1. Incubate at 37°C for 1 hr.
5. Following completion of the nuclease P1 reaction, add 2.4 µl of 0.5 M Tris base.
6. Prepare labeling mixture by mixing 2.4 µl kinase buffer, 0.13 µl of 30 U/µl (4 U) polynucleotide kinase, 0.625 µl of 160 mCi/ml (100 µCi) [γ-^{32}P]ATP, and a volume of 100 mM Bicine, pH 9.6, sufficient to bring the total volume to 5 µl. Add 5 µl labeling mixture to each sample, and incubate at 37°C for 45 min.
7. Following completion of the labeling reaction, add 2 µl of 20 U/µl apyrase and incubate at 37°C for an additional 30 min.
8. Attach a 5 × 20–cm Whatman 17 wick along the bottom of a prewashed 13 × 20–cm TLC plate. Spot the entire incubation mixture onto the TLC plate 1.5 and 2 cm from the left and bottom edges, respectively.
9. Position the plate in the TLC tank with the wick directed outside the tank, and develop overnight in 1.0 M NaH_2PO_4, pH 6.0.
10. Cut off wick, rinse plate in a tray containing water with gentle agitation, and dry using a blow dryer.
11. Develop the plate in the opposite direction using a solution of 5.3 M lithium formate/8.5 M urea, pH 3.5, to the top of the plate.
12. Rinse the plate in water, dry using a blow dryer, and develop 90° to the previous direction in a solution of 1.2 M LiCl/0.5 M Tris·Cl/8.5 M urea, pH 8.0.
13. Rinse plate and dry using a blow dryer. Attach a 2.5-cm Whatman no. 1 filter paper wick, and develop in the same direction as the previous development in a solution of 1.7 M NaH_2PO_4, pH 6.0.
14. Dry plate using a blow dryer and mark with phophorescent pen. Expose to X-ray film in a cassette. Store at −80°C for 12 to 24 hr. Develop film.

15. Align film with the plate using marks from the phophorescent pen as guides. Mark area of plate corresponding to adduct spot, cut, and count using a liquid scintillation counter.
16. To determine the amount of normal nucleotides, dilute 2 µl digest (step 3) with 18 µl water. Prepare labeling mixture as in step 6, except use 10 µCi per sample.
17. Add 5 µl labeling mixture to 2 µl of the diluted sample and incubate 45 min at 37°C.
18. Add 1 ml water, spot 5 µl onto a TLC plate 1.5 cm from the bottom, and develop in 0.25 M LiCl.

    Several samples can be spotted on the same plate 1.5 cm apart.
19. Dry, and expose to X-ray film for 1 hr. Locate radioactive spots on origins, mark, and cut. Count using a liquid scintillation counter.
20. Determine relative adduct labeling by dividing dpm of adducted nucleotides by dpm of total nucleotides. To account for dilution, divide relative adduct labeling by 8000.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Hydrolysis buffer

Combine equal volumes of 200 mM sodium succinate, pH 6.0, and 100 mM $CaCl_2$. Store up to 1 month at 4°C.

Kinase buffer

Combine equal volumes of 200 mM Bicine, pH 9.6, 100 mM dithiothreitol, 10 mM spermidine, and 100 mM $MgCl_2$. Store in ~100-µl aliquots up to 1 year at −80°C.

N7-MG standards

Prepare stock solution by dissolving powder (Sigma-Aldrich) in water, adding concentrated HCl if there are problems with solubility. Make serial dilutions in water to give a range of standards between 1 and 1000 pmol/50 µl. Store up to 6 months at −80°C.

8-OH-dG standards

Prepare stock by dissolving powder (Sigma-Aldrich) in water. Make serial dilutions with water to give a range of standards between 0.005 and 1 pmol/50 µl. Store up to 6 months at −80°C.

PBS/azide

Add 500 ml 10× PBS—i.e., 10 mM phosphate buffer, pH 7.5/0.85% (w/v) NaCl (saline)—and 1 g sodium azide (0.02% w/v final) to 4500 ml water. Store up to 6 months at 4°C.

PFBBr, 5%

In a fume hood, add 25 ml 2,3,4,5,6-pentafluorobenzyl bromide (PFBBr) to 475 ml acetone for every 12 samples. Prepare fresh daily.

CAUTION: *PFBBr is a potent lachrymator; therefore, concentrated solutions should be handled only in an operating chemical fume hood. Carefully review MSDS before use.*

Sodium phosphate buffer, 500 mM, pH 7.2

Dissolve 76 g dibasic sodium phosphate in 1 liter water. Dissolve 35 g monobasic sodium phosphate in 500 ml water and add to dibasic solution until the pH is 7.2. Store up to 1 month at 4°C.

COMMENTARY

Background Information

HPLC quantification

Quantification of the DNA used for the measurement of specific adducts is necessary in order to give a common denominator. While spectrophotometric absorbance is useful as an estimate (*UNIT 3.8*), the best method for determining DNA content in samples that have been hydrolyzed by mild acid is HPLC analysis of the purines (see Basic Protocol 1). In the authors' laboratories, the most common method for the HPLC measurement of guanine (and adenine) is an adaptation of the method for the measurement of methylpurines in alklyated DNA (Lawley, 1976; Beranek et al., 1980).

Many previous papers have reported human DNA adducts based on milligram quantities of DNA, micromole quantities of guanine, or total number of nucleotides. These numbers can be equalized using the following conversion factors: 1 pmol adduct/mg DNA = 0.318 adducts/1 $\times 10^6$ nucleotides and 1 µmol guanine = 1.6 mg human DNA (Walker et al., 2000).

When measuring the amounts of DNA adducts in nucleosides, it is best to use a DNA quantification method that measures nucleosides. The method described in this unit (see Basic Protocol 2) has an advantage over the base measurement in that with this one assay, one can also measure RNA contamination in the same sample (Boucheron et al., 1987).

HPLC quantification of adducts with electrochemical detection

Many insults occur to genomic and mitochondrial DNA due to the action of exogenous or endogenous agents. The types of lesions that result from such interactions include single-strand breaks, AP sites, chromosome aberrations, and DNA adducts. The modification of DNA bases can compromise the integrity of the genetic code leading to mutation, carcinogenesis, or apoptosis. Understanding the relationship between exposure dose, adduct formation, and biological response allows for a more mechanistic approach to risk assessment (La and Swenberg, 1996).

Aerobic metabolism produces a number of reactive oxygen species (ROS) such as H_2O_2 as well as hydroxyl and superoxide radicals. The cell employs a number of defense mechanisms against ROS like superoxide dismutase and glutathione peroxidase; however, the amount of oxidants can overwhelm these anti-oxidants, thereby leading to oxidative stress. The result of such an imbalance leads to protein damage, lipid peroxidation, and DNA adduct formation. Of the oxidized bases, 8-OH-dG is the most studied. While appearing harmless, 8-OH-dG has been shown to cause misreading during DNA replication (Kuchino et al., 1987), but the primary importance of 8-OH-dG is in its use as a biomarker for oxidative stress within the genome.

Alkylation of DNA bases can cause base substitutions, AP sites, or strand breaks. Caused endogenously by S-adenosylmethionine and exogenously by agents that yield carbonium ions (*N*-nitroso compounds); these adducts have been used in studies to monitor the dosimetry of carcinogens (Bianchini and Wild, 1994; van Delft et al., 1997). Because N7-MG is repaired by DNA glycosylases, its measurement can yield information regarding the efficiency of base-excision repair.

Many DNA bases are not electrochemically active while their adducts are (Park et al., 1989). This allows for selective quantification of DNA adducts by HPLC with electrochemical detection (ECD) without the interference of normal bases (see Quantifying DNA Adducts: HPLC with Electrochemical Detection). The use of a multi-channel array detector increases this selectivity when compared to a single-potential detector. Coulometric array systems increase the resolving power by prohibiting a detected compound from interfering with analysis at subsequent electrodes. Compounds that co-elute can be differentiated on the basis of their oxidation potentials. Poor chromatographic resolution cannot be corrected with the use of a single-potential detector. The greater selectivity in array systems also allows for more sensitive detection due to the removal of interfering peaks.

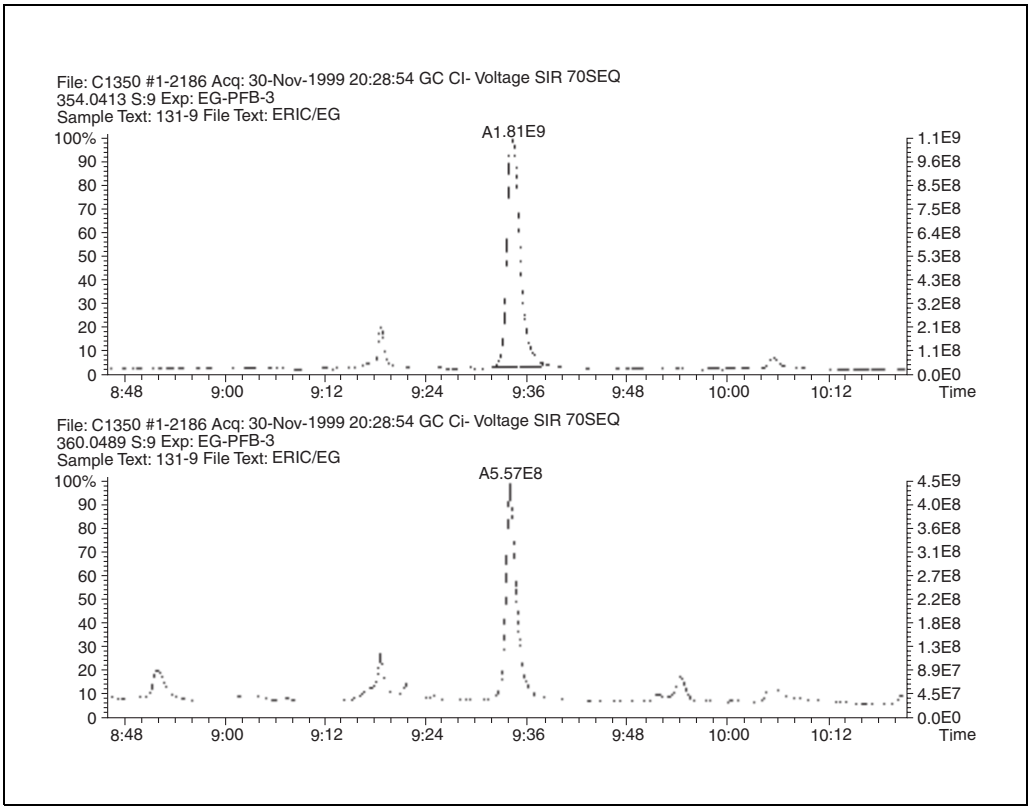

Figure 3.9.1 Detection of di-pentafluorobenzylated N^2,3-εGua (top) in rat liver DNA after exposure to vinyl chloride. The analyte is quantitated by comparison of the peak area to that of the [$^{13}C_4$, $^{15}N_2$]N^2,3-εGua internal standard (bottom).

The methods described can be used to measure other DNA adducts with little or no modification to the described protocols. A small drawback to these methods is that ECD requires total oxidation of the analyte, making sample recovery impossible.

Quantification of N^2,3-ethenoguanine

The DNA adduct N^2,3-ethenoguanine (εGua; see Fig. 3.9.1) is formed from a number of carcinogens, including vinyl chloride (VC; Bartsch et al., 1994). The formation of this adduct occurs from the reaction of guanine with electrophiles that are produced from carcinogens as well as from endogenous sources, presumably from products of lipid peroxidation (Sodum and Chung, 1988, 1989, 1991; Chen and Chung, 1994; Ham et al., 1999, 2000). In the case of VC, the highly reactive electrophile chloroethylene oxide (CEO), which is formed from the metabolic activation of vinyl chloride by cytochrome P450, alkylates DNA and forms a variety of etheno adducts, including εGua (Guengerich, 1994). The major VC-induced adduct, 7-(2′-oxoethyl)guanine, does not induce mutations in vitro (Barbin et al., 1985) and thus is not thought to play a significant role in VC-induced mutagenesis; however, the exocyclic derivatives 1,N^6-ethenoadenine, 3,N^4-ethenocytosine, N^2,3-ethenoguanine, and 1,N^2-ethenoguanine (εAde, εCyt, εGua and 1,N^2-εGua, respectively) have demonstrated miscoding potential in vitro and in vivo (Singer et al., 1987, 1991; Cheng et al., 1991; Mroczkowska and Kusmierek, 1991; Basu et al., 1993; Langouët et al., 1997, 1998). Both in vitro and in vivo studies have shown that εAde caused A to G transversions, εCyt caused C to A transversions and C to T transitions, and εGua caused G to A transitions. The results of these studies were consistent with the mutations observed in tumors from vinyl chloride–exposed humans and rats in two separate studies. In five out of six human liver angiosarcomas associated with vinyl chloride exposure, GC to AT transitions were observed at codon 13 of the c-Ki-*ras*-2 gene, consistent with either εGua or εCyt mutagenic properties (Marion et al., 1991). In another study, tumors from vinyl chloride–exposed rats showed G to A transitions, A to C transversions, and C to T transitions in N-*ras* genes, all of which are consistent with promutagenic properties of etheno adducts (Froment et al., 1994).

Although εGua is formed from VC exposure to a lesser extent than some other adducts, its greater mutagenic potential points to its possible significance in the carcinogenicity of a number of carcinogens. Fedtke et al. (1990) originally reported that εGua appeared to have a very long half-life in hepatic DNA (exceeding 30 days). It is now believed, however, that in this original report the half-life of εGua could not be calculated accurately because baseline levels of endogenous εGua were being measured rather than that of additional εGua after vinyl chloride treatment (Swenberg et al., 2000). The occurrence of DNA adducts from endogenous sources has become increasingly apparent. Most of these adducts have been postulated to occur from the reaction of DNA with products of lipid peroxidation or directly from reactive oxygen species. Chung and colleagues have shown that the related etheno adducts, 1,N^2-ethenoguanine and 1,N^6-ethenoadenine, are formed from the epoxide of the lipid peroxidation product *trans*-4-hydroxynonenal, 2,3-epoxy-4-hydroxynonenal (Sodum and Chung, 1988, 1989, 1991; Chen and Chung, 1994). Recently, the authors have also shown that εGua is formed as a result of the reaction between dGuo and 4-hydroxynonenal or ethyl linoleate under peroxidizing conditions (Ham et al., 2000). Since εGua may be formed from both endogenous and exogenous sources, it will be important to determine its formation from both sources, particularly with carcinogens that may produce εGua by both direct alkylation and by increasing lipid peroxidation. In order to study these relationships and their relevance to carcinogenicity, the authors have developed a sensitive immunoaffinity/gas chromatography/electron capture negative chemical ionization/high-resolution mass spectrometry (IA/GC/EC-NCI/HRMS) assay for the analysis of εGua (see Basic Protocol 6). This method analyzes εGua using enrichment of the adduct by IA chromatography clean up, followed by GC/EC-NCI/HRMS analysis of its pentafluorobenzyl derivative. The utility of both immunoaffinity and mass spectrometry allow for a very specific and sensitive method for this DNA adduct.

Immunoaffinity purification

Immunoaffinity chromatography is the most specific purification technique that has been applied to the routine quantitation of DNA adducts. It relies on the specific binding between an appropriate immunoglobulin and the adduct of interest. It can be used to separate species with very similar chemical and physical properties with high efficiency, even when the adducts are present at parts-per-billion concentrations relative to the parent base.

Protein A is a bacterial molecule with a high affinity for the Fc region of most immunoglobulins. When attached to a solid support, Protein A can be used to purify antibodies from biological matrices including ascites, cell culture supernatant, or serum. Once bound to Protein A, the homobifunctional imidoester cross-linker DMP is used to covalently attach the antibody to the support through amidine linkages (Hermanson, 1996). The coupling procedure is complete when ethanolamine is used to block excess imidoester functional groups (see Support Protocol 2).

^{32}P postlabeling

This assay (see Basic Protocol 8) was a major advance in the study of DNA adducts because it provided the sensitivity of radioassays, without the requirement for specific radiolabeled chemicals. It continues to be among the most sensitive methods for analyzing DNA adducts. Each adduct requires separate method development, as TLC conditions vary for different adducts. Once method development has been completed, up to 16 samples can be analyzed per assay. Analysis takes 2 days to complete, and another day is required to obtain results.

The major limitation of this assay is that it does not provide structural information about DNA adducts. In addition, adducts derived from small molecules are difficult to resolve from unmodified nucleotides and cannot be detected with great sensitivity. This method does provide high sensitivity for larger bulky aromatic compounds. The method also has particular advantage as a screening tool, since prior knowledge of adduct structure is not required. Standards of known structure can be synthesized and used as a comparison to identify DNA adducts.

Adduct enrichment is required to remove unmodified nucleotides because these nucleotides compete for phosphorylation with the modified nucleotides. This increases the amount of radioisotope required for analysis and increases the background, which decreases sensitivity. Different methods are available for enrichment. The described protocol is for the nuclease P1 method of enrichment (Reddy and Randerath, 1986). This method is based on the fact that DNA adducts are generally resistant to dephosphorylation by nuclease P1 and are

available as a substrate for polynucleotide kinase–mediated phosphorylation. By contrast, unmodified nucleotides are dephosphorylated by nuclease P1 and are not available as substrates for labeling. C-8 modified adducts, modified by aromatic amines or nitroaromatic compounds, are known to be sensitive to nuclease P1 digestion and thus would not be good candidates for analysis by this method. Other methods include HPLC enrichment and butanol extraction (Gupta, 1985; Dunn and San, 1988). HPLC enrichment involves separation of DNA adducts prior to ^{32}P-labeling. Butanol enrichment involves extractions using butanol to isolate DNA adducts from normal nucleotides. In addition, HPLC has been used to resolve DNA adducts, which provides greater reproducibility compared to TLC methods (Möller, 1993). Readers are directed to the listed references for experimental details for these methods (see Literature Cited).

Critical Parameters

HPLC quantification

DNA, after extraction (especially from tissue) and rehydration, must be sheared to give a homogenous solution to provide the most accurate pipetting. This will also ensure that the aliquot taken for guanine analysis is representative of the entire sample. The concentration of DNA can be estimated by measuring the absorbance of the solution spectrophotometrically (*UNIT 3.8*). This is only an estimation, however, and an assay (see Basic Protocol 1) must be run in order to relate the value to micromolar quantities of guanine.

Mobile phase must be made up of HPLC-grade methanol and either HPLC-grade water or distilled deionized water. Filtering and degassing is necessary to ensure the solution is free from debris and bubbles that can form when aqueous and organic solutions are mixed together. Bubbles that pass through the UV detector can appear to be peaks. Be sure to have enough mobile phase made to finish all samples and standards. If the mobile phase runs out and must be made again, rerun the standard curve and finish the remaining samples. While small changes in mobile phase rarely affect the samples, it is best to be consistent and have standards and samples run in the same mobile phase.

For guanine quantification, guanine used as the stock solution must be made well in advance of the day of assay. Guanine has limited solubility and must be prepared ahead of time to allow for dissolution. Make the stock ~3 to 5 mM in 0.1 N HCl (~3 mg/10 ml) and incubate in a 37°C environmental shaker until dissolved. Verify concentration of guanine solution by spectrophotometric measurement at 254 nm (ε_{254} = 10,000 $M^{-1}cm^{-1}$). For nucleoside quantification, make the stock solutions of standards ahead of time. Verify stock concentration spectrophotometrically and dilute in water ~1:100. Measure the absorbance of each at their absorbance maxima (λ_{max}: dGuo and rGuo, 252 nm at pH 7.0, ε = 13,700 $M^{-1}cm^{-1}$; dAdo and rAdo, 259 nm at pH 7.0, ε = 15,000 $M^{-1}cm^{-1}$). Use the Beer-Lambert equation: $A = \varepsilon bc$, where A is the absorbance at λ_{max}, b is the path length of the cuvette (typically 1 cm), and c is the concentration of the solution. This can be rearranged to $c = A/\varepsilon b$. Dilute stock solutions, aliquot, and freeze up to 1 year at −20°C.

HPLC quantification with electrochemical detection

When working with DNA-containing adducts, especially those that are heat labile, it is crucial to keep the samples on ice at all times. Care should be taken to avoid artifactual generation of 8-OH-dG when processing samples (Möller et al., 1998). If drying a DNA sample is necessary, do not completely dry the sample and add an anti-oxidant to reduce the generation of 8-OH-dG. All water used should be distilled and deionized. Reagents can be made fresh the day of sample preparation or beforehand. The potential at which the desired analyte shows the greatest response (e.g., peak area, peak height) may vary between ECD systems. To determine the optimum potential for a compound, construct a hydrodynamic voltammogram using a standard (Kissinger, 1977; Park et al., 1989).

Mobile phase should be filtered through a 0.45-µm filter and degassed. In addition to equilibrating the system for 1 hr prior to analysis, the mobile phase should be recirculated through the system overnight. This will oxidize impurities and reduce the background noise. Since samples should be kept cold until analysis, placing all the samples in an autosampler is not recommended, except if an apparatus with a refrigeration unit is available.

Quantification of N^2,3-ethenoguanine

DNA extracted from a variety of tissues, cultured cells, or other in vitro experiments can be used for this assay. Because there is evidence that the adducts may be formed from lipid peroxidation, care should be taken during DNA extraction procedures to minimized any artifac-

tual lipid peroxidation generated during extraction (see *UNIT 2.3*). The DNA should also be free from any RNA. Since the nucleobase, not the nucleoside, is being measured in the immunoaffinity assay, RNA contamination could contribute to the final εGua value making the DNA results artificially high.

Standard and internal standard solutions should be prepared in water and stored in a –80°C freezer and defrosted just prior to use. These standards are very stable and can also be stored at 4°C on a short-term basis. Check the standards for the accuracy of their concentration. As with any analytical method for quantitation, the accuracy of the standards is critical. Equally important for the quantification of this adduct is the quantification of guanine in the hydrolysate. Although the amount of DNA is quantified by UV spectrophotometry, this is only an estimate of the amount of DNA because many interferences can skew these results. Since there is no internal standard to control for the amount of guanine in the sample during work-up, it is vital that care is taken when pipetting DNA, water, internal standard, and HCl. The accuracy of the final volume of the hydrolysis mixture is important for the determination of total guanine in the sample.

The authors have also observed increases in εGua, presumably artifactual, when the pH of the mixture prior to immunoaffinity is basic (i.e., pH >8.0). Care should be taken not to allow the pH to become basic during any step of this procedure.

Derivatization efficiency may be decreased by the presence of water. Additionally, the presence of water may affect the analysis of this adduct by GC/MS. Therefore, all solvents used for derivatization, and toluene used for resuspension prior to GC/MS, should be kept as dry as possible. This can be achieved by using solvents that are relatively fresh and stored in sealed containers with desiccant when not in use. The potassium carbonate should also be kept as dry as possible, especially since it is hygroscopic. To keep the potassium carbonate as dry as possible it should be stored in an oven at 60°C.

Immunoaffinity purification

The most important aspect of developing an immunoaffinity chromatography procedure is selection of a suitable antibody. Unfortunately, this is difficult to predict and must be determined largely by trial and error. First, the antibody must have an appreciable affinity for Protein A so that it can be purified from solution and attached to the solid support. The antibody must demonstrate low affinity for unmodified bases or other potential interferences. The binding of adducts to the antibody must be strong enough to withstand the washing steps but labile enough to be eluted in a convenient solvent. Finally, because the supply of antibody is often limited and the support is expensive, the antibody should be stable enough so that the columns can be reconditioned and used many times.

It is the authors' experience that polyclonal antibodies are generally more compatible with immunoaffinity chromatography than monoclonal antibodies. They have used some polyclonal-based columns for over a year with little reduction in performance. These columns typically recover >95% of standards when new, and carryover between samples has not been observed. Due to their polyclonal nature, some interfering species may be retained by these columns, so they are best suited for use with selective quantitation techniques such as mass spectrometry. Less-specific methods of analysis, such as ^{32}P-postlabeling, may require that monoclonal antibodies be used to obtain samples of even higher purity.

It is critical that the standards or samples be applied in appropriate solutions. The pH of each sample must be near-neutral to allow binding. This is especially important when DNA is hydrolyzed in acid. In addition, the salt concentration of the sample must not be too high. Samples have been successfully neutralized in buffer to final salt concentrations of up to 250 mM.

Dimethylpimelidate (DMP) is moisture-sensitive and should be stored desiccated at 4°C. Allow the container to come to room temperature before opening and prepare the solution immediately before use. All other chemicals and materials are stable for months when refrigerated.

Extremely sensitive methods, such as GC/MS, might detect a low background amount of adduct leeching from the columns. This contamination is not due to carryover, since it is observed both in new and used columns. This release is most significant when the columns are first used, so the initial washing steps are very important. The problem may be exacerbated when using strong solvents for elution. The authors have found that this contamination with N^2,3-ethenoguanine was only detected when samples were treated with acid after immunoaffinity purification (to hydrolyze deoxynucleosides to nucleobases when using

enzymatic DNA digestion). This problem is overcome by using a DNA hydrolysis method that yields nucleobases prior to the immunoaffinity step (i.e., mild acid hydrolysis or neutral thermal hydrolysis). It is important to include appropriate blanks to ensure this does not contribute to the measurement.

Gas chromatography

Extremely high voltage (8000 V) is present when the mass spectrometer is turned on from the instrument console. Ion source access should only be attempted after turning off the instrument (push the Standby button from the console). Various components of GC and MS are at very high temperatures during operation (100° to 300°C). The operators are advised to refer to the respective instrument manuals for operation and safety information.

Liquid chromatography

If it is not done carefully, the desalting step is where most sample losses could occur; therefore, it is important to make sure SPE cartridges are equilibrated with water and samples are loaded by gravity. Particulate material could be present in the SPE eluents. Check the samples visually before injection.

Volatile buffers such as ammonium formate or acetate should be used in LC mobile phase instead of nonvolatile buffers, and the concentration of the buffers used should be kept as low as possible because they do suppress the ionization and cause a decrease in sensitivity.

Although neutral thermal hydrolysis is very specific for releasing N-7 and N-3 alkylated adducts, at least 1% to 2% unmodified Gua and Ade are released as well; therefore, the samples will still contain a high level of purine bases. Most N-7 guanine adducts elute close to unmodified Gua and Ade. To achieve a satisfactory separation between the adduct and unmodified bases, one typically needs to use a highly aqueous mobile phase. With these kinds of mobile phases, polar endcapped reversed-phase columns perform better than the conventional reversed-phase material. The authors have had good experience with Aquasil C-18 columns (Keystone Scientific) for quantification of N7-(2-hydroxyethyl)guanine.

A blank should be run after a high-level sample to ensure no carryover takes place. Most HPLC systems can rinse the needle of the injector both outside and inside after every injection. As a rule of thumb, one should avoid introducing high concentrations of the analyte of interest into the injector.

A quality control sample should be analyzed to determine whether or not the instrument has the required sensitivity and selectivity.

Troubleshooting

HPLC quantification

Table 3.9.6 provides a troubleshooting guide to problems that may be encountered during HPLC quantification of guanine, while Table 3.9.7 provides a guide for quantification of nucleosides.

HPLC quantification with electrochemical detection

Since sample preparation is simple and requires little effort, any problems that arise will most likely be from the HPLC-ECD system. Important things to monitor are the quality of the chromatograms (interfering peaks, shifts in retention time, erratic baseline) and the sensitivity of the electrochemical detector. Routine maintenance and care of the column and HPLC components will ensure accurate and reproducible chromatograms. Running standards prior to sample analysis will provide a good indication of when desired peaks will elute and the degree of response. Keeping track of the response (peak area) of the standards over a period of time will give an indication of any change in the sensitivity of the ECD. Standard degradation must also be considered and concentrations of stock solutions should be checked spectrophotometrically when preparing a series of standards. Standard degradation is retarded when they are stored at −80°C.

Quantification of N^2,3-ethenoguanine

If no peaks are seen in the GC/MS chromatogram, there are four possible problems. First, there may be a problem with the GC/MS. See Basic Protocol 6 for instructions on troubleshooting this problem. Second, the sample may have been lost during solid-phase extraction. Check all solvents and the silica gel to make sure that the correct materials were used and the columns were washed and eluted with the proper solvents. Third, derivatization may not have been efficient. Make sure all solvents are fresh and free of any water contamination. Also make sure that the samples are completely dry before staring the derivatization. If there is a lapse between the time that the samples are dried in the SpeedVac evaporator and the samples are derivatized, the samples may need to be dried again in the evaporator just to ensure the absence of water. Finally, the immunoaf-

Table 3.9.6 Troubleshooting Guide for HPLC Quantification

Problem	Possible cause	Solution
Flocculated material in guanine stock	Undissolved material	Centrifuge to pellet flocculates. Transfer supernatant to a fresh tube and measure A_{254}
Unresolved guanine and adenine peaks	Old column	Replace HPLC column
No peaks detected by UV in HPLC profile	No DNA in sample	Shear DNA and redilute for hydrolysis
	Too little DNA in sample	Use less acid (more concentrated) for hydrolysis
	No injection	Be sure sample is in injector and injector is in the proper position
Off-scale peaks	Saturation of detector	Dilute sample in 0.1N HCl and reinject

Table 3.9.7 Troubleshooting Guide to Quantification of Nucleosides by HPLC

Problem	Possible cause	Solution
Unresolved peaks	Old column	Replace HPLC column
No peaks in HPLC by UV	Not enough DNA	Concentrate DNA sample and reinject
Off-scale peaks	Saturation of detector	Dilute sample and reinject

finity columns may not be retaining the samples. If there is a peak for the internal standard, but not for the analyte, there are two possible problems, either the hydrolysis was not complete or the amount of DNA used was inadequate. Check the guanine concentrations. If guanine is present in amounts that are approximately those predicted for the amount of DNA used, then the hydrolysis was not the problem; use more DNA for analysis. If the guanine concentrations are low, the estimated value of DNA may have been miscalculated or the DNA had some contamination that interfered with its estimation by UV spectrophotometry. Again, use more DNA. If guanine is absent, then the hydrolysis was inadequate. Check the acid used for the hydrolysis for the correct concentration. Also check calculations for the volumes of water and DNA added to make sure the final concentration of acid is 0.1 N HCl.

If the amount of εGua is higher than predicted, there are several possibilities. First, check the concentration of standards, both analyte and internal, for accuracy. Also check the guanine standard and the calculation of guanine in the sample. If the guanine is miscalculated or misquantified, the results will be skewed. As discussed, there may also be artifactual generation of εGua if the samples are allowed to become too basic. Check all solutions and buffers for pH to make sure that it is not allowed to go above 8.0. Also, avoid extremes in pH and temperature after immunoaffinity. There is a contaminant that elutes from the IA columns that is converted to εGua if exposed to acid and heat (e.g., 45 min of 1% formic acid, 60°C).

Immunoaffinity purification

The recovery of standards from immunoaffinity columns should be tested before the first use and periodically afterwards. It is important to test the recovery both with the standard solution alone and with standard spiked into the sample matrix (e.g., DNA hydrolysate). When problems are encountered, it is instructive to determine under which conditions the adduct will or will not elute.

If the standard is found in the load or wash fractions, the column is not retaining the adduct. It is possible that the antibody was not bound because it has a low affinity for Protein A. This is characteristic of the IgG_1 and IgG_3 subclasses of mouse monoclonal antibodies. If this is the case, using Protein G–Sepharose or Protein A/G–Sepharose (Amersham Pharmacia Biotech) may improve binding. It is also possible that the crosslinking step was ineffective. Alternatively, the antibody may have a

relatively weak affinity for the adduct. Minimizing the number and strengths of the washing steps may increase recovery in this case.

If the standard is not found in the load, wash, or elution fractions, it is probably being bound too tightly by the antibody. It may be possible to increase the strength of the elution solvent by making it more organic, acidic, basic, or salty. It is possible that such solvents will degrade or destroy the columns, however, so extremes should be avoided whenever possible.

If recovery is high with standards alone but low when standards are spiked into samples, the antibody may have some affinity for unmodified bases. In this case, it is best to find a more specific antibody since this cross-reactivity will also increase the sample background. Alternatively, a preliminary purification step with disposable solid-phase extraction columns may help to eliminate some of the interference. It is also possible that the sample is present in an incompatible solvent (see Critical Parameters).

Some degradation of column performance over time is expected. If column recovery declines sharply, the antibody may be unstable in the solvents or its bond to the Protein A may be labile. The use of polyclonal instead of monoclonal antibodies may result in more durable columns.

Gas chromatography

GC/HRMS is a hyphenated technique, therefore the loss of the analyte signal can be caused by either GC- or MS-related problems. The first step is to isolate the problem in relation to the respective region of the instrumentation. For example, the loss of signal due to PFK tuning compound bleeding through the reservoir indicates MS problems typically resulting from the ion source due to detuning, dirty ion source, or filament deterioration. MS problems should be fixed first before attempting to fix any GC-related problems. MS problems related to the ion source can be corrected by cleaning the ion source and installing a new filament and a new heater element. GC-related problems originate mostly from a contaminated injector liner and chromatography peak broadening due to column deterioration after many sample injections. Chromatography problems can typically be fixed by cutting the column ~6 in. at the injector side and cleaning the injector liner. If the problems still persist and the sensitivity of the analyte signal from a known standard cannot be restored, the GC column should be replaced.

Instrument instability is a major concern in HRMS because the peak width of the signal is narrower (100 PPM at an RP of 10,000) compared to LRMS. The instability can be caused by several factors including mechanical vibration, electrical noise, and chemical interferences. A typical HRMS-selected ion monitoring (SIM) experiment involves monitoring the analyte ion, the corresponding labeled analog, and a reference peak originating from the calibration compound which is continuously introduced at a constant rate into the ionization chamber during HRMS analysis. While the analyte and internal standard are solely for quantitation, monitoring of the reference peak serves as a check for instrument instability and detuning of the electron capture ion source. The use of lock mass, which can be the same as the check mass, is important in HRMS because the peaks are narrow at high resolving powers. Periodically the SIM control unit may shift the acceleration voltage in order to maximize the intensity of the calibration peak which necessitates the need for the continuous lock onto the reference peak, thus keeping the instrument calibrated for each cycle of mass scanning. When large amounts of interferences are present in the ion source, the SIM control unit can misidentify an interfering peak as the reference peak and shift the accelerating voltage to a different value, causing source detuning and mass miscalibration. During each GC/MS run, any weakness or sudden disappearance of the check mass as measured (5 to 10 V) on the oscilloscope indicates instability problems. It is normal for the check mass to disappear during the first 2 min of each injection due to the solvent front. Injection of a known standard (typically a calibration standard) after every five injections of biological samples is recommended in order to test the stability of the signal.

Liquid chromatography

Table 3.9.8 is a troubleshooting guide to adduct quantification by LC/ESI/IDMS/MS.

^{32}P postlabeling

Most difficulties with the ^{32}P-postlabeling method involve improper chromatography conditions, particularly for smaller-sized DNA adducts (e.g., those derived from single aromatic ring compounds). Problems with DNA hydrolysis and labeling can be detected during analysis of normal nucleotides. For smaller DNA adducts, reducing the concentrations of the mobile phase for TLC development (see

Table 3.9.8 Troubleshooting Guide for LC/ESI/MS/MS

Problem	Possible cause	Solution
Analyte peak not detected, strong IS peak	Levels are below detection limit of the method	Either introduce more of the sample or increase sensitivity (e.g., decrease column i.d., sample preconcentration)
Both IS and AN peaks are lower than expected	Low sample recovery	Perform sample preparation more carefully to improve recovery
	Instrument sensitivity is low	Check the instrument sensitivity by running a quality control sample. If it is low, perform maintenance on the instrument to improve the sensitivity.
Sensitivity goes down after several samples	Samples contain salt or interfering compound that elutes before the analyte	Perform desalting more efficiently. Try increasing the amount of water or buffer used for rinsing in SPE.
		Divert the LC effluent to waste instead of ESI source until shortly before the analyte
		Rinse source parts with methanol or water as necessary

Basic Protocol 8, steps 11 and 12) may be required. These solutions can be diluted to 1:2 with water. If DNA adducts are not detected, other enrichment methods mentioned in the Commentary section should be explored. Initial chromatography using C-18 plates (in place of steps 8 and 9) may be particularly useful for detection of smaller DNA adducts.

Anticipated Results

HPLC quantification

The guanine standard curve should be linear. Sample peak areas should be within the range of the standard curve. The nucleoside standard curves should give linear curves. Sample peak areas should be within the range of the standard curve.

HPLC quantification with electrochemical detection

Results will vary between experiments depending on the agent used for exposure and the sample being exposed (i.e., viable cells or DNA). Samples exposed to a range of concentrations should exhibit a dose-response. Detection limits will vary among ECD systems and if any additional steps (purification) are added to the protocol.

Quantification of N^2,3-ethenoguanine

The results are calculated based on the results of a standard curve run with each experiment. The detection limits of this assay are ~3 to 5 fmol in an entire sample. This gives a good signal for an endogenous sample using 300 to 400 mg DNA, although as little as 200 mg has been used for endogenous samples. A representative GC/ECNCI/HRMS of endogenous εGua from a sample of human colonic DNA is shown in Figure 3.9.1. Table 3.9.9 shows some expected values of εGua in samples from a variety of tissues and cells.

Immunoaffinity purification

With the proper antibody, it is possible to routinely achieve recoveries of nearly 100% while obtaining a highly purified sample. There should be no detectable carryover between experiments. Since the intrinsic properties of antibodies vary greatly, these results may not be achievable in every case.

Liquid chromatography

A detection limit of 10 fmol injected amount of the N7 adducts should be easily achievable. A detection limit in terms of adducts per guanine is dependent on how much DNA is used and how much of the sample is injected. If the clean-up is efficient, an increase in DNA amount should improve the detection limit. Sample recovery should not be <60%. If it is low, it is most probably due to losses during desalting.

Table 3.9.9 εGua Content of Typical Cells

Tissue/cells	εGua (εGua/1 × 10^6 guanine)[a]
F344 rat liver—control	0.046 ± 0.028
Sprague-Dawley rat hepatocytes—control	0.035 ± 0.012
Sprague-Dawley rat brain—control	0.054 ± 0.019
Sprague-Dawley rat hepatocytes—VC exposed[b]	1.1 ± 0.6
B6C3F1 mouse liver—control	0.036 ± 0.010
Human colon—normal	0.16 ± 0.05

[a]Values expressed as mean ± standard deviation.

[b]Rats exposed to 1100 ppm vinyl chloride by inhalation 6 hr/day, 5 day/week for 4 weeks.

^{32}P postlabeling

The ^{32}P-postlabeling assay is best suited for the detection of DNA adducts arising from bulky aromatic compounds. For such DNA adducts, detection of levels as low as 1 adduct per 1 × 10^{10} nucleotides have been reported, although concentrations in the range of 1 per 1 × 10^8 to 1 × 10^9 nucleotides are more typical.

Time Considerations

HPLC quantification

Depending on the number of samples that need to be assayed, the measurement can be done in 1 day. Time must be allocated for shearing the DNA and then its dilution with HCl. As the samples are being hydrolyzed at 70°C for 30 min, the HPLC can be equilibrated and the guanine can be spectrophotometrically measured and diluted.

Because of the time involved in the enzymatic hydrolysis of the nucleoside samples and the time involved with the HPLC, this assay can take 2 days. If possible, use an autosampler and allow the HPLC to run overnight. If this is not possible, at the end of the day, run the HPLC slowly (0.2 ml/min) overnight in 100% mobile phase A. Be sure to reequilibrate the column again for 30 min in the morning at the assay flow rate. Inject one or two standards again on the second morning to verify that conditions have not changed.

HPLC quantification with electrochemical detection

The methods described allow for quick preparation and analysis for DNA adducts. The protocols require not much more than the addition of reagents and incubation periods. The preparation and analysis for the adducts described can be performed in 1 day. The preparation of 8-OH-dG samples will require at least 2 hr for enzymatic digestion while the total time for quantification, 15 min per sample, will depend on the number of samples. Sample preparation for N7-MG analysis is rapid and convenient, requiring <2 hr. The time allotment for quantitation of N7-MG, under 30 min per sample, will depend on the number of samples. Adjusting chromatographic conditions may shorten retention times, however the possibility of introducing interfering peaks becomes a risk (Park and Ames, 1988b).

Quantification of N^2,3-ethenoguanine

One and a half to 2 days are generally necessary for the preparation of samples for mass spectrometry analysis. It takes ~7 to 8 hr to hydrolyze and purify the samples by immunoaffinity (including regeneration of the immunoaffinity columns). Generally, eluent from the immunoaffinity columns can be left in the SpeedVac evaporator overnight (no heat) to dry if there is not enough time to finish this in a workday; otherwise, the samples take 2 to 3 hr to dry. Derivatization and preparation of samples takes an additional 4 to 5 hr. The sample runs on the GC/MS take ~17 min per sample so analysis time will vary.

Immunoaffinity purification

It takes ~6 hr to construct and wash a new set of columns. Approximately 4 hr are required to precondition columns, purify samples, and recondition columns. It is convenient to perform DNA hydrolysis and immunoaffinity pu-

rification in a single day, and allow the eluent to dry overnight.

Liquid chromatography

It takes ~2 days to complete LC/ESI/IDMS/MS: 1 hr for neutral thermal hydrolysis, 2 hr for filtration, 3 hr for desalting, 4 to 5 hr for evaporation to dryness, and 30 to 35 min per sample for LC/MS.

^{32}P postlabeling

It takes two full days to complete the assay. Another day is required for autoradiography and to obtain results.

CHAPTER 4
Techniques for Analysis of Chemical Transformation

INTRODUCTION

The mode of toxic action may be thought of as a cascade of events that starts with exposure and ends with the expression of a toxic endpoint. Events occurring during this sequence may increase the extent to which the toxic endpoint is expressed or may mitigate or even prevent toxicity. Metabolism, or biotransformation, of xenobiotics has long been known to play a key role in this process.

In general, xenobiotics enter the body because they are lipophilic. Biotransformation, which reduces lipophilicity, has been regarded as a detoxication process. However, biotransformation can lead to increased toxicity through the generation of reactive intermediates. In general, biotransformation of xenobiotics consists of two phases. In phase I, a polar group is introduced into the molecule, and in phase II this polar group serves as a center for conjugation with an endogenous metabolite. Reactions in either phase may be catalyzed by one or more of a broad array of enzymes, often referred to as xenobiotic metabolizing enzymes or XMEs. These enzymes have specific cellular locations (endoplasmic reticulum "microsomal," mitochondrial, or cytoplasmic), are usually present in multiple forms (isoforms), and have overlapping substrate specificities. XMEs are under genetic control and can be up or down regulated by both exogenous and endogenous factors. Inter-individual variation is also affected by the existence of genetic polymorphisms. Polymorphisms in coding regions of the genes for XMEs can affect expression, while polymorphisms in the coding region can cause the expression of proteins with different properties, including substrate specificity.

The anticipated format for this chapter follows; Table 4.0.1 provides indications as to which units are already included, which units are in progress, and which have yet to be initiated.

UNIT 4.1 presents a variety of classical procedures used to prepare subcellular fractions of liver and to determine the concentration of cytochrome P450 in the microsomal and mitochondrial fractions. It includes both enzymatic analysis and immunological techniques that are useful in characterizing the isoforms of cytochrome P450 present in microsomes. *UNIT 4.2* describes protocols for purifying the cytochrome P450 isoforms 2E1 and 1A2 from an *Escherichia coli* overexpression system. These isoforms are of interest to toxicologists because of their role in the bioactivation of a number of toxicants and carcinogens.

UNIT 4.3 presents a number of protocols that can be used to assess microsomal UDP-glucuronosyl transferase activity. The thin-layer chromatography procedure, based on the use of [^{14}C]UDPGA, is suitable for screening a large number of substrates simultaneously. Other procedures are described that are useful for separating glucuronides of particular classes of substrates.

UNIT 4.4 provides a general overview of high-performance liquid chromatography (HPLC) coupled to mass spectrometry (MS) as a powerful analytic tool in separation and structural characterization of metabolites of xenobiotics. This analytical system combines the

Table 4.0.1 Format of Chapter 4 in *Current Protocols in Toxicology*

Topic	Unit status
PHASE I	
Microsomal	
Cytochrome b_5/cytochrome b_5 reductase	*UNIT 4.16*
Cytochrome P450	*UNITS 4.1 & 4.2*[a]
CYP3A4	*UNIT 4.13*
FMO	*UNIT 4.9*
Cyclooxygenases	Not yet covered
Nonmicrosomal	
Alcohol dehydrogenase	In progress
Aldehyde dehydrogenase	In progress
Amine oxidases	Not yet covered
Monoamine oxidases	Not yet covered
Diamine oxidases	Not yet covered
Reductases	
Nitro reduction (probably P450)	Not yet covered
Azo reduction (probably P450)	Not yet covered
Carbonyl reductases	*UNIT 4.17*
Sulfoxide reductases	Not yet covered
Hydrolases	
Esterase/amidase enzymes	*UNITS 4.7 & 4.10* (one additional unit in progress)
Epoxide hydrolases	Not yet covered
PHASE II	
Glucuronosyl transferases	*UNIT 4.3*
Glucosyltransferases	Not yet covered
Sulfotransferases	*UNIT 4.5*
Methyltransferases	
N-Methylases	Not yet covered
O-Methylases	Not yet covered
S-Methylases	Not yet covered
Biomethylation of elements	Not yet covered
Glutathione S-transferases	Not yet covered
Mercapturic acid formation	Not yet covered
Cysteine conjugate β-lyase	Not yet covered
Acylation reactions	
Acetylases	Not yet covered
N-acetyltransferase	*UNITS 4.6 & 4.15*
N,*O*-acyltransferases	Not yet covered
Amino acid conjugation	*UNIT 4.11*
Deacetylation	Not yet covered
Phosphate conjugation	Not yet covered
Enzymes and subcellular preparations	
Induction of biotransformation enzymes	*UNIT 4.8*
Proximal tubule cells	*UNIT 4.14*
Other topics	
Detection of metabolites	*UNIT 4.4*

[a]Future units involving cytochrome P450 will focus on diagnostic and/or important substrates and inhibitors for human isoforms that metabolize xenobiotics (e.g., 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4).

separation power of HPLC with the sensitivity and structural characterization power of MS. The author provides information on selection and optimization of the HPLC-MS interface, discussion on the various scan modes, and a variety of examples of metabolites that have been characterized by HPLC-MS and HPLC-MS/MS.

UNIT 4.5 describes two methods for measuring aryl and alcohol sulfotransferase activity, an enzyme activity of considerable importance in both detoxication and activation of a number of xenobiotics. The first protocol is for a colorimetric method that depends upon the chloroform extraction of a paired ion formed between methylene blue and an organic sulfuric acid ester; the absorbance of the paired ion is measured at 651 nm. The second protocol is more flexible since it measures, by HPLC, adenosine 3′,5′-diphosphate (PAP), a product formed from 3′-phosphoadenosine 5′-phosphosulfate (PAPS) that is common to all sulfotransferase reactions.

UNIT 4.6 describes two methods for the measurement of the activity of arylamine *N*-acetyltransferase (NAT). This important phase II enzyme catalyzes the acetylation of aromatic amines, heterocyclic amines, and hydrazines. It may serve, depending upon the substrate and the position acetylated, as an enzyme of either detoxication or activation. The first protocol utilizes a measurement of the acetylated product, generally by HPLC, formed in the presence of a low concentration of coenzyme A maintained by a recycling system. This protocol is particularly useful for determination of kinetic constants. The Bratton-Marshall Assay measures the disappearance of an arylamine substrate.

Carboxylesterases (EC 3.1.1.1) are members of a multigene family with broad distribution in mammalian tissues, including those of humans. They hydrolyze an extensive number of exogenous and endogenous esters and amides, their importance in toxicology arising from the fact that their exogenous substrates include prodrugs, environmental contaminants (including pesticides), and carcinogens of various origins. These hydrolyses are, in the case of xenobiotics, usually detoxication reactions but, less commonly, may be activation reactions. *UNIT 4.7* describes methods for assessing carboxylesterase activity: first, a photometric method useful as a screening method; second, a highly sensitive fluorometric method; and third, an HPLC method also useful as a screening method.

The aryl hydrocarbon receptor (AhR) signal transduction pathway is of critical importance in several aspects of the mechanisms of toxic action, the mode of action of TCDD and related dioxins, and the induction of certain CYP isoforms. Several protein elements are involved in the binding of exogenous ligands followed by translocation into the nucleus, dissociation of several of these elements, and interaction of the receptor-ligand complex with DNA, thus affecting gene expression. *UNIT 4.8* is a comprehensive approach to measuring the functionality of this pathway, the importance of the unit being enhanced by the fact that the methods described measure the pathway at different points, thus providing information on how variation in different steps can affect overall function of the pathway. Basic Protocol 1 and Alternate Protocol 1 provide two different methods for measuring receptor-ligand binding. Basic Protocol 2 and Alternate Protocol 2 describe gel retardation assays for AhR-DNA binding. Basic Protocol 3 describes immunoblotting of two components, AhR and Arnt. Basic Protocol 4 is a RT-PCR method to examine mRNA for these same two components as well as that for CYP1A1 and CYP1B1 while Basic Protocol 5 utilizes yet another method, northern blotting, for measuring human CYP1A1 mRNA. Thus a broad range of the methods of contemporary molecular biology is brought to bear on a pathway with important implications for mechanistic toxicology.

UNIT 4.9 details methods for the estimation of the activity of the flavin-containing monooxygenases (FMOs). Because of the common localization of FMOs and xenobiotic-metabolizing cytochrome P450s in the endoplasmic reticulum, common cofactor requirements, and the fact that cytochrome P450 isoforms and FMOs may share common

substrates, the activity of the FMOs is often overlooked or underestimated. This problem may be important in that both P450s and FMOs are polymorphic in humans and that even with a common substrate the products may vary. *UNIT 4.9* provides procedures for measurement of FMO activity and also for the separate measurement of FMO and cytochrome P450 activities when both are present in the same preparation.

UNIT 4.10 provides methods for the identification and measurement of two types of esterase, carboxylic ester hydrolase and phosphoric triester hydrolase. The esterases, in toto, comprise an enormous group of enzymes that, because of its size and complexity, is not well understood. It is clear, however, that esterases are of critical importance in the metabolism of toxicants, including clinical drugs and agricultural chemicals, and this unit advances our ability to deal with the complexities of this important group of enzymes.

UNIT 4.11 addresses two aspects of an important pathway for the metabolism of toxicants not yet addressed in this chapter, the amino acid conjugation pathway. The enzymes addressed are carboxylic CoA ligase and acyl-CoA *N*-acetyltransferase. The coverage of the available methodology is particularly complete, and includes two basic protocols and seven alternate protocols. These protocols include radiometric and spectrophotometric methods based on different characteristics of the reactions.

UNIT 4.12 is a comprehensive method for the determination of paraoxonase I (PON1) status with information for genotyping specific polymorphic sites. Paraoxonase has been known for some time as an enzyme important in the metabolism of organophosphorus chemicals and is now known to have an important physiological function, the metabolism of oxidized lipids.

UNIT 4.13 is the first unit devoted to a single, important human CYP isoform. CYP 3A4 is quantitatively the most important CYP isoform in the human liver; it is involved in the oxidation of many drugs and xenobiotics as well as steroid hormones such as testosterone.

UNIT 4.14 is important for those who are interested in extrahepatic metabolism of xenobiotics, particularly in the function of the kidney in this regard. This unit describes several methods for the determination of toxicant biotransformations, both in subcellular fractions and in intact proximal tubule cells.

UNIT 4.15 brings this chapter into an area of increasing importance, the detection of polymorphisms in the various isoforms of xenobiotic metabolizing enzymes. This area is already critical in drug development and safety, and it is becoming of equal importance in human health risk analysis in such areas as chemical carcinogenesis. *UNIT 4.15* addresses the detection of polymorphisms in *N*-acetyltransferase-1 (NAT-1) and *N*-acetyltransferase-2 (NAT-2).

It has been known for some time that cytochrome b_5 is an absolute requirement for the cytochrome P450-dependent oxidation of some xenobiotics and is stimulatory for others. Furthermore cytochrome b_5 reductase is involved in the associated electron transfer. These effects are both substrate and P450 isoform dependent. *UNIT 4.16* is a comprehensive set of protocols to measure many aspects of the cytochrome b_5/cytochrome b_5 reductase system.

UNIT 4.17 describes comprehensive methods for the identification and measurement of different types of carbonyl reductases that are known to reduce xenobiotics, particularly in human liver.

Ernest Hodgson

Measurement of Cytochrome P-450

The majority of the forms of cytochrome P-450 in the body are located in the endoplasmic reticulum, and methods for their detection and quantification must allow for the influence of the membranes in the assays. For example, in spectrophotometric analyses, the light-scattering properties of membrane vesicles and fragments must be compensated for. The cytochromes P-450 are hemoproteins, and hemoproteins generally have extinction coefficients for their Soret peaks of ~100 $mM^{-1}cm^{-1}$. This means that one can readily detect concentrations as low as 0.1 nmol/ml spectrophotometrically, depending on the sensitivity of the spectrophotometer used.

Spectrophotometric measurements, however, will provide only quantitative information on the total pool of cytochrome P-450, and not details of its composition. In liver microsomes, for example, more than a dozen forms have been isolated; generally one or two make up the major amount, and others are present in amounts <10%. The identity of these forms can be determined by use of specific antibodies or enzyme assays with the ability to oxidize certain substrates known to be more or less specifically metabolized by one form of cytochrome P-450. All the methods of measurement have some drawbacks. For example, measurement of total cytochrome P-450 content in microsomes provides no information about the nature of the forms present. Depending on the exposure of the animals to different xenobiotics, either deliberately or serendipitously, the composition of the microsomal pool of cytochrome P-450 may vary greatly. The use of specific antibodies provides information on specific forms of cytochrome P-450 but generally will also detect denatured protein and apoprotein of the measured form, although such proteins are nonfunctional and do not form the P-450 spectrum. Substrate metabolism also has its drawbacks. Although some forms of cytochrome P-450 have high specificity toward certain substrates, almost all have very broad, overlapping substrate-metabolizing capabilities. Although one form may be capable of turning over a substrate at a rate 100 times greater than other forms, in microsomes where it is present at 1% of the total cytochrome P-450 content, it might be responsible for only half of the total observed activity. With these caveats in mind, the various methods of cytochrome P-450 measurement can be considered. For spectrophotometric analyses, the tissue preparation is merely suspended in the buffer, and the samples are subjected to difference spectroscopy in the presence or absence of carbon monoxide (see Basic Protocol 1). Although this provides a clear indication of the presence of cytochrome P-450 and allows its quantification, it is not nearly as sensitive as immunochemical analysis or substrate metabolism. The spectrophotometric analysis can be performed on microsomes, liver homogenates (see Alternate Protocol 1), or mitochondria (see Alternate Protocol 2).

Immunochemical methods (see Basic Protocol 2) take advantage of the specificity of antibodies and allow the identification of specific forms of cytochrome P-450 with a sensitivity that allows measurement in amounts as low as picomoles of cytochrome P-450. Such measurements are several orders of magnitude smaller than those possible by spectrophotometric analysis. The procedure involves immobilizing the cytochrome P-450, or antigen, on nitrocellulose and reacting it with its antibody (primary antibody). Then an alkaline phosphatase–coupled antibody (secondary antibody) to the primary antibody is bound and exposed to a substrate that forms a colored precipitate. The density of the precipitate gives a semiquantitative indication of the amount of antigen present.

Substrate metabolism, too, can give a very sensitive indication of the presence of forms of cytochrome P-450 (see Basic Protocol 3). For such measurements, small amounts of microsomes or cytochrome P-450 are added to an assay medium containing the substrate.

Contributed by John B. Schenkman and Ingela Jansson

Current Protocols in Toxicology (1999) 4.1.1-4.1.14

The cofactor NADPH is added to start the reaction; after a designated period of time, the reaction is terminated and the amount of product formed or substrate consumed is determined. Some of the highest sensitivities are obtained when fluorescent products are produced. Activities as low as picomoles per minute can be measured; but, as discussed above, precise quantification of the amounts of individual forms of cytochrome P-450 in tissues is not possible by substrate metabolism, owing to the broad, overlapping substrate specificities of the cytochromes P-450. Subcellular fractions (see Support Protocols 1 and 2) can be analyzed for the presence of cytochromes P-450 using any of these assays.

BASIC PROTOCOL 1

SPECTROPHOTOMETRIC MEASUREMENT OF CYTOCHROME P-450

This procedure takes advantage of the ability of difference spectroscopy to cancel background absorption and light scattering of membranous vesicles and fragments for the amplification and measurement of pigments at low concentrations. Hemoproteins with a sixth coordination position on the heme iron have the ability to complex with small molecules, and this is reflected in the absorption spectrum of the complex. Cytochrome b_5, which lacks a free coordination position, will not complex with carbon monoxide and, therefore, can be eliminated from interference with measurements of cytochrome P-450, which does have a reactive sixth coordination position. Because these two are the only hemoproteins present in the microsomal fraction, the assays are considerably simpler than, for example, measurements of cytochrome P-450 content in homogenates or mitochondria. In mitochondria, the presence of cytochrome oxidase, which possesses an available sixth coordination position as well as a large number of other pigments, makes spectrophotometric measurements more complicated.

Materials

Microsomal preparation containing 20 mg/ml protein (see Support Protocols 1 and 2)
0.05 M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Oxygen-free carbon monoxide in tank with two-stage valve
Dithionite: crystalline sodium hydrosulfite ($Na_2S_2O_4$)
4% (w/v) NADH in 1% $KHCO_3$ (prepared fresh daily; optional)

Spectrophotometric cuvettes with 1-cm light path for spectral analyses between 400 and 500 nm
Dual-beam UV/VIS spectrophotometer *or* spectrophotometer capable of optically or electronically producing a difference spectrum
Plastic microspatulas for stirring cuvette contents

CAUTION: When wet, dithionite will release hydrogen. It is also hygroscopic and decomposes with time. For convenience, when opening the jar for the first time, separate contents into a number of smaller vials, such as scintillation vials, 1 g into each. Tape covers with plastic electrical tape to ensure sealed jars stay dry.

1. Dilute 0.3 ml of microsomal preparation in 5.7 ml of 0.05 M Tris·Cl, pH 7.4 (to 1 mg protein/ml). Vortex gently to ensure good dispersion. Divide suspension between two spectrophotometer cuvettes.

   When liver is the source tissue, the microsomal preparation should be free of glycogen, because glycogen makes the suspension quite turbid, limiting the amount of microsomes that can be used.

2. On the spectrophotometer, record a baseline between 400 and 500 nm of equal light absorption with the suspension.

3. Slowly bubble carbon monoxide (CO) into the sample cuvette for 30 sec to allow saturation of the buffer with the gas.

   CAUTION: *This should be done in a chemical fume hood.*

   A two-stage valve is necessary to allow the very slow rate of bubbling of CO into the cuvette without foaming or displacing the microsomal suspension from the cuvette.

   The concentration of CO in the buffer will rise to 1 mM in 30 sec of slow bubbling. It is preferable to gas with CO before reduction, rather than the reverse, because bubbling will also expose the surface to oxygen. If dithionite is present, it will reduce the cytochrome P-450, which will react with the oxygen and form oxygen radicals, resulting in destruction of a portion of the cytochrome P-450. If appreciable amounts of adsorbed hemoglobin are present, a very large carbon monoxy hemoglobin peak will be seen at 420 nm.

4. Add a few crystals of dithionite to both cuvettes with a plastic microspatula, and stir gently. Wait ~1 min to ensure complete reduction, and record the spectrum. Record another spectrum after 1 to 2 min to ensure that no further change has occurred.

   If hemoglobin is adsorbed to the microsomes, the addition of dithionite to the reference cuvette will result in a large absorption peak at 445 nm in the reference cuvette. This will diminish values obtained for carbon monoxy cytochrome P-450 in the sample cuvette. To prevent this problem, when hemoglobin is present in the microsomes, bubble CO in the reference cuvette to convert it to carbon monoxy hemoglobin and do not add dithionite to that cuvette. Alternatively, add 5 μl of 4% NADH per milliliter to the reference cuvette instead of dithionite (Matsubara et al., 1982), and immediately record the difference spectrum. The NADH will reduce and cancel the absorbance of the cytochrome b_5 and will influence the measurement of the cytochrome P-450 only minimally.

   Glass spatulas may scratch the cuvette, so using plastic is advisable.

5. Calculate the concentration of cytochrome P-450 using the absorption difference between 450 and 500 nm and the equation described by Beer's law:

   $$A = \varepsilon Cl$$

   where A is the absorbance, ε is the extinction coefficient, C is the concentration, and l is the length of the light path

   Using this equation, it is possible to calculate the absorption of 0.3 nmol of P-450 in 1 ml (0.0003 mM). This is about the amount in 1 mg rat kidney microsomes suspended in 1 ml. Using cuvettes of 1-cm light path and a value for the extinction coefficient for cytochrome P-450 of 91 $mM^{-1}cm^{-1}$ (Omura and Sato, 1964), the absorbance value would be 0.027, well within the range of measurement of most spectrophotometers. If the absorbance difference of the cytochrome P-450 is known, the concentration can be calculated.

6. Determine the amount of cytochrome P-450 per milligram of microsomal protein from the concentration of cytochrome P-450 in the cuvette and the concentration of microsomal protein.

   For example, if the absorbance peak at 450 nm relative to the baseline at 500 nm is 0.12 A units, then

   $A = \varepsilon Cl$; $0.12 = 91\ mM^{-1}cm^{-1} \times C \times 1\ cm$

   $0.12 \div (91\ mM^{-1}cm^{-1} \times 1\ cm) = C$

   $C = 1.3 \times 10^{-3}$ mM cytochrome P-450, or 1.3 μM cytochrome P-450

   If a 1 mg/ml suspension of microsomes is used, then the preparation will contain 1.3 nmol of cytochrome P-450 per mg of microsomes.

ALTERNATE PROTOCOL 1

SPECTROMETRIC MEASUREMENT OF CYTOCHROME P-450 IN LIVER HOMOGENATES

The liver, with its well-developed endoplasmic reticulum, contains the highest levels of cytochrome P-450 of any of the various tissues studied. The fairly high content of cytochrome P-450 in the endoplasmic reticulum makes it possible to detect cytochrome P-450 in liver tissue by spectrophotometry. If the source of the tissue has been exposed to compounds that induce one or another form of the hemoprotein, it becomes relatively easy to monitor the cytochrome P-450. The endoplasmic reticulum cytochrome P-450 content in rat liver is more than three times higher than the content of mitochondrial cytochrome a_3 (Cinti and Schenkman, 1972). It is possible to measure this in tissue slices using specially constructed cuvettes; these are unnecessary, however, because it is easier and faster to make such measurements in the whole liver homogenate just as described for microsomes (see Basic Protocol 1). It is, however, necessary to obviate the effect of spectral overlap by mitochondrial cytochrome a_3—which in the presence of CO has an absorption peak at 420 nm, and when reduced in the absence of CO or O_2 has a peak at 445 nm. If a difference spectrum is recorded, as described in Basic Protocol 1, cytochrome oxidase in the sample cuvette will have a 420-nm peak that minimally overlaps the 450-nm cytochrome P-450 peak. In the reference cuvette, however, the dithionite-reduced cytochrome oxidase absorption peak will subtract from that of the cytochrome P-450 peak in the sample cuvette and give artificially low values. To overcome the spectral overlap, it is necessary to shift the absorption peak in the reference cuvette to a region in which it does not influence that of cytochrome P-450. This may be done by generating a cyanide complex of cytochrome oxidase (Matsubara et al., 1982) or by reducing only the mitochondrial hemoproteins in the reference cuvette by the addition of succinate in the presence of CO. All the pigments in the sample cuvette are reduced by dithionite, and the absorbance of the cytochrome oxidase complexed with CO in both cuvettes cancels.

Additional Materials *(also see Basic Protocol 1)*

Liver tissue
0.9% NaCl (*APPENDIX 2A*)
Buffered sucrose: 0.25 M sucrose/0.05 M Tris·Cl, pH 7.4 (see *APPENDIX 2A* for Tris·Cl recipe)
0.6 M sodium ascorbate (optional)
0.3 M sodium succinate in distilled water (optional)
0.6 M sodium cyanide in distilled water (optional)
Potter-Elvehjem glass homogenizer with motor-driven Teflon pestle

CAUTION: Before discarding sodium cyanide, add a few milliliters of alkali. HCN can form if the pH drops.

1. Gently perfuse the liver with 0.9% NaCl to remove blood until the liver is a pale tan.

   Perfusion is necessary because hemoglobin will absorb strongly and interfere with spectrophotometric measurements. If the animals have been treated with a cytochrome P-450–inducing agent, such as phenobarbital, the liver may be dark red to almost reddish brown after perfusion.

2. Homogenize 10 g of liver in 90 ml buffered sucrose in a Potter-Elvehjem glass homogenizer with Teflon pestle.

3. Dilute 1 ml homogenate with 9 ml of 50 mM Tris·Cl, pH 7.4. Bubble the suspension with CO for 30 sec in a fume hood. Add 3 ml gassed suspension to each of two cuvettes in the spectrophotometer.

4. Allow the cuvettes to stand 2 to 3 min to allow reduction of the mitochondrial pigment before recording a baseline of equal light absorption between 400 and 500 nm.

The mitochondrial pigments are reduced by endogenous substrates, and the reduced cytochrome oxidase–CO complex in each cuvette will cancel. Similarly, CO complexes of hemoglobin in each cuvette will cancel. If an appreciable amount of methemoglobin is present, it may cause a problem when the sample cuvette is reduced with dithionite. In that case, the addition of 15 µl of 0.6 M ascorbate (1 mM final concentration) will reduce the methemoglobin in the reference cuvette and solve the problem.

5. Add a few grains of dithionite to the sample cuvette with a plastic microspatula, and record the spectrum of the carbon monoxy cytochrome P-450.

   Another way to obtain clean carbon monoxy cytochrome P-450 spectra in homogenates without interference from hemoglobin, methemoglobin, or cytochrome oxidase is to add 5 µl of 0.6 M sodium cyanide (1 mM final concentration) and 5 µl sodium succinate (0.5 mM final concentration) to the reference cuvette (Matsubara et al., 1982). This causes reduction of the mitochondrial pigments, and the cyanide forms a complex with methemoglobin that does not overlap with the cytochrome P-450 spectrum.

6. Quantify the cytochrome P-450 (see Basic Protocol 1, steps 5 and 6).

SPECTROMETRIC MEASUREMENT OF CYTOCHROME P-450 IN MITOCHONDRIA

ALTERNATE PROTOCOL 2

Mitochondria of the adrenal gland, a steroid-synthesizing organelle, are especially high in cytochrome P-450. Measurements in bovine adrenal mitochondria have indicated levels as high as 0.6 nmol/mg protein (Cammer and Estabrook, 1967). Levels in mitochondria of other tissue, such as brain (Walther et al., 1986), are considerably lower and more difficult to measure. Procedures used must overcome interference by the mitochondrial electron transport pigments, especially cytochrome oxidase. This is easily accomplished by blocking the mitochondrial electron transport chain with cyanide.

Additional Materials *(also see Basic Protocol 1)*

Mitochondrial preparation containing 10 mg/ml protein (see Support Protocol 1, step 6)
Buffered sucrose: 0.25 M sucrose/0.05 M Tris·Cl, pH 7.4 (see *APPENDIX 2A* for Tris·Cl recipe)
0.6 M sodium cyanide in distilled water

CAUTION: Before discarding sodium cyanide, add a few milliters of alkali. HCN can form if the pH drops.

1. Dilute 1.2 ml washed mitochondria with 4.8 ml buffered sucrose (to 2 mg protein/ml). Add 10 µl of 0.6 M sodium cyanide (1 mM final concentration).
2. Gently bubble CO into the suspension for 30 sec and divide it into two cuvettes of 1 cm light path for difference spectroscopy.

   If hemoglobin is present, it will complex CO in the reference cuvette and in the sample cuvette, and the absorbances will cancel.

3. Record a baseline of equal light absorption between the cuvettes, and then add a few grains of sodium dithionite to the sample cuvette with a plastic microspatula; stir gently.
4. Allow 1 to 3 min for complete reduction of the cytochrome P-450, and record the dithionite-reduced CO difference spectrum.

   The presence of cyanide in the reference cuvette will result in reduction of the mitochondrial pigments by endogenous substrates and will prevent reducing equivalent transfer to the cytochrome P-450. If any methemoglobin is present, it will complex with the cyanide and the cyanomethemoglobin absorption peak of the reference cuvette will not interfere with the carbon monoxy cytochrome P-450 spectrum.

5. Quantify the cytochrome P-450 (see Basic Protocol 1, steps 5 and 6).

IMMUNOLOGICAL MEASUREMENT OF CYTOCHROME P-450

Cytochromes P-450 can be detected by immunoblotting, after SDS-PAGE (*APPENDIX 3*) and electroblotting (*UNIT 2.3*). Bound antibodies are detected using alkaline phosphatase–conjugated secondary antibodies.

A number of investigators will generously provide small amounts of their cytochrome P-450 and antibodies on request. Some commercial enterprises also sell forms of cytochrome P-450 and antibodies to individual forms of cytochrome P-450 (Gentest, Oxford Biomedical Research, Amersham Life Science). One can also obtain samples of human tissues, characterized with respect to cytochrome P-450 concentration and selected forms of cytochrome P-450 (International Institute for the Advancement of Medicine).

Materials

Samples for analysis
Individual forms of cytochrome P-450 as positive controls
Ponceau S solution (Sigma; dilute the solution—obtained as 2% Ponceau S in 30% TCA/30% sulfosalicylic acid—10-fold with distilled water for use)
Blocking buffer: 2.5% (w/v) BSA in PBS (with 0.1% ovalbumin, if chicken antibodies are used; *APPENDIX 2A* for PBS)
Primary antibodies: antibodies to individual forms of cytochrome P-450
Secondary antibodies: alkaline phosphatase conjugated IgG antibodies (e.g., Sigma)
Transfer buffer: 25 mM Tris base in 192 mM glycine
PBS (*APPENDIX 2A*)
5-Bromo-4-chloro-3-indolyl phosphate/nitroblue tetrazolium (BCIP/NBT) phosphatase substrate reagent (Kirkegaard & Perry; sold ready for use)
Molecular weight standards (e.g., Sigma, Amersham, Pharmacia, Biotech; 10 to 100 kDa, premixed)

Additional reagents and equipment for SDS-PAGE gel (*APPENDIX 3*) and electroblotting (*UNIT 2.3*)

Immunologically quantify individual forms of cytochrome P-450

1. Run samples (10 to 25 µg microsomes) containing cytochrome P-450 on SDS-PAGE gel (*APPENDIX 3*). To quantify the amount of a single form of the hemoprotein, interrupt electrophoresis when the bromphenol blue tracking dye has moved halfway down the lanes, and add incrementally increasing amounts (0 to 10 pmol) of that form of cytochrome P-450 in sample buffer to the individual tracks of the gel. Continue electrophoresis until the original tracking dye reaches within 1 cm of the bottom of the gel.

   For example, on a ten-track gel, assuming tracks 1 and 10 contain molecular weight standards, start additions from track 2 and add increasing amounts up to track 9.

2. Electroblot the gel onto nitrocellulose membrane (*UNIT 2.3*).
3. Rinse off the nitrocellulose membrane with transfer buffer and place in a plastic container. Add Ponceau S solution to just cover the membrane, and shake the container gently to stain all protein bands.
4. Rinse membrane with several changes of distilled water, and mark bands for the standards with a waterproof marking pen to indicate positions of the molecular-weight-marker proteins. Remove red dye by rinsing with distilled water until all red color is removed.

   Even if no protein bands are detected by Ponceau S staining, immunodetection may reveal proteins.

5. Place nitrocellulose membrane in a container with sufficient blocking buffer to cover. Shake gently for 1 hr at room temperature.

   The albumin binds to nonspecific protein-binding sites, blocking these sites so antibodies do not bind to them. This reduces background staining with the immunodetecting reagents.

Immunodetect cytochrome P-450

6. Decant blocking buffer from nitrocellulose membranes, and add primary antibody at a concentration of 1 μg IgG/ml in the same blocking buffer. Shake gently for 2 hr at room temperature.

   The antibody should be tested against the pure protein to which it has been raised to ensure that the concentration of antibody is sufficient to develop the immunoreaction color rapidly. If not, a higher concentration should be used. For some antibodies, particularly monoclonal and monospecific polyclonal antibodies, concentrations as high as 10 μg IgG/ml are sometimes needed.

7. Rinse the membrane three times by shaking with fresh blocking buffer 5 min each time.

8. Decant the last rinse, and cover the membrane with alkaline phosphatase–conjugated antibody to the species of antibodies used, diluted according to the manufacturer's specification. Shake gently 1 hr at room temperature.

   If the primary antibody to the cytochrome P-50 was raised in rabbit, then use anti–rabbit IgG–conjugated alkaline phosphatase. If the anti–cytochrome P-450 antibodies were raised in chickens, then use anti–chicken IgG–conjugated alkaline phosphatase.

9. Decant the secondary antibody from the membrane, and gently rinse nitrocellulose membrane twice 5 min with the blocking buffer, then once in PBS.

10. Develop the reaction by just covering nitrocellulose membrane with BCIP/NBT. Allow to develop 5 to 20 min, until sharp bands of intense purple color appear.

    A number of methods are available for the immunodetection, such as the use of horseradish peroxidase–conjugated second antibody and 4-chloro-1-napthol as the color-developing reagent on addition of hydrogen peroxide. The BCIP/NBT procedure is recommended because of its ease, convenience, and reproducibility. Longer development periods result in high background (pink) color levels that make visualization of low levels of protein difficult. It is better to use more primary antibody and secondary antibody in cases when low levels of protein antigen are expected.

    The BCIP/NBT solution is available as a ready-to-use reagent in the kit supplied by Kirkegaard & Perry.

11. Stop the reaction by decanting the reagent and rinsing the membrane several times with cold distilled water.

    Do not let the membranes sit too long in the reagent without rinsing, or rinse inadequately, or the background color will begin to rise, as noted.

12. Dry the nitrocellulose membrane by placing between filter papers. Place a weight on top to keep the membrane flat until dry.

13. Cover the dry nitrocellulose sheet with plastic wrap (e.g., Saran Wrap) for protection.

14. If desired, measure the density of color developed using a densitometer or by comparison with pure protein standards added to the tracks during electrophoresis for quantification.

    Match the color development of reactive bands in the immunoblot with those of the added pure proteins, which have only partially migrated and are located higher up in the tracks, to determine the amount of that form of cytochrome P-450 in the electrophoresed tissue. Individual forms of cytochrome P-450 in 10 μg of liver microsomal protein and 1 μg of pure cytochrome P-450 are readily detected by this procedure.

BASIC PROTOCOL 3

ENZYMATIC ANALYSES OF CYTOCHROME P-450 FORMS

The basic method for analysis of cytochrome P-450 forms in tissue or microsomal fraction takes advantage of an activity toward one or another substrate that is very much higher with one form of cytochrome P-450 than with other forms. This is not an absolutely accurate way of determining the presence or quantifying a specific form of cytochrome P-450 in microsomes or tissues, because the presence of a larger amount of a form with a much lower activity could still catalyze a considerable rate of metabolism of the test substrate. Nevertheless, laboratories do measure in vitro metabolism of substrates, such as 7-ethoxyresorufin O-deethylation and the 3-demethylation of caffeine as an indication of the activity of CYP1A2, the 7-hydroxylation of coumarin as an indicator of CYP2A6, the *p*-hydroxylation of aniline as an indication of CYP2E1, and the 6β-hydroxylation of testosterone as an indication of CYP3A. A general method is provided here for the assay of cytochrome P-450 enzyme activities in subcellular fractions of tissues. Various substrates may be assayed by their addition at concentrations ranging from 5 μM to 5 mM, depending on the substrate. For substrates that undergo demethylation reactions, a simple colorimetric assay may be used, based on the formation and quantification of the formaldehyde produced (Schenkman et al., 1967). Another colorimetric assay is available for the oxidation of aniline to *p*-aminophenol (Schenkman et al., 1967). Similarly, a fluorometric assay may be used for fluorescent products of 7-ethoxyresorufin O-deethylase activity (Burke et al., 1977). A very large number of drugs and chemicals are metabolized by cytochrome P-450 forms and can be quantified by gas chromatographic or HPLC analyses of metabolites formed, using the same basic assay procedure for production of metabolites—e.g., 6β-hydroxytestosterone—or consumption of substrate. Specific details are provided for measuring formaldehyde production during enzymatic N-dealkylation.

Materials

0.1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.15 M $MgCl_2$
Substrates for specific forms of cytochrome P-450 (e.g., 10 mM benzphetamine·HCl)
0.15 mM glucose-6-phosphate
Glucose-6-phosphate dehydrogenase
Microsomal suspension containing 6 mg/ml protein (see Support Protocols 1 and 2)
10 mg/ml NADPH in 1% $KHCO_3$
12.5% trichloroacetic acid (TCA)
Nash reagent (see recipe)
2 mM HCHO
Water bath, 58°C

1. For each substrate to be tested, prepare the following assay medium in a 25-ml Erlenmeyer flask (3 ml total):

   1.5 ml 0.1 M Tris·Cl, pH 7.4
   0.1 ml 0.15 M $MgCl_2$
   0.3 ml substrate in distilled H_2O (e.g., 10 mM benzphetamine·HCl)
   1 U glucose-6-phosphate dehydrogenase
   0.1 ml 0.15 mM glucose-6-phosphate
   0.5 ml distilled H_2O
   0.5 ml diluted microsomal suspension (1 mg/ml final).

   An alternative to glucose-6-phosphate dehydrogenase is isocitric dehydrogenase (1 U) and 0.1 ml of 0.24 mM isocitrate. These are added to keep the NADPH in the reduced state, because the NADP formed during the monooxygenase reaction is inhibitory.

2. Place the flasks in a 37°C water bath and shake at a rate sufficient to keep the surface swirling for aeration. Wait 2 min to allow temperature equilibration.

3. Start the reaction by adding 0.1 ml of 10 mg/ml NADPH.

   The reaction is linear for at least 10 min with most substrates, and for some may be linear for up to 30 min.

4. Remove 0.4-ml aliquots at different times, and add to test tubes containing 0.1 ml of 12.5% TCA.

   CAUTION: *TCA is a very corrosive acid. Rinse promptly if any spills occur.*

   Depending on what enzyme activity will be assayed, the reaction may be stopped at different time points by removing aliquots and combining with TCA, or by extraction with organic solvent. For example, aliquots could be removed at 0.0, 0.5, 1.0, 2.0, 5.0, and 10.0 min.

   If a time course is run, the initial rate may determined. The initial rate with a substrate is often determined with microsomes from animals pretreated with different inducing agents, such as phenobarbital, and compared with initial rates obtained with microsomes of the untreated animal, because such action selectively elevates one or more forms of P-450.

5. Centrifuge tubes to precipitate the protein into a tight pellet, and add 0.4 ml of clear supernatant to 0.4 ml Nash reagent. Place tubes in a 58°C water bath for 8 min, then cool to room temperature.

6. Also prepare formaldehyde standards containing 0, 4, 8, 16, and 30 µl of 2 mM HCHO in 0.4 ml assay medium (step 1). Add 0.1 ml of 12.5% TCA and 0.5 ml Nash reagent. Heat at 58°C and cool, as in step 5.

7. Read absorbance of all standards and samples at 420 nm (yellow color) and use the values for standards to construct a standard plot of absorbance versus cytochrome P-450 concentration. Determine cytochrome P-450 concentrations of samples by comparison of their absorbance values to the standard curve.

   The formaldehyde concentration range indicated will produce an absorbance range of 0.05 to 0.5. Rat liver microsomal metabolism of substrates like benzphetamine, which are N-demethylated, will produce an amount of formaldehyde in this range within 10 min.

SUBFRACTIONATION OF DIFFERENT TISSUES FOR ANALYSIS OF CYTOCHROME P-450 CONTENT

SUPPORT PROTOCOL 1

Current methods are all modifications of the procedure for fractionation of liver by Schneider (1948). Similar methods are used for brain tissues (Walther et al., 1986), skin of newborn mice and rats (Mukhtar and Bickers, 1981), term placenta (Juchau and Smuckler, 1973), and lung tissue (Hook et al., 1972), the latter two starting with 1:3 and 1:4 homogenates, respectively. A major difference among these tissues is large amounts of contaminating hemoglobin. Alternative methods are suggested for the skin of older animals (e.g., rats; Moloney et al., 1982).

Materials

Tissue to be fractionated
0.9% NaCl (*APPENDIX 2A*), ice cold
0.25 M sucrose/10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A* for Tris·Cl)
1.15% KCl/10 mM Tris·Cl, pH 7.4 (optional; see *APPENDIX 2A* for Tris·Cl recipe), ice cold
0.15 M KCl

Potter-Elvehjem glass homogenizer with motor-driven Teflon pestle (optional)
Liquid nitrogen (optional)

NOTE: Carry out all steps at 0° to 4°C.

1a. *Liver:* Remove liver from animal, then chill and carefully perfuse with ice-cold 0.9% NaCl.

1b. *Kidney:* Perfuse kidney in situ to remove blood, then remove from animal. Pierce the capsules, and squeeze the kidneys out. Split the organs, and scrape out the medullas and discarded before homogenizing the cortex.

1c. *Bovine adrenal glands:* Remove adrenals from animal. Split the organ and scrape away the medullas.

1d. *Skin of older animals:* Excise the skin, chill in ice-cold 1.15% KCl/10 mM Tris·Cl, pH 7.4, and remove the adipose and muscle layers.

2. Prepare a 1:10 homogenate in 0.25 M sucrose/10 mM Tris·Cl, pH 7.4: mince and homogenize the tissue in a Potter-Elvehjem glass homogenizer.

   The skin of older animals is too tough to homogenize. Freeze it in liquid nitrogen, grind to a fine powder, and then homogenize.

   The 10% homogenate allows for good fractionation of subcellular material without providing excessively large volumes. The tissue is easily homogenized in a glass homogenizer with a motor-driven Teflon pestle (e.g., Potter-Elvehjem) in two or three passes. Do not over-homogenize, as that can break mitochondria and decrease the efficiency of fractionation. Similarly, blade-driven blenders can fragment mitochondria. The liquid nitrogen freezing procedure is based on Moloney et al. (1982) and is very useful for subfractionating skin tissue.

3. Centrifuge the homogenate 10 min at 600 × *g* (measured at the bottom of the tube), 4°C, in a refrigerated preparative centrifuge to sediment the unbroken cells, nuclei, and cell debris.

   A layer of white lipid will float to the top of the liquid. This should be carefully removed. If yield is important, the pellet may be gently stirred in 0.2 vol sucrose/Tris·Cl, homogenized, and centrifuged again for 10 min at 600 × g. The supernatant should then be recombined with the prior supernatant fluid. This can increase the yield of microsomes by as much as 30% and will recover larger mitochondria pulled down with the debris.

4. Carefully pour the supernatant and washings into centrifuge tubes. Sediment the mitochondria from the supernatant by centrifuging 15 min at 6500 × *g*, 4°C.

   The mitochondrial pellet is dark brown in the center to beige or light tan in toward the periphery. A slight pink peripheral color is the result of lightly packed microsomes. If yield of microsomes is important, the mitochondrial fraction may be gently stirred, resuspended in 0.1 vol sucrose/Tris·Cl, and centrifuged again 10 min at 6500 × g, and the resulting supernatant added to the postmitochondrial supernatant.

5. *Optional:* If mitochondria are to be used, gently resuspend the pellets from the 6500 × *g* centrifugation and wash in half of the original volume in sucrose/Tris·Cl. Centrifuge 5 min at 15,000 × *g*, 4°C, to wash them. Repeat the wash one more time, and finally resuspend the mitochondria in the sucrose/Tris·Cl to 10 mg protein/ml. Keep on ice until use.

6. Centrifuge supernatant (from step 4) 10 min at 12,000 × *g*, 4°C, to sediment light mitochondria. Carefully decant the supernatant from the centrifuge tubes into a beaker on ice to prevent carryover of traces of mitochondria that may be lightly packed at the bottom.

   If it is important to have microsomes free of traces of mitochondria, add an additional centrifugation for 10 min at 18,000 × g. This will pellet any remaining light mitochondria, but will also sediment larger fragments of rough endoplasmic reticulum. To minimize loss of microsomes, if the brown to beige mitochondrial pellet has a significant overlaying of pink, carefully decant the supernatant. Add 5 ml sucrose/Tris·Cl to the tube, and gently swirl to recover the pink layer from the more densely packed mitochondria. Add the liquid to the supernatant fluid, and continue to the next step.

7. Centrifuge the supernatant 1 hr at 100,000 × *g* (measured at the bottom of the tube), 4°C, in a refrigerated ultracentrifuge.

   The microsomes will sediment as a pink pellet.

8. Decant the supernatant from the pellets to remove all the liquid. Add ~5 ml of 0.15 M KCl to tube.

9. Remove the microsomal pellet into the homogenizing tube with additional 0.15 M KCl to restore the volume and homogenize the pellet. Centrifuge the suspension 30 min at 100,000 × *g* to sediment the microsomal pellet.

   This step washes away traces of hemoglobin that may have been adsorbed to the microsomes. Some laboratories also buffer the KCl with 50 mM Tris·Cl, pH 7.4 (Matsubara et al., 1982). Under the pink pellet is a small translucent unpigmented pellet of glycogen. Some investigators starve the animals for 24 hr before sacrifice to remove this pellet, because glycogen will make microsomes much more turbid and spectroscopic measurements more difficult. Starvation, however, also influences the population of cytochrome P-450 in the microsomes (Favreau et al., 1987) and is best avoided. The next step makes starvation unnecessary.

10. Decant supernatant from pellets to remove all liquid. Add ~5 ml buffered sucrose to tube, and give tube a vigorous shake.

    This will cause the microsomal pellet to float free of the more tightly packed pellet of glycogen.

11. Add microsomal pellet to a chilled homogenizing vessel, and suspend in buffered sucrose to a convenient protein concentration (generally 20 mg/ml) for use (*APPENDIX 3*).

    Keep at 4°C until used, for up to 5 hr, or freeze to ≤20°C (not in frost-free freezer).

RAPID PREPARATION OF MICROSOMES

SUPPORT PROTOCOL 2

This protocol is an alternative method for preparation of microsomes, developed by Schenkman and Cinti (1978).

Additional Materials *(also see Support Protocol 1)*

80 mM $CaCl_2$

1. Homogenize tissue and prepare through 12,000 × *g* centrifugation as for subfractionation procedure (see Support Protocol 1, steps 1 to 6).

2. Determine the volume of the supernatant from the 6500 × *g* centrifugation, and add sufficient volume of 80 mM $CaCl_2$ to give a final concentration of 8 mM.

3. Allow the suspension to stand on ice for 15 min, then centrifuge 15 min at 25,000 × *g*.

   The microsomes will be a reddish opalescent pellet over a clear translucent pellet of glycogen (in fed animals).

4. Decant the supernatant fluid from the microsomal pellets, and carefully add ~5 ml of 0.15 M KCl to the tubes. Give each tube an individual, vigorous, swirling shake to float the microsomal pellet off of the glycogen pellet.

   For spectroscopy, it is important that the microsomes be free of glycogen.

5. Decant the microsomal pellets into the homogenizer and homogenize in 0.15 M KCl to a volume equivalent to the prior centrifuge tube volume.

   This procedure serves two purposes. The KCl wash removes almost all of the $CaCl_2$ and the remaining traces of hemoglobin that might be adsorbed to the microsomes.

6. Centrifuge the microsomal pellet 20 min at 25,000 × *g*.
7. Decant the supernatant. Add microsomal pellet to a chilled homogenizing vessel and suspend in buffered sucrose to 20 mg/ml for use.

Keep at 4°C until used, for up to 5 hr, or freeze to ≤20°C (not in frost-free freezer).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Nash reagent

Dissolve 150 g ammonium acetate in 900 ml distilled water and add ~3 ml glacial acetic acid to pH 6.0. Add 2 ml of colorless acetylacetone (if not colorless, redistill it), and dilute to 1 liter. Store up to 3 months at 4°C in a dark bottle.

COMMENTARY

Background Information

A very large number of forms of cytochrome P-450 exist in nature. Over 450 forms are currently on record, based on gene identification (*http://drnelson.utmem.edu/*). The various forms of cytochrome P-450 found in eukaryotic cells, from yeast to mammalian tissues, are membrane bound. In the rat >30 different forms have been identified, and estimates suggest perhaps a similar number exist in human tissues. Although spectrophotometrically these forms look alike, they differ in primary structure and catalytic activities toward different chemical substrates. The different forms of cytochrome P-450 strongly affect the physiologic, pharmacologic, and toxicologic influences of xenobiotics in the body. In recognition of this, many studies have been conducted and will continue to be carried out on the effect of the cytochrome P-450 enzymes on chemicals that enter the body.

Because cytochrome P-450 forms are hemoproteins, they have a strong absorption peak in the Soret region of the UV/VIS spectrum. Furthermore, when reduced and complexed with CO, they have an unusual strong absorption peak at 450 nm, which makes an ideal parameter for identifying and quantifying the hemoprotein. Because a large number of cytochrome P-450 forms exist in the different tissues (at least a dozen forms in liver microsomes alone) and because all have the same broad absorption peak at ~450 nm, it is not possible to discriminate among the forms and determine which form is present based on the 450-nm peak. Specific antibodies to one or another form of cytochrome P-450 in a tissue can be used for immunoquantification of that form; however, because antibodies will react with the apoproteins of the cytochrome P-450 forms, this procedure gives no indication of how much functionally active protein is present. Immunoquantification also gives no indication of the amount of other forms of cytochrome P-450 or of the total amount of cytochrome P-450 present in the tissue.

A third manner of measuring cytochrome P-450 is by enzyme activity, the measurement of the ability of the protein to metabolize a substrate. Although much has been written about the use of specific substrates of some forms of cytochrome P-450, in fact the cytochrome P-450 forms have a broad, overlapping ability to oxidize the different known substrates. One form may have a 10-fold or greater specific activity toward a substrate than does another form; but unless one knows precisely the amount of the other form present and its specific activity toward that substrate, it is not possible to determine from activity how much of a particular form of cytochrome P-450 is present in a tissue. Even antibody inhibition of substrate metabolism is not a precise measure of the amount of an enzyme present but only an indication of the possible inhibitable portion of activity in that tissue fraction attributable to the cytochrome P-450 form to which the antibody reacts. Although each of the methods discussed has drawbacks, all nevertheless have utility, depending on the information needed.

About as many different methods of subfractionating brain tissue for analysis of cytochrome P-450 forms in mitochondria and microsomes have been published as there are investigators carrying out such studies. Methods in the literature range from homogenization in 4 vol of 1.15% KCl and subfractionation as

for liver (Cohn et al., 1977; see Support Protocol 1) to homogenization in 1.15% KCl/0.02 M Tris·Cl, pH 7.4/15% glycerol/0.5 mM dithiothreitol/0.2 mM EDTA (Sasame et al., 1977) to similar preparations with sucrose concentrations ranging from 0.32 to 0.4 M. Basically, it would appear that separation of brain mitochondria and brain microsomes follows procedures similar to that of liver, and that, although cytochrome P-450 levels are considerably lower, they are readily measured in these fractions by procedures indicated in the Support Protocols.

Critical Parameters

Each of the methods discussed here has critical parameters. For example, in spectrophotometric analysis with membranous material, light scattering is a potential problem. Many spectrophotometers solve this problem by having the cuvette positioned close to the photomultiplier or detector. The farther the cuvette is from the detector, the greater the loss of light owing to scattering by the sample suspension. Turbidity of a sample increases the amount of error after additions to the cuvette, because small dilutions of a turbid sample can cause major baseline shifts if not precisely matched in the two cuvettes during difference spectroscopy. One of the major sources of turbidity in measuring liver cytochrome P-450 is glycogen. In the past, investigators would starve the animals for 24 hr before killing them. Although this did reduce glycogen levels in the liver, subsequent studies revealed that cytochrome P-450 forms present in tissue respond to starvation, some increasing in content in the microsomes and others decreasing. A better method, which does not alter the relative amounts of the different forms, is to separate the microsomes from the glycogen pellet very carefully, as described in this unit. Another potential problem, which can cause considerable confusion, involves the stability of dithionite. It is possible to detect erroneously only small amounts of cytochrome P-450, or even none, in microsomes if degraded dithionite is used. If dithionite has degraded, it will not reduce the hemoprotein or will possess only a small amount of reducing capacity. For this reason, it is important to keep the dithionite dry and periodically test its utility by its ability to reduce a known sample, for example cytochrome *c* or even a known concentration of cytochrome P-450.

In some tissues, such as brain and testes, microsomal levels of cytochrome P-450 are very low. Attempts to measure the hemoprotein level in the microsomes spectrophotometrically are often confounded by the presence of large amounts of hemoglobin adsorbed to the microsomes. It is necessary to wash away most of the hemoglobin so as not to interfere with the measurements by spectral overlap. Techniques are indicated for bypassing spectral overlap; but if too much hemoglobin is present, even these procedures are ineffectual.

In the electroblotting methods, it cannot be stressed too strongly that bubbles will interfere with the transfers. These must be carefully eliminated when preparing the transfer sandwich. Bubbles can also appear during the actual transfer if one is not careful to control the temperature of the medium. If the temperature is allowed to rise, dissolved gases will come out of solution and can collect between the polyacrylamide gel and the nitrocellulose, causing a distortion and a loss of integrity of the transfer. To prevent this, maintain the transfer temperature either by using circulating cooling water, if the transfer unit is so constructed; by running the transfer in a cold room; or by lowering the transfer voltage. In the latter case, the transfer time has to be increased.

Anticipated Results

Although some variability exists among laboratories with respect to the content of cytochrome P-450 in tissues and subcellular fractions, the variation is not that great. In general, expect to find on the order of 0.5 to 1.0 nmol of constitutive cytochrome P-450 in liver microsomes per milligram of liver microsomal protein of male rats and about twice that concentration in rabbits. Levels in female rats are generally about half those in males. The cytochrome P-450 forms are inducible by drugs and chemicals; different forms respond to exposure to different agents. Greater variability has been seen in human liver microsomes. Levels in kidney cortex microsomes generally are about half that in the liver, and much lower levels are seen in other tissues. For example, total cytochrome P-450 levels in the lung may be as low as 10% that in the liver, whereas levels in the brain are generally as low as 1% of the content in the liver, necessitating partial purification for spectral measurements.

If a specific antibody prepared against a form of cytochrome P-450 is available, it is generally possible to make measurements of that form in different tissues, even when present at picomole levels; 0.5 µg of cytochrome P-450 (10 pmol) gives a strong band in immunoblots.

Measurements of enzyme activity have a sensitivity that depends on the substrate used. For some substrates, activity is generally low but a fluorescent product is produced with an extremely high sensitivity of measurement. Of the three procedures described here, perhaps the most variable is the metabolism assay, because it requires functionally active cytochrome P-450 and functionally active NADPH–cytochrome P-450 reductase. A number of conditions of the assays will also influence the observed specific activity obtained.

Time Considerations

Spectrophotometric analyses are fairly quick, easy methods if the various buffers needed are available. Typically, the time needed is <1 hr, including zeroing of the spectrophotometer and balancing of the cuvettes spectrophotometrically. Preparation of subcellular membrane fractions could take as long as 4 or 5 hr, depending on the procedure used, the subcellular fraction desired, and the tissue examined. Immunoblotting requires ~6 hr for the various steps and intermediary handling. About 1 hr is required for the transfer of protein from the polyacrylamide gel to the nitrocellulose, followed by 1 hr for shaking the sample in blocking buffer and 2 hr for exposure to the primary antibody. Reaction with the secondary antibody takes 1 hr and development of the color up to 20 min.

The assays of metabolic activity vary with the methods used; the actual metabolism ranges from 10 to 60 min, depending on the substrate chosen. Analysis of product formed could be as short at 1 hr for the colorimetric determination of formaldehyde formed during N-demethylations to 2 or 3 hr for some of the analyses that require extractions and preparations for chromatographic measurement.

Purification of Cytochrome P-450 Enzymes

The microsomal cytochromes P-450 (P-450s) are notable as major xenobiotic-metabolizing enzymes in mammalian liver. A variety of P-450 enzymes are found in most animal tissues. P-450 2E1 is of general interest because of its role in the bioactivation of a number of potent animal carcinogens. P-450 1A2 is of interest because of its role in the oxidation of many drugs and carcinogens. In humans, P-450 1A2 is the major enzyme involved in the oxidation of caffeine and in the activation of many aryl and heterocyclic amines. Successful purification and reconstitution of the individual mammalian P-450 enzymes is useful for discriminating between their contributions when there is overlapping substrate specificity and for accurately characterizing the kinetic parameters of the individual P-450s.

Microsomal P-450s have been solubilized and at least partially purified from a variety of sources. A number of procedures have been described for purification of individual P-450s from animal tissues. The protocols described in this unit specifically describe the purification steps for isolation of microsomal P-450s 2E1 and 1A2 from an *Escherichia coli* over-expression system in which the N termini have been modified to improve expression levels. These protocols are useful for purification from other expression systems, although the yield and purity of the preparations may vary.

COLUMN CHROMATOGRAPHY FOR PURIFICATION OF RECOMBINANT HUMAN P-450 2E1

BASIC PROTOCOL 1

This protocol describes the chromatographic steps required to purify P-450 2E1 to electrophoretic homogeneity from a preparation of homogenized *E. coli* membranes over-expressing human P-450 2E1 in which the N terminus has been modified to improve expression levels (Gillam et al., 1994). Before beginning chromatographic purification, membrane-bound P-450 2E1 must be solubilized from the membranes with a detergent solution (sodium cholate and Triton N-101), and the active site stabilized by the addition of 4-methylpyrazole (4-MP), a tight-binding inhibitor of P-450 2E1. P-450 2E1 is isolated through a series of ion-exchange steps using both ionic and nonionic detergents, as well as the stabilizing ligand 4-MP, to maintain the structural integrity of the protein throughout purification. Binding and recovery at each step can easily be quantified by spectrophotometric measurement of the reduced carbon monoxide–bound P-450, observed at 450 nm (Omura and Sato, 1964; see *UNIT 4.1*). The purified protein can be stored for at least 2 years at −20°C.

NOTE: A key to success with this procedure is careful equilibration of columns before protein loading. In addition, binding is improved at lower loading rates, which can be achieved by diluting the protein or decreasing sample flow rates.

Materials

E. coli membrane preparation containing P-450 2E1 (Gillam et al., 1994)
Membrane solubilization solution for P-450 2E1 (see recipe)
Diethylaminoethyl (DEAE) Sephacel ion exchanger resin (Pharmacia Biotech)
DEAE equilibration buffer for P-450 2E1 (see recipe)
Carboxymethyl (CM) Sepharose Fast Flow ion exchanger resin (Pharmacia Biotech)
CM equilibration buffer for P-450 2E1 (see recipe)
20% (v/v) glycerol (see recipe)
0.1 to 1 M H_3PO_4

Contributed by L.C. Bell-Parikh, N.A. Hosea, M.V. Martin, and F.P. Guengerich
Current Protocols in Toxicology (1999) 4.2.1-4.2.12

50 mM CM wash buffer for P-450 2E1 (see recipe)
10 mM CM elution buffer (see recipe)
200 mM CM elution buffer (see recipe)
Hydroxylapatite (HA) Fast Flow chromatographic support (Calbiochem)
HA equilibration buffer (see recipe)
HA elution buffer (see recipe)
Post-HA dialysis buffer for P-450 2E1 (see recipe)

Empty 20- and 100-ml chromatographic columns
Empty CM Sepharose Fast Flow column
Spectrapor 12,000- to 14,000-MWCO dialysis tubing (Spectrum Medical Industries)

Additional reagents and equipment for ion exchange chromatography (*APPENDIX 3*) and for SDS-PAGE and silver staining of gels (*APPENDIX 3*)

Solubilize membranes

1. Dilute *E. coli* membrane preparation to a protein concentration of 2 mg/ml in membrane solubilization solution for P-450 2E1.

   Volumes will vary depending on the total amount of protein in the membrane preparation. For a protocol describing preparation of membranes, see Gillam et al. (1993).

Perform DEAE chromatography

2. For a bacterial membrane preparation containing ~3.5 g of total protein with a specific content of 0.4 nmol P-450/mg protein (i.e., 1400 nmol P-450), pack a 100-ml column with DEAE Sephacel resin to a volume of 75 ml (2.5 × 15 cm).

   Although CM and HA resins can be re-equilibrated and reused following protein elution, regeneration of the DEAE Sephacel column is not recommended. A freshly prepared column is highly desirable for successful purification of P-450s.

3. Equilibrate column with a minimum of 5 column volumes of DEAE equilibration buffer for P-450 2E1 at a flow rate of ~1 ml/min.

4. Remove membrane components from the solution of solubilized membranes by ultracentrifugation 60 min at $10^5 \times g$, 4°C.

   Failure to do this will result in destruction of the chromatographic bed.

5. Load solubilized membranes onto column at a flow rate of ~1 ml/min.

   P-450 2E1 elutes in the void volume. Often most, if not all, of the cytochrome P-450 (representing any denatured P-450 plus non-P-450 bacterial hemoproteins) will be removed from the sample during this step.

6. Follow the solubilized membrane preparation with at least 1 column volume of DEAE equilibration buffer to displace the P-450 in the column void volume. Collect the eluate.

Perform CM chromatography

7. Pack a CM Sepharose Fast Flow column and equilibrate with a minimum of 5 column volumes of CM equilibration buffer for P-450 2E1.

   A CM column packed to ~20 ml (1.5 × 10 cm) will typically bind up to 1000 nmol of P-450 2E1.

   It is essential that the pH of this buffer be adjusted to 6.5. At pH >6.5, P-450 2E1 will not bind well to the column. If the pH is too acidic, however, the structural integrity of the P-450 may be compromised.

8. Dilute the DEAE Sephacel void volume (step 6) 3-fold with 20% (v/v) glycerol, and adjust to pH 6.5 using dilute H_3PO_4 (0.1 to 1 M).

   The volume of the 3-fold-diluted DEAE void is substantial and it may take up to 3 days to load completely onto the CM column. Because P-450 2E1 is slightly more stable at pH 7.4 than at 6.5, dilute fractions recovered from only one DEAE column at a time. Another batch can be diluted and pH adjusted to 6.5 once the previous batch has been completely loaded onto the CM column. Alternatively, CM columns can be run in parallel if a larger preparation is done.

9. Load the protein onto the column.

   The P-450 should bind tightly to the top of the column, forming a visible brownish-red zone of binding. If the protein does not bind well, even if all of the solutions are properly adjusted to pH 6.5, decrease the flow rate of the protein solution onto the column. This may be all that is required to improve binding.

10. After the protein has completely loaded, wash the column extensively with a minimum of 5 column volumes of 50 mM CM wash buffer for P-450 2E1.

11. Elute the protein using a K^+ gradient from 10 mM to 200 mM (250 ml each of 10 mM and 200 mM CM elution buffer) at a flow rate of 1 ml/min . Collect eluate in ~5-ml fractions.

12. Analyze CM fractions by running aliquots on a 7% (w/v) acrylamide SDS-PAGE gel and visualizing proteins by silver staining (*APPENDIX 3*, Guengerich, 1994). Pool fractions that are electrophoretically homogeneous (M_r 50 kDa).

    The purified protein must be further chromatographed to remove detergent and 4-MP from the preparation.

Perform HA chromatography

13. Dialyze the pooled CM fractions ~8 to 12 hr at 4°C against three 2-liter changes of HA equilibration buffer.

    This will reduce ionic strength to permit HA binding.

14. Pack a column with HA Fast Flow chromatographic support and equilibrate with 5 column volumes HA equilibration buffer.

    A column packed to ~15 ml (1.5 × 8 cm) with HA Fast Flow will usually accommodate up to 1000 nmol of P-450 2E1.

15. Load the P-450 slowly onto the HA column at a flow rate of ≤0.5 ml/min.

    Again, the P-450 should bind tightly, forming a brownish-red zone of binding at the top of the column.

16. Wash the column extensively with HA equilibration buffer to remove Triton N-101.

    In this case, 10 or more column volumes may be required to remove the detergent completely. Detergent removal can be monitored by measuring absorbance at 280 nm. Absorbance should decrease to ≤0.01.

17. Elute the protein from the HA column using HA elution buffer.

    At this ionic strength, P-450 2E1 elutes in a very sharp band, which can easily be collected manually or by using a fraction collector.

    HA from different suppliers yields varying success at this step. Calbiochem Fast Flow HA has consistently provided the highest yield. Other preparations of HA have proven resistant to protein elution.

Dialyze protein

18. Dialyze the purified P-450 2E1 using Spectrapor 12,000- to 14,000-MWCO dialysis tubing for ~8 to 12 hr at 4°C against three successive 2-liter changes of post-HA dialysis buffer for P-450 2E1.

    This dialysis serves to decrease the concentration of potassium phosphate for long-term storage of the protein.

    When stored at 4°C, the protein is stable 1 to 2 weeks. When stored at −20°C, the preparation remains spectrally and catalytically stable ~2 years. Storage at −70°C does not significantly improve the shelf life of the purified P-450.

BASIC PROTOCOL 2

COLUMN CHROMATOGRAPHY FOR PURIFICATION OF RECOMBINANT HUMAN P-450 1A2

This protocol describes the chromatographic steps required to purify P-450 1A2 to electrophoretic homogeneity from a preparation of homogenized *E. coli* membranes over-expressing P-450 1A2 (Sandhu et al., 1994). Detergent-solubilized membranes containing P-450 1A2, stabilized by the specific inhibitor α-naphthoflavone (α-NF), are purified through a two-step chromatographic protocol. Purified P-450 1A2 can be stored for at least 2 years at −20°C.

Materials

E. coli membrane preparation containing P-450 1A2 (Sandhu et al., 1994)
Membrane solubilization solution for P-450 1A2 (see recipe)
Diethylaminoethyl (DEAE) Sephacel Fast Flow ion exchanger resin (Pharmacia Biotech)
DEAE equilibration buffer for P-450 1A2 (see recipe)
Carboxymethyl (CM) Sepharose Fast Flow ion exchanger resin (Pharmacia Biotech)
CM equilibration buffer for P-450 1A2 (see recipe)
2× dilution solution (see recipe)
50 mM CM wash buffer for P-450 1A2 (see recipe)
100 mM CM wash buffer (see recipe)
300 mM CM elution buffer (see recipe)
500 mM CM elution buffer (see recipe)
Empty 40- and 70-ml chromatographic columns
Additional reagents and solutions for ion exchange chromatography (*APPENDIX 3*) and for SDS-PAGE and silver staining of gels (*APPENDIX 3*)

Solubilize membranes

1. Dilute *E. coli* membrane preparation to a protein concentration of 2 mg/ml in membrane solubilization solution for P-450 1A2.

   For a protocol describing preparation of membranes, see Gillam et al. (1993). For further reference, see Sandhu et al. (1994).

Perform DEAE chromatography

2. Pack DEAE Sephacel resin into a column according to manufacturer's instructions to a size of 2.5 × 13 cm.
3. Equilibrate column at a flow rate of ~1 ml/min with DEAE equilibration buffer for P-450 1A2 until the pH and ionic strength of the eluate is that of the equilibration buffer.

   This usually requires 5 to 10 column volumes of buffer.

4. Remove membrane components from the solution of solubilized membranes by ultracentrifugation 60 min at $10^5 \times g$, 4°C.

   Failure to do this will result in destruction of the chromatographic bed.

5. Load solubilized membranes onto the column at a flow rate of ~1 ml/min.

6. Wash the column with 1 column volume of DEAE equilibration buffer to displace the P-450 in the column void volume. Collect the eluate.

Perform CM chromatography

7. Pack CM Sepharose resin into a column according to manufacturer's instructions to a size of 2.5 × 6 cm.

8. Equilibrate the column with CM equilibration buffer for P-450 1A2 until the pH and ionic strength of the eluate are equal to those of the equilibration buffer.

   The proper pH of the CM resin is important, because the efficiency of binding for P-450s to a CM column is sensitive to the pH of the column resin.

9. Pool the void fractions from step 6 and dilute 2-fold with 2× dilution solution to achieve a final concentration of 25 mM Tris·Cl, pH 7.4 (all other components remain at same concentration as in DEAE equilibration buffer).

10. Load the diluted P-450 sample onto the equilibrated CM column at a flow rate of ~1 ml/min.

    As the P-450 1A2 binds the CM resin, a dark brown band should appear and should not occupy >75% of the column. If overloading occurs, begin loading onto a second CM column. If the P-450 does not bind, reduce the flow rate and/or dilute the solution further before loading.

11. After the P-450 sample has completely loaded, sequentially wash column with 400 ml each of 50 mM CM wash buffer for P-450 1A2 and 100 mM CM wash buffer.

    This step will remove the α-NF and the detergent.

12. Sequentially elute the P-450 1A2 protein with 300 mM and 500 mM CM elution buffers; collect 10-ml fractions.

13. Analyze CM fractions by running aliquots on a 7% (w/v) acrylamide SDS-PAGE gel and visualizing proteins by silver staining (*APPENDIX 3*; Guengerich, 1994).

14. Pool homogeneous fractions and freeze in 1-ml aliquots at −20°C.

    For storage, the protein may be in 100, 300, or 500 mM CM elution buffer; the potassium phosphate concentration can vary between 100 mM and 500 mM, but should not be <100 mM.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent forall recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

For buffers containing dithiothreital (DTT), the DTT should be added immediately before use because it slowly oxidizes in solution at neutral pH. Without DTT, all buffer solutions are stable for several months at 4°C.

Carboxymethyl (CM) elution buffer, 10 mM

2.5 ml 1 M potassium phosphate, pH 7.4 (10 mM final)
2.5 ml 20% (v/v) Triton N-101 (0.2% v/v final)
50 ml glycerol (20% v/v final)
0.5 ml 100 mM sodium EDTA (see recipe; 0.2 mM final; see recipe)
40 mg DTT (1.0 mM final)
250 µl 50 mM 4-MP (50 µM final)
H_2O to 250 ml

Carboxymethyl (CM) elution buffer, 200 mM

50 ml 1 M potassium phosphate, pH 7.4 (200 mM final)
2.5 ml 20% (v/v) Triton N-101 (see recipe; 0.2% v/v final)
50 ml glycerol (20% v/v final)
0.5 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
40 mg DTT (1.0 mM final)
250 µl 50 mM 4-MP (50 µM final)
H_2O to 250 ml
Store up to several months at 4°C

Carboxymethyl (CM) elution buffer, 300 mM

300 ml 1 M potassium phosphate, pH 7.4 (300 mM final)
200 ml glycerol (20% v/v final)
2 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
160 mg DTT (1.0 mM final)
H_2O to 1 liter
Store up to several months at 4°C

Carboxymethyl (CM) elution buffer, 500 mM

500 ml 1 M potassium phosphate, pH 7.4 (500 mM final)
200 ml glycerol (20% v/v final)
2 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
160 mg DTT (1.0 mM final)
H_2O to 1 liter
Store up to several months at 4°C

Carboxymethyl (CM) equilibration buffer for P-450 2E1

10 ml 1 M sodium phosphate, pH 6.5 (20 mM final)
100 ml glycerol (20% v/v final)
1.0 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
H_2O to 500 ml
Store up to several months at 4°C

Carboxymethyl (CM) equilibration buffer for P-450 1A2

20 ml 1 M sodium phosphate, pH 7.4 (20 mM final)
200 ml glycerol (20% v/v final)
2.0 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
160 mg DTT (1.0 mM final)
6 ml 5 mM α-NF (see recipe; 30 µM final)
H_2O to 1 liter
Store up to several months at 4°C

Carboxymethyl (CM) wash buffer, 50 mM, for P-450 2E1

25 ml 1 M sodium phosphate, pH 6.5 (50 mM final)
100 ml glycerol (20% v/v final)
1.0 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
80 mg DTT (1.0 mM final)
H_2O to 500 ml
Store up to several months at 4°C

Carboxymethyl (CM) wash buffer, 50 mM, for P-450 1A2

25 ml 1 M sodium phosphate, pH 7.4 (50 mM final)
100 ml glycerol (20% v/v final)
1.0 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
80 mg DTT (1.0 mM final)
H_2O to 500 ml
Store up to several months at 4°C

Carboxymethyl (CM) wash buffer, 100 mM

100 ml 1 M sodium phosphate, pH 7.4 (100 mM final)
200 ml glycerol (20% v/v final)
2.0 ml 100 mM sodium EDTA (see recipe; 0.2 mM final)
160 mg DTT (1.0 mM final)
H_2O to 1 liter
Store up to several months at 4°C

DEAE equilibration buffer for P-450 2E1

25 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*; 50 mM final)
100 ml glycerol (20% v/v final)
5.0 ml 100 mM sodium EDTA (see recipe; 1.0 mM final)
80 mg DTT (1.0 mM final)
16 ml 20% (w/v) sodium cholate (see recipe; 0.6% w/v final)
32 ml 20% (v/v) Triton N-101 (see recipe; 1.2% v/v final)
0.5 ml 50 mM 4-MP (50 μM final)
H_2O to 500 ml
Store up to several months at 4°C

DEAE equilibration buffer for P-450 1A2

25 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*; 50 mM final)
100 ml glycerol (20% v/v final)
5.0 ml 100 mM sodium EDTA (see recipe; 1.0 mM final)
80 mg DTT (1.0 mM final)
16 ml 20% (w/v) sodium cholate (see recipe; 0.6% w/v final)
32 ml 20% (v/v) Triton N-101 (see recipe; 1.2% v/v final)
3 ml 5 mM α-NF (see recipe; 30 μM final)
H_2O to 500 ml
Store up to several months at 4°C

Dilution solution, 2×, for P-450 1A2

200 ml glycerol (20% v/v final)
10 ml 100 mM sodium EDTA (see recipe; 1.0 mM final)
160 mg DTT (1.0 mM final)
31.25 ml 20% (w/v) sodium cholate (see recipe; 0.625% w/v final)
62.5 ml 20% (w/v) Triton N-101 (see recipe; 1.25% w/v final)
6 ml 5 mM α-NF (see recipe; 30 μM final)
H_2O to 1 liter
Store up to several months at 4°C

Glycerol solution, 20% (v/v)

Dissolve 200 ml glycerol in ~700 ml of water with stirring. Dilute to 1 liter. Store up to several months at 4°C

Hydroxylapatite (HA) elution buffer

150 ml 1 M potassium phosphate, pH 7.4 (300 mM final)
100 ml glycerol (20% v/v final)
250 µl 100 mM sodium EDTA (see recipe; 50 µM final)
H_2O to 500 ml
Store up to several months at 4°C

Hydroxylapatite (HA) equilibration buffer

5 ml 1 M potassium phosphate, pH 7.4 (10 mM final)
100 ml glycerol (20% v/v final)
250 µl 100 mM sodium EDTA (see recipe; 50 µM final)
H_2O to 500 ml
Store up to several months at 4°C

Membrane solubilization solution for P-450 2E1

50 mM Tris·Cl buffer, pH 7.4 (*APPENDIX 2A*)
20% (v/v) glycerol
0.625% (w/v) sodium cholate (see recipe)
1.25% (v/v) Triton N-101 (see recipe)
1.0 mM sodium EDTA (see recipe for 100 mM EDTA stock)
1.0 mM DTT
50 µM 4-MP
Store up to several months at 4°C

Membrane solubilization solution for P-450 1A2

50 mM Tris·Cl buffer, pH 7.4 (*APPENDIX 2A*)
20% (v/v) glycerol
0.625% (w/v) sodium cholate (see recipe)
1.25% (v/v) Triton N-101 (see recipe)
1.0 mM sodium EDTA (see recipe for 100 mM EDTA stock)
1.0 mM DTT
30 µM α-NF (add from 5 mM α-NF stock solution; see recipe)
Store up to several months at 4°C

4-Methylpyrazole (4-MP), 50 mM

Dissolve 410 mg 4-methylpyrazole (solid, Sigma) in 100 ml acetone. Store at 4°C in sealed glass container to prevent evaporation.

α-Naphthoflavone (α-NF), 5 mM

Dissolve 64 mg α–NF (7,8-benzoflavone, FW 272.3) in 50 ml methanol. Store in a sealed amber bottle at 4°C to prevent evaporation.

Post-HA dialysis buffer

200 ml 1 M potassium phosphate, pH 7.4 (100 mM final)
1.0 ml 100 mM sodium EDTA (see recipe; 50 µM final)
400 ml glycerol (20% v/v final)
H_2O to 2 liters
Store up to several months at 4°C

Sodium cholate, 20% (w/v)

Add 100 g cholic acid (sodium salt; Sigma) to 400 ml water. Adjust to pH 6.5 with 1 M acetic acid (slowly). Adjust volume to 500 ml with water. Store at 4°C.

As acid is added to the sodium cholate mixture, precipitation will occur. Once precipitate has redissolved, continue to add more acid. Preparation of this stock solution is tedious; therefore, as a matter of convenience, it is recommended that this stock be prepared before beginning any purification steps.

Sodium EDTA, 100 mM

Add 38.0 g EDTA (tetrasodium salt) to 900 ml water. Stir until in solution (if difficult, adjust pH >8 with NaOH). Adjust pH to 7.4 with HCl. Adjust volume to 1 liter with water. Store up to several months at 4°C.

Triton N-101, 20% (w/v)

Dissolve 100 g Triton N-101 (Sigma) in water to a total volume of 500 ml. Store at 4°C.

Dissolving the detergent may be difficult; to facilitate solution the beaker containing the mixture can be stirred in an ice bucket containing warm tap water. Do not heat excessively.

COMMENTARY

Background Information

Microsomal P-450s have been solubilized and purified from a variety of sources. A number of procedures have been described for purification of individual P-450s from animal tissues (Guengerich, 1987). The choice of purification method depends on the P-450; the source of the protein; and other factors, such as whether co-purification of additional proteins is desired. Many systems have been developed for expression of various P-450s (Porter et al., 1990; Waterman and Johnson, 1991). *E. coli* has provided excellent success with high levels of expression and relatively low cost. In addition, the ease of purification is much greater than from mammalian tissues.

P-450 2E1 is of general interest because of its role in the bioactivation of a number of potent animal carcinogens. P-450 2E1 exhibits a particular difficulty in regard to purification from animal sources, because there is a high degree of interindividual variability of expression with this protein (Peter et al., 1990). The protocol in this unit specifically describes the purification steps for isolation of P-450 2E1 from an *E. coli* over-expression system in which the N terminus has been modified to improve expression levels (Gillam et al., 1994).

Other purification procedures for P-450 2E1 have been reported. Omata et al. (1994) described a method for the immunopurification of P-450 2E1 using an immunosorbent comprised of a Sepharose–monoclonal antibody conjugate. Although 10% to 20% of total microsomal P-450 can be immunopurified from rat microsomes, the specific yield of P-450 2E1 is not clear, nor is the catalytic activity following elution from the sorbent. This method, however, has the advantage that associated proteins may be co-purified. Purification using a flavodoxin affinity column has been attempted with an overall yield of ~15% (Gillam et al., 1995). The procedure reported here uses DEAE and CM ion exchange chromatography followed by binding to HA to remove detergent from the preparation. Typically, the yield of purified P-450 2E1 is 50% of the total P-450 measured in the solubilized membrane preparation. Hydrophobic chromatography has been offered as a faster alternative to CM for fractionation of proteins (Grogan et al., 1995). FPLC using an octyl-Sepharose hydrophobic column generated an electrophoretically homogeneous protein with essentially no P-420, and catalytic activities were comparable to microsomal levels. The yield was comparable to that of the procedure reported here.

P-450 1A2 is of interest because of its role in the oxidation of many drugs and carcinogens (Guengerich, 1995). In humans this P-450 is the major one involved in oxidation of caffeine and in the activation of many aryl and heterocyclic amines (Butler et al., 1989; Guengerich, 1995). Human P-450 1A2 was first purified from liver samples, but the yield and purity were problematic (Butler et al., 1989). The enzyme has been expressed in bacteria after modification of the N-terminal sequence for optimal translation (Sandhu et al., 1994). Purification was hindered by the instability of the holoprotein in the presence of detergents, but this problem was overcome by the use of the tightly bound ligand α-NF.

Other bacterial expression systems include an approach by which a fusion protein is produced with rat NADPH-P-450 reductase (Parikh and Guengerich, 1997). The fusion protein can be purified using a 2é,5é-ADP affinity column and used in catalytic assays. The catalytic activity, however, is not as high as that of purified P-450 1A2 reconstituted with reductase.

The same basic pCW vector that is used in *E. coli* can be used to express human P-450 1A2 in *Salmonella typhimurium* TA1538 (Josephy et al., 1995), and the protein can be purified using the method described here. Human P-450

1A2 has also been expressed in yeast and purified using an alternate procedure (Imaoka et al., 1996).

Modified versions of the protocols have been used to purify other human P-450 enzymes expressed in bacteria (Guengerich et al., 1996).

Critical Parameters and Troubleshooting

Sample loss during these procedures is generally not a result of the chromatography steps. During purification, P-450, in general, is most stable when bound to a column. Large sample volumes, however, prohibit rapid loading of protein onto columns. One may find that the P-450 slowly degrades in solution before it is passed over DEAE. To minimize this problem, it is important to keep all enzyme solutions and buffers at 4°C. Ideally, all chromatography is done in a refrigerated space at 4°C. Glycerol, 4-MP, and α-NF structurally stabilize the P-450 and aid in minimizing degradation. If desired, more than one column can be prepared for sample loading so that the enzyme may be more ra! pidly loaded. If materials are properly stored at 4°C, however, this is not necessary and will not substantially increase yields. This may be worthwhile in the interest of saving time.

It is useful to reiterate that an important key to success with this procedure is careful equilibration of columns before protein loading. In addition, binding is improved at lower loading rates, which can be achieved by protein dilution or by decreasing sample flow rates. Use care not to overload the columns. CM and HA columns should be no more than ~70% colored as a result of to protein binding.

Purified P-450s are not particularly soluble proteins. Glycerol (20%) is required for maintaining microsomal P-450 stability. The active site inhibitors 4-MP and α-NF should be added to all solutions, as specified, to stabilize the protein until the final purification step, when the detergent and inhibitors are removed to yield catalytically active enzymes.

Purification of P-450 2E1

For CM chromatography with P-450 2E1, pH is critical in moderating protein-binding interactions. All solutions should be adjusted to pH 6.5 for proper binding of the protein. Here again, stability may be an issue. P-450 2E1 may begin to denature at pH 6.5. To minimize protein loss, dilute and adjust the pH of the DEAE void volume in fractions. Do not prepare more enzyme solution than can be loaded within 12 hr.

In regard to the HA purification step, it should be noted that some preparations of HA bind P-450 2E1 so tightly that the purified protein is eluted with difficulty, giving rise to very poor yields. The greatest success with P-450 2E1 (but not with certain other P-450s) has been obtained with HA from Calbiochem.

Purification of P-450 1A2

One very important point regarding human P-450 1A2 is that α-NF must be present during the initial steps when detergents are added. Some other ligands have been tried but are not as effective in preventing degradation of the protein (Sandhu et al., 1994). Another point, which applies to P-450 1A2 enzymes purified from rats and rabbits as well, is that the ionic

Table 4.2.1 Typical Yields of P450 2E1 from Purification Steps

	P450 (nmol)	% yield from previous step	Total % yield
Solubilized membranes	1350	100	100
DEAE void	1200	89	89
CM-pooled fractions	700	58	52
HA-purified P450 2E1	650	93	48

Table 4.2.2 Typical Yields of P450 1A2 from Purification Steps

	P450 (nmol)	% yield from previous step	Total % yield
Solubilized membranes	684	100	100
DEAE void	470	69	69
CM-pooled fractions	210	45	31

strength of purified preparations must not be low in the absence of detergents. A safe guide is 100 mM phosphate or the equivalent ionic strength with other buffers containing NaCl, etc (e.g., Tris·Cl plus 300 mm NaCl).

Anticipated Results

Tables 4.2.1 and 4.2.2 present typical yields for the two protocols. In both cases, the resulting protein is electrophoretically homogenous.

Time Considerations

This entire purification, from solubilized membranes to purified, detergent-free P-450, takes ~1 week. Each equilibration and washing step takes ~3 hr. Equilibration of the columns can be completed in advance or overnight (be sure the columns do not run dry) to expedite the purification process. Elution of the CM column takes ~3 hr, as well. As mentioned, protein loading can take 2 or more days. Elution from the HA column may require as little as 30 min.

As with most P-450s, P-450s 2E1 and 1A2 are fairly stable at 4°C in solution. Thus loading of the P-450 sample onto all columns need not be rushed. Keep flow rates near 1 ml/min. P-450s are apparently stable for weeks when bound to CM or HA columns. It is recommended that the CM column first be washed to remove any proteins that may contribute to the degradation of the P-450 before coming to any lengthy stopping point.

Although solutions of these P-450s are somewhat stable, the unpurified protein is usually less stable in solution than when it is bound to the column. It is good practice to begin the next chromatography step within a few hours of solubilizing or eluting the protein.

After protein elution, CM and HA columns can be regenerated through extensive washing (~500 ml) with the high salt (>200 mM potassium phosphate) elution buffers. Before re-use, the columns must be re-equilibrated with the equilibration buffers described in Basic Protocols 1 and 2. In the presence of sodium EDTA, these columns can be stored for several months at 4°C.

Measurements of UDP-Glucuronosyltransferase (UGT) Activities

The mammalian UDP-glucuronosyltransferases (EC 2.4.1.17, UGTs) are a family of isoenzymes that catalyze the reaction of endobiotics and xenobiotics with UDP-glucuronic acid (UDPGlcUA), resulting in the formation of hydrophilic glucuronides (see Fig. 4.3.1). This pathway is an important step in the metabolism and subsequent excretion of many compounds that would otherwise have toxic effects.

The UGT enzymes are located in the endoplasmic reticulum; microsomal preparations from tissue, whole cultured cells, or membrane preparations from cultured cells are used in the glucuronidation assays. The activity of a UGT is measured as the moles of glucuronide formed during a given time period via catalysis by a standard amount of protein. The method for detecting glucuronide formation described here uses nonradioactive aglycone substrates and the radioactive cosubstrate [^{14}C]UDPGlcUA in the reaction. One of several methods is then used to separate the radioactive glucuronide from the unreacted [^{14}C]UDPGlcUA. There are no known substrates for which the glucuronidation is catalyzed by all UGT isoforms.

This unit describes three methods for measuring UGT activities. Thin-layer chromatography (TLC; see Basic Protocol 1) is a powerful screening method, and a great many substrates may be analyzed simultaneously. The Sep-Pak C18 cartridge extraction method (see Basic Protocol 2) has been specifically developed to separate opioid glucuronides from UDPGlcUA. The ethyl acetate extraction method (see Basic Protocol 3) is used for separating the glucuronides of bilirubin, steroids, and bile acids from UDPGlcUA. In each procedure, the enzyme reaction is performed using a microsome preparation from tissue (see Support Protocol 1) or cultured cells expressing cDNA for UGT (see Support Protocol 2).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

BASIC PROTOCOL 1

THIN-LAYER CHROMATOGRAPHY ASSAY FOR UGT ACTIVITY

This method is suitable for most substrates and is useful for screening a large number of substrates simultaneously. Its drawback is that it is very slow. It takes 1 to 4 hr to evaporate the sample to dryness and another 2 hr to apply the samples to TLC plates, although several plates can be prepared at the same time. Finally, long exposure of the X-ray film adds to the time from assay to result.

The assays for glucuronidation catalyzed by UGTs are performed using the following conditions: 50 mM Tris·Cl; 10 mM $MgCl_2$, pH 6.8 to 8.4 (aglycone dependent); 100 µg/ml phosphatidylcholine; 8.5 mM saccharolactone; 0.1 to 1 mg/ml microsomal or membrane protein; 0.1 to 5.0 mM substrate; and 2 mM [^{14}C]UDPGlcUA (specific radioactivity 1 µCi/µmol). Incubation takes place in shaker bath at 37°C for 10 min to 4 hr.

Materials

Microsomal pellet (see Support Protocol 1 or 2)
Enzyme buffer (see recipe), ice cold
Bio-Rad protein assay kit
Reaction buffer (see recipe and Table 4.3.1)
Phosphatidylcholine (see recipe)
Saccharolactone (see recipe)
Substrate solutions (see recipe and Table 4.3.1)
20 mM [^{14}C]UDPGlcUA solution (1 µCi/µmol; see recipe)
100% ethanol
1-Butanol
Acetone
Glacial acetic acid
28% (w/w) ammonium hydroxide
48% (w/w) hydrofluoric acid

3a70B counting cocktail (Research Products International) or equivalent
TLC plates: PSC plates (silica gel 60F_{254}, 20 × 20 cm, concentration zone 4 × 20 cm, 0.5 mm thickness; Merck)
TLC tanks for 20 × 20–cm plates
EN^{3}HANCE (NEN Life Science)
Kodak XAR 5 or Kodak BioMax MR film
Electronic flash (Vivitar or equivalent), dimmed by covering the emission surface with Whatman no. 3 filter paper

Table 4.3.1 Optimal Assay Conditions for Glucuronidation of Common Substrates

Substrate	Species	pH	Substrate concentration (mM)	Reaction time (min)	Basic Protocol(s)
Androsterone	Rat	8.0	0.1	10-15	1 and 3
	Human	8.4	0.1	15-30	1 and 3
Bilirubin	Rat	7.7	0.345	30-60	3
	Human	7.8	0.345	30-60	3
Codeine	Human	8.4	5	30-60	2
Morphine	Rat	8.4	5	15-30	2
	Human	8.4	5	15-30	2
Sapogenins	Human	7.5	0.1	30-120	1 and 3
Testosterone	Human	7.5	0.1	15-30	1 and 3

Carry out UGT reaction

1. Suspend the microsomal pellet in a small aliquot of ice-cold enzyme buffer using a Potter-Elvehjem homogenizer with a Teflon pestle.
2. Determine the protein concentration by the Bio-Rad protein assay and adjust the concentration to 4 to 10 mg/ml with ice-cold enzyme buffer.
3. Place incubation tubes on ice, and add the following to each tube (total volume 100 µl):

   10 µl reaction buffer (50 mM Tris·Cl/10 mM $MgCl_2$ final)
   10 µl phosphatidylcholine solution (100 µg/ml final)
   10 µl saccharolactone solution (8.5 mM final)
   1 to 10 µl aglycone substrate (0.1 to 5 mM final)
   10 to 25 µl microsomal or membrane protein (10 to 100 µg final)
   H_2O to 90 µl.

   Use round-bottomed incubation tubes, because the protein will not stay suspended in a conical microcentrifuge tube during long incubation periods.

   Include control assays with the incubations. Prepare controls without the aglycone substrate, and incubate the same time as the assays; add the aglycone after termination of the reaction (step 5). Also prepare a zero-time control by adding 200 µl of 100% ethanol before adding [^{14}C]UDPGlcUA and place the tube on ice until step 6.
4. Vortex the tubes and preincubate 5 min at 37°C.
5. Add 10 µl [^{14}C]UDPGlcUA to start the reaction; vortex the tubes, and place them in a 37°C water bath with shaking. Incubate 10 min to 4 hr.

   The optimal pH for the reaction buffer depends on the substrate used (see Table 4.3.1).

   For glucuronidation of substrates with which the reaction efficiency is very low, it may be necessary to incubate overnight to obtain measurable amounts of glucuronides.

Prepare samples for TLC

6. Stop the reaction by adding 200 µl of 100% ethanol.
7. Spin in microcentrifuge 10 min at 13,000 rpm, room temperature.
8. Transfer 200 µl of supernatant to a fresh conical 1.7-ml microcentrifuge tube.
9. Evaporate the supernatant to dryness in a spin vacuum drier (e.g., SpeedVac).

   This will take 2 to 3 hr, depending on the equipment.

Load samples on TLC plate

10. Resuspend the contents of the tube in 12 µl water to dissolve most of the formed glucuronide. Spot the 12-µl suspension in a single area, 2 cm from the lower edge in the concentration zone, in 2-µl aliquots on a TLC plate, allowing each spot to dry before making the next application.

    The spots can be dried between spottings using an air drier for 3 to 5 min at room temperature.

    Spotting one aliquot at a time ensures that the glucuronide will be concentrated in a small area, making it easier to detect small amounts.

    Up to 18 samples may be spotted on one plate as long as the samples belong to the same class.
11. Rinse the tube with 10 µl of 100% ethanol, and spot 2-µl aliquots as in step 10.
12. Add 6 µl of water to the tube, and spot 2 µl at a time onto the plate as in step 10.

13a. *For plates with glucuronides of amines and opioids (except morphine):* Prepare TLC tank with alkaline mobile phase to a height of 1 cm. Alkaline mobile-phase composition:

70 ml 1-butanol
70 ml acetone
40 ml water
20 ml 28% ammonium hydroxide.

13b. *For plates with glucuronides of all other substrates:* Prepare TLC tank with acidic mobile phase to a height of 1 cm. Acidic mobile-phase composition:

70 ml 1-butanol
70 ml acetone
40 ml water
20 ml glacial acetic acid.

14. Grease top edge of tank with vacuum grease, and replace lid to form tight seal. Equilibrate tank system 1 hr before adding plate.

Chromatograph the plate

15. Working in a fume hood, chromatograph the plate until the solvent front is ½ in. (~1.25 cm) from the top. Air dry the plate. Inspect the plate under UV light to ascertain if development was satisfactory.

CAUTION: *Steps 15 and 16 must be performed in a chemical fume hood.*

This step generally takes 2 to 4 hr. Remove the plate from the tank, and air dry the plate.

Sometimes the glucuronides streak. This may be the result of using a defective (old) TCL plate, placing the spots too close together, insufficiently drying the plates before placing them in the tank, or using the wrong solvent system.

The substrates and the solvent front are generally visible. Glucuronides generally have R_f values of 0.5 to 0.7. (R_f is the distance from the origin to the compound spot of interest divided by the distance from the origin to the solvent front; an R_f value of 0.5 means the compound spot moved halfway from the origin to the solvent front).

16. Check the plate with a hand-held Geiger counter.

If the radioactivity is detectable at the R_f of the glucuronides, a 24-hr exposure of the X-ray film is sufficient.

17. Spray the plate with EN^{3}HANCE. Air dry at least 20 min.

Visualize the products

18. Place the plate in a film cassette. Expose an X-ray film to an electronic flash at a distance of 15 in (~38 cm) from the source, and place the preflashed surface of the film against the plate. Close the cassette, and store in a −80°C freezer until sufficient exposure has been obtained.

Preflashing the film will increase the sensitivity of the film to light.

If glucuronides were not detected with the Geiger counter, an exposure time of 48 to 72 hr is necessary; for very low radioactivity an exposure time of 1 week might be necessary.

19. Develop the film either manually according to the manufacture's instructions or in an automated film developer.

Quantify radioactivity

20. Mark the positions of the radioactive spots on the TLC plate; be sure to mark the corresponding spots for the control incubations.

21. Scrape the silica gel spots off the TLC plate using a razor blade and place the gel in a scintillation vial.
22. Add 500 µl water to the vial, and vortex to break up the gel.
23. Add 500 µl of 48% hydrofluoric acid to the vial. Incubate 30 min at room temperature.
24. Add 15 ml 3a70B counting cocktail, and count the sample once it has cooled.

In this method, the radioactive glucuronide counted is two-thirds of that formed: 200 of 300 µl total reaction mixture (100 µl incubation plus 200 µl to stop the reaction).

The specific activity (picomoles glucuronide/minute/milligrams protein) is, therefore,

$$\frac{3 \times (\text{dpm}_{\text{sample}} - \text{dpm}_{\text{control}})}{2 \times (\text{dpm/pmol UDPGlcUA}) \times \text{min} \times \text{g protein}}$$

SEP-PAK ASSAY FOR UGT ACTIVITY

BASIC PROTOCOL 2

This method was developed as a fast technique for analyzing the formation of opioid glucuronides. Because many samples can be processed within a short time, it is well suited to kinetic studies. After incubation, the glucuronides can be separated from the radioactive UDPGlcUA within 10 min per twelve samples, using the manifold described here.

Materials

20 mM [^{14}C]UDPGlcUA solution (0.5 µCi/µmol; see recipe)
100% methanol
10 mM ammonium acetate (see recipe)
1 M ammonium acetate, pH 9.2 (see recipe), ice cold

13 × 100–mm glass or 75 × 12–mm polypropylene tubes
Sep-Pak C18 cartridges (Millipore)
Budget-Solve counting cocktail (Research Products International) or similar

Additional reagents and equipment for UGT reaction (see Basic Protocol 1)

1. Carry out the UGT reaction (see Basic Protocol 1, steps 1 to 5), setting up the reaction in 13 × 100–mm glass or 75 × 12–mm polypropylene tubes and using 0.5 µCi/µmol [^{14}C]UDPGlcUA solution in the reaction mixture.
2. Prepare one Sep-Pak cartridge assembly for each sample (see Fig. 4.3.2).

   It is advisable to have three flasks between the manifold and the vacuum pump. Flask 1 contains accidental radioactive overflow from the manifold. Flask 2 contains water to absorb ammonia from the ammonium acetate elutions. The water should be changed daily, according to use. Flask 3 contains a desiccant to prevent water vapor from reaching the pump.

   An inexpensive vacuum manifold can be obtained by modifying a Millipore 1225 Sampling Manifold (Millipore); see Figure 4.3.2.

3. To preequilibrate the Sep-Pak cartridges to be used for the first time, rinse the cartridges with 10 ml of 100% methanol followed by 10 ml of 10 mM ammonium acetate using vacuum aspiration. Do not allow the cartridges to become dry.

   Steps 3 to 5 are also done with vacuum aspiration.

4. Stop the reaction by adding 5 ml ice-cold 1 M ammonium acetate.
5. Rinse a Sep-Pak cartridge with 10 ml ice-cold 1 M ammonium acetate.

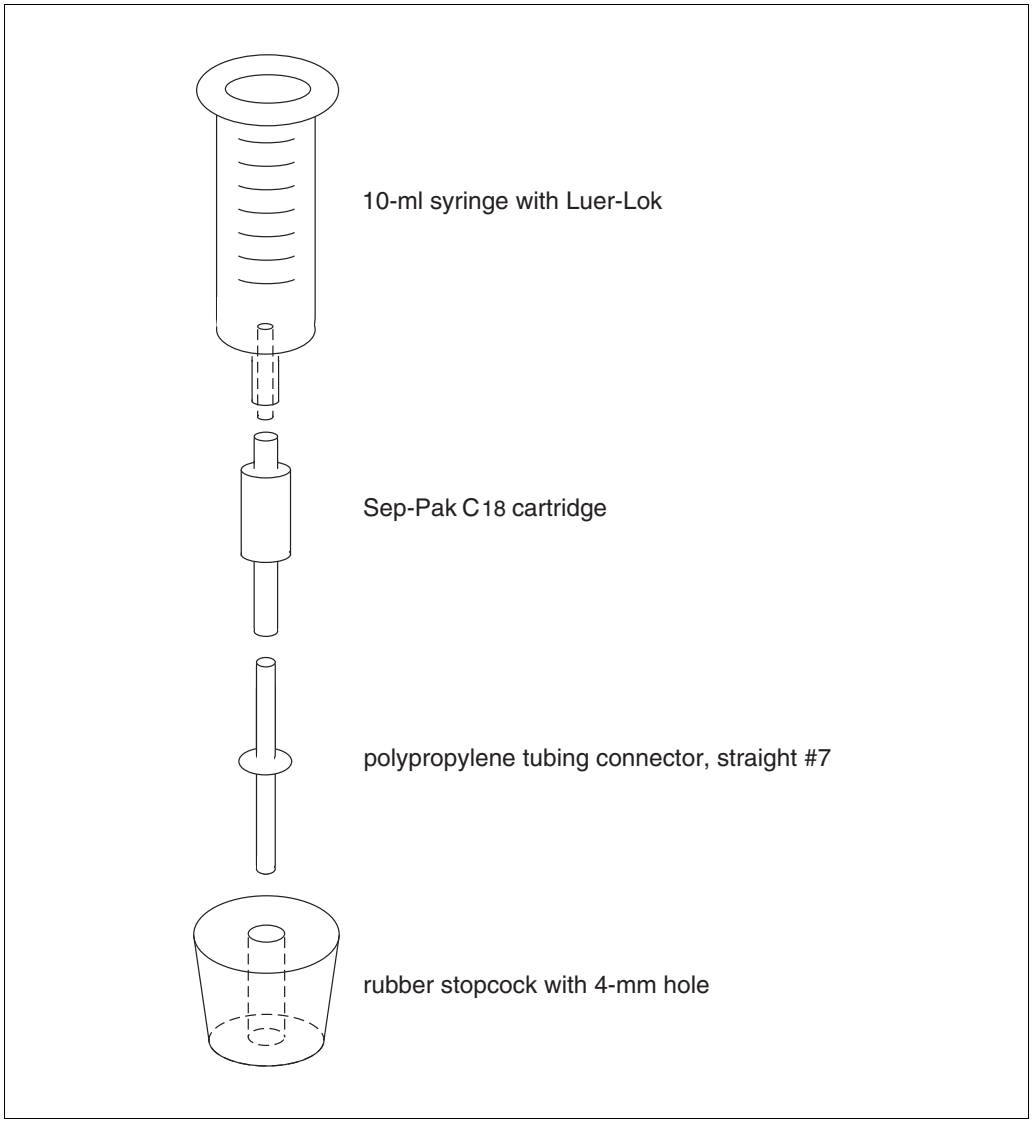

Figure 4.3.2 An assembly of a Sep-Pak cartridge and receptacle for use with the Millipore 1225 Sampling Manifold or similar manifold using stopcocks.

6. Apply the assay sample to the Sep-Pak cartridge, and rinse the reaction tube with 1 to 5 ml of 1 M ammonium acetate.
7. Wash the Sep-Pak cartridge two times with 10 ml of 10 mM ammonium acetate. Aspirate each aliquot.
8. Remove the Sep-Pak cartridge and syringe unit from the manifold, and manually elute the cartridge with 5 ml of 100% methanol directly into a scintillation vial by using the syringe plunger. Disconnect the syringe from the Sep-Pak cartridge before removing the plunger (in order not to disturb the packing of the Sep-Pak). Reassemble the cartridge unit before mounting the unit in the manifold.

   The cartridges can be regenerated with two 10-ml applications of methanol and can be reused 20 to 40 times, depending on the amount of protein that has been applied to the cartridges. When elution becomes slow and the radioactivity in the control samples doubles, the cartridges must be replaced.

9. Add 10 ml of Budget-Solve counting cocktail to the vial.

10. Count the radioactivity in the vial.

The radioactivity of the total amount of glucuronide formed is counted in this method, so the specific activity (picomoles glucuronide/minute/milligram protein) is

$$\frac{(\text{dpm}_{\text{sample}} - \text{dpm}_{\text{control}})}{(\text{dpm/pmol UDPGlcUA}) \times \text{min} \times \text{mg protein}}$$

ETHYL ACETATE EXTRACTION ASSAY FOR UGT ACTIVITY

BASIC PROTOCOL 3

This method relies on the fact that the glucuronides of bilirubin, steroids, and bile acids are more soluble in ethyl acetate than in aqueous solution at pH 2. This method is also fast: after the incubation period, it takes only ~20 min to separate the glucuronides from the [^{14}C]UDPGlcUA.

Materials

20 mM [^{14}C]UDPGlcUA solution (0.5 µCi/µmol; see recipe)
Glycine/Triton buffer (see recipe)
Water-saturated ethyl acetate
Budget-Solve counting cocktail (Research Products International) or similar

Additional reagents and equipment for UGT reaction (see Basic Protocol 1)

1. Perform the UGT enzyme reaction (see Basic Protocol, steps 1 to 5), setting up the reaction in 75 × 12-mm polypropylene tubes and using 0.5 µCi/µmol of [^{14}C]UDPGlcUA solution in the reaction mixture.
2. Stop the reaction by adding 0.1 ml glycine/Triton buffer.
3. Add 1.0 ml water-saturated ethyl acetate.
4. Shake in horizontal shaker 10 min or vortex the tube 1 min.
5. Spin 5 min in a low-speed centrifuge, room temperature.
6. Carefully pipet 0.5 ml of the organic phase (top) into a scintillation vial.

   Up to 750 µl can be removed for counting if a higher sensitivity is needed.

7. Add 10 ml of Budget-Solve counting cocktail to the vial.
8. Count the radioactivity in the vial.

   In this method, the radioactive glucuronide counted is (one-half × three-quarters) of that formed; the whole reaction is extracted with 1 ml of ethyl acetate; therefore, the specific activity (picomoles glucuronide/minute/milligram protein) is

$$\frac{2\,(\text{or } 1.33) \times (\text{dpm}_{\text{sample}} - \text{dpm}_{\text{control}})}{(\text{dpm/pmol UDPGlcUA}) \times \text{min} \times \text{mg protein}}$$

PREPARATION OF MICROSOMES FROM TISSUE

SUPPORT PROTOCOL 1

The UGTs reside in the endoplasmic reticulum anchored across the membrane. The microsomal and cell membrane preparations contain the endoplasmic reticulum and, therefore, possess an increased amount of enzyme per milligram of preparation compared with the relative amount of the enzymes in tissue snips or whole cells. This protocol is used to isolate microsomes from fresh or frozen tissue.

Materials

Organ tissue, freshly recovered or frozen tissue from a commercial source
1.15% (w/v) KCl

NOTE: Perform all steps at 4°C.

1. Weigh the tissue in grams
2. Add (4 × the weight) ml of 1.15% KCl.
3. Homogenize in a Potter-Elvehjem homogenizer using a motorized Teflon pestle.

   Be careful that the temperature of the homogenate does not rise above 4°C.
4. Centrifuge the homogenate 20 min at 9000 × *g*.
5. Carefully decant the supernatant through a layer of cotton gauze to remove fatty substances associated with tissue (especially prevalent in liver). Discard the pellet.
6. Centrifuge the supernatant in polycarbonate tubes 60 min at 100,000 × *g*. Discard the supernatant.
7. Wash the pellet by resuspending it in 4 vol of 1.15% KCl. Homogenize by hand, using a Potter-Elvehjem homogenizer.

   The homogenate can be divided into smaller tubes at this point, if desired.
8. Centrifuge the homogenate 60 min at 100,000 × *g* to sediment the pellet.
9. Decant the supernatant.
10. Overlay the pellet with at least 1 ml of 1.15% KCl, and store up to 1 year at −80°C.

SUPPORT PROTOCOL 2

PREPARATION OF MICROSOMES FROM CULTURED CELLS

This protocol is used to prepare microsomes from tissue culture cells transfected to express UGT cDNA.

Materials

Cultured cells, such as HK293, V79, or COS cells, expressing UGT after transfection with vector containing UGT cDNA
PBS (*APPENDIX 2A*)
Cell suspension buffer (see recipe)
Cell homogenate dilution buffer (see recipe)

Tissue tearer: 985-370 (Biospec Products) or equivalent
Sonifier cell disrupter: Hat system (Ultrasonic) or equivalent

NOTE: Perform all procedures at 4°C.

1. Harvest the cells and wash three times with PBS.
2. Suspend the cell pellet 1:3 (v/v) in cell suspension buffer.
3. Disrupt the cells 10 sec with a tissue tearer.
4. Dilute the homogenate 1:4 (v/v) with cell homogenate dilution buffer.
5. Sonicate three times in 10-sec bursts with a Sonifier cell disrupter, keeping the cell homogenate in a ice-water bath.
6. Homogenize by hand using a Potter-Elvehjem homogenizer with a Teflon pestle (10 strokes).

7. Centrifuge 20 min at 9000 × *g*.
8. Centrifuge the supernatant 1 hr at 100,000 × *g*.
9. Discard the supernatant.
10. Overlay the pellet with at least 1 ml of cell homogenate dilution buffer, and store up to 1 year at −80°C.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ammonium acetate, pH 9.2, 1 M

Dissolve 308 g ammonium acetate in 4 liters water. Adjust the pH to 9.2 at 4°C with 28% (w/v) ammonium hydroxide. Store up to 1 month at 4°C.

Ammonium acetate, 10 mM

Add 20 ml of 1 M ammonium acetate, pH 9.2, to 2 liters water. Do not adjust the pH. Store up to 1 month at room temperature.

Cell homogenate dilution buffer

For 1 liter, weigh 85.6 g sucrose. Add 5 ml of 1 M HEPES, pH 7.4 (*N*-2-hydroxylthylpiperazine-*N*^{1}-2-ethanesulfonic acid; commercially prepared). Dilute to 1 liter with water; adjust the pH to 7.4 with 1 N NaOH. (Final: 0.25 M sucrose/5 mM HEPES, pH 7.4.) Store up to 1 month at 4°C.

Cell suspension buffer

Weigh 7.71 mg dithiothreitol (DTT). Add 100 ml cell homogenate dilution buffer (see recipe). (Final: 0.25 M sucrose/0.5 mM DTT/5 mM HEPES, pH 7.4.) Store up to 1 month at 4°C.

Enzyme buffer

Tris-buffered saline: Weigh 121 mg Tris·Cl and 900 mg NaCl; add water, and adjust the pH to 7.4 at 4°C with HCl. Adjust with water to a final volume of 100 ml. Store up to 1 month at 4°C.

1 M dithiothreitol (DTT): Dissolve 1.54 g DTT in 10 ml water. Store up to 2 weeks at −20°C.

Enzyme buffer: Add 5 µl of 1 M DTT to 10 ml Tris-buffered saline. Prepare just before use. (Final: 10 mM Tris-buffered saline, pH 7.4/0.5 mM DTT.)

Glycine/Triton solution

Weigh 5.25 g glycine, and dissolve in water to 90 ml. Add 1 ml Triton X-100, adjust the pH to 2 with concentrated HCl, and add water to 100 ml. (Final: 0.7 M glycine HCl, pH 2.0/1% Triton X-100.) Store up to 1 month at 4°C.

KCl, 1.15% (w/v)

Dissolve 11.5 g KCl in 1 liter water. Store up to 1 month at 4°C.

Phosphatidylcholine (1 mg/ml)

For 25 ml, weigh 25 mg L-α-phosphatidylcholine, type XVI-E from egg yolk, lyophilized powder. Add 25 ml ice-cold water, vortex, and sonicate on ice until a clear suspension is obtained. Divide into 1-ml aliquots in capped tubes, and store up to 1 year at −20°C.

Reaction buffer

For 100 ml, weigh 6.05 g Tris·Cl. Add 10 ml of 1 M $MgCl_2$ (50.8 g $MgCl_2 \cdot 6H_2O$ in 250 ml water). Add water to 100 ml and adjust the pH as needed with HCl at 37°C. (Final: 0.5 M Tris·Cl/0.1 M $MgCl_2$.) Store up to 1 month at 4°C.

Because the optimal pH for the reaction depends on the substrates used, it is convenient to prepare stock solutions of buffers with different pH values (7.0, 7.4, 7.7, 8.0, and 8.4). For a pH lower than 7.0, use 10.5 g bis-Tris instead of Tris. Although a buffer at pH 7.4 is useful for screening substrates using the TLC method, a negative result may indicate that an inappropriate pH was used. Generating an activity-versus-pH curve for unknown substrates is highly recommended.

Saccharolactone (85 mM)

For 25 ml, dissolve 408 mg saccharolactone in 25 ml water. Store in 1-ml aliquots up to 1 year at −20°C. Discard unused solution after 24 hr.

Substrate solutions

As an overall guideline, 200- to 500-µl stock solutions should be prepared in water, methanol, ethanol, DMF, or DMSO to obtain final concentrations in the incubation mixture of 0.1 to 5 mM. 1- to 50-mM solutions may be prepared in water, and 10- to 250-mM solutions in alcohol, dimethylformamide (DMF), or dimethyl sulfoxide (DMSO). The solutions should be stored at −20°C. The following solutions have generally proved convenient:

Opioids: Prepare 50-mM solutions of opium salts in water and store up to 3 months at −20°C.

Morphine: Prepare 25-mM solution of morphine sulfate in water. Store up to 1 year at −20°C.

Codeine: Prepare 100-mM solution of codeine in methanol. Store up to 2 weeks at −20°C.

Sapogenin: Prepare 10-mM solution in DMF. Store up to 2 weeks at −20°C.

Steroids: Prepare 10-mM solution in methanol. Store up to 2 weeks at −20°C.

Bilirubin: Dissolve 5 mg bilirubin in 250 µl of 0.1 N NaOH (3.4 mM bilirubin final). Add 2.25 ml of 40 mM Tris·Cl, pH 7.4, containing 30 mg/ml bovine serum albumin. Store up to 24 hr at 4°C in the dark.

The bilirubin assay should take place in the dark or shielded from light; and the tubes should be flushed with argon or nitrogen and capped before being placed in the shaker incubator.

[^{14}C]UDPGlcUA solutions (in 20 mM unlabeled UDPGlcUA)

100 mM unlabeled UDPGlcUA stock: Dissolve 315.7 mg UDPGlcUA ammonium salt in 5 ml H_2O.

20 mM [^{14}C]UDPGlcUA (1 µCi/µmol) for TLC: For 500 µl, add 400 µl of [^{14}C]UDPGlcUA (0.025 µCi/µl, 318 mCi/mmol) to 100 µl of unlabeled 100 mM UDPGlcUA.

20 mM [^{14}C]UDPGlcUA (0.5 µCi/µmol) for extractions: For 500 µl, add 200 µl [^{14}C]UDPGlcUA (0.025 µCi/µl, 318 mCi/mmol) and 200 µl H_2O to 100 µl of 100 mM unlabeled UDPGlcUA.

Store all solutions up to 1 year at −20°C.

For aglycone substrates that exhibit high activity, a lower specific activity of UDPGlcUA can be used, decreasing costs.

COMMENTARY

Background Information

Glucuronidation, the principal conjugation pathway in all vertebrate species, takes place in a wide range of tissues and accounts for most of the detoxified material in bile and urine. Conjugation with glucuronic acid confers greater polarity and water solubility on the aglycone, leading to more rapid excretion. Some generated glucuronides, however, can be pharmacologically and toxicologically relevant. For example, both the morphine-3- and -6-glucuronides have physiologic effects (Christrup, 1997), and *N*-hydroxyglucuronides from arylamines are known to initiate colon or bladder cancer in humans (Bock, 1991). The glucuronidation process is also involved in the metabolism of compounds that participate in cell growth or differentiation, such as retinoic acid and thyroid hormones (Nebert, 1991).

The glucuronidation reaction is catalyzed by a family of UGT isoenzymes. Molecular biology techniques have made it possible to identify the genes for individual mammalian UGTs and to express the UGT proteins. Thus it has been feasible to study the substrate specificities and kinetic parameters of individual UGTs (Clarke and Burchell, 1994; Burchell et al., 1995). The nomenclature for the isoenzymes is based on evolutionary divergence (Mackenzie et al., 1997).

The UGTs are membrane-bound proteins present in the liver, kidney, skin, intestine, prostate, brain, and lung; however, not all isoforms are present in all tissues. There is a great deal of overlap of substrate acceptance among the isoforms. No substrate has so far been found for which glucuronidation is catalyzed by all isoenzymes, although compounds such as 4-methylumbelliferone and *p*-nitrophenol are substrates for many of them. Therefore, using nonspecific substrates in induction and inhibition studies in tissue preparations may result in data that are difficult to interpret. The glucuronidation of some substrates is catalyzed with great efficiency by specific isoforms. These substrates are listed in Table 4.3.2 and may be used as markers for individual isoenzymes.

Earlier analytical methods made use of the spectrophotometric properties of the aglycones and their glucuronides. Herweigh and co-workers (1972) found that by diazotization of bilirubin glucuronides and solvent extraction of the products, the formation of bilirubin glucuronides could be measured spectrophotometrically. Many assay methods have used radioactive aglycones, such as *p*-nitrophenol (Frei et al., 1974), morphine (Del Villar et al., 1974), and steroids (Tukey and Tephly, 1981). Many aglycones, however, are not available in radioactive form. Lillienblum and Bock (1984) developed spectrophotofluorimetric assays for the glucuronidation of 4-methylumbelliferone, α-naphthylamine, and 4-aminobiphenyl.

The methods described in this unit are based on the use of [^{14}C]UDPGlcUA and are applicable to most substrates. The TLC method (see Basic Protocol 1) presented here was originally developed by Bansal and Gessner (1980). It has been modified to include two different resolving systems, because the glucuronides of amines and opioids (except morphine) can be separated from UDPGlcUA only in a basic solvent system. This method is excellent for screening many aglycone substrates at the same time, but relatively time-consuming.

The Sep-Pak C18 method (see Basic Protocol 2) was published by Puig and Tephly (1986). It was originally developed for detection of morphine glucuronides, but it is also applicable to other morphinan and oripavine substrates as well as tertiary amines such as imipramine. Matern et al. (1994) published a radioassay of UGT activities toward endo-

Table 4.3.2 Substrates Glucuronidated Primarily by a Single Isoenzyme

Substrate	Species	Isoenzyme
Bilirubin	Rat	rUGT1A1
Bilirubin	Human	hUGT1A1
Sapogenins	Human	hUGT1A4
Morphine	Rat	UGT2B1
Codeine (morphine)	Human	UGT2B7
Testosterone	Human	UGT2B15

genous substrates, such as hyodeoxycholic acid, bilirubin, estriol, androsterone, and testosterone, in which ethyl acetate was used as the extraction solvent. This method is given here (see Basic Protocol 3) with slight modifications to allow larger aliquots to be counted.

Finally, many HPLC methods have been developed for identifying metabolites in urine and plasma from in vivo metabolism of xenobiotics and endogenous compounds. These methods can also be used to identify and quantify glucuronides from the assays described here. Some of the methods are useful for identifying and quantifying metabolites for which the glucuronidation reaction yields several glucuronides. Svensson (1986) and Yue et al. (1990) developed a system for separating morphine-3- and -6-glucuronides, and Spivak and Yuey (1986) published a method for separating monoglucuronides and diglucuronides of bilirubin. Glucuronide formation can be quantified either by assessing peak areas or, when using radioactive UDPGlcUA, by collecting the peak volumes and quantifying the radioactivity.

These are all sensitive assays, capable of detecting activities in the range of a few picomoles per minute per milligram protein. The sensitivity depends on the specific radioactivity of the UDPGlcUA and the efficiency of catalysis of the glucuronidation reaction.

Critical Parameters and Troubleshooting

Although most UGTs are able to catalyze the reaction between UDPGlcUA and the aglycone at pH 7.4, the optimal pH may vary greatly among substrates. For example, among the opioids, the optimal pH is 8.4 for morphine and 7.0 for buprenorphine (King et al., 1997). The incubation time is also critical. For some substrates, such as testosterone and estrone, the reaction is not linear beyond 10 min. The use of optimal amounts of protein and substrates is required for linear product formation. Many substrates, especially bilirubin and morphine, exhibit product inhibition at high substrate concentrations. For these reasons, it is necessary to establish the optimal assay conditions for unknown substrates if the results are to be used for comparison with known substrates and for establishing kinetic parameters.

The K_M for UDPGlcUA is in the range of 150 to 300 μM for the UGT isozymes identified

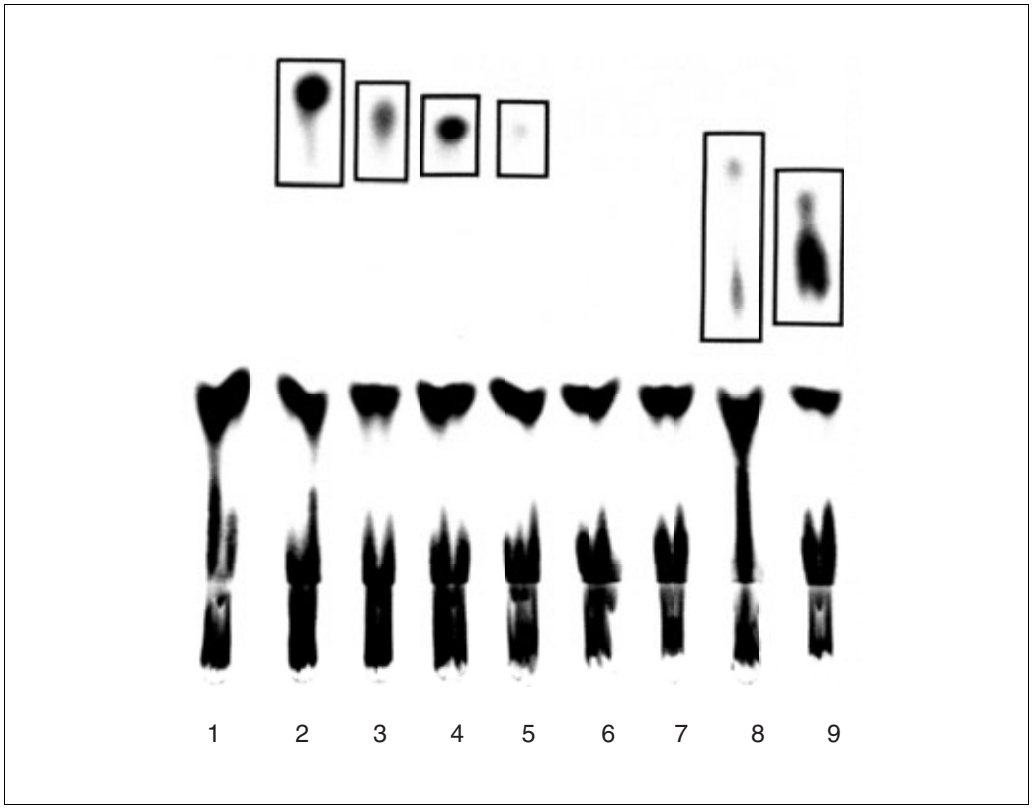

Figure 4.3.3 Autoradiogram of TLC chromatogram. The aglycones used in lanes 1 to 9 were 1, none; 2, naringenin; 3, apigenin; 4, eugenol; 5, *p*-nitrophenol; 6, hecogenin; 7, diosgenin; 8, 4-methylumbelliferone; and 9, scopoletin. The areas of the TLC plate indicated by the rectangles were scraped, and the radioactivity in the silica gel was determined as described in Basic Protocol 1.

thus far, so it is reasonable to use a concentration of 2 mM UDPGlcUA in assays. It is tempting to lower the UDPGlcUA concentration while increasing its specific radioactivity to obtain greater sensitivity; however, at concentrations that are too low, glucuronides may form so slowly that they are not detectable.

It has always been necessary to use detergents when solubilizing the UGTs in purification procedures using microsomes from tissue. Some detergents increase the UGT activity toward certain aglycones while decreasing or destroying the activity toward others. The most common detergents used are nonionic compounds, such as Brij 58, Triton X100, Emulgen 911, and digitonin or zwitterionic detergents (e.g., CHAPS and CHAPSO). For activation, very low concentrations—0.004% to 0.01% (w/v)—are used. It must be emphasized that an activity-versus-detergent-concentration curve must be established for any given substrate and detergent, before detergents are employed in assays.

When measuring very low activity, it is necessary to keep the radioactivity in the control samples as low as possible. If a radioactive spot occurs in all lanes, samples and control, of the autoradiogram of samples analyzed by Basic Protocol 1, it is an indication that the radioactive UDPGlcUA contains an impurity or that the common components of the assays have become contaminated with a compound that is a substrate for UGTs. The same conditions would cause high background counts in the assays performed using Basic Protocols 2 and 3. The [^{14}C]UDPGlcUA must have a purity >99% as measured by Sep-Pak C18 extraction (see below). If the level of impurities is too high, check with the manufacturer. Preparing new assay reagents will normally eliminate possible contaminants.

Impurity check for [^{14}C]UDPGlcUA

Remove 2 µl of [^{14}C]UDPGlcUA from the manufacturer's vial, and dilute with 5 ml ice-cold 1 M ammonium acetate, pH 9.2. Count 0.5 ml of the dilution. Apply to a Sep-Pak C18 cartridge, wash with ammonium acetate, and elute with methanol (see Basic Protocol 2, steps 6 to 11). If the counts from the methanol extraction are >0.95% of the applied counts, the [^{14}C]UDPGlcUA is not sufficiently pure.

Anticipated Results

This section gives examples of assays that were analyzed by each of the three methods described here.

Basic Protocol 1

A membrane preparation from cultured cells expressing an UGT isozyme was analyzed for activity toward naringenin, apigenin, eugenol, *p*-nitrophenol, hecogenin, diosgenin, 4-methylumbelliferone, and scopoletin. The general assay requirements are described in Basic Protocol 1. The specific conditions for this assay were pH 7.4, 50 µg 0.5 mM protein substrate, and 2 mM [^{14}C]UDPGlcUA (specific activity 1.9 dpm/pmol). The assays were incubated 60 min at 37°C, and then stopped with 200 µl of 100% ethanol. The analysis was carried out using steps 7 to 24 of Basic Protocol 1. The TLC plate was developed in an acidic system (step 13) and exposed to X-ray film for 60 hr. Figure 4.3.3 shows the developed autoradiogram. The areas on the TLC plate indicated by the rectangles were counted.

Specific activities (picomoles glucuronide/minute/milligram protein) were calculated using the following formula:

$$\frac{3 \times (\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})}{2 \times (\mathrm{dpm/pmol\ UDPGlcUA}) \times \mathrm{min} \times \mathrm{mg\ protein}}$$

$$= \frac{3 \times (\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})\ \mathrm{pmol}}{2 \times 1.9 \times 60 \times 0.050\ \mathrm{min} \times \mathrm{mg\ protein}}$$

$$= \frac{3.8 \times (\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})\ \mathrm{pmol}}{\mathrm{min} \times \mathrm{mg\ protein}}$$

See Table 4.3.3 for results.

Basic Protocol 2

Microsomes prepared from rat liver were analyzed for activity toward morphine. The general assay requirements are described in Basic Protocol 2. The specific conditions for this assay were pH 8.4, 50 µg protein, 5 mM morphine, and 2 mM [^{14}C]UDPGlcUA (specific activity 107 dpm/nmol). The assays were incubated 25 min at 37°C, and then stopped with 5 ml of 1 M ammonium acetate.

The specific activity (nanomoles glucuronide/minute/milligram protein) of morphine was calculated using the following formula:

$$\frac{(\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})}{(\mathrm{dpm/nmol\ UDPGlcUA}) \times \mathrm{min} \times \mathrm{mg\ protein}}$$

$$= \frac{(\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})\ \mathrm{nmol}}{107 \times 25 \times 0.050\ \mathrm{min} \times \mathrm{mg\ protein}}$$

$$= \frac{0.0075 \times (\mathrm{dpm}_{\mathrm{sample}} - \mathrm{dpm}_{\mathrm{control}})\ \mathrm{nmol}}{\mathrm{min} \times \mathrm{mg\ protein}}$$

See Table 4.3.4 for results.

Table 4.3.3 Results from TLC Assay[a]

Substrate	dpm_{sample}	pmol/min/mg[b]
Apigenin	2739	689
Narengenin	6220	1605
Eugenol	3427	870
p-Nitrophenol	719	157
Hecogenin	NA	NA
Diosgenin	NA	NA
4-Methylumbelliferone	4852	1245
Scopoletin	17237	4500
No substrate	119	NA

[a]NA, not analyzed.
[b]Limit of detection was 35 pmol.

Table 4.3.4 Results from Sep-Pak Assay

Substrate	dpm_{sample}	nmol/minutes/mg[a]
Morphine	4332, 4091, 4399	31.7, 29.9, 32.2
No substrate	120, 100	—

[a]Limit of detection was 0.5 nmol.

Table 4.3.5 Results from Ethyl Acetate Extraction Assay

Substrate	dpm_{sample}	pmol/min/mg[a]
Androsterone	595, 604	285, 291
No substrate	133, 115	—

[a]Limit of detection was 35 pmol.

Basic Protocol 3

A membrane preparation from cultured cells expressing an UGT isozyme was analyzed for activity toward androsterone. The general assay requirements are described in Basic Protocol 3. The specific conditions for this assay were pH 8.4, 50 µg protein, 0.3 mM androsterone, and 2 mM [^{14}C]UDPGlcUA (specific activity 1.65 dpm/pmol). The assays were incubated 40 min at 37°C, and then stopped with 100 µl of 100% glycine/Triton solution. The analysis was carried out according to steps 3 to 8 of Basic Protocol 3. A total of 500 µl ethyl acetate was counted.

The specific activity (picomole glucuronide/minute/milligram protein) of androsterone was calculated using the following formula:

$$\frac{2 \times (dpm_{sample} - dpm_{control})}{(dpm/nmol\ UDPGlcUA) \times min \times mg\ protein}$$

$$= \frac{2 \times (dpm_{sample} - dpm_{control})\ pmol}{1.65 \times 40 \times 0.050\ min \times mg\ protein}$$

$$= \frac{0.606 \times (dpm_{sample} - dpm_{control})\ pmol}{min \times mg\ protein}$$

See Table 4.3.5 for results.

Time Considerations

For all the assays, the total time required depends in part on the duration of the reaction and the level of activity and can range from 10 min to 5 hr to overnight. TLC requires 2 to 4 hr plus 1 to 7 days for autoradiography. Sep-Pak extraction can be completed in 10 min. Ethyl acetate extraction can be completed in ~20 min.

Detection of Metabolites Using High-Performance Liquid Chromatography and Mass Spectrometry

The eventual goal of xenobiotic metabolism is to increase excretion of harmful or potentially harmful molecules. Ease of excretion is directly related to polarity of the molecule. Almost without exception, metabolites are more polar than the parent compound. The order of polarity is phase II metabolites >> phase I metabolites > parent compound (Johnston et al., 1991). This broad range of polarity between parent and metabolites translates into significant differences in chemical and physical properties including solubility, volatility, and thermal stability. The differences in these three properties between parent compound and metabolites continue to provide a challenge when attempting to identify the chemical intermediates and products (metabolites) of biotransformation reactions. Mass spectrometry (MS) is routinely used to detect, characterize, and quantify metabolites in biological samples. Yet, MS, like almost any other spectroscopic technique, suffers from the need for analytes to be pure in order to achieve high sensitivity and unambiguous structural identification. Tandem MS methods reduce the degree of purity necessary for unambiguous identification; however, problems exist when characterizing metabolites in complex mixtures by tandem MS alone. A tandem mass spectrometer can isolate and separate ions of the compounds of interest from the background by mass-to-charge ratio (*m/z*). Separation and isolation of these ions occurs in the mass analyzer after ionization, so that species that interfere with ionization are not eliminated.

Consequently, chromatographic separation must be employed prior to MS analysis of these "messy" biological samples. Gas chromatography (GC) is especially useful as a precursor to MS for resolution and separation of compounds. GC does require that the compounds being analyzed be thermally stable and volatile. Typically, metabolites are polar and tend to be both nonvolatile and thermally labile. This is especially true of phase II metabolites such as glutathione conjugates, which historically have been difficult to study due to their thermal lability and nonvolatile properties. Derivatization for gas chromatography/mass spectrometry (GC-MS) offers a partial solution; however, similar or interfering compounds present in the biological matrix can complicate or prevent derivatization and isolation of metabolites (especially phase II metabolites). Baillie and Davis (1993) summarized the situation by suggesting that MS can only make a significant contribution to studying phase II conjugation processes if a way can be found to study the conjugate intact.

High-performance liquid chromatography (HPLC) is widely used to separate and isolate metabolites. Routine detectors for liquid chromatography such as ultraviolet (UV) and refractive index (RI) often lack sensitivity and provide little structural information. When detected by these methods, metabolite identity can be deduced by cochromatography with authentic standards, if available. Obtaining authentic standards requires some prior knowledge about the identity of the metabolite. Another approach is to collect the HPLC peaks and then perform MS analysis. This approach works well but is time intensive, particularly if the sample matrix is complicated. A logical solution is to combine the separation power of HPLC with the sensitivity and structural characterization power of MS.

Although it provides a very powerful analytical concept, instrumentally the marriage of HPLC and MS has been, until recently, more of a truce than an actual joining. Numerous problems result from coupling a liquid-based high-pressure technique to a gas-phase high-vacuum technique. Chapman (1993) presents the dilemma as follows. A conventional high-vacuum pumping system of the sort found in most mass spectrometers will maintain a maximum pressure of 2.5×10^{-4} torr when faced with a vapor load of 5 to 7 ml/min. This is the approximate vapor load resulting from 5 µl/min of water or 15 µl/min of acetonitrile. HPLC separation at these flow rates can be achieved with capillary columns. However, continued operation of the mass spectrometer at pressures in the range of 10^{-4} torr would result in high background from the solvent, reduced analyte sensitivity, and greatly increased instrument maintenance. Consequently, considerable work has been done to develop an interface between the HPLC and MS that separates and

removes or reduces solvent without loss of analyte.

Within the last 20 years, several HPLC-MS interfaces have been made with varying degrees of success. This discussion will be limited to interfaces/source combinations that are currently the most widely available: atmospheric-pressure chemical ionization (APCI; Linscheid, 1992) and electrospray ionization (ESI; Whitehouse et al., 1995).

INSTRUMENTAL CONSIDERATIONS

HPLC

Chromatography is a physical separation method in which the compounds being separated are selectively distributed between two immiscible phases: a mobile phase flowing through a stationary phase bed (Niessen and Van der Greef, 1992). For HPLC, the flowing phase is a liquid solvent or solvents pumped under pressure. The stationary phase bed is a high–surface area solid material with specific physical properties. The solvent and stationary materials used are dictated by the samples/analytes and define the type of liquid chromatography. This discussion will be limited to two of the most common methods. Snyder et al. (1997) is necessary reading for the scientist developing HPLC methods for metabolite studies.

Normal- and reversed-phase HPLC

Normal-phase chromatography (NP-HPLC), also known as adsorption chromatography, uses polar functional groups (hydroxy, amino, and cyano) on the stationary phase to promote interaction with polar functional groups on analytes. The mobile phase is composed of nonpolar solvents such as hydrocarbons and chlorinated hydrocarbons. Solvent gradient programs increase in mobile phase polarity. The elution order in NP-HPLC is usually nonpolar molecules, then polar molecules, and then charged molecules.

Reversed-phase chromatography (RP-HPLC) is the opposite of NP-HPLC. The stationary phase relies on nonpolar functional groups (e.g., C_4, C_8, and C_{18} hydrocarbons, phenyl, cyanopropyl) for interaction with the nonpolar groups on the molecules being separated. The mobile phase includes varying amounts of polar organic solvents, water, and inorganic buffers. Gradient programs decrease mobile phase polarity over time. The elution order is the opposite of NP-HPLC: charged molecules, then polar molecules, and then nonpolar molecules.

Stationary phase selection

The stationary phase is packed into a cylindrical column that varies in length and inside diameter. Longer columns provide more resolving power up to an optimum. The inside diameter of the column defines the maximum flow rate through the column as shown in Table 4.4.1. HPLC flow rate is important when interfacing to a mass spectrometer. Low flow rates (nl/min) can mean less sample consumption and increased sensitivity.

The stationary phase used routinely in analytical applications consists of a solid support material ranging in particle size from 3 to 20 µm. The individual particles have pores ranging in size from 90 to 300 Å. The pores provide increased surface area; however, nonporous solid phases are also used. For different brands of columns, varying amounts of the support surface is linked to an organic bonded phase, which in turn varies the amount of interaction between the support and the analyte(s).

The most common stationary phases used in NP-HPLC are silica, alumina, and silica bonded with exposed organic functional groups

such as cyanopropyl and aminopropyl. The most common stationary phases in RP-HPLC are silica supports to which a hydrocarbon chain with four, eight, or twelve carbons is bonded. The most common RP stationary phases bonded to silica supports are listed in Figure 4.4.1.

An extensive description of stationary phases for NP- and RP-HPLC is beyond the scope of this manuscript. However, Neue (1997) has presented a comprehensive discussion on HPLC column technology with valuable chapters on column selection and maintenance.

HPLC-MS Interface and Source

Ionization of the analyte is a necessary process for detection by mass spectrometry and occurs via one of two processes: (1) solvent chemistry results in preformed ions in solution and the solvent is removed as the ions are transferred to the gas phase (via ESI), or (2) molecules are transferred to the gas phase and are then ionized. In either process, attention must be given to the gas-phase transfer process, especially if heat is used, to prevent decomposition. Often the choice between APCI and ESI involves deciding which method is best for producing ions for a given mobile phase composition and pH.

APCI

APCI is a variation on high-vacuum chemical ionization and was first described in the early 1960s (Linscheid, 1992). APCI ionizes the sample after it has been desolvated and introduced into the gas phase. The incoming solvent stream containing the analyte(s) is entrained with an inert nebulizing gas (usually nitrogen) and sprayed as a fine mist into a heated desolvation chamber at atmospheric pressure. Thermal decomposition in the desolvation chamber is minimized by using a high gas flow to keep the residence time to the minimum required for desolvation. A corona discharge is maintained at the end of the desolvation chamber from a needle held at between 1 and 5 kV. The corona discharge ionizes primarily gas-phase solvent molecules, which then ionize analyte molecules by charge transfer reactions. Once formed, the ions are accelerated through a reduced-pressure skimmer into the high-vacuum portion of the mass spectrometer for mass analysis and detection (van Baar, 1996; Hoja et al., 1997).

APCI mass spectra show little difference from their high-vacuum chemical ionization (high-vacuum CI) counterparts for the same compound. In addition, as with high-vacuum CI, the choice of the reagent gas (or HPLC solvent in the case of APCI) is an important factor in the degree of fragmentation observed in the mass spectrum. APCI spectra usually contain signals for $[M + H]^+$ or $[M - H]^-$ ions, but may be dominated by facile-fragmentation and neutral-loss ion signals. Furthermore, the mass spectra of some compounds also contain signals for $M^{+\cdot}$ or $M^{-\cdot}$ ions. Signals for ions from fragmentation of the most facile bonds are often observed.

A number of APCI source parameters can be adjusted experimentally for optimal results, as described below.

1. The HPLC mobile phase, once vaporized, becomes the CI reagent gas and should be chosen to provide chromatographic separation and promote ionization of the analyte as much as possible. Incompatibilities between ionization and chromatography can be reduced by adding ionization-enhancing materials to the mobile phase post column (i.e., volatile salt buffers such as ammonium acetate).
2. The flow rate of the mobile phase should be high enough to support chemical ionization. Typical APCI flow rates are 1 to 1.5 ml/min.
3. The temperature of the desolvation chamber should be set high enough to vaporize the HPLC solvent and analyte, but should not cause thermal decomposition.
4. The gas flow rate should be adjusted to reduce residence times in the desolvation chamber.
5. The discharge voltage should be experimentally optimized for selected analyte ions.
6. The degree of in-source fragmentation can be controlled by adjusting the accelerating potential of the newly formed ions, thus increasing or decreasing the amount and energy of collision-induced dissociation (CID) with solvent molecules.

ESI

ESI, as used for organic analysis, was first reported by Fenn and colleagues in 1984 (Yamashita and Fenn, 1984; Whitehouse et al., 1995). The liquid flow stream containing ionized analytes is pumped through a capillary in which the exit tip is held at high voltage (~4.5 kV). The liquid stream is nebulized upon exiting the capillary by nitrogen gas. The high voltage on the capillary tip attracts ions of opposite charge, so the droplets exiting the capillary are charged with the same polarity as the tip. The nebulizing gas directed around the

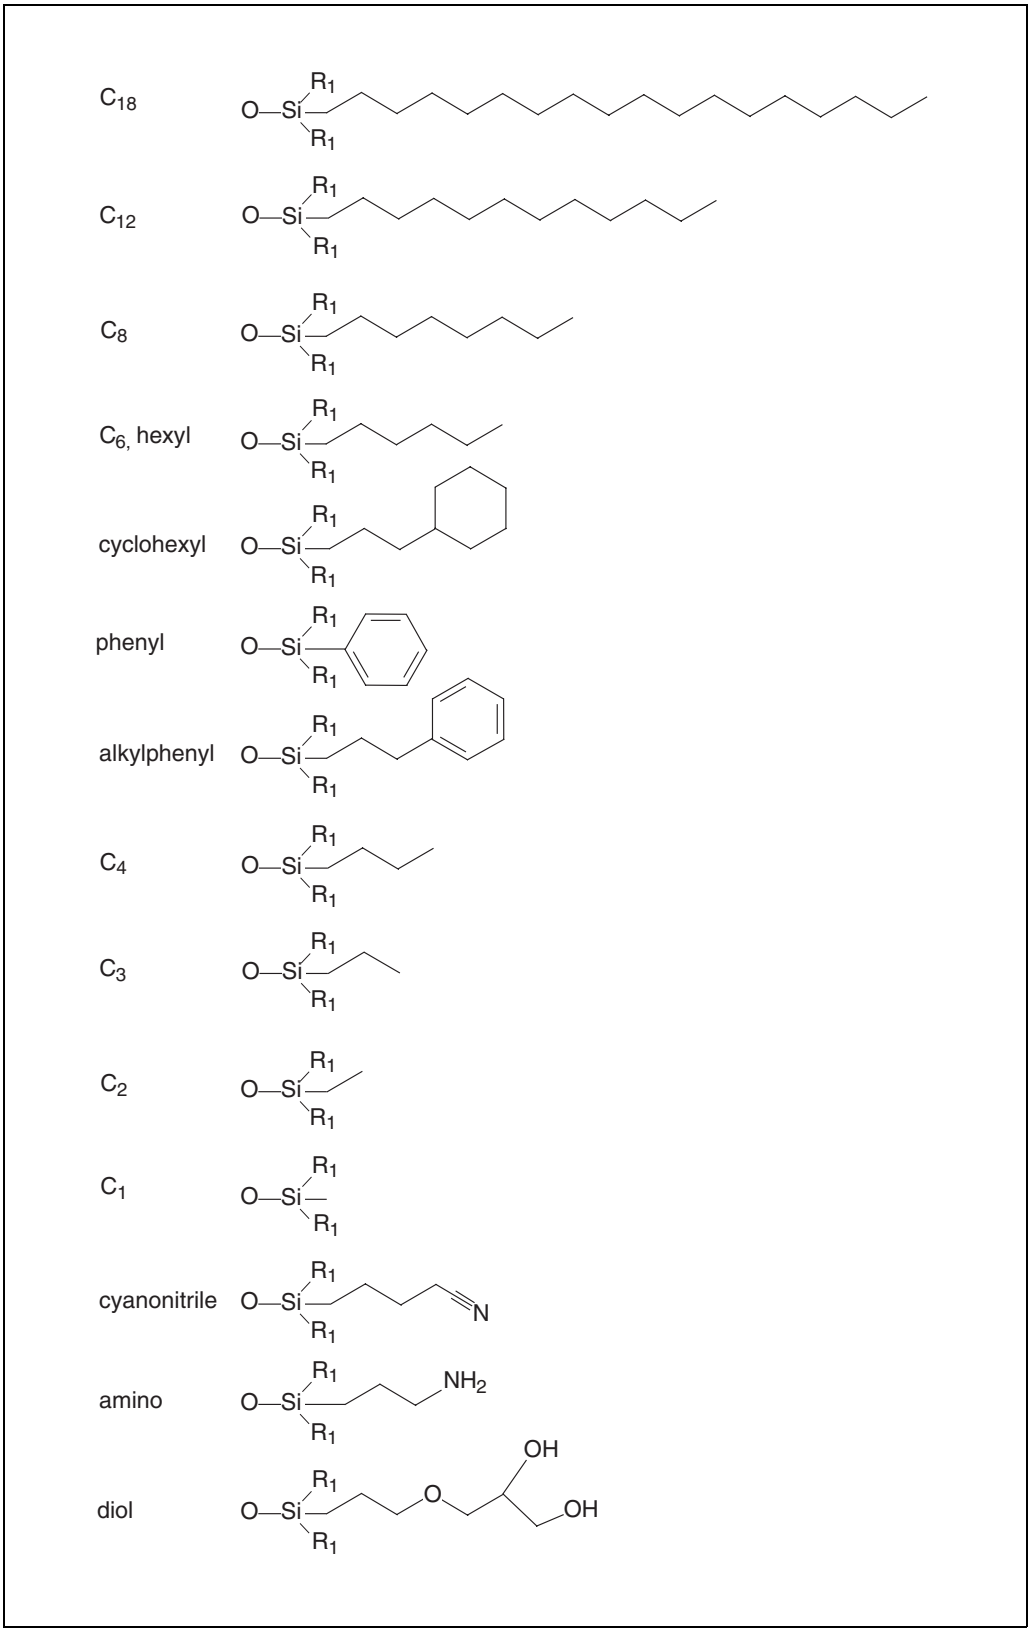

Figure 4.4.1 Bonded phases for RP-HPLC. Reprinted from Neue (1997) with permission from Wiley-VCH.

outside of the capillary helps to evaporate the neutral solvent molecules from the droplets, bringing like-charged ions closer together until coulombic repulsion destabilizes and breaks the droplets apart. This process is repeated until the gas-phase ions are desolvated. The charged particles are drawn toward a counter electrode-orifice into the mass analyzer and the remaining solvent vapor is pumped away (Linscheid, 1992; Dear et al., 1995; Hoja et al. 1997; Kebarle and Yeunghaw, 1997). The gas-phase ions may still contain a solvation layer that can be removed by gentle heating or additional gas flow.

ESI mass spectra usually contain signals for $[M + H]^+$ or $[M - H]^-$ for positive and negative experiments, respectively. Sometimes signals representing adducts with the HPLC solvent or metals (e.g., Na^+ or K^+) are observed. Some compounds will form M^+/M^- ions. Signals indicating in-source fragmentation are not usually seen in ESI spectra unless in-source CID is used. Some analyte ions support multiple charges as determined by their functional groups. ESI-MS studies of large biopolymers such as proteins, polypeptides, and oligonucleotides take advantage of this phenomenon. The molecular weight of these molecules lies outside the mass range of most mass analyzers. However, since the mass analyzer separates based upon mass-to-charge ratio (*m/z*), a sufficient number of charges on a molecule will bring the *m/z* to within the range of the mass analyzer. The ESI mass spectra of large biomolecules contain a distribution of *m/z* values corresponding to several different charge states. The multiple charge peaks in the spectrum can be mathematically deconvoluted to provide molecular weights with a high degree of accuracy.

Performance of the ESI interface is optimized by adjusting a number of parameters.

1. A mobile phase is selected that will encourage formation of ions in solution and that is compatible with the mass spectrometer. Nonvolatile buffers and salts should be eliminated from consideration, as they tend to plug the inlet to the mass analyzer and contaminate the source of conventional ESI systems. A number of instrument manufacturers are now offering ESI systems with modifications that permit the use of nonvolatile buffers without source contamination. Analyte signals can also be suppressed by ions in the sample matrix and even in the mobile phase (e.g., peptide signals are suppressed by trifluoroacetic acid in the mobile phase). Sometimes the optimum mobile phase for ESI is incompatible with optimum separation in reversed-phase chromatography. A compromise can be achieved with the use of volatile buffers that permit ion pairing (e.g., ammonium acetate). Post-column addition of mobile-phase modifiers can also be used at the expense of increased flow.

2. The flow rates into the ion source should be as low as possible, as limited by the chromatographic system, for maximum sensitivity. Flow rates range from nl/min to 1 ml/min (Gaskell, 1997).

3. The nebulizer gas flow rates should be adjusted based upon flow rate into the source. The gas flow needs to be high enough so that solvent cluster signals are eliminated but not so high that the spray current is unstable.

4. The capillary tip voltage should be set high enough to support and maintain desolvation of analyte ions without causing spray-destabilizing discharges.

5. A sheath liquid can be added to reduce the droplet surface tension and increase desolvation.

6. The degree of in-source fragmentation can be controlled by adjusting the accelerating potential of the newly formed ions, thus increasing or decreasing the amount of CID with solvent molecules.

Mass Analysis

ESI and APCI produce mass spectra that contain primarily molecular weight–related ion signals. Consequently, little structural information is revealed by these techniques. Increased fragmentation is observed by subjecting molecular weight–related ions to collision-induced dissociation (CID) in a collection of techniques termed mass spectrometry/mass spectrometry or tandem mass spectrometry (MS/MS). MS/MS is a two-dimensional technique in which one stage of mass analysis isolates the precursor ions of interest, subsequent fragmentation is induced (usually by collision with neutral gas molecules), and then a second stage of mass analysis detects the fragment or product ions (Brunnee, 1982). The type of MS/MS experiment chosen is a function of the type of information being sought and is outlined below. A graphical representation of these scan modes is presented in Figure 4.4.2.

Product ion MS/MS. Previously termed daughter-ion MS/MS, this method uses the first stage of mass analysis to select and isolate a precursor ion. The precursor ions are then fragmented via CID, and the resulting product ions are separated and detected during the second

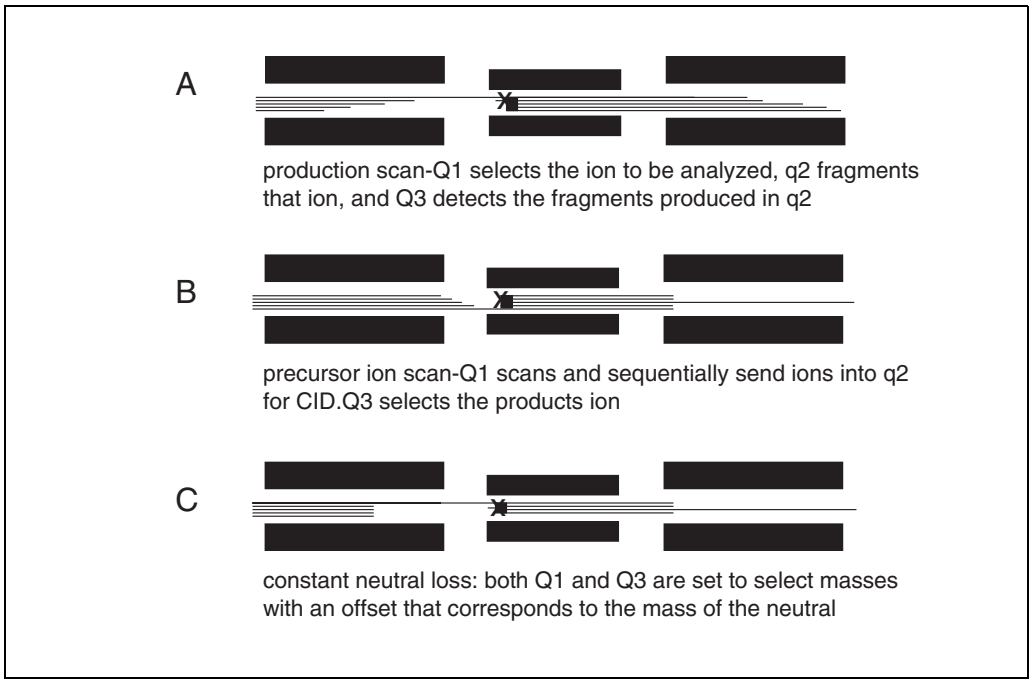

Figure 4.4.2 A graphic representation of scanning modes for (**A**) product ion, (**B**) precursor ion, and (**C**) CNL MS/MS. Q1, q2, and Q3 represent the different stages in an MS/MS experiment. These stages may be separated temporally but occur in the same device, or they may occur in three separate devices.

mass analysis stage. The resulting production spectrum contains signals for fragments directly derived from the selected precursor ion. This experiment answers the question: What are the fragments of the selected ion?

Precursor ion MS/MS. Formerly termed parent-ion MS/MS, this method separates and sequentially transmits all ions from the source during the first stage of mass analysis. These ions undergo CID fragmentation, and an ion of selected *m/z* is isolated and detected in the second stage of mass analysis. A precursor-ion mass spectrum contains signals at precursor *m/z* values for all precursor ions that fragmented to produce the selected product ion. This experiment answers the question: What ions fragment to produce ions at the selected *m/z*?

Constant neutral loss (CNL) scanning. In this MS/MS experiment, the first stage of mass analysis and the second stage of mass analysis are scanning but at a selected *m/*z offset. This offset corresponds to the mass of a lost neutral species (atom, molecule, or radical). The resulting CNL spectrum contains signals for all precursor masses that loose a selected neutral mass. This experiment answers the question: What precursor ions fragment and loose a neutral species at the offset mass?

Selected-reaction monitoring (SRM). SRM is an MS/MS scan mode using one of the three above tandem mass analysis methods. Rather than scanning one or both of the mass analyzers, both mass analyzers are held to transmit only a selected mass window. Thus, ion intensities are measured for specific MS/MS transitions. SRM has the advantage of providing increased sensitivity over scanning MS and MS/MS experiments because only one transition is monitored, and background ions generally do not have either the precursor mass or product mass being monitored. Multiple-reaction monitoring (MRM) is the same as SRM except that the mass analyzer system is stepped through more than one MS/MS transition. For example, Murphy and coworkers (Sun et al., 1996) used MRM to quantify xanomeline and its *N*-desmethyl metabolite. Low limits of quantification were reported as 0.075 ng/ml for the parent compound and 0.20 ng/ml for the *N*-desmethyl metabolite. The instrumental analysis time is 3 min per sample, allowing 130 samples plus standards to be processed in 4.4 hr (Sun et al., 1996).

In-source CID. These experiments are not true MS/MS experiments since precursor selection does not occur before induced fragmentation. The mass spectrum will contain signals for all parent and CID fragment ions in the source. However, as with the MS/MS experiments, fragmentation is increased yielding structurally significant product-ion-like spectra if only one compound is present.

COMBINED HPLC-MS METHODOLOGY

Sample Preparation for HPLC-MS Analysis

Usually some sort of sample preparation is necessary prior to HPLC-MS analysis. If an HPLC column is used (as opposed to direct introduction into the mass spectrometer), most sample matrix problems for the mass spectrometer, such as ionization suppression and coelution, are eliminated. Sample matrix–derived problems for the HPLC column usually can be reduced or eliminated by precipitation, filtration, or extraction. These preliminary preparation methods may be sufficient to allow the sample to be analyzed without HPLC separation. Introducing the sample into the mass spectrometer without a column is known as flow injection, and this method is used for uncomplicated mixtures or when MS/MS methods provide sufficient separation. Several sample extraction methods can be used.

Liquid-liquid extraction is one of the most commonly used sample preparation tools. The analytes are partitioned into a solvent that is immiscible with the sample matrix. Most importantly, the analytes must have an affinity for the extracting solvent that is not shared by the interfering substance. For example, acidic phase II metabolites (e.g., glucuronides and sulfates) can be extracted from an aqueous, salt-containing system for flow-injection MS/MS analysis. Acidic compounds are protonated to reduce polarity, causing them to partition into the organic phase while leaving the polar salts in the aqueous phase. The presence of salts in the sample may have a buffering effect that can thwart this effort. Using a strong buffer to adjust the pH eliminates this concern. Often the xenobiotic parent compound is less polar than the metabolites and will extract into the organic phase without pH adjustment. Ventura et al. (1993) extracted the phase II metabolites of mesocarb from salt-containing urine. After addition of internal standards, the samples were adjusted to alkaline pH with an ammonium chloride buffer (pH 9.5) and extracted with ethyl acetate. The ethyl acetate was evaporated and the residue dissolved in the HPLC mobile phase. The primary metabolite was identified by HPLC-MS as a sulfate conjugate of hydroxymesocarb.

Solid-phase extraction is another sample preparation technique that uses small chromatographic columns containing a limited amount of stationary phase. The column can be used to retain either the analyte or the interfering species. If the analyte is retained, the column is washed to remove all traces of the sample matrix, and the analyte is desorbed with an appropriate solvent or buffer. The packing material in these columns can be any chromatographic solid phase with particle size large enough to permit gravity flow through the column. Appropriate materials include C_{18} bound to silica (reversed phase; retains less polar compounds), alumina (normal phase; retains polar compounds), and boronate gel (retains poly-ols such as polysaccharides).

On-line solid-phase extraction, also known as column switching, is becoming popular in environments where a large number of samples are to be analyzed and sample cleanup represents much of the analysis time and effort. Two chromatographic columns are used in this technique. The first column, a trapping column, is used to separate the compounds of interest from the matrix and trap them. The trapping column is plumbed into the flow stream with multiple port valves. At the start of the analysis, the valves are configured so that the sample is introduced onto the front of the column with the effluent directed to waste. A polar aqueous mobile phase is used during this first step so that the analytes are retained and salts, proteins, and other polar interfering substances are washed through the column. At the start of the next step, the valves are switched and the HPLC mobile phase is back-flushed through the trapping column carrying the analytes to the front of the analytical column. During this step, the analytes are separated and sequentially introduced into the mass spectrometer. Zell et al. (1997) describes an analytical scheme using column switching to detect and quantify drug metabolites in plasma. Sample preparation was limited to precipitating the plasma proteins with perchloric acid, centrifuging, then neutralizing the supernatant with ammonium formate. One millilter of supernatant was injected on to the trapping column—much more than is commonly used in analytical HPLC methods. The trapping column was an LC-ABZ column (20 × 4.6–mm) and the mobile phase used to wash the trapping column was an aqueous ammonium formate buffer. The analytical column was a standard C18 column and the HPLC mobile phase used for metabolite separation was an aqueous ammonium formate/ethanol mixture. The parent compound and metabolites were detected using ESI with SRM. The analysis time from one injection to the next was 9 min. With the exception of the protein precipitation and pH adjustment, the analytical method was completely automated (Zell et al., 1997).

Important Considerations in Combined HPLC-MS

Mobile phase selection in an HPLC-MS method must consider more than just chromatography. For routine operation, none of the interface/source combinations tolerates the use of nonvolatile buffers, acids, bases, or salts for an extended period. Volatile buffer salts include ammonium acetate, ammonium formate, and ammonium carbonate. Acceptable volatile acids include trifluoroacetic acid, acetic acid, and formic acid. Usable volatile bases include ammonium hydroxide, N-methylmorpholine, and triethylamine. The use of high-boiling-temperature organic solvents such as dimethyl sulfoxide and dimethylformamide, which are slowly pumped away, can cause problems to the vacuum system of the mass spectrometer. Trial experiments should be conducted before these solvents are used routinely.

Short-column HPLC methods have been developed that take advantage of the extra separation possible with MS/MS systems. A short HPLC column (≤100 mm) is used to retain analytes long enough to separate them from ionization interferences in the matrix. An MS/MS scan mode (MRM or SRM for quantification) is used to provide any necessary additional separation. Short-column methods permit very rapid analysis of a large number of samples, as analysis times of 3 to 5 min are possible. Volmer et al. (1997) used a 4.0-mm-i.d. × 50-mm-length reversed-phase column and a 1-ml/min flow rate to quantify 4-quinolone antibiotics in biological samples. Ana-

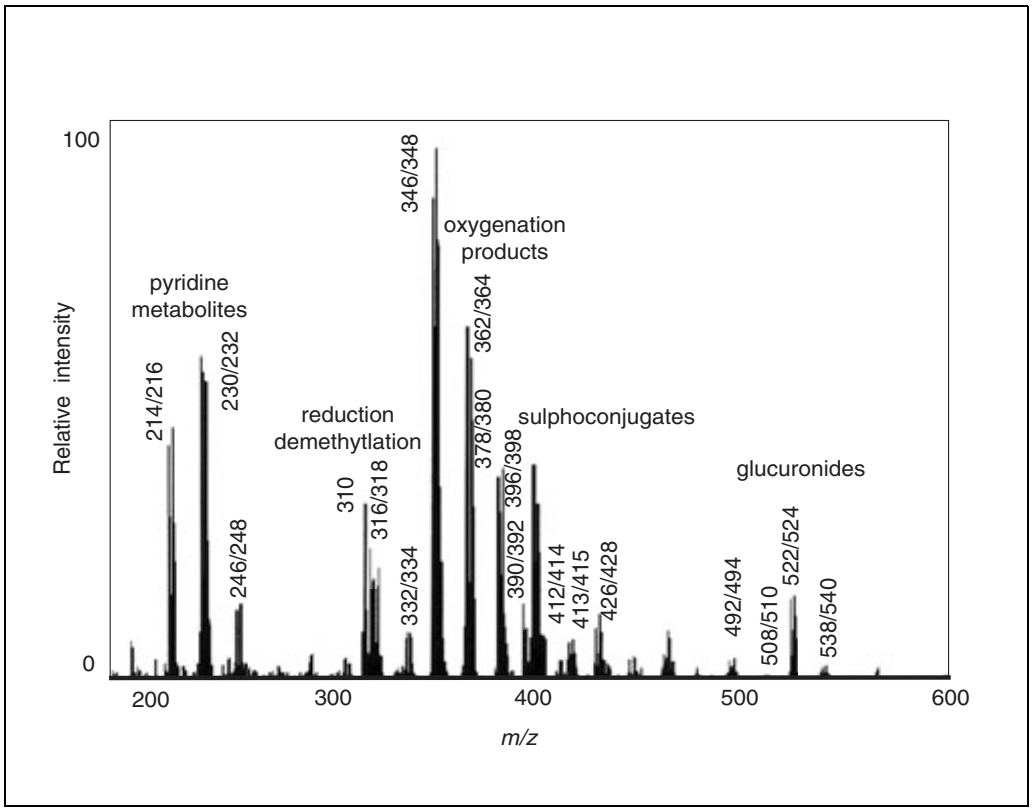

Figure 4.4.4 The metabolic mass profile of omeprazole in the rat. Reprinted from Weidolf and Covey (1992) with permission from John Wiley & Sons.

lytes in the effluent from the column were introduced into the mass spectrometer via an ESI source. The MRM scan mode was defined by the antibiotic being detected. The total analysis time was <8 min for 15 compounds. In another study, Volmer (1996) describes the use of short-column HPLC-MS/MS to study 21 sulfonamide antibiotics with analysis times of <6 min.

NP-HPLC mobile phases are nonpolar organic solvents without buffers that work well with APCI. A limitation of NP-HPLC is that analytes usually have to be extracted from aqueous biological samples.

RP-HPLC mobile phases are polar HPLC solvents that are well suited for separating polar phase II metabolites. These polar mobile phases usually contain a high water content, which works well with ESI interfaces. Beattie and Blake were able to characterize glucuronide and glutathione drug conjugates by direct injection of supernatants (from hepatocyte incubations) onto a C18 column. The mobile phase consisted of 0.1 M aqueous ammonium acetate and acetonitrile (Beattie and Blake, 1989). RP-HPLC tends to require less preparation of biological samples than does NP-HPLC, as demonstrated in the previous example.

HPLC-MS AND HPLC-MS/MS OF METABOLITES

The literature is replete with useful examples of HPLC-MS and HPLC-MS/MS techniques for detecting and characterizing phase I and phase II metabolites. Weidolf and Covey graphically demonstrate the power of HPLC-MS in the identification of the metabolites of omeprazole detected in rat urine. Figure 4.4.3 shows the pathways for the metabolism of omeprazole. Figure 4.4.4 contains a spectrum produced by summing the HPLC-ESI-MS spectra and labeling the metabolite ion signals according the their class of metabolism (Weidolf and Covey, 1992).

Phase I Metabolite Identification

Phase I metabolism adds or removes functional groups toward increased hydrophilicity and increased reactivity toward phase II conjugation. These reactions involve hydrolysis, oxidation, or reduction, and either introduce or expose the following functional groups: $–NH_2$, –OH, –SH, or –COOH. The result is only a minor increase in polarity (Parkinson, 1996). However, under the right solvent or gas-phase conditions, each of these groups will support charge. Consequently, introduction or unmask-

ing of these groups often allows the metabolite molecule to be ionized by either APCI or ESI.

Time-consuming method development can be reduced by modifying an existing method for compounds with similar functionality. Toward this end, Table 4.4.2 and Figure 4.4.5 provide sample methodology for phase I metabolites. Some of the HPLC-MS methods listed are for ionization methods other than ESI or APCI, but none-the-less provide useful information.

Phase II Metabolite Identification

Phase II conjugation reactions include glucuronidation, sulfation, acetylation, methylation, conjugation with glutathione (mercapturic acid synthesis), and conjugation with amino acids (such as taurine, glycine, and glutamic acid; Parkinson, 1996). In contrast with phase I metabolism, these reactions result in a large increase in polarity. Furthermore, conjugation with glutathione, glucuronic acid, and sulfate increase the thermal lability and decrease the volatility of the metabolite. Finally, these compounds tend to be easily charged in solution and can be analyzed by HPLC-ESI-MS.

In an excellent review, Baillie (1992) discusses strategies for using MS/MS to detect phase II metabolites via "metabolic mapping." One begins by precursor or CNL scanning for charged or neutral structural moieties indicative of each category of metabolite. Once an indicative charged or neutral structural element is detected, the associated precursor ion m/z is selected and a product ion scan is performed. A list of MS/MS scan and selected or offset m/z values for a number of metabolites has been compiled by Baillie (1994) and is reproduced in Table 4.4.3. As mentioned above for phase I metabolites, method development time and frustration is reduced by beginning with established methodology; methods used for a number of phase II metabolites are presented in Table 4.4.4 and Figure 4.4.6.

SUMMARY

In the last 20 years, major developments have resulted in direct coupling of analytical HPLC systems to mass spectrometers. This union, HPLC-MS and HPLC-MS/MS, has become routine even with the use of polar aqueous solvent systems and has proven to be a sensitive and structurally informative tool in the hands of the toxicologist seeking to identify xenobiotic metabolites.

FUTURE DIRECTIONS

The need for extreme sensitivity and low amounts of sample has always plagued those who work with samples of biological origin, especially metabolite samples. Developments in both HPLC and MS continue to push toward smaller sample size and lower detection limits.

Nano-flow electrospray MS, or nano-spray, is one of these developments (Wilm and Mann, 1994). The primary use of nano-spray has been to sequence peptides with exceptional sensitivity (working with amounts of peptide in the femtomole to attomole range). However, these extremes in sensitivity will apply to any electrospray-amenable compound, including xenobiotic metabolites.

Analogously, nano-scale HPLC has been described in a recent report by Chervet et al. (1996). Separations have been achieved using RP-HPLC with flow rates of 180 nl/min through 75-µm-i.d. × 150-mm-length columns packed with C_{18} stationary phase. The authors

were able to show high reproducibility under gradient as well as isocratic flow conditions. Solvent use and sample consumption were low with injection volumes of ~20 nl and total analyte consumption in the 4-ng range.

A combination of nano-spray and nano-scale HPLC with a tandem mass spectrometer capable of MS^3 (MS/MS/MS) or more in a fully automated environment could conceivably provide the ultimate analytical tool. This tool would provide rapid analysis, extreme sensitivity, high resolution, and the ability to isolate xenobiotic metabolites directly from the biological matrix.

Measurement of Aryl and Alcohol Sulfotransferase Activity

Sulfation is an important reaction in the metabolism and toxicology of a wide variety of structurally diverse drugs, carcinogens, and other xenobiotics. Whereas the sulfation of xenobiotics usually leads to decreased toxicity, there is a growing number of exceptions in which the formation of chemically reactive sulfuric acid esters is an essential step in metabolic pathways leading to toxic and/or carcinogenic responses. The enzymes that catalyze these reactions in mammals constitute a family of cytosolic sulfotransferases that transfer a sulfuryl group from 3′-phosphoadenosine 5′-phosphosulfate (PAPS) to an acceptor molecule (see Figure 4.5.1). The products of sulfation reactions are adenosine 3′,5′-diphosphate (PAP) and sulfuric acid esters (also called sulfates, sulfooxy derivatives, or sulfonoxy derivatives) or sulfamates when amines are the sulfuryl acceptor. Several previous reviews on mammalian cytosolic sulfotransferases provide background information about their importance and characteristics (Jakoby et al., 1980; Mulder and Jakoby, 1990; Weinshilboum and Otterness, 1994; Yamazoe et al., 1994; Duffel, 1997; Falany, 1997).

This unit provides two protocols for determining the activity of aryl and alcohol sulfotransferases. Basic Protocol 1 describes one of the oldest and simplest methods for rapid determination of either aryl (phenol) sulfotransferase or alcohol (hydroxysteroid) sulfotransferase activity. Originally developed for hydroxysteroid sulfotransferases (Nose and Lipmann, 1958), the method has been modified for use with phenols (Sekura et al., 1981), amines (Ramaswamy and Jakoby, 1987), and benzylic alcohols (Duffel and Janss, 1986) as sulfuryl acceptors. This procedure uses chloroform to quantitatively extract the paired ion formed between methylene blue and an organic sulfuric acid ester, either 2-naphthylsulfate or dehydroepiandrosterone sulfate. Following extraction of the paired ion, its absorbance at 651 nm is determined. Basic Protocol 2 is suitable for both aryl and alcohol sulfotransferases, and relies on HPLC determination of PAP as a product of the reaction. This method is particularly useful for molecules in which the sulfuric acid ester product is chemically reactive with nucleophiles or is otherwise unstable (Duffel et al., 1989).

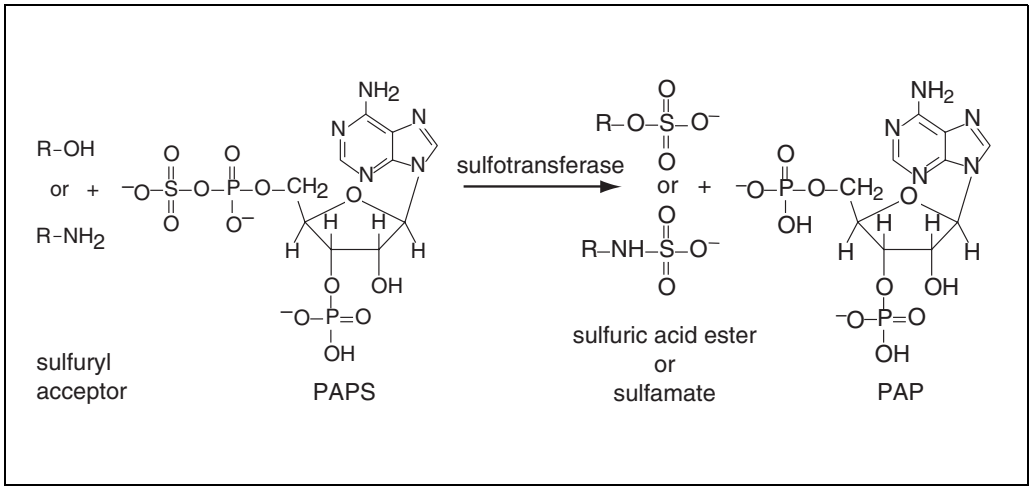

Figure 4.5.1 Reactions catalyzed by aryl and alcohol sulfotransferases. The sulfuryl acceptor is represented by either R-OH (for phenols, alcohols, *N*-hydroxy arylamines, oximes, and arylhydroxamic acids) or R-NH_2 (for amines).

BASIC PROTOCOL 1

METHYLENE BLUE EXTRACTION ASSAY FOR ARYL OR ALCOHOL SULFOTRANSFERASE ACTIVITY

This method utilizes PAPS as substrate and either 2-naphthol (for aryl sulfotransferase) or dehydroepiandrosterone (for alcohol sulfotransferase) as sulfuryl acceptor. It measures the aryl or alcohol sulfotransferase activities in various samples, including tissue homogenates, bacterial cell extracts for heterologous expression of mammalian sulfotransferases, intermediate fractions during purification, and homogenous proteins. This protocol is a slightly modified version of previously described methods (Nose and Lipmann, 1958; Sekura et al., 1981; Ramaswamy and Jakoby, 1987).

Materials

Reaction buffer: 41.0 g/liter sodium acetate, adjusted to pH 5.5 with acetic acid
0.1 M 2-mercaptoethanol (2-ME)
4 mM 3′-phosphoadenosine 5′-phosphosulfate (PAPS; see recipe)
10 mM 2-naphthol (recrystallized from water) in acetone (ACS reagent grade)
2.0 mM dehydroepiandrosterone (DHEA) in acetone (ACS reagent grade)
Enzyme sample of known protein concentration
Methylene blue reagent (see recipe)
Chloroform (ACS spectrophotometric grade)
Sodium sulfate (anhydrous)
13 × 100–mm glass test tubes
Spectrophotometer and quartz cuvettes

Perform sulfotransferase-catalyzed reaction

1a. *For aryl (phenol) sulfotransferase:* Place a 13 × 100–mm glass test tube on ice, and add sequentially:

200 µl reaction buffer
30 µl 0.1 M 2-mercaptoethanol
20 µl 4.0 mM PAPS
10 µl 10 mM 2-naphthol
130 µl water.

Single reactions are used for rapid analysis of fractions from chromatography in enzyme purification. Otherwise, at least three replicate reactions are performed.

1b. *For alcohol (hydroxysteroid) sulfotransferase:* Place a 13 × 100–mm glass test tube on ice, and add sequentially:

200 µl reaction buffer
30 µl 0.1 M 2-mercaptoethanol
20 µl 4.0 mM PAPS
10 µl 2.0 mM DHEA
130 µl water.

2. Set up a separate tube with the same reaction mixture as a control (incubation time = 0 min).
3. Mix on a vortex mixer, then preincubate 2 min in a 37°C water bath.
4. Add 10 µl enzyme sample to the sample tube to start the reaction, mix 1 to 2 sec on a vortex mixer, and incubate 5 to 30 min in a 37°C water bath. Meanwhile, add 10 µl enzyme to the control tube and immediately stop the reaction (step 5).

The volume of enzyme solution may be modified as necessary. The total volume should be kept constant by also changing the amount of water added to the mixture.

Extract sulfuric acid ester

5. Add 0.5 ml methylene blue reagent to stop the reaction.
6. Immediately add 2.0 ml chloroform and vortex vigorously 20 sec.
7. Centrifuge mixture 10 min at ~2000 × *g* at room temperature, to separate organic and aqueous phases.
8. Using a Pasteur pipet, transfer chloroform (lower) layer to a test tube containing 50 to 100 mg anhydrous sodium sulfate. Mix gently by hand or vortex mixer and allow sodium sulfate to settle to the bottom.

Determine specific activity

9. Carefully remove ~1.0 to 1.5 ml chloroform and measure the A_{651} with a spectrophotometer.

   The extraction of 10 nmol of 2-naphthylsulfate yields A_{651} = 0.3. This value is used in the calculation of product formed based on absorbance at 651 nm.

10. Calculate specific activity (sp. act.; nmol product/mg protein/min) using the equation:

$$\text{sp. act.} = \frac{(\text{sample } A_{651} - \text{control } A_{651}) \times (10 \text{ nmol} / 0.3 \text{ absorbance units})}{\text{mg protein} \times \text{incubation time}}$$

HPLC ASSAY FOR SULFOTRANSFERASE ACTIVITY

BASIC PROTOCOL 2

This assay was originally developed to measure sulfotransferase reactions in which sulfuric acid ester products may be chemically unstable (Duffel et al., 1989). However, the formation of PAP as the reaction product makes it applicable to many sulfotransferases and acceptor substrates, and it has been applied successfully to cytosolic fractions and bacterial cell extracts as well as purified sulfotransferases.

Materials

HPLC mobile phase (see recipe)
4.0 mM 3′-phosphoadenosine 5′-phosphosulfate (PAPS; see recipe) or 4.0 mM adenosine 3′,5′-diphosphate (PAP; see recipe)
HPLC-grade water
PAP standards (see recipe)
Reaction premix (see recipe)
Substrate solution (see recipe)
Solvent used for substrate solution
Enzyme sample of known protein concentration
HPLC-grade methanol

C18 5-µM reversed-phase HPLC column (i.d. = 4.6 mm, length = 250 mm)
High-performance liquid chromatograph (HPLC) with 20-µl sample-injection loop, uv/vis detector, and integrator
6 × 50–mm glass test tubes

Prepare HPLC for sample injection

1. About 3 hr before beginning sulfotransferase assays, equilibrate the HPLC column with HPLC mobile phase at 2.0 ml/min flow rate.
2. Make a test sample by diluting 1.5 µl of 4.0 mM PAPS or PAP in 60 µl HPLC-grade water.

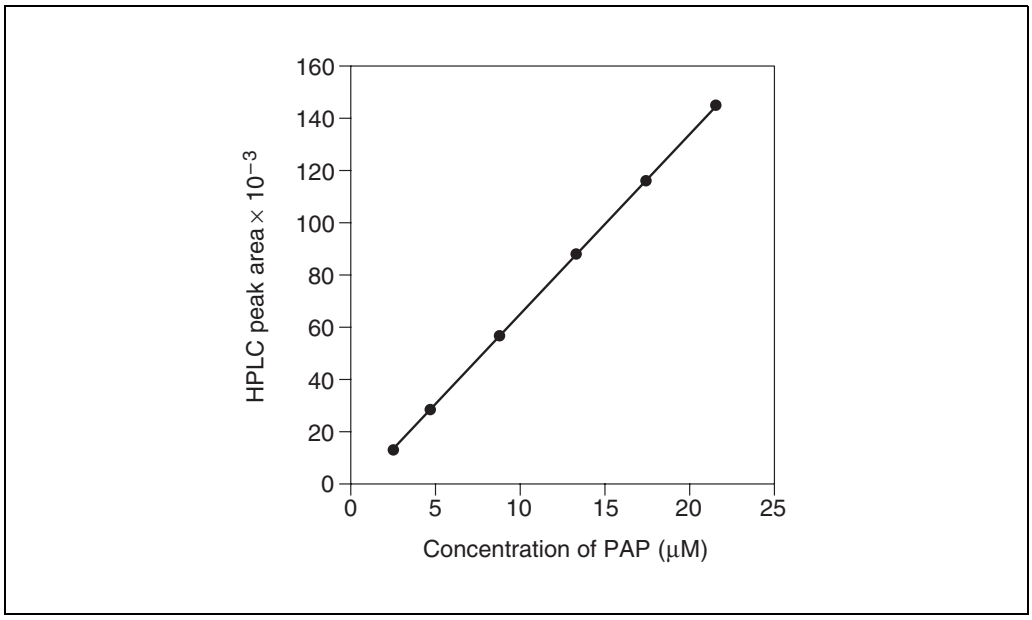

Figure 4.5.2 Representative standard curve relating the concentration of PAP to the integrated area under the corresponding HPLC peak. Peak area is in arbitrary units.

3. Completely fill the 20-µl HPLC sample-injection loop with test sample (40 to 50 µl), taking care to avoid air bubbles. Vent excess to a waste container. Maintain flow rate at 2.0 ml/min.

   The baseline absorbance should be stable, and PAP test samples should have consistent retention times.

Determine relationship between HPLC peak area and PAP concentration

4. Inject PAP standards onto the column and plot the area under the curve versus PAP concentration in µM (Figure 4.5.2).

Perform sulfotransferase-catalyzed reaction

5. Place a 6 × 50–mm glass test tube on ice and add 27.5 µl reaction premix and 1.5 µl substrate solution.
6. Prepare a control tube containing 27.5 µl reaction premix and 1.5 µl solvent used to prepare substrate solution.
7. Mix contents of each tube on a vortex mixer, then preincubate tubes 2 min at 37°C.
8. Add 1.0 µl enzyme sample to start the reaction, briefly vortex, and incubate tubes 10 min in a 37°C water bath.

   Reaction times may vary from 2 to 20 min. Use the exact time to calculate specific activity.

9. Add 30 µl HPLC-grade methanol to stop the reaction and mix vigorously on a vortex mixer. Keep tubes on ice until the HPLC analysis for PAP is completed.

Analyze by reversed-phase HPLC

10. Fill the injection loop with sample and inject onto the HPLC column. Maintain mobile phase flow rate at 2.0 ml/min.
11. Calculate the concentration of PAP formed (µM) in each tube using the standard curve. Calculate specific activity (sp. act.; nmol product/mg protein/min) as follows:

$$\text{sp. act.} = \frac{([\text{PAP}]_{\text{sample}} - [\text{PAP}]_{\text{control}}) \times 60\ \mu\text{l}}{\text{mg protein} \times \text{incubation time}}$$

The volume (60 µl) corresponds to the assay volume after dilution with methanol.

REAGENTS AND SOLUTIONS

Use glass-distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Adenosine 3′,5′-diphosphate (PAP), 4.0 mM

Purchase adenosine 3′,5′-diphosphate (PAP) as sodium salt containing 4 mol/mol sodium and 2.5 mol/mol water (formula wt. 464.2). Dissolve 25 mg PAP in 13.5 ml water. Store up to 6 months at −20°C. Keep PAP solutions at 4°C while waiting to add to reaction mixtures.

HPLC mobile phase

Dissolve 20.4 g KH_2PO_4 and 8.03 g NH_4Cl in 1760 ml HPLC-grade water. Add 340 µl *n*-octylamine, stir until it completely dissolves, and adjust to pH 5.45 with KOH. Degas solution using a trapped vacuum pump for 30 min. Add 240 ml HPLC-grade methanol and filter through a 0.45-µm membrane filter. Degas briefly. Alternatively, sparge the mobile phase with helium gas to displace air bubbles. Use at room temperature and prepare fresh daily.

The mobile phase should only be degassed briefly (3 to 5 min) after addition of methanol to avoid altering the concentration of methanol.

This mobile phase contains 75 mM potassium phosphate and 75 mM ammonium chloride. To vary salt concentrations, use different amounts of potassium phosphate and ammonium chloride as shown in Figure 4.5.3.

Methylene blue reagent

250 mg/liter methylene blue
50 g/liter anhydrous sodium sulfate
10 ml/liter sulfuric acid
Store up to 6 months at 25°C

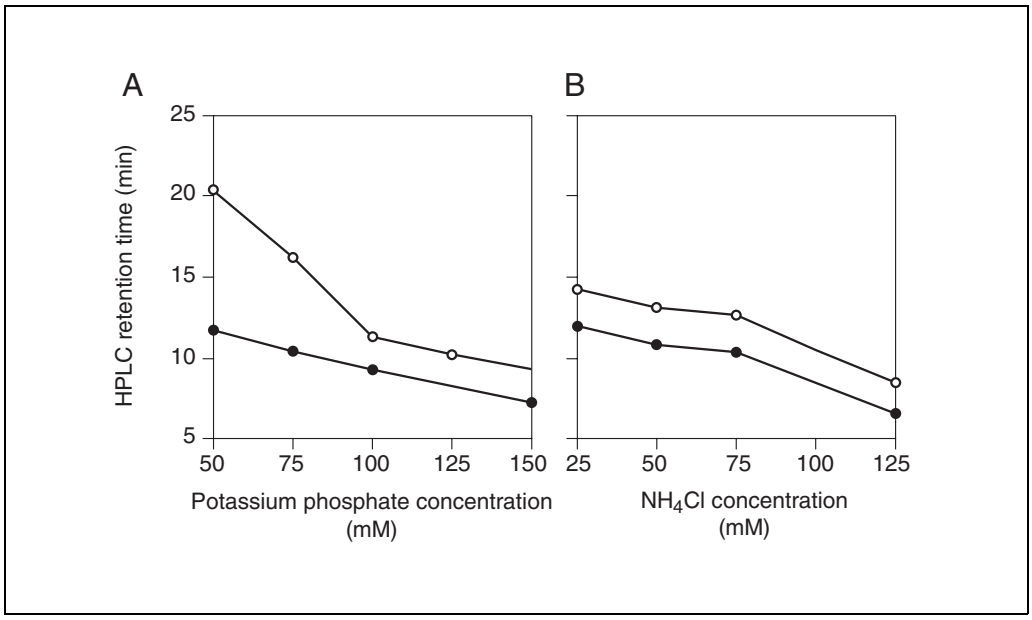

Figure 4.5.3 Effect of the concentration of potassium phosphate and the concentration of ammonium chloride on the separation of PAP (closed circles) and PAPS (open circles) by HPLC under the conditions described in Basic Protocol 2. (**A**) The effect of varied concentrations of potassium phosphate on the retention times of PAP and PAPS at 50 mM ammonium chloride. (**B**) The effect of varied concentrations of ammonium chloride on the retention times of PAP and PAPS at 75 mM potassium phosphate.

PAP standards

To six vials, add 1.2, 2.5, 5.0, 7.5, 10.0, and 12.5 µl of 4.0 mM PAP (see recipe). Add 2.0 ml water to each vial. Determine A_{259} for each standard solution, and calculate the concentration of PAP using a molar absorptivity of 15.4×10^3 at 259 nm.

3′-Phosphoadenosine 5′-phosphosulfate (PAPS), 4.0 mM

Purchase 3′-phosphoadenosine 5′-phosphosulfate (PAPS) as lithium salt containing 4 mol/mol lithium and 3 mol/mol water (formula wt. 589.1). Dissolve 25 mg PAPS in 10.6 ml water. Store up to 6 months at −20°C. Keep on ice after thawing, and refreeze the remaining stock solution.

Reaction premix

15 µl 4.0 mM PAPS (see recipe)
50 µl 1.5 M potassium phosphate, pH 7.0
25 µl 0.1 M 2-mercaptoethanol
185 µl water
Prepare just before use

The reaction premix contains all reaction components except the sulfuryl acceptor substrate and enzyme sample. This recipe makes enough for ten assays.

Substrate solution

Prepare substrate solutions in acetone, tetrahydrofuran, or acetonitrile, because most sulfuryl acceptor substrates of aryl and alcohol sulfotransferases are hydrophobic. Mix 100-µl stock solutions to give final substrate concentrations of 0.01 to 5.0 mM in the incubation mixture. In addition, be sure that the volume of acetone or acetonitrile in the enzymatic reaction does not exceed 5% of the total assay volume, and that the volume of tetrahydrofuran does not exceed 3% of the total assay volume. Prepare substrate solutions immediately before use.

COMMENTARY

Background Information

A combination of the diversity of chemicals that can serve as substrates for sulfotransferases and the many different isoforms of these enzymes has led to the development of many varied assay methods. This unit focuses on two of these methods: one that utilizes an ion-pair extraction technique with methylene blue and a second that uses HPLC to determine the substrate-dependent production of PAP.

In addition to these assays, there are various other methods available for determining the activity of aryl and alcohol sulfotransferases. Among these are procedures for direct quantitation of phenolic reactants or products by HPLC (Honkasalo and Nissinen, 1988) and fluorometric methods (Beckmann, 1991). Coupled reactions with 4-nitrophenyl sulfate have also been utilized for assay of sulfotransferases. One such assay employs an exchange reaction between 4-nitrophenyl sulfate and an acceptor phenol under conditions of limiting concentrations of PAP (Gregory and Lipmann, 1957; Duffel and Jakoby, 1981). Moreover, a coupled-enzyme assay has recently been described wherein recombinant aryl sulfotransferase IV, PAP, and 4-nitrophenyl sulfate are utilized as both a source of PAPS and an indicator of the rate of reaction for a second sulfotransferase that does not utilize phenols or phenyl sulfates as substrates (Burkart and Wong, 1999).

Several radiochemical methods are also available for the assay of sulfotransferases. A common feature of many of these procedures is the use of [^{35}S]PAPS with an unlabeled sulfuryl acceptor molecule followed by separation of the [^{35}S]labeled reaction product. Specific radiochemical assays predominantly vary by whether the radiolabeled product is separated by means of thin-layer chromatography (Sekuar et al., 1979), ecteola-cellulose chromatography (Borchardt et al., 1983), or precipitation with barium (Foldes and Meek, 1973). Radiolabeled sulfuryl acceptors such as ster-

oids (Sekura et al., 1979) and arylamines (Ramaswamy and Jakoby, 1987) have also been employed for determination of sulfotransferases. The relative merits and disadvantages of several of the radiochemical assays for sulfotransferases have been reviewed (Ramaswamy and Jakoby, 1987; Weinshilboum and Otterness, 1994).

Critical Parameters and Troubleshooting

Although the methylene blue extraction assay (Basic Protocol 1) is often preferred due to the fact that it is rapid and simple to perform, it is not as sensitive as the HPLC method (Basic Protocol 2) or the radiochemical methods that are available for assay of sulfotransferases. Troubleshooting of the methylene blue extraction assay is relatively straightforward. The assay is sensitive to the final ionic strength of the solution, because high salt concentrations increase the solubility of the methylene blue in chloroform. This effect of high salt is independent of the presence of any sulfuric acid ester. However, corrections for the effect of ionic strength on the extraction of methylene blue into chloroform are easily made either by the use of a control reaction mixture that contains all reaction components except PAPS, or by the use of a reaction mixture that contains all components but is stopped immediately after addition of the enzyme (t = 0 control). Additional compounds that might potentially interfere with the methylene blue dye-binding assay include other organic anions. For example, free fatty acids in crude cellular homogenates may interfere, but as in the case of enzyme samples with high salt concentrations, control reaction mixtures without incubation or without PAPS often provide an appropriate resolution of the problem.

For both basic protocols, it is advisable to perform preliminary experiments to determine if the enzyme is rate-limiting in the assay. The suggestions presented in these protocols for concentration of PAPS, concentration of sulfuryl acceptor, and incubation time often ensure that initial velocities are determined under conditions of saturating substrate. However, it is useful to confirm this or alter the conditions as needed.

The HPLC assay for sulfuryl acceptor–dependent formation of PAP is especially useful in cases where the sulfuric acid ester may be subject to hydrolysis, reaction with nucleophiles, or other modes of decomposition. The major difficulties that may be encountered with this assay relate either to the purity of PAPS employed in the assays or to chromatographic problems resulting from subtle changes in the resolution of the HPLC column. Commercial preparations of PAPS sometimes contain 10% to 15% PAP, and this level of contamination may prove problematic for this assay. If this is the case, purification of PAPS is readily accomplished by chromatography on DEAE-cellulose as previously described (Sekura, 1981). PAPS solutions can be stored frozen (–20°C) at a concentration of 4.0 mM in water for up to 6 months. After thawing, the stock solutions of PAPS should be kept on ice until the reaction mixtures are prepared, and the remainder of the stock solution should be refrozen as soon as possible following the sulfotransferase assays. PAPS may be stored and used in this manner until the concentration of PAP in the solution becomes >5% of the concentration of PAPS.

A final comment relevant to the HPLC assay involves optimization of the mobile phase. As the reversed-phase HPLC column is used repeatedly over the course of several weeks, the properties of the column will eventually begin to change, and thus the separation of PAP and PAPS will be altered. Compensation for this effect can be readily achieved by altering the concentration of potassium phosphate or the concentration of ammonium chloride in the elution solvent. The effects of these ions on the retention times of PAP and PAPS are seen in Figure 4.5.3, and these data can be used as a guide to altering the composition of the mobile phase as necessary to optimize the separation.

Anticipated Results

Basic Protocol 1

The catalytic activity of a preparation of recombinant rat hepatic aryl sulfotransferase (AST) IV was analyzed by the methylene blue extraction assay with 2-naphthol as substrate. The assay was conducted at pH 5.5 with 250 μM 2-naphthol as sulfuryl acceptor and 6 μg purified AST IV in a final assay volume of 0.40 ml. Enzymatic reactions were carried out at 37°C for 10 min as described in Basic Protocol 1. Absorbance at 651 nm of the chloroform extract derived from the control mixture (i.e., when all components were present, but the reaction was terminated before any incubation) was 0.038; the absorbance after 10 min incubation with AST IV was 0.325. The specific activity was calculated as follows:

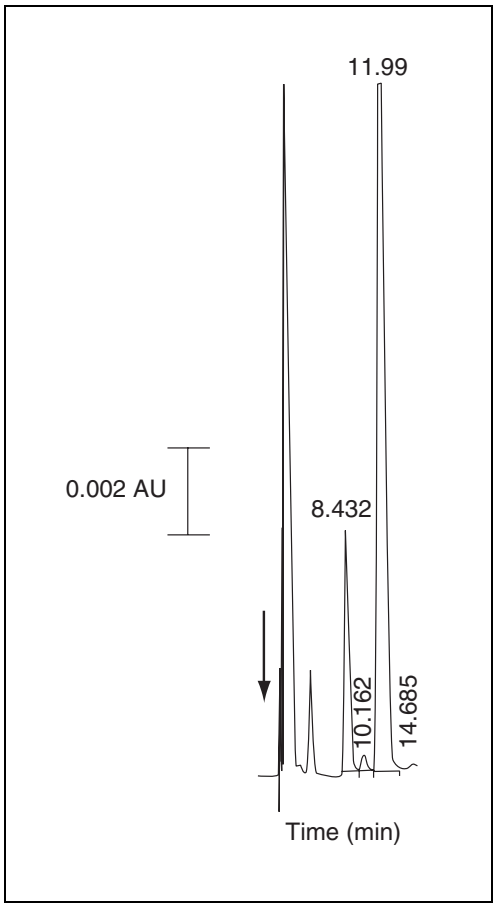

Figure 4.5.4 Representative HPLC chromatogram of the activity of 0.5 μg recombinant rat alcohol (hydroxysteroid) sulfotransferase STa as described in Basic Protocol 2. The reaction was carried out for 10 min at pH 7.0 with 50 μM DHEA as sulfuryl acceptor. The arrow in the chromatogram indicates injection of a 20-μl sample onto the HPLC column. Elution of the column was monitored at 259 nm; the chromatographic peak at 8.43 min was PAP and the peak at 11.99 min was PAPS.

$$\text{sp. act.} = \frac{(0.325 - 0.038) \times 10 \text{ nmol} / 0.3 \text{ units}}{0.006 \text{ mg protein} \times 10 \text{ min}}$$

$$= 159 \text{ nmol product/mg protein/min}$$

Basic Protocol 2

Enzymatic activity of a purified preparation of recombinant rat alcohol (hydroxysteroid) sulfotransferase STa was determined using the HPLC assay method. The assay was carried out at pH 7.0 with 50 μM DHEA as sulfuryl acceptor and 0.5 μg purified STa in a final assay volume of 30 μl. The sulfation reaction was carried out at 37°C for 10 min as described in Basic Protocol 2. The HPLC chromatogram of the reaction mixture is seen in Figure 4.5.4, with PAP eluting at 8.43 min and PAPS eluting at 11.99 min. A reaction mixture where 1.5 μl of acetone was substituted for the substrate solution served as a control assay. The concentrations of PAP in the 20 μl HPLC injection (12.2 μM sample, 10.1 μM control) were determined through the use of a standard curve relating PAP concentration to HPLC peak areas (as demonstrated in Fig. 4.5.2), and these values were used to calculate the specific activity as follows:

$$\text{sp. act.} = \frac{(12.2\,\mu\text{M} - 10.1\,\mu\text{M}) \times 60\,\mu\text{l}}{0.5 \times 10^{-3} \text{ mg protein} \times 10 \text{ min}}$$

$$= 25.2 \text{ nmol product/mg protein/min}$$

Time Considerations

The total time required for each of the two procedures will vary with the chosen incubation time. However, assuming that there is a 2-min temperature equilibration before the enzyme is added, and the sulfotransferase-catalyzed reaction is carried out for 10 min, it is possible to estimate the total time involved. For the methylene blue extraction procedure, a total time of ~40 min is required to carry out the procedure. The overall process can, however, be made more efficient by staggering the starting times for the incubation of several reaction mixtures, so that several reaction tubes are carried through the procedure simultaneously. Using the same assumptions about reaction times, the HPLC assay for PAP requires ~40 to 50 min per assay. While simultaneous reactions can also be incubated for this assay, the rate-limiting portion of the method is the HPLC separation, which typically takes 20 to 25 min per sample. Therefore in an 8-hr period, 12 to 15 samples could be assayed by the HPLC method, or ~70 to 80 samples could be analyzed by the methylene blue extraction assay.

Measuring the Activity of Arylamine *N*-Acetyltransferase (NAT)

Arylamine *N*-acetyltransferases (NAT; EC 2.3.1.5) catalyze the acetylation of aromatic amines, heterocyclic amines, and hydrazines. The reaction can be viewed as either a detoxification or activation step depending on the substrate and the position of the acetyl group. For hydrazine derivatives, addition of an acetyl group, which is generally donated by the cofactor acetyl coenzyme A (acetyl CoA), results in the formation of a product that is less reactive than the parent. *N*-acetylation of drugs such as isoniazid (INH) results in a product that is less toxic than the parent and therapeutically inactive. *N*-acetylation of aromatic amines and heterocyclic amines is also viewed as a detoxification step. In contrast, *O*-acetylation of arylhydroxylamines or the intramolecular *N*,*O*-acetyl transfer within arylhydroxamic acids are considered to be activation steps.

NATs are cytoplasmic proteins and activities can be measured in cytosolic fractions of whole tissue or cultured cells. NAT 1 and NAT 2 have selective but overlapping substrate specificities. The three acetylation reactions, *N*-acetylation, *O*-acetylation, and *N*,*O*-acetyl transfer, are illustrated in Figure 4.6.1. All three reactions are catalyzed by the proteins designated as NAT. This unit describes methods for measuring *N*-acetylation, using either an acetyl CoA recycling system (see Basic Protocol 1) or a single concentration of acetyl CoA (see Alternate Protocol) coupled with HPLC separation of the parent aromatic amine from the acetylated product. The Bratton-Marshall method (see Basic Protocol 2) measures NAT activity by spectrophotometric monitoring of the decrease in substrate concentration over time.

CAUTION: Many aromatic amines are mutagens and carcinogens and must be handled as hazardous materials. Experimental procedures and waste disposal must follow the appropriate institutional guidelines.

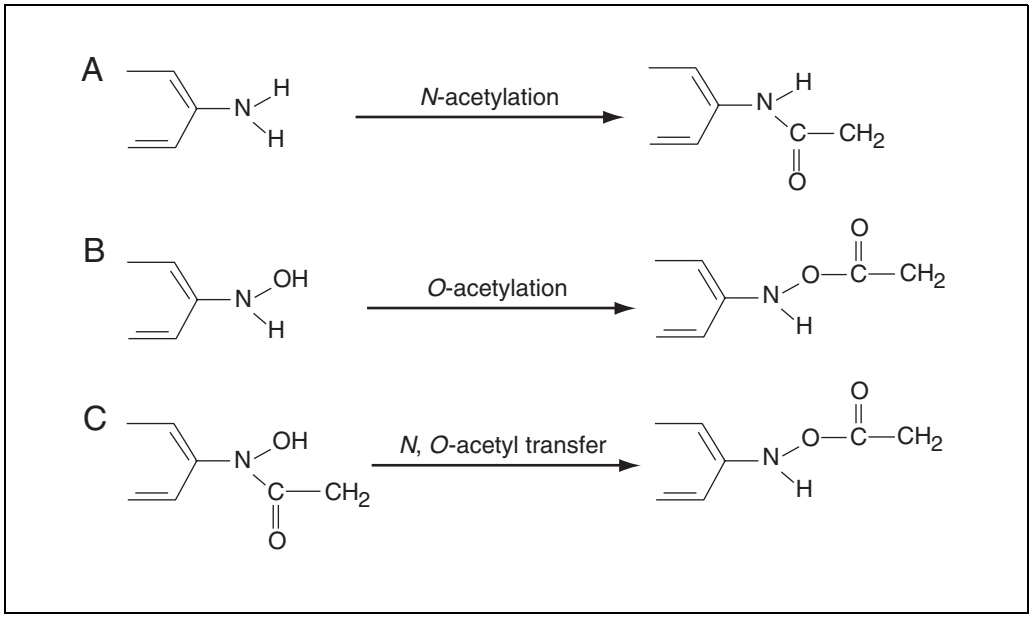

Figure 4.6.1 Reactions catalyzed by NATs. (**A**) The *N*-acetylation of an arylamine. (**B**) The *O*-acetylation of an arylhydroxylamine. (**C**) The intramolecular *N*,*O*-acetyl transfer of an arylhydroxamic acid.

HPLC ASSAY FOR NAT ACTIVITY USING THE ACETYL CoA RECYCLING SYSTEM

The use of a recycling system to convert coenzyme A (CoA) back to acetyl coenzyme A (acetyl CoA) results in the use of acetyl CoA concentrations within a physiologic range, which is desirable when determining kinetic constants. Additionally, CoA concentrations are kept low to decrease the possibility of product inhibition of NAT by CoA. The separation and quantification of the resulting acetylated aromatic amines is most commonly done by HPLC. The major advantage is that the amount of product is measured rather than the disappearance of substrate (Basic Protocol 2); however, the conditions for the separation of product from substrate must be modified depending on the arylamine substrate.

Arylamine NAT activity is measured under the following conditions: 15 mM acetylcarnitine, 2 U carnitine acetyltransferase/µl, 2 mM EDTA, 2 mM DTT, 50 mM Tris·Cl, pH 7.5, 0.5 mM acetyl CoA, 44.4 µM arylamine substrate, and 0.5 to 2 mg/ml protein. Samples are incubated for 10 min at 37°C.

NOTE: It is advisable to do preliminary experiments to determine that assays are being performed under initial velocity conditions. This is done by varying the time of incubation and the amount of protein.

Materials

Cytosolic or S-9 fraction (see Support Protocol 1 or 2)
Pierce protein assay kit
Homogenization buffer (see recipe)
10× acetyl CoA solution 1 (22.7 mM; see recipe)
Recycling mix (RCM; see recipe)
10^{-2} M arylamine substrate (see recipe and Table 4.6.1)
~80 U/mg carnitine acetyltransferase (CAT; from pigeon breast muscle; Sigma; keep refrigerated but do not freeze, put on ice, or keep at room temperature >5 min)
Methanol, ice-cold
Solvents for mobile phase (see Tables 4.6.2, 4.6.3, and 4.6.4)

1.5-ml microcentrifuge tubes
HPLC with UV detector and column (see Tables 4.6.2, 4.6.3, and 4.6.4)

Perform NAT reaction and prepare samples for HPLC

1. Thaw a sufficient number of tubes of cytosol or S-9 for the experiment (200 µl). Keep on ice.
2. Determine the protein concentration of the cytosol or S-9 using protein assay kit. Adjust the concentration to 0.5 to 2 mg protein/50 µl with homogenization buffer.

Table 4.6.1 Commonly Used Selective Substrates[a,b]

Species	NAT1	NAT2
Human	PABA	SMZ
Mouse	INH	PABA
Rat	—	PABA
Hamster	—	PABA

[a]Grant et al., 1991; Doll and Hein, 1995; Ferguson et al., 1996; Estrada-Rogers et al., 1998.
[b]Abbreviations: INH, isoniazid; PABA, *p*-aminobenzoic acid; SMZ, sulfamethazine.

3. Thaw a sufficient number of tubes, each containing a 50-µl aliquot of 10× acetyl CoA solution 1, on ice. Prepare 1× acetyl CoA solution 1 (2.27 mM) by adding 450 µl ice-cold Milli-Q purified water to each tube. Keep on ice.
4. Add 1 µl of 10^{-2} M arylamine substrate stock solution and sufficient CAT to give ~9 U/µl RCM.

   The ratio of RCM/arylamine substrate/CAT is 97:2:1. The amount of substrate may be changed, if necessary, for determination of kinetic constants.

   There is lot-to-lot variation in CAT preparations, so it is necessary to adjust the amount used to give the desired concentration.
5. For each reaction to be performed, combine, in a 1.5-ml microcentrifuge tube, 50 µl of cytosol or S-9 protein solution (from step 2) and 20 µl of RCM/arylamine substrate/CAT (from step 4). Mix gently and incubate 1 min at 37°C.

   When the acetyl CoA solution is added in the next step, total reaction volume will be 90 µl.
6. Add 20 µl of 1× acetyl CoA solution 1 (from step 3) to each tube, gently mix, and begin timing incubation (generally 10 min) at 37°C in a water bath.
7. Stop the reaction by adding 90 µl ice-cold methanol; mix and keep on ice.
8. Microcentrifuge samples for 4 min at 14,000 × *g*, room temperature, to precipitate protein. Use 20 to 50 µl of the supernatant for HPLC analysis.

Perform HPLC analysis

9. Prepare a standard curve by injecting known amounts of an authentic standard of the acetylated product of interest (see Support Protocol 3). Plot nanograms standard (*y* axis) versus absorbance ($AUC_{product}$; *x* axis). Calculate slope and *y*-intercept by linear regression analysis.
10. Inject sample (20 to 50 µl or amount necessary for a specific instrument) onto the column and elute according to the conditions for the product being analyzed (see Tables 4.6.2, 4.6.3, and 4.6.4) at a flow rate of 1 ml mobile phase/min.
11. Calculate activity in nmol/min/mg protein by comparison of the absorbance (AUC peak area) of the product in the sample with that obtained with known amounts of authentic standard using the following formulas:

Table 4.6.2 HPLC Conditions for Sulfamethazine (SMZ)

	Method 1[a]	Method 2
Column	Microsorb-MV C18 (4.6 × 250–mm, 5 µm)	Adsorbosphere C18 (4.6 × 250–mm, 5 µm)
Mobile phase	20 mM ammonium acetate (A) and methanol (B)	18% acetonitrile in H_2O with 0.5% acetic acid
Gradient	Linear: 2% to 100% B	Isocratic
Flow rate	1 ml/min	1 ml/min
Retention (min)

[b]2-acetylaminofluorene.

$$\text{area under curve}_{\text{product}} \times \text{slope}_{\text{std. curve}} + y\ \text{intercept}_{\text{std. curve}} = \text{ng product/injected sample vol.}$$

$$\frac{\text{ng product} \times \text{mol. wt.}_{\text{product}} \times \text{total sample vol./injected sample vol.}}{(\text{min incubation})(\text{mg protein/sample})} = \text{nmol acetylated product/min/mg protein}$$

ALTERNATE PROTOCOL

HPLC ASSAY FOR NAT ACTIVITY USING A FIXED CONCENTRATION OF ACETYL CoA

This method uses a single concentration of acetyl CoA, which simplifies the number of components required during incubation. Arylamine NAT activity is measured under the following conditions: 2 mM EDTA, 2 mM DTT, 50 mM Tris·Cl, pH 7.5, 2.2 mM acetyl CoA, and 44.4 µM arylamine substrate.

Additional Materials *(also see Basic Protocol 1)*

1× acetyl CoA solution 2 (10^{-2} M; see recipe)
2×10^{-4} M arylamine substrate (see recipe and Table 4.6.1)

NAT reaction

1. Thaw and adjust protein concentration of cytosol or S-9 (see Basic Protocol 1, steps 1 and 2).
2. Add the following to each tube (total reaction volume 90 µl):

   50 µl cytosol or S-9 protein solution (see Basic Protocol 1, step 2)
   20 µl 2×10^{-4} M arylamine substrate solution
   20 µl 1× acetyl CoA solution 2

   Mix gently and incubate 10 min at 37°C.
3. Stop the reaction by adding 90 µl of ice-cold methanol, mixing, and keeping on ice.
4. Prepare sample and analyze by HPLC (see Basic Protocol 1, steps 8 to 11).

THE BRATTON-MARSHALL ASSAY FOR NAT ACTIVITY

BASIC PROTOCOL 2

The Bratton-Marshall assay measures the disappearance of an arylamine substrate rather than the formation of the acetylated product. The unacetylated arylamine is converted to the diazo cation by sodium nitrite, which is then reacted with *N*-1-(naphthyl)ethyl-enediamine (NED) forming a colored diazo compound with an absorbance at 540 nm. This method can potentially be utilized with any arylamine substrate of NAT. Arylamine NAT activity is measured under the following conditions: 2 mM EDTA, 2 mM DTT, 50 mM Tris·Cl, pH 7.5, 2.2 mM acetyl CoA, and 44.4 µM arylamine substrate.

Materials

Cytosolic or S-9 fraction (see Support Protocol 1 or 2)
Pierce protein assay kit
Homogenization buffer (see recipe)
1× acetyl CoA solution 2 (10^{-2} M; see recipe)
2×10^{-4} M arylamine substrate (see recipe and Table 4.6.1)
10% (w/v) trichloracetic acid (TCA; store up to 1 month at room temperature)
0.1% (w/v) sodium nitrite (prepared fresh)
0.5% (w/v) ammonium sulfamate (store up to 1 month at room temperature)
0.05% (w/v) *N*-1-(naphthyl)ethylene-diamine dihydrochloride (NED; Sigma; store up to 1 month at room temperature)
UV spectrophotometer

Perform NAT reaction

1. Thaw a sufficient number of tubes of cytosol or S-9 for the experiment (200 µl). Keep on ice.
2. Determine the protein concentration of the cytosol or S-9 using protein assay kit. Adjust the concentration to 0.5 to 2 mg protein/50 µl with homogenization buffer.
3. In a 1.5-ml microcentrifuge tube combine the following for each experimental sample or control (total volume 90 µl):

   Experimental:
   50 µl cytosol or S-9 protein solution (from step 2)
   20 µl 2×10^{-4} M arylamine substrate
   20 µl 1× acetyl CoA solution 2

   Control:
   50 µl cytosol or S-9 protein solution (from step 2)
   20 µl water
   20 µl 2×10^{-4} M arylamine substrate solution

   IMPORTANT NOTE: *Each cytosol sample needs an appropriate control tube run simultaneously with the experimental tube.*

4. Mix gently and incubate 10 min at 37°C.
5. Stop the reaction by adding 50 µl of 10% TCA and mixing.

Prepare sample

6. Add 20 µl of freshly prepared 0.1% sodium nitrite, mix, and incubate 3 min at room temperature.
7. Add 20 µl of 0.5% ammonium sulfamate, mix, and incubate at room temperature for 3 min.
8. Add 100 µl of 0.05% NED, mix, and incubate for 10 min.
9. Microcentrifuge 4 min at 14,000 × *g*, room temperature, to precipitate the protein.

Spectrophotometric analysis

10. Read each sample at 540 nm against a water blank.
11. Subtract the control from the corresponding experimental sample to determine the change in absorbance.
12. Calculate the NAT activity as follows:

$$\frac{\text{absorbance}_{\text{control}} - \text{absorbance}_{\text{exp}}}{\text{incubation time (min)}} \times \frac{1}{(\text{absorbance/ng arylamine})(\text{mol. wt.}_{\text{arylamine}})} \times \frac{1}{\text{mg/sample}} = \text{nmol/min/mg}$$

SUPPORT PROTOCOL 1

PREPARATION OF S-9 FROM TISSUE

This protocol can be used for organs or isolated cells. An S-9 fraction is generally used when only small amounts of tissue or cells are available.

Materials

Mammalian liver or cultured cells
Homogenization buffer (see recipe), ice-cold

Tissue homogenizer: Polytron (Kinematica) or equivalent
Cryovials

1. Harvest and weigh tissue. Add a volume of ice-cold homogenization buffer equal to three times the tissue weight. Homogenize using the Polytron homogenizer.

   If S-9 is being prepared from cultured cells, the medium is removed and the cells are suspended in the homogenization buffer.

2. Centrifuge 10 min at 9000 × *g*, 4°C.
3. Divide supernatant into 200- to 400-µl aliquots in cryovials and store up to 6 weeks at −80°C.

SUPPORT PROTOCOL 2

PREPARATION OF CYTOSOL

This protocol is used to prepare cytosol from mammalian liver. It can be modified for other tissues or cells by adjusting the amount of homogenization buffer.

Materials

Mammalian liver
Homogenization buffer (see recipe), ice-cold

Tissue homogenizer: Polytron (Kinematica) or equivalent
Ultracentrifuge
Cryovials

1. Harvest and weigh tissue. Add a volume of ice-cold homogenization buffer equal to three times the tissue weight. Homogenize using the Polytron homogenizer.
2. Centrifuge 10 min at 9000 × *g*, 4°C.
3. Discard pellet and ultracentrifuge supernatant 1 hr at 100,000 × *g*, 4°C.
4. Divide supernatant into 200- to 400-µl aliquots in cryovials and store up to 6 weeks at −80°C.

PREPARING A STANDARD CURVE FOR HPLC ASSAY OF NAT ACTIVITY

SUPPORT PROTOCOL 3

Known amounts of the authentic standard are used to determine absorbance (AUC peak area) at a specific wavelength.

Materials

Acetyl PABA or other acetylated arylamine of interest
DMSO (for acetyl PABA) or other appropriate solvent for acetylated arylamine
Mobile phase (see Tables 4.6.2, 4.6.3, and 4.6.4)

1. Prepare a solution of 1 mg/ml acetyl PABA in DMSO. Dilute with the mobile phase so that there are 8 to 10 tubes ranging from 0 to 10 ng/µl.
2. Inject sample into the column and elute the sample under the conditions for the appropriate arylamine (Tables 4.6.2, 4.6.3, and 4.6.4).

   For PABA, absorbance (AUC) is determined at 270 nm using reversed-phase HPLC with a C18 column and acetic acid/acetonitrile (Table 4.6.3) as the mobile phase.
3. Plot absorbance (AUC peak area; *x* axis) versus ng standard (*y* axis). Determine the slope and *y* intercept with linear regression analysis.

PREPARING A STANDARD CURVE FOR COLORIMETRIC ASSAY OF NAT ACTIVITY

SUPPORT PROTOCOL 4

Known amounts of authentic arylamine solution are used to determine the absorbance at 540 nm following diazotization with sodium nitrite and coupling with NED.

Materials

5×10^{-3} M sulfamethazine (SMZ; see recipe) or other arylamine substrate of interest
10% (w/v) trichloracetic acid (TCA; store up to 1 month at room temperature)
0.1% (w/v) sodium nitrate (prepared fresh)
0.5% (w/v) ammonium sulfamate (store up to 1 month at room temperature)
0.05% (w/v) *N*-1-(naphthyl)ethylenediamine dihydrochloride (NED; Sigma; store up to 1 month at room temperature)

1. Dilute 5×10^{-3} M SMZ 1:100 with water.
2. Pipet a series of aliquots of SMZ ranging from 0 to 450 µl, in duplicate, into separate tubes. Add water as necessary to bring the volume to 450 µl.
3. Add 250 µl of 10% TCA to each tube. Mix.
4. Add 100 µl of 0.1% sodium nitrite to each tube. Mix and wait 3 min.

   The sodium nitrate solution must be freshly prepared each day. It is also critical to allow sufficient time (3 min) for the diazotization reaction to occur.

5. Add 100 µl of 0.5% ammonium sulfamate to each tube. Mix and wait 3 min.

   It is important to wait 3 min for the reaction with the excess nitrite to occur.

6. Add 500 µl of 0.05% NED to each tube. Mix.
7. Read at 540 nm after 10 min. Do not allow more than 30 min to elapse before reading.
8. Plot the concentration of sulfamethazine (*x* axis) versus absorbance at 540 nm (*y* axis).

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acetyl CoA solution 1, 10× (22.7 mM)

Weigh 9.19 mg acetyl CoA (lithium salt) add to 500 µl and water. Aliquot 50 µl into separate tubes and store at −20°C. Use within 30 days.

Acetyl CoA solution 2 (10^{-2} M)

Weigh 8.09 mg acetyl CoA and add to 1 ml water. Store at −20°C. Use within 30 days.

Arylamine substrate solutions

10^{-2} M p-aminobenzoic acid (PABA): Weigh 137 mg PABA and add 100 ml water.

2×10^{-4} M PABA: Weigh 2.74 mg PABA and add 100 ml water.

10^{-2} M sulfamethazine (SMZ): Weigh 278 mg SMZ (e.g., Sigma) and add 80 ml water. The solubility of SMZ is increased at a basic pH. Add a few drops of 0.1 M sodium hydroxide if necessary. Adjust volume to 100 ml with water.

2×10^{-4} M SMZ: Weigh 5.56 mg SMZ and dissolve as described above for 10^{-2} M.

10^{-2} M 2-aminofluorene (2-AF): Weigh 181.2 mg 2-AF (e.g., Sigma) and dissolve in 100 ml DMSO.

2×10^{-4} M 2-AF: Weigh 3.6 mg 2-AF and dissolve in 100 ml DMSO.

CAUTION: *2-AF is a carcinogen and mutagen and must be weighed, used, and disposed of following appropriate institutional procedures.*

Homogenization buffer

Prepare 1 liter of 20 mM Tris·C1, pH 7.5 (*APPENDIX 2A*). To this, add 0.15 g dithiothreitol (DTT; 1 mM final) and 0.37 g disodium ethylenediamine tetraacetate (EDTA; 1 mM final). On day of assay, add 1 ml of 50 mM phenylmethylsulfonyl fluoride (PMSF; 50 µM final) and 1 ml of 10 mM leupeptin (10 µM final).

To prepare the 50 mM PMSF stock, weigh 87 mg PMSF and add 10 ml acetonitrile. To prepare 10 mM leupeptin stock, weigh 48 mg leupeptin and add 10 ml water.

Recycling mix (RCM)

Prepare the following stock solutions:
1 M Tris hydrochloride: Weigh 78.80 g Tris hydrochloride and add 500 ml water.
100 mM dithiothreitol (DTT): Weigh 15.23 mg DTT and add 10 ml water.
100 mM EDTA: Weigh 372.24 mg disodium EDTA and add 10 ml water.

To make 50 ml RCM combine 11.25 ml of 1 M Tris hydrochloride, 4.50 ml of 100 mM DTT, and 4.50 ml of 100 mM EDTA. Bring to 40 ml with water, then add 876.5 mg acetyl-DL-carnitine (Sigma; 73.1 mM final). Adjust pH to 7.8. Bring final volume to 50 ml with water and store in 1-ml aliquots at −20°C. Use within 30 days.

The total volume of this recipe is 50 ml; final concentrations are: 225 mM Tris, 9 mM DTT, 9 mM EDTA, and 73.1 mM acetylcarnitine.

COMMENTARY

Background Information

In mammalian species, NATs are encoded by two polymorphic genes, *NAT1* and *NAT2* (see reviews by Vatsis and Weber, 1997, and Hein et al., 2000a). There is a human pseudogene, *NATP*, as well as an *NAT3* locus in the mouse. Little or no activity has been associated with the latter two genes. The acetylation of aromatic amines and hydrazines is mainly catalyzed by *NAT 1* and *NAT 2*. These genes have been isolated from mammalian species, sequenced, and expressed. A consensus nomenclature for NAT genes was first published in 1995 (Vatsis et al., 1995) and recently reviewed (Hein et al, 2000b). The Human Gene Nomenclature Committee (*http://www.gene.ucl.ac.uk/nomenclature*) has designated *NAT* as the gene symbol. A committee and web site (*http://www.louisville.edu/medschool/pharmacology/NAT.html*) is ensuring the use of the consensus nomenclature will be maintained and reviewed as necessary (Hein et al., 2000b). Rodent species also have two genes designated *NAT1* and *NAT2*, but based on substrate specificities and homologies it appears that rodent *NAT1* is comparable to human *NAT2* while rodent *NAT2* is comparable to human *NAT1* (Vatsis et al., 1995; Hein et al., 2000b).

The human *NAT* genes are both located on chromosome 8. These genes share greater than 80% nucleotide homology in the coding region (Blum et al., 1990; Hickman et al., 1994). Each gene has an intronless coding region of 870 bp (Blum et al., 1991; Vatsis et al., 1991). Allelic variants that alter enzyme activity have been reported for both human genes, with nucleotide changes representing the most common source of variation (see reviews by Vatsis and Weber, 1997, and Hein et al., 2000a). The allelic variations in *NAT 1* or *NAT 2* result in phenotypes with different activities.

NATs have a wide tissue distribution. Human NAT1 and NAT2 are found in liver as well as in extrahepatic tissue including gastrointestinal tract, urinary tissue, bladder, and lung (Windmill et al., 2000). In addition to overlapping tissue distributions, these two enzymes also share substrate specificities. While there are substrates that are selective for NAT1 or NAT2, only one specific substrate, *p*-aminobenzoylglutamate (PABAGlu), has been identified for human NAT1 and rodent NAT2 (Minchin, 1995; Ward et al., 1995). One commonly used substrate that is selective for human NAT1 is *p*-aminobenzoic acid (PABA; Grant et al., 1991). This is also used to evaluate rodent NAT2 activities (Doll and Hein, 1995; Ferguson et al., 1996; Estrada-Rogers et al., 1998). Sulfamethazine (SMZ) is a selective substrate for human NAT2 but a poor substrate for rodent NAT1. Some compounds such as the aromatic amine carcinogen 2-aminofluorene are substrates for both enzymes (Grant et al., 1991; Doll and Hein, 1995; Ferguson et al., 1996; Estrada-Rogers et al., 1998).

Acetylation is a conjugation, or phase II, reaction that may either increase or decrease toxicity of the parent compound. For hydrazines such as isoniazid or hydralazine, *N*-acetylation results in the formation of a less reactive product. A decrease in the genotoxicity of hydralazine is associated with an increase in NAT activity (Lemke and McQueen, 1995). *N*-acetylation of arylamines generally decreases toxicity. In contrast, *O*-acetylation of *N*-hydroxylamines is a major step in the activation of aromatic amines to DNA-damaging products (see review by Delclos and Kadlubar, 1997).

The enzymes that are designated as NATs catalyze the following acetylation reactions: the addition of an acetyl group to the nitrogen of an extracyclic amino or hydrazine moiety, the addition of an acetyl group to the oxygen of an *N*-hydroxylamine or the *N*,*O* intramolecular transfer of the acetyl group (Fig. 4.6.1). These activities reside in the same protein (Glowinski et al., 1980). Recombinant-expressed NATs catalyze both *N*- and *O*-acetylation reactions (Fretland et al., 1997). Since the *N*-acetyl derivatives are generally

more stable than the *O*-acetylated compounds, the former reaction is commonly measured.

The choice of methods for determination of NAT activities involves consideration of the incubation conditions and the analytical system. Initially, measurement of NAT activity for a given arylamine or hydrazine utilized a fixed concentration of acetyl CoA (Hearse and Weber, 1973). This was modified to use a system which continually regenerates acetyl CoA (Andres et al., 1985). This allows measurements at lower, more physiologic concentrations of acetyl CoA, limits inhibition of NAT by coenzyme A, and is particularly suited for determination of kinetic constants (Andres et al., 1985).

NAT activity is generally expressed as nanomole acetylated product/minute/milligram protein. Two approaches to measuring activity can be used. Since the disappearance of substrate is directly proportional to the appearance of product (Hearse and Weber, 1973), the decrease in substrate concentration may be determined. A micro-modification (Hearse and Weber, 1973) of the Bratton-Marshall method (Bratton and Marshall, 1939) involves a colorimetric determination of the parent amine. Since the method detects aromatic amines but not arylamides, the conditions for product analysis need not be altered to reflect which substrate is measured. An alternative approach for quantifying amines is based on decreasing Schiff's base formation with dimethylaminobenzaldehyde (Andres et al., 1985).

HPLC methods allow direct measurement of product formation. Although the HPLC conditions must be developed, product can be confirmed by the comigration with authentic standards and quantified by comparison to a standard curve. Conditions suitable for commonly used substrates are in Tables 4.6.2, 4.6.3, and 4.6.4. Comparable methods for these and other substrates have been reported by several laboratories.

Critical Parameters and Troubleshooting

NATs catalyze the acetylation of aromatic amines and hydrazines by a ping-pong mechanism (Fig. 4.6.2). The reaction first involves the formation of a covalent acetyl-cysteinyl NAT intermediate and CoA. The acetyl group from this intermediate is then transferred to the acceptor amine, resulting in the acetylated amine and NAT (Fig. 4.6.2; also see Weber and Cohen, 1968). The two-step process requires that the enzyme have a reactive cysteinyl thiolate (Andres et al., 1988), which in human NAT2 is Cys^{68}. Substitution at this site with Gly abolishes catalytic activity (Dupret and Grant, 1992).

Instability of NATs, particularly in highly purified preparations, is presumably caused by oxidation of sulfhydryl groups. This requires that care be taken in the handling and storage of samples. Postmortem delays in harvesting tissue increase the likelihood of enzyme degradation. Small samples of tissue or cultured cells can be frozen intact and stored for at least 1 month at −80°C. The inclusion of compounds such as DTT, PMSF, and leupeptin in the homogenization buffer are helpful in maintaining key sulfhydryl groups such as Cys^{68} in human NAT2.

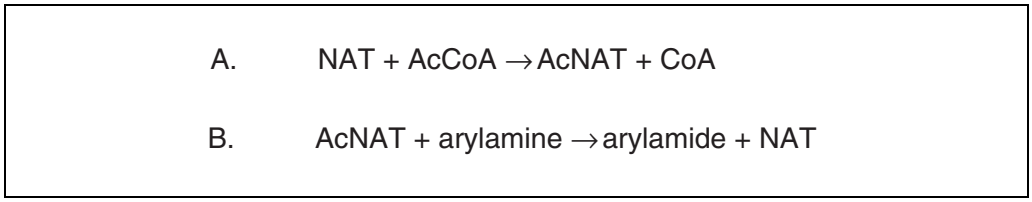

Figure 4.6.2 Mechanism of NAT catalyzed *N*-acetylation.

NAT activity can be inhibited by high concentrations of CoA. This can be minimized by using lower concentrations of acetyl CoA or the regenerating system described in Basic Protocol 1. The enzyme can also be affected by solvents such as dimethysulfoxide (DMSO). Due to the poor solubility of many aromatic amines in aqueous solutions, compounds such as 2-AF are generally dissolved in DMSO. Care should be taken to minimize the amount of DMSO in the assay. NAT activity was not inhibited by 1% DMSO, but inhibition was observed at concentrations >5% (Mattano and Weber, 1987).

Anticipated Results

Examples of the range of NAT activities calculated for human or rodent liver are illustrated in Tables 4.6.5 and 4.6.6. For human samples, cytosols were prepared from livers and analyzed for NAT activities according to Basic Protocol 1. A sample (0.5 mg protein) was incubated at 37°C for 10 min. Substrate concentration was 44.4 µM PABA or SMZ. The amount of product was determined by HPLC. Calculation of NAT activity was:

$$\frac{\text{area under curve}_{\text{sample}} \times \text{slope}_{\text{std. curve}} + \text{y intercept}_{\text{std. curve}} \times \dfrac{1}{\text{ng/nmol}} \times \dfrac{180\,\mu\text{l}}{50\,\mu\text{l}}}{(10\text{ min incubation})(0.5\text{ mg protein})} = \text{nmol product/min/mg protein}$$

The conversion from nanogram standard to nanomole requires that the molecular weight of the parent be used.

Table 4.6.5 Human Hepatic NAT Activities[a]

Sample	NAT1		NAT2	
	Alleles	PABA activity	Alleles	SMZ activity[b]
1	1*4/4	1.98	2*4/*5B	0.87
2	1*4/*10	0.64	2*5B/*5B	0.16
3	1*3/*10	1.53	2*4/*4	2.15

[b]Abbreviations: AAF, 2-acetylaminofluorene.

Time Considerations

For NAT assays, incubations generally are <20 min. Sample preparation for HPLC takes ~5 min per sample. The HPLC run may vary, but 30 min is usually sufficient to separate product from parent. Additional time will be necessary to equilibrate the column to the initial conditions for the separation. The use of an autosampler in conjunction with the HPLC allows samples to be processed unattended.

Measurement of Carboxylesterase (CES) Activities

Mammalian carboxylesterases (CES; EC 3.1.1.1) comprise a multigene family whose gene products exist in many mammalian species and humans. These enzymes efficiently catalyze the hydrolysis of a variety of ester- and amide-containing chemicals, as well as drugs (including prodrugs), to the respective free acids (Fig. 4.7.1). They are involved in detoxification or metabolic activation of various drugs, environmental toxicants, and carcinogens. CES also catalyzes the hydrolysis of endogenous compounds such as acyl-glycerol, acyl-carnitine, and acyl-CoAs. Multiple isozymes of hepatic microsomal CES exist in various animal species, and some of these isozymes are involved in the metabolic activation of certain carcinogens as well as being associated with hepatocarcinogenesis.

The CES isozymes are located on the lumen side of the endoplasmic reticulum. Microsomal preparations from tissues, whole cultured cells, or membrane preparations from cultured cells are used in hydrolysis assays. The activity of a CES is measured as the moles of respective acids or alcohol formed from substrates during a given time period via catalysis by a standard amount of protein. This unit describes three methods for measuring CES activity: (1) the photometric assay (see Basic Protocol 1), which is a simple and rapid screening method and can be used with a variety of substrates (see Alternate Protocols 1 through 3); (2) the fluorometric assay (see Basic Protocol 2), which is a high sensitivity method; and (3) the high-performance liquid chromatography (HPLC) method (see Basic Protocol 3), which is a general screening method. A great many substrates may be analyzed by these methods. In each procedure, the enzyme reaction is

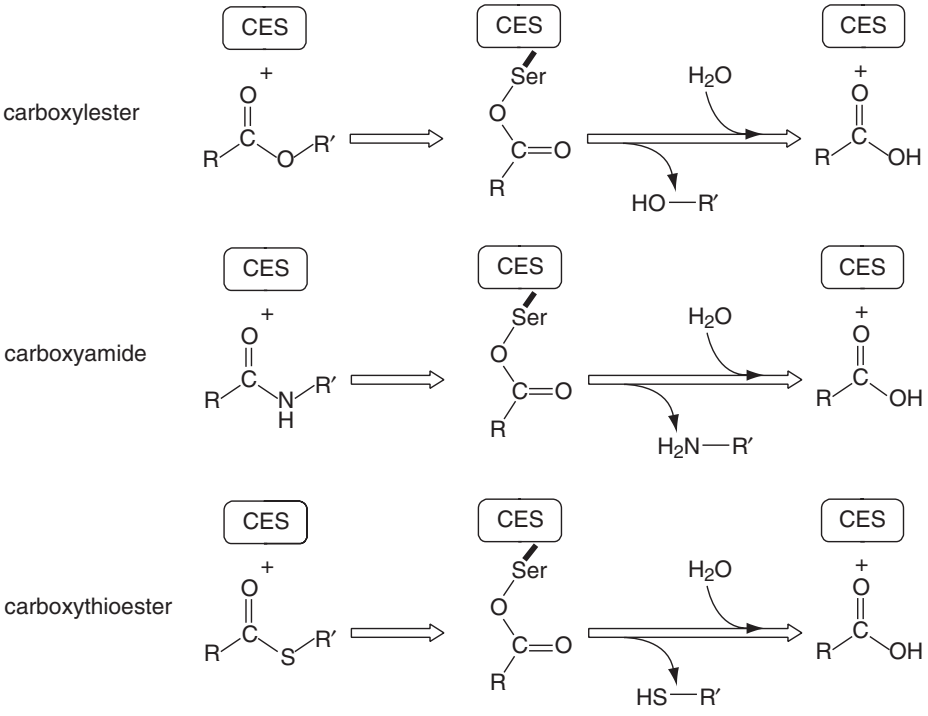

Figure 4.7.1 Reactions catalyzed by CES.

Contributed by Masakiyo Hosokawa and Tetsuo Satoh
Current Protocols in Toxicology (2001) 4.7.1-4.7.14

performed using a microsome preparation from tissue (see Support Protocol 1) or cultured cells expressing cDNA from CES isozymes (see Support Protocol 2).

BASIC PROTOCOL 1

PHOTOMETRIC ASSAY FOR CES USING *p*-NITROPHENYL ACETATE

Since this assay can be processed within 1 or 2 min, this assay system has been developed as a fast technique for analysis of hydrolysis in tissues or cultured cells. Another advantage of the assay is that all CES isozymes catalyze the hydrolysis of *p*-nitrophenyl acetate. The phenol liberated from *p*-nitrophenyl esters in basic solution is observed spectrophotometrically at 405 nm using a UV/VIS spectrophotometer with a computer.

Materials

Microsomes (see Support Protocol 1 or 2)
GET solution (see recipe), ice cold
Bio-Rad DC protein assay kit II
1 mM *p*-nitrophenyl acetate solution (see recipe for substrate solutions)
1 M Tris·Cl buffer, pH 8.0 (*APPENDIX 2A*)

5-ml Potter-Elvehjem homogenizer with Teflon pestle
5-ml test tubes
30°C water bath
1.0-ml semimicro cuvettes, 1-cm path length
UV/VIS spectrophotometer with a computer and temperature-controlled Peltier cuvette holder

1. Suspend the microsome pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle (see Support Protocol 1 or 2).
2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to within the range of 0.01 to 0.5 mg/ml with ice-cold GET solution and keep on ice.
3. Transfer 0.9 ml *p*-nitrophenyl acetate solution to 5-ml test tubes and place tubes for 5 min in a 30°C water bath.
4. Add 50 µl of 1 M Tris·Cl buffer, pH 8.0, to each 5-ml test tube at room temperature.
5. Start the enzymatic reactions by adding 50 µl of 0.01 to 0.5 mg/ml microsome preparation (from step 2) to each 5-ml test tube and vortex 5 sec at maximum speed.
6. Transfer the reaction mixture to a 1.0-ml semimicro cuvettes, 1-cm path length, in a 30°C cuvette holder (temperature controlled by a peltier cell holder).
7. Monitor the release of *p*-nitrophenol using a UV/VIS spectrophotometer at 405 nm for 60 to 120 sec.

   If a recorder is used instead of a computer, record for 120 to 240 sec. The increase in absorbance is linear with time, with a difference of up to 1.0.

8. Monitor spontaneous hydrolysis in a blank, GET solution alone without addition of the microsome preparation, using a UV/VIS spectrophotometer at 405 nm.

   In this method, the molar absorbance of 16,400 liters/M(cm) as p-nitrophenol is used; therefore, the specific activity (µmol of p-nitrophenol formed/min/mg protein) is

$$\frac{(\Delta absorbance/min - \Delta blank/min) \times 1.0}{16.4 \times 0.05 \times protein\ (mg/ml)}$$

   The method for measuring the hydrolase activities towards p-nitrophenyl esters, such as p-nitrophenyl propionate, p-nitrophenyl butylate, and p-nitrophenyl valeate, are the same as that used for p-nitrophenyl acetate hydrolase activity.

PHOTOMETRIC ASSAY FOR CES USING MALATHION AND OTHER ETHYL ESTERS

Malathion hydrolysis is coupled to the reduction of *p*-iodonitrophenyl tetrazolium violet (INT) with alcohol dehydrogenase and NADH diaphorase via the following reactions:

Malathion + CES → malathion monoacid + ethanol
Ethanol + NAD + alcohol dehydrogenase → acetaldehyde + NADH
NADH + INT + diaphorase → NAD + INT (reduced form).

The absorption at 500 nm due to the reduction of INT is recorded with a UV/VIS spectrophotometer.

Additional Materials *(also see Basic Protocol 1)*

p-iodonitrophenyltetrazolium violet (INT) solution (see recipe)
72 mM NAD (see recipe)
1000 U/ml alcohol dehydrogenase
4 U/ml NAD diaphorase
60 mM malathion (see recipe for substrate solutions)

37°C water bath
2.0-ml cuvette, 1-cm path length

1. Suspend the microsome pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle (see Support Protocol 1 or 2).
2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to within 0.1 to 0.5 mg/ml with ice-cold GET solution and keep on ice.
3. Transfer 1.75 ml INT solution to 5-ml test tubes and place tubes for 5 min in a 37°C water bath.
4. Add 50 µl of 72 mM NAD to each 5-ml test tube at 37°C.
5. Add 50 µl of 1000 U/ml alcohol dehydrogenase to each test tube at 37°C.
6. Add 50 µl of 4 U/ml NAD diaphorase to each test tube at 37°C.
7. Add 100 µl of 0.1 to 0.5 mg/ml microsomal preparation (from step 2) to each 5-ml test tube at 37°C.
8. Start the enzymatic reactions by adding 10 µl of 60 mM malathion to each test tube and vortex 5 sec at maximum speed.
9. Transfer the reaction mixture to 2.0-ml cuvettes, 1-cm path length, in a 37°C cuvette holder (temperature controlled by a peltier cell holder).
10. Monitor the reduction of INT for 5 to 15 min at 500 nm using a UV/VIS spectrophotometer.

    If a recorder is used instead of a computer, record for 10 to 30 min. The increase in absorbance is linear with time, a difference of up to 1.0.

11. Monitor spontaneous hydrolysis in the blank, GET solution alone without the addition of the microsome preparation, using a UV/VIS spectrophotometer at 500 nm.

    In this method, the molar absorbance of 13,750 liters/M(cm) as reduced INT is used; therefore, the specific activity (µmol of ethanol formed (INT reduced)/min/mg protein) is

$$\frac{(\Delta absorbance/min - \Delta blank/min) \times 2.01}{13.75 \times 0.1 \times protein\ (mg/ml)}$$

The method for measuring the hydrolase activity of several ethylesters, such as chlofibrate and ethyl succinate, are the same as the method used for measuring malathion hydrolase activity.

ALTERNATE PROTOCOL 2

PHOTOMETRIC ASSAY FOR CES USING BUTANILICAINE

Most CES isozymes also hydrolyze some aromatic amides. Normally, it is not possible to assay the hydrolysis of these amides by a photometric assay because the rate of cleavage of amides by CES is usually low. The photometric assay described here is more sensitive and faster than previously used methods.

Additional Materials *(also see Basic Protocol 1)*

CES assay solution (see recipe)
10 mM butanilicaine solution (see recipe for substrate solutions), prewarm to 30°C

1. Suspend the microsome pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle (see Support Protocol 1 or 2).
2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to 0.1 to 1.0 mg/ml with ice-cold GET solution and keep on ice.
3. Transfer 450 µl CES assay solution to 5-ml test tubes and incubate tubes 5 min in a 30°C water bath.
4. Add 50 µl microsome preparation to each test tube at room temperature.
5. Start the enzymatic reactions by adding 500 µl of prewarmed 10 mM butanilicaine to each 5-ml test tube and vortex 5 sec at maximum speed.
6. Transfer the reaction mixture to a 1-ml semimicro cuvette, 1-cm path length, in a 30°C cell holder (temperature controlled by a peltier cuvette holder).
7. Monitor the release of produced amine using a UV/VIS spectrophotometer at 285 nm for 3 to 10 min.

If a recorder is used instead of a computer, record 6 to 20 min. The increase in absorbance is linear with time, a difference of up to 1.0.

In this case, corrections for spontaneous hydrolysis of the substrate are not necessary.

In this method, the molar absorbance of 2080 liters/M(cm) as 2-chloro-6-methylaniline is used; therefore, the specific activity (µmol of 2-chloro-6-methylaniline formed/min/mg protein) is

$$\frac{\Delta absorbance/min \times 1.0}{2.080 \times 0.05 \times protein\ (mg/ml)}$$

ALTERNATE PROTOCOL 3

PHOTOMETRIC ASSAY FOR CES USING ACYL-CoA ESTER

CES isozymes catalyze the hydrolysis of endogenous compounds such as acyl-CoA esters. Hydrolysis of acyl-CoA derivatives has been carried out by spectrophotometric methods. A convenient spectrophotometric method uses 5,5′-dithiobis-(2-nitrobenzoic acid) to detect the release of the free thiol group.

Additional Materials *(also see Basic Protocol 1)*

120 mM HEPES buffer, pH 7.4 (see recipe)
5 mM EDTA, pH 7.4 (*APPENDIX 2A*)
3 mM DTNB solution (see recipe)
400 µM long-chain acyl-CoA solution (see recipe for substrate solutions)

1. Suspend the microsomal pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle.
2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to 0.01 to 0.5 mg/ml with ice-cold GET solution and keep on ice.
3. Transfer 500 µl of 120 mM HEPES buffer, pH 7.4, to 5-ml test tubes and incubate tubes for 5 min in a 30°C water bath.
4. Add 100 µl of 5 mM EDTA, pH 7.4 and 100 µl of 3 mM DTNB solution to each tube at 30°C.
5. Add 100 µl of 400 µM long-chain acyl-CoA solution to each tube at 30°C.
6. Start the enzymatic reaction by adding 100 µl microsomal preparation (from step 2) to each test tube and vortex 5 sec at maximum speed.
7. Transfer the reaction mixture to a 1-ml semimicro cuvette, 1-cm path length, in a 30°C cuvette holder (temperature controlled by peltier cell holder).
8. Monitor the release of produced 5-thio-2-nitro-benzoic acid for 1 to 2 min using a UV/VIS spectrophotometer at 412 nm.

   If a recorder is used instead of a computer, record for 2 to 4 min. The increase in absorbance is linear with time, a difference of up to 1.0.

9. Monitor spontaneous hydrolysis in a blank, GET solution alone without the addition of the microsome preparation, using a UV/VIS spectrophotometer at 412 nm.

   In this method, the molar absorbance of 13,600 liters/M(cm) CoA-SH is used; therefore, the specific activity (µmol of CoA-SH formed/min/mg protein) is

$$\frac{(\Delta absorbance/min - \Delta blank/min) \times 1.0}{13.6 \times 0.10 \times protein\ (mg/ml)}$$

FLUOROMETRIC ASSAY FOR CES USING PHENACETINE, ACETANILIDE

BASIC PROTOCOL 2

Most CES isozymes also hydrolyze some aromatic amides. Normally, it is not possible to assay the hydrolysis of these amides by a photometric assay because the rate of cleavage of amides by CES is usually low. The fluorometric assay described here is the most sensitive method for the cleavage of amides.

Materials

Microsomes (see Support Protocol 1 or 2)
GET solution (see recipe), ice cold
Bio-Rad DC protein assay kit II
250 mM Tris·Cl, pH 8.6 (*APPENDIX 2A*)
Substrate solution, e.g., 10 mM phenacetin solution or 20 mM acetanilide solution (see recipe), 30°C
1.2 M TCA solution (see recipe)
1 N NaOH

5-ml Potter-Elvehjem homogenizer with Teflon pestle
37°C water bath with shaker
Fluorometric quartz cuvette, 1-cm path length
Spectrofluorometer with a computer

Carry out CES reaction

1. Suspend the microsome pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle (see Support Protocol 1 or 2).
2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to 1.0 to 10 mg/ml with ice-cold GET solution.
3. Place microcentrifuge tubes on ice and add the following to each tube:

   400 µl 250 mM Tris·Cl buffer, pH 8.6

   100 µl 1.0 to 10 mg/ml microsome preparation

   Prepare blanks with GET solution alone without the addition of microsome preparation and incubate for the same time as that for the assays. Also prepare substrate solutions without the microsome preparation; add 100 µl substrate solution after termination of the reactions (step 6).

4. Vortex tubes and pre-incubate for 5 min at 37°C.
5. Add 500 µl of prewarmed substrate solution, e.g., 10 mM phenacetin or 20 mM acetanilide solution, to start the reaction; vortex the tube and incubate for 10 to 60 min in a 37°C water bath with shaking.

Perform spectrofluorometric analysis

6. Stop the reaction by adding 500 µl of 1.2 M TCA solution.
7. Microcentrifuge for 10 min at maximum speed, 4°C.
8. Transfer 1.0 ml of the supernatant to a fresh 2-ml microcentrifuge tube.
9. Add 1.0 ml of 1 N NaOH to the tube and vortex.
10. Transfer the mixture to a fluorometric quartz cuvette.
11. Select excitation wavelengths of 282 and 305 nm for aniline and phenetidine, respectively.
12. Estimate the fluorescence using a spectrofluorometer at emission wavelengths of 348 and 372 nm for aniline and phenetidine, respectively.

    In this method, since the ratio of fluorescence between the sample and standard was used for the hydrolysis of aromatic amide, the specific activity (nmol of product formed/min/mg protein) is

$$\frac{0.1\times(\text{sample [fluorescence]} - \text{blank [fluorescence]})\times 1.0\times 1000}{(\text{standard [fluorescence]} - \text{blank [fluorescence]})\times 0.1\times \text{time (min)}\times \text{protein (mg/ml)}}$$

BASIC PROTOCOL 3

HPLC METHODS TO MEASURE CES ACTIVITY

Many HPLC methods have been developed for identifying metabolites in plasma and urine from in vivo metabolism of xenobiotics. These methods can also be used to identify and quantify metabolites of esters and amides from in vitro systems.

Materials

Microsomes (see Support Protocol 1 or 2)
GET solution (see recipe), ice cold
Bio-Rad DC protein assay kit II
120 mM HEPES buffer, pH 7.4 (see recipe)
200 µM irinotecan hydrochloride (CPT-11; see recipe for substrate solutions), 37°C
0.05 N HCl containing 200 nM CPT as an internal standard (see recipe for substrate solutions)

5-ml Potter-Elvehjem homogenizer and Teflon pestle
37°C water bath with a shaker
HPLC system consisting of model L-6000 pump (Hitachi), model L7480 FL detector (Hitachi), model AS-2000 auto-sampler (Hitachi), model D-2500 integrator (Hitachi), and a 4.6 × 150–mm YMC-Pack Ph A-402 column (YMC Co.) or equivalent.

Carry out CES reaction

1. Suspend the microsome pellet in a small aliquot of ice-cold GET solution using a 5-ml Potter-Elvehjem homogenizer with a Teflon pestle (see Support Protocol 1 or 2).

2. Determine the protein concentration using a Bio-Rad DC protein assay kit II and adjust the concentration to 0.1 to 1.0 mg/ml with ice-cold GET solution.

3. Place microcentrifuge tubes on ice and add the following to each tube:

   50 µl 120 mM HEPES buffer, pH 7.4

   50 µl 0.1 to 1.0 mg/ml microsome preparations

   Prepare blanks of GET solution alone without the addition of the microsome preparation and incubate for the same time as that of the assays.

4. Vortex tubes and preincubate for 5 min at 37°C.

5. Add 100 µl of prewarmed 200 µM irinotecan hydrochloride solution to start reaction, vortex, and place tube in a 37°C water bath with shaking. Incubate 5 to 10 min.

Analyze by HPLC

6. Stop the reaction by adding 200 µl of 0.05 N HCl containing 200 nM CPT.

7. Microcentrifuge for 10 min at maximum speed, 4°C.

8. Transfer 30 µl of supernatant to an HPLC system and analyze.

   For example, for the determination of SN-38, the mobile phase consisted of 3 mM sodium heptane sulfonic acid in 66:34 (v/v) 0.1 M potassium phosphate, pH 4.0/acetonitrile and was delivered at a flow rate of 0.8 ml/min. The fluorescence was determined using a Hitachi L7480 FL detector at an excitation wavelength of 380 nm and emission wavelength of 556 nm.

   A calibration curve is generated by the peak height ratio of SN-38/CPT.

   In this method, peak height ratio of SN38/CPT is used for the calibration curve, the specific activity (pmol of SN-38 formed/min/mg protein) is

$$\frac{SN38\,(\ pmol/ml\ ) \times 1.0}{0.1 \times time\,(min) \times protein\,(\ mg/ml\ )}$$

   This amount of SN-38 was derived from a calibration curve.

SUPPORT PROTOCOL 1

PREPARATION OF MICROSOMES FROM TISSUE

CES is located in the lumen of endoplasmic reticulum and is retained there by interaction with the KDEL receptor. The microsome preparations contain endoplasmic reticulum. This protocol is used to isolate microsomes from any of several tissues.

Materials

Organ tissue, freshly recovered or frozen
SET solution (see recipe)
GET solution (see recipe)

Potter-Elvehjem homogenizer with a motorized Teflon pestle
50-ml centrifuge tubes
30-ml ultracentrifuge tubes
Ultracentrifuge

NOTE: Perform all steps at 4°C.

1. Weigh the organ tissue in grams (~0.1 to 5 g) and add four times the weight in milliliters of SET solution.
2. Homogenize for 5 strokes in a Potter-Elvehjem homogenizer using a motorized Teflon pestle at 800 rpm.
3. Transfer the homegenate to a 50-ml centrifuge tube. Centrifuge the homogenate 20 min at 9000 × *g*, 4°C.
4. Transfer the supernatant to a 30-ml ultracentrifuge tube.

   When the tissue contains many fatty substances, filter the supernatant through a layer of cotton gauze to remove them.
5. Ultracentrifuge the supernatant 60 min at 105,000 × *g*, 4°C. Carefully discard the supernatant using a pipet.
6. Suspend the pellet in SET solution (1 g organ weight/ml) using a Potter-Elvehjem homogenizer.
7. Centrifuge the suspension for 30 min at 105,000 × *g*. Discard the supernatant.
8. Suspend pellet in GET solution (1 g organ weight/ml) using a Potter-Elvehjem homogenizer. Store for up to 1 year at −80°C

SUPPORT PROTOCOL 2

PREPARATION OF MICROSOMES FROM CULTURED CELLS

This protocol is used to prepare microsomes from tissue culture cells transfected with CES cDNA.

Materials

Cultured cells, such as V79, COS7, or HepG2 cells, expressing CES after transfection with a mammalian expression vector with CES cDNA
PBS (*APPENDIX 2A*)
SET solution (see recipe)
GET solution (see recipe)

5-ml round-bottom tubes
Sonicator with a narrow probe
Microscope
Potter-Elvehjem homogenizer with a motorized Teflon pestle
2-ml centrifuge tubes
5-ml ultracentrifuge tubes and ultracentrifuge

NOTE: Perform all procedures at 4°C.

1. Harvest the cells (1×10^8 cells) and wash with 5 ml PBS by centrifuging for 5 min at $800 \times g$, 4°C.
2. Suspend the cell pellet in 1×10^8 cells/ml SET solution. Transfer to 5-ml round-bottom tubes.
3. Sonicate with a narrow probe for 10 to 15 sec, two times, and check for lysis with a microscope.
4. Add 1×10^8 cells/ml SET solution and homogenize for 5 strokes in a Potter-Elvehjem homogenizer with a motorized Teflon pestle at 800 rpm.
5. Transfer the homogenate to a 2-ml centrifuge tube and centrifuge homogenate for 20 min at $9000 \times g$, 4°C.
6. Transfer the supernatant to a 5-ml ultracentrifuge tube and ultracentrifuge the supernatant 60 min at $105{,}000 \times g$, 4°C.
7. Carefully discard the supernatant using a pipet and suspend the pellet in 1×10^8 cells/ml GET solution using a Potter-Elvehjem homogenizer. Store for up to 1 year at −80°C

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all recipes and in all protocol steps . For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CES assay solution

For 1 liter, weigh 200 g glycerol. Add 25 ml of 10% cholic acid, pH 8.0, and 220 ml of 1 M Tris·Cl buffer, pH 8.6 (*APPENDIX 2A*), and water to 1 liter. Store up to 1 month at 4°C.

DTNB solution, 3 mM

Dissolve 5.95 mg 5,5′-dithiobis-(2-nitrobenzoic acid (DTNB) in 0.5% $NaHCO_3$. Prepare just before use.

GET solution

For 100 ml, weigh 20 g glycerol. Add 0.2 ml of 0.5 M EDTA (*APPENDIX 2A*), and add 1 ml of 1 M Tris·Cl buffer, pH 7.4 (*APPENDIX 2A*). Adjust with water to a final volume of 100 ml. Store for up to 1 month at 4°C.

HEPES buffer, pH 7.4, 120 mM

Dissolve 2.86 g *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) in 80 ml water. Adjust the pH to 7.4 at room temperature with 5 M NaOH (*APPENDIX 2A*). Adjust with water to a final volume of 100 ml. Store up to 1 month at 4°C.

p-Iodonitrophenyl tetrazolium violet (INT) solution

Dissolve 52.44 mg INT in 60 ml of 0.2 M Tris·Cl buffer, pH 7.5 (*APPENDIX 2A*). Adjust with water to a final volume of 105 ml. Prepare just before use.

NAD, 72 mM

Dissolve 143 mg NAD in 3 ml water. Store for up to 2 weeks at −20°C

SET solution

Add 25 ml of 1.0 M sucrose, 0.2 ml of 0.5 M EDTA (*APPENDIX 2A*), and 1 ml of 1 M Tris·Cl buffer, pH 7.4 (*APPENDIX 2A*). Adjust with water to a final volume of 100 ml. Store up to 1 month at 4°C.

Substrate solutions

p-Nitrophenyl acetate: Dissolve 18.1 mg of the ester in acetnitrile and add water to 100 ml

Malathion: Dissolve 19.82 mg in 1 ml of acetone

Clofibrate: Dissolve 14.56 mg in 1 ml of acetone

Butanilicaine hydrochloride: Dissolve 29.1 mg in 10 ml hot water

Acyl-CoA: Dissolve 2 mg of palmitoyl-CoA in 5 ml water

Phenacetine: Dissolve 17.9 mg in 10 ml hot water

Acetanilide: Dissolve 27 mg in 10 ml hot water

Phenetidine hydrochloride: Dissolve 137 mg in 1000 ml water

Aniline hydrochloride: Dissolve 130 mg in 1000 ml water

Irinotecan (CPT-11) hydrochloride: Dissolve 6.67 mg in 10 ml water

SN-38: Dissolve 6.7 mg in 10 ml methanol

Butanilicaine, N-butylaminoacetyl-2-chloro-6-methylanilide

CPT-11, 7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycamptothecin

SN-38, 7-ethyl-10-hydroxycamptothecin

Since the most of esters are spontaneously hydrolyzed in water, substrates are prepared just before use.

TCA solution, 1.2 M

Dissolve 19.608 g trichloroacetic acid (TCA) in 100 ml water. Store up to 1 month at 4°C.

COMMENTARY

Background Information

Various carboxylesterases (CES) play important roles in the hydrolytic biotransformation of a vast number of structurally diverse drugs (Satoh and Hosokawa, 1998). These enzymes are a major determinant of the pharmacokinetic behavior of most therapeutic agents containing ester or amide bonds (Heymann et al., 1981; Satoh and Hosokawa, 1998). CES activity can be influenced by interactions of a variety of compounds either directly or at the level of enzyme regulation (Mentlein et al., 1986; Hosokawa et al., 1988; Hosokawa and Satoh, 1993). Since a significant number of drugs are metabolized by CES, altering the activity of this enzyme class has important clinical implications. Drug elimination decreases and the incidence of drug-drug interactions increases when two or more drugs compete for hydrolysis by the same CES isozyme (Mentlein et al., 1980; Hosokawa et al., 1987, 1990). Exposure to environmental pollutants or lipophilic drugs can result in induction of CES activity (Hosokawa and Satoh, 1993; Hosokawa et al., 1994). Therefore, the use of drugs known to increase the microsomal expression of a particular CES increases the associated drug hydrolysis capacity in humans.

Hydrolysis is catalyzed by a family of CES isozymes. Molecular biology techniques have made it possible to identify the genes for individual mammalian CESs and to express CES proteins (Satoh and Hosokawa, 1998). Thus, it has become possible to study the substrate specificities and kinetic parameters of individual CESs. The nomenclature for the isozymes is based on evolutionary divergence (Satoh and Hosokawa, 1998).

Mammalian CESs comprise a multigene family whose gene products are localized in the endoplasmic reticulum of many tissues, such as the liver, kidney, intestine, lung, and brain, however, not all isozymes are present in all tissues. There is a great deal of overlap of substrate acceptance among the isoforms (Yamada et al., 1994; Satoh and Hosokawa,

1998). For example, *p*-nitrophenyl acetate is a substrate for many CES isozymes (Mentlein et al., 1980; Heymann and Mentlein, 1981; Hosokawa et al., 1990).

Earlier analytical methods made use of pH-stat analysis (Heymann and Mentlein, 1981). In weakly buffered solutions, the amount of acid released by enzymatic hydrolysis can be recorded continuously by the pH-stat technique. Many other assay methods have used spectrophotometric analysis. The methods described here are based on the use of spectrophotometric analysis and are applicable to most substrates (Berge, 1979; Talcott, 1979; Heymann and Mentlein, 1981; Hosokawa et al., 1990). Furthermore, these assay systems have been developed as fast techniques for analyzing the hydrolysis in tissues or cultured cells (Mori et al., 1999).

The fluorometric method (see Basic Protocol 2) was developed for assaying the hydrolysis of aromatic amides (Heymann et al., 1981). Normally, it is not possible to assay the hydrolysis of these amides by a photometric assay because the rate of cleavage of amides by CES is usually low. The fluorometric assay described here is the most-sensitive method for cleavage of amides.

Recently, many HPLC methods have been developed for identifying metabolites. Thus, HPLC methods can also be used to identify and quantify metabolites from esters and amides (Satoh et al., 1994; Kurita and Kaneda, 1999; Mori et al., 1999). The HPLC method described here (see Basic Protocol 3) is useful for identifying and quantifying metabolites for which the hydrolytic reaction yields several esters and amides.

Critical Parameters and Troubleshooting

In CES assays, incubation time is critical. For some substrates, such as *p*-nitrophenyl acetate, palmitoyl-CoA, and CPT-11, the reaction is not linear beyond 5 to 10 min. The Michaelis constant (K_m) of CES is dependent on the structure of the substrate and is also dependent on tissues, species, or isozymes. For example, the K_m value for CPT-11 is in the range of 3 to 200 μM. Since the use of an optimal amount of protein and substrate is required for linear product formation, it is necessary to establish the optimal conditions for unknown substrates.

When dissolving the hydrophobic substrates of esters and amides, the type of organic solvent is critical for CES assay. Ethanol and methanol must not be used and the concentration of other organic solvents should be <1% in the assay mixture.

When solubilizing the CES from microsomes in purification procedures, it is necessary to use some detergent. Many detergents can affect the CES activities. High concentrations of detergents, such as 1.0% (v/v) Triton X-100, 1.0% (v/v) cholic acid, and 1.0% (v/v) Emulgen 911, decrease the CES activity by 10% to 50%. But low concentrations of detergents such as 0.001% to 0.05% Triton X-100 can increase the CES activity in microsomes. Therefore, the effect of detergent towards each substrate must be determined before detergent is employed in the CES assay.

Anticipated Results

This section provides examples of assays that were analyzed by each of the three methods described in this unit.

Basic Protocol 1

A microsome preparation from rat liver was analyzed for activity towards *p*-nitrophenyl acetate, malathion, butanilicaine, and palmitoyl-CoA. The general assay requirements are described in Basic Protocol 1.

p-Nitrophenyl acetate. The specific conditions of this assay were pH 8.0, 50 µl of 0.2 mg/ml rat liver microsomes, and a substrate concentration of 900 µM. The release of *p*-nitrophenol was monitored by UV/VIS spectrophotometer at 405 nm. The assay was incubated 1 to 2 min at 30°C.

Specific activity (µmol/min/mg protein) was calculated using the following formula with Δabsorbance/min = 0.612, Δblank/min = 0.025:

$$\frac{(\Delta\text{absorbance/min} - \Delta\text{blank/min}) \times 1.0}{16.4 \times 0.05 \times \text{protein (mg/ml)}} =$$

$$\frac{(0.612 - 0.025) \times 1.0}{16.4 \times 0.05 \times 0.2} = 3.58 \text{ (µmol/min/mg)}$$

Malathion. The specific conditions of this assay were pH 7.5, 100 µl of 2.0 mg/ml rat liver microsomes, and a substrate concentration of 300 µM. The reduction of INT was monitored by UV/VIS spectrophotometer at 500 nm. The assay was incubated 5 to 10 min at 37°C.

Specific activity (µmol/min/mg protein) was calculated using the following formula with Δabsorbance/min = 0.325, Δblank/min = 0.045:

$$\frac{(\Delta\text{absorbance/min} - \Delta\text{blank/min}) \times 2.01}{13.75 \times 0.1 \times \text{protein (mg/ml)}} =$$

$$\frac{(0.325 - 0.045) \times 2.01}{13.75 \times 0.1 \times 2.0} = 0.204 \text{ (µmol/min/mg)}$$

Butanilicaine. The specific conditions of this assay were pH 8.6, 50 µl of 2.5 mg/ml rat liver microsomes, and a substrate concentration of 5 mM. The formation of 2-chloro-6-methylaniline was monitored by UV/VIS spectrophotometer at 285 nm. The assay was incubated 3 to 10 min at 30°C.

Specific activity (µmol/min/mg protein) was calculated using the following formula with Δabsorbance/min = 0.027:

$$\frac{\Delta\text{absorbance/min} \times 1.0}{2.080 \times 0.05 \times \text{protein (mg/ml)}} =$$

$$\frac{0.027 \times 1.0}{2.080 \times 0.05 \times 2.5} = 0.103 \text{ (µmol/min/mg)}$$

Palmitoyl-CoA. The specific conditions of this assay were pH 7.4, 100 µl of 0.6 mg/ml rat liver microsomes, and a substrate concentration of 40 µM. The 5-thio-2-nitro-benzoic acid produced was monitored by UV/VIS spectrophotometer at 412 nm. The assay was incubated 1 to 2 min at 30°C.

Specific activity (µmol/min/mg protein) was calculated using the following formula with Δabsorbance/min = 0.128, Δblank/min = 0.004:

$$\frac{(\Delta\text{absorbance/min} - \Delta\text{blank/min}) \times 1.0}{13.6 \times 0.1 \times \text{protein (mg/ml)}}$$

$$\frac{(0.128 - 0.004) \times 1.0}{13.6 \times 0.1 \times 0.6} = 0.152 \text{ (µmol/min/mg)}$$

Basic Protocol 2

Microsomes prepared from rat liver were analyzed for activity towards acetanilide and phenacetine. The general assay requirements are described in Basic Protocol 2. The

specific conditions of this assay were pH 8.6, 100 µl of 10 mg/ml rat liver microsomes, and a substrate concentration of 10 mM and 20 mM, phenacetine and acetanilide, respectively. The assays were incubated 30 min at 37°C and then were stopped with 500 µl of 1.2 M TCA solution.

The specific activity (nmol phenetidine formed/min/mg protein) of phenacetine was calculated using the following formula:

$$\frac{0.1\times(\text{sample [fluorescence]}-\text{blank [fluorescence]})\times 1.0\times 1000}{(\text{standard [fluorescence]}-\text{blank [fluorescence]})\times 0.1\times \text{time (min)}\times \text{protein (mg/ml)}} =$$

$$\frac{0.1\times(98-3)\times 1.0\times 1000}{(60-3)\times 0.1\times 30\times 10} = 5.56\ (\text{nmol/min/mg})$$

Basic Protocol 3

Microsomes prepared from rat liver were analyzed for activity towards CPT-11. The general assay requirement is described in Basic Protocol 3. The specific conditions of this assay were pH 7.4, 100 µl of 10 mg/ml rat liver microsomes, and a substrate concentration of 100 µM. The assays were incubated 10 min at 37°C, and then were stopped with 200 µl of 0.05 N HCl solution.

The specific activity (pmol of SN-38 formed/min/mg protein) of CPT-11 was calculated using the following formula:

$$\frac{\text{SN38 (pmol/ml)}\times 1.0}{0.1\times \text{time (min)}\times \text{protein (mg/ml)}} =$$

$$\frac{68.5\times 1.0}{0.1\times 10\times 2.3} = 29.8\ (\text{pmol/min/mg})$$

The amount of SN-38 was derived from a calibration curve.

CES is located in the lumen of the endoplasmic reticulum. Microsomal preparations of organ tissue contain the endoplasmic reticulum. The total yield of microsomal organ protein from rat liver is ~20 mg protein/1 g liver weight (see Support Protocol 1). The total yield of microsomal protein obtained from 1×10^8 V79 cells expressing CES isozome is ~1 mg (see Support Protocol 2).

Time Considerations

For all assays, the total time required depends, in part, on the duration of the reaction and the level of activity, and can range from 1 min to 2 hr. Photometric assays require 1 to 15 min. Fluorometric assays require 1 to 2 hr. HPLC assays require 10 to 20 min and an additional 2 hr for HPLC analysis.

Analysis of the Aryl Hydrocarbon Receptor (AhR) Signal Transduction Pathway

The aryl hydrocarbon receptor (AhR) is a soluble, ligand-dependent transcription factor that mediates many of the biological and toxicological actions of a structurally diverse group of natural and synthetic hydrophobic chemicals, including the environmental contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD; Safe, 1990; Schmidt and Bradfield, 1996; Denison et al., 1998a,b). Exposure to AhR agonists results in a variety of effects, the most studied of which is the induction of gene expression (Fig. 4.8.1). Following ligand binding, the cytosolic ligand-AhR complex undergoes transformation during which it translocates into the nucleus and dissociates from two molecules of hsp90 (a heat shock protein of 90 kDa), p20, and at least one additional protein termed XAP2, AIP, or ara9. Following its association with at least one nuclear factor, the AhR nuclear translocator (Arnt) protein, the AhR complex is converted into its high affinity DNA-binding form. The binding of the transformed heteromeric ligand-AhR-Arnt complex to its specific DNA recognition site, the dioxin responsive element (DRE), leads to chromatin and nucleosome disruption, increased promoter accessibility, and increased rates of transcription of an adjacent gene. The AhR signal transduction pathway is present in a diverse range of species, tissues, and cell types, and to date, the majority of genes which respond to AhR ligands have been shown to utilize the AhR-DRE-dependent mechanism of action.

This unit describes several procedures for detecting the AhR and characterizing its functional activity. Measurement of AhR ligand binding is accomplished by two different methods. The sucrose density gradient (SDG) binding assay (see Basic Protocol 1) provides the greatest amount of information and allows direct determination and visualization of the binding of [^{3}H]TCDD to cytosolic AhR, but it is time consuming and not

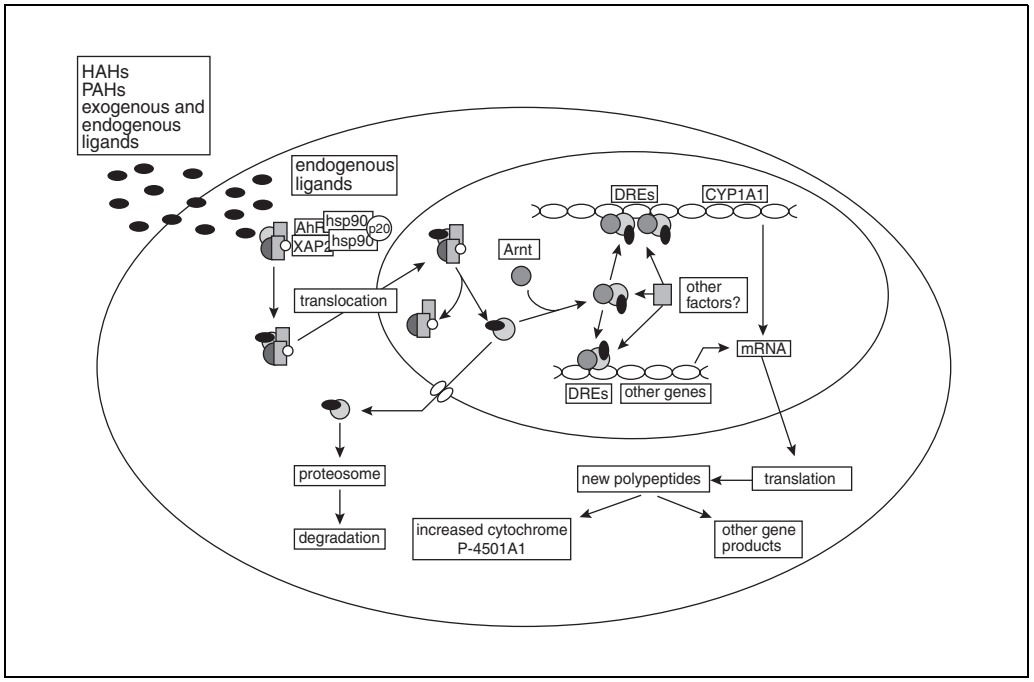

Figure 4.8.1 Molecular mechanism of Ah receptor-dependent regulation of gene expression. Abbreviations: AhR, aryl hydrocarbon receptor; Arnt, AhR nuclear translocator protein; DRE, dioxin responsive element; HAHs, halogenated aromatic hydrocarbons; PAHs, polycyclic aromatic hydrocarbons.

Current Protocols in Toxicology (2002) 4.8.1-4.8.45

amenable to analysis of large numbers of samples. In contrast, the hydroxyapatite (HAP) binding assay (see Alternate Protocol 1) is relatively rapid, requires less equipment, and is amenable to analysis of relatively large numbers of samples, but it does not provide direct visualization of [^{3}H]TCDD-specific binding.

Measurement of AhR transformation and DNA binding is carried out using a gel retardation analysis (GRA; see Basic Protocol 2 or Alternate Protocol 2 for competitive GRA). GRA and SDG analysis of nuclear extracts from treated cells provide a measure of AhR transformation, nuclear translocation, and DNA binding in intact cells. All of these procedures can be carried out using cytosolic ligand–AhR complexes transformed in vitro, nuclear ligand–AhR complexes transformed in vivo, or in intact cells. Detection of AhR in tissue samples can be accomplished by demonstration of specific ligand binding or by direct measurement of AhR protein or mRNA using immunoblot analysis (see Basic Protocol 3), RT-PCR (see Basic Protocol 4), or northern blot analysis (see Basic Protocol 5). AhR ligand–dependent induction of expression of a specific gene known to be regulated by the AhR—e.g., cytochrome P4501A1 (CYP1A1) or P4501B1 (CYP1B1)—provides indirect evidence for the presence of the AhR signaling system in tissues or cells in culture and is commonly accomplished by examining mRNA levels for the gene of interest by RT-PCR or northern blot analysis.

Support protocols are included for preparation of hepatic cytosol (see Support Protocol 1), cytosol from cultured cells (see Support Protocol 2), nuclear extract (see Support Protocol 3), ^{32}P-labeled probes for GRA (see Support Protocol 4), and total RNA (see Support Protocol 5).

CAUTION: When working with radioactivity, and TCDD or other carcinogens, take extreme care to avoid contaminating work areas and personnel. Use these materials only in appropriately designated areas with all necessary precautions, including the use of laboratory coats, protective eyewear, and disposable benchtop paper, gloves, plasticware, and glassware. In addition, follow all chemical and radiation safety guideline for handling and disposal of these materials (also see *APPENDIX 1A*). It is particularly important that when handling any hazardous chemical dissolved in DMSO or other solvent that appropriate solvent-resistant nitrile gloves are used. Latex gloves provide little or no barrier to solvent penetration and subsequent chemical exposure. Finally, given the hazards associated with TCDD and related chemicals, laboratory use of these chemicals usually requires prior permission of the local chemical and radiation safety officers.

NOTE: All DMSO should be 99% pure.

BASIC PROTOCOL 1

SUCROSE DENSITY GRADIENT ANALYSIS OF CYTOSOLIC Ah RECEPTOR LIGAND BINDING

The sucrose density gradient (SDG) method allows direct determination and visualization of the binding of [^{3}H]TCDD to cytosolic AhRs and its competitive displacement by other AhR ligands. Cytosolic samples incubated with [^{3}H]TCDD in the absence or presence of an unlabeled competitor ligand, such as 2,3,7,8-tetrachlorodibenzofuran (TCDF), are centrifuged through a linear 10% to 30% (w/v) sucrose gradient and, following fractionation, the distribution of radioactivity throughout the gradient is determined. The peak of radioactivity that is competitively eliminated by TCDF represents the amount of [^{3}H]TCDD specifically bound to the AhR. The ability of other chemicals to competitively bind to the AhR can be determined in the same manner by adding these chemicals in place of TCDF in the incubation. Although this method is somewhat time consuming and is not amenable for analysis of large numbers of samples, it provides important additional information that is not obtained using solid phase AhR ligand binding methods like

hydroxylapatite binding (HAP; see Alternate Protocol 1). The procedure described here is based on the method of Tsai and Okey (1981) and uses 5-ml gradients in a vertical tube rotor (which reduces centrifugation time to 2.5 hr as compared to 16 hr for swinging bucket rotors). Other tube sizes and rotors can be used with appropriate adjustments for volumes and centrifugation times (Okey et al., 1979).

Materials

Cytosol sample (see Support Protocols 1 and 2)
Bio-Rad protein assay
HEDG buffer (see recipe)
1 µM [^{3}H]TCDD in DMSO (specific activity 10 to 50 Ci/mmol; Eagle-Picher Technologies or Terrachem)
DMSO
100 µM TCDF in DMSO (Accustandard, Cambridge Isotope Laboratories, or Wellington Laboratories)
Test ligand in DMSO
Dextran-coated charcoal (see recipe)
60% (w/v) sucrose in HEDG or HEDGK4 (see recipes)
200 cpm/µl [^{14}C]formaldehyde-labeled protein sedimentation standards (e.g., BSA, catalase; Dottavio-Martin and Ravel, 1978)
Scintillation cocktail

12 × 75–mm glass culture tubes
Heat-sealable, vertical, 13 × 51–mm ultracentrifuge tubes (Beckman) and sealing device
Sucrose gradient maker and fractionator (optional)
Ultracentrifuge with slow acceleration/deceleration modes and vertical rotor (Beckman VTi65.2 or equivalent), 4°C
18-G solid-metal wire
7-ml scintillation vials
Needle (optional)
Liquid scintillation counter with dual isotope counting function

NOTE: All steps should be performed at 4°C.

Incubate sample

1. Determine the protein concentration of the cytosol sample using the Bio-Rad protein assay. Adjust the sample to a protein concentration of 5 mg/ml with HEDG buffer.

2. For each binding incubation, prepare two 12 × 75–mm glass culture (incubation) tubes, one for total and one for nonspecific binding. Prepare a third tube if another compound is also to be assessed for binding inhibition. To each incubation tube add 500 µl cytosol and keep on ice.

   Glass culture tubes are recommended for incubations since a loss of radioactivity may result with some plastics.

3. For each set of incubations (i.e., total binding and nonspecific binding samples), add 5 µl of 1 µM [^{3}H]TCDD in DMSO to each tube. Then add 5 µl DMSO (carrier solvent) to the total binding sample tube and 5 µl of 100 µM TCDF in DMSO to the nonspecific binding sample tube. If the ability of another chemical to competitively bind to the AhR is also being assessed, add 5 µl [^{3}H]TCDD and 5 µl test ligand in DMSO at the desired concentration to the third tube.

   The standard SDG binding reaction uses final chemical concentrations of 10 nM [^{3}H]TCDD and 1 µM TCDF. These concentrations are generally sufficient for saturation

of AhR binding in the above conditions. Although use of higher TCDD concentrations have been reported, use of TCDD at concentrations over 50 nM is not recommended because of its limited aqueous solubility. This is also the reason TCDD is not used as a competitor—i.e., TCDF has a greater solubility. The concentration of test compound necessary to observe competitive AhR binding is dependent upon its affinity for the AhR and as such, multiple analyses may be required using a range of competitor concentrations.

Incubate in dextran-coated charcoal to remove free and loosely bound [^{3}H]TCDD

No incubation period or charcoal treatment is necessary when using nuclear extracts prepared from cells or tissues that have been incubated with [^{3}H]TCDD (in the absence or presence of TCDF). Aliquots of these sample preparations can be loaded directly onto the gradients as described below (step 9).

4. Incubate samples 2 hr at 4°C.

5. While the cytosol is incubating, prepare charcoal pellets by pipetting 700 µl dextran-coated charcoal into a 1.5-ml microcentrifuge tube and microcentrifuging 10 min at ~12,000 to 15,000 rpm, 4°C. Prepare one charcoal tube per sample incubation.

   These charcoal treatment conditions have been optimized for guinea pig hepatic cytosol at 5 mg protein/ml buffer. The optimal protein-charcoal concentration for AhR binding analysis must be experimentally determined when cytosol from other species or tissues are to be used. Once the protein/charcoal ratio has been established, it should be maintained if cytosol containing more or less protein is used. Too high a charcoal concentration can result in stripping of ligand from the receptor and too low a concentration will result in lack of complete removal of free and loosely bound [^{3}H]TCDD. This is especially important when analyzing AhR from species that have reduced affinity for TCDD (i.e., human and nonmammalian species).

6. Aspirate the supernatant from the tube without disturbing the charcoal pellet. Store the pellets at 4°C until needed.

7. After the incubation period (step 4), transfer the 500-µl binding reaction into appropriately labeled microcentrifuge tubes containing charcoal pellets. Vortex immediately and incubate 10 min at 4°C.

8. Microcentrifuge the tubes 10 min at high speed (i.e., ~12,000 to 15,000 rpm), 4°C. Transfer 400 µl supernatant into a fresh 1.5-ml microcentrifuge tube without disturbing the charcoal pellet. Keep tubes on ice.

Load sample on the gradient and centrifuge

9. Prepare 4.7-ml linear 10% to 30% (w/v) gradients of sucrose in HEDG (cytosolic samples) or HEDGK4 (nuclear extracts) in heat-sealable, vertical, 13 × 51–mm ultracentrifuge tubes using one of several commercial sucrose gradient makers, or by simply successively layering five 1-ml aliquots of buffer containing decreasing amounts of 60% (w/v) sucrose (i.e., 10%, 15%, 20%, 25%, and 30% w/v sucrose). Before allowing the gradients to linearize, remove 300 µl from the top of the gradient (this provides the space needed for sample addition).

   The sucrose stock is prepared at 60%, since this concentration appears to be inhibitory to the growth of contaminating organisms (growth has been observed in 30% sucrose stock solutions).

   The sucrose will diffuse into a linear gradient if left for 1 hr at room temperature or overnight at 4°C. Gradients can be prepared in advance and stored frozen at −20°C. The linear sucrose gradients will remain intact for up to a year or more if kept frozen and then slowly thawed in an ice bath just before use.

10. Layer 300 µl of each sample onto a linear sucrose gradient. If desired, add 5 µl (1000 cpm) of each 200 cpm/µl [^{14}C]formaldehyde-labeled protein sedimentation standard as internal controls to allow accurate alignment of different gradients, more accurate estimation of specific binding, and determination of the sedimentation coefficient of the AhR complex.

    [^{14}C]Catalase (CAT; 11.3 S) and [^{14}C]BSA (4.4 S) are common internal standards and are easily radiolabeled using [^{14}C]formaldehyde as described in detail by Dottavio-Martin and Ravel (1978).

11. Seal the cooled gradient tubes with the appropriate sealing device (there are several options for sealing vertical rotor tubes) and load them into a prechilled vertical ultracentrifuge rotor (Beckman VTi65 or equivalent). Centrifuge 2.3 hr at 416,000 × *g* (65,000 rpm for a VTi65 rotor), 4°C, in an ultracentrifuge with programmed slow acceleration and deceleration.

    CAUTION: *It is extremely important to make sure that the tubes have been completely sealed before loading into the rotor. A leaking tube will not only contaminate the rotor and centrifuge, but will cause the rotor to become unbalanced, which can be dangerous. The adequacy of the seal can easily be assessed by gently squeezing the tubes after sealing and making sure that no liquid leaks out of the tube.*

    The slow acceleration and deceleration mode feature must be available on the ultracentrifuge to be able to use a vertical tube rotor. If this feature is not available, the gradients must be centrifuged in a swinging-bucket rotor. The slow acceleration/deceleration modes are needed to ensure that the gradients do not mix during their transition from vertical to horizontal orientation during centrifugation.

12. After centrifugation, puncture the top of the heat-sealed tubes with a heated 18-G solid metal wire and collect twenty-five 200-µl fractions from each gradient directly into 7-ml scintillation vials using a commercially available gradient tube fractionator or by simply puncturing the bottom of the tube with a needle and collecting two-drop fractions.

13. Add 5 ml scintillation cocktail to each vial, cap, and shake. Determine the amount of radioactivity in each vial/fraction in a liquid scintillation counter. Perform dual isotope counting for all gradients containing both [^{3}H]TCDD and [^{14}C]protein standards

    The solution will appear cloudy after shaking, but this will not affect scintillation counting efficiency. If after shaking, the gradients are not uniformly cloudy, then the amount of sample in each vial is not the same.

14. Determine the specific binding of [^{3}H]TCDD by subtracting the radioactivity present in each fraction of a gradient containing [^{3}H]TCDD and TCDF (nonspecific binding) from the radioactivity in the corresponding fractions from a gradient containing [^{3}H]TCDD alone (total binding; also see Anticipated Results).

HYDROXYAPATITE SOLID-PHASE ANALYSIS OF Ah RECEPTOR LIGAND BINDING

ALTERNATE PROTOCOL 1

The hydroxyapatite (HAP) binding assay is basically similar to the SDG assay (see Basic Protocol 1) in that it allows determination of the amount of specific binding of [^{3}H]TCDD to cytosolic proteins and its competitive displacement by AhR ligands. This assay has several advantages over the SDG assay in that it is relatively simple, rapid, not extremely labor intensive, and is amenable to analysis of relatively large numbers of samples. A disadvantage of the HAP assay is that the results only provide information as to whether the addition of a specific competitor chemical reduces [^{3}H]TCDD binding to cytosolic

proteins. It does not absolutely confirm that the reduction in bound radioactivity actually results from competitive displacement of [^{3}H]TCDD from the AhR as would be visualized with the SDG assay. Since it is always possible that the reduction in binding can result from a loss of [^{3}H]TCDD binding to some nonspecific site or sites (as is commonly observed with [^{3}H]TCDD which is not of high chemical purity), it is always prudent to confirm competitive binding of test compounds to AhRs using the SDG assay.

Additional Materials *(also see Basic Protocol)*

Hydroxyapatite (HAP; Bio-Rad Biogel HTP)
HEG buffer (see recipe)
Cytosol (see Support Protocol 1 or 2)
200 nM [^{3}H]TCDD in DMSO (specific activity 10 to 50 Ci/mmol; Eagle-Picher Technologies or Terrachem)
20 µM TCDF in DMSO (Accustandard, Cambridge Isotope Laboratories, or Wellington Laboratories)
HEGT buffer (see recipe)
95% ethanol

Buchner funnel containing #1 Whatman filter paper with vacuum source
1-ml micropipettor in which the opening of the disposable pipet tip has been enlarged
Benchtop centrifuge with swinging bucket rotor for microcentrifuge tubes

NOTE: All binding assay steps are performed at 4°C

Prepare HAP slurry

1. Gently resuspend 15 g dry hydroxyapatite (HAP) resin in 10 to 15 vol room-temperature HEG buffer. Allow the HAP to settle for 10 min and then decant the supernatant containing the fine HAP particles. Repeat 2 to 3 times, or until the supernatant is relatively clear.
2. After the last decantation, resuspend the HAP in HEG buffer and pour into a Buchner funnel containing #1 Whatman filter paper. Wash the HAP several times with HEG buffer under vacuum until the wash pH is 7.5.

   ~500 ml HEG buffer is used for the wash.
3. Scoop the vacuum-dried HAP into a bottle, add 30 ml HEG buffer (2 ml/gram original dry-weight HAP) and gently resuspend with swirling. Store the slurry up to 2 months at 0° to 4°C.

   Do not use a stir bar to resuspend the HAP as the resin may fragment and release fine particles that will be lost during the washing steps and add to assay variability.

Perform HAP binding assay

4. Determine the protein concentration of the cytosol sample using the Bio-Rad protein assay and adjust the sample to a protein concentration of 2 mg/ml with HEDG buffer.

   The 2 mg/ml protein concentration has been optimized for both [^{3}H]TCDD binding saturation and for HAP binding. If higher protein concentrations are needed, increase the [^{3}H]TCDD/TCDF in the incubation and the amount of HAP in the binding assay tubes proportionately.
5. For each binding incubation, prepare two 12 × 75–mm glass culture (incubation) tubes, one for total and one for nonspecific binding. Prepare a third tube if another test inhibitor is also to be assessed. To each incubation tube add 500 µl cytosol.

   Glass culture tubes are recommended for incubations since a loss of radioactivity may result when using some plastics.

6. For each set of incubations (i.e., total binding and nonspecific binding samples), add 5 µl of 200 µM [^{3}H]TCDD in DMSO to each tube (2 nM final concentration). Then add 5 µl DMSO (carrier solvent) to the total binding sample tube and 5 µl of 20 µM TCDF (200 nM final concentration) to the nonspecific binding sample tube. If the ability of another chemical to competitively bind to the AhR is also being assessed, add 5 µl [^{3}H]TCDD and 5 µl of the test ligand in DMSO at the desired concentration to the third tube.

7. Incubate the samples 2 hr in a room-temperature water bath.

8. While the sample is incubating, add 0.25 ml HAP slurry to a set of labeled 1.5-ml microcentrifuge tubes (2 tubes per incubation) using a 1-ml micropipettor in which the opening of the disposable pipet tip has been enlarged to allow easy pipetting of the HAP slurry. Store the tubes at 4°C.

   The HAP in the stock solution will settle out during storage and must be gently resuspended with swirling prior to use. Because it is a slurry, the HAP can be problematic to pipet, thus the need for the enlarged tip.

9. After the incubation period, transfer 0.2 ml (0.4 mg protein) of the incubation into an appropriately labeled microcentrifuge tube containing the HAP. Resuspend the mixture gently but thoroughly with vortexing and incubate 30 min at 0° to 4°C, with gentle vortexing every 10 min. If desired, count 25-µl aliquots of the remaining incubation mixture to determine the total [^{3}H]TCDD present in the binding incubation.

   Resuspend the HAP pellets by gentle vortexing since vigorous vortexing may fragment the HAP, resulting in loss of these "fines"(and their bound proteins) during the washing steps. Also make sure that the HAP pellet in each microcentrifuge tube is completely broken up by the initial vortexing, since failure to do so will result in reduced protein binding to the HAP and underestimation of the amount of bound [^{3}H]TCDD.

10. Add 0.9 ml of HEGT buffer to each tube. Cap the tubes, mix by vortexing, and centrifuge in a benchtop centrifuge with swinging bucket rotor for microcentrifuge tubes 2 min at 1500 rpm, 4°C.

11. Remove the supernatant by aspirating without disturbing the pellet. Wash the HAP pellet twice more with 1 ml HEGT buffer.

12. After the last wash, add 1.0 ml of scintillation cocktail to each tube, vortex the mixture, and transfer it into a 7-ml scintillation vial with a Pasteur pipet.

13. Wash the incubation tube and the Pasteur pipet with 0.75 ml of 95% ethanol and transfer this wash into the scintillation vial using the same Pasteur pipet.

14. Add 4 ml scintillation cocktail to each vial, cap, and shake. Determine the amount of radioactivity in each vial/fraction in a liquid scintillation counter.

15. Determine the specific binding of [^{3}H]TCDD by subtracting the radioactivity present in the tube containing [^{3}H]TCDD and TCDF (i.e., non-specific binding) from the radioactivity present in the corresponding tube containing [^{3}H]TCDD alone (i.e., total binding). Express AhR ligand binding as the number of femtomoles [^{3}H]TCDD specific binding per milligrams protein (see Anticipated Results).

SUPPORT PROTOCOL 1

PREPARATION OF HEPATIC CYTOSOL

The method as described is used to prepare cytosol from liver tissue; however, it can be used with any tissue by incorporating minor alterations in homogenization buffer volume.

Materials

Liver (or tissue) samples
HEDG buffer (see recipe)
Bio-Rad protein assay

Cheesecloth
Polytron or motorized Teflon-glass homogenizer
40-ml Oakridge polypropylene capped centrifuge tubes
Sorvall SS34 rotor or equivalent
Funnel plugged with glass wool
25-ml polycarbonate ultracentrifuge tubes
Beckman SW70Ti (or equivalent)

Additional reagents and equipment for liver perfusion (*UNIT 14.2*)

NOTE: Perform all steps at 4°C.

1. Sacrifice the animal. Open the abdominal cavity and cut the vena cava immediately above the liver with scissors. Slowly perfuse the liver with HEDG buffer using a syringe inserted into the hepatic portal vein to remove the blood.
2. Place tissue in a beaker and mince into small pieces with scissors.
3. Wash tissue with HEDG buffer until the rinse is clear.

   Livers should be perfused and the minced tissue washed as thoroughly as possible to minimize the amount of blood associated with the tissue. This is because there are several serum proteins which can bind TCDD, resulting in elevated background binding of [^{3}H]TCDD if cytosol is to be used in the binding assays (Denison et al., 1986).
4. Pass the last wash through cheesecloth to remove excess buffer and put the minced and washed liver pieces into a clean beaker and weigh.
5. For each gram of tissue, add 1 to 1.5 ml HEDG buffer to the beaker.
6. Homogenize tissue with a Polytron homogenizer or in a motorized Teflon-glass homogenizer on ice.

   Homogenates prepared using a Polytron or similar type of tissue disrupter tend to warm up during the homogenization process. Thus, make sure to homogenize using only short bursts and keep the beaker on ice to prevent samples from heating up.
7. Transfer the homogenate into a 40-ml Oakridge polypropylene-capped centrifuge tube. Centrifuge in a Sorvall SS34 rotor or equivalent 20 min at 21,000 × *g*, 4°C.
8. Pour the supernatant through a funnel plugged with glass wool into a flask.

   This step removes much of the lipid that is present in the homogenate.
9. Pour the supernatant into 25-ml polycarbonate ultracentrifuge tubes, balance, and cap. Centrifuge in a Beckman SW70Ti ultracentrifuge rotor (or equivalent) for 1 hr at 105,000 × *g*, 4°C.
10. Carefully collect the resulting supernatant (cytosol) from below the surface lipid layer using a Pasteur pipet, minimizing the amount of lipid collected, and transfer into another tube.

    Alternatively, the lipid layer can be aspirated off the top of the supernatant prior to collecting the cytosol, but typically more cytosol is lost using this method.

11. Store cytosol samples at −80°C in small aliquots (i.e., 200 to 400 µl) in 500-µl microcentrifuge tubes. Determine sample protein concentration in one aliquot using Bio-Rad protein assay.

    Cytosol has been stored in this manner for more than 7 years with no significant loss of AhR functionality.

PREPARATION OF CYTOSOL FROM CELLS IN CULTURE

SUPPORT PROTOCOL 2

This method as described has been used to prepare cytosol from a variety of cells in culture with little or no modification.

Materials

Confluent 100- or 150-mm plates of cells
Phosphate-buffered saline (PBS; see recipe)
0.5% (w/v) trypsin/0.05% (w/v) tetrasodium EDTA (Life Technologies)
HED buffer (see recipe)
HED2G buffer (see recipe)
Bio-Rad protein assay

Teflon glass homogenizer
4-ml Sorvall polycarbonate microultracentrifuge tubes
Sorvall RCM100 microultracentrifuge and RPT80 rotor, or equivalent

1. Wash confluent 100- or 150-mm plates of cells twice with 5 ml phosphate buffered saline (PBS).

   Cytosol is generally prepared from twenty 100- or ten 150-mm plates of confluent cell cultures.

2. Detach cells from the plate by adding 0.5% (w/v) trypsin/0.05% (w/v) tetrasodium EDTA and transfer into a 15-ml tube. Collect the cells by centrifuging 5 min at 1000 × *g*, room temperature.

3. Wash the cell pellet once with 10 ml cold 1× PBS.

   NOTE: *All subsequent procedures should be carried out at 4°C.*

4. Resuspend cells in HED buffer at a ratio of 1 ml HED per ten 100-mm plates of cells and transfer into a Teflon glass homogenizer.

5. Homogenize cells with 15 strokes. Mix the resulting homogenate with an equal volume of HED2G buffer, bringing the final concentration of glycerol to 10% (v/v). Transfer homogenates into 1.5-ml microcentrifuge tubes.

6. Microcentrifuge the diluted homogenate 5 min at ~12,000 × *g*, 4°C.

7. Collect the supernatant and transfer into 4-ml Sorvall polycarbonate microultracentrifuge tubes. Centrifuge in a Sorvall RCM100 microultracentrifuge and Sorvall RPT80 rotor, or equivalent, 1 hr at 105,000 × *g*, 4°C.

8. Store the resulting supernatant (cytosol) frozen at −80°C or in liquid nitrogen until use (up to 1 year). Determine protein concentrations using the Bio-Rad assay.

BASIC PROTOCOL 2

GEL RETARDATION ANALYSIS OF AhR-DNA BINDING

The gel retardation assay is a relatively simple procedure for separation of protein-free DNA from protein-bound DNA and the subsequent identification of ligand-dependent AhR-Arnt-DRE complex formation. This procedure can be used with cytosol that has been incubated with or without an AhR ligand (agonist) in vitro or nuclear extracts prepared from cells or tissues exposed to an AhR ligand or carrier solvent in vivo. The binding of AhR to the DRE is assessed by examining its ability to bind to DNA oligonucleotides or DNA fragments containing putative DREs by gel retardation analysis. The DRE-dependent nature of AhR DNA complex formation can also be determined using competitive gel retardation analysis with wild-type and mutant DRE oligonucleotides (see Alternate Protocol 2). Procedures for both cytosol and nuclear extracts are described.

Materials

95% ethanol
1× and 10× TAE buffer (see recipe)
30% acrylamide/0.8% bisacrylamide (*APPENDIX 3F*)
10% (w/v) ammonium persulfate (APS), fresh
TEMED (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)
Cytosol (see Support Protocols 1 and 2) or nuclear extracts (see Support Protocol 3)
Bio-Rad protein assay
HEDG buffer (see recipe)
Chemical to be tested
HEDGK8 buffer (see recipe)
Cytosolic and nuclear poly(dI·dC) (Roche Diagnostics) in HEDG buffer
^{32}P-labeled double-stranded wild-type DRE-oligonucleotide (see Support Protocol 4)
10× Ficoll GRA gel-loading buffer (see recipe)
HEDGK4 buffer (see recipe)

Polyacrylamide gel electrophoresis (PAGE) apparatus (e.g., V16-2; Life Technologies) with 1.5-mm spacers (*APPENDIX 3F*)
Syringe with bent needle
Peristaltic pump with two pump heads and appropriate tubing
Micropipettor with gel-loading tip or 50-µl Hamilton syringe
3 MM blotting paper

Additional reagents and equipment for PAGE (*APPENDIX 3F*) and detection and quantitation of radiolabeled proteins in gels and blots (*APPENDIX 3D*)

NOTE: When water is indicated in the procedure, use MilliQ-purified water or equivalent

Prepare the nondenaturing gel

1. Wash the glass plates of the polyacrylamide gel electrophoresis (PAGE) apparatus and rinse with plenty of water followed by 95% ethanol. Assemble washed glass plates and 1.5-mm spacers for casting of the gel as described (*APPENDIX 3F*).

   Plates are washed with water and rinsed with ethanol to ensure detergent removal. Trace amounts of detergent may affect protein-DNA complex formation.

2. For each gel to be poured, combine 4.5 ml of 10× TAE, 34 ml water, and 6 ml 30% acrylamide/0.8% bisacrylamide solution in a flask. To this mixture, add 0.45 ml fresh 10% ammonium persulfate and 22.5 µl TEMED. Swirl gently to mix and degas under vacuum.

   The volumes can be scaled up or down depending upon the number and size of the gels required.

3. Immediately pour the gel between the plates, ensure that no bubbles are formed and insert a comb. Allow the gel to polymerize (~20 min).

   Combs with 1-cm-wide teeth are recommended. For running larger numbers of samples, combs with 0.5-cm-wide teeth can be used, but the volume of sample loaded in the lane must be reduced accordingly to reduce smearing of the protein-DNA complexes.

4. Carefully remove the combs and bottom spacer, attach the plates to the gel box and fill the reservoirs with 1× TAE buffer. Flush out the wells with buffer and remove any air bubbles trapped between the glass plates beneath the gel by washing with 1× TAE buffer using a syringe with a bent needle.

5. Attach a peristaltic pump via appropriate tubing and recirculate the buffer between the top and bottom reservoirs at a moderate speed. Prerun the gel 2 hr at 130 V.

   Buffer recirculation is important when using this low ionic strength buffer, otherwise the buffering capacity will be exhausted and the resulting change in pH will disrupt protein-DNA complex formation. Alternative buffers with a greater buffering capacity have been described, but the effect on AhR DNA binding should be examined if buffer conditions are changed from that described here. An electrophoresis apparatus that is not completely enclosed is needed both to allow construction of a simple system for buffer recirculation and to provide the option of running two gels simultaneously in the same apparatus (e.g., Life Technologies V16-2 gel apparatus).

Prepare binding reactions

For binding reactions using cytosol

6a. Determine the protein concentration of the cytosol using the Bio-Rad protein assay and adjust the sample to a protein concentration of 8 mg/ml for cytosol samples from tissues and 2 to 4 mg/ml for cytosol samples from cultured cells with HEDG buffer. Keep samples at 4°C until ligand addition.

7a. Aliquot 125 µl diluted cytosol into 500-µl microcentrifuge tubes, one tube for each ligand, as well as tubes for the appropriate control solvent or solvents.

8a. To each tube add 2.5 µl of the chemical to be tested at the desired concentration(s) or control solvent or solvents. Incubate the tubes in a room-temperature water bath for 2 hr.

   For TCDD, the final concentration in the incubation is generally 10 to 20 nM in DMSO.

9a. After the incubation, combine 10 µl control or treated cytosol (from step 8a), 4 µl HEDG buffer, 3 µl HEDGK8 buffer, and 4 µl of cytosolic poly(dI·dC) in HEDG buffer in a 500-µl microcentrifuge tube. Mix gently and incubate 15 min at 20°C.

   The poly(dI·dC) concentration used with cytosolic samples is generally in the range of 100 to 400 ng per incubation; however, the exact amount of poly(dI·dC) required in a given incubation is not only species- and tissue-specific, but also dependent upon the protein concentration and the specific lot and source of poly(dI·dC) used. Identical concentrations (based on their absorbance at 260 nm) of different lots of the same poly(dI·dC) product from the same company are not necessarily equally effective as carrier DNA. Thus, with each new lot number of poly(dI·dC) used, the optimal concentration needed for maximal AhR-DRE complex formation must be established. The optimal ratio of protein/poly(dI·dC) must be maintained in order to generate maximal protein-DNA complex formation.

10a. Add 4 µl of ^{32}P-labeled double-stranded wild-type DRE oligonucleotide (~100,000 cpm) to each tube and incubate 15 min at 20°C.

11a. Add 3 µl of 10× Ficoll GRA gel-loading buffer to each tube (the solution will turn blue).

   The sample is now ready to load onto the gel.

For binding reactions using nuclear extracts

6b. Determine the protein concentration of the nuclear extract using the Bio-Rad assay.

7b. Adjust the sample to a protein concentration of 1.5 to 2 mg/ml with HEDGK4 buffer (although lower concentrations can be used).

The nuclear extracts of the matched control and treated nuclear extract must be diluted to the same protein and salt concentrations.

8b. Combine 5 µl nuclear extracts from control or treated cells with 7 µl HEDG buffer, 5 µl HEDGK4 buffer, and 4 µl of nuclear poly(dI·dC) solution (in HEDG) in a 500-µl microcentrifuge tube.

Because of the large amount of DNA binding proteins in nuclear extracts, the poly(dI·dC) concentration used with nuclear samples is generally in the range of 1 to 4 µg per incubation; however, the optimal amount of poly(dI·dC) needed for nuclear extracts from a given cell line or tissue must be determined experimentally.

9b. Mix gently and incubate 15 min at 20°C.

10b. Add 4 µl of ^{32}P-labeled DRE oligonucleotide to each tube and incubate 15 min at 20°C.

The final KCl concentration should be between 80 to 160 mM.

11b. Add 3 µl of 10× Ficoll GRA gel-loading buffer to each microcentrifuge tube (the solution will turn blue).

The sample is now ready to load onto the gel.

Run the gel

12. Turn the power supply and peristaltic pump off.

13. Flush the wells with 1× TAE and carefully load 20 µl of each sample into the appropriate 1-cm wide well of the prerun gel using either a micropipettor equipped with a gel-loading tip or a 50-µl Hamilton syringe (be sure to rinse the syringe between samples).

For 0.5-cm-wide wells, load only 10 to 15 µl sample.

14. Restart the peristaltic pump and electrophorese the samples at ~80 V until they have completely entered the gel and then increase the power to ~130 V (*APPENDIX 3F*). Stop the gel once the dye front has reached ~4 cm from the bottom of the gel (~2 to 2.5 hr for a 15- to 20-cm gel).

During the run, the glass plates should be slightly warm. If they get hot, reduce the voltage. Since the bromphenol blue dye runs slightly slower than the 25-bp oligonucleotide probe used in the standard protocol, the free [^{32}P]-labeled oligonucleotide will run off the gel if the dye front is run too close to the end of the gel.

Remove and dry the gel

15. Turn off the peristaltic pump and the power supply, remove the plates from the apparatus and carefully remove the side spacers. Gently pry the plates apart with a spatula, being careful to keep the gel adhered to only one plate. Notch a corner of the gel for orientation.

If the gel sticks to the plates and/or folds over onto itself as the plates are separated, gentle shaking of the folded gel and plate under a slow flow of water will allow the gel to resume its original shape without tearing. Be careful not to wash the gel off the plate.

16. Roll a piece of 3 MM blotting paper onto the exposed gel (making sure to keep track of the gel orientation). Lift the blotting paper up slowly to peel the gel away from the plate.

17. Cover the gel with a piece of plastic wrap. Trim off the excess paper and plastic wrap, and dry under vacuum with heat (i.e., in a gel dryer).

    A 20-cm^2 gel of 1.5 mm thickness will dry in ~1 hr at 80°C.

18. After the gel is dried, appose it to film and place at −80°C with one or two intensifying screens (*APPENDIX 3D*).

    The time needed for adequate exposure of the dried gels to X-ray film can vary greatly and is dependent on the amount and specific activity of the [^{32}P]DNA probe used and the amount of protein DNA complex formed. DNA-binding complexes can be readily quantitated by use of a phosphorimager or by excision of the desired bands from the dried gel and measurement of the radioactivity by liquid scintillation counting. Alternatively, densitometric analysis of the autoradiograms will provide a relative estimate of complex formation.

COMPETITIVE GEL RETARDATION ANALYSIS OF AhR-DNA BINDING

ALTERNATE PROTOCOL 2

This procedure allows confirmation of the sequence specificity of binding of a given DNA-binding protein and provides an avenue to confirm that a particular protein-DNA complex contains the AhR-Arnt complex. Relative to the AhR, this can be confirmed both by the demonstration of the ligand (TCDD)-dependence of formation of the specific protein-DNA complex and confirmation of the nucleotide specificity of DNA binding of the protein. Competitive displacement of the induced AhR-DRE protein DNA complex by oligonucleotides containing a wild-type DRE element (i.e., one which is known to bind the ligand AhR-Arnt complex) and the lack of competitive displacement by mutant DRE oligonucleotides (i.e., which fail to bind the AhR complex) support the identity of the protein-DNA complex as containing the AhR. Competitive gel retardation analyses using oligonucleotides containing a series of nucleotide substitutions (mutations) within the DRE have defined the nucleotides critical for formation of the ligand AhR-Arnt DRE complex. Competitive displacement curves with DNA containing known and unknown DREs can be used to estimate the relative affinity of the AhR complex for the competitor DREs (Yao and Denison, 1991; Shen and Whitlock, 1992). This procedure has been used with both cytosolic and nuclear AhR extracts. The steps in this alternate protocol are identical to those described for the method above (see Basic Protocol 2), except that the binding reactions with the cytosol and nuclear extracts are modified as described.

Additional Materials *(also see Basic Protocol 2)*

Cytosolic and nuclear poly(dI·dC) in HEDG buffer (see recipe for buffer; Roche Diagnostics)
Competitor DNA in HEDG buffer: unlabeled wild-type and mutant DRE oligonucleotides (see recipe), or other competitor DNA fragments

For cytosolic samples

9a. After the incubation, combine 10 µl control or treated cytosol, 3 µl HEDGK8 buffer, and 4 µl cytosolic poly(dI·dC) in HEDG buffer (see Basic Protocol 2, step 9a) in a 500-µl microcentrifuge tube. Mix gently and incubate for 15 min at 20°C.

10a. Add 4 µl competitor DNA in HEDG buffer or HEDG buffer alone, and 4 µl of ^{32}P-labeled double-stranded wild-type DRE oligonucleotide to each tube. Incubate 15 min at 20°C.

For nuclear extracts

8b. Combine 5 µl nuclear extracts from control or treated cells with 3 µl HEDG buffer, 5 µl HEDGK4 buffer, and 4 µl of nuclear poly(dI·dC) in HEDG buffer (see Basic Protocol 2, step 8b) in a 500 µl microcentrifuge tube.

9b. Mix gently and incubate 15 min at 20°C.

10b. Add 4 µl competitor DNA in HEDG buffer or HEDG buffer alone and 4 µl of ^{32}P-labeled DRE oligonucleotide to each tube. Incubate 15 min at 20°C.

Competitor DNA is commonly added at a 10- to 50-fold molar excess relative to the labeled DNA oligonucleotide. At a 10-fold excess, an identical unlabeled DNA fragment should theoretically reduce the amount of specific protein-DNA complexes by 10-fold. The specific competitor generally used is the same DNA fragment that was radiolabeled, while the nonspecific competitor DNA can be a DNA fragment of an unrelated sequence. To confirm the presence of the AhR in the induced protein DNA complex, the optimal nonspecific control competitor is a DNA fragment that is identical to the radiolabeled probe fragment except for the presence of a targeted mutation within the DRE core sequence which eliminates binding of the transformed AhR complex (see Support Protocol 4 for specific oligonucleotides).

SUPPORT PROTOCOL 3

PREPARATION OF NUCLEAR EXTRACTS FROM CELLS IN CULTURE

This method involves isolation of nuclear proteins from cell cultures that have been incubated with or without TCDD, [^{3}H]TCDD, or another AhR agonist. After chemical treatment, cells are collected, washed, and incubated with hypotonic buffer. The swollen cells are harvested by scraping, homogenized, and the nuclei pelleted. The crude nuclear pellet is washed and resuspended in high-salt buffer which releases soluble nuclear proteins. Following centrifugation, the nuclei are pelleted and the high-salt nuclear extract (supernatant) is collected.

Materials

Culture medium
1 µM TCDD in DMSO
DMSO
100-mm plates of confluent cells
10 mM HEPES buffer (see recipe)
MDH buffer (see recipe)
MDHK buffer (see recipe)
HEDGK4 buffer (see recipe)
Bio-Rad protein assay

6-ml Dounce homogenizer with loose-fitting pestle cooled on ice
15-ml polyethylene tubes
1-ml micropipettor with a pipet tip in which the opening has been enlarged
0.5-ml polypropylene microultracentrifuge tubes
Sorvall RCM100 microultracentrifuge and RP100AT2 rotor, or equivalent

1. Prepare an appropriate amount of culture medium containing either 1 nM TCDD or 0.1% (v/v) DMSO by adding 1 µl of 1 µM TCDD in DMSO or DMSO alone per milliliter medium in a test tube. Mix and add 2 ml treated medium to 100-mm plates of confluent cells. Incubate 1 hr in a 37°C tissue culture incubator.

A typical preparation uses six 100-mm plates of cells for each treatment.

Treatment of cells which contain a lower affinity AhR (i.e., human and nonmammalian species) requires 10 nM TCDD. The optimal TCDD concentration needed for maximal response in a given cell type should be determined empirically.

2. Place plates of cells on ice, decant medium, and wash the cells twice with 5 ml of 10 mM HEPES buffer each. Add 2 ml HEPES buffer to each plate and incubate for 15 min in a 37°C incubator.

   NOTE: *All subsequent steps should be carried out at 4°C.*

3. Aspirate HEPES buffer and add 1 ml MDH buffer per plate.
4. Collect cells by scraping and transfer them into a 6-ml Dounce homogenizer.
5. Homogenize cells using 15 to 20 strokes with a loose fitting pestle cooled on ice, and transfer the homogenate into a 15-ml polypropylene tube.
6. Centrifuge the homogenate 5 min at ~1000 × *g*, 4°C.
7. Remove the supernatant, add MDHK buffer (2 ml per 100-mm plate), resuspend the pellet with vortexing, and again centrifuge 5 min at 1000 × *g*, 4°C. Discard the supernatant and wash the crude nuclear pellet one more time.
8. Add 1 ml MDHK buffer to the tube and resuspend the crude nuclear pellet by gently vortexing. Transfer the mixture into a 1.5-ml microcentrifuge tube with a 1-ml micropipettor using a pipet tip in which the opening has been enlarged.

   Do not use a Pasteur pipet since the pellet will stick to the glass and be lost. Make sure to transfer all of the resuspended pellet.

9. Centrifuge the tube 5 min at 1000 × *g*, 4°C. Remove the supernatant.
10. Resuspend the crude nuclear pellet with HEDGK4 buffer (50 µl per plate confluent cells) by mixing gently by flicking the tube. Incubate 20 min on ice, mixing every 5 min. Microcentrifuge 15 min at ~12,000 to 15,000 × *g*, 4°C.

    The final protein concentration of the nuclear extract can be increased or decreased by decreasing or increasing the volume of HEDK5 buffer added to the pellet.

11. Transfer the supernatant (crude nuclear extract) into 0.5-ml polypropylene microultracentrifuge tubes. Centrifuge in a Sorvall RCM100 microultracentrifuge and RP100AT2 rotor, or equivalent, 1 hr at 105,000 × *g*, 4°C.
12. Store the resulting supernatant (crude nuclear extract) frozen at −80°C in 25-µl aliquots.
13. Determine protein concentrations using Bio-Rad protein assay.

    The desired working protein concentration should be ≥2 mg/ml.

PREPARATION OF ^{32}P-LABELED DOUBLE-STRANDED OLIGONUCLEOTIDES FOR GEL RETARDATION ANALYSIS

SUPPORT PROTOCOL 4

The two major methods for radiolabeling DNA for gel retardation analysis are end labeling and nick translation. End labeling generally produces a more highly labeled DNA fragment than nick translation and therefore is most commonly used for preparation of gel retardation analysis probes. In this protocol, the single-stranded oligonucleotides are reannealed and phosphorylated on their 5′-end using T4 polynucleotide kinase and [γ-^{32}P]ATP. After removal of the free [γ-^{32}P]ATP, the probe is diluted to the desired concentration and is then ready for gel retardation analysis.

Materials

DRE oligonucleotides, single-stranded and purified (wild type and mutant; see recipe)
Oligonucleotide reannealing buffer (see recipe)

10 U/µl T4 polynucleotide kinase (New England Biolabs) and 10× T4 kinase buffer (see recipe)
5000 to 8000 Ci/mmol [γ-^{32}P]ATP
TE buffer (see recipe)
Sephadex G-50 spin column (e.g., CpG Spin-pure G-50; also see recipe) equilibrated with TE buffer
HEDG buffer (see recipe)
20 µg/ml ethidium bromide in TE buffer

Heated rotary evaporator (e.g., Speedvac; Savant)
0.5-ml screw-cap microcentrifuge tubes
UV transilluminator

Reanneal single-strand oligonucleotides

1. Determine the DNA concentration of the purified single-stranded DRE oligonucleotides (wild type and mutant) by measuring the absorbance of an aliquot of each at 260 nm and using the following conversion:

   One A_{260} unit = 34 µg DNA/ml for single-stranded oligonucleotides.
2. Combine 225 µg of each of the two complementary oligonucleotides into a 1-ml microcentrifuge tube.
3. Evaporate to dryness in a heated rotary evaporator.
4. Dissolve the DNA in 75 µl oligonucleotide reannealing buffer and incubate 5 min at 90°C.
5. Turn off the heat and allow the tubes to slowly cool to room temperature.
6. Determine the DNA concentration of the reannealed DNA oligonucleotides by measuring the absorbance of an aliquot of each at 260 nm and using the following conversion:

   One A_{260} unit = 50 µg DNA/ml for double-stranded oligonucleotides.

Radiolabel double-stranded oligonucleotides

7. In a 0.5-ml screw-cap microcentrifuge tube, combine the following in order:

   25 µl water
   10 µl 20 to 25 ng/µl dsDNA oligonucleotide
   5 µl 10× T4 kinase buffer
   8 µl 5000 to 8000 Ci/mmol [γ-^{32}P]ATP
   2 µl 10 U/µl T4 DNA polynucleotide kinase

   The T4 kinase buffer supplied by the manufacturer can be used or the buffer can be made in house.
8. Incubate the reaction 30 min at 37°C.
9. To each reaction mixture add 50 µl TE buffer.
10. Pipet the radiolabeled reaction mixture directly onto a Sephadex G-50 spin column equilibrated with TE buffer. Centrifuge 2 min at 1000 × *g*, room temperature.

    This step removes the majority of unincorporated radiolabeled nucleotides.
11. Transfer the radiolabeled DNA sample in the collection tube following centrifugation into a 0.5-ml screw-cap microcentrifuge tube.
12. Dilute the sample 1:4 with HEDG buffer and count 4 µl sample by liquid scintillation.

    If the labeling was successful, the radioactivity of the original Sephadex eluant should be ~1 × 10^6 cpm/µl.

13. Dilute the radiolabeled stock solution with HEDG buffer to 100,000 cpm/4 µl for use in the gel retardation assay (see Basic Protocol 2 and Alternate Protocol 2).

The specific activity of the radiolabeled probe can be readily determined by measuring both the radioactivity and the amount of DNA in an aliquot of the final radiolabeled stock. The amount of DNA can be accurately estimated using the spot quantitation method described below.

Perform spot quantitation

For competitive gel retardation analysis, the specific activity of the radiolabeled probe must be determined in order to prepare accurate competitor concentrations.

14. Spot a 1- to 2-µl aliquot of the sample (1 to 20 ng DNA) onto a piece of plastic wrap that has been placed on a UV transilluminator. Do the same for a range of DNA standard concentrations from 1 to 20 µg/ml. Add an equal volume 20 µg/ml ethidium bromide in TE to each spot. Mix by repeated pipetting with a micropipettor.

15. Photograph the spots and estimate the DNA concentration of the sample by direct comparison of its fluorescence intensity to those of the standards.

CAUTION: *Do not look at the UV light without wearing an appropriate full-face shield that efficiently blocks the UV light.*

IMMUNOBLOT OF AhR AND Arnt

BASIC PROTOCOL 3

Immunoblot analysis is a useful technique for direct detection of the presence and size of a specific protein using an antibody specific for that protein. This procedure can be used with whole cell lysates, cytosol, or nuclear extracts (prepared from cells or tissues exposed to an AhR ligand). In this technique, proteins in a sample extract are denatured and separated in a denaturing polyacrylamide gel (also see *APPENDIX 3F*). The proteins are transferred onto a nitrocellulose or PVDF membrane and the AhR or Arnt is bound by anti-AhR or -Arnt antibodies, which are subsequently bound by a secondary antibody coupled to horseradish peroxidase (HRP). Detection of the antibody complex is readily observed using a chemiluminescent substrate for HRP and subsequent autoradiography.

Materials

4× PAGE running gel buffer (see recipe)
4× PAGE stacking gel buffer (see recipe)
95% ethanol
Immunoblot tank buffer (see recipe)
Mammalian cells or whole cell lysate, cytosol (see Support Protocols 1 and 2), or nuclear extracts (see Support Protocol 3)
PBS (see recipe)
1× trypsin (Life Technologies)
Lysis buffer, fresh (see recipe)
Bio-Rad protein assay
2× immunoblot treatment buffer, frozen (see recipe)
Prestained protein standards (e.g., Bio-Rad Kaleidoscope), frozen
Towbin transfer buffer (see recipe)
Nitrocellulose (Amersham Hybond-ECL) or PVDF (NEN Polyscreen) transfer membrane
100% methanol (for PVDF membranes only)
Phosphorescent paint (obtain from an art supply store or hobby shop)
Blotto (see recipe)

Primary antibody: rabbit anti-AhR and mouse anti-Arnt antibodies (Affinity Bioreagents, Novus Biologicals, or Santa Cruz Biotechnology)
TBST (see recipe)
Secondary antibody: Anti-rabbit or -mouse antibody conjugated to horseradish peroxidase (Pierce)
Tris buffered saline (TBS; see recipe)
Renaissance Western Blot Chemiluminescence Reagent Plus, Enhanced Luminol (NEN Life Science Products)
Stripping buffer (see recipe)

100-mm tissue culture plates
Chromatography paper (Whatman 3 MM or equivalent)
Transfer apparatus (Idea Scientific)
Plastic sheet protectors
Autoradiography film
Rocking platform (Labquake)
Shallow plastic box or tray with lid, slightly larger than blot

Additional reagents and equipment for PAGE (*APPENDIX 3F*) and autoradiography (*APPENDIX 3D*)

NOTE: When water is indicated in the procedure, use MilliQ-purified water or equivalent.

Prepare the gel

1. Prepare a 10 × 8–cm minigel with a 10% running and 4% stacking gel as described (*APPENDIX 3F*) using 4× PAGE running gel buffer and 4× PAGE stacking gel buffer. Make sure to first wash the plates with water and then 95% ethanol to remove detergent and wipe dry with Kimwipes. Use immunoblot tank buffer in the reservoirs.

Prepare samples

If using cytosol, nuclear extracts, or in vitro synthesized AhR or Arnt from rabbit reticulocyte lysates, skip to step 7.

2. Grow mammalian cells to confluence in 100-mm tissue culture plates. One plate per treatment should be sufficient.

   In general, tissue or cell extracts prepared by any of the protocols in this unit (see Support Protocols 1 to 3) will yield sufficient AhR or Arnt for detection by immunoblot analysis. Liver cytosol extracts prepared for use in gel retardation analysis experiments (see Support Protocol 1), when diluted to 2 to 3 mg protein/ml, make excellent positive controls for immunoblot experiments.

3. Rinse each plate twice with PBS. Add 1 ml of 1× trypsin and incubate 5 min at room temperature. Harvest cells by scraping and transfer them into separate 1.5-ml microcentrifuge tubes. Microcentrifuge 20 sec at 2000 rpm. Rinse twice with 1 ml PBS each and discard the supernatant.
4. Add 1.2 ml fresh lysis buffer, suspend cells and incubate 30 min at 4°C with shaking.
5. Microcentrifuge the cell lysate 15 min at 12,000 rpm, 4°C. Transfer 1 ml cleared lysate to a clean microcentrifuge tube and discard the pellet.
6. Measure sample protein concentration by Bio-Rad protein assay.

   This protocol will yield a protein concentration of 0.6 to 1 mg/ml. Lysate may be stored indefinitely at –80°C.

Perform electrophoresis

7. If using frozen samples, thaw on ice. Thaw 2× immunoblot treatment buffer and prestained protein standards at room temperature.

8. If necessary, dilute samples with water to 2 to 3 mg protein per milliliter.

   The protein concentration needed is dependent upon the AhR/Arnt concentration in the sample and preliminary experiments may need to be run to determine the optimal protein concentration to use for a given extract. For mouse hepatoma (hepa1c1c7) cells, a protein concentration of 2 to 3 mg/ml is sufficient.

9a. *For nonreticulocyte samples:* Mix 20 µl of each sample with 20 µl of 2× immunoblot treatment buffer.

9b. *For reticulocyte lysate samples:* Dilute 3 µl of a standard 20-µl reaction with 7 µl water and 10 µl of 2× treatment buffer. Boil samples 3 min and cool on ice.

   Reticuloctye lysates must be diluted significantly due to the high salt concentration of these samples, otherwise these samples will resolve poorly in the denaturing gel.

10. Briefly microcentrifuge the samples at full speed and load 7 µl prestained protein standards in the outermost wells of the gel. Load up to 30 µl (40 to 60 µg protein) of sample per lane. Electrophorese 1 hr at 20 mA/gel (*APPENDIX 3F*).

    Proteins smaller than ~20 kDa, such as the smallest two Kaleidoscope standard proteins, will not resolve in a 10% gel and will migrate with the dye front.

Prepare and blot membrane

11. Disassemble the electrophoresis unit. Lift the top plate from the gel and cut off and discard the stacking gel. Notch one corner of the gel to allow maintenance of gel orientation. Squirt water on edge of gel and carefully work the gel loose from plate. Place the gel into a plastic container containing several milliliters of Towbin transfer buffer (i.e., enough to cover the gel). Incubate the gel 20 min with shaking at room temperature.

12. With gloved hands, carefully cut the nitrocellulose or PVDF transfer membranes to gel size (8 × 6 cm). For each gel, cut two pieces of chromatography paper to a size slightly smaller than the pads in transfer unit.

    Dry membranes are very fragile and should never be handled with bare hands.

13. *For PVDF membranes only:* Wet membrane in 100% methanol for 15 sec. Rinse in water 2 min.

14. Place the membrane in the container with the gel for 5 min. Moisten chromatography paper with Towbin transfer buffer.

15. Assemble the transfer apparatus according to manufacturer's instructions, making sure to remove any bubbles, especially those between the membrane and gel.

    Two gels may be simultaneously transferred using an Idea Scientific transfer unit, but make sure that they are staggered and not placed directly above each other.

16. Transfer proteins to the membrane 45 min at 24 V for one gel, or 1 hr for two.

    Examination of the gel after transfer will reveal that much of the topmost band in the protein standard lane has not transferred; however, the AhR and Arnt are much smaller than this protein and they transfer much more efficiently.

17. *For PVDF membranes only:* Immerse in 100% methanol for 10 sec.

18. Place membrane, protein side up, on a paper towel on the lab bench and allow to dry for at least 15 min.

19. Mark the positions of the protein standards with a small dot of phosphorescent paint.

    The ability of the paint to glow in the dark will allow the positions of the weight standards to appear on the autoradiograph.

    The dry blot may be wrapped in plastic wrap and stored overnight at 4°C or indefinitely at −20°C. Sandwich the blot between two pieces of cardboard for extended storage.

Probe blot with antibodies

Perform all incubations at room temperature with rocking.

20. Block additional protein binding sites on the membrane blot by immersing it in Blotto (protein side up) in a plastic container and incubating for 30 min.

    The volume of solutions used is dependent upon the size of the container. For probing with antibody, the liquid should just cover the blot; during blocking and washing steps, use twice this volume. In the containers with a 10.5 × 8.5 cm base, 5 and 10 ml are used, respectively.

21. Remove the solution, add fresh Blotto and incubate an additional 30 min.

    Blotto is used twice in order to minimize background.

22. Remove the solution and incubate the blot with primary antibody diluted (e.g., 1:5000) in Blotto for 60 min.

    Titration may be necessary for different antibody preparations.

23. Wash membrane six times for 5 min each with TBST.

24. Incubate blot with anti-rabbit or -mouse secondary antibody conjugated to horseradish peroxidase, diluted 1 to 2 µl antibody/5 ml Blotto (e.g., 1:5000 or 2:5000) for 45 min.

25. Wash membrane five times for 5 min each with TBST. Wash once for 5 min with Tris buffered saline (TBS).

26. Mix equal volumes of each reagent supplied in the Renaissance Western Blot Chemiluminescence Reagent Plus kit (3.5 ml each per blot). Incubate membrane in the freshly prepared solution for exactly 1 min in a clean plastic container.

27. Remove membrane from solution with forceps and blot off excess. Do not overdry the membrane. Place membrane inside sheet protector.

28. Expose the blot to autoradiographic film for 1 min and develop (*APPENDIX 3D*).

    If necessary, adjust exposure time and repeat. Both the phosphorescent protein standards and the chemiluminescent proteins will appear on the autoradiographic film.

29. Compare the position of the proteins (chemiluminescent) on the blot to the position of the protein molecular weight standards (phosphorescent) to allow estimation of the size of the AhR.

    Immunoblots using anti-AhR antibodies commonly contain multiple protein bands in addition to the AhR. The authors have not identified any AhR antibody that will only produce a single band on immunoblots; however, the major band on the blot should be that of the AhR, which should be ~95 to 120 kDa in size (depending on the species examined).

30. Once an adequate autoradiogram has been obtained, rinse the blot 5 min with TBS at room temperature to remove excess chemiluminescent reagent, and wrap the wet blot in plastic wrap. Store up to 4 weeks at 4°C.

    If the membrane is to be reprobed with another antibody it will need to be stripped prior to reuse.

Strip the membrane (optional)

31. Immerse the membrane in stripping buffer and incubate 30 min at 50°C.
32. Wash membrane six times for 5 min each with TBST at room temperature.
33. Incubate membrane for exactly 1 min in freshly prepared chemiluminescence reagent.
34. Place membrane in plastic sheet protector. Expose film for 30 min and develop to make sure that the membrane is adequately washed (no chemiluminescent signal should be observed; *APPENDIX 3D*).
35. Wash membrane four more times for 5 min each with TBST at room temperature.

The blot may now be reprobed with antibody as described above.

DETECTION OF HUMAN AND MOUSE AhR, Arnt, CYP1A1, and CYP1B1 mRNA BY RT-PCR

BASIC PROTOCOL 4

The reverse transcriptase–polymerase chain reaction (RT-PCR) is perhaps the most sensitive technique developed to measure gene expression in tissues or cells. RT-PCR can be used to determine the presence and abundance of a message and also to clone a particular cDNA product. In the protocol described here, the reverse transcriptase enzyme synthesizes the first strand of cDNA from mRNA, and then the second strand of cDNA is synthesized and PCR amplification is performed using Platinum *Taq* DNA polymerase. The mixture containing the polymerase, oligonucleotide primers, and dNTPs is cycled several times (20 to 30) through a series of temperatures that allows the DNA to denature, anneal to the primers, and amplify the product. Although a number of one-enzyme/one-step kit technologies have been developed, the best results are generally obtained using a two-step approach which results in maximum integrity and efficiency of each enzyme. This protocol describes the optimal procedure for amplification and detection of the C57BL/6 mouse and human AhR, Arnt, CYP1A1, and CYP1B1 mRNAs. Minor modifications in this protocol will allow amplification of these products in other species using appropriate primer sets and amplification conditions. For more information concerning PCR, refer to *APPENDIX 3C*.

Materials

Single-stranded oligonucleotide primers (Table 4.8.1)
Total RNA (see Support Protocol 5)
Oligo$(dT)_{12\text{-}18}$ primer (Life Technologies or InVitrogen)
200 U/µl Superscript II reverse transcriptase with 5× first-strand buffer and 0.1 M dithiothreitol (DTT; Life Technologies or InVitrogen)
2 mM dNTP mix (Life Technologies or InVitrogen)
Random hexamers (Life Technologies or InVitrogen)
25 mM $MgCl_2$
5 U/µl Platinum *Taq* DNA polymerase (InVitrogen) and 10× PCR buffer (Life Technologies)
1% agarose gel in 1× TAE buffer (see recipe)
1 mg/ml ethidium bromide solution (see recipe)
100 bp or 1 Kb DNA ladder (Life Technologies)

Thin-walled PCR tubes
PCR thermocycler with heated lid
100 bp or 1 Kb DNA ladder (Life Technologies)
DNA/RNA gel electrophoresis apparatus and power supply

Additional reagents and equipment for performing agarose gel electrophoresis (*APPENDIX 3A*)

Table 4.8.1 PCR Primers for Amplification of Human and Mouse AhR, Arnt, CYP1A1, CYP1B1, and Housekeeping Gene Products (GAPDH and HPRT)

Target	5′-primer	3′-primer
Human PCR primers		
AhR	5′-GTGACTTGTACAGCATAATG-3′	5′-ATCTTCTGACACAGCTGTTG-3′
Arnt	5′-GAATTGGACATGGTACCAGG-3′	5′-AAGCTGATGGCTGGACAATG-3′
CYP1A1	5′-CCTTTGAGAAGGGCCACATC-3′	5′-GATGGGTTGACCCATAGCTT-3′
CYP1B1	5′-TATCCTGATGTGCAGACTCG-3′	5′-TCCTTGTTGATGAGGCCATC-3′
GAPDH	5′-GAGCCACATCGCTCAGAC-3′	5′-CTTCTCATGGTTCACACCC-3′
Mouse PCR Primers		
AhR	5′-GTGTCTGCCATTGTCTCTGTTC-3′	5′-CAATACAGACAAACAAATAGGCAG-3′
Arnt	5′-CCCCTCCTGTAACCATTGTC-3′	5′-ACGGAGGGAGAGGACTTTTAT-3′
CYP1A1	5′-CCAGGATGCTCACCCGCCCAG-3′	5′-ATGTAGGGTGAACAGAGGTGC-3′
CYP1B1	5′-AATGAGGAGTTCGGGCGCACA-3′	5′-GGCGTGTGGAATGGTGACAGG-3′
HPRT	5′-GTAATGATCAGTCAACGGGGGAC-3′	5′-CCAGCAAGCTTGCAACCTTAACCA-3′

CAUTION: Ethidium bromide is a mutagen and should be handled, stored, and disposed of with appropriate care.

NOTE: Use RNase-free water for solutions that come in direct contact with the RNA.

Oligonucleotide PCR Primers

1. Resuspend the single-stranded oligonucleotide primers in RNase-free water. Determine the DNA concentration by measuring the absorbance of an aliquot of each at 260 nm and using the following conversion:

   One A_{260} unit = 34 µg/ml for single-stranded oligonucleotides.

   Store primers at −20°C until use.

Perform first-strand cDNA synthesis using oligo(dT)$_{12\text{-}18}$ primer

2a. For a 20 µl reaction volume, incubate 2 µg total RNA and 200 ng oligo(dT)$_{12\text{-}18}$ primer for 10 min at 70°C to denature the RNA and then quickly chill the tubes on ice.

3a. To each reaction tube, add 4 µl of 5× first strand buffer, 2 µl of 0.1 M DTT, 1 µl of 2 mM dNTP mix, and RNase-free water to a final volume of 19 µl. Mix the reaction components gently and allow to equilibrate at 37°C for 2 min.

The 5× first-strand buffer consists of 250 mM Tris·Cl, pH 8.3, 375 mM KCl, and 15 mM $MgCl_2$. The buffer, along with 0.1 M DTT, is supplied with Superscript II reverse transcriptase.

4a. Add 1 µl (200 U) Superscript II reverse transcriptase and further incubate at 37°C for 1 hr. Terminate the reaction by heating 15 min at 70°C and adding 230 µl sterile water to each reaction. Store reactions up to 6 months at −20°C.

Perform first-strand cDNA synthesis using random hexamers

2b. Mix 5 µg total RNA with 100 ng random hexamer primers in a reaction volume of 12 µl. Incubate the mixture 10 min at 70°C to denature the RNA and then quickly chill the tubes on ice.

3b. Add 4 µl of 5× first strand buffer, 2 µl of 0.1 M DTT, and 1 µl of 2 mM dNTP mix to the reaction tube. Incubate 10 min at room temperature and then 2 min at 42°C.

4b. Add 1 µl (200 U) Superscript II reverse transcriptase and incubate 50 min at 42°C. Terminate the reaction by heating 15 min at 70°C. Store reactions up to 6 months at –20°C.

PCR amplify

5. For a 50 µl PCR amplification reaction, add the following to a thin-walled PCR tube:

   1 µl synthesized cDNA
   0.5 µl of 2 mM dNTP mix (20 µM final)
   1 µl of 25 mM $MgCl_2$ (0.5 mM final)
   5.0 µl of 10× PCR buffer
   50 pmoles of each primer (from step 1)
   1.25 U Platinum *Taq* DNA polymerase.

   The PCR primers for amplification of the human and mouse AhR, Arnt, CYP1A1, CYP1B1, glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and hypoxanthene phosphoribosyl transferase (HPRT) are presented in Table 4.8.1. Primers for these specific gene products from other species can readily be found in the published literature or they can be easily and efficiently designed using software programs such as Oligo 5.0 (Molecular Biology Insights). Primers can be synthesized inexpensively by a large number of commercial labs. GAPDH, HPRT, and β-actin are housekeeping genes whose expression can be used to demonstrate successful RT-PCR reactions and to normalize for variations in sample loading. In addition to the primers described here, primer sets for β-actin and GAPDH are also commercially available from Clontech Laboratories.

   Platinum Taq DNA Polymerase is one of many "hot start" polymerases. Such enzymes are often bound to an inhibitor and thus maintained in an inactive state until they reach 94°C whereby the inhibitor is released and the enzyme becomes activated. Hot start polymerases generally increase the sensitivity and specificity of the reaction and eliminate the effort associated with manual hot start methods.

   Use of thermocyclers without heated tops requires the addition of an oil overlay to prevent loss of the reaction to the top of the tube during thermocycling. If multiple reactions are to be performed, a master mix can be prepared to minimize variations in pipetting between reactions. Be sure to confirm the amplification conditions, magnesium concentrations and cycle number since variations can occur between PCR machines.

   10× PCR buffer consists of 500 mM KCl, 15 mM $MgCl_2$, 0.01% gelatin, and 100 mM Tris·Cl, pH 8.3 (at room temperature), and is supplied with Platinum Taq DNA polymerase.

6. Amplify cDNA samples using the programs given in Table 4.8.2.

   The number of cycles should be optimized to ensure amplification within the linear range of cycle number versus amount of product formed.

7. Electrophorese a 15-µl aliquot of each PCR reaction in a 1% agarose gel in 1× TAE buffer containing 0.24 µg/ml ethidium bromide (*APPENDIX 3A*).

   The ethidium bromide is added to the heated agarose gel solution prior to pouring.

8. Visualize the PCR products under UV light and determine the size of the amplified products by direct comparison to 100 bp or 1 Kb DNA molecular weight markers included in the same gel.

   The sizes of the expected fragments are shown in Table 4.8.3.

Table 4.8.2 PCR Program for Amplification of RT-PCR Products

Primer	Initial step[a]	Denaturation[b]	Annealing[b]	Extension[b]	Extension/hold
Human PCR primers					
AhR	2 min at 94°C	45 sec at 94°C	1 min at 55°C	1 min at 72°C	10 min at 72°C
Arnt	2 min at 94°C	45 sec at 94°C	1 min at 55°C	1 min at 72°C	10 min at 72°C
CYP1A1	2 min at 94°C	45 sec at 95°C	1 min at 55°C	1 min at 72°C	10 min at 72°C
CYP1B1	2 min at 94°C	45 sec at 95°C	1 min at 55°C	1 min at 72°C	10 min at 72°C
Mouse PCR Primers					
AhR	2 min at 94°C	45 sec at 94°C	1 min at 64°C	1 min at 72°C	10 min at 72°C
Arnt	2 min at 94°C	45 sec at 94°C	1 min at 58°C	1 min at 72°C	10 min at 72°C
CYP1A1	2 min at 94°C	1 min at 95°C	30 sec at 64°C	2 min at 72°C	10 min at 72°C
CYP1B1	2 min at 94°C	1 min at 95°C	30 sec at 64°C	2 min at 72°C	10 min at 72°C

[a]The initial step is to both denature the primers and activate the enzyme.

[b]These steps are to be performed for 30 to 35 cycles.

Table 4.8.3 Expected Size of the RT-PCR Amplification Products Using the Specific Primers Described in Table 4.8.1

	Expected PCR Product Size (bp)	
Gene Product	Human	Mouse
AhR	310	797
Arnt	310	647
CYP1A1	460	448
CYP1B1	320	797
GAPDH	430	—
HPRT	—	177

BASIC PROTOCOL 5

NORTHERN BLOT DETECTION OF HUMAN CYP1A1

Northern blot analysis is a useful technique for detecting the presence and size of mRNA for a particular gene, and whether the abundance of the message is altered by a particular treatment. Either total RNA or poly(A)$^+$ mRNA is isolated from tissues or cells and separated on a denaturing formaldehyde/agarose gel. The RNA is transferred to a nylon membrane and the message of interest is subsequently detected by hybridization with a radioactively or nonradioactively labeled cDNA probe. Transcripts can be quantified using a phosphorimager (Molecular Dynamics) and normalizing the signal to that obtained for a control message such as GAPDH or β-actin. Although northern blot analysis will detect moderately to highly expressed messages in total RNA, isolation of poly(A)$^+$ mRNA may be required to detect rare messages (also see *APPENDIX 3E*). Although the procedure described here is for northern blot analysis of CYP1A1 mRNA, it can readily be adapted for detection of AhR and Arnt mRNA, the cDNAs of which are available from numerous laboratories.

Materials

Total RNA sample (see Support Protocol 5)
RNase-free H_20
1 mg/ml ethidium bromide (see recipe)
Northern sample buffer (see recipe)

1× MOPS buffer (see recipe)
NaOH/SSC (see recipe)
Tris/SSC (see recipe)
10× SSC (see recipe)
hCYP1A1 plasmid (pBR322 vector; ATCC #57258)
*Eco*RI restriction endonuclease
GAPDH or β-Actin cDNA probes (Clontech Laboratories; optional)
Oligolabeling kit (Amersham Pharmacia Biotech):
  Reagent mix
  Klenow fragment
[α-^{32}P]dCTP (3000 Ci/mmol)
Spin-Pure Sephadex G50 spin column or equivalent
Scintillation cocktail
Northern hybridization buffer, 65°C (see recipe)
0.5× and 2× SSC (see recipe)/0.1% (w/v) SDS

Fluorescent ruler
Whatman 3 MM paper
1-ml screw-cap microcentrifuge tube
95°C water bath
Roller bottle hybridization oven and appropriate bottle
Additional reagents and equipment for northern blot analysis (*APPENDIX 3E*), agarose gel purification (*APPENDIX 3A*), and autoradiography (*APPENDIX 3D*)

NOTE: Use RNase-free water (Life Technologies) for solutions that come in direct contact with the RNA.

Prepare, run, and transfer gel

1. Prepare a formaldehyde/agarose gel as described (*APPENDIX 3E*).
2. Combine 10 to 20 µg total RNA, adjusted to 5 µl with RNase-free water, with 20 µl Northern sample buffer in a 0.5-ml microcentrifuge tube. Heat to 65°C for 15 min and immediately chill on ice. Add 1 µl of 1 mg/ml ethidium bromide, mix well, and briefly microcentrifuge to collect contents in the bottom of the tube.
3. Load 25 µl into a lane of the gel and electrophorese at 47 V for 3 to 3.5 hrs in 1× MOPS buffer (i.e., until the bromphenol blue band migrates ~75% the length of the gel).
4. View the gel under UV light to check the integrity of the 28S and 18S ribosomal bands.

   The human 28S band (5.0 Kb) should be approximately twice the intensity of the 18S band (1.9 Kb). If there is significant smearing or degradation of these bands, it is an indication that the RNA is degraded. If this is the case, it is best to prepare a new sample of RNA.

5. Use a fluorescent ruler to record the migration of the ribosomal bands and photograph the gel.
6. *For mRNA >6 Kb (optional):* Soak the gel 10 min in NaOH/SSC and then 10 min in Tris/SSC.

   Soaking the gel in NaOH/SSC results in partial lysis of the RNA and allows for more efficient transfer to the membrane.

7. Soak the gel 15 min in 10× SSC, discard the solution, and resoak in fresh 10× SSC for an additional 15 min.

8. Translocate the mRNA to the membrane by upward transfer as described (*APPENDIX 3E*), except use 10× SSC.

9. View the nylon "blot" under UV light to ensure the transfer was successful.

   The ethidium-stained ribosomal bands should be visible.

10. Place the membrane, RNA side up, on a piece of Whatman 3 MM filter paper and crosslink the RNA to the membrane as described (*APPENDIX 3E*). Place the blot between two pieces of Whatman 3 MM paper and bake in a vacuum oven 1 hr at 80°C.

Radiolabel the cDNA probe

11. Create a 1000-bp CYP1A1 probe by digesting 1 µg hCYP1A1 plasmid with 20 U *Eco*RI restriction endonuclease according to the manufacturer's instructions. Electrophorese the digest on a 1% agarose gel in 1× TAE buffer and gel-purify the appropriate fragment (*APPENDIX 3A*).

    A number of kits are currently available for gel purifying DNA fragments. Qiagen's gel extraction kit is simple, rapid, and inexpensive. This method involves cutting the appropriate fragment from the gel, dissolving it in the buffer provided, binding the DNA to a column, and washing several times before eluting the desired DNA fragment.

12. Radiolabel probes for CYP1A1 and if desired, either GAPDH or β-actin, using the Oligolabeling Kit (or equivalent) and the recommended protocols (briefly described below in steps 13 to 15).

    Probes for GAPDH or β-actin should also be used to normalize for sample loading and can be obtained from collaborative colleagues or from Clontech Laboratories. If detection of AhR and/or Arnt is desired, cDNA probes for these gene products are also readily obtained from numerous investigators.

13. Combine 50 ng DNA probe with water to a total volume of 34 µl in a 1-ml screw-cap microcentrifuge tube. Heat 3 min in a 95°C water bath to denature the DNA. Immediately place on ice 5 min and briefly microcentrifuge at top speed to collect contents in the bottom of the tube.

14. To this tube, add 10 µl reagent mix (dATP, dGTP, dTTP, and random hexadeoxyribonucleotides), 5 µl of 3000 Ci/mmol [α-^{32}P]dCTP (50 µCi), and water to a total of 49 µl. Add 1 µl Klenow fragment, mix gently, and incubate 37°C for 1 hr.

    This incubation results in random priming (labeling) of the resulting nascent DNA fragment.

15. Remove unincorporated nucleotides by running the sample through a Spin–Pure Sephadex G-50 spin column or equivalent as described by the supplier. Count 1 µl radioactive probe in 5 ml scintillation cocktail.

    A good "hot" probe should be between 1 to 2 × 10^6 cpm/µl; however, probes with lower specific activity may still work well, depending on the amount of desired mRNA in the sample. Radiolabeled probes may be kept at −20°C for 7 to 10 days; however, probes labeled at high specific activity will undergo significant radiolytic degradation if kept for much longer than 10 days. Thus, optimal results are obtained with a freshly labeled probe.

Hybridize and wash the blot

16. Place the membrane in a roller bottle with the RNA-bound side facing the inside of the bottle. Add 10 ml of 65°C northern hybridization buffer. Prehybridize the blot at 65°C in a roller bottle hybridization oven for 1 hr or more.

17. Incubate 1×10^7 cpm radiolabeled probe in 100 µl water in a screw-cap microcentrifuge tube for 3 min at 95°C. Chill immediately on ice and then add to the solution in the roller bottle. Allow to hybridize with mixing overnight at 65°C.

    The desired probe concentration should be ~1×10^6 cpm/ml northern hybridization buffer.

    If a hybridization roller apparatus is not available, prehybridization and hybridization can also be carried out at the same temperatures in a plastic box weighed down in a water bath.

18. Discard the hybridization solution into a radioactive waste container and wash the blot three times for 5 min each at 65°C in the hybridization oven with 10 ml of 2× SSC/0.1% (w/v) SDS. Measure the radioactive background of the blot in an area that should not have any RNA (i.e., a corner of the blot) with a Geiger counter. If the counts are still significantly above background, then wash the blot for an additional 15 to 30 min with 15 ml 0.5× SSC/0.1% SDS.

19. Continue washing the blot until the radioactivity of the blot is near background levels. Quickly wrap the blot in plastic wrap without letting it dry out and expose to X-ray film with one or two intensifying screens overnight at −80°C (*APPENDIX 3D*).

    The time required for adequate exposure of the blot to X-ray film can vary greatly and is dependent on the amount of CYP1A1 mRNA, the specific activity of the radiolabeled probe used, and the degree of hybridization.

ISOLATION OF TOTAL RNA

SUPPORT PROTOCOL 5

There are many kits and technologies available for isolating total RNA from animal tissues and cells. The procedure described here uses the RNeasy mini kit from Qiagen and their recommended protocol and supplied buffers. This protocol, briefly described below, has proven to yield total RNA of very high purity and integrity. In general, one RNeasy mini spin column, which consists of a silica gel based membrane, was found to be suitable for isolating ~50 µg of total RNA from one 100-mm plate of confluent cells. The maximum binding capacity of each column is 100 µg RNA. If the number of plates of cells are increased, the amount of solution used must be increased proportionately. An alternative method, which has also proven very useful, is the TRIzol reagent from Life Technologies. TRIzol is a phenol and guanidine isothiocyanate solution that lyses the cells and inactivates RNases. Following homogenization and addition of chloroform, centrifugation separates the solution into an organic and an aqueous phase. RNA partitions into the aqueous phase and is recovered by precipitation with isopropyl alcohol. RNases are ubiquitous, very stable and can easily be introduced into the RNA sample. Consequently, when working with RNA, great care should be taken to wear gloves at all times and to use RNase-free disposable plasticware whenever possible.

Materials

100-mm plates of confluent control (DMSO) and treated (TCDD) cells
Medium
RNeasy mini kit (Qiagen) containing:
  Qiagen denaturing buffer
  RNeasy mini spin column and collection tube
  Wash buffers
14.2 M 2-mercaptoethanol
100% and 70% ethanol, cold
3 M sodium acetate, RNase free (see recipe)
40 U/µl RNaseOUT recombinant ribonuclease inhibitor (Life Technologies)

1-ml plastic syringe with 20-G needle
65°C water bath

Additional reagents and equipment for trypsinizing cells (see Support Protocol 2).

NOTE: Use RNase-free water (Life Technologies) for solutions that come in direct contact with the RNA. All steps are performed at room temperature. Once RNA is isolated, it should be kept on ice or at −80°C.

1. Trypsinize plates of control (DMSO) and treated (TCDD) cells as described in the kit instructions (also see Support Protocol 2, step 2). Add the trypsinized cell suspension to 10 ml medium and then pellet the cells by centrifuging 5 min at 300 × *g*.
2. Remove the supernatant and resuspend the cell pellet by vortexing in 600 µl Qiagen denaturing buffer, supplied in the RNeasy mini kit, and 1% (v/v) 2-mercaptoethanol per one 100 mm-plate of cells (5×10^6 to 1×10^7 cells).

   This step ensures lysis of the plasma membrane and release of the RNA. RNases are inactivated in the presence of the denaturing solution which allows for isolation of intact RNA.
3. Homogenize the lysate by passing it through a sterile 1-ml plastic syringe with 20-G needle 20 times.

   This step reduces the viscosity of cell lysates and shears high-molecular-weight genomic DNA.

   Use one sterile syringe and needle per treatment.
4. To optimize binding of the RNA sample to the column, add an equivalent volume of 70% ethanol to the lysate, load the sample onto an RNeasy mini spin column sitting in a collection tube, and microcentrifuge the column 15 sec at 12,000 to 15,000 rpm.

   Successive aliquots may be loaded onto the column but remember to discard the flow-through after each addition.
5. Wash the column with the two different Qiagen wash buffers provided and microcentrifuge after each buffer addition for 15 sec at 12,000 to 15,000 rpm.
6. Transfer the column to a new collection tube, add 50 µl RNase-free water onto the column and microcentrifuge 1 min at 12,000 to 15,000 rpm. Add an additional 50 µl water to the column and microcentrifuge again to obtain a final RNA sample volume of ~100 µl.

   The resulting total RNA may be used directly for techniques such as RT-PCR where the concentration of RNA is not critical. In this case, the RNA concentration is determined as described in step 10 and the sample stored frozen at −80°C until use; however, to obtain the high concentration of RNA typically needed for use in northern blot analysis, it is recommended that the RNA be precipitated and resuspended in a smaller volume as described below.
7. To concentrate the RNA sample, add 10 µl RNase-free 3M sodium acetate and ~1 ml cold 100% ethanol to the RNA and vortex to mix. Store 2 hr to overnight at −80°C.
8. Collect the RNA precipitate by microcentrifuging 15 min at 12,000 to 15,000 rpm, 4°C. Wash the pellet with 1 ml of cold 70% ethanol.
9. Air dry the RNA pellet for 5 min, resuspend in 20 µl RNase-free water, and incubate in a 65°C water bath for 10 min to completely dissolve the RNA. Add 1 µl (40 U) of RNaseOUT recombinant ribonuclease inhibitor to the sample. Store frozen at −80°C until use (up to 1 year).

10. Calculate RNA concentration by determining the absorbance of an aliquot of the sample at 260 nm and using following information:

One A_{260} unit = 40 µg/ml RNA.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Blotto

Mix 5 g Carnation nonfat dry milk in 100 ml TBST (see recipe). Heat gently while stirring until milk dissolves. Do not allow the solution to become too hot to touch. Filter and chill on ice. Use fresh.

Final concentrations are 10 mM Tris·Cl, pH 8.0 (APPENDIX 2A), 150 mM NaCl, 0.05% (v/v) Tween 20, and 5% (w/v) nonfat milk.

DRE oligonucleotides, single stranded

Wild-type DRE oligonucleotides:

5′- GATCTGGCTCTTCTCACGCAACTCCG -3′

3′- ACCGAGAAGAGTGCGTTGAGGCCTAG -5′

Mutant DRE oligonucleotides:

5′- GATCTGGCTCTTCTCAC**A**CAACTCCG -3′

3′- ACCGAGAAGAGTG**T**GTTGAGGCCTAG -5′

Bold type indicates the single base mutation within the DRE core recognition site which disrupts AhR DNA binding (Yao and Denison, 1991)

Dextran-coated charcoal

Dissolve 50 mg of ~100,000 g/mol dextran in 100 ml HEDG buffer (see recipe) with stirring, followed by the addition of 500 mg Norit A charcoal (Fisher). Store up to 6 months at 4°C.

Ethidium bromide solution

Mix 50 mg ethidium bromide in 50 ml water and mix well. Store up to 6 months at 4°C in the dark.

CAUTION: *Ethidium bromide is a mutagen and must be handled carefully.*

Ficoll GRA gel-loading buffer

Mix 25 mg bromphenol blue, 2.5 g Ficoll 400, and 10 ml water in a 50-ml conical tube with cap. Mix on a shaker overnight at room temperature. Transfer 1-ml aliquots into 1.5-ml microcentrifuge tubes and microcentrifuge at ~12,000 rpm for 15 min, room temperature. Avoiding the pellet of undissolved material, transfer 800 µl supernatant to new 1.5-ml tubes. Store up to 6 months at room temperature.

Avoid transferring any undissolved dye particles into the final tubes since high concentrations of dyes added to GRA incubations act as DNA intercalating agents and disrupt protein-DNA binding interactions. The presence of excess dye in a given incubation/GRA lane (i.e., uneven addition) is readily apparent by comparing the blue color intensity between lanes of the gel.

HED buffer

Dissolve 5.96 g HEPES (FW 238.3 g/mol) and 372 mg disodium EDTA in 800 ml water, and adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, and 1 mM DTT.

HED2G buffer

Dissolve 5.96 g HEPES, 372 mg disodium EDTA, and 200 ml glycerol in 800 ml water, and adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, 1 mM DTT, and 20% (v/v) glycerol.

HEDG buffer

Dissolve 5.96 g HEPES, 372 mg disodium EDTA, and 100 ml glycerol in 800 ml water. Adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, 1 mM DTT, and 10% (v/v) glycerol.

HEDGK4 buffer

Dissolve 5.96 g HEPES, 372 mg disodium EDTA, 100 ml glycerol, and 29.82 g KCl in 800 ml of water, and adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, 1 mM DTT, 10% (v/v) glycerol, and 400 mM KCl.

HEDGK8 buffer

Dissolve 5.96 g HEPES, 372 mg disodium EDTA (disodium), 100 ml glycerol, and 59.65 g KCl in 800 ml of water, and adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, 1 mM DTT, 10% (v/v) glycerol, and 800 mM KCl.

HEG buffer

Dissolve 5.96 g HEPES, 372 mg disodium EDTA, and 100 ml glycerol in 800 ml water, and adjust pH to 7.5 with 10 N NaOH. Add water to 1000 ml. Store up to 1 month at 4°C.

Final concentrations are 25 mM HEPES, pH 7.5, 1 mM EDTA, and 10% (v/v) glycerol.

HEGT buffer

Add 5 ml Tween 80 (0.5% v/v final) to 1000 ml HEG buffer (see recipe) using a 5 ml micropipettor in which the opening of the disposable pipet tip has been enlarged to allow easy pipetting. Once the solution has been added, eject the tip into the buffer solution, add a magnetic stir bar, and stir until all of the Tween 80 goes into solution. Leave the tip stirring until the residual amount that remained in the tip after pipetting has also dissolved. Store up to 6 months at 4°C.

HEPES buffer

Dissolve 2.38 g HEPES (10 mM final) into 800 ml water and adjust the pH to 7.5 with 10 N NaOH. Add water to 1000 ml and store up to 2 months at 4°C.

Immunoblot tank buffer

Dissolve 3.03 g Tris·Cl (121.1 g/mol) and 14.4 g glycine into 1000 ml water, and transfer into a storage bottle. There is no pH adjustment. Add 1 g SDS and invert the bottle several times to mix. Store up to 2 months at room temperature.

Final concentrations are 25 mM Tris·Cl, 192 mM glycine, and 0.1% (w/v) SDS.

Immunoblot treatment buffer, 2×

Mix 2.5 ml of 0.5 M Tris·Cl, pH 6.8 (*APPENDIX 2A*), 4.0 ml of 10% (w/v) SDS, 2.0 ml glycerol, 2.0 mg bromphenol blue, and 0.31 g DTT. Add water to 10 ml. Store in 0.5-ml aliquots up to 6 months at −20°C.

Final concentrations are 125 mM Tris·Cl, pH 6.8, 4% (w/v) SDS, 20% (v/v) glycerol, 0.02% bromphenol blue, and 200 mM DTT.

Lysis buffer

Mix 1.5 ml PBS (see recipe), 7.5 µl Triton X-100, 15 µl of 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*), 15 µl of 0.2 M phenylmethylsulfonyl fluoride (PMSF), and 15 µl protease inhibitor cocktail for use with mammalian cell and tissue extracts in DMSO (Sigma). Make fresh immediately prior to use and chill on ice.

Final concentrations are 58 mM Na_2HPO_4, 17 mM NaH_2PO_4, pH 7.5, 68 mM NaCl, 0.5% (v/v) Triton X-100, 5 mM EDTA, 2 mM PMSF, and 1% (v/v) protease inhibitors.

MDH buffer

Dissolve 61 mg $MgCl_2$ and 0.596 g HEPES in 80 ml water, and adjust the pH to 7.5 with 10 N NaOH. Add water to 100 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 2 mM $MgCl_2$, 1 mM DTT, and 2 mM HEPES, pH 7.5.

MDHK buffer

Dissolve 610 mg $MgCl_2$, 5.96 g HEPES, and 7.456 g KCl in 800 ml water. Adjust the pH to 7.5 with 10 N NaOH, and add water to 1000 ml. Store up to 1 month at 4°C. Just prior to use, add 154 mg DTT.

Final concentrations are 3 mM $MgCl_2$, 1 mM DTT, 25 mM HEPES, pH 7.5, and 100 mM KCl.

MOPS, 10×

Combine 42 g MOPS (FW 209.26), 17 ml of 3 M sodium acetate, and 20 ml of 0.5 M EDTA (disodium; *APPENDIX 2A*) in 900 ml of water. Adjust pH to 7.0 with 10 N NaOH and add water to 1000 ml. Store up to 1 month at 4°C.

Final concentrations are 200 mM MOPS, pH 7.0, 50 mM sodium acetate, and 10 mM EDTA.

NaOH/SSC

Mix 2.5 ml of 10 N NaOH (*APPENDIX 2A*) and 25 ml of 20× SSC (see recipe), and add water to 500 ml. Store up to one month at room temperature.

Final concentrations are 500 mM NaOH, 150 mM NaCl, and 15 mM sodium citrate.

Northern hybridization buffer

Combine 12.5 ml of 1 M monobasic sodium phosphate, pH 7.5, 0.1 ml of 0.5 M EDTA, pH 7.5 (*APPENDIX 2A*), 35 ml of 10% (w/v) SDS (*APPENDIX 2A*), and water to 50 ml. Store up to 6 months at room temperature.

Final concentrations are 25 mM sodium phosphate, pH 7.5, 1 mM EDTA, and 7% (w/v) SDS.

Northern sample buffer

Combine 0.75 ml formamide, 0.24 ml formaldehyde, 0.15 ml of 10× MOPS (see recipe), and 0.2 ml of 50% (v/v) glycerol/0.25% bromphenol blue in water. Store up to 1 month at −20°C.

Oligonucleotide reannealing buffer

Dissolve 405 mg Tris·Cl, 132 mg $MgCl_2$, 16 mg spermidine, and 242 mg EDTA in 45 ml water, and adjust the pH to 7.5 with 12 N HCl. Adjust volume to 50 ml with water. Store up to 6 months at −20°C. Just prior to use, add 154 mg DTT.

Final concentrations are 67 mM Tris·Cl, pH 7.5, 1.3 mM $MgCl_2$, 7 mM DTT, 1.3 mM spermidine, and 13 mM EDTA.

PAGE running gel buffer, 4×

Dissolve 36.3 g Tris·Cl (121.1 g/mol) in 150 ml water and adjust the pH to 8.8 with 12 N HCl. Bring to 200 ml with water. Store up to 1 month at 4°C in the dark.

Final concentration is 1.5 M Tris·Cl, pH 8.8.

PAGE stacking gel buffer, 4×

Dissolve 3.0 g Tris (121.1 g/mol) in 40 ml water and adjust the pH to 6.8 with 12 N HCl. Bring to 50 ml with water. Store up to 1 month at 4°C in the dark.

Final concentration is 500 mM Tris·Cl, pH 6.8.

Phosphate buffered saline (PBS)

Dissolve 1.55 g $Na_2HPO_4 \cdot 7\ H_2O$, 0.23 g NaH_2PO_4, and 400 mM NaCl in 80 ml water, and adjust to pH 7.4 with 1 N NaOH. Add water to 100 ml. Store up to 3 months at room temperature.

Final concentrations are 58 mM Na_2HPO_4 and 17 mM NaH_2PO_4, pH 7.4, and 68 mM NaCl.

Sephadex G-50 spin column

There are numerous commercially available Sephadex-G-50 spin columns for DNA radiolabeling experiments (such as the Spin-pure G-50 columns from CpG) and detailed instructions are provided for their use by the manufacturer. Alternatively, spin columns are relatively easy to make. To prepare a spin column, plug a 1-ml plastic syringe with a small amount of glass wool and fill the syringe with a Sephadex G-50 slurry in TE buffer (see recipe) using a long 9-in. Pasteur pipet. Insert the syringe into a 15-ml Corex tube which contains a capless 1.5-ml microcentrifuge tube for sample collection (the tip of the syringe should reach into the tube itself). Centrifuge the column in a swinging bucket rotor in a benchtop centrifuge for 2 min at 1000 × g, room temperature. Discard the capless microcentrifuge tube containing the excess packing buffer and replace it with a clean capless tube and reinsert the column into the tube. This spin column is now ready for radiolabeled sample addition. Use fresh.

Sodium acetate, 3 M

Dissolve 123 g sodium acetate in 240 ml water (RNase-free if appropriate) and adjust pH to 4.6 with glacial acetic acid. Add water to 500 ml. Store up to 1 year at room temperature.

SSC, 0.5×, 2×, 10×, and 20×

Make 20× SSC by dissolving 175.3 g NaCl and 88.2 g sodium citrate into 600 ml water. Add water to 1000 ml. Store up to 2 months at room temperature. Dilute to appropriate concentration (e.g., 0.5×, 2×, 10×) as necessary.

Final concentrations of the 20× solution are 3 M NaCl and 300 mM sodium citrate.

Stripping buffer

Dissolve 0.757 g Tris·Cl, 2 g SDS, and 781 µl 2-mercaptoethanol in 80 ml water. Adjust the pH to 6.8 with 12 N HCl and add water to 100 ml. Store up to 1 month at room temperature.

Final concentration is 62.5 mM Tris·Cl, pH 6.8, 2% (w/v) SDS, and 100 mM 2-mercaptoethanol.

T4 kinase buffer

Mix 660 µl of 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*), 10 µl of 1M spermidine, 100 µl of 1 M $MgCl_2$, 150 µl of 1 M DTT, 40 µl of 500 mg/ml BSA, and 100 ml water. Store in 50-µl aliquots up to 1 year at −80°C.

Final concentrations are 623 mM Tris·Cl, pH 7.5, 9 mM spermidine, 94 mM $MgCl_2$, 141 mM DTT, and 20 mg (w/v) BSA.

TAE buffer, 1× and 10×

Mix 67 ml of 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*), 11 ml of 3 M sodium acetate (see recipe), and 20 ml of 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*) in 700 ml of water. Adjust volume to 1000 ml. Store up to 4 months at room temperature. Dilute with water to make 1× working solution.

Final concentrations are 67 mM Tris·Cl, pH 8.0, 33 mM sodium acetate, and 10 mM EDTA.

TBS (Tris buffered saline)

Dissolve 8.77 g NaCl in 800 ml water. Add 10 ml of 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*). Add water to 1000 ml. Store up to 6 months at room temperature.

Final concentrations are 10 mM Tris·Cl, pH 8.0 and 150 mM NaCl.

TBST

Mix 50 µl of Tween 20 in 100 ml TBS (see recipe). Prepare fresh.

Final concentrations are: 10 mM Tris, pH 8.0, 150 mM NaCl, 0.05% (v/v) Tween 20.

TE buffer

Dissolve 1.21 g Tris (121.1 g/mol) and 0.37 g disodium EDTA into 800 ml water. Adjust the pH to 8.0 with 12 N HCl. Add water to 1000 ml. Store up to 6 months at room temperature.

Final concentrations are 10 mM Tris·Cl, pH 8.0, and 0.1 mM EDTA.

Towbin transfer buffer

Dissolve 3.03 g Tris·Cl (121.1 g/mol), 14.4 g glycine, 0.1 g SDS, and 200 ml methanol into 600 ml water. There is no pH adjustment. Add water to 1000 ml. Store up to 1 month at room temperature.

Final concentrations are 25 mM Tris·Cl, 192 mM glycine, 20% (v/v) methanol, and 0.01% (w/v) SDS.

Tris/SSC

Mix 50 ml of 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*) with 25 ml of 20× SSC (see recipe), and add water to 500 ml. Store up to 2 months at room temperature.

Final concentrations are 100 mM Tris·Cl, pH 7.5, 150 mM NaCl, and 15 mM sodium citrate.

COMMENTARY

Background Information

The existence of the AhR signal transduction pathway was originally suggested by the results of biochemical and genetic studies on the mechanism of induction of cytochrome P_1 450 (now referred to as CYP1A1). Utilizing a dextran-coated charcoal (DCC) binding assay, Poland and coworkers (1976) provided the first direct evidence for the existence of a [^{3}H]TCDD-specific binding protein (the AhR) in hepatic cytosol from mice. Subsequent studies revealed that the mechanism of AhR action resembled that established for steroid hormone receptors and their regulation of gene expression, although the AhR is now known to be a member of a distinctly different family of nuclear transcription factors termed basic helix-loop-helix-PAS proteins (Schmidt and Bradfield, 1996); however, researchers examining AhR and AhR action have continued to adapt experimental approaches and techniques used in the analysis of steroid hormone receptor

action to characterize the AhR and AhR-dependent gene expression. The methodological approaches described in this unit allow measurement and analysis of each step of the AhR signal transduction pathway, from initial ligand binding to gene expression.

The presence and/or expression of the AhR and Arnt in cell or tissue extracts has been demonstrated by measurement of AhR mRNA using northern blot (Hoffman et al., 1991; Burbach et al., 1992) or RT-PCR analysis (Hakkola et al., 1997), and AhR protein (using immunoblot analysis; Holmes and Pollenz, 1997). Although detection of mRNA for a given gene product in a sample extract clearly demonstrates expression of the desired gene, it provides no information as to whether the resulting protein is actually produced in the target cell/tissue. Confirmation of the presence of the AhR/Arnt in a given cell or tissue extract requires use of an AhR- or Arnt-specific antibody in immunoprecipitation and/or immunoblot analysis. In addition, these reagents can also be used to demonstrate AhR/Arnt expression in intact tissues and cells using immunohistochemical and in situ approaches (Tscheudschilsuren et al., 1999). These approaches and others have been used to demonstrate the presence and expression of the AhR in a wide variety of species and tissues (Hahn, 1999). In addition to direct detection of the proteins, the presence of the AhR and/or AhR-dependent signal transduction pathway can be determined by functional analysis (AhR ligand binding, nuclear localization, and DNA binding and gene expression).

Several approaches have been described for the analysis of AhR ligand binding and the majority of these assays utilize [^{3}H]TCDD as the radioligand. These assays are based on the measurement of bound [^{3}H]TCDD in the absence and presence of an excess of unlabeled competitor ligand (generally TCDF). The reduction in [^{3}H]TCDD ligand binding in the presence of TCDF provides a quantitative measure of the amount of [^{3}H]TCDD specific binding. The DCC binding assay, a procedure based on the ability of the charcoal to bind and remove unbound and loosely bound [^{3}H]TCDD from the binding incubation, was used in initial analysis of AhR ligand binding (Poland et al., 1976); however, the extremely high levels of nonspecific [^{3}H]TCDD binding commonly observed with this assay made accurate and consistent ligand binding assessment problematic. The hydroxyapatite (HAP) assay (see Alternate Protocol 1) is based on the ability of proteins in the [^{3}H]TCDD binding incubations to bind to the HAP and the free or loosely bound radiolabel is removed by repeated washing of the HAP pellet with buffer containing Tween 80 detergent (Gasiewicz and Neal, 1982). A similar rapid binding assay based on the ability of protamine sulfate to quantitatively precipitate [^{3}H]TCDD binding proteins has been described (Denison et al., 1984) and like the HAP assay, free or loosely bound radiolabel is removed by repeated washing of the pellet with buffer containing detergent. Perhaps the most sensitive AhR ligand binding assay that has been developed utilizes a high-specific-activity [^{125}I]2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin ligand (Bradfield and Poland, 1988); however, the relatively short half-life of the radiolabel requires periodic preparation of new radio-iodination reactions to be carried out. In addition, the limited availability of the reagent necessary to prepare the radioiodinated ligand and the additional biohazard and containment associated with the use of this radiolabel, makes this assay somewhat impractical for general ligand binding analysis. Still, when extremely high sensitivity ligand binding assays are needed, use of the [^{125}I]ligand binding assay should be considered. Even given its slightly lower sensitivity, the relatively high specific activity of the [^{3}H]TCDD ligand (10 to 50 Ci/mmol) is generally sufficient for most analysis, and coupled with the commercial availability of this radioligand in high purity makes it the ligand of choice for most AhR ligand binding analysis.

The HAP assay has been used by numerous investigators and it allows relatively rapid binding analysis of large numbers of samples. It is the approach the authors most often use when determining ligand binding affinity (i.e., by saturation binding analysis) and for large-scale screening for competitive AhR ligands; however, although the HAP assay might reveal a decrease in [^{3}H]TCDD binding in the presence of a competitor chemical, this assay does not absolutely confirm that the reduction in bound radioactivity actually results from competitive displacement of [^{3}H]TCDD from the AhR, since only radioactivity present in the HAP pellet is being measured. Since it is always possible that the reduction in binding can result from a loss of [^{3}H]TCDD binding to some nonspecific site or sites, it is always prudent to confirm the direct competitive displacement of [^{3}H]TCDD from the AhR by unknown chemicals using the SDG assay (see Basic Protocol 1). This method allows separation of proteins

by size and shape in the gradient, and as such, it allows direct determination and visualization of the binding of [^{3}H]TCDD to the cytosolic AhR and its competitive displacement by unlabeled AhR ligands (Okey et al., 1979; Tsai and Okey, 1981; Denison et al., 1986). The presence of other [^{3}H]TCDD binding peaks and elevated binding background commonly observed with radiolabeled material of lower purity (resulting from radiolysis of the chemical and/or due to the reduced purity of the starting material used for [^{3}H]-labeling) is readily observed using the SDG assay. In addition to analysis of cytosolic AhR ligand binding, SDG analysis can also be carried out using nuclear extracts from intact cells exposed to [^{3}H]TCDD in the absence and presence of unlabeled TCDF competitor. Although the SDG method is somewhat time consuming and is not amenable for analysis of large numbers of samples (as compared to the HAP method), it does allow measurement of AhR ligand binding and direct confirmation of the ability of a chemical or chemicals to displace [^{3}H]TCDD from the AhR. Overall, the HAP and SDG assays provide complementary approaches to measure ligand binding, with each assay having unique advantages and disadvantages.

Measurement of AhR transformation and DNA binding is carried out using gel retardation analysis (see Basic Protocol 2) and can be performed using either crude cytosol or nuclear extracts. Gel retardation analysis provides a sensitive and specific assay system to examine and characterize the binding of transformed ligand AhR complex to its specific DNA recognition site, the dioxin responsive element (DRE), and is based on the ability of protein-bound DNA complexes to be separated from protein-free DNA in nondenaturing polyacrylamide gels (Denison et al., 1988a,b; Denison and Yao, 1991). This technique is a significant improvement over earlier techniques that measured the DNA binding activity of transformed AhR complexes by their ability to bind to DNA cellulose (Cuthill and Poellinger, 1988; Prokipcak et al., 1990). This latter assay only assesses the ability of the AhR complex to bind to DNA and does not differentiate between nonspecific and specific DNA binding. Although transformation of the AhR into its DNA binding form requires its dimerization with Arnt, a nuclear protein, AhR transformation and DNA binding in vitro can be carried out using cytosol preparations (Denison and Yao, 1991; Yao and Denison, 1991). This is due to the fact that Arnt is readily released from the nucleus during cell homogenization and thus is present and available to bind to the AhR in cytosol preparations. Thus, gel retardation analysis using cytosolic preparations provides an avenue for rapid analysis of large numbers of chemicals or chemical mixtures for their ability to stimulate AhR transformation and DNA binding in vitro; however, although this method allows demonstration of the direct ability of a chemical to activate the AhR in vitro, it does not provide any information as to whether the chemical can stimulate AhR transformation and DNA binding in intact cells. Final confirmation of this is carried out by gel retardation analysis of nuclear extracts prepared from control and chemical-treated cells. Detection of transformed AhR complexes in nuclear extracts from exposed cells in a ligand-dependent manner confirms the ability of the inducing chemical to stimulate AhR transformation, nuclear accumulation, and DNA binding of the ligand AhR complex in intact cells. The DNA binding activity of the nuclear AhR complexes is indirectly confirmed by the fact that these AhR complexes are only released from the nuclei by conditions that disrupt protein DNA interactions (i.e., high salt or the addition of DNA intercalating agents). The presence of nuclear AhR complexes can also be demonstrated by SDG analysis of nuclear extracts from cells treated with [^{3}H]TCDD in the absence or presence of unlabeled TCDF (Prokipcak et al., 1990).

The above methodological approaches allow detection and characterization of the functionality of the AhR; however, the mere presence of the AhR and Arnt as well as nuclear accumulation of transformed AhR complexes do not guarantee that the AhR signal transduction pathway is fully functional in a given tissue or cell line. Since AhR and Arnt have been identified in cells which lack inducible AhR-dependent gene expression (Walsh et al., 1996), the functional activity of the AhR signal transduction pathway should be confirmed by demonstration of TCDD-inducible, AhR-dependent gene expression (see Basic Protocols 4 and 5). Inducible expression of a gene known to be regulated by the AhR (such as CYP1A1 and CYP1B1) provides indirect evidence for the presence of a functional AhR signaling system in the target tissue. Measurement of induction of CYP1A1/1B1 gene expression is readily accomplished by examining mRNA levels for each enzyme by northern blot analysis and/or measurement of increased CYP-dependent enzyme activity (i.e., ethoxyresorufin *O*-deethylase activity in the case of CYP1A1;

Safe, 1990). Demonstration of TCDD-inducible expression of a DRE-linked reporter gene in transfected cells has also been used to confirm the presence of a fully functional AhR signal transduction pathway in a given cell line (Garrison et al., 1996). In some instances, CYPs are not inducible in a given tissue/cell, although a functional AhR signaling pathway is present. In this instance, analysis of the expression (mRNA, protein) of other genes known to be induced in a TCDD- and AhR-dependent manner (reviewed in Denison et al., 1998a) should be carried out. Overall, the above procedures for detection of the AhR, Arnt, and AhR-dependent gene expression are well established and all of the necessary reagents are readily available from researchers and commercial sources.

Critical Parameters and Troubleshooting

Sucrose density gradient (SDG) analysis of cytosolic AhR binding

Perhaps one of the most important parameters to consider in the AhR ligand binding assay (see Basic Protocol 1) is in regards to the [^{3}H]TCDD ligand itself, specifically in regard to its radio- and chemical purity. If the batch of [^{3}H]TCDD used for ligand binding assay is not of high purity, then increased background nonspecific binding can occur, leading to inaccurate estimates of AhR ligand binding, causing binding affinity to be inaccurate. Another important issue with regard to the amount of [^{3}H]TCDD in a binding assay is when the competitive binding by weak AhR ligands is being examined. If [^{3}H]TCDD is added to an incubation at much higher concentrations than needed to saturate the AhR (i.e., 20 to 40 nM), it is very unlikely that a weak ligand (one with a K_d in the low to mid micromolar range) would be able to compete effectively. This is due to the fact that the "free" [^{3}H]TCDD (which has a K_d in the picomolar range) would compete more effectively for the AhR because of its significantly greater binding affinity. In this instance, the authors have found that by increasing the concentration of the weak competitor and reducing the [^{3}H]TCDD concentration to just saturating (i.e., 5 nM per 5 mg cytosolic protein/ml), thus minimizing the amount of "free" [^{3}H]TCDD available to compete, that direct ligand binding of weak AhR ligands to the AhR can be observed (Denison et al., 1998c).

A second important parameter to consider with the SDG assay is that of the concentration of DCC used to strip unbound and loosely bound [^{3}H]TCDD from solution prior to centrifugation. The concentration of DCC added to the incubation is critical since too little will not remove the [^{3}H]TCDD and too much can strip [^{3}H]TCDD off the AhR. The authors have found that the DCC concentration described in this unit is optimal for rat, mouse, and guinea pig cytosolic AhRs; however, the DCC concentration should be optimized for each specific system and extract. For those AhRs with low TCDD binding affinity (i.e., human and nonmammalian species) DCC at the above concentration will likely strip off some of the ligand from the AhR, resulting in underestimation or lack of observable [^{3}H]TCDD specific binding. In fact, this is the reason that little [^{3}H]TCDD binding to human AhR was detected for many years. In order to analyze [^{3}H]TCDD binding to these lower affinity AhRs, the DCC concentration must be reduced. Preliminary SDG analysis using various DCC concentrations will allow optimization of the concentration needed to detect ligand binding in specific samples. In addition, sodium molybdate (20 mM) has been shown to help stabilize the AhR and is commonly included in buffers when analysis of low affinity AhR is planned.

Hydroxyapatite (HAP) solid-phase analysis of AhR ligand binding

Although the HAP assay (see Alternate Protocol 1) is less complicated than the SDG assay, there are still several aspects that need to be considered. Like the SDG assay, concerns regarding the purity and solubility limitations of TCDD also apply in the HAP assay and as a rule, the authors almost never exceed 10 nM [^{3}H]TCDD in an incubation containing 2 mg protein/ml. One major problem which can arise with the HAP assay is high [^{3}H]TCDD background activity in the HAP pellets. Inclusion of one or more additional washes with the Tween 80–containing wash buffer should reduce the background to acceptable levels, although it should be noted that the background [^{3}H]TCDD will never drop to zero (see Table 4.8.1 for an example of typical binding and nonspecific background results). Although one might be tempted to increase the amount of Tween 80 in the wash buffer in order to reduce background activity, it is best not to do this since the increased detergent could also strip the [^{3}H]TCDD off the AhR. In fact, for those receptors with lower TCDD binding affinities

(i.e., humans and nonmammalian species), the amount of detergent currently in the assay may strip some ligand from these AhRs. Thus, the HAP assay may need to be modified to accurately measure AhR ligand binding in species with low-affinity AhRs. Reductions in the amount of Tween 80 in the wash buffer and inclusion of additional wash steps would be possibilities to consider if problems arise in these specific situations. Another parameter that is important if alterations in the assay protocol are being considered is the limited protein binding capacity of the HAP. If the amount of specific binding detected by HAP is relatively low, do not immediately assume that it is possible to simply add more incubation mixture to the HAP pellet. If the protein binding capacity of the HAP pellet is exceeded, then the additional protein will not bind but be lost during the buffer washes, resulting in an underestimation of ligand binding activity.

Gel retardation analysis of AhR-DNA binding

There are several critical parameters relative to the electrophoresis and binding reactions that can affect the results obtained with the gel retardation assay method. Using the low ionic strength TAE buffer electrophoresis conditions described for the gel retardation assay, buffer recycling is absolutely required. Failure to recycle the buffer will exhaust its buffering capacity and the resulting change in pH of several units which develops between the top and bottom reservoirs will disrupt protein DNA complex formation. Alternative buffers using a greater buffering capacity have been described, but their utility in analysis of AhR-DNA binding remains to be determined.

The type and amount of nonspecific carrier DNA added to the binding incubation is also critically important in gel retardation assays. The authors have tested numerous types of carrier DNAs and found that poly(dI·dC) consistently produced the greatest amount of TCDD-inducible protein DNA complex formation. Other carrier DNAs do work in the assay, but they were found to competitively reduce the amount of TCDD-inducible complex at only moderate competitor concentrations. Although high concentrations of poly(dI·dC) will also competitively inhibit TCDD-inducible protein [^{32}P]DRE complex formation, transformed AhR complexes bind to poly(dI·dC) at a 1400-fold lower affinity compared to the DRE (Yao and Denison, 1991), and as long as the amount of poly(dI·dC) is maintained at a moderate ratio it is an effective carrier DNA in AhR gel retardation assays. On the other hand, if too little or no carrier DNA is added to DNA binding reactions using nuclear extracts, all of the radiolabeled probe will remain bound in the well and none will enter the gel. In contrast, if too little or no carrier DNA is added to DNA binding reactions using cytosolic extracts, the complexes still enter the gel and are resolved normally, but additional protein DNA complexes will be produced and the total amount of AhR-DRE complex formation is reduced (Yao and Denison, 1991); therefore, the optimal ratio of protein to poly(dI·dC) must be maintained. The poly(dI·dC) concentration used with cytosolic samples is generally in the range of 100 to 400 ng per incubation and the amount for nuclear extracts is 1 to 3 μg per incubation; however, the exact amount of poly(dI·dC) needed in a given incubation is not only species- and tissue-specific, but also dependent upon the protein concentration and the specific lot of poly(dI·dC) used. Identical concentrations (based on their absorbance at 260 nm) of different lots of the same poly(dI·dC) product (from the same company) are not necessarily equally effective as carrier DNA. Thus, with each new lot number of poly(dI·dC) used, the optimal concentration needed for maximal AhR DRE complex formation needs to be established.

Immunoblot of AhR and Arnt

A key issue with regard to the immunoblotting protocols (see Basic Protocol 3) is to minimize proteolysis and degradation of the protein sample. This is manifested by smearing of the proteins in the gel and/or loss of proteins. Accordingly, keep the samples on ice prior to boiling and make sure to add sufficient amounts of the protease inhibitor cocktail to the lysis buffer. It is also important to note that AhR antibodies will bind nonspecifically to proteins in addition to the AhR and as such, multiple antibody positive bands will always be present on immunoblots using AhR antibodies. In the authors' hands, two smaller bands always appear on AhR immunoblots, one at ~45 and one at ~25 kDa. Immunoblots with Arnt antibodies tend to be much cleaner.

Detection by RT-PCR and northern blot analysis

Perhaps the most important factor in ensuring success in RT-PCR (see Basic Protocol 4) or northern blot analysis (see Basic Protocol 5) is the quality of the RNA sample. Since RNases

are very stable, ubiquitous, and active enzymes, it is important to avoid contaminating the RNA sample with them either during the RNA isolation procedure or during RNA analysis. A clean work area, and the use of gloves and sterile disposable plasticware when working with RNA will help minimize RNase contamination. RNA obtained from the Qiagen RNeasy columns is generally of high purity; however, other methods of RNA isolation may not yield such clean RNA. The ratio of the absorbance readings at 260 and 280 nm (A_{260}/A_{280}) will give some indication of the purity of the sample. Pure RNA has an A_{260}/A_{280} ratio of 1.8 to 2.1 in TE buffered at pH 7.5 to 8.0. A low A_{260}/A_{280} ratio indicates contamination with protein and may require an additional acidic extraction step with phenol/chloroform/isoamyl alcohol, pH 4.3 to 4.7 (*APPENDIX 3A*). The integrity of the RNA can also be determined by examining an aliquot of the RNA by denaturing agarose gel electrophoresis and ethidium bromide staining. A nondenaturing gel can be used but be sure to use nuclease-free water for the gel and dye. The 18S and 28S ribosomal bands should appear as sharp bands and there should be ~2:1 ratio between ethidium bromide staining of the 28S and 18S bands. With significant RNA degradation, the 28S band will degrade to an 18S-like species. If there is a large amount of smearing towards the positive electrode or if the 18S band appears more intense than the 28S band it is best to isolate fresh RNA before continuing with the experiment.

When conducting RT-PCR using primers other than those indicated in this protocol, a number of variables including primer concentration, magnesium chloride concentration, annealing temperature, and cycle number may have to be optimized and determined empirically (*APPENDIX 3C*). Optimal magnesium chloride concentration can range from 1.5 to 4.0 mM. The use of a gradient cycler such as the Robocycler Gradient 40 from Stratagene allows rapid optimization of several parameters simultaneously.

Anticipated Results

Ligand binding

Techniques for measurement of AhR ligand binding can vary significantly; however, the ultimate quantitation of the amount of [^{3}H]TCDD-specific binding by these methods is essentially the same. In all cases, the amount of [^{3}H]TCDD bound to the AhR (specific binding) is the difference between the amount of [^{3}H]TCDD bound in the absence of competitor (total binding) and the total amount of [^{3}H]TCDD bound in the presence of TCDF or other chemical (nonspecific binding).

HAP assay results of the binding of [^{3}H]TCDD to guinea pig hepatic cytosol are shown in Table 4.8.4. Subtraction of the [^{3}H]TCDD (dpms) present in a nonspecific binding sample (column 2) from the [^{3}H]TCDD (dpms) present in the total binding sample (column 1) yields the amount of [^{3}H]TCDD specifically bound to proteins in the HAP pellet (column 3); however, final binding results are expressed as the number of fmoles of [^{3}H]TCDD specifically bound/mg protein. To normalize the specific binding to that in 1 mg of protein, the HAP-specific binding results in column 3 are multiplied by 2.5, since 0.4 mg protein (0.2 ml of the original 2 mg/ml incubation) was added to the HAP pellet. The resulting values (column 4) represent the total amount of [^{3}H]TCDD specific binding (dpms) per milligram cytosolic protein. To determine the actual concentration of [^{3}H[TCDD bound, the disintegrations per minute/milligram protein value must be corrected to a molar concentration. This is accomplished by simply correcting the specific binding value using the specific activity of the [^{3}H]TCDD used in the experiment. The specific activity of [^{3}H]TCDD commonly used for AhR binding assays is in the range of

Table 4.8.4 Results and Calculations of the Specific Binding of [^{3}H]TCDD[a] to Guinea Pig Hepatic Cytosol as Determined Using the HAP Binding Assay

Total binding (dpm/HAP pellet)	Nonspecific binding (dpm/HAP pellet)	Specific binding (dpm/HAP pellet)	Specific binding (dpm/mg protein)	Specific binding (fmoles/mg protein)
3697	2212	1485	3712	84.4
3710	2172	1538	3845	86.6
3617	2235	1382	3455	77.8

[a]The specific activity of the radiolabel was 20 Ci/mmol (1 Ci = 2.22×10^{12} dpm).

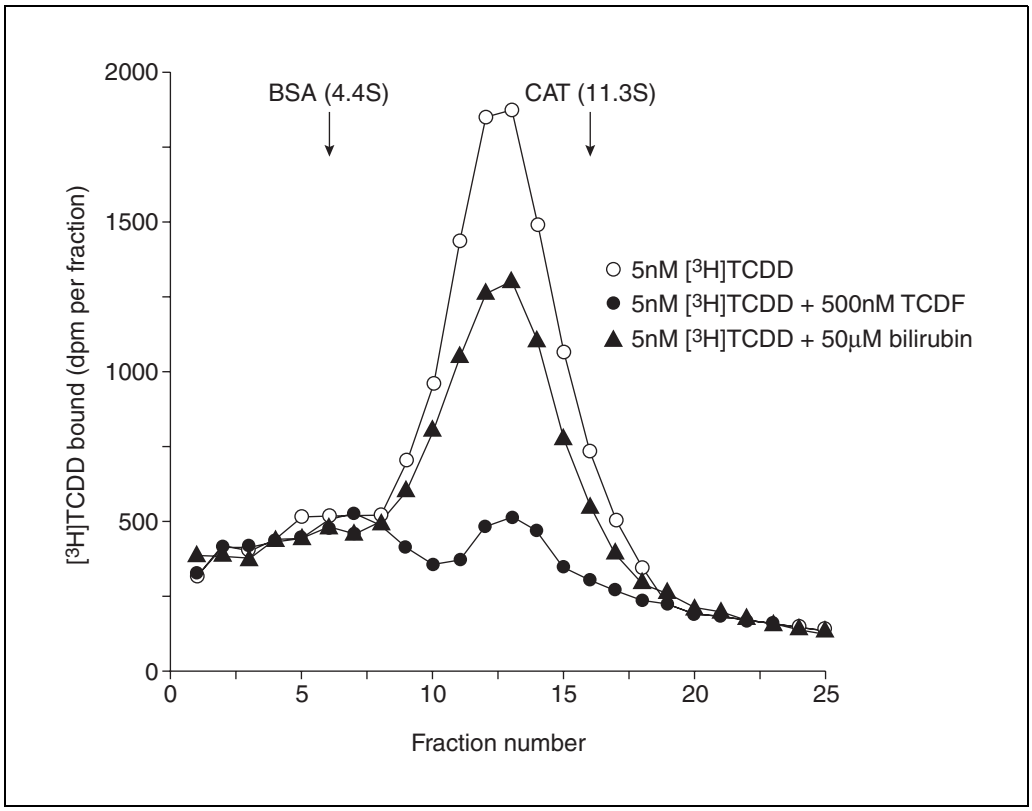

Figure 4.8.2 Sucrose density gradient analysis of the competitive binding between [^{3}H]TCDD, TCDF, and bilirubin to guinea pig hepatic cytosol. Guinea pig hepatic cytosol (5 mg protein/ml) was incubated with 5 nM [^{3}H]TCDD in the absence or presence of 1 μM TCDF or 50 μM bilirubin for 1 hr at 4°C. Aliquots (300 μl) of each incubation were analyzed by sucrose density gradient centrifugation.

10 to 30 Ci/mmol. For these experiments, the specific activity of the radiolabel was 20 Ci/mmol, and since 1 Ci is equal to 2.22×10^{12} dpm, the specific activity of the radiolabeled [^{3}H]TCDD is 4.44×10^{13} dpms/mmol or 44.4 dpms/fmole. The specific binding (dpm/milligram) is divided by the specific activity of the [^{3}H]TCDD (44.4 dpm/fmole) and the final calculated amount of [^{3}H]TCDD specific binding to guinea pig hepatic cytosol in these triplicate HAP binding incubations was between 77.8 and 86.6 fmoles/mg protein (column 5).

With the SDG assay, the calculation of specific binding requires comparison of the radioactivity gradient profiles of two different tubes after alignment of one tube of total binding ([^{3}H]TCDD alone) and one tube of nonspecific binding ([^{3}H]TCDD + TCDF). In the standard SDG experiments, [^{14}C]BSA and [^{14}C]CAT are included in each gradient as internal sedimentation control. Alignment of the [^{14}C]BSA and [^{14}C]CAT peaks between two gradients corrects for any differences in the linearity between the two gradients and allows for a more accurate calculation of [^{3}H]TCDD-specific binding. An example of a typical sucrose gradient result of [^{3}H]TCDD specific binding to guinea pig hepatic cytosol (the same cytosol used in the HAP assay) after alignment of the internal markers is shown in Figure 4.8.2. The specific binding peak is readily identified by those fractions in the total binding sample gradient ([^{3}H]TCDD) which have higher amounts of radioactivity than those in the corresponding fractions of the nonspecific binding gradient ([^{3}H]TCDD + 500 nM TCDF). Thus, the [^{3}H]TCDD-specific binding peak in the results presented in Figure 4.8.2 is contained within fractions 9 to 18. The total specific binding (7171 dpms) in the gradient in Figure 4.8.2, was calculated by subtracting the sum of the radioactivity in fractions 9 to 18 of the nonspecific binding sample (3789 total dpms) from the sum of the radioactivity in fractions 9 to 18 of the total binding sample (10,960 total dpms). To normalize the specific binding to that in 1 mg of protein, the total specific binding value (7171 dpms) was divided by 1.67, since 1.67 mg of cytosolic protein (0.3 ml of the 5 mg/ml incubation) was layered onto the gradient, resulting in a specific binding 4294 dpms/mg protein. Correction for the specific activity of

the [^{3}H]TCDD (44.4 dpms/fmole) revealed that the specific binding of [^{3}H]TCDD to guinea pig hepatic cytosol in the sample gradient in Figure 4.8.2 was 96.7 fmoles/mg protein. Although multiple gradients must be run in order to obtain a statistically accurate measure of the variability of this value, the specific binding measured by the SDG assay is comparable to that obtained using the HAP assay.

The relative competitive binding by another AhR ligand can also be compared using HAP and SDG assays. In this instance, the amount of specific binding is determined using both TCDF and the additional competitor for nonspecific binding measurements. An example of the ability of 50 μM bilirubin (a relatively weak ligand) to compete with [^{3}H]TCDD-specific binding is shown in Figure 4.8.2. Subtraction of the amount of radioactivity in fractions 9 to 18 of the bilirubin gradient (8179 dpms) from that in the same fractions of the total binding gradient (10,960 dpms) provides a measure of the competitive displacement of [^{3}H]TCDD binding by bilirubin (2781 dpms, corrected for protein to 1665 dpms/mg). Given that the amount of displacement of [^{3}H]TCDD obtained with TCDF (4294 dpms/mg) represents 100% displacement, the ratio of the amount of displacement obtained with bilirubin to that obtained with TCDF provides a relative measure of the potency of bilirubin. This comparison indicates that 50 μM bilirubin was only effective at displacing 42% of the total [^{3}H]TCDD-specific binding in this guinea pig hepatic cytosolic sample (2781 divided by 4294 dpm/mg). Not only can similar analysis of the ability of other chemicals to compete with [^{3}H]TCDD binding to the AhR be carried out using the HAP assay, many more samples can be analyzed at one time using the HAP assay.

In addition to allowing gradient alignment and more accurate measurements of ligand binding, inclusion of the internal standards [^{14}C]BSA and [^{14}C]CAT also allow accurate estimation of the sedimentation coefficient (S) of the AhR (i.e., the [^{3}H]TCDD-specific-binding peak) in a given gradient. Sedimentation coefficients provide some insight into the size and shape of a protein or protein complex since these factors affect the movement of the proteins through the gradient during centrifugation. With regard to the AhR, a sedimentation coefficient of 8S to 10S for the AhR corresponds to the >300 kDa multiprotein cytosolic form of the AhR (bound with XAP2, p20 and 2 molecules of hsp90), a sedimentation coefficient of 4S to 5S corresponds to the monomeric AhR subunit (~100 kDa), and a sedimentation coefficient of ~6S corresponds to the AhR-Arnt heterodimer (~200 kDa). Direct comparison of the position of the peak of the [^{3}H]TCDD-specific binding in Figure 4.8.2 (fraction 12.5) to that of the two internal sedimentation controls—[^{14}C]BSA (4.4S); fraction 6—and [^{14}C]CAT (11.3S); fraction 16—reveals that the [^{3}H]TCDD binding peak has a calculated sedimentation coefficient of ~8.9S, corresponding to the multiprotein AhR complex.

DNA binding

Typical autoradiograms from gel retardation analysis of nuclear and cytosolic extracts are shown in Figure 4.8.3. For orientation on the figure, samples are loaded at the top of the gel and they migrate downward. The fastest moving band at the bottom of each of the lanes represents unbound [^{32}P]DNA, while the slower moving bands represent individual protein-DNA complexes. There are distinct differences between the protein complexes formed using nuclear and cytosolic extracts. With nuclear extracts (Fig. 4.8.3A) one major and two minor protein DNA complexes are detected, while with cytosolic extracts (Fig. 4.8.3B), two major protein DNA complexes are observed. With both extracts, complex A represents the TCDD-AhR-DRE complex and is formed in a TCDD-inducible manner—compare the DMSO- (lane 1) versus TCDD-treated (lane 2) samples. Competitive gel retardation analysis demonstrates the specificity of this protein DNA complex for the DRE since it is eliminated by the addition of a 100-fold excess of unlabeled DRE oligonucleotide (lane 3), but not by an excess of DNA containing a mutated DRE sequence which fails to bind the AhR (lane 4 of Fig. 4.8.3A and lane 6 of Fig. 4.8.3B). The other major protein DNA complex formed when using cytosolic extracts (complex B) represents a constitutive protein DNA complex (i.e., it is formed in the absence and presence of TCDD). Competitive displacement of protein-[^{32}P]DNA complex B by an excess of single-stranded DNA oligonucleotide (lane 4 of Fig. 4.8.3.B), but not by purified double-stranded DRE-containing DNA which lacks any single-stranded DNA (lane 5 of Fig. 4.8.3B), indicates that complex B represents the binding of a protein or proteins to the small amount of single-stranded DRE oligonucleotide remaining after reannealing and ^{32}P-labeling. The absence of this complex when the DRE oligonucleotide is ^{32}P-labeled by Klenow fill-in reactions (which does not generate any

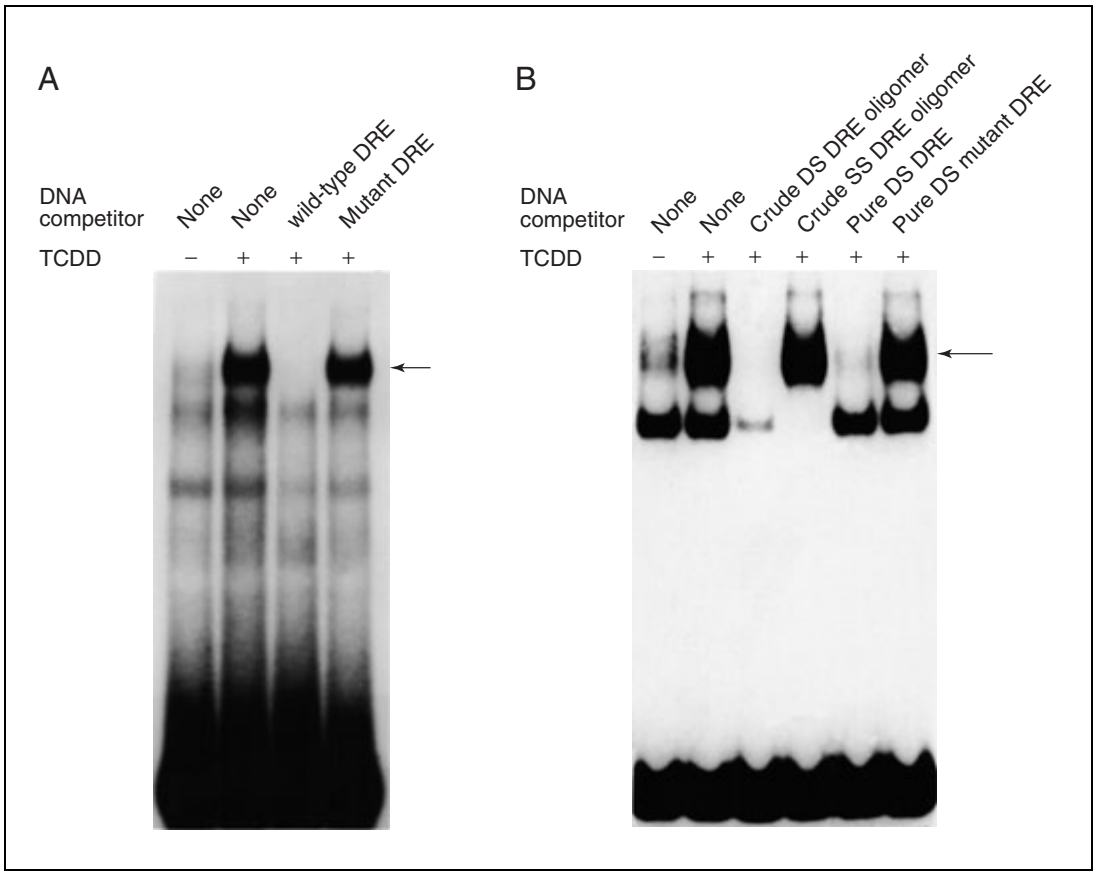

Figure 4.8.3 Typical gel retardation analysis of nuclear and cytosolic extracts. (**A**) Nuclear extracts (6 μg protein/ml) prepared from mouse hepatoma (hepa1c1c7) cells incubated for 1 hr at 37°C with DMSO (lane 1) or 1 nM TCDD (lanes 2 to 4), were incubated with wild-type (wt) [^{32}P]DRE oligonucleotide in the absence (lanes 1 and 2) or presence of a 100-fold molar excess of unlabeled wtDRE (lane 3) or mutant (m) DRE (lane 4) oligomer, and protein-DNA complexes were determined by gel retardation analysis. The arrow indicates the position of the induced protein DNA complex. (**B**) Rat hepatic cytosol (8 mg protein/ml) incubated for 2 hr at room temperature with DMSO (lane 1) or TCDD (lanes 2 to 6), was incubated with [^{32}P]wtDRE oligonucleotide in the absence (lanes 1 and 2) or presence of a 100-fold molar excess of unlabeled reannealed double-stranded wtDRE oligomer (lane 3), single-stranded wtDRE oligomer, (lane 4), pure double-stranded wtDRE (lane 5) or mDRE (lane 6), and protein-DNA complexes were determined by gel retardation analysis. Reprinted from Denison and Yao (1991).

radiolabeled single-stranded DNA) supports this conclusion; however, since formation of complex B actually provides a useful internal control (for sample loading) this residual single-stranded DNA is not removed from the oligonucleotide mixture after the reannealing step.

Gene expression

Typical results from immunoblot, RT-PCR, and northern blot analysis of various components of the AhR signal transduction pathway are shown in Figure 4.8.4. Immunoblot analysis of a whole cell lysate from mouse hepatoma (hepa1c1c7) cells using polyclonal antibodies to AhR and Arnt is shown in Figure 4.8.4A. The protein bands corresponding to the immunoreactive 95 kDa AhR and 85 kDa Arnt are indicated, as are the positions of the prestained protein standards. It is important to note that the AhR and Arnt antibodies bind nonspecifically to proteins in addition to the AhR or Arnt and as such, multiple antibody-positive bands will always be present on immunoblots using these antibodies. Although the identity of these additional immunoreactive proteins is unknown, some of them may represent AhR or Arnt, protein degradation products. Detection of AhR, Arnt, and CYP1A1 expression by RT-PCR analysis of RNA isolated from human choriocarcinoma (JEG3) cells that had been treated with DMSO (–) or TCDD (+) is shown in Figure 4.8.4B. PCR products corresponding to the 310-bp AhR, the 310-bp Arnt, the 460-bp CYP1A1, and the 430-bp GAPDH are detected in both DMSO- and TCDD-treated samples. As

expected, CYP1A1 was only detected in the presence of TCDD. Although these results are not quantitative, approaches for quantitative RT-PCR for these gene products have been described (Hakkola et al., 1997). Northern blot analysis of CYP1A1 mRNA isolated from human ovarian carcinoma (BG-1) cells that had been treated with DMSO or 10 nM TCDD is shown in Figure 4.8.4C. As with the RT-PCR analysis, CYP1A1 mRNA was only detected in cells treated with TCDD. The relative migration of the CYP1A1 mRNA (2.56 Kb) falls between that of the 28S (5.0 Kb) and the 18S (1.9 Kb) ribosomal RNA bands, while GAPDH (1.27

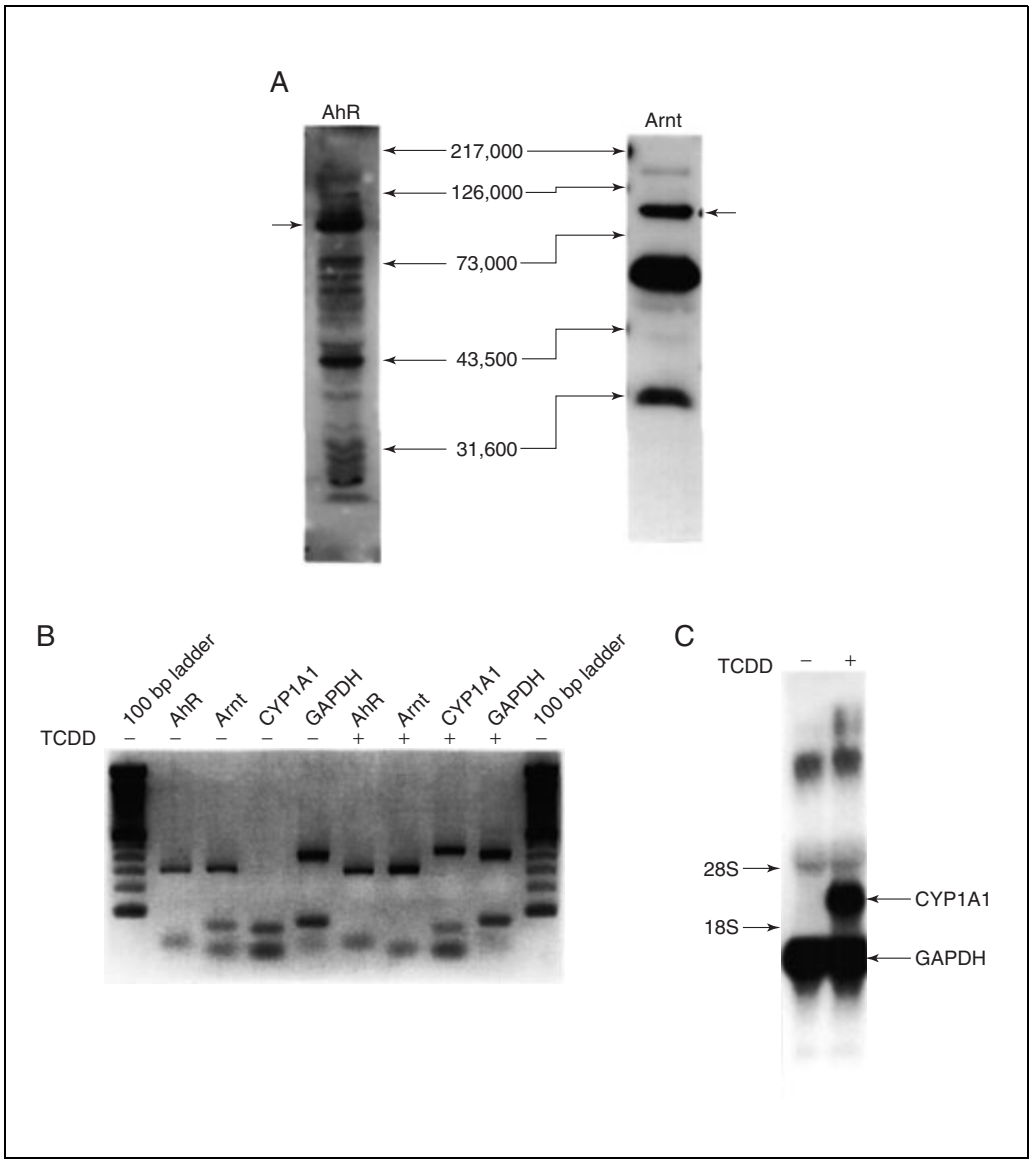

Figure 4.8.4 Analysis of the AhR signal transduction pathway by immunoblotting, RT-PCR, and northern blotting. (**A**) Immunoblot analysis of a whole cell lysate from mouse hepatoma (hepa1c1c7) cells using polyclonal antibodies to the AhR and monoclonal antibodies to Arnt. The positions and sizes of the Kaleidoscope protein standards (BioRad) are shown. The arrows indicate the positions of the AhR and Arnt proteins. Additional bands on the AhR immunoblot are common with all antibodies tested so far. (**B**) RT-PCR analysis of RNA isolated from human choriocarcinoma (JEG3) cells that had been treated with DMSO or TCDD (5 nM) for 24 hr at 37°C. PCR products corresponding to the AhR (310 bp), Arnt (310 bp) and GAPDH (430 bp) are detected in both DMSO- and TCDD-treated samples. A PCR product corresponding to that of the CYP1A1 (460 bp) was only detected in the TCDD-treated sample. The 100 bp DNA standards are shown in lanes 1 and 10. (**C**) Northern blot analysis for CYP1A1 mRNA isolated from human ovarian carcinoma (BG-1) cells that had been treated with DMSO or 10 nM TCDD for 24 hr at 37°C. The positions of CYP1A1 (2.56 Kb) and GAPDH (1.27 Kb) mRNAs and the relative positions of the human 28S (5.0 Kb) and 18S (1.9 Kb) ribosomal bands are indicated.

Kb) runs slightly faster than the 18S ribosomal band.

Time Considerations

AhR ligand binding analysis by SDG analysis (see Basic Protocol 1) is somewhat time-consuming and labor intensive during several steps, and the total time is dependent upon the number of sample gradients to be analyzed. The maximum number of gradients is dependent upon the capacity of the rotor (commonly eight or sixteen samples). For sixteen gradients, the overall procedure, from initial sample incubation until the fractionated samples are loaded into the scintillation counter takes ~8 hr. For a full rotor run of sixteen samples, the sample preparation and incubation takes 2.5 hr, charcoal treatment and gradient loading takes ~1 hr, centrifugation takes ~2.5 hr, and gradient fractionation another 1 to 2 hr. Scintillation counting of the gradient fractions adds significantly to the analysis time (~1.2 hr per 25 fraction gradient; >19 hr for counting of sixteen gradients). By staggering incubations and utilizing a vertical tube rotor for centrifugation, 32 gradients can be analyzed by a single person in one day. If a swinging bucket rotor is used, overnight centrifugation (16 hr) is required with a maximum of 6 gradients (Okey et al., 1979).

HAP binding analysis (see Alternate Protocol 1) is relatively rapid and the overall protocol time is dependent upon the number of samples to be analyzed. For example, complete analysis of 24 binding reactions (not including scintillation counting time) can be completed in ~4 hr. Set up of the incubations should take less than 30 min, even when large numbers of samples are to be run. The samples incubate for 2 hr and HAP binding of sample aliquots takes 30 min. Complete washing of HAP pellets is dependent upon the number of samples and the tube capacity of the centrifuge rotor, but 24 samples can be completed in less than 30 min. Washing times can be reduced significantly with the use of a repeating pipettor to add wash buffer and a vacuum aspirator to remove the wash supernatant. Incubations and washes can also be staggered so that large numbers of samples can be analyzed simultaneously. A convenient stopping point is immediately after the last wash of the pellets; the samples can sit at room temperature until they are transferred into the scintillation vials. Scintillation counting is commonly for 5 min per sample. One person can run over 100 samples in a single day.

Gel retardation analysis (see Basic Protocol 2) is relatively rapid once the radiolabeled probe is prepared. The overall procedure itself takes 5 to 6 hr, although only a small fraction of this time is labor intensive. Less than 1 hr is needed to complete the set up of the gels and the incubations with TCDD or other test chemicals. The samples are incubated and the gels prerun simultaneously for 2 hr. Set up and incubation of the DNA binding reactions and loading of the gels takes <1 hr (depending upon the number of samples to be analyzed) and electrophoresis takes 2 to 2.5 hr to complete. Gels are commonly dried for 1 hr at 80°C, although the time for drying can be shorter. The time necessary for autoradiography of the dried gels can vary significantly and it depends on the specific activity of the radiolabeled DNA and the amount of protein DNA complex formation. Autoradiographic results can be obtained in as little as 3 to 4 hr under optimal conditions.

Once the sample extract is in hand, immunoblot analysis (see Basic Protocol 3) can be completed in 1 long day or divided into 2 days. The authors usually complete the preparatory work (i.e., gel and sample preparation, electrophoresis, and transfer) on the first day and probe the blot on the second day; however, if the gels and samples are prepared ahead of time, electrophoresis, transfer, and probing the membrane may be completed in 1 day. Stripping and reprobing a blot may also be completed in 1 day.

For analysis of mRNA by RT-PCR (see Basic Protocol 4) or northern blotting (see Basic Protocol 5), the authors isolate RNA using the RNeasy Mini Kit from Qiagen (see Support Protocol 5). Isolation of enough material for RT-PCR analysis can be completed in <1 hr. For northern blot analysis, a more concentrated RNA sample is needed and this necessitates an additional two hour precipitation step. RT-PCR analysis can be easily accomplished in 1 day. First-strand cDNA synthesis takes ~1.5 hr and the PCR reactions take an additional 1.5 to 2 hr to complete depending on the number of cycles to be run. PCR reactions can also be set up and run overnight providing the temperature is maintained at 4°C after the cycles are completed. The resulting PCR products are viewed by ethidium bromide staining on an agarose gel, which adds an additional hour to the procedure.

In contrast, northern blot analysis takes 3 days. The cDNA fragment to be radiolabeled can be digested and isolated from its plasmid in advance and stored at −20°C for later use. The enzymatic digestion, gel separation, and fragment isolation should be completed in ~3.5

hr. A sufficient quantity of the desired fragment should be isolated so that it can be used in many northern experiments. On the first day, the agarose/formaldehyde gel is poured and the RNA samples denatured while the gel solidifies (~1 hr). The gel takes ~3 to 3.5 hr to run and the RNA is transferred to the membrane overnight. On the second day, the blot is dried for one hour and the probe is radiolabeled which takes ~1.5 hr. After successful labeling of the probe has been confirmed, the blot can be prehybridized for 1 hr and then hybridized with the radiolabeled probe overnight. On the third day, the blot is washed (~1 hr) and can either be placed on a phosphorimager screen or autoradiographic film overnight and subsequently developed.

Measurements of Flavin-Containing Monooxygenase (FMO) Activities

The flavin-containing monooxygenases (FMOs, EC 1.14.13.8) are a family of xenobiotic-metabolizing enzymes that catalyze the flavin-adenine dinucleotide (FAD)-, NADPH-, and O_2-dependent oxidation of numerous xenobiotics containing nitrogen, sulfur, phosphorus, or selenium heteroatoms. The FMOs have been thoroughly described in a number of mammalian species, including the pig, rabbit, human, rat, and mouse, and more recently in fish. At least five different isoforms have been described by amino acid or cDNA sequencing and are classified as FMO1 to FMO5.

Many FMO substrates are also substrates for cytochrome P450s (CYPs). Since both FMOs and CYPs are membrane-bound enzymes that are sedimented during the preparation of microsomes, it can be difficult to distinguish which metabolites are produced by one or the other of these enzymes. To study the relative contributions of these two enzymes with common substrates, methods have been developed to measure the contribution of each of these enzyme systems. The most useful of these is a combination of two methods; the first involving inhibition of CYPs through the use of an antibody to cytochrome P450 reductase, thus allowing measurement of FMO activity alone. The second procedure involves the heat treatment of microsomal preparations (1 min at 50°C), which inactivates the heat labile FMO, leaving activity of CYPs intact. However, since the lung FMO (FMO2) is more heat stable than the liver forms, use of the anti-reductase with lung microsomal preparations is necessary.

Studies of drug and pesticide metabolism can also be conducted with the use of purified preparations of FMO isoforms as expressed in *E. coli*, yeast, baculovirus, and others. In these studies, NADPH oxidation can be used to determine whether a particular isoform has activity towards a given substrate. Although this procedure has proven useful for a wide variety of substrates, there is at least one case where NADPH oxidation occurred in the absence of FMO protein, indicating that appropriate controls are essential for proper interpretation of results.

Although there are a variety of substrates that can be used for the characterization of FMO activities, methimazole and *n*-octylamine are two substrates that are widely used for such characterization. Methimazole can be metabolized by FMO1 to FMO4 and to a slight extent by FMO5 while *n*-octylamine is a good substrate for FMO5.

This unit describes methods used for measuring the presence of FMOs using two basic procedures. NADPH oxidation (see Basic Protocol 1) is an important screening method used to identify potential FMO substrates; often using recombinant FMO isoforms. Because methimazole is a substrate that is easily oxidized by most FMO isoforms, methimazole oxidation (see Basic Protocol 2) is also commonly used for the characterization of FMO isoforms. Methods are also provided to determine the relative contributions of FMO versus CYP from microsomal tissues (see Basic Protocol 3).

NADPH OXIDATION

BASIC PROTOCOL 1

NADPH oxidation is a useful method to determine if a substrate is metabolized by FMOs. Previous studies have validated the stoichiometric relationships between substrate addition, NADPH oxidation, and oxygen consumption for a variety of FMO substrates (Tynes and Hodgson, 1985). This method monitors NADPH consumption by following the decrease in spectral measurement of NADPH at 340 nm. Since endogenous NADPH is high in microsomal preparations, this method is not recommended for measurement of FMOs in microsomal preparations unless NADPH cytochrome P450 reductase is inhib-

Contributed by Randy L. Rose

Current Protocols in Toxicology (2002) 4.9.1-4.9.11

ited by antibodies. The magnitude of such inhibition should be carefully checked to ensure that subsequent oxidations are significantly less than prior to the addition of the antibody. It is also important to check that the substrate and products of the reaction do not interfere with this wavelength for successful quantitation.

Materials

2× tricine/KOH buffer, pH 8.5 (see recipe)
10 mM nicotinamide adenine dinucleotide phosphate, reduced form (NADPH; see recipe)
Enzyme (usually purified or recombinant FMO)
0.1 M substrate (see recipe for suggestions on preparation and storage)

1.5-ml UV grade (methacrylate) cuvettes, 1-cm path-length
Spectrophotometer
37°C water bath

1. Add the following ingredients to a 1.5-ml sample cuvette (total 1 ml).

   500 µl 2× prewarmed tricine/KOH buffer, pH 8.5
   10 µl 10 mM NADPH
   Enzyme plus prewarmed water to a final reaction volume of 990 µl.

2. Prepare a reference cuvette with the same ingredients as the sample cuvette, but without 10 mM NADPH.

3. Place sample and reference cuvettes in the spectrophotometer and measure the decrease of OD at 340 nm.

   This provides the background rate of NADPH oxidation.

4. Add 10 µl of 0.1 M substrate to the sample cuvette, mix by inversion, and again record the decrease of OD at 340 nm.

5. Calculate NADPH oxidase activity. Applying Beer's Law: $A = \varepsilon cl$. The extinction coefficient for NADPH oxidation (ε) at 340 nm is 6200 $M^{-1}cm^{-1}$. The cell path-length (l) is 1 cm and A is the measured absorptivity at λ_{max}.

$$c = \frac{\Delta A/\text{min}}{\varepsilon l}$$

$$c = \frac{\Delta A/\text{min}}{(6200\ \text{liter/mol cm})(1\ \text{cm})(1000\ \text{ml/liter})(1\ \text{mol}/10^9\ \text{nmol})}$$

$$c = (\Delta A/\text{min})(161\ \text{nmol/min})(\text{ml}/x\ \text{mg protein}) = \text{nmol/min/mg protein}$$

BASIC PROTOCOL 2

METHIMAZOLE/DTNB ASSAY

The measurement of FMO activity in microsomal fractions is best accomplished by monitoring methimazole oxidation as originally described by Dixit and Roche (1984). Methimazole (*N*-methyl-2-mercaptoimidazole) is a highly specific substrate for the FMO and is somewhat unusual in that it is a poor substrate for CYPs. The measurement of methimazole oxidation relies upon the ability of its disulfide conjugate (formed after oxidation of methimazole) to rapidly and completely oxidize nitro-5-thiobenzoate (TNB) to DTNB (Fig. 4.9.1). This reaction is accomplished following the reduction of DTNB to TNB by DTT, allowing for subsequent oxidation of TNB to DTNB, which can be followed spectrophotometrically. The reaction has been a favorite method for characterization of FMO activity in microsomes as well as for the characterization purified or recombinant FMO isoforms. It is a preferred substrate because it can be used over a wide range of

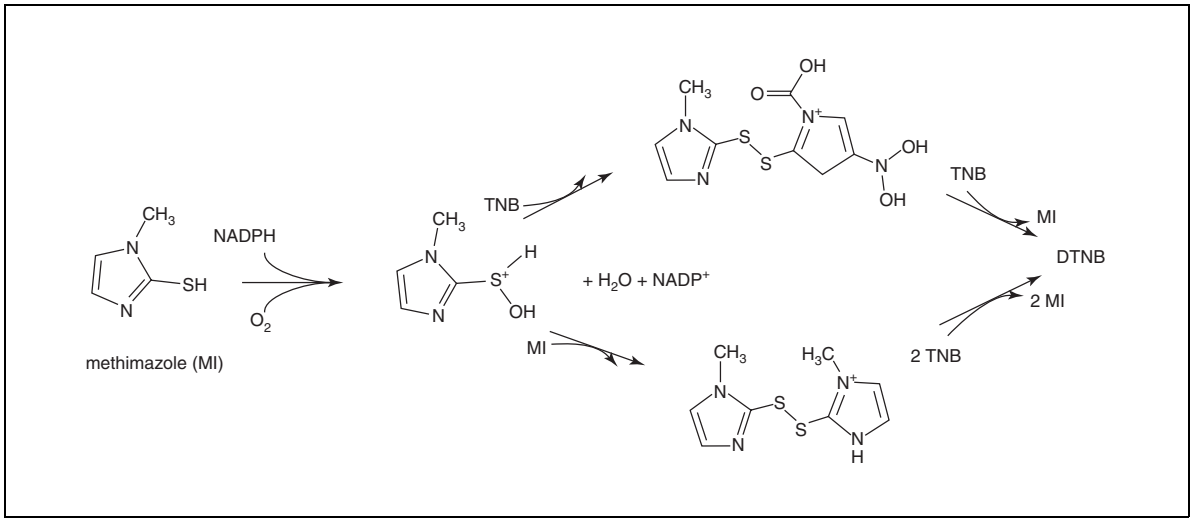

Figure 4.9.1 Oxidation of methimazole and reaction of the oxidized product with TNB to generate DTNB (modified from Dixit and Roche, 1984).

concentrations, is easily assayed, and can be used for both microsomal and purified preparations. This substrate is most suitable for studies of FMO isoforms 1 to 4, having less suitability for FMO5 due to the much higher K_m value of FMO5. For studies of FMO5 expression, NADPH oxidation using *n*-octylamine as substrate has proven to be a suitable alternative method.

Materials

2× tricine/KOH buffer, pH 8.5 (see recipe)
1 mM 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB; see recipe)
10 mM nicotinamide adenine dinucleotide phosphate, reduced form (NADPH; see recipe)
2 mM dithiothreitol (DTT; see recipe)
100 mM methimazole (see recipe)
Inhibitors (optional)
Microsomes
Enzyme

Spectrophotometer
37°C water bath
1.5-ml UV grade (methacrylate) cuvettes, 1-cm path-length

1. Turn on spectrophotometer (412 nm) and 37°C water bath. Warm 2× tricine/KOH buffer, pH 8.5, to 37°C.
2. Prepare 1 mM DTNB, 10 mM NADPH, 2 mM DTT, 100 mM methimazole, and inhibitors.

   Methimazole may be frozen and used again. It is best if a fresh solution of NADPH is used. DTT and DTNB must be fresh preparations.

3. To sample and reference cuvettes, add the following (total volume 1 ml):

   500 µl 2× tricine/KOH buffer, pH 8.5
   10 µl 2 mM DTT
   60 µl 1 mM DTNB
   10 µl 10 mM NADPH

continued

x µl microsomes
x µl water
total volume 990 µl.

The solution turns yellow when DTT and DTNB are mixed.

4. Wait 30 to 60 sec, then record the substrate-independent rate for 2 min until a good baseline is established.
5. Add 10 µl of 100 mM methimazole to the sample cuvette, mix, wait 30 to 60 sec, then record the reaction rate for at least 2 min.
6. If inhibitors are used, add 1 to 10 µl of inhibitor to sample cuvette, wait 30 sec for equilibration, then re-record the reaction rate.
7. Measure the change in absorbance that occurs between 1 and 2 min.
8. Calculate nitro-5-thiobenzoate (TNB) oxidation activity. The extinction coefficient for TNB oxidation (ε) is 28,000 $M^{-1}cm^{-1}$ at pH 8.4. Applying Beer's Law: $A = \varepsilon\, c\, l$ and incorporating protein concentration,

$$c = \frac{\Delta A/\text{min}}{(28{,}000\ \text{liter/mol cm})(1\ \text{cm})(1000\ \text{ml/liter})(1\ \text{mol}/10^9\ \text{nmol})}$$

$$= (\Delta A/\text{min})(1\ \text{nmol}/0.028\ \text{ml})(\text{ml}/x\ \text{mg protein}) = \text{nmol/min/mg protein}.$$

BASIC PROTOCOL 3

DETERMINATIONS OF FMO VERSUS CYP CONTRIBUTIONS TO METABOLISM FOR COMMON SUBSTRATES

Both the CYPs and FMOs catalyze the microsomal oxidations of a variety of drugs and pesticides. Since both enzyme families are membrane bound enzymes that are sedimented during microsomal preparations, it is often difficult to determine which has the predominant role in the oxidations being examined. In some cases, a substrate may first be oxidized by one of these enzyme systems and then subsequently oxidized by the other. By preferentially inhibiting either the FMO activity or the CYP activity in microsomal incubations the relative contributions of both enzyme systems can be determined. To do this, FMOs can be eliminated from the microsomes by a brief heat treatment (90 sec at 50°C) or the metabolic contributions of CYPs can be eliminated either by use of general CYP inhibitors (e.g., *N*-benzylimidazole) or by use of antibodies to cytochrome P450 reductase as described below.

Materials

Microsomes
100 mM potassium phosphate buffer, pH 7.4 (see recipe)
NADPH regenerating system (see recipe)
Substrate (see recipe for suggestions of preparation and storage)
Antibodies to NADPH cytochrome P450 reductase (BD Biosciences)
2× tricine/KOH buffer, pH 8.5 (see recipe)
1 mM *N*-benzylimidazole (NBI; prepare from 300 mM stock; see recipe)
50°C water bath

For FMO inactivation (heat treatment)

1a. Add microsomes to 100 mM potassium phosphate buffer, pH 7.4, so that the final concentration is 0.1 to 0.8 mg/ml.

Potassium phosphate buffer, pH 7.4, is used when examining CYP contribution to metabolism.

2a. Heat microsomes (in the absence of NADPH regenerating system and substrate) for 90 sec at 50°C.

3a. Add 25 µl NADPH regenerating system and the appropriate substrate. Incubate for 5 to 15 min, 37°C, and monitor product formation as necessary.

For CYP inactivation (antibody inhibition)

1b. Preincubate microsomes with anti-reductase antibody (1 to 2 mg/mg microsomal protein) in 500 µl of 2 × tricine/KOH buffer, pH 8.5, for 5 to 7 min at 4° C.

Tricine/KOH buffer, pH 8.5, is used when measuring the contribution of FMO.

2b. Add 25 µl NADPH regenerating system and the appropriate substrate to a final volume of 1 ml.

3b. Incubate for 5 to 15 min, and monitor product formation as necessary.

For CYP inactivation (chemical inhibition)

1c. Preincubate microsomes with 3.3 µl NBI stock solution for 5 min at 37°C in 500 µl of 2× tricine/KOH buffer, pH 8.5.

Tricine/KOH buffer, pH 8.5, is used when measuring the contribution of FMO.

2c. Add 25 µl NADPH regenerating system and the appropriate substrate to a final volume of 1 ml.

3c. Incubate for 5 to 15 min at 37°C, and monitor product formation as necessary.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for supplies, see **SUPPLIERS APPENDIX**.*

5,5′-dithiobis(2-nitrobenzoate) (DTNB), 1 mM

Dissolve 10 mg DTNB in 25 ml of 2× tricine/KOH buffer (see recipe). Prepare fresh.

Dithiothreitol (DTT), 2 mM

Dissolve 15 mg dithiothreitol per 50 ml deionized water. Prepare fresh.

Methimazole, 100 mM

Dissolve 11.4 mg methimazole in 1 ml methanol. Store up to 2 months at 4°C.

Nicotinamide adenine dinucleotide phosphate, reduced (NADPH), 10 mM

Dissolve 8.3 mg NADPH in 1 ml deionized water.

N-benzylimidazole (NBI), 300 mM

Dissolve 24 mg NBI in 0.5 ml acetonitrile:water (1:1).

NADPH regenerating system

Add 4.2 mg $NADP^+$ to 14.1 mg glucose-6-phosphate and 20 U of glucose-6-phosphate dehydrogenase in a final volume of 0.5 ml of reaction buffer. Dispense into 25-µl aliquots per 1 ml assay volume, bring final concentrations to 0.25 mM $NADP^+$, 2.5 mM glucose-6-phosphate, and 1 U glucose-6-phosphate dehydrogenase. If NADPH-RGS is left over, it may be used up to 2 weeks if stored frozen at −20°C.

Potassium phosphate buffer (pH 7.6), 100 mM, with 0.1 mM EDTA

Combine 2.176 g KH_2PO_4 and 14.64 g K_2HPO_4 in 1 liter of water. Add 33.6 g disodium EDTA. Adjust to pH 7.6 with 1 M HCl or NaOH if necessary. Store up to 6 months at 4°C.

Substrate solutions

Prepare 200- to 500-µl aliquots of stock solutions in water, ethanol, methanol, or dimethylsulfoxide to obtain final concentrations in the incubation mixture of 10 to 100 mM. Do not exceed solvent concentrations >5 to 10 µl per milliliter.

Tricine/KOH buffer (pH 8.5), 2×

Add 35.8 g tricine and 0.744 g disodium EDTA per 1 liter. Adjust to pH 8.4 with KOH. Store up to 6 months at 4°C.

COMMENTARY

Background Information

The flavin-containing monooxygenase enzymes (FMO, EC 1.14.13.8) have been characterized from several mammalian species, including humans, rabbits, mice, rats, and pigs. This enzyme, isolated from the endoplasmic reticulum, catalyzes the oxygenation of a variety of nucleophilic nitrogen-, sulfur-, and phosphorus-containing drugs, pesticides, and other xenobiotics (Ziegler, 1980; 1988; Hodgson et al., 1995). The ability of these enzymes to oxygenate a variety of xenobiotics is important in both activation and detoxication processes. Interestingly, unlike the related CYP enzymes, FMOs do not seem to be induced by their own substrates. Although several endogenous substrates have been identified (Elfarra, 1995), the physiological role of these enzymes has not been established.

The oxidative reactions carried out by both FMOs and cytochrome P450s (CYPs) generally result in the production of less toxic metabolites that can then be subsequently conjugated and/or excreted; although in some cases, increased toxicity can result. Not only can the products of these enzymes vary, but different isomers of the same product may also be produced (Hodgson et al., 1997). Because tissue and subcellular locations of these enzymes are essentially the same, it is often difficult to separate their respective oxidative activities. However, methods have been developed to determine the relative contributions of FMO and CYPs, including the manipulation of microsomes in which both enzymes are found. The best method to determine the contribution of CYP activity to the overall metabolism of specific substrates involves heat inactivation of FMOs. Since FMOs are more heat labile than CYPs (with the exception of the lung FMO2), brief heating of microsomal preparations to 50°C for 90 sec effectively eliminates the FMO contribution to metabolism with minimal inactivation of CYPs.

To more fully examine the relative contribution of FMO enzyme activity within microsomes, two methods have been used successfully. The traditional method involves use of an antibody to NADPH cytochrome P450 reductase to abolish the CYP contribution to metabolism. More recently, a general CYP inhibitor (*N*-benzylimidazole, NBI) has been used by some investigators to discriminate between CYP and FMO activity. The combination of heat treatment with antibody treatment was used to characterize the contributions of FMO versus CYP activities towards the pesticide substrate, phorate, in various tissues (Kinsler et al., 1988) and under different induction and inhibition treatments (Kinsler et al., 1990). Use of NBI was shown to nearly completely eliminate CYP metabolism of up to seven diagnostic CYP substrates without harming FMO-mediated metabolism (Grothusen et al., 1996). Use of this CYP inhibitor in place of an inhibitory antibody reduces the need to perform exploratory assays in the case of the antibody to determine optimal concentrations for CYP inactivation. By comparing uninhibited metabolism rates with those obtained following FMO inactivation (heat treatment) versus those obtained following CYP inactivation (NBI or NADPH cytochrome P450 reductase antibody treatment) assignments of FMO and CYP contributions to the production of specific metabolites can be realized.

FMO-specific substrate oxidations can also be performed using purified preparations of enzyme either from microsomes (Sabourin et al., 1984) or from heterologously expressed preparations. The first purified FMO was obtained from pig liver microsomes (Zeigler and Mitchell, 1972), and its catalytic mechanism was extensively characterized. Subsequently, purification procedures were developed for the rat, mouse, rabbit, guinea pig, and macaque. Differences observed in the modulation of FMO activities by metal ions from FMOs de-

rived from partially purified rabbit lung and liver FMO resulted in the suggestion that these tissues might possess different forms of the enzyme (Devereux et al., 1977). Subsequent studies more conclusively demonstrated that purified lung and liver FMOs were catalytically and immunochemically distinct (Williams et al., 1984; Tynes et al., 1985). Sequencing of the corresponding cDNAs yielded evidence of distinctly different but related genes (Lawton et al., 1990). To date, five distinct FMO genes (designated FMO1 to FMO5) have been identified by amino acid or cDNA sequencing (Lawton et al., 1994). Orthologous genes share at least 80% amino acid identity, while homologous FMOs are 52% to 57% identical. Highly related forms (>98% identity) within a single species are the result of allelic variation.

At least one human polymorphism of FMOs has been described. In this case, different mutations of the FMO3 gene result in the inability of human subjects to metabolize trimethylamine (Cashman et al., 1997). Subjects with this autosomally recessive disorder exude a characteristic "fish odor" resulting from their excretion of large amounts of unmetabolized trimethylamine.

One of the interesting features of FMOs involves their tissue-specific expression. Williams et al. (1984) and Tynes et al. (1985) demonstrated that the pulmonary (FMO2) and hepatic (FMO1) forms from the rabbit were immunochemically and catalytically distinct. It was also shown that both FMO1 and FMO2 were present in rabbit kidney, but that in the lung and liver, only one form was present (FMO2 and FMO1, respectively). FMO3 expression was demonstrated in rabbit liver but not in kidney or lung, while FMO4 was found in rabbit kidney, but not liver or lung (Burnett et al., 1994). Expression of FMO5 was highest in liver, followed by kidney, and was absent in lung (Atta-Asafo-Adjei et al., 1993).

Possible physiological functions of FMOs are indicated not only by tissue-specific expression but also by variations in FMO levels according to gender, nutritional status, diurnal rhythms, and pregnancy (Williams et al., 1985). Gender and developmental differences in the expression of FMO have been characterized in several species. In mice, oxidation of FMO substrates has long been known to be greater in females than in males. Based on protein and mRNA levels in CD-1 mice, it was shown that FMO3 was expressed only in females and that FMO1 was expressed to a greater extent in females than in males. In contrast, the lesser abundant hepatic isoform, FMO5, was expressed to an approximately equal extent in both males and females. Northern blotting methods did not detect either FMO2 or FMO4 in livers of mice from either gender (Falls et al., 1995). Studies examining the roles of testosterone, 17 β estradiol, and progesterone demonstrated that testosterone is involved in the modulation of the activities of FMO isoforms 1 and 3 (Falls et al., 1997).

Developmentally in CD-1 mice, FMO1 is already expressed by gestational day 13 and continues to increase in expression until 2 weeks of age when expression is equivalent in males and females (Cherrington et al., 1998). By 4 weeks of age, at which time mice are becoming sexually mature, FMO1 levels decline in males to levels less than one-half those of females. In contrast, FMO3 is not present at any level in either sex until 2 weeks post-partum. By 4 weeks of age, FMO3 is present in both males and females at a level similar to those seen in adult females. By 6 weeks of age (post-puberty), FMO3 is no longer apparent in the adult male due to the repressive effects of testosterone. Some similarities between mice and humans exist in that FMO1 is the principal FMO in human fetal tissues while FMO3 is the primary expressed form in adults. However, no gender differences in humans have been described.

Although the FMOs have been studied and well characterized in several mammalian species, considerably less is known about this family of enzymes in other vertebrates and invertebrates. In fish, FMO activity has been shown to be directly correlated with osmotic regulation, suggesting a possible physiological role. Activity towards typical FMO substrates is indicative that FMOs are present in invertebrates, but corresponding transcripts or proteins have yet to be identified (Schlenk, 1998).

Critical Parameters

NADPH oxidation in conjunction with the use of recombinant FMO or purified FMO preparations is an excellent way to determine if a given drug or pesticide is metabolized by FMO. However, certain precautions should be considered prior to the use of this method. First, neither the substrate nor product should absorb strongly at 340 nm. Strong absorbance at this wavelength would interfere with the disappearance of NADPH as it is used in the reaction. Second, some substrates may interact with re-

combinant proteins resulting in a spontaneous oxidation of NADPH as occurred with tamoxifen. In these cases, more direct measurements of substrate oxidation, such as quantitation by HPLC and/or radioisotope detection, may be necessary.

Detergents are often used during enzyme purification to solubilize the enzymes prior to placing them on columns for separation. Early observations indicated that detergent-solubilized FMO enzymes retained activity, while CYPs lost activity upon solubilization. As a result, some early studies used detergents such as Emulgen 911 as a means to inhibit oxidations due to CYP (Tynes and Hodgson, 1985). Further examination of this method as a technique to identify the FMO contributions to metabolism indicated that for certain substrates, detergents including Emulgen 911, Triton X-100, and cholate, are also inhibitory to FMO metabolism (Venkatesh et al., 1991).

Although NADPH oxidation is a valid method for determining whether a chemical is metabolized by CYPs or FMOs, its use in microsomal preparations for these purposes is not strongly encouraged because of several potential difficulties. It is difficult, for example, to be able to properly distinguish between CYP metabolism and FMO metabolism without properly inhibiting one or the other system as discussed in Basic Protocol 3. In addition, there are some cases where NADPH can be oxidized in the absence of substrate, particularly when using microsomal preparations. These oxidations may or may not be enzymatic. In some of these cases, addition of substrate can actually result in decreasing the NADPH oxidation rate. In these cases, it may not be appropriate to subtract the rate of substrate-independent NADPH oxidation from the rate of substrate-dependent oxidation. Usually, substrate-independent oxidation is <5% of substrate-dependent NADPH oxidation and can be ignored.

Troubleshooting

See Table 4.9.1 for a troubleshooting guide.

Anticipated Results

Table 4.9.2 illustrates the use of NADPH oxidation (see Basic Protocol 1) as a means to measure metabolism of several pesticides and other xenobiotics in mouse liver, lung, and kidney microsomes (Tynes and Hodgson, 1985). In this example, microsomal enzymes were used to determine possible involvement of FMOs in the metabolism of these compounds. To eliminate cytochrome P450 metabolism, microsomal enzymes were incubated on ice in 5 mg of NADPH cytochrome P450 antireductase IgG/mg of microsomal protein prior to initiation of the incubation. The inclusion of 3 mM *n*-octylamine had previously been demonstrated to increase both K_m and V_{max} for several substrates by ~25%. Note that the endogenous rate of NADPH oxidation shown at the bottom of the table was subtracted from activity levels shown.

NADPH oxidation levels shown are typical of many substrates. Consumption of molecular oxygen and the rate of appearance of oxidized products were demonstrated by Tynes and Hodgson (1985) to be equivalent to the rate of disappearance of NADPH. The activity level of thiourea in liver microsomes is near the maximal level that can be expected from this assay. Similar levels might also be expected for methimazole, cysteamine, and *N*,*N*-dimethylaniline as all of these shared common maximal velocities in kinetic studies.

Table 4.9.3 is an illustration of results obtained after inhibition of FMO activity by heat treatment and CYP activity by antireductase treatment as described in Basic Protocol 3. In this example, the antipsychotic drug, thioridazine is metabolized by both CYP and FMO to several products, including sulfoxide and *N*-oxide metabolites. Production of these metabolites was observed directly by high-performance liquid chromatography. It is interesting to note that one product, thioridazine 2-sulfoxide *N*-oxide (2SONO) is produced to approximately the same extent in all incubations, including boiled microsomes. This is indicative of a metabolite that is produced by autoxidation, rather than by metabolic processes.

The application of heat (45°C for 90 sec) resulted in significant decreases in two metabolites, northioridazine (NOR), and thioridazine *N*-oxide (NO). For NOR, the decrease was 50% of the original activity while for the NO 87% of the activity was eliminated by heat treatment. For the two other metabolites (not including 2SONO), heat treatment had minimal effects. These results suggest a minimal role of FMO in the metabolism to the 2SO and 5SO products and an important role of FMO in metabolism to the NO product. A possible role of FMO is also implicated by this data for metabolism to NOR.

Much of the data derived from heat treatment was verified by the pre-incubation of

Table 4.9.1 Troubleshooting Guide to Analysis of FMO Activity

Problem	Possible cause	Solution
High rates of NADPH oxidation independent of presence of FMO	Futile cycling of NADPH in presence of substrate	Find alternate method to NADPH oxidation
Results not consistent with loss of NADPH (i.e., baseline increases)	Substrate or product of reaction interferes with absorption at 340 nm	Scan substrate or product and monitor direct product formation and/or substrate disappearance
Prolonged initial lag phase of NADPH oxidation in the presence of substrate	Transient intermediates	Add 1 mM glutathione
Rapid, nonlinear initial rate of NADPH oxidation	Substrate insolubility in solution	Decrease substrate concentration or find alternate method to get substrate into solution

Table 4.9.2 Rates of Metabolism by the Flavin-Containing Monooxygenase in Rat Liver, Lung and Kidney Microsomes (Tynes and Hodgson, 1985)

Substrate	Concentration (mM)	Activity (nmol/min/mg of microsomal protein)[a]		
		Liver	Lung	Kidney
Organophosphate and carbamate insecticides				
Phorate	0.1	3.4 ± 0.6	1.4 ± 0.5	1.6 ± 0.7
Disulfoton	0.1	4.3 ± 0.6	1.8 ± 0.5	2.4 ± 0.2
Aldicarb	0.1	1.9 ± 0.4	0.3 ± 0.1	0.7 ± 0.1
Croneton	0.1	3.2 ± 1.5	1.2 ± 0.2	n.d.[b]
Other xenobiotics				
α -Naphthylthiourea	0.1	4.6 ± 0.7	1.4 ± 0.4	n.d.[b]
Methyl phenyl sulfide	0.1	5.4 ± 0.3	1.9 ± 0.2	n.d.[b]
Diethylphenylphosphine	0.1	4.0 ± 1.4	0.8 ± 0.2	n.d.[b]
Thiourea[c]	1.0	8.3 ± 1.3	2.8 ± 0.6	9.1 ± 1.7
Endogenous NADPH oxidation rate		2.9 ± 0.4	0.6 ± 0.3	1.5 ± 0.6

[a]All incubations included 5 mg antireductase IgG/mg of microsomal protein and 3 mM *n*-octylamine. Velocities represent substrate-stimulated minus endogenous rates. Rates are the mean ±SD.

[b]n.d., not determined.

[c]Thiourea completely saturates the enzyme at a concentration of 1 mM; these rates approximate the maximal velocities of these microsomal preparations.

microsomes with NADPH cytochrome P450 antireductase. In this example, antireductase treated microsomes completely or nearly abolished metabolism to NOR and 2SO; implicating a major role of CYPs in formation of these metabolites. The puzzling effect of heat treatment in the reduction of the NOR metabolite is less puzzling if one considers that production of the NO product by FMO is likely to lead to subsequent formation of NOR. In the case of the 5SO and NO products, which were inhibited in the antireductase treatments by ~50%, the data indicates that both P450 and FMO are nearly equally responsible for formation of these products.

Time Considerations

For NADPH oxidation, the preparation of substrate, reagents and buffers requires 1 hr. Each assay takes 5 to 10 min.

For methimazole oxidation, the preparation of substrate, reagents, and buffers requires 2 hr. Each assay takes 10 min.

For FMO versus CYP contributions, the preparation of substrate, reagents, and buffers requires 2 hr. Each assay takes 5 to 15 min.

Table 4.9.3 Metabolism of Thioridazine by Control and Treated Mouse Liver Microsomes (Blake et al., 1995)

Treatment	Metabolites[a] (nmol/mg/min)[b]				
	NOR	2SO	5SO	2SONO	NO
Control microsomes	0.26 ± 0.03	1.49 ± 0.09	0.57 ± 0.04	0.13 ± 0.01	0.23 ± 0.00
Boiled microsomes[c]	0[f]	0[f]	0[f]	0.09 ± 0.03	0[f]

[c]Microsomes were boiled for 2 min prior to substrate addition.

[d]Heat treatment was at 50°C for 90 sec.

[e]Rabbit antibodies to NADPH cytochrome P450 reductase were incubated with microsomes for 10 min at 37°C using 2 mg antireductase per mg microsomal protein. This amount of antireductase was shown in preliminary assays to inhibit >90% cytochrome c reducatase.

[f]Significantly different from control microsomes, $p < 0.05$.

Assays for the Classification of Two Types of Esterases: Carboxylic Ester Hydrolases and Phosphoric Triester Hydrolases

Esterases (EC 3.1) are a large, heterogeneous group of enzymes classified under the general category of hydrolases (EC 3). Possessed by virtually all organisms, esterases hydrolyze a wide variety of substrates that contain ester linkages. It is well known that some esterases are involved in detoxication or activation of exogenous compounds, such as therapeutic drugs, anesthetics, and pesticides. Additionally, metabolism of certain chromogenic esters allow for esterase detection and quantitation. These enzymes also hydrolyze endogenous esters, although the substrates and their physiological roles have been difficult to determine.

This unit provides assay protocols to quantitate two common classes of esterases that are known to metabolize xenobiotics in a number of organisms. The first class is called the carboxylic ester hydrolases (CEHs; EC 3.1.1). Within this group are the B-esterases, which are inhibited by organophosphates. The CEH assay (see Basic Protocol 1) colorimetrically measures endpoint metabolism of the substrate 1-naphthyl acetate to the product 1-naphthol (Fig. 4.10.1A). The other class of esterases to be assayed is the phosphoric triester hydrolases (PTEHs; EC 3.1.8). Within this class is A-esterase, which also is referred to as paraoxonase due to its ability to metabolize the insecticide, paraoxon, as well as other organophosphates. The PTEH assay (see Basic Protocol 2) colorimetrically measures endpoint metabolism of the substrate, methyl paraoxon (dimethyl-*p*-nitrophenylphosphate), to the product *p*-nitrophenol (Fig. 4.10.1B).

Esterases are commonly found in serum and in both the microsomal and soluble fractions of cells. Therefore, whole homogenates from tissues or cultured cells can be used in either assay after clarification by a single centrifugation ($10{,}000 \times g$). A serum, tissue, or cell sample can be subjected to both protocols to determine the presence of one or both classes of esterases, and to quantitate respective enzyme activities. Alternatively, these assays can aid in the identification of a purified CEH or PTEH.

CAUTION: The Material Safety Data Sheet (MSDS) on methyl paraoxon labels this compound as "highly toxic." 1-Naphthol and phenyl thiourea are labeled "toxic," while Fast Blue B Salt and sodium dodecyl sulfate (SDS) are labeled "harmful." 1-Naphthyl acetate is labeled with "caution." Handle these materials under a chemical fume hood when making stock and assay solutions. Investigators should access and read the MSDS of all chemicals prior to their use to be aware of hazards, proper handling procedures, and appropriate safety wear. At the end of experiments, extreme care should be taken to appropriately package, label, and temporarily store all chemical waste that is generated from performance of these protocols. Promptly contact the hazardous waste office of the institution for proper disposal instructions.

MEASUREMENT OF CARBOXYLIC ESTER HYDROLASE (CEH) ACTIVITY

BASIC PROTOCOL 1

This method measures hydrolysis of the carboxylic ester substrate, 1-naphthyl acetate to the product, 1-naphthol, in an endpoint assay. The product then forms a complex with Fast Blue B Salt to yield a purple-blue color, which is detectable spectrophotometrically at 595 nm. Several concentrations of 1-naphthol are used to create a standard curve for estimation of CEH activity in samples. Multiple samples can be analyzed simultaneously, as the assay is formatted for a microtiter plate reader using 96-well plates. The procedure is rapid, with a total incubation time of 35 min. With a total reaction volume of 200 µl, only a small volume of sample is necessary.

Current Protocols in Toxicology (2002) 4.10.1-4.10.14

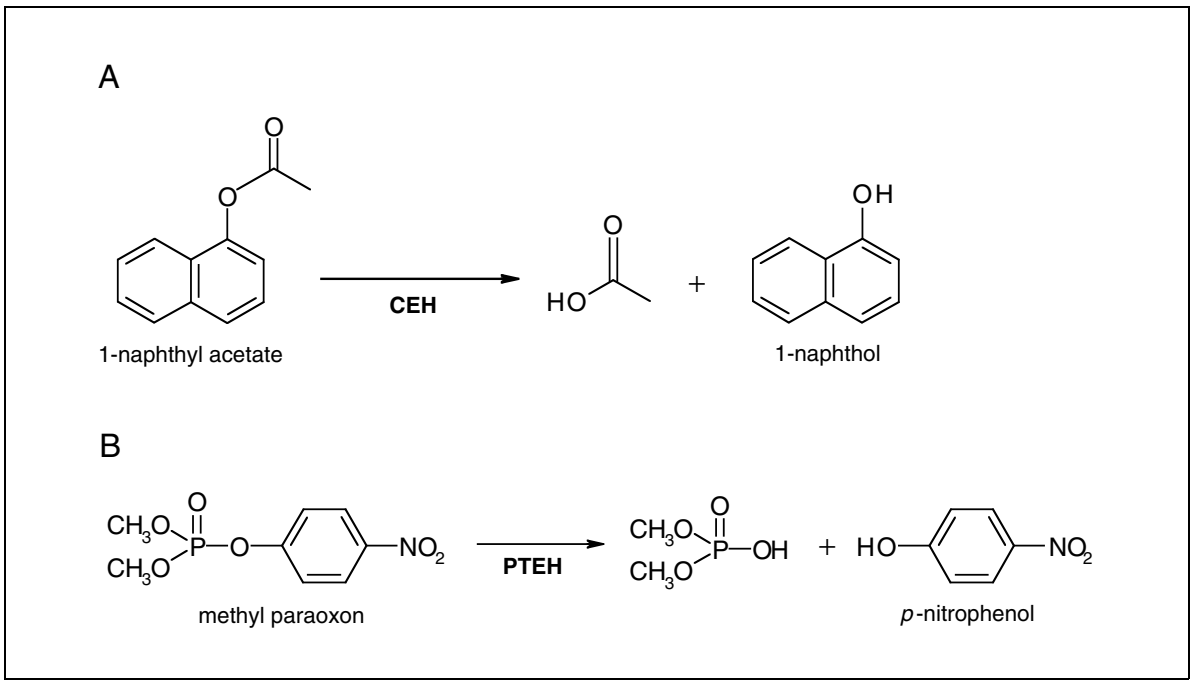

Figure 4.10.1 (**A**) Metabolism of 1-naphthyl acetate by carboxylic ester hydrolases (CEHs). (**B**) Metabolism of methyl paraoxon by phosphoric triester hydrolases (PTEHs).

Materials

100 µmol/ml 1-naphthol (see recipe)
200 mM 1-naphthyl acetate (see recipe)
0.3% (w/v) Fast Blue B Salt solution containing 3.4% (w/v) SDS (see recipe)
100 mM methyl paraoxon (see recipe)
Enzyme sample (purified protein or clarified homogenate)
100 mM sodium phosphate assay buffer, pH 7.4 (see recipe)

Spectrophotometer for microtiter plates with temperature control
Plastic 96-well, flat-bottom microtiter plates

Prepare samples and solutions

1. Turn on the microtiter plate spectrophotometer and select the endpoint mode for reading absorbance at 595 nm. Also, set the incubator to the desired assay temperature.

   Samples from mammals, birds, and E. coli normally are incubated at 37°C. An incubation temperature of 30°C may be more appropriate for fish, insect, reptile, and plant samples.

2. From stock solutions, make fresh assay solutions of 1-naphthol (100, 50, 25, 12.5, 6.25, 3.13, nmol/ml), 1-naphthyl acetate (1 mM), and methyl paraoxon (10 mM). Use sodium phosphate assay buffer for these dilutions. Also, prepare a 0.3% (w/v) Fast Blue B Salt solution containing 3.4% (w/v) SDS in distilled water (see recipes).

3. Perform preliminary CEH assays with several dilutions of enzyme sample to determine an enzyme concentration that is within the linear range for substrate hydrolysis. Make sample dilutions in ice-cold sodium phosphate assay buffer.

   A regression of sample concentration versus absorbance (OD_{595}) should produce a straight line that intersects the origin in the linear range of the assay.

4. Prepare an adequate volume of the sample concentration in the linear range of the assay for addition (steps 8 and 9) of 70 µl to each well that requires enzyme sample.

Use ice-cold sodium phosphate assay buffer for sample dilutions. Keep enzyme samples on ice before the addition of substrate.

CEH activity calculations may be inaccurate if the sample concentration assayed does not produce a linear rate of substrate hydrolysis.

Different sample preparations may vary significantly in CEH activity. If quantitating multiple samples, be aware that concentrations within the linear range of substrate hydrolysis for one sample may be different for other samples.

Avoid any delays during the execution of steps 5 to 15.

Perform CEH assay

5. For the standard blank, add 175 µl sodium phosphate assay buffer to each of three empty wells of a 96-well microtiter plate.
6. For the standards, add 175 µl to each of three empty wells for each 1-naphthol concentration (3.13, 6.25, 12.5, 25, 50, and 100 nmol/ml).
7. For the sample blank, add 75 µl of sodium phosphate assay buffer to each of three empty wells.

   This blank will detect color formation from non-enzymatic sources.

   Do not confuse sample blanks with the standard blanks (step 5). These two types of blanks differ in content.

8. For each sample, add the following in sequence to each of three empty wells:

   5 µl sodium phosphate assay buffer
   70 µl enzyme sample

9. For each sample plus methyl paraoxon treatment, add in sequence the following to each of three empty wells:

   5 µl 10 mM methyl paraoxon
   70 µl enzyme sample

   To calculate percentage inhibition, see CEH Activity Calculations below. Methyl paraoxon at the assay concentration should inhibit B-esterases (carboxylesterases, acetylcholinesterases, and cholinesterases), which generally are in abundance in many types of samples.

   Additional sample wells can be included to evaluate other inhibitors or activators of CEH activity.

10. Immediately place the plate into the microtiter plate spectrophotometer and incubate for 10 min at the assay temperature.

    If the spectrophotometer has an automix function, enable it to shake-mix the contents of the plate wells at the beginning and end of each incubation period throughout the assay.

    This incubation period allows for the methyl paraoxon to inhibit B-esterases.

11. Remove the plate from the spectrophotometer. Add 100 µl of 1.0 mM 1-naphthyl acetate substrate to all wells *except* those containing the standard blank and the standards.
12. Place the plate back into the spectrophotometer and incubate for 15 min at the assay temperature.
13. Remove the plate and add 25 µl of 0.3% Fast Blue B Salt solution containing 3.4% SDS to all wells of the assay.

14. Return the plate to the spectrophotometer and incubate for 10 min at the assay temperature.

    This incubation period allows for color development from the conjugation of naphthol-Fast Blue B.

Read samples

15. Read simultaneously the absorbance of each well at 595 nm.

16. Remove the microtiter plate from the spectrophotometer. Appropriately package and label hazardous waste from the assay, and arrange for prompt removal and disposal by the hazardous waste office of the institution.

SUPPORT PROTOCOL 1

CEH SPECIFIC ACTIVITY CALCULATIONS

The following steps for activity calculations are based on acquisition of raw absorbance readings from the endpoint mode of a microtiter plate spectrophotometer. Spectrophotometers with accompanying computer and software may be programmable for automated blank subtraction, standard curve plotting and enzyme activity calculations.

1. Subtract the mean absorbance of the three standard blank wells from the absorbance of each well that contains 1-naphthol standards. Then calculate the mean absorbance (blank subtracted) of each standard concentration from the three replicate wells per concentration.

2. Create a standard curve by plotting each 1-naphthol concentration versus its corresponding absorbance.

   After plotting the standard curve, make sure that the best-fitted line passes through the origin of the graph. Also, the correlation coefficient (r^2 value) of the line typically should be ≥0.9. If necessary, the standard curve should be repeated until these criteria are met.

3. Subtract the mean absorbance of the three sample blank wells from the absorbance of each well that contains sample and sample plus methyl paraoxon.

   The blank-subtracted absorbance value of each sample well must be between the minimum and maximum OD_{595} values of the 1-naphthol standard curve. If necessary, adjust the sample concentration and repeat the assay until the sample absorbance is in this range.

4. Use the linear regression equation of the standard curve to determine the concentration (nmol/ml) of 1-naphthol produced in each of the wells containing sample and sample plus methyl paraoxon.

   For example, with the equation $y = mx + b$, the concentration (x) can be determined by applying the blank-subtracted sample absorbance (y). The slope of the line is m, and b is the y-intercept.

5. Measure the protein concentration (mg/ml) of each sample.

6. Calculate the CEH specific activity for each well containing sample and sample plus methyl paraoxon using the following parameters: the concentration of 1-naphthol produced, the assay dilution factor of the enzyme sample, incubation time, and the protein concentration of the enzyme sample.

$$\frac{\text{nmol/ml 1-naphthol} \times \text{sample dilution factor}}{\text{incubation time (min)}} \times \frac{1\ \text{ml}}{\text{mg protein}}$$
$$= \text{nmol min}^{-1}\ \text{mg protein}^{-1}$$

7. For each sample and sample plus methyl paraoxon treatment, calculate the mean specific activity of CEH from the three replicate wells per treatment.
8. To calculate the percentage of CEH inhibition by methyl paraoxon, use the following equation:

$$\frac{(\text{specific activity of sample}) - (\text{specific activity of sample + methyl paraoxon})}{(\text{specific activity of sample})} \times 100$$

MEASUREMENT OF PHOSPHORIC TRIESTER HYDROLASE (PTEH) ACTIVITY

BASIC PROTOCOL 2

This method measures hydrolysis of the phosphoric triester substrate, methyl paraoxon. The yellow product, *p*-nitrophenol, is detectable spectrophotometrically at 405 nm. Several concentrations of *p*-nitrophenol are used to create a standard curve for estimation of PTEH activity in samples. Multiple samples can be analyzed simultaneously, as the assay is formatted for a microtiter plate reader using 96-well plates. This procedure is rapid, with a total incubation time of 45 min. With a total reaction volume of 300 µl, only a small volume of sample is necessary.

Materials

100 µmol/ml *p*-nitrophenol (see recipe)
100 mM methyl paraoxon (see recipe)
Enzyme sample (purified or clarified homogenate)
100 mM Tris·Cl assay buffer, pH 8.0 (see recipe)

Spectrophotometer for microtiter plates with temperature control
Plastic 96-well, flat-bottom microtiter plates

Prepare samples and solutions

1. Turn on the microtiter plate spectrophotometer and select the endpoint mode for reading absorbance at 405 nm. Also, set the incubator to the desired assay temperature.

   Samples from mammals, birds, and E. coli normally are incubated at 37°C. An incubation temperature of 30°C may be more appropriate for fish, insect, reptile, and plant samples.

2. For stock solutions, make fresh assay solutions of *p*-nitrophenol (100, 50, 25, 12.5, 6.25, 3.13 nmol/ml), and methyl paraoxon (2 mM). Use Tris·Cl assay buffer for these dilutions.
3. Perform preliminary PTEH assays with several dilutions of enzyme sample to determine an enzyme concentration that is within the linear range for substrate hydrolysis. Make sample dilutions in ice-cold Tris·Cl assay buffer.

   A regression of sample concentration versus absorbance (OD_{405}) should produce a straight line that intersects the origin in the linear range of the assay.

4. Prepare an adequate volume of the sample concentration in the linear range of the assay for addition (step 8) of 289 µl to each well that requires enzyme sample. Use ice-cold Tris·Cl assay buffer for sample dilutions. Keep enzyme samples on ice before the addition of substrate.

   PTEH activity calculations may be inaccurate if the sample concentration assayed does not produce a linear rate of substrate hydrolysis.

Different sample preparations may vary significantly in PTEH activity. If quantitating multiple samples, be aware that concentrations within the linear range of substrate hydrolysis for one sample may be different for other samples.

Avoid any delays during the execution of steps 5 to 10.

Perform PTEH assay

5. For the standard blank, add 300 µl of 100 mM Tris·Cl assay buffer to each of three empty wells of a 96-well microtiter plate.
6. For the standards, add 300 µl to each of three empty wells for each *p*-nitrophenol concentration (3.13, 6.25, 12.5, 25, and 100 nmol/ml).
7. For the sample blank, add the following to each of three empty wells of the microtiter plate:

   11 µl of 2 mM methyl paraoxon
   289 µl of 100 mM Tris·Cl assay buffer

   This blank will measure the non-enzymatic rate of substrate hydrolysis.

   Do not confuse sample blanks with the standard blanks (step 5). These two types of blanks differ in content.
8. For each sample, add the following to each of three empty wells of the microtiter plate:

   11 µl of 2 mM methyl paraoxon
   289 µl of enzyme sample
9. Immediately place the microtiter plate into the spectrophotometer and incubate for 45 min at the assay temperature.

   If the spectrophotometer has an automix function, enable it to shake-mix the contents of the plate wells at the beginning and end of the incubation period.

   Within the first few minutes of incubation, a fraction of methyl paraoxon will bind and inhibit B-esterases. The remainder of the organophosphate then acts solely as a substrate for PTEH.

Read samples

10. Read simultaneously the absorbance of each well at 405 nm.
11. Remove the microtiter plate from the spectrophotometer. Appropriately package and label hazardous waste from assay, and arrange for prompt removal and disposal by the hazardous waste office of the institution.

SUPPORT PROTOCOL 2

PTEH SPECIFIC ACTIVITY CALCULATIONS

The following steps for activity calculations are based on acquisition of raw absorbance readings from the endpoint mode of a microtiter plate spectrophotometer. Spectrophotometers with accompanying computer and software may be programmable for automated blank subtraction, standard curve plotting, and enzyme activity calculations.

1. Subtract the mean absorbance of the three standard blank wells from the absorbance of each well that contains *p*-nitrophenol standards. Then calculate the mean absorbance (blank subtracted) of each standard concentration from the three replicate wells per concentration.

2. Create a standard curve by plotting each *p*-nitrophenol concentration versus its corresponding absorbance.

   After plotting the standard curve, make sure that the best-fitted line passes through the origin of the graph. Also, the correlation coefficient (r^2 value) of the line typically should be ≥0.9. If necessary, the standard curve should be repeated until these criteria are met.

3. Subtract the mean absorbance of the three sample blank wells from the absorbance of each well that contains sample.

   The blank-subtracted absorbance value of each sample well must be between the minimum and maximum OD_{405} values of the p-nitrophenol standard curve. If necessary, adjust the sample concentration and repeat the assay until the sample absorbance is in this range.

4. Use the linear regression equation of the standard curve to determine the concentration (nmol/ml) of *p*-nitrophenol produced in each of the wells containing sample.

   For example, with the equation $y = mx + b$, the concentration (x) can be determined by applying the blank-subtracted sample absorbance (y). The slope of the line is m, and b is the y-intercept.

5. Measure the protein concentration (mg/ml) of each sample.

6. Calculate the PTEH specific activity for each well containing sample using the following parameters: the concentration of *p*-nitrophenol produced, the assay dilution factor of the enzyme sample, incubation time, and the protein concentration of the enzyme sample.

$$\frac{\text{nmol/ml } p\text{-nitrophenol} \times \text{sample dilution factor}}{\text{incubation time (min)}} \times \frac{1\text{ ml}}{\text{mg protein}}$$
$$= \text{nmol min}^{-1}\text{ mg protein}^{-1}$$

7. For each sample, calculate the mean specific activity of PTEH from the three replicate wells.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for supplies, see* ***SUPPLIERS APPENDIX****.*

Fast Blue B Salt solution, 0.3% (w/v) containing 3.4% (w/v) SDS

In a foil-covered container, dissolve 30.0 mg of Fast Blue B Salt (~90%; Aldrich) in distilled water for a total volume of 3.0 ml. In a separate container, add 340.0 mg of SDS (sodium dodecyl sulfate salt) in distilled water for a total volume of 7.0 ml. To dissolve the SDS, gently swirl its container by hand to minimize foaming. When both chemicals are dissolved, add the SDS solution to the Fast Blue B Salt solution container. Mix by gentle hand swirling. This solution is stable for ~2 hr.

Fast Blue B Salt is light sensitive and must be kept in darkness except when weighing, and during addition of this solution to the assay.

CAUTION: *SDS is a respiratory irritant. A dust mask should be worn during weighing and mixing of SDS.*

Methyl paraoxon, 100 mM

Stock solution: Add 24.71 mg of methyl paraoxon (99.1%; Chem Service) to 100% ethanol for a final volume of 1.0 ml. Vortex until dissolved. Store in a tightly sealed container for up to 1 month at 4°C.

Inhibitor solution for CEH assay (10 mM): Make fresh daily by diluting the stock solution with 100 mM sodium phosphate assay buffer, pH 7.4 (see recipe).

Substrate solution for PTEH assay (2 mM): Make fresh daily by diluting the stock solution with 100 mM Tris·Cl assay buffer, pH 8.0 (see recipe).

CAUTION: *Methyl paraoxon is highly toxic! Appropriate protective gloves and eyewear should be worn, and a chemical fume hood should be used when making and diluting solutions.*

1-Naphthol, 100 µmol/ml

Stock solution: Add 14.42 mg of 1-naphthol (99+%; Aldrich) to 100% ethanol for a total volume of 1.0 ml. Vortex until dissolved. Store in a tightly sealed container for up to 1 month at −20°C.

CEH standard assay solutions (100, 50, 25, 12.5, 6.25, and 3.13 nmol/ml): Make fresh daily by diluting the stock solution with 100 mM sodium phosphate assay buffer, pH 7.4 (see recipe).

1-Naphthyl acetate, 200 mM

Stock solution: Add 37.24 mg of 1-naphthyl acetate (99+%; Sigma) to 100% ethanol for a total volume of 1.0 ml. Vortex until dissolved. Store in a tightly sealed container for up to 1 month at −20°C.

CEH substrate assay solution (1 mM): Make fresh daily by diluting the stock solution with 100 mM sodium phosphate assay buffer, pH 7.4 (see recipe).

p-Nitrophenol, 100 µmol/ml

Stock solution: Add 13.91 mg of *p*-nitrophenol (99%; Fluka Chemical) to 100% ethanol for a total volume of 1.0 ml. Vortex until dissolved. Store in a tightly sealed container for up to 1 month at −20°C.

PTEH standard assay solutions (100, 50, 25, 12.5, 6.25 and 3.13 nmol/ml): Make fresh daily by diluting the stock solution with 100 mM Tris·Cl assay buffer, pH 8.0 (see recipe).

Sodium phosphate assay buffer, 100 mM (pH 7.4)

Monobasic stock solution, 1 M: Add 11.996 g of monobasic sodium phosphate (NaH_2PO_4) to distilled water for a total volume of 100 ml. Heat to dissolve if necessary. Store for up to 2 months at 4°C. Heat to re-dissolve if precipitation occurs.

Dibasic stock solution, 1 M: Add 14.196 g of dibasic sodium phosphate (Na_2HPO_4) to distilled water for a total volume of 100 ml. Heat to dissolve if necessary. Store for up to 2 months at 4°C. Heat to re-dissolve if precipitation occurs.

Sodium phosphate assay buffer, 100 mM (pH 7.4): At 25°C, add 2.26 ml of 1 M monobasic stock solution and 7.74 ml of 1 M dibasic stock solution to 90 ml of distilled water. Mix thoroughly and measure to assure a pH of 7.4. If pH is not 7.4, remake assay buffer with new monobasic and dibasic stock solutions. Store for up to 2 months at 4°C.

For homogenization of insects, add phenyl thiourea (PTU) to the assay buffer. Under a chemical fume hood, heat-dissolve the PTU in a small volume of water, and then add to the assay buffer for a concentration of 0.01% (w/v). PTU will present blackening of the sample by inhibiting tyrosinases.

Tris·Cl assay buffer, 100 mM (pH 8.0)

Dissolve 1.211 g of Tris base in distilled water for a total volume of 80 ml. Adjust the pH to 8.0 with concentrated HCl. Bring total volume to 100 ml with distilled water. Store up to 1 month at 4°C.

For homogenization of insects, add phenyl thiourea (PTU) to the assay buffer. Under a chemical fume hood, heat-dissolve the PTU in a small volume of water, and then add to the assay buffer for a concentration of 0.01% (w/v). PTU will prevent blackening of the sample by inhibiting tyrosinases.

COMMENTARY

Background Information

Esterases are monomeric (mol. wt. 40,000 to 60,000) or heteromeric (mol. wt. ≤200,000) proteins present in the soluble and microsomal cell fractions. Some may have post-translational modifications, including glycosylation and the addition of lipids (Urich, 1994). The types of esterases present and levels of activity can be highly variable from one species to another, and may differ even between individuals of the same species. Several factors can influence these differences, including life stage, hormones, sex, diet, food quality, genetic polymorphism, disease, and environmental conditions. Some esterases are associated with specific tissues, while others are ubiquitous within an organism (Devorshak and Roe, 1998).

The esterases cleave aliphatic esters of short-chain carboxyl acids, aromatic esters, aromatic amides, phosphoesters, and thioesters. The physiological function of many esterases is still obscure, but they probably are essential because their genetic codes have been preserved throughout evolution (Van Zutphen et al., 1988; Urich, 1994). Several studies have suggested that human serum esterases are involved in metabolizing various classes of lipids, such as mono- and triacylglycerols (Tsujita and Okuda, 1983; Shirai et al., 1988). Accumulation of such lipids may be caused by poor esterase metabolism, which has been implicated in the development of human atherosclerosis and myocardial infarction (McElveen et al., 1986; Mackness, 1989). A well-known endogenous esterase substrate is acetylcholine, which is specifically metabolized by acetylcholinesterase in nerve tissue for proper impulse transmission. In insects, an esterase has been discovered that is highly specific for the endogenous substrate, juvenile hormone (JH). JH esterase metabolism of JH at critical time points is essential for proper insect development and metamorphosis (Roe et al., 1993). In general, however, evidence of specific endogenous substrates for esterases is scarce.

Numerous exogenous esterase substrates, including xenobiotics, have been identified. Typically, esterase metabolism of xenobiotics is a detoxication mechanism that produces a less toxic, more water-soluble compound for excretion. In some cases however, the parent compound is activated by esterases, rendering higher toxicity to the intermediates or final products. Examples of exogenous substrates include ester and amide derivatives of drugs, nerve gases (tabun, sarin, and DFP), plasticizers that contain phthalic acid esters, herbicides with phenoxyacetic and picolinic acid esters, and several classes of insecticides (Hodgson and Levi, 1994). Development of resistance in insects to the organophosphate, pyrethroid, and carbamate insecticides has been attributed to esterases. The mechanism of resistance usually is associated with increased esterase production, which enhances detoxication or sequestration of the insectisides (see Devorshak and Roe, 1998).

In 1953, Aldridge proposed a classification system of esterases based upon their interaction with organophosphorus compounds (OPs). "A"-esterases hydrolyze OPs like paraoxon, methyl paraoxon, and diisopropylphosphorofluoridate (DFP), while "B"-esterases are inhibited by OPs. With A- and B-esterases, the OPs are substrates for the enzyme. But in the case of the B-esterases, these compounds act as suicide substrates by binding their phosphoryl moieties to the enzymes (Walker, 1989).

Since the time of Aldridge's discovery of A- and B-esterases, hundreds of types of esterases have been discovered. The Enzyme Commission of the International Union of Biochemistry and Molecular Biology (IUBMB, 1992) has classified these esterases based upon their metabolic activities toward a variety of artificial substrates. This classification system has been

criticized heavily for several reasons (Pen and Beintema, 1986; Urich, 1994). First, artificial substrates are used, since neither the endogenous substrate nor the biological function is known for most esterases. Second, substrate preferences can be highly overlapping between the defined classes. Third, many esterases exist in multiple forms (isozymes) due to genetic polymorphism, or as a result of variable glycosylation and other post-translational modifications. Fourth, other enzymes have esterase activity, such as serine proteases. Also, proteins that usually are not considered to be enzymes, like serum albumins, can have esterase activity. Finally, only a few esterases have been purified extensively for characterization. When working with unpurified homogenates, substrate metabolism may result from more than one type of esterase, or perhaps from a protein other than an esterase. Because of these pitfalls, the classification system used today lends itself to problems of ambiguity and redundancy. Ideally, the classification of esterases would be similar to that of enzymes such as the cytochrome P450s, which is based on a genealogical tree constructed from the relativity of nucleic acid and peptide sequences. Unfortunately molecular genetics data on esterases are insufficient at this time to derive such nomenclature. Until the volume of molecular data is adequate to develop this type of classification system for esterases, suggestions for improvement (e.g., Heymann 1989; Walker, 1989) of the current system should be considered and implemented when deemed appropriate.

Despite the difficulties and controversy associated with the identification and classification of esterases in the past, Aldridge's scheme still is used today to distinguish and quantitate esterases that metabolize OPs, and those that are inhibited by these compounds. However, the methodology of detecting these esterases, and the nomenclature (discussed below) has changed significantly. Originally, Aldridge used *p*-nitrophenyl esters (acetate, propionate, and butyrate) as substrates in a manometric, rather than a colorimetric method. Enzyme activity was estimated kinetically, based on the CO_2 liberated from bicarbonate buffer by the acid produced during hydrolysis (Aldridge, 1953). A- and B-esterases were distinguished by the difference in activity between reactions with, and without paraoxon. The disadvantages of this assay include a tedious protocol, low sensitivity of detection, and use of large sample volumes. Also, it was time consuming since only one sample could be measured at a time. The esterase protocols presented here have the advantages of being colorimetric and miniaturized for multi-well microtiter plates. This simpler format allows for rapid, simultaneous quantitation of multiple samples. Additionally, these assays are very sensitive and require less sample material. Other colorimetric esterase assays have been published previously (see below), but these macroassay procedures utilized large sample volumes and were limited to one sample reading at a time.

The first assay presented (see Basic Protocol 1) is for the measurement of carboxylic ester hydrolases (CEHs; EC 3.1.1). Currently, there are 66 subclasses of enzymes within this group, including the B-esterases, which are inhibited by OPs. B-esterases include carboxylesterase (EC 3.1.1.1), acetylcholinesterase (EC 3.1.1.7), and cholinesterase (EC 3.1.1.8). Besides the B-esterases, there is a wide variety of other CEHs, such as arylesterase (EC 3.1.1.2), sterol esterase (EC 3.1.1.13), α-amino acid esterase (EC 3.1.1.43), insect juvenile hormone esterase (EC 3.1.1.59), and several lipases and lactonases. Originally, the assay for CEHs was miniaturized and modified by Abdel-Aal et al. (1990) from macroassays by Gomori (1953) and van Asperen (1962). This procedure measures hydrolysis of the substrate, 1-naphthyl acetate, to the product, 1-naphthol. Although some researchers consider 1-naphthyl acetate to be specific for carboxylesterases, the protocol presented here is titled more generally due to the possibility that other CEHs can metabolize this substrate. To determine if metabolism of 1-naphthyl acetate was a result of B-esterases, esterase activity can be quantitated from samples with, and without the addition of methyl paraoxon.

The second protocol described (see Basic Protocol 2) is for detection of phorphoric triester hydrolases (PTEHs; EC 3.1.8). Currently, there are only two subclasses of esterases in this group. Besides A-esterase, now called aryldialkylphosphatase (EC 3.1.8.1) by the IUBMB, the other member is diisopropyl-fluorophosphatase (EC 3.1.8.2), or DFP-ase. Both of these enzymes metabolize OPs, including esters of phosphonic and phosphinic acids, and those with phosphorus anhydride bonds (IUBMB, 1992). The assay is a modification of a microtiter plate procedure developed by Devorshak and Roe (2001), which is based on a macroassay described by Furlong et al. (1988). The substrate is methyl paraoxon, which when

metabolized by PTEHs, yields the yellow-colored product, *p*-nitrophenol. The assay discriminates against B-esterases, as this activity is inhibited by the organophosphorus substrate.

Several inhibitors and activators of PTEH activity have been documented (Aldridge, 1953; Shishido and Fukami, 1972; Konno et al., 1990; Devorshak and Roe, 2001). Perhaps the most effective PTEH inhibitors are mercuric compounds such as *p*-chloromercuribenzoate (PCMB). Other metal ions such as Ag^{+}, Cd^{2+}, Cu^{2+}, and Sn^{4+} can also inhibit PTEHs, as well as PO_4 and ethylenediaminetetraacetic acid (EDTA). In general, these inhibitors are not as potent as mercury, and results differ widely among various biological samples. PTEH activity may be enhanced by addition of Ca^{2+}, Co^{2+}, and Mn^{2+}. These ions act as important cofactors for PTEH activity, and may be present naturally in samples from serum or whole homogenates from cells or tissues. Purified PTEH samples, however, may require addition of one or more of these cofactors to elicit activity. In mammals, Ca^{2+} appears to be the most important cofactor, while Co^{2+} and Mn^{2+} activate insect PTEH activity (Dauterman, 1976). Inhibition of PTEH by Hg^{2+} and the metal chelator EDTA, and activation by divalent cations suggests that PTEH may have a cysteine residue involved in the catalytic mechanism. This is not the case for the B-esterases, which have a serine at the active site of the enzyme (Aldridge, 1989).

Utilizing both protocols, one can determine quickly if biological samples contain CEHs, PTEHs, or both types of esterases. Furthermore, esterase activity can be detected in the pmol min^{-1} mg $protein^{-1}$ range. With the miniaturized microtiter plate design of these assays, multiple, small-volume samples can be tested simultaneously. Finally, additional treatments can be added to either assay for screening of classical or putative inhibitors or activators of these esterases.

Critical Parameters and Troubleshooting

Sample preparation

Small particles suspended in the supernatants of sample homogenates following centrifugation (10,000 × *g*) can cause erroneous absorbance readings. This suspended material can be eliminated by filtration of supernatants through glass wool. The glass wool should be cleaned with HPLC-grade hexane and then air-dried before use. Supernatants of samples can be assayed fresh or can be stored at –20° to –80°C until the time of assay. When freezing, make small aliquots of each sample to avoid repetitive freeze-thawing that could decrease enzyme activity. Always hold samples on ice immediately after thawing and until addition to the microtiter plate.

It is advisable to include in all assays a positive control sample (if available) that is known to have detectable activity of the esterase of interest. Modifications to the assay protocol may be necessary if activity is detectable in the positive control, but not in an unknown sample. For example, increasing sample concentration or incubation time may be necessary to detect low levels of activity. Additionally, some esterases are more active at slightly higher or lower pH than is listed in the protocol. Samples can be assayed at a range of pH values to determine optimal conditions for esterase activity. If the adjustment of assay conditions does not elicit detectable enzyme activity, it may be possible that the sample either has no activity, or it is too low for detection.

Assay conditions

For CEH and PTEH assays, enzyme activity measurements will be inaccurate if the enzyme concentration is not within the linear range of substrate hydrolysis. As described in Basic Protocols 1 and 2, preliminary assays may be necessary to identify an appropriate enzyme concentration.

The substrates, 1-naphthyl acetate and methyl paraoxon, are considered to be specific for carboxylic ester hydrolases and phosphoric triester hydrolases, respectively. Despite this consideration, it should be realized that there is the possibility for the substrates to be metabolized by other enzymes.

Whenever inhibitors or activators are added to the assays in a solvent, rather than an aqueous diluent, the total percentage of solvent (including substrate addition) in the final reaction volume should never exceed 1.0%. Higher solvent percentages could significantly affect enzyme activity.

When performing CEH assays, potassium phosphate should not be substituted for sodium phosphate buffer. Potassium will precipitate upon the addition of Fast Blue B-SDS solution in the assay.

Concerning the PTEH assay, there are several parameters that are critical for successful activity quantitation. Perhaps most important is proper pH of the enzymatic reactions. If the assay pH is too basic, high background may

Table 4.10.1 Results from Carboxylic Ester Hydrolase (CEH) Assay

	CEH activity (nmol min^{-1} mg $protein^{-1}$)	% Inhibition by methyl paraoxon[a]
Mouse liver	171	100

result from non-enzymatically hydrolyzed methyl paraoxon. If the assay pH is too acidic, the *p*-nitrophenol product loses its yellow color, and PTEH activity will not be detectable. For ideal activity measurements with low background, the assay should be pH 8.0 to 8.5. PTEH activity is highest at this pH range in mammals and insects. Also, the use of Tris·Cl buffer (pH 8.0) is highly recommended for sample preparation and assay reactions in PTEH assays. Other buffers may have constituents that affect PTEH activity. For instance, buffers containing phosphate ions or ethylenediaminetetraacetic acid (EDTA) can reduce or even fully inhibit PTEH activity.

Anticipated Results

Mouse liver, porcine liver, and the tobacco budworm, *Heliothis virescens* (whole body, 5th stadium larva) were analyzed for CEH (Table 4.10.1) and PTEH (Table 4.10.2) specific activity by following the two protocols above. Whole homogenates were prepared from mouse liver and tobacco budworm in Tris·Cl buffer (pH 8.0) by use of a Polytron PT10/35 homogenizer (Brinkman Instruments). The homogenates were centrifuged for 15 min at 10,000 × *g*, and then filtered through glass wool. The porcine liver (41 U/mg) was ordered as a crude lyophilized powder from Sigma Chemical, and was resuspended in Tris·Cl assay buffer, pH 8.0. Samples were diluted in sodium phosphate assay buffer, pH 7.4, for CEH assays and Tris·Cl assay buffer, pH 8.0, for PTEH assays. Protein concentrations were determined by the Bio-Rad assay with bovine serum albumin as the standard.

Basic Protocol 1

See the CEH protocol for general assay requirements. Assays were performed at pH 7.4, and incubated with substrate for 15 min. The incubation temperature for mouse liver and porcine liver was 37°C, while the tobacco budworm sample was incubated at 30°C. Protein concentrations used for assays were 180, 382, and 37 μg for mouse, porcine, and tobacco budworm, respectively. For inhibitor treatments, methyl paraoxon (667 μM final assay concentration) was added to the sample for a 10-min incubation before addition of substrate. The specific activity (nmol min^{-1} mg $protein^{-1}$) and % inhibition by methyl paraoxon for each sample were calculated using the formulae in the CEH Calculations (see Support Protocol 1). See Table 4.10.1 for results.

Basic Protocol 2

See the PTEH protocol for general assay requirements. Assays were performed at pH 8.0, and incubated with substrate for 45 min. The incubation temperature for mouse liver and porcine liver was 37°C, while the tobacco budworm sample was incubated at 30°C. Protein concentrations used for assays were 2.30, 0.03, and 3.81 μg for mouse, porcine, and tobacco budworm, respectively. The specific activity (pmol min^{-1} mg $protein^{-1}$) for each sample was calculated using the formula in the PTEH Cal-

culations (see Support Protocol 2). See Table 4.10.2 for results.

Time Considerations

For both assays, the total time required to perform the reactions depends on the number of samples and inhibitors to be analyzed. If adequate activity is detected with the incubation times listed for each protocol, the CEH assay can be performed in 45 to 60 min, while the PTEH assay may take 60 to 75 min. This time estimation does not include the preparation of buffers, standards, substrates, or enzyme dilutions.

Techniques for Measuring the Activity of Carboxylic Acid:CoA Ligase and Acyl-CoA:Amino Acid *N*-Acyltransferase: The Amino Acid Conjugation Pathway

A wide variety of carboxylic acid compounds are metabolized to their amino acid conjugates via a pathway that exists primarily in liver and kidney (Vessey, 1997). This conjugation occurs in two steps and is catalyzed by two distinct classes of enzymes:

$$\text{R-COOH} + \text{CoASH} + \text{ATP} \xrightarrow{\text{(Ligases)}} \text{R-CO-SCoA} + \text{AMP} + \text{PP}_i \quad \text{(step 1)}$$

$$\text{R-CO-SCoA} + \text{H}_2\text{N-CHR-COOH} \xrightarrow{\text{(Transferases)}} \text{R-CO-NH-CHR-COOH} + \text{CoASH} \quad \text{(step 2)}$$

In the first step, xenobiotic carboxylic acids and fatty acids are activated by acyl-CoA ligases, which catalyze formation of a thioester bond between the carboxylic acid moiety and coenzyme A in a reaction that results in pyrophorylytic cleavage of ATP to AMP. The activated xenobiotic is then conjugated with an amino acid (usually glycine) in a second reaction catalyzed by *N*-acyltransferases. Conjugation of carboxylic acid xenobiotics with an amino acid is important in that it can decrease toxicity or biological activity and enhance excretion. Activated short-chain and medium-chain fatty acids are subsequently metabolized by either oxidation or pathways for complex lipid synthesis.

Methods for determining the rates of reaction of carboxylic acid:CoA ligases include direct measurement of CoA-adduct formation by radiochemical (see Basic Protocol 1), spectrophotometric (see Alternate Protocol 2), or HPLC assays (see Alternate Protocol 4), as well as measurement of radiolabeled pyrophosphate (PP_i) release upon ATP cleavage (see Alternate Protocol 1) and detection of AMP by coupled spectrophotometric and fluorometric assays.

Methods for determining rates of reaction of acyl-CoA with glycine (or glutamine) catalyzed by the acyl-CoA amino acid *N*-acyltransferases include monitoring either the release of CoA by reaction with 5,5′-dithiobis(2-nitrobenzoate) (DTNB; see Basic Protocol 2), radioassay (see Alternate Protocol 6), HPLC (see Alternate Protocol 7), or the disappearance of the CoA thioester bond by UV spectroscopy (see Alternate Protocol 5).

NOTE: Accurate determination of binding constants requires accurate reagent concentrations.

DIRECT MEASUREMENT OF CARBOXYLIC ACID:CoA LIGASE ACTIVITY USING A RADIOLABELED CARBOXYLIC ACID

BASIC PROTOCOL 1

This assay measures the formation of the CoA adduct directly using a radiolabeled carboxylic acid substrate. Multiple aliquots are removed from the reaction mixture at timed intervals into tubes containing EDTA, which stops the reaction. They are then extracted with butanol to remove unreacted substrate, leaving radiolabeled acyl-CoA product in the aqueous phase. This simplified sample protocol illustrates this approach for determining rates of reaction at varied concentrations of carboxylic acid substrate, in this case optimized for [^{14}C]benzoate, with fixed concentrations of ATP and coenzyme A. If desired, other substrates (see Reagents and Solutions), other ATP or coenzyme A concentrations, or other variable parameters can be used to thoroughly investigate the

Contributed by Michael Kelley and Donald A. Vessey
Current Protocols in Toxicology (2002) 4.11.1-4.11.16

system at hand. Controls are generally not needed; although, one could leave out the CoA if desired.

Materials

Kill/acidification mix (see recipe) in dispenser set to deliver 0.4 ml
Water-saturated butanol (see recipe) in dispenser set to deliver 1 ml
1 M Tris·Cl, pH 8.0 at 30°C (*APPENDIX 2A*)
1 M KCl
100 mM $MgCl_2$
5 mM coenzyme A (see recipe)
Radiolabeled carboxylic acid substrate (e.g., 100 μM 80 cpm/mol [^{14}C]benzoate; see recipe)
1 mM ATP (see recipe)
Carboxylic acid:CoA ligase preparation (see Commentary)
Scintillation fluid

Positive-displacement pipet (e.g., Drummond)
30°C water bath
Vacuum pipettor
Scintillation vials

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*). Also note that short-chain fatty acids are volatile and should be maintained in sealed tubes to avoid contamination of storage areas.

Prepare tubes containing reaction-terminating "kill" reagents

1. For each of five substrate concentrations, label a set of four 12 × 75–mm "kill" tubes with time points appropriate to determine the initial rate of reaction (i.e., twenty tubes).

   The reaction time points are chosen so that the rate is large enough for accurate determination, without significantly changing the substrate concentration over the course of the reaction; therefore, true initial rates are ensured. This is more difficult at substrate concentrations at or below K_M, as the reaction is not linear over long time courses. For the fast rate of the example (Fig. 4.11.1A), where the reactions are linear over 1 min, time points as short as 0, 20, 40, and 60 sec can be chosen by an experienced researcher.

2. Add the appropriate kill/acidification mix into each tube from a dispenser set to deliver 0.4 ml, followed by water-saturated butanol from a dispenser set to deliver 1 ml.

   The butanol may be added just before extraction if ventilation is inadequate and the vapor is objectionable.

Prepare reaction tubes

3. Prepare a mixture of the four invariant reagents in sufficient volume for the number of reactions according to Table 4.11.1.

   For the reagents that are not varied in the study, it is both easier and more accurate to prepare a mix in the appropriate proportions and then pipet this mix into each tube. A vacuum pipet (e.g., Pipetman) may be used, which while slightly less accurate is convenient and highly consistent, ensuring minimal variation of the fixed reagent concentrations when large numbers of assays are done.

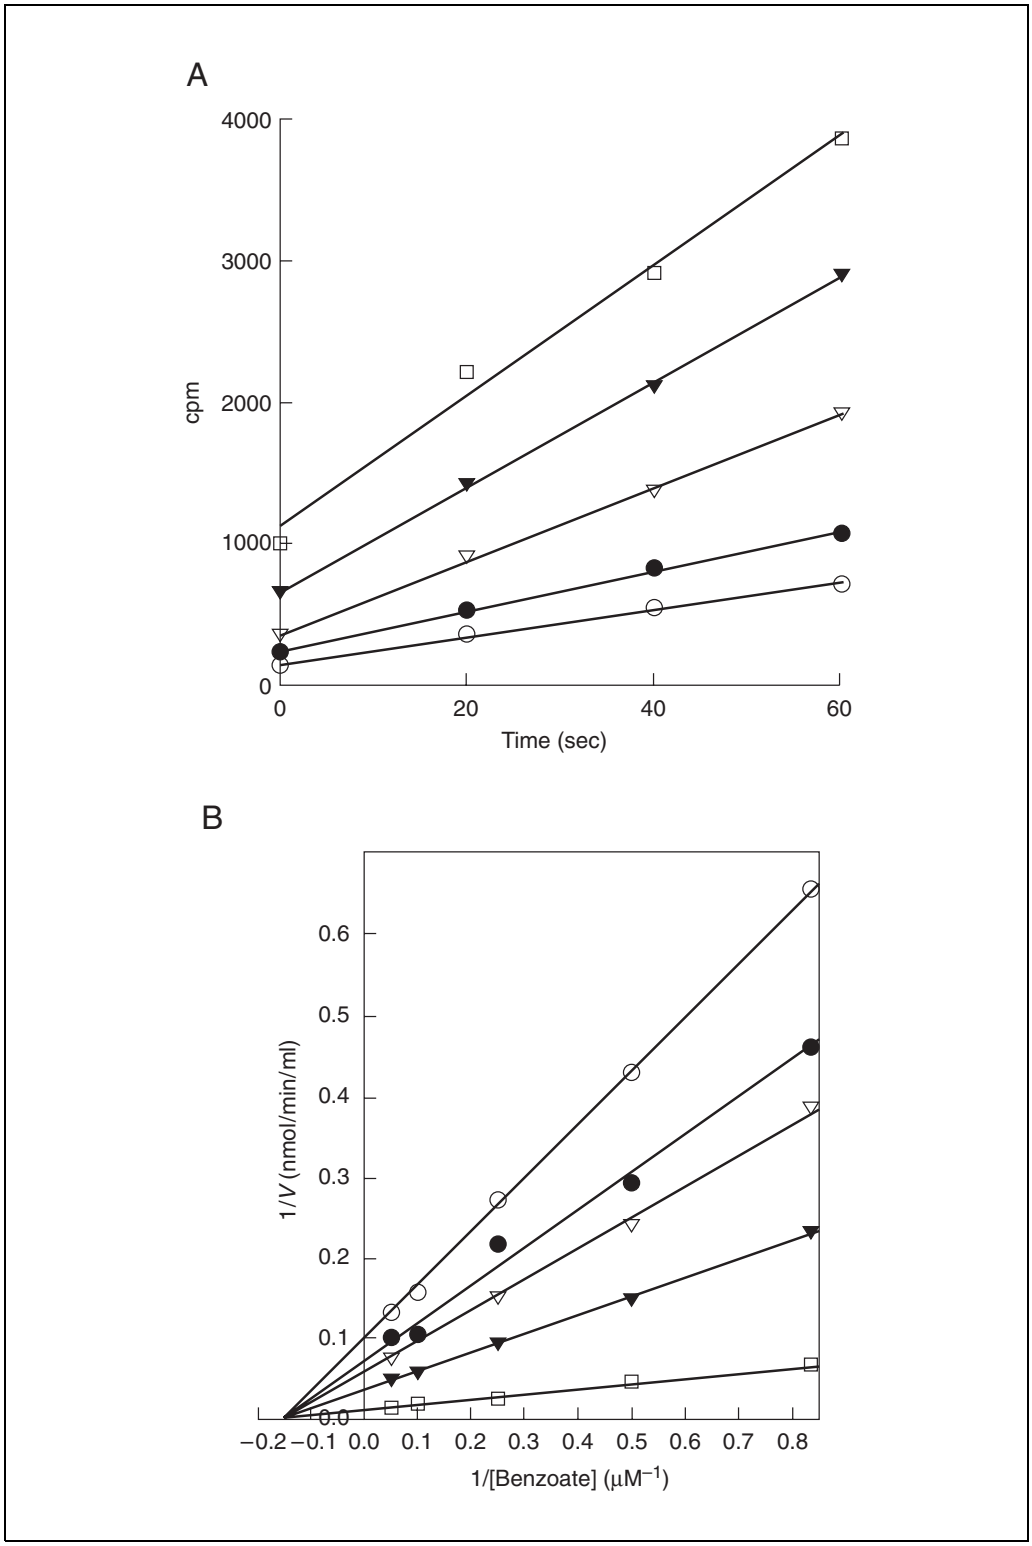

Figure 4.11.1 (**A**) Data from the scintillation counter are plotted as counts per minute (cpm) versus reaction time using 300 μM ATP and [^{14}C]benzoate concentrations of 1.2 (open circles), 2 (closed circles), 4 (open triangles), 10 (closed triangles), and 20 μM (open squares). Rates (uncorrected for extraction loss) are calculated from these data, which represent one-tenth of the total reaction, using the formula: [radioactivity (cpm)/incubation time (min) × dilution factor]/specific activity of substrate (cpm/pmol) = amount acylated product (pmol)/min/volume enzyme = *V*. (**B**) Reciprocals of these rates (1/*V*) are plotted versus the reciprocal of the benzoate concentration for these 300 μM ATP rates (open squares), as well as for rates conducted at ATP concentrations of 15 μM (open circles), 20 μM (closed circles), 29 μM (open triangles), and 50 μM (closed triangles).

Table 4.11.1 Invariant Reagent Mix

Reagent	Volume per individual assay (µl)	Volume to prepare invariant reagent mix (ml)[a]	Final concentration
1 M Tris·Cl, pH 8.0 at 30°C	50	1.3	100 mM
1 M KCl	25	0.65	50 mM
100 mM $MgCl_2$	25	0.65	5 mM
5 mM coenzyme A	50	1.3	500 µM

[a]Final volume is sufficient for 25 individual assays.

In the example shown (Fig. 4.11.1A), the rates of five reactions, each containing a different benzoate concentration but a constant concentration of ATP, were determined. The final reaction volume is 0.5 ml to allow removal of 100-µl aliquots of the reaction to the kill tubes at each of the desired time points. For example, in this series each reaction contains 100 mM Tris·Cl, pH 8.0 at 30°C, 50 mM KCl, 5 mM $MgCl_2$, 500 µM coenzyme A, 300 µM ATP, and either 1.2, 2, 4, 10, or 20 µM [^{14}C]benzoate. The reaction was initiated with 5 µl of N-acyltransferase preparation.

4. To accurately achieve the desired concentrations, prepare a stock solution of radiolabeled carboxylic acid substrate at a known specific activity (e.g., 10 to 100 cpm/pmol) and a concentration chosen for maximum accuracy of pipetting.
5. Pipet radiolabeled substrate at the desired concentration and specific activity (e.g., 100 µM 80 cpm/pmol [^{14}C]benzoate) into separate reaction tubes with a positive-displacement micropipet.

   For example, for a kinetic study of variable concentrations of carboxylic acid (Fig. 4.11.1), pipet 6, 10, 20, 50, and 100 µl of 100 µM benzoate into separate tubes.

6. Add 150 µl of 1 mM ATP and 150 µl of the invariant reagent mix (step 3) to each of the 300-µM ATP reaction tubes with a positive-displacement pipet.
7. Adjust the volume of each reaction with water such that when enzyme is added, the final volume will be 0.5 ml and place in a 30°C water bath.

Initiate reaction and remove aliquots at timed intervals

8. Initiate each reaction by adding an assayable amount of carboxylic acid:CoA ligase preparation using a positive-displacement micropipet.
9. Vortex the tube gently and, using a vacuum pipettor, transfer a 100-µl aliquot to the first (zero time) kill tube while simultaneously starting timing.
10. Remove subsequent 100-µl aliquots to the assigned kill tubes at the predetermined times.

    When the time course of the reaction is >1 min, several reactions can be run at once by initiating and killing successive reactions at intervals as allowed by the time course.

Extract unreacted radiolabeled substrate

11. Vortex the kill tubes thoroughly and place in a bench-top centrifuge. Centrifuge briefly at top speed, room temperature, until a clear separation of the aqueous and butanol layers is achieved (~5 sec).
12. Remove the top butanol layer by vacuum aspiration, then repeat the extraction by adding 1 ml water-saturated butanol.

    For very nonpolar substrates, such as myristate and palmitate, where a second extraction causes excessive loss of the CoA adduct, use only one extraction. Slightly longer centrifugation times may be required if larger amounts of protein are assayed. The vacuum aspiration system needs to be equipped with an inline filter.

Determine counts remaining in aqueous layer of each kill tube

13. Quantitatively remove 250 µl extracted aqueous phase of each kill tube to a scintillation vial containing 10 ml scintillation cocktail and count using a liquid scintillation counter.

Determine reaction rates

14. Display the reaction rate by plotting the data as counts per minute (cpm) versus reaction time (Fig. 4.11.1A).

15. After determining the initial rates of reaction, compute the rate of appearance of radioactive product over time.

    Each scintillation vial contains one-half of the aqueous phase of each kill tube, and each kill tube contains one-fifth of the total assay volume. The displayed rates therefore represent one-tenth of the product formed by the enzyme protein that was assayed.

16. Quantitate product by dividing these rates by the specific radioactivity of the substrate to convert counts per minute to moles.

    The results can be conveniently expressed as moles of product formed per minute per milliliter enzyme solution. For comparison purposes, it is useful to determine the protein concentration of the enzyme solution so that the results can be expressed on a per milligram protein basis. Any standard protein determination procedure can be used, but in general each procedure will yield a slightly different value. Thus, it is important to use the same protein determination method as was used in the study to which the results are to be compared.

MEASUREMENT OF RADIOLABELED ATP CLEAVAGE BY CARBOXYLIC ACID:CoA LIGASE

ALTERNATE PROTOCOL 1

This assay measures the rate of radiolabeled [γ-^{33}P]ATP cleavage to radiolabeled pyrophosphate (PP_i) and AMP. Unreacted ATP is removed by adsorption to activated charcoal and the remaining pyrophosphate is measured by liquid scintillation counting.

Additional Materials *(also see Basic Protocol 1)*

ATP-assay kill mix (50 mM Na_2EDTA/5 mM K_2HPO_4) in a dispenser set to deliver 1.9 ml
Unlabeled carboxylic acid substrate (e.g., 1 mM hydrocinnamic acid)
[γ-^{33} P]ATP of known concentration and specific activity (e.g., 10 mM, 6.8 cpm/pmol; also see recipe for radiolabeled carboxylic acid substrates for specific activity determination)
Phosphoric and sulfuric acid-washed activated charcoal (e.g., Sigma)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Prepare kill tubes

1. Label a set of four 12 × 75–mm kill tubes for time points appropriate to the time course of the reaction being studied.
2. Add ATP-assay kill mix into each tube from a dispenser set to deliver 1.9 ml.

Prepare reaction tubes

3. Construct an appropriate mixture of the four invariant reagents to achieve the desired assay concentrations, such as that described in the example for the previous assay (see Basic Protocol 1, step 3 and Table 4.11.1).

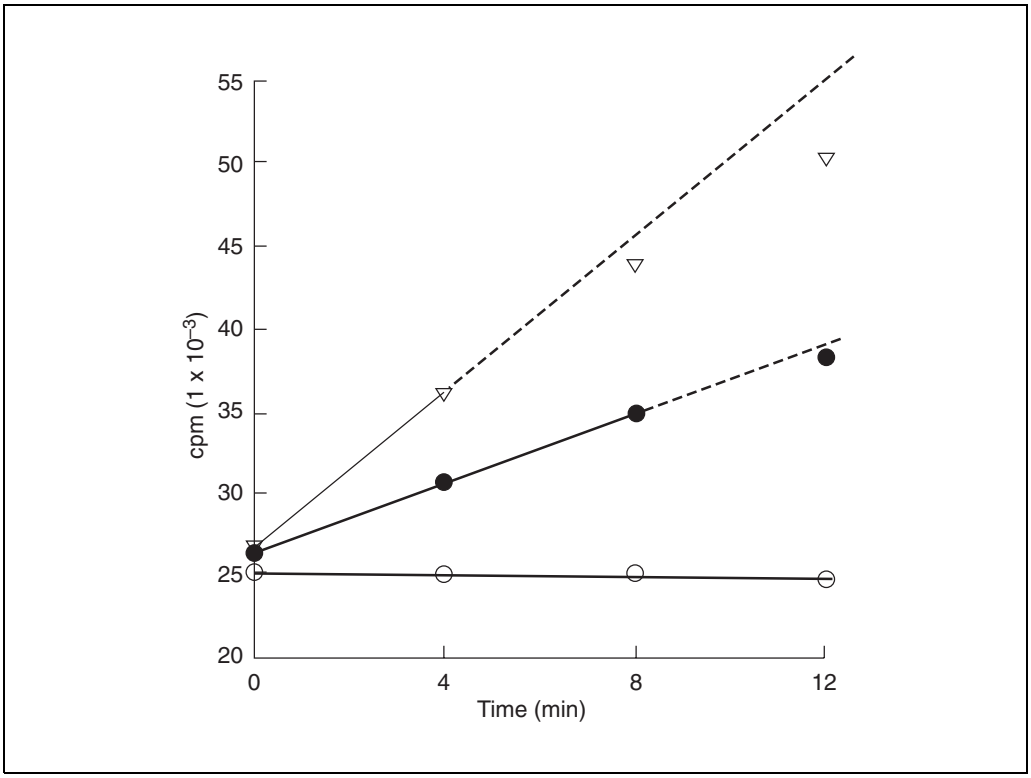

Figure 4.11.2 Data from the scintillation counter are plotted as cpm (divided by 1×10^3 for convenience) versus reaction time for the substrates hydrocinnamic acid (open triangles) and indole-3-propionic acid (closed circles), as well as a control reaction omitting CoA (open circles). Rates are calculated from these data, which represent one-tenth of the total reaction using the following formula: [radioactivity (cpm)/incubation time (min) × dilution factor]/specific activity of ATP (cpm/pmol) = amount inorganic phosphate formed (pmol)/min/volume enzyme = *V*.

4. To each reaction tube add the invariant reagent mix, unlabeled carboxylic acid substrate (e.g. 1 mM hydrocinnamic acid), 25 µl [γ-^{33}P]ATP of known concentration and specific activity (e.g., 10 mM 6.8 cpm/pmol), and sufficient water such that the final volume of the assay after enzyme addition is 0.5 ml.

   Final concentrations in this example are as follows: 100 mM Tris·Cl, pH 8 at 30°C, 50 mM KCl, 2 mM $MgCl_2$, 200 µM hydrocinnamic acid, 250 µM coenzyme A, and 500 µM [γ-^{33}P]ATP (assumed).

   [γ-^{33}P]ATP is typically supplied at >1000 Ci/mmol. Small amounts may be added to precisely made solutions of unlabeled ATP to achieve specific radioactivities of 10 to 100 cpm/pmol or more without significantly changing the concentration.

   In the example (Fig. 4.11.2), 100 µl ligase preparation was reacted with 200 µM hydrocinnamic acid at 250 µM coenzyme A and 500 µM [γ-^{33}P]ATP.

Initiate reaction and remove aliquots at timed intervals

5. Initiate each reaction at 30°C with 100 µl carboxylic acid:CoA ligase preparation and transfer 100-µl aliquots to kill tubes at the predetermined times (step 1).

   The reactions can be initiated at staggered intervals so that many reactions can be conducted simultaneously.

Adsorb unreacted ATP

6. Add 0.2 g phosphoric and sulfuric acid–washed activated charcoal to each kill tube and vortex at 10-min intervals over 30 min.

7. Sediment the charcoal from the kill tubes by centrifuging in a bench-top centrifuge 1 min at 1000 × *g* (3,000 rpm), room temperature. Transfer 1.5 ml supernatant to a second set of appropriately labeled tubes.
8. Centrifuge again (see step 7) to remove most of the fine charcoal particulate.

Determine counts remaining in each kill tube

9. Quantitatively remove 1 ml supernatant from each kill tube to a vial containing 10 ml scintillation cocktail and count using a liquid scintillation counter.

Determine reaction rates

10. Display reaction rate by plotting the data as cpm versus reaction time (min) and check that the rates are linear.

    Each scintillation vial contains one-half of the volume of each kill tube, which contained one-fifth of the total assay volume; therefore, the displayed rate represents one-tenth of the activity of the protein assayed.

11. Divide these rates by the specific radioactivity of the [γ-^{33}P]ATP to convert cpm to moles.
12. Repeat the assay without coenzyme A to determine rates of [γ-^{33}P]ATP hydrolysis independent of this substrate.

    This is especially important with crude preparations.

SPECTROPHOTOMETRIC ASSAY OF CARBOXYLIC ACID:CoA LIGASE ACTIVITY USING DTA

ALTERNATE PROTOCOL 2

Some ligase forms may be assayed accurately spectrophotometrically by exploiting the strong absorbance at 376 nm (ε_M = 34,000) of the CoA adduct of 2,4,6,8-decatetraenoic acid (DTA; Garland et al., 1970); however, not all ligases have DTA activity (Vessey, 1997).

Additional Materials *(also see Basic Protocol 1 and Alternate Protocol 1)*

5 mM DTA (see recipe)
Recording spectrophotometer, thermostatically-controlled at 30°C

1. Prepare a 1-ml cuvette containing the desired concentrations of invariant reagents (e.g., Table 4.11.1) and unlabeled substrate, minus *N*-acyltransferase and ATP:

100 µl	1 M Tris·Cl, pH 8.0 at 30°C (100 mM final)
50 µl	1 M KCl (50 mM final)
50 µl	100 mM $MgCl_2$ (5 mM final)
5 µl	5 mM DTA (25 µM or 0.5% w/v final)
50 µl	5 mM coenzyme A (250 µM final)
690 µl	H_2O.

   In this example, 25 µl ligase preparation will be assayed in a reaction initiated with 3 mM (30 µl of 100 mM) ATP.

2. On a recording spectrophotometer, thermostatically-controlled at 30°C, observe the absorbance at 376 nm over 1 min, which should not change with time.
3. Add carboxylic acid:CoA ligase preparation (25 µl in the current example) and again observe the absorbance change.

   A blank (ATP-independent) rate, seen as a small steady increase in A_{376} with time, may be unavoidable when extraneous protein is added with impure preparations. Adjust the amount of protein added as necessary so that this blank rate, if present, is as small as possible in the slowest accurately determinable reactions.

4. Initiate the reaction with ATP (e.g., 3 mM) and observe the rate of change of absorbance at 376 nm.

   This initiation order ensures that the net rate is ATP-dependent.

5. Repeat the experiment but omit the coenzyme A to confirm dependence on both cosubstrates.

ALTERNATE PROTOCOL 3

INDIRECT ASSAY OF CARBOXYLIC ACID:CoA LIGASE USING AMP FORMATION COUPLED TO NADH OXIDATION

This assay couples the formation of AMP to NADH oxidation via adenylate kinase, myokinase, phosphoenol pyruvate/pyruvate kinase, and lactate dehydrogenase. NADH oxidation is monitored spectrophotometrically at 340 nm (Kasuya et al., 1996). This assay is less sensitive than those discussed above (see Basic Protocol 1 and Alternate Protocols 1 and 2), but can be used with any carboxylic acid substrate. The sensitivity can be increased by following NADH oxidation fluorometrically with excitation at 340 nm and monitoring at 465 nm (Rodriguez-Aparicio et al., 1991). The assay is limited in its applicability because it cannot be used with crude extracts nor with any preparation containing ATPase, ADPase, or AMPase activity.

ALTERNATE PROTOCOL 4

MONITORING CARBOXYLIC ACID:CoA LIGASE ACTIVITY BY HPLC DETERMINATION OF ACYL-CoA PRODUCT FORMATION

Several investigators have described assays employing different HPLC systems for separating the acyl-CoA product from CoA and ATP (Bronfman et al., 1986; Knights and Roberts, 1994; Brugger et al., 1996; Gregus et al., 1996). The acyl-CoA is then quantitated with a UV detector. The sensitivity of this assay is dependent on the sensitivity of the UV detector.

BASIC PROTOCOL 2

MONITORING CoA RELEASE USING A DTNB-COUPLED ASSAY TO DETERMINE *N*-ACYLASETRANSFERASE ACTIVITY

The most commonly employed assay for CoA release uses 5,5′-dithiobis(2-nitrobenzoate) (DTNB), which forms an intensely yellow adduct when reacted with sulfhydryl compounds. Reactions contain buffer and DTNB (combined for solubility; see Reagents and Solutions), monovalent cation, acyl-CoA substrate, and amino acid as required for the study. A continuously recording spectrophotometric assay can be conducted by following CoA release with DTNB at 412 nm (Webster et al., 1976).

As DTNB can react with sulfhydryl groups on proteins, it is preferable to observe the blank (nonspecific) rate of change of absorbance. Any significant absorbance change due to protein reaction is first measured, then the reaction is initiated with amino acid. This usually cannot be done when glutamine is the acceptor amino acid, which due to its low solubility and high K_M will occupy a large proportion of the assay volume. The N-acyltransferase sample must be free of sulfhydryl-containing compounds such as DTE, DTT, mercaptoethanol, or cysteine.

Materials

1 mM DTNB (see recipe)
1 M KCl
1 mM benzoyl-CoA
N-acyltransferase preparation (see Commentary)
Acceptor amino acid (i.e., glycine or glutamine)
Recording spectrophotometer, thermostatically-controlled at 30°C

1. Prepare a cuvette containing for each of the concentrations of substrates to be studied:

100 µl	1 mM DTNB (100 µM final)
80 µl	1 M KCl (80 mM final)
50 µl	1 mM benzoyl-CoA (50 µM final)
710 µl	H_2O

In this example, 10 µl N-acyltransferase preparation will be assayed in a 1 ml reaction volume initiated with 50 mM (50 µl of 1 M) glycine.

2. Observe the absorbance at 412 nm in a continuously recording spectrophotometer thermostatically-controlled at 30°C. Add *N*-acyltransferase preparation (10 µl in this example) and observe the rate of change in absorbance for 1 min, which should be minimal. Decrease the amount of protein if necessary.

3. Initiate the reaction by adding acceptor amino acid.

In this example, use 50 µl of 1 M glycine for a final concentration of 50 µM.

4. Quantitate the reaction rate from the net rate of absorbance change (to correct for any nonspecific protein reaction and acyl-CoA thiolase activity) by dividing by the extinction coefficient for DTNB at 412 nm, pH 7.0 to 8.0 (ε_M = 13,600), to obtain the concentration of coenzyme A released in the 1-ml reaction volume (see Fig. 4.11.3).

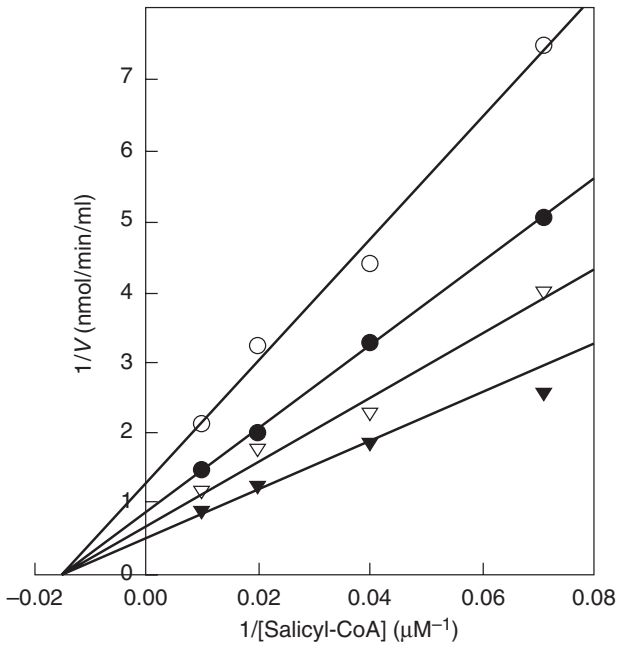

Figure 4.11.3 Lineweaver-Burk double reciprocal plots of the rates of salicyl-CoA glycine conjugation (as nanomoles per minute per milliliter enzyme) versus the concentration of salicyl-CoA for four different glycine concentrations: 5 (open circles), 10 (closed circles), 20 (open triangles), and 50 mM (closed triangles). Rates are calculated from the absorbance change with time using the extinction coefficient for DTNB: (ΔOD_{412}/incubation time (min)/volume enzyme)/[(13.6 AU liters/mmol) × 1000 ml/liter] = amount product formed (mmol)/min/100 µl enzyme = *V*.

ALTERNATE PROTOCOL 5

DIRECT ASSAY OF *N*-ACYLTRANSFERASE ACTIVITY BY MONITORING THE DISAPPEARANCE OF THIOESTER BOND ABSORBANCE

The reaction can also be followed spectrophotometrically by observing the disappearance of acyl-CoA thioester bond absorbance in the ultraviolet range.

Additional Materials *(also see Basic Protocol 2)*

0.5 M Tris·Cl, pH 8.0 at 30°C (*APPENDIX 2A*)
1-ml quartz cuvettes

1. Prepare the reaction in a 1-ml quartz cuvette as described in the previous assay (see Basic Protocol 2, step 1), but use 0.5 M Tris·Cl, pH 8.0 at 30°C instead of 1 mM DTNB.
2. Observe the absorbance at the appropriate wavelength for the chosen acyl-CoA in a continuously recording spectrophotometer thermostatically controlled at 30°C (see Table 4.11.2).
3. Initiate by adding acceptor amino acid (usually 50 µl of 1 M glycine).

Table 4.11.2 Absorption Wavelengths and Corresponding Extinction Coefficients for Acyl-CoA Substrates

Substrate	λ_{MAX}	ε_M
Benzoyl-CoA	280 nm	7,300
Phenylacetyl-CoA	236 nm	4,300
Salicyl-CoA	296 nm	3,400

ALTERNATE PROTOCOL 6

RADIOACTIVE ASSAYS FOR *N*-ACYLTRANSFERASES

An alternate radioassay (James and Bend, 1978) utilizes a radiolabeled acyl-CoA adduct with a different procedure. The reaction mixture is deproteinized with TCA and the product extracted with ethyl acetate.

If the carboxylic acid is extremely nonpolar, it is possible to utilize radiolabeled glycine and extract the glycine conjugate into butanol. The authors have used this method to assay the *N*-acyltransferases involved in bile acid conjugation (Vessey et al., 1977).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

ALTERNATE PROTOCOL 7

HPLC ASSAYS FOR *N*-ACYLTRANSFERASES

The reaction can also be followed by HPLC analysis of the appearance of products (i.e., acyl-CoA) in deproteinized assay extracts as described by Kasuya (1990) or by measuring the disappearance of acyl-CoA.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ATP and coenzyme A

The strong adenine absorbance at 260 nm can be used to ensure consistent concentrations of these substrates. This is important when K_M comparisons are to be made with experiments performed at different times. These compounds are subject to oxidation and hydrolysis and should be freshly made each week and stored frozen (i.e., <0°C). The millimolar extinction coefficient of ATP at 260 nm is ~15 and varies slightly with pH (Dawson et al., 1986). The millimolar extinction coefficient of CoA is 16.8 at 260 nM.

DTA, 5 mM

Prepare 2,4,6,8-decatetraenoic acid (DTA; Toronto Research Chemicals) at a concentration of 5 mM in dimethyl sulfoxide (DMSO). Store up to 1 week at <0°C. Store left over powder indefinitely at <0°C (i.e., in the freezer) to minimize oxidation.

DMSO appears to be less inhibitory to ligases than other usable solvents (e.g., ethanol) and can be used at lower final concentrations in the assay as it dissolves DTA readily.

DTNB, 1 mM

5,5′-dithiobis(2-nitrobenzoate) (DTNB) is poorly soluble and readily oxidizes in water; therefore, weigh out an appropriate amount of the yellow powder, and combine with an appropriate volume of 0.5 M Tris·Cl, pH 8 at 30°C (*APPENDIX 2A*) to make a 1 mM solution. Once the solution is made, measure the absorbance of an aliquot at 412 nm. Store at <0°C until the initial A_{412} increases significantly.

DTNB is also known as Ellman's reagent.

Kill/acidification mix

These mixtures contain EDTA (Table 4.11.3), which stops the reaction by chelating Mg^{2+}. Most also contain succinic acid, chosen to achieve the acidic conditions which favor maximum extraction of the unreacted substrate (which depends upon the butanol:water partition coefficient and the pK_a of the carboxylic acid group) with minimum loss of the CoA adduct. Tetrasodium EDTA is used when possible as it is freely soluble. These mixtures are effective for assays conducted in 100 mM Tris buffer in the pH range of 7.1 to 8.0. Adjustments may be necessary to achieve optimal pH when other buffer systems are used.

Radiolabeled carboxylic acid substrates

For water-soluble nonvolatile substrates, dry the radioisotope in a fume hood under nitrogen in a glass tube to eliminate ethanol from the assay. Redissolve in water to the desired concentration based on the stated specific radioactivity.

Table 4.11.3 Kill/Acidification Mixes for Various Substrates Used in Direct Measurement of Ligase Rate

Substrate	Kill/acidification mix
Myristate or palmitate	12 mM Na_2EDTA, pH 7.0
Benzoate, decanoate, 2,4-dichlorophenoxyacetate, hexanoate, naphthylacetate, octanoate, phenylacetate, or valproate	12 mM Na_4EDTA/30 mM succinic acid, pH 4.5
Butyrate, propionate, or salicylate	12 mM Na_4EDTA/200 mM succinic acid, pH 3.6

For substrates which contain long alkyl chains (e.g., palmitic acid), dissolve in ethanol as they are poorly water soluble. However, ensure that they are prepared at sufficiently high concentration that the assay is no more than 1% to 2% ethanol, as ethanol can affect the reaction.

For butyric and propionic acids, which are volatile liquids at standard temperature and pressure, handle as the sodium salt, which is a solid.

Determine specific activity using a scintillation counter of known efficiency. Adjust the specific activity by combining with an equal concentration of unlabeled carboxylic acid.

For example, the sodium salt of [^{14}C]benzoate is supplied as a 50 mCi/mmol solution in ethanol. When counted in a 90% efficient scintillation counter, 2.2 × 10^6 dpm/μCi is equivalent to 2.0 × 10^6 cpm/μCi, and the supplied [^{14}C]benzoate is 100 cpm/pmol. When dissolved in water such that 10 μl contains 100,000 cpm, the reagent is 1 mM 100 cpm/pmol [^{14}C]benzoate. This solution can be mixed with a precise solution of unlabeled 1 mM sodium benzoate to produce the specific radioactivity required for the study.

Water-saturated butanol

Add water to rapidly stirring *n*-butanol until the mixture is cloudy. Allow excess water to settle and pour the upper clear butanol phase into the dispenser. This reagent is stable indefinitely.

Butanol is saturated with water to avoid volume reduction in the aqueous phase.

COMMENTARY

Background Information

Carboxylic acid-CoA ligases

Three distinct classes of acyl-CoA ligase are separable from liver mitochondria. A freeze-thaw lysate can be fractionated by DEAE chromatography to yield a soluble short-chain fatty acid:CoA ligase, which does not have activity with xenobiotic carboxylic acids (SC ligases), and at least two soluble forms which activate xenobiotic carboxylic acids as well as short- and medium-chain fatty acids (XM ligases). Ligases with activity toward long- and very long-chain fatty acids are found in the membrane fraction (long-chain and very long-chain fatty acid:CoA ligases). Care should be taken to identify the separate activity peaks and to chromatograph again as necessary, especially when studying effects of a compound with greatly varying activity and binding affinity toward another narrowly-separated ligase subform.

Ligases catalyze a trisubstrate reaction in which activation of a xenobiotic or fatty acid to a coenzyme A-conjugate requires hydrolysis of ATP. Kinetic characterization is complex, as the binding of one cosubstrate, particularly carboxylic acid–containing substrates of widely varying structures, can modulate the binding of the others. Both monovalent and divalent cations affect activity in a substrate-dependent manner. It is important to remain mindful of the potential of these variable co-substrates and ionic effects to confound standard kinetic analyses by introducing uncontrolled effects, such as those which vary with different relative stoichiometries. Complex effects are usually apparent as nonlinear Dixon or Lineweaver-Burk plots. Conventional modeling of rates, binding constants, and competition patterns will demonstrate conditions under which the data are internally consistent and fit these models, and conditions where the data diverge from these models in a meaningful pattern.

N-acyltransferases

Acyl-CoA:amino acid *N*-acyltransferases determine the nature of the amino acid conjugate (Vessey, 1997). In mammals, glycine conjugates predominate, but glutamine conjugates of arylacetic acids are seen in primates. The addition of a methyl group to the β-methylene group of an arylacetic acid (e.g., 2-phenylpropionate) blocks conjugation in primates. One enzyme form, "aralkyl" *N*-acyltransferase (ArAlk), conjugates the CoA adducts of substituted benzoates, medium-chain fatty acids, and certain branched-chain alkyl acids. Another enzyme form, "arylacetyl" *N*-acyltransferase (AAc), only conjugates the CoA adducts of arylacetic acids (e.g., naphthylacetate, indoleacetate, phenoxyacetate, phenylacetate).

Acyl-CoA:amino acid *N*-acyltransferases are soluble enzymes located in the matrix space of the mitochondria of both liver and kidney. These enzymes can be extracted from mitochondria by a simple freeze-thaw lysis, and the two forms can be easily separated by chromatofocusing chromatography (Kelley and Vessey, 1990).

Kinetic studies of bovine liver AAc and ArAlk revealed that they differ not only in their specificity for acyl-CoAs, but also in their acceptor amino acid specificity. The ArAlk accepts only glycine while the AAc has a low but measurable rate with glutamine as the acceptor amino acid. Both forms follow sequential Bi Bi mechanisms (Vessey, 1997). Kinetic analysis of ArAlk and AAc suggested that they were almost completely product-inhibited by in vivo concentrations of CoA. The extent of this end-product inhibition by CoA is greatly reduced by adding K^+ to the assay; however, for in vitro assays in which CoA is not added, K^+ is inhibitory to both ArAlk and AAc (Kelley and Vessey, 1990). Thus, to measure the highest possible rates, K^+ should be omitted from assays, while to measure kinetic constants that exist under in vivo conditions, K^+ should be added.

In man and rhesus monkey, the conjugation of benzoic acid and phenylacetic acid has been shown to be due to the existence of two distinct enzymes, a glycine-specific benzoyl-CoA transferase and a glutamine-specific arylacetyl transferase. The human benzoyl-CoA transferase (ArAlk) does not differ significantly from bovine ArAlk. While human glutamine-specific arylacetyltransferase has a specificity for acyl-CoAs similar to that of bovine AAc, it differs in that it has such poor affinity for glycine that the inefficient acceptor glutamine is the preferred substrate. When assaying for this activity, concentrations of glutamine should be in excess of 50 mM (300 mM is the limit of solubility).

A significant source of interference when assaying the *N*-acyltransferases is acyl-CoA hydrolase activity. Mitochondria contain low level hydrolase activity toward most acyl-CoAs. This activity is characterized by very high K_M values for acyl-CoA (usually in excess of 0.5 mM) and so is less of a problem for substrates for which the *N*-acyltransferase has a low K_M.

Critical Parameters and Troubleshooting

Precise measurement of substrate concentrations and the amount of enzyme is essential for production of useful kinetic data. This can be accomplished by using positive-displacement pipets (e.g., Drummond) for critical measurements, ensuring that sets of reactions with small differences in substrate concentration are precise.

Carboxylic acid-CoA ligase assay

This assay (see Basic Protocol 1) is suitable for detailed kinetic studies as it can be optimized to accurately determine large numbers of reaction rates over the necessarily large ranges of activity and substrate concentration. As a given form of ligase might activate a wide variety of substrate structures with widely varying velocities and binding constants, the time course of the reaction must be adjusted in order to maximize accuracy while measuring the true initial reaction rate. Substrates that are slowly activated, bind with low affinity, or partition poorly into butanol are more difficult to assay accurately, and adjustments of the amount of enzyme protein, specific radioactivity of the substrate, and acidity of the kill/acidification mix must be made. Adjust the specific radioactivity, enzyme concentration, and time points such that the most difficult rate to determine (e.g., concentrations of any of the three cosubstrates at or below K_M) is as large as possible, while still linear over the time course. The time course can be altered for the other reactions of the study if desired. The enzyme concentration should be held constant to avoid any nonlinearity and a minimal volume of enzyme should be used, especially if glycerol or salts are used to stabilize the enzyme preparation, as they can greatly affect the rates under some conditions.

Choose specific radioactivity appropriate to the study. In the example (Fig. 4.11.1), an enzyme form that activates benzoate with good binding and rate was studied at benzoate concentrations below K_M. A relatively small amount of protein was assayed for a short time using benzoate of undiluted specific radioactivity. For studies at higher benzoate concentrations, the specific radioactivity could be decreased to 10 cpm/pmol and the time course increased to several minutes. If this form were studied with butyrate, for which the velocity and binding affinity are poor and the extraction less efficient, the study would call for more protein to be assayed over longer periods of time with butyrate used at a high concentration but at diluted specific radioactivity.

When it is necessary to relate the reaction rates of different carboxylic acid substrates, the differences in extraction losses of the CoA

adducts must be accounted for. These differences depend upon the structure of the substrate and the kill/acidification mix used, and should be determined using the appropriate CoA adduct. When the assay and extraction protocols are used as described, extraction losses of the CoA adduct of ~30% are typically observed. Differential extraction losses become significant as conjugation rates of substrates of substantially varying chemical structure are compared, necessitating determination of and correction for extraction efficiency in such comparisons. There is generally an ~25% loss of acyl-CoA product into the butanol layer in the assays described. This loss can be precisely determined for any acyl-CoA by carrying a known amount of the acyl-CoA through the extraction process and directly measuring the recovery (usually by following the $O.D._{360}$ of the CoA).

The charcoal adsorption method (see Alternate Protocol 1) is cumbersome, and because it relies on a 1:1 stoichiometry of pyrophosphate release to monitor CoA-adduct formation, nonspecific "blank" rates of ATP hydrolysis must be determined. Hydrolysis can be negligible in purified preparations but significant in cruder ones. For these reasons this assay is most useful for the study of the activation of substrates that are unavailable radiolabeled. Adsorption of radiolabeled inorganic phosphate ($^{33}PP_i$) to charcoal is minimized by including phosphate in the kill mix. Use of the phosphoric and sulfuric acid–washed activated charcoal is important. ATP is available labeled with ^{33}P, which has a half-life of 25 days. It is less hazardous and has a longer half-life than ^{32}P. Count the stock isotope daily to maintain stoichiometry.

The DTA spectrophotometric assay (see Alternate Protocol 2) is less sensitive than the radioassay, and protein can cause a "blank" (nonspecific absorbance increase) reaction. DTA is not a substrate for all of the medium-chain fatty acid:CoA ligases, nor for short-chain fatty acid ligases.

While direct observation of the decrease in absorbance of the thioester bond (see Alternate Protocol 5) avoids some of the problems due to an increase in nonspecific absorbance which occurs in the DTNB-linked reaction (see Basic Protocol 2), the smaller extinction coefficients make this assay less sensitive. In addition, the shorter wavelengths are subject to high background absorbance due to UV-absorbing compounds and proteins, and potentially also via light scattering. Also, to reduce the possibility of interference by acyl-CoA hydrolase activity, more highly purified enzyme preparations are required.

Anticipated Results

Ligase assay: Direct measurement of radiolabeled product (see Basic Protocol 1). This is the best method for determining kinetic constants, as small differences in rates can be measured with accuracy sufficient to produce meaningful kinetic data. As the time course and the specific radioactivity of the substrate can be adjusted over wide ranges, it is also good for comparing rates that vary greatly.

Ligase assay: ATP cleavage (see Alternate Protocol 1). As this method measures ATP cleavage, rates must be verified as specific to the ligase reaction (dependent on substrate or CoA). The cumbersome and time-consuming charcoal adsorption of the uncleaved ATP makes this assay unsuitable for large numbers of reactions, but most useful for studying substrates unavailable in radiolabeled form.

Ligase assay: DTA (see Alternate Protocol 2). For the ligase subforms that metabolize DTA, this spectrophotometric assay is quick and convenient. The rate is determined directly from the display of absorbance change over time, allowing rapid adjustments to produce readable, linear rates, while ATP initiation ensures specificity; however, the operational concentration range of DTA is limited.

Ligase assay: AMP/NADH coupled (see Alternate Protocol 3). This spectrophotometric assay is less sensitive than the DTA assay due to the relatively low extinction coefficient of the NADH. It is also less convenient due to the balancing of several linked enzymes.

Ligase assay: HPLC (see Alternate Protocol 4). This assay, as with all HPLC assays, requires considerable development time and appropriate standards. It is laborious if an HPLC run is required for each time point. Its sensitivity is dependent upon the sensitivity of the HPLC detector.

N-Acyltransferase assay: DTNB (see Basic Protocol 2). This spectrophotometric assay determines activity directly from the absorbance change of DTNB reaction with the free sulfhydryl group of the CoA liberated in the course of the reaction; it is therefore subject to nonspecific sulfhydryl reaction, which limits its use. It is however quick, and the high extinction coefficient makes the assay very sensitive for a spectrophotometric assay.

N-Acyltransferase assay: Thioester bond absorbance (see Alternate Protocol 5). In another spectrophotometric assay, the reaction is

followed by measuring the disappearance of the substrate thioester bond. The thioester bond absorbance is measured directly and rates are determined quickly from the rate of decrease of absorbance. This method is not susceptible to nonspecific sulfhydryl reaction. It is however less sensitive than DTNB due to lower extinction coefficients.

N-Acyltransferase assay: Radiolabeled CoA adduct (see Alternate Protocol 6). Radiolabeled CoA adducts are generally available only for short and long chain fatty acids.

N-Acyltransferase assay: HPLC (see Alternate Protocol 7). This assay requires considerable development time, and then an HPLC run for each time point. It is only as sensitive as the method of detection.

Time Considerations

Ligase assay: Direct measurement of radiolabeled product (see Basic Protocol 1). Once conditions (e.g., time course, specific radioactivity, amount of enzyme) are determined to give linear rates within the parameters of the study, many assays can be efficiently conducted simultaneously, then extracted and loaded into scintillation vials at once, allowing a kinetic study involving a large number of assays to be completed within a day, allowing overnight for scintillation counting.

Ligase assay: ATP cleavage (see Alternate Protocol 1). While the time courses of reaction are similar to other assays, the 30 min charcoal absorption step, multiple centrifugations and extensive handling make this assay much more time consuming thus allowing fewer assays to be completed daily as compared with the ligase assay using direct measurement of radiolabeled product (see Basic Protocol 1). The length of time to set up and analyze the reaction (i.e., not including actual reaction time) is ~3 hrs per 12 samples for the experienced researcher.

Ligase assay: DTA (see Alternate Protocol 2). Once the reagents are prepared, cuvettes can be prepared, reactions run, and rates determined all within a few minutes per sample.

Ligase assay: AMP/NADH coupled (see Alternate Protocol 3). The setup time for this assay is system dependent as the experimenter must balance the levels of several linked enzymes. Thus there may be considerable time spent optimizing reactions. Once set up, though, it is quick.

Ligase assay: HPLC (see Alternate Protocol 4) and N-acyltransferase assay: HPLC (see Alternate Protocol 7). HPLC assays usually require considerable development time to get them up and running. To do kinetics requires an HPLC run for each time point. Thus, this type of assay can be quite time consuming.

N-Acyltransferase assay: DTNB (see Basic Protocol 2) and N-acyltransferase assay: Thioester bond absorbance (see Alternate Protocol 5). Since these assays are more or less the inverse of one another (i.e., one measuring appearance of a product the other disappearance of a substrate), they have similar time requirements. Once reagents are prepared, cuvettes can be pipetted and rates determined at a rate of a few minutes per sample.

N-Acyltransferase assay: Radiolabeled CoA adduct (see Alternate Protocol 6). Assuming a suitable radiolabeled substrate exists, this is a rapid and sensitive assay.

Determination of Paraoxonase 1 Status and Genotypes at Specific Polymorphic Sites

Paraoxonase 1 (PON1; EC 3.1.1.2/EC 3.1.8.1) is encoded by the first of three tandem genes on human chromosome 7. It was thought that PON1 and arylesterase were different enzymes. Subsequent research, however, has shown that they are not; thus, the enzyme has two EC designations. The *PON1* gene is followed by paraoxonase 3 (*PON3*) and paraoxonase 2 (*PON2*). A main physiological role of PON1 appears to be the metabolism of toxic oxidized lipids. In addition to its physiological role, PON1 also hydrolyzes a number of xenobiotic compounds including toxic organophosphorus insecticides, nerve agents, and some drugs (a process that activates some and inactivates others). The catalytic efficiency of hydrolysis of the xenobiotic compounds determines whether the hydrolysis of a specific compound is physiologically important in modulating the effect of exposure to the specific compound. A polymorphism at position 192 (Q192R) affects the catalytic efficiency of a number of PON1 substrates. In addition to the coding-region polymorphism that affects the catalytic efficiency of PON1, there are a number of other polymorphisms in the 5′ regulatory region that have been characterized. One of these (C108T) has a significant effect on the expression and plasma levels of PON1. Recently, >140 new PON1 single-nucleotide polymorphisms (SNPs) have been described, but most have not yet been characterized for effects on PON1 expression (Brophy et al., 2002; Costa and Furlong, 2002; Costa et al., 2003).

The most important consideration for a given individual is the actual level of PON1 in his or her plasma; for determining the risk of exposure to some compounds, the amino acid present at position 192 is also important. This is most reliably assessed by a two-substrate analysis that provides both an accurate determination of the amino acid at position 192 as well as PON1 plasma levels. The authors have designated the identity of the position 192 polymorphism and the PON1 level as an individual's PON1 status. Although it might be possible to determine all of the PON1 SNPs for a given individual, doing so would not provide an accurate assessment or prediction of the individual's "PON1 status."

This unit describes the enzymatic method used to establish an individual's PON1 status (see Basic Protocol 1) as well as protocols for determining SNPs at characterized positions in the PON1 gene (see Basic Protocol 2 and see Alternate Protocols 1 to 5). It is not possible to overemphasize the importance of using the PON1 status determination as opposed to SNP analysis for examining the relationship of an individual's PON1 status to disease or risk associations. The two-substrate enzyme analysis provides an accurate assessment of an individual's PON1 level and position 192 functional status (i.e., the individual's PON1 functional genomics), whereas the SNP analyses cannot provide this information. Disagreements between the PON1 functional status and genotyping at position 192 can identify individuals with mutations elsewhere in their PON1 gene. Comparisons of PON1 status and regulatory region SNPs and haplotypes can provide information on the effects of various SNPs on plasma PON1 levels.

PHENOTYPING INDIVIDUALS FOR PARAOXONASE STATUS

BASIC PROTOCOL 1

The two-substrate assays are carried out using a Molecular Devices SPECTRAmax *PLUS* Microplate Spectrophotometer or equivalent instrument. Initial rates of substrate hydrolysis are determined, and rates of diazoxon hydrolysis (*y* axis) are plotted against the rates of paraoxon hydrolysis (*x* axis). Hydrolysis of paraoxon produces *p*-nitrophenol, which is monitored at 405 nm; hydrolysis of diazoxon produces 2-isopropyl-4-methyl-6-hydroxypyrimidine (IMHP), which is monitored at 270 nm (Fig. 4.12.1). As noted above,

Contributed by Rebecca J. Richter, Rachel L. Jampsa, Gail P. Jarvik, Lucio G. Costa, and Clement E. Furlong

Current Protocols in Toxicology (2004) 4.12.1-4.12.19

this method separates individuals into the three phenotypes of $PON1_{192}$ activity, $PON1_{192Q/Q}$, $PON1_{192Q/R}$, and $PON1_{192R/R}$ (Fig. 4.12.2). As seen in Figure 4.12.2, the functional position 192 genotype is accurately inferred (Jarvik et al., 2000). In addition, PON1 activities within a genotype provide information on the levels of PON1 in the plasma of a given individual within that genotype group, a key bit of information that is relative to an individual's sensitivity to a specific organophosphate. This point is readily visible in Figure 4.12.2. Note that both groups of homozygotes fall on the trend lines, whereas the heterozygote data points are scattered. This means that other polymorphisms in the respective promoter regions (or other regulatory polymorphisms) result in more of one $PON1_{192}$ alloform relative to the other being expressed in a given individual.

Kinetic values determined on the Microplate Spectrophotometer are in mOD/min, which are converted to U/liter (μmol substrate hydrolyzed per min per liter of plasma) using conversion factors obtained by a linear regression analysis of initial rate data from a standard spectrophotometer (e.g., Beckman DU-70). This converts the data relative to a standard 1-cm path length, which then makes use of the standard molar extinction coefficient for either *p*-nitrophenol or IMHP. Alternatively, the Molecular Devices plate reader can give a path length value, which can be used in a formula to correct to a 1-cm light path for U/liter of each end product being measured. The latter approach is much less time consuming.

The PON1 phenotype at position 192 can be verified by genotyping the individual's DNA as described (see Basic Protocol 2). The authors have found this PON1 functional genomic analysis to be highly accurate, however, and it does not require verification (Jarvik et al., 2000). Some inactive *PON1* alleles can be identified by comparing *PON1* genotype at position 192 with the PON1 status analysis. For example, finding an individual who genotypes as a $PON1_{192Q/R}$ heterozygote but whose PON1 status functional analysis indicates a $PON1_{192Q}$ or $PON1_{192R}$ homozygote, shows that one of the alleles is nonfunctional. This is another major advantage of the PON1 status analysis, it provides the functional genomics of PON1.

The use of different temperatures for the two assays is based only on historical development considerations. The conditions were maintained so as to compare recent results with past results. It should be possible to run the paraoxonase at 23°C. A correction factor could be determined if it is useful to compare results with other published studies.

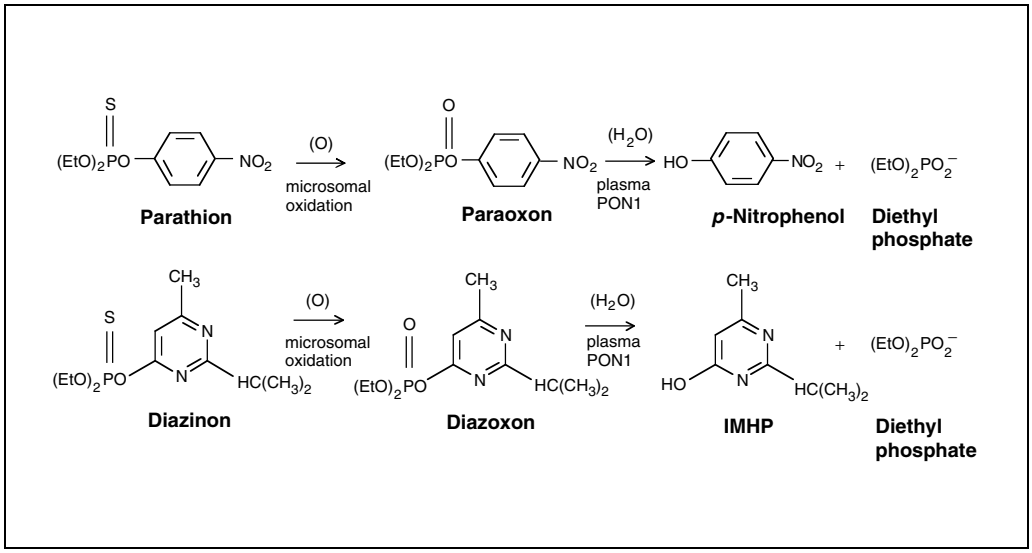

Figure 4.12.1 Metabolism of parathion and diazinon via the cytochrome P450/PON1 pathway. Abbreviations: EtO, CH_3CH_2O; IMHP, isopropyl-4-methyl-6-hydroxypyrimidine.

Materials

Plasma samples: blood samples collected in lithium heparin (green-top) tubes, centrifuged 5 min at 500 × *g*, 4°C, to remove cells
Dilution buffer (see recipe)
Paraoxon (Chem Service)
Assay buffer (see recipe), 37° and 23°C
Diazoxon (Chem Service)

Standard flat-bottom 96-well plates (Dynatech)
50-ml polypropylene tube (Falcon)
37°C water bath
Plate reader (e.g., SPECTRAmax PLUS Microplate Spectrophotometer; Molecular Devices), 37°C
UV-transparent 96-well plates (Costar)
15-ml screw-cap tubes (Falcon)
Conventional spectrophotometer (e.g., DU-70; Beckman), optional

CAUTION: Utmost care must be used with these organophosphate substrates, as they are potent cholinesterase inhibitors. All substrate-containing waste needs to be hydrolyzed in strong NaOH solution. Wear gloves and goggles for all assays and procedures using diazoxon or paraoxon. In a fume hood, add wastes to 5 N NaOH and let stand overnight. Then wash the wastes down the drain with lots of water (Mueller et al., 1983).

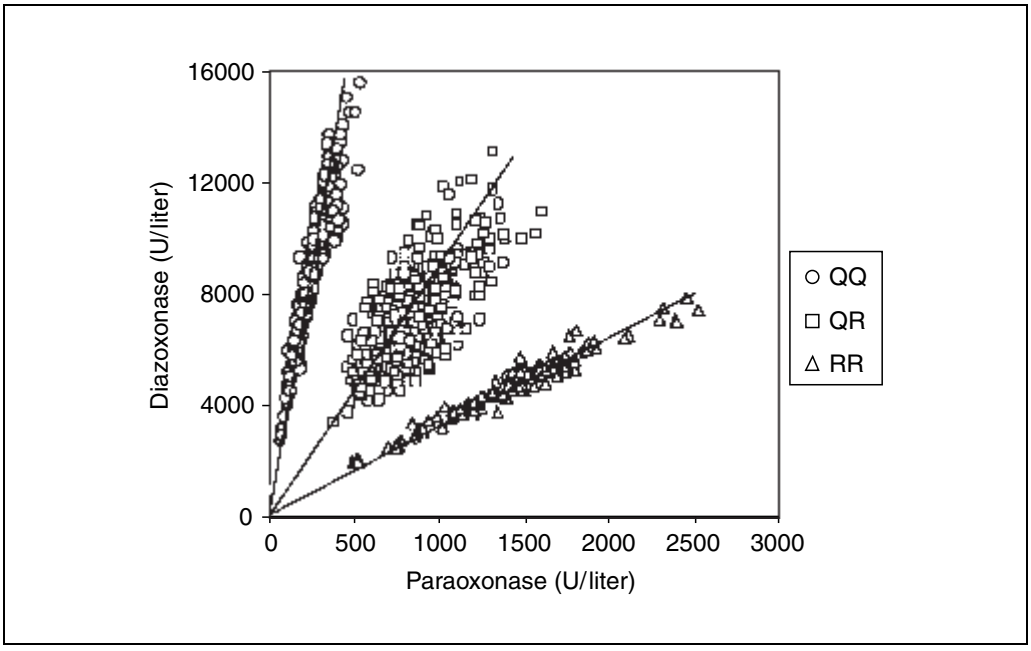

Figure 4.12.2 Determination of the functional genomics of plasma PON1 using citrate-stored plasma. Plotting the rates of hydrolysis of diazoxon versus paraoxon for plasma (or serum) samples from a population divides the population into three distinct groups: individuals functionally homozygous for $PON1_{192Q}$ (QQ), heterozygotes ($PON1_{Q/R192Q/R}$; QR) and individuals homozygous for $PON1_{192R}$ (RR). Whereas PCR analysis of the position 192 polymorphism may reveal that an individual possesses one copy of each allele, this analysis will pick up alleles in heterozygotes that are inactivated by any number of mutations (i.e., the analysis provides the functional status of an individual's PON1 genomics).

Measure paraoxonase activity

1. Dilute plasma samples 1:10 in dilution buffer just before use and mix samples thoroughly.

   It is best to microcentrifuge the plasma sample for 1 min at 14,000 rpm, 4°C, after thoroughly mixing (especially if the sample has just been thawed) to clear the sample of any particulate matter.

   If possible, samples should be diluted in 0.6-ml microcentrifuge tubes that have been set up in a rack so that an 8-channel pipet can quickly withdraw samples for high-throughput loading of the 96-well plate.

2. Pipet 20 µl diluted plasma into wells of a standard flat-bottom 96-well plate in triplicate.

3. Add 12.9 µl paraoxon to 50 ml prewarmed (37°C) assay buffer in a 50-ml tube (e.g., Falcon 352098; 1.2 mM final). Cap tube and shake vigorously and very carefully over a sink. Store in a 37°C water bath while performing the assay. Prepare fresh each hour.

   Paraoxon must be as pure as possible, because free p-nitrophenol interferes with the assay. Chem Service is an excellent source of very pure substrate.

   Gan et al. (1991) provide a method for substrate purification; however, the authors do not recommend purifying paraoxon because it is highly toxic. It is best to buy pure material.

   Paraoxon solution must be made fresh in prewarmed (37°C) assay buffer.

4. Add 200 µl of 1.2 mM paraoxon solution to each sample in the plate.

5. Quickly place plate in a prewarmed plate reader.

6. Set the plate reader to mix for the first 5 sec and then to monitor the initial rates of hydrolysis at 405 nm, taking readings each 15 sec for 4 min. Use only the initial linear rates for calculations.

7. Set plate reader software to measure the pathlength of each well in centimeters after the assay is complete. Set plate reader temperature to return to room temperature (23°C).

   Time must be allowed for the temperature of the plate reader to re-equilibrate before diazoxonase activity can be measured. Alternatively, diazoxonase can be measured first, and then the plate reader can be warmed to 37 °C.

Measure diazoxonase activity

8. Dilute plasma samples and set up a 96-well plate as described in steps 1 and 2, using a UV-transparent 96-well plate.

9. Add 2.8 µl diazoxon to 10 ml assay buffer (23°C) in a 15-ml tube (Falcon 352097; 1.0 mM final), cap securely, and shake vigorously but carefully. Prepare fresh each hour.

10. Add 200 µl of 1.0 mM diazoxon solution to each sample in the plate.

11. Quickly place plate in the plate reader (at room temperature).

12. Set the plate reader to mix for the first 5 sec and then to monitor the initial rates of hydrolysis at 270 nm, taking readings each 15 sec for 4 min. Use only the initial linear rates for calculations.

13. Set the plate reader software to measure the pathlength of each well in centimeters after the assay is complete.

Convert activity to units per liter

To convert without using pathlength correction

14a. Run replicate samples for paraoxonase and diazoxonase activity in the microtiter-plate spectrophotometer and a conventional spectrophotometer. Determine the conversion factor for mOD/min from the above plate reader assay to U/liter. Continue with step 19.

Conversion factors determined in the authors' laboratory using this approach are as follows.

Paraoxonase assay: plate reader mOD/min × 11.4 = U/liter

Diazoxonase assay: plate reader mOD/min × 53.2 = U/liter

To convert using pathlength correction feature

14b. Calculate paraoxonase activity using the absorbance of *p*-nitrophenol and the following equation:

$$A = \varepsilon \times l \times c$$

where A is absorbance (i.e., the OD), ε is the extinction coefficient of *p*-nitrophenol (18 $mM^{-1}cm^{-1}$), l is the pathlength of the well, and c is the concentration of *p*-nitrophenol. Rearranging this equation gives:

$$c = \frac{A}{(\varepsilon \times l)}$$

$$c\,(\mathrm{mM}) = \frac{\mathrm{OD}}{18\ \mathrm{mM}^{-1}\ \mathrm{cm}^{-1} \times\ l\ (\mathrm{cm})}$$

15b. Calculate moles *p*-nitrophenol in solution as follows:

Concentration (M) = mol/liter

mM = mmol/liter = µmol/ml

µmol = mM × ml

Hence, µmol *p*-nitrophenol = c (mM) × total vol (ml)

Because 20 µl sample is assayed in 200 µl assay buffer, the total volume is 220 µl (0.22 ml). Thus,

$$\mu\mathrm{mol}\ p\text{-nitrophenol} = \frac{\mathrm{OD}}{18\ \mathrm{mM}^{-1}\ \mathrm{cm}^{-1} \times\ l} \times 0.22\ \mathrm{ml}$$

and therefore:

$$\mu\mathrm{mol}\ p\text{-nitrophenol / min} = \frac{\mathrm{OD / min}}{18\ \mathrm{mM}^{-1}\ \mathrm{cm}^{-1} \times\ l} \times 0.22\ \mathrm{ml}$$

where µmol *p*-nitrophenol/min is the amount that is produced per minute by 20 µl of diluted sample.

16b. Calculate the amount of *p*-nitrophenol that will be produced by 1 liter of sample as follows:

μmol/min/liter = (μmol *p*-nitrophenol/min)/2×10^{-6} liter

where 2×10^{-6} liter (i.e., 2 μl) is the amount of the original plasma sample (before dilution).

17b. Because the readings from the plate reader are shown as mOD/min, modify the equation further by converting OD to mOD. Thus, the complete equation is:

$$\mu\text{mol/min/liter} = \left(\frac{\text{mOD/min}}{18\ \text{mM}^{-1}\text{cm}^{-1} \times l} \times \frac{10^3\ \text{mOD}}{\text{OD}} \times 0.22\ \text{ml} \right) / 2 \times 10^{-6}\ \text{liter}$$

which simplifies to:

$$\mu\text{mol/min/liter} = \frac{(\text{mOD/min}) \times 0.22}{1000 \times 18 \times l \times \left(2 \times 10^{-6}\right)}$$

$$= \frac{0.22\ \text{mOD/min}}{0.36\, l}$$

$$= \frac{6.1\ \text{mOD/min}}{l}$$

The pathlength correction feature is a standard component of the SPECTRAmax PLUS software. For other plate readers, the manufacturer's instructions must be consulted.

18b. Calculate diazoxonase activity using the formulas for paraoxonase (steps 14b to 17b) but substitute the extinction coefficient for 2-isopropyl-4-methyl-6-hydroxypyrimidine (IMHP; 3 $\text{mM}^{-1}\text{cm}^{-1}$).

This should yield a conversion factor of 36.7 for diazoxonase instead of 6.1 for paraoxonase.

Analyze activity

19. Plot initial rates of diazoxon hydrolysis on the *y* axis versus rates of paraoxon hydrolysis on the *x* axis.

This analysis will clearly separate a population into three groups: individuals homozygous for the Q alloform ($PON1_{192Q/Q}$), heterozygotes ($PON1_{192Q/R}$), and individuals homozygous for the R alloform ($PON1_{192R/R}$).

BASIC PROTOCOL 2

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM 192QR

The 192R polymorphism of the paraoxonase 1 gene ($PON1_{192R}$) has a native *Alw*I restriction site at codon 192. To genotype this polymorphism, a 99-bp polymerase chain reaction (PCR) product containing the site is amplified. When cut with *Alw*I, it produces 63-bp and 36-bp bands if the 192R codon is present; no digestion occurs if the 192Q codon is present.

Materials

~100 ng/µl purified human DNA
10× Opti-prime buffer #3 (Stratagene)
16 µM forward primer 192: 5′-TAT TGT TGC TGT GGG ACC TGA G-3′
16 µM reverse primer 192: 5′-CAC GCT AAA CCC AAA TAC ATC TC-3′
10 mM dNTPs
Dimethyl sulfoxide (DMSO), molecular biology grade
2 U/µl *Vent* DNA polymerase (NEB)
5 U/µl *Taq* DNA polymerase (Promega)
100 mM $MgSO_4$ (*APPENDIX 2A*)
5 U/µl *Alw*I and NEBuffer #4 (NEB)
6× Blue/orange loading dye (Promega)
Low-molecular-weight DNA ladder (standards for 25- to 100-bp fragments)
0.1 µg/ml ethidium bromide (see recipe) diluted in water *or* comparable staining solution

0.2-ml PCR tubes
Thermal cycler (e.g., PE 9700; PE Biosystems)
37°C water bath
Camera and UV light box or other instrument for recording the stained gel image

Additional reagents and equipment for DNA agarose gel electrophoresis (*UNIT 2.2*)

Prepare PCR Reactions

1. Make up the following on ice in a 0.2-ml PCR tube for each sample for hot-start PCR.

   2.0 µl ~100 ng/µl purified human DNA
   2.0 µl 10× Opti-prime buffer #3
   1.0 µl 16 µM forward primer 192
   1.9 µl 16 µM reverse primer 192
   0.4 µl 10 mM dNTPs
   1.0 µl DMSO
   11.6 µl H_2O
   19.0 µl total.

   This PCR requires a hot start, which involves adding the polymerase when the sample has reached denaturing temperature (the final volume after addition of polymerase is 20 µl).

   When more than one sample is being analyzed, it is convenient to make up a master mix of appropriate volume to divide between the PCR tubes, with subsequent addition of the individual DNA samples.

   It is preferable to include characterized DNA control samples for all three polymorphisms: 192QQ, 192QR, and 192RR.

2. Make up the following polymerase mix on ice for each sample.

   0.1 µl 2 U/µl *Vent* DNA polymerase
   0.2 µl 5 U/µl *Taq* DNA polymerase
   0.2 µl 100 mM $MgSO_4$
   0.5 µl H_2O
   1.0 µl total.

   A master mix can also be made for the polymerases.

Run PCR program

3. Program a thermal cycler to run the following cycling procedure.

First cycle:	5 sec	75°C (hot start)
	3 min	93°C (denaturation)
35 cycles:	1 min	93°C (denaturation)
	30 sec	61°C (annealing)
	1 min	72°C (extension)
Final step:	7 min	72°C (extension).

4. Load tubes into thermal cycler and begin the PCR program. Pause thermal cycler during the first 5 sec at 75°C and add 1 µl polymerase mix to each sample and continue the program.

Digest PCR products

5. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   10.0 µl DNA from PCR amplification
   1.0 µl 5 U/µl *Alw*I
   2.0 µl 10× NEBuffer #4
   7.0 µl H_2O
   20.0 µl total.

   Incubate >2 hr at 37°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes.

Run agarose gel

6. Add 2 µl of 6× Blue/orange loading dye to each undigested sample and 4 µl to each digested sample. Also add loading dye to low-molecular-weight DNA ladder as per supplier's recommendations.
7. Place gel in electrophoresis tank and fill with 0.5× TBE buffer to cover the gel no more than 1 mm. Load the ladder into one well of a 3% (w/v) agarose gel made with 0.5× TBE and alternately load 10 µl of matched undigested and digested samples into the other wells.

   A small-toothed comb should be used when pouring the gel to allow ~15 µl per well.

8. When ready, close lid to tank and attach leads. Apply voltage of 1 to 5 V/cm. Run gel until the blue dye reaches a point ~75% down the gel.

   Actual gel run times may need to be determined for each manufacturer's instrument.

9. Stain gel in 0.1 µg/ml ethidium bromide or equivalent stain solution for 20 min. Destain gel in water for additional 20 min.

   CAUTION: *Appropriate safety precautions should be taken when working with ethidium bromide solutions.*

Analyze gel

10. Photograph stained gel using a camera and UV light box or other imaging system.

    CAUTION: *Appropriate safety equipment must be used with UV light.*

11. Determine the genotype as follows:

Complete digestion	192RR
Partial digestion	192QR
No digestion	192QQ.

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM –909CG

In the paraoxonase 1 gene (*PONI*), a native *Bsm*AI site is present with the –909G polymorphism; it is appropriate for distinguishing between the –909G and –909C alleles. This is complicated by a second *Bsm*AI site shifted 2 bp away from the first that is present in the –909C allele. Because a PCR product would fully digest with *Bsm*AI with either polymorphism, the second site associated with –909C is destroyed using the mismatch in the forward primer. The forward primer is large enough with its nonbinding DNA to be visible after the PCR product is restriction digested. When amplified, the PCR product is 256 bp, which digests when the –909G allele is present, producing 50-bp and 206-bp fragments. No digestion occurs with the –909C polymorphism.

Additional Materials *(also see Basic Protocol 2)*

10× *Taq* polymerase buffer (Promega)
25 mM $MgCl_2$ (Promega or *APPENDIX 2A*)
25 µM forward primer –909: 5′-TAT TAT AAT ATA TTA TAT CAT TCA CAG TAA CAG CAG ACA GCA GAG AAA AGA-3′
25 µM reverse primer –909: 5′-AAC ATG TCA CTG TGG CAT ATA TAA TGC TC-3′
5 U/µl *Bsm*AI and NEBuffer #3 (NEB)
Low-molecular-weight DNA ladder (standards for 50- to 250-bp fragments)
55°C water bath

1. Make up the following on ice in a 0.2-ml PCR tube for each sample.

   2.0 µl ~100 ng/µl purified human DNA
   1.5 µl 10× *Taq* polymerase buffer
   1.2 µl 25 mM $MgCl_2$
   0.1 µl 25 µM forward primer –909
   0.1 µl 25 µM reverse primer –909
   0.3 µl 10 mM dNTPs
   0.75 µl DMSO
   0.2 µl 5 U/µl *Taq* DNA polymerase
   8.85 µl H_2O
   15.0 µl total.

   When more than one sample is to be analyzed, it is convenient to make up a master mix of appropriate volume to divide between the PCR tubes, with subsequent addition of the individual DNA samples.

   It is preferable to include characterized DNA control samples for all three polymorphisms: –909CC, –909CG, and –909GG.

2. Program a thermal cycler to run the following cycling procedure.

First step:	2 min	94°C (denaturation)
35 cycles:	30 sec	93°C (denaturation)
	30 sec	69°C (annealing)
	30 sec	72°C (extension)
Final step:	2 min	72°C (extension).

3. Load tubes into thermal cycler and begin the PCR program.

4. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   5.0 µl DNA from PCR amplification
   0.5 µl 5 U/µl *Bsm*AI
   1.0 µl 10× NEBuffer #3
   3.5 µl H_2O
   10.0 µl total.

   Incubate >2 hr at 55°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes.

5. Load matched undigested and digested samples as described (see Basic Protocol 2, steps 6 and 7), using 2 µl loading dye for each sample and a low-molecular-weight DNA ladder for 50- to 250-bp fragments.

6. Resolve samples by electrophoresis according to manufacturer's specifications (see Basic Protocol 2, step 8).

7. Stain gel and record gel image as described (see Basic Protocol 2, steps 9 and 10).

8. Determine the genotype as follows:

   Complete digestion –909GG
   Partial digestion –909CG
   No digestion –909CC

ALTERNATE PROTOCOL 2

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM –162GA

A native *Bst*UI restriction site in the paraoxonase 1 gene (*PON1*) at −162G allows differentiation between the −162G and −162A alleles by PCR amplification and digestion. The PCR amplifies a 1210-bp product that digests into 674- and 536-bp segments when −162G is present. No digestion occurs with the −162A polymorphism.

Additional Materials *(also see Basic Protocol 2)*

10× Opti-prime buffer #1 (Stratagene)
25 µM forward primer −162: 5′-GCT ATT CTT CAG CAG AGG GT-3′
25 µM reverse primer −162: 5′-TGA ATC TGT AGC CAG GGC AC-3′
10 U/µl *Bst*UI (NEB)
NEBuffer #2 (NEB)
1× TAE (see recipe)
1-kb DNA ladder (Promega) or equivalent
60°C water bath

1. Make up the following on ice in a 0.2-ml PCR tube for each sample.

   0.5 µl ~100 ng/µl purified human DNA
   1.5 µl 10× Opti-prime buffer #1
   0.12 µl 25 µM forward primer −162
   0.12 µl 25 µM reverse primer −162
   0.3 µl 10 µM dNTPs
   0.75 µl DMSO
   0.2 µl 5 U/µl *Taq* DNA polymerase
   11.5 µl H_2O
   15.0 µl total.

When more than one sample is to be analyzed, it is convenient to make up a master mix of appropriate volume to divide between the PCR tubes, with subsequent addition of the individual DNA samples.

It is preferable to include characterized DNA controls for all three polymorphisms: −162AA, −162AG, and −162GG.

2. Program a thermal cycler to run the following cycling procedure.

First step:	2 min	94°C (denaturation)
30 cycles:	30 sec	94°C (denaturation)
	30 sec	56°C (annealing)
	30 sec	72°C (extension)
Final step:	2 min	72°C (extension).

3. Load tubes into thermal cycler and begin the PCR program.

4. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   5.0 µl DNA from PCR amplification
   0.5 µl 10 U/µl *Bst*UI
   1.0 µl 10× NEBuffer #2
   3.5 µl H_2O
   10 µl total.

   Incubate >2 hr at 60°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes

5. Add 2 µl of 6× Blue/orange loading dye to each undigested and digested sample. Also add loading dye to 1-kb DNA ladder as per supplier's recommendations.

6. Load the ladder into one well of a 1% (w/v) agarose gel made with 1× TAE and alternately load 10 µl of matched undigested and digested samples into the other wells.

   A small-toothed comb should be used when pouring the gel to allow ~15 µl per well.

7. Resolve samples by electrophoresis in 1× TAE according to manufacturer's specifications (see Basic Protocol 2, step 8).

8. Stain and record gel image as described (see Basic Protocol 2, steps 9 and 10).

9. Determine the genotype as follows:

Complete digestion	−162GG
Partial digestion	−162AG
No digestion	−162AA

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM −108TC

ALTERNATE PROTOCOL 3

In the paraoxonase 1 gene (*PONI*), there is no usable native restriction site that differentiates between the position −108 alleles. To resolve this problem, a reverse primer is used that introduces a *Bst*UI site when −108C is present. This primer is long enough that when the PCR product is digested, the resulting fragments are visible on a 3% (w/v) agarose gel. The digestion results in 52- and 67-bp bands from the 119-bp product when −108C is present and no digestion when −108T is present.

Additional Materials *(also see Basic Protocol 2)*

10× *Taq* polymerase buffer (Promega)
25 mM $MgCl_2$ (Promega or *APPENDIX 2A*)
25 µM forward primer −108: 5′-GAC CGC AAG CCA CGC CTT CTG TGC ACC-3′
25 µM reverse primer −108: 5′-TAT ATT TAA TTG CAG CCG CAG CCC TGC TGG GGC AGC GCC GAT TGG CCC GCC GC-3′
10 U/µl *Bst*UI and NEBuffer #2 (NEB)
Low–base pair DNA ladder (standards for 50- to 125-bp fragments)
60°C water bath

1. Make up the following on ice in a 0.2-ml PCR tube for each sample.

   2.0 µl ~100 ng/µl purified human DNA
   1.5 µl 10× *Taq* polymerase buffer
   1.2 µl 25 mM $MgCl_2$
   0.1 µl 25 µM forward primer −108
   0.1 µl 25 µM reverse primer −108
   0.3 µl 10 mM dNTPs
   0.75 µl DMSO
   0.2 µl 5 U/µl *Taq* DNA Polymerase
   8.85 µl H_2O
   15.0 µl total.

   When more than one sample is to be analyzed, it is convenient to make up a master mix of appropriate volume to divide between the PCR tubes, with subsequent addition of the individual DNA samples.

   It is preferable to have characterized DNA controls for all three polymorphisms: −108CC, −108CT, and −108TT.

2. Program a thermal cycler to run the following cycling procedure.

First step:	2 min	94°C (denaturation)
25 cycles:	30 sec	94°C (denaturation)
	30 sec	63°C (annealing)
	30 sec	72°C (extension)
Final step:	2 min	72°C (extension).

3. Load tubes into thermal cycler and begin the PCR program.

4. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   5.0 µl DNA from PCR amplification
   0.5 µl 10 U/µl *Bst*UI
   1.0 µl 10× NEBuffer #2
   3.5 µl H_2O
   10 µl total.

   Incubate >2 hr at 60°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes.

5. Load matched undigested and digested samples as described (see Basic Protocol 2, steps 6 and 7), using 2 µl loading dye for each digested and undigested sample and a low-molecular-weight DNA ladder for 50- to 125-bp fragments.

6. Resolve samples by electrophoresis in 0.5× TBE buffer according to manufacturer's specifications (see Basic Protocol 2, step 8).
7. Stain and record gel image as described (see Basic Protocol 2, steps 9 and 10).
8. Determine the genotype as follows:

Complete digestion	−108CC
Partial digestion	−108CT
No digestion	−108TT

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM 55LM

ALTERNATE PROTOCOL 4

The paraoxonase 1 gene (*PONI*) has a native *Nla*III restriction site at the 55M codon. In this genotyping strategy, a 386-bp polymerase chain reaction (PCR) product containing the site is amplified. When cut with *Nla*III, it produces a 296-bp and 90-bp band when 55M is present. No digestion is observed with DNA containing the 55L codon.

Additional Materials *(also see Basic Protocol 2)*

10× *Taq* polymerase buffer (Promega)
25 mM $MgCl_2$ (Promega or *APPENDIX 2A*)
25 µM forward primer 55: 5′-AGA GGA TTC AGT CTT TGA GGA AA-3′
25 µM reverse primer 55: 5′-CTG CCA GTC CTA GAA AAC GTT-3′
10 U/µl *Nla*III and NEBuffer #4 (NEB)
10× BSA (NEB)
Low–base pair DNA ladder (suitable for 100- to 400-bp fragments)

1. Make up the following on ice in a 0.2-ml PCR tube for each sample.

0.5 µl ~100 ng/µl purified human DNA
2.0 µl 10× *Taq* polymerase buffer
1.6 µl 25 mM $MgCl_2$
0.2 µl 25 µM forward primer 55
0.2 µl 25 µM reverse primer 55
0.2 µl 10 mM dNTPs
0.2 µl 5 U/µl *Taq* DNA polymerase
15.1 µl H_2O
20.0 µl total.

When more than one sample is to be analyzed, it is convenient to make up a master mix of appropriate volume to divide between the PCR tubes, with subsequent addition of the individual DNA samples.

It is preferable to have characterized DNA controls for all three polymorphisms: 55LL, 55LM, and 55MM.

2. Program a thermal cycler to run the following cycling procedure.

First step:	5 min	94°C (denaturation)
35 cycles:	30 sec	94°C (denaturation)
	30 sec	61°C (annealing)
	30 sec	72°C (extension)
Final step:	7 min	72°C (extension).

3. Load tubes into thermal cycler and begin the PCR program.

4. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   5.0 µl DNA from PCR amplification
   0.3 µl 10 U/µl *Nla*III
   1.0 µl 10× NEBuffer #4
   1.0 µl 10× BSA
   2.7 µl H_2O
   10.0 µl total.

   Incubate >2 hr at 37°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes.

5. Add 3 µl of 6× Blue/orange loading dye to each undigested sample and 2 µl to each digested sample. Also add loading dye to low-molecular-weight DNA ladder for 100- to 400-bp fragments as per supplier's recommendations.

6. Load the ladder into the well of a 2% (w/v) agarose gel made with 0.5× TBE and alternately load 10 µl of matched undigested and digested samples.

   A small-toothed comb should be used when pouring the gel to allow ~15 µl per well.

7. Resolve samples by electrophoresis in 0.5× TBE according to manufacturer's specifications (see Basic Protocol 2, step 8).

8. Stain and record gel image as described (see Basic Protocol 2, steps 9 and 10).

9. Determine the genotype as follows:

Complete digestion	55MM
Partial digestion	55LM
No digestion	55LL

ALTERNATE PROTOCOL 5

PARAOXONASE 1 GENOTYPING FOR POLYMORPHISM 194WX

The paraoxonase 1 gene (*PONI*) has a native *Bst*NI restriction site at 194W. With this strategy, a 99-bp polymerase chain reaction (PCR) product containing the site is amplified. (This is the same fragment that is amplified for the codon 192 genotyping; see Basic Protocol 2.) When cut with *Bst*NI, it produces 73- and 26-bp bands when 194W is present; no digestion occurs with 194X.

Additional Materials *(also see Basic Protocol 2)*

10 U/µl *Bst*NI and NEBuffer #2 (NEB)
10× BSA (NEB)
60°C water bath

1. Set up and run PCR reactions as described (see Basic Protocol 2, steps 1 to 4), except use 0.7 µl of 100 mM $MgSO_4$ in the polymerase mix and add no water (1.0 µl final volume).

2. Prepare the following on ice for each PCR sample. Save the remaining undigested, amplified DNA for comparison on the agarose gel.

   10.0 µl DNA from PCR amplification
   1.0 µl 10 U/µl *Bst*NI
   2.0 µl 10× BSA
   2.0 µl 10× NEBuffer #2
   5.0 µl H_2O
   20.0 µl total.

   Incubate >2 hr at 60°C.

   As before, it is convenient to make up a master mix of appropriate volume to divide between the tubes.

3. Load matched undigested and digested samples, run gel, and stain gel and record gel image as described (see Basic Protocol 2, steps 6 to 10).

4. Determine the genotype as follows:

Complete digestion	194WW
Partial digestion	194WX
No digestion	194XX

   The 194XX genotype has not yet been observed.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers and in all protocol steps. For common stock solutions, see ***APPENDIX 2A;*** *for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer

Dissolve 116.8 g NaCl (2 M final) in ~800 ml water containing 100 ml of 1 M Tris·Cl, pH 8.5 (0.1 M final) and 2.0 ml of 1 M $CaCl_2$ (2.0 mM final). Bring volume to 1 liter with water. Store up to 6 months at room temperature.

Dilution buffer

Combine 10 ml of 1 M Tris·Cl, pH 8.5 (10 mM final) and 2.0 ml of 1 M $CaCl_2$ (2.0 mM final) and bring volume to 1 liter with water. Store up to 6 months at room temperature.

Ethidium bromide, 1 mg/ml

Weigh 0.1 g ethidium bromide and add to 100 ml water. Store in a light-protected bottle at 4°C indefinitely. Dilute 1:10,000 in running buffer or water to stain gel.

CAUTION: *Ethidium bromide is a mutagen, is moderately toxic, and must be handled carefully. Gloves should be worn at all times to avoid contact. Solutions should be discarded in accordance with institutional guidelines.*

TAE, 50×

Add 242 g Tris base and 18.61 g $Na_2EDTA{\cdot}2H_2O$ to 800 ml water. Add 57.1 ml glacial acetic acid and bring volume to 1 liter with water. Mix until all solid is dissolved. Store up to 6 months at room temperature.

COMMENTARY

Background Information

The human high-density-lipoprotein (HDL)-associated enzyme paraoxonase 1 (PON1; EC 3.1.8.1 or 3.1.1.2) is encoded by a gene on human chromosome 7 q21-22 (Humbert et al., 1993). Two common coding region polymorphisms have been described, 55LM and 192QR (Hassett et al., 1991; Adkins et al., 1993). The latter affects catalytic efficiency of hydrolysis of a number of different substrates (Davies et al., 1996; Furlong et al., 2000). In addition to these coding-region polymorphisms, five polymorphisms in the 5′ regulatory region have been described: −108TC, −126GC, −162GA, −832GA, and −909CG (Brophy et al., 2001). The −108TC polymorphism has the largest effect on PON1 expression of these five polymorphisms, with the −108C allele generating on average approximately twice the amount of plasma PON1 as the −108T allele generates. Recently, eight new polymorphisms in the 5′ regulatory region have been described, but they are not yet characterized, which is also true of >140 polymorphisms in PON1 introns. One new functional coding region polymorphism, W194X, has been described and characterized (Jarvik et al., 2003; see Internet Resource).

Early investigations centered around the role of the PON1 polymorphisms in resistance to organophosphorus insecticides (reviewed in Costa et al., 2002; La Du, 2002). More recent studies have focused on the role of the *PON1* polymorphisms in vascular disease (reviewed in Lusis et al., 2000; Brophy et al., 2002; Mackness et al., 2002; Shih et al., 2002). These studies merit special comments. Nearly all of the studies investigating the relationship between *PON1* polymorphisms and vascular disease have considered only *PON1* genotype(s) and have ignored the equally or more important consideration of PON1 levels. The mechanism of prevention of vascular disease appears to be related to the ability of PON1 to degrade biologically active oxidized lipids (Watson et al., 1995; reviewed in Navab et al., 2002). Fundamental biochemical principles dictate that the more PON1 molecules present in the plasma, the faster an individual can detoxify toxic organophosphate compounds or oxidized lipid molecules. Thus, it is important to analyze both PON1 quantity as well as quality.

PON1 knockout mice show a dramatic increase in sensitivity to chlorpyrifos oxon (Shih et al., 1998) and diazoxon (Li et al., 2000). Resistance can be restored by injecting purified PON1. The degree of resistance provided by the injected purified PON1 depends on the catalytic efficiency of the position 192 alloform injected ($PON1_{192Q}$ or $PON1_{192R}$). Because it is both the level and catalytic efficiency of PON1 that determine sensitivity to organophosphate exposures (Li et al., 2000), and probably risk for vascular disease as well (Jarvik et al., 2000), it does not make sense to analyze for PON1 genotype alone. A simple two-substrate analysis, when used with a population analysis, provides an individual's PON1 status relative to the rest of the population. Plotting the rates of diazoxon hydrolysis versus paraoxon hydrolysis (Fig. 4.12.2) for individuals within a population clearly divides the subjects into three groups: individuals homozygous for $PON1_{192Q}$, heterozygotes ($PON1_{192Q/R}$), and individuals homozygous for $PON1_{192R}$ (Richter and Furlong, 1999).

Figure 4.12.2 illustrates a typical population distribution using the method for determination of PON1 status (see Basic Protocol 1). Whereas most of the authors' studies make use of heparin plasma, this figure shows that PON1 status can also be determined using stored citrate plasma. Plasma for a given study should all be prepared with the same preservative because there are some small differences in activity between citrate- and heparin-stored plasma samples (serum has also been used in the authors' laboratory). EDTA plasma cannot be used because EDTA irreversibly denatures PON1. If only stored EDTA plasma samples are available, it is recommended that PON1 levels be determined via immunoassay protocols (Blatter Garin et al., 1994).

Interindividual variability of PON1 levels can be at least 13-fold within a given $PON1_{192}$ genotype (Q/Q, Q/R, R/R; Davies et al., 1996). A number of factors govern the levels of plasma PON1. These include polymorphisms in the 5′ regulatory region of the *PON1* gene, possibly the as yet uncharacterized polymorphisms in the 3′ UTR of PON1, various coding region mutations such as the nonsense mutation at codon 194, and mutations in splice or acceptor sites and possibly enhancer sequences that have not yet been characterized. In addition to regulatory factors upstream from, within, and downstream from the *PON1* gene, other transacting factors, often referred to as genetic background factors, also influence the level of expression of PON1. One example is the devel-

opmental regulation of expression of PON1 controlled by as yet uncharacterized factors, which in turn will also most likely be genetically variable. Thus, while it is neither feasible nor sufficient to examine all of the different genetic factors that contribute to the variability in PON1 expression, it is straightforward to evaluate the final result of all of these effects (i.e., the level of expression and functional genomics of *PON1*). The two-substrate analysis provides an accurate analysis of an individual's PON1 status (position 192 functional genotype and level of expression) using high-throughput assay methods.

Methods are also provided for genotyping a number of the *PON1* DNA polymorphisms (see Basic Protocol 2 and see Alternate Protocols 1 to 5). It should be noted, however, that the authors do not recommend the use of PON1 genotype alone for determining susceptibility to specific exposures or for determining PON1-associated risk for specific diseases. The PON1 status determination provides essential information not provided by genotyping *PON1* polymorphisms or even more sophisticated haplotype analysis. The genotyping methods may be useful for forensic procedures or other applications such as gene frequency determination for specific populations.

Critical Parameters and Troubleshooting

The most critical parameter for determining PON1 status is to be sure that the rates used to generate the data points are derived from the linear portions of the rate versus time plots. Examination of the rate curves from the plate reader will provide the information necessary to make this determination. If some of the higher rates become nonlinear versus time, rates over shorter times can be selected. For plasma with slow rates of hydrolysis, times can be selected that provide appropriate linear rates.

It is also important that plasma not be drawn into EDTA tubes, as EDTA irreversibly inhibits PON1. Lithium-heparin has been used as the anticoagulant of choice. As noted in this unit, however, citrate plasma may also be used. For a given study, the same anticoagulant should be used, as there may be differences in activity between plasma drawn into different anticoagulants. See Table 4.12.1 for troubleshooting PON1 genotyping.

Table 4.12.1 Troubleshooting Guide to PON1 Genotyping

Problem	Possible cause	Suggested solution
No or low PCR amplification	Not enough DNA	Check DNA concentration of samples
		Increase cycle number
	EDTA or other contaminant in DNA sample	Get new samples without EDTA
		Remove EDTA with purification column
	Improper reagent mixing	Mix all components properly
Incorrect or ambiguous results	Digestion not complete	Increase incubation time
	Wrong incubation temperature	Check temperature
	Poor quality restriction enzyme	Purchase new enzyme and store properly
	Restriction enzyme not fresh	Check expiration date
	Mis-genotyped	Find new reliable controls
	Cross-contamination	Use aerosol-resistant tips
	Gel was not run long enough	Run gel until bands are well separated
	Agarose gel not prepared correctly	Make sure gel is well mixed and without bubbles or contaminants

Anticipated Results

The results obtained from the two-substrate analysis of PON1 status should generate a distribution such as that seen in Figure 4.12.2. If they do not, the most likely problem would be the use of rates derived from the nonlinear portion of the hydrolysis rate curves.

The gene frequencies obtained from the SNP analyses will vary according to the ethnic composition of the sampled population. For example, the gene frequency of the $PON1_{192Q}$ allele in populations of Northern European origin should be approximately 0.7. For populations of Asian or African origin, the gene frequency for $PON1_{192Q}$ will be significantly lower, perhaps as low as 0.3.

Time Considerations

The determination of PON1 status by the two-substrate procedure can be completed in a single day for 32 individuals when the samples are run in triplicate and rates are determined for the two substrates, paraoxon and diazoxon.

Each genotyping experiment can be completed in ~8 hr when assaying 28 samples. It can be convenient to break up the procedure by stopping after the PCR or digestion step and freezing the experiment overnight so that it can be finished in 2 days.

Human Cytochrome P450: Metabolism of Testosterone by CYP3A4 and Inhibition by Ketoconazole

The cytochrome P450 (CYP) monooxygenase system comprises a superfamily of heme-containing enzymes expressed in many mammalian tissues, with the highest levels found in liver. These enzymes are capable of catalyzing the metabolism of a wide range of both endogenous and exogenous substrates. Human CYP3A4 is one of the most important and abundant drug-metabolizing CYP isoforms in human liver microsomes—it accounts for ~40% of the total CYP in human liver microsomes. CYP3A4 not only metabolizes xenobiotics but is also responsible for the metabolism of endogenous compounds such as testosterone. Assessing the role of CYP3A4 in drug metabolism often requires a well characterized CYP3A4 selective substrate to probe CYP3A4 activity. Among the different CYP3A4 assays available, the regioselective and stereoselective hydroxylation of testosterone is one of the most commonly used metabolism assays for the assessment of CYP3A4 activity in humans and other species. Testosterone hydroxylation assays may be used in drug metabolism studies to help assess enzyme induction, predict drug-drug interactions, characterize structure-activity relationships, and facilitate drug candidate selection. This unit begins by describing the HPLC method for measuring testosterone oxidation, which is a simple screening method (see Basic Protocol 1). Determination of testosterone metabolism by this protocol is also a very sensitive method to detect the inhibition of CYP3A4 by chemicals of interest.

Chemical inhibition studies (see Basic Protocol 2) take advantage of the specificity of the particular isoform involved in the metabolism of the chemical of interest. To understand potential interactions with other CYP3A4 substrates and effects of polymorphisms, it is important to determine whether CYP3A4 is responsible for metabolism of the chemical of interest. One method to determine the role of a CYP isoform is to use a selective chemical inhibitor. If such an inhibitor significantly inhibits the metabolic activity of CYP3A4, this indicates that CYP3A4 is responsible for the metabolism; otherwise, one may infer that CYP3A4 plays little role in the metabolism. Ketoconazole, an imidazole fungicide, is a selective inhibitor of CYP3A4. Basic Protocol 2 describes a method of using ketoconazole to determine the role of CYP3A4 in metabolism, with testosterone as a model substrate.

TESTOSTERONE OXIDATION BY CYP3A4

BASIC PROTOCOL 1

Testosterone oxidation is predominantly catalyzed by CYP3A4 and, therefore, is often used as a diagnostic pathway for CYP3A4 activity. This procedure takes advantage of the specificity of CYP3A4 toward testosterone metabolism and is a sensitive method for the measurement of testosterone metabolites.

Materials

0.1 M potassium phosphate buffer, pH 7.4, with 5 mM $MgCl_2$ (see recipe)
100 mM testosterone stock (Steraloids, Inc.; dissolve 28.841 mg testosterone in 1 ml methanol; store up to 3 months at −20°C)
NADPH regenerating system (see recipe)
1 pmol/μl CYP3A4 (BD Bioscience)
Methanol, ice-cold
Testosterone metabolites in methanol for standard curve (see recipe and Table 4.13.1)

Contributed by Khawja A. Usmani and Jun Tang
Current Protocols in Toxicology (2004) 4.13.1-4.13.9

Table 4.13.1 HPLC Retention Times for Testosterone and Hydroxylated Testosterone Metabolites[a]

Common name	Chemical name	Retention time (min)
6α-Hydroxytestosterone	4-Androsten-6α,17β-diol-3-one	14.38
15β-Hydroxytestosterone	4-Androsten-15β,17β-diol-3-one	15.11
6β-Hydroxytestosterone	4-Androsten-6β,17β-diol-3-one	16.25
11-Ketotestosterone	4-Androsten-17β-ol-3,11-dione	18.24
16β-Hydroxytestosterone	4-Androsten-16β,17β-diol-3-one	19.34
11β-Hydroxyandrostenedione	4-Androsten-11β-ol-3,17-dione	19.68
2α-Hydroxytestosterone	4-Androsten-2α,17β-diol-3-one	20.68
2β-Hydroxytestosterone	4-Androsten-2β,17β-diol-3-one	21.55
Androstenedione	4-Androsten-3,17-dione	24.92
4-Hydroxyandrostenedione	4-Androsten-4-ol-3,17-dione	27.20
Testosterone	4-Androsten-17β-ol-3-one	28.90

[a]Testosterone and its metabolites are purchased from Steraloids, Inc.

1-ml HPLC vials
HPLC system and reagents (Table 4.13.2)

Perform reaction

1. Add the following ingredients to a 1.5-ml microcentrifuge tube (total 250 μl).

   221 μl potassium phosphate buffer, pH 7.4, with 5 mM $MgCl_2$
   4 μl of 6.125 mM testosterone in methanol (prepare from 100 mM stock; final concentration in reaction, 100 μM)
   12.5 μl NADPH regenerating system.

2. Preincubate for 3 min at 37°C.
3. Initiate reaction by adding 12.5 μl of ice-cold 1 pmol/μl CYP3A4 (final concentration 50 pmol/ml).
4. Incubate for 10 min at 37°C water bath with gentle shaking.

Analyze by HPLC

5. Terminate the reaction by the addition of 250 μl of ice-cold methanol.
6. Vortex for 5 sec.
7. Microcentrifuge 10 min at maximum speed, room temperature.
8. Transfer 400 μl of supernatant to a 1-ml HPLC vial.
9. Analyze testosterone metabolite concentrations by reversed-phase HPLC using the conditions described in Table 4.13.2. Analyze a series of testosterone metabolites (see Table 4.13.1 and Reagents and Solutions) in parallel to create a standard curve.

   The recommended injection volume is 50 μl.

10. Detect the products by their absorbance at 247 nm and quantify them by comparing the absorbance to standard curves of testosterone metabolites.
11. Obtain concentrations of metabolites by extrapolation of peak heights from a standard curve.

Table 4.13.2 Reversed-Phase HPLC Conditions for Separation of Testosterone and its Potential Metabolites

Conditions	Information
Mobile phase A	5% tetrahydrofuran/95% H_2O[a]
Mobile phase B	100% methanol
Gradient	0–1 min (30% B) 1–10 min (30%–60% B) 10–22 min (60%–65% B) 22–28 min (65%–80% B) 28–30 min (80%–90% B) 30–32 min (90% B)
Flow rate	0.5 ml/min
Column	Phenomenex Prodigy ODS(3), 3 μm, 150 × 4.6 mm, 100 Å
Detector	Absorbance at 247 nm
Retention times	see Table 4.13.1
Limits of detection	For most testosterone metabolites, ~0.04 μM, except for 6β-hydroxytestosterone (0.15 μM) and 4-hydroxyandrostenedione (0.30 μM)

[a]Do not use HPLC mobile phase A for more than 1 week, because the concentration of tetrahydrofuran changes; prepare fresh every week, otherwise retention time may shift.

INHIBITION OF CYP3A4-MEDIATED TESTOSTERONE 6β-HYDROXYLASE BY KETOCONAZOLE

BASIC PROTOCOL 2

Ketoconazole is one of the most frequently used selective chemical inhibitors for CYP3A4. Although some researchers preincubate microsomes with ketoconazole to obtain a substantial inhibition before adding a substrate, most find that adding substrate and ketoconazole to microsomes simultaneously achieves the required inhibition, because of the potency of ketoconazole. The assay described here is a straightforward method to study the inhibition of CYP3A4 activity by ketoconazole.

Materials

1 pmol/μl CYP3A4 (BD Bioscience) or liver microsomes (*UNIT 4.3*; 20 mg protein/ml)
0.1 M potassium phosphate buffer, pH 7.4, with 5 mM $MgCl_2$ (see recipe)
25 mM testosterone (Steraloids, Inc.) in methanol (store up to 3 months at −20°C)
0.5 mM ketoconazole stock (Sigma) in DMSO (store up to 3 months at −20°C)
NADPH regenerating system (see recipe)
Methanol, ice-cold
6β-hydroxytestosterone in methanol for standard curve (see recipe for testosterone metabolites)

1-ml HPLC vials
HPLC system and reagents (Table 4.13.2)

Additional reagents and equipment for measurement of testosterone metabolites by HPLC (see Basic Protocol 1)

Perform reaction

1. Quickly thaw CYP3A4 or human liver microsomes and place on ice.
2. Add 451 μl of 100 mM potassium phosphate buffer (pH 7.4) with 5 mM $MgCl_2$ to each of a series of 1.5-ml plastic microcentrifuge tubes representing different concentrations of ketoconazole to be tested (see step 4, below).

3. To each tube, add 2 μl of 25 mM testosterone (to make a final concentration of 100 μM) or 2 μl of methanol as a solvent control for substrate.
4. To each tube, respectively, add 2 μl of a different concentration of ketoconazole in DMSO to make final concentrations of 0, 0.02, 0.2, and 2 μM.

   Ketoconazole is soluble in DMSO but is less soluble in acetonitrile and methanol. Make a 0.5 mM ketoconazole stock solution and dilute to 0.05 and 0.005 μM to obtain final concentrations of 2, 0.2, or 0.02 μM in the reaction mixture. Add an equal volume (2 μl) of DMSO to obtain a 0 μM ketoconazole control.

   CAUTION: *DMSO is hazardous; avoid skin contact.*
5. Add 25 μl of NADPH-regenerating system or 25 μl of 100 mM potassium phosphate buffer (pH 7.4) with 5 mM $MgCl_2$ as a control for potential non-CYP-mediated reactions.
6. Vortex tubes and preincubate 3 min at 37°C.
7. Add 20 μl of ice-cold 1 pmol/μl CYP3A4 (final concentration, 40 pmol/ml) or 20 μl of ice-cold 20 mg/ml human liver microsomes (final concentration, 800 μg/ml to start the reaction; vortex the tube and incubate for 10 min in a 37°C water bath with gentle shaking.

Analyze by HPLC

8. Stop the reaction by adding 250 μl of ice-cold methanol.
9. Microcentrifuge 10 min at maximum speed, room temperature.
10. Transfer 500 μl of the supernatant to a 1-ml HPLC vial.
11. Analyze testosterone 6β-hydroxylase by reversed-phase HPLC using the conditions described in Table 4.13.2. Analyze a series of testosterone metabolites (see Table 4.13.1 and Reagents and Solutions) in parallel to create a standard curve.

    The recommended injection volume is 50 μl.
12. Detect the products by their absorbance at 247 nm and quantify them by comparing the absorbance to standard curves of testosterone metabolites.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all solutions and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

NADPH regenerating system

Add 4.2 mg $NADP^+$ (sodium salt; Sigma) to 14.1 mg glucose-6-phosphate (monosodium salt; Sigma) and 20 U of glucose-6-phosphate dehydrogenase in a final volume of 0.5 ml of the same potassium phosphate buffer as the reaction buffer. Dispense into 25-μl aliquots per 1-ml assay volume, bring final concentrations to 0.25 mM $NADP^+$, 2.5 mM glucose-6-phosphate, and 1 U glucose-6-phosphate dehydrogenase. Excess solution may be used for up to 2 weeks if stored frozen at −20°C.

Potassium phosphate buffer, pH 7.4, 100 mM, with 5.0 mM $MgCl_2$

Combine 0.517 g KH_2PO_4 and 2.822 g K_2HPO_4 in 200 ml of water. Add 0.205 g $MgCl_2$ (hexahydrate; Fisher). Adjust to pH 7.4 with 1 M HCl or NaOH if necessary. Store up to 6 months at 4°C.

Testosterone metabolites

Make solutions of each of the testosterone metabolites (Steraloids, Inc.) in methanol, all of which are 50 μM. Take half of the 50 μM solution and add an equal volume of methanol to get a 25 μM concentration. Repeat the procedure to get the 0.1 μM concentration. Inject 50 μl testosterone metabolites on HPLC system and make a standard curve of each metabolite of testosterone based on the peak heights on Microsoft Excel.

The metabolites may be stored up to 3 months at −20°C

COMMENTARY

Background Information

Cytochrome P450s (CYPs) are the main enzymes responsible for the Phase I reactions, which are considered to be one of the rate-limiting steps of the overall drug metabolism process (Madan et al., 2001). In some cases, the products of Phase I reaction are more active or toxic than their corresponding parent compounds (Neal, 1980). Of the several human CYP enzymes, those of the CYP3A subfamily have major importance because they are the most abundant of the human CYP isoforms. Substrate specificity of the CYP3A subfamily is extremely broad, and these enzymes have been shown to be expressed in tissues of particular relevance to drug disposition, such as liver, intestine, lung, kidney, and brain (Shimada et al., 1994, Thummel and Wilkinson 1999, Madan et al., 2001). At least three members of the CYP3A subfamily have been described as having functional proteins in humans: CYP3A4, CYP3A5, and CYP3A7. It has been reported that CYP3A4 in humans represents up to 50% of the cytochrome P450 expressed in liver and 70% of that in small intestine (Kolars et al., 1994, McKinnon et al., 1995). Initial data suggested that CYP3A5 accounted for only a small percentage of total hepatic CYP3A content in only about 20% of samples. However, recent data have indicated that CYP3A5 might exceed 50% of the total CYP3A in some individuals (Kuehl et al., 2001). Expression of CYP3A7 functional protein is mainly confined to the fetal liver, although in some cases it has been detected in adults (Schuetz et al., 1994). P450-dependent hydroxylation appears to be a major pathway of oxidative metabolism of testosterone in mammals. CYP3A4 is one of the major isoforms responsible for testosterone metabolism, and 6β-hydroxytestosterone is the major testosterone metabolite. It has been shown (Usmani et al., 2003) that, among members of the CYP3A subfamily, CYP3A4 produced the highest amount of testosterone metabolites (88.5%) compared with 3A5 (6.9%) and 3A7 (4.6%). The same study indicated that among members of the CYP3A subfamily CYP3A4 produced the highest amount of 6β-hydroxytestosterone (90.6%) compared with 3A5 (7.1%), and 3A7 (2.2%). Other major TST metabolites formed by CYP3A4 were 15β-hydroxytestosterone, 2β-hydroxytestosterone, and 4-hydroxyandrostenedione. Other members of the CYP3A subfamily, CYP3A5 and 3A7, also oxidized testosterone, but their activity was 10 to 20 fold less than that of CYP3A4 (Usmani et al., 2003). Several studies have shown that CYP3A4 is the major P450 involved in the metabolism of testosterone in human liver microsomes. Either inhibition or induction can modulate the activity of an enzyme; P450s may exhibit stimulation or inhibition in the presence of certain xenobiotic compounds. It has been suggested that CYP3A4 is an allosteric enzyme, even though the identity of the allosteric site is not known (Shimada and Guengerich 1989; Lee et al., 1995). In addition, little is known about the active-site topology of CYP3A4, although it is generally recognized that the active site of this enzyme has the capacity to accommodate large molecules and even more than one substrate (Shou et al., 1994). Inhibition may, in some interactions, be more serious than enzyme induction, since inhibition happens more rapidly, not taking time to develop, as with induction (Guengerich, 1997). It is very important to know that a chemical of interest inhibits or induces CYP3A4 activity. Testosterone oxidation is one of the most important tools employed as a diagnostic test for CYP3A4 activity and its inhibition or induction. Basic Protocol 1 describes a method to study the activity of CYP3A4. This method can be used for inhibition or induction studies of CYP3A4 by chemicals of interest in human hepatocytes or in recombinant CYP3A4. Similarly testosterone oxidation can be used as a diagnostic test for CYP3A5 and CYP3A7 isoforms (Lee et al., 2003).

CYP3A4 is responsible for the P450-mediated metabolism of ~50% of marketed pharmaceuticals, although the levels vary by as much as 20-fold among individuals (Shimada et al., 1994, Rodrigues, 1999). Due to the large number of drug molecules metabolized by CYP3A4, potent inhibition can have a detrimental effect on another drug. It is very important to determine reaction phenotyping of a given drug or test compound, i.e., to understand all reaction pathways of the drug and the CYP isoforms catalyzing these reactions (see Internet Resources). One of the tools used to analyze reaction phenotyping is the use of selective chemical inhibitors to identify the CYP isoforms responsible for the reaction (Rodrigues, 1999). The information obtained from a reaction phenotyping study can predict effects of polymorphism. For example, if a phenotyping study found that a drug is predominantly metabolized by certain CYP isoforms, then it is predictable that this drug would have low clearance in a person with a mutated allele of this isoform (Dai et al., 2001). Reaction phenotyping studies can also identify potential drug-drug interactions, i.e., the metabolism of a test drug may change if it is coadministered with another drug that significantly inhibits or induces the CYP isoform that predominantly catalyzes the metabolism of the test drug, or a test drug may significantly affect the metabolism of a coadministered drug by inhibiting or inducing the CYP isoform responsible for the metabolism of the latter (Varhe et al., 1994; von Moltke et al., 1996).

CYP3A4 is the most abundant CYP isoform in human liver and is involved in the metabolism of more than half of currently used drugs as well as a number of steroids, environmental chemicals, and carcinogens (Shimada et al., 1994). It is important to identify the involvement of CYP3A4 in the metabolism of a test compound. Ketoconazole has been used as a selective chemical inhibitor for CYP3A4 in reaction phenotyping studies (Jonsson et al., 1995; Moody et al., 1997; Oda and Kharasch, 2001). Ketoconazole is an imidazole fungicide. The mechanism underlying its antifungal activity, like other azole fungicides, is the inhibition of ergosterol synthesis by binding of the unsubstituted nitrogen (N-3) of its imidazole moiety to the heme iron and binding of its N-1 substituent to the apoprotein of a fungal CYP (Vanden Bossche et al., 1989). The affinity and selectivity of azole fungicides for CYP are determined by the nitrogen heterocycle and the hydrophobic N-1 substituent. Ketoconazole not only inhibits fungal CYP, which makes it a good fungicide (Gascoigne et al., 1981), but it is also a potent CYP3A4 inhibitor, which results in adverse interactions with other drugs (Mosca et al., 1985; Brown et al., 1985; Back and Tjia, 1985; Varhe et al., 1994). Ketoconazole is a very potent and selective mixed-type CYP3A inhibitor with a $K_i \leq 0.3$ μM (Maurice et al., 1992; Bourrie et al., 1996; von Moltke et al., 1996; Satoh et al., 2000).

Basic Protocol 2 describes a method to study inhibition of testosterone metabolism by ketoconazole. This method can be used for reaction phenotyping or inhibition studies of other chemicals of interest. For example, a test compound can be used as a potential CYP3A4 substrate to replace testosterone for a reaction phenotyping study of the test compound (for more detail about phenotyping studies, see Rodrigues 1999). For inhibition studies, a test compound can be used as a potential CYP3A4 inhibitor to replace ketoconazole (for more detail about inhibition studies, see Madan et al. 2001).

Critical Parameters and Troubleshooting

For a reaction phenotyping study, it is necessary to make sure that CYP3A4 activity is significantly inhibited (% inhibition > 83%) while the other CYP isoforms are not significantly affected (Rodrigues, 1999). It has been shown that ketoconazole is selective for CYP3A at an $[I]/K_i$ ratio as high as 30 (Bourrie et al., 1996), although CYP2C9 can also be inhibited at high concentrations (20 μM) of ketoconazole (Zhang et al., 2002). To obtain an IC_{50} value, a series of concentrations of ketoconazole from 0- to 10-fold K_i is sufficient. For a single point concentration, 1 or 2 μM of ketoconazole is often used (Desta et al., 2000; Venkatakrishnan et al., 2001).

Because inhibition effect is calculated as a comparison of activities in the presence or absence of the inhibitor, ketoconazole, an addition of equal volume of solvent into the tube for 0 μM ketoconazole is important. Organic solvent, especially DMSO, has been shown to damage microsomes (Madan et al., 2001). Therefore, an appropriate control for these solvents is necessary.

The concentration of testosterone used in Basic Protocols 1 and 2 is 100 μM, which is around its K_m (Usmani et al., 2003). High concentrations of testosterone (400 to 800 μM) have been shown to inhibit testosterone metabolism. The substrate concentration affects the percent of inhibition, especially

Table 4.13.3 Testosterone Hydroxylation by CYP3A4 Expressed in Baculovirus-Infected Insect Cells

Testosterone metabolites	nmol/nmol CYP3A4/min
6α-Hydroxytestosterone	0.22 ± 0.02
15β-Hydroxytestosterone	3.18 ± 0.11
6β-Hydroxytestosterone	157.7 ± 6.00
11-Ketotestosterone	1.04 ± 0.04
16β-Hydroxytestosterone	0.44 ± 0.01
11β-Hydroxyandrostenedione	1.70 ± 0.02
2α-Hydroxytestosterone	0.19 ± 0.01
2β-Hydroxytestosterone	7.05 ± 0.23
Androstenedione	0.27 ± 0.01
4-Hydroxyandrostenedione	2.23 ± 0.24

when inhibition is competitive. It is important to choose a substrate concentration close to its K_m, because, at this concentration, the percent inhibition will be independent of substrate concentration (Rodrigues, 1999). As for inhibition by ketoconazole, which is a mixed-type inhibitor (Bourrie et al., 1996), choose a substrate concentration at a level equal to or less than K_m, so as not to affect percent of inhibition (Rodrigues, 1999).

It needs to be emphasized again that microsomal protein concentration and time of incubation should be kept in the linear range. Microsomal protein concentration needs to be as low as possible in order to minimize the nonspecific binding of substrate to proteins (Rodrigues, 1999).

persomes; BD Biosciences) may be used. The general assay requirements are described in Basic Protocol 2. The specific conditions of this assay were pH 7.4, 0.4 mg/ml human liver microsomes or 20 pmol/ml recombinant CYP3A4 (Supersomes), a substrate concentration of 100 μM testosterone, and inhibitor concentrations of 0.02 to 2 μM ketoconazole. The assay was incubated for 10 min at 37°C and was stopped with 250 μl ice-cold methanol.

The specific activity (nmol 6β-hydroxytestosterone formed/min/mg microsomal protein or nmol CYP3A4) was calculated according to the Basic Protocol 1. Percent of inhibition or percent of control was calculated using the following formula:

$$\%\ \text{inhibition} = \frac{\text{activity with solvent only} - \text{activity with ketoconazole in solvent}}{\text{activity with solvent only}} \times 100\%$$

$$\%\ \text{control} = \frac{\text{activity with ketoconazole in solvent}}{\text{activity with solvent only}} \times 100\%$$

Anticipated Results

This section gives an example of an assay that was performed by the method described in this unit. Table 4.13.3 is an illustration of results for Basic Protocol 1, obtained after the concentrations of metabolites were obtained by extrapolation of peak height from a standard curve.

Human liver microsomes from commercially available sources were analyzed for testosterone 6β-hydroxylase activity in the presence or absence of ketoconazole. Alternatively, recombinant CYP3A4 (e.g., Su-

The result using this protocol is shown in Figure 4.13.1. Testosterone 6β-hydroxylation activity was inhibited 95% when using 2 μM ketoconazole. An IC_{50} of 0.2 μM for the inhibition of testosterone 6β-hydroxylation has been reported (Baldwin et al., 1995).

Time Considerations

After all the reagents have been prepared, the enzyme assay requires a 3-min preincubation followed by 10 min of incubation. Time for HPLC run is described in the Basic Protocol 1, which is ~40 min per sample.

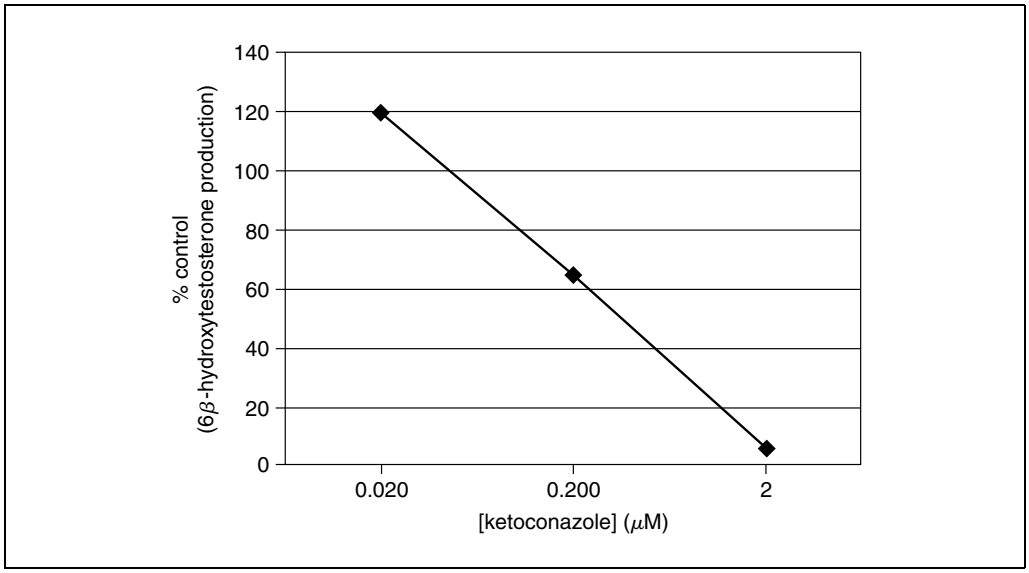

Figure 4.13.1 Inhibition of testosterone 6β-hydroxylation in the presence of ketoconazole (J. Tang, unpub. observ.).

Biotransformation Studies Using Rat Proximal Tubule Cells

The mammalian kidneys fulfill an important excretory function and, as a consequence, are frequently exposed to potentially toxic compounds. Within the kidneys, the cells of the proximal tubule are considered to be the main target for nephrotoxic substances, as they are the first to be exposed to the glomerular ultrafiltrate, and they actively transport a wide variety of charged organic and inorganic compounds. Moreover, proximal tubule cells (PT cells), in particular, express multiple biotransformation enzymes, enabling these to actively metabolize many endogenous substrates including hormones, as well as drugs and xenobiotics. This capacity makes the PT vulnerable to various (bioactivated) compounds, for instance, the susceptibility of the PT to glutathione-derived *S*-conjugates is well-described (Commandeur et al., 1995). Thus, the assessment of the biotransformation potential of PT cells is important in the evaluation of toxicological and kinetic properties of diverse substances. Biotransformation (iso)enzyme expression and activity can be determined in situ (immunostaining) as well as in cell-based assays. This unit describes several methods for the determination of biotransformation enzyme activities both in subcellular fractions (see Basic Protocol 2) and in intact PT cells (see Basic Protocol 1). Upregulation of these enzyme activities by specific inducers is only possible in intact cells, while inhibition experiments can be conducted in intact cells as well as in subcellular fractions.

An enriched population of PT cells can be obtained in several ways, including microdissection of the kidneys and subsequent cell isolation as described elsewhere (Stanton et al., 1986; Takenaka et al., 1998), or via in situ perfusion of the kidneys, followed by cell purification (see Support Protocol 1). A number of different methods for cell purification have been described, including centrifugation over a density gradient. Isolated cells can be cultured directly (see Support Protocol 2), or can be processed to subcellular preparations (see Support Protocol 3). The procedure to isolate cells by in situ perfusion is straightforward and relies on common laboratory equipment, making it easily adaptable to each laboratory setting. Although the protocols described here are optimized for the rat model, simple modifications will allow application for other species, including mouse, rabbit, pig, or any other experimental animal species.

In brief, rats are anaesthetized and the kidneys are isolated from the main blood stream and connected to a perfusion system. The perfusion consists, in principle, of three steps commencing with the use of a calcium-free phosphate buffer containing EGTA (EGTA scavenges calcium, which is an important element in the tight cell junctions) to remove all blood from the kidneys, followed by perfusion with a EGTA-free buffer (EGTA inhibits collagenase activity) and, finally, a collagenase-containing solution is used to reduce the tissue integrity. Note that collagenase exerts its optimal activity in cleaving the tight cell-cell junctions only in the presence of calcium ions (Seglen, 1976).

Following perfusion, the kidneys are placed in an ice-cold BSA solution and the cortex is mechanically separated from the renal medulla and its surrounding tissue. The obtained suspension of cortical cells is washed with BSA-containing buffers before layering the cells onto Nycodenz solutions for gradient centrifugation. Following centrifugation, PT cells are present at the interface of the Nycodenz layers and can be easily recovered and transferred to culture flasks where they are cultured in supplemented DMEM/F12 medium, which is commercially available.

	Sulphate conjugation	ST	Monolayers/ microsomes	HPLC	Wortelboer et al. (1992)

[a]Abbreviations: CDNB, 1-chloro-2,4 dinitrobenzene; GGT, gamma-glutamyltranspeptidase; GST, glutathione-*S*-transferase; ST, sulfotransferase; TFE-cys, S-(1,1,2,2 tetrafluoroethyl)-L-cysteine; UGT, UDP-glucuronyltransferase.

During culture, the biotransformation capacity of PT cells decreases rapidly, therefore, the cells can only be used for a few days. The most rapid decline occurs with CYP450 enzymes, whereas Phase II enzymes remain stable for many days (for details, see Schaaf et al., 2001). The activity of biotransformation enzymes, in particular, those of the CYP450 enzyme family, is much lower than that of other organs, e.g., the liver. Both factors, the intrinsic low activity and the time-dependent loss of biotransformation capacity, have to be taken into account in the design of biotransformation studies with PT cells.

Biotransformation Studies Using Rat Proximal Tubule Cells

Biotransformation enzyme activity can be measured by using a large variety of model substrates, selected according to the targeted (iso)enzyme, or the animal species under investigation. Two examples of such enzyme activity assays will be provided (see Basic Protocols 1 and 2). A detailed database of model substrates and inducers and

Table 4.14.2 Suggested Assay Conditions to Determine the Biotransformation Enzyme Activity in Primary Cultured PT Cells and Microsomal PT-Fractions by Means of HPLC[a]

Substrate	Concentration	Solvent for substrate	Incubation time[b]	Internal standard	Extraction fluid	Mobile phase for HPLC analysis
Caffeine	5 mM	Water	1 hr	20 µl (50 mg/ 1 water) 7-(β-hydroxypropyl)-theophylline	Chloroform:2-propanol 85:15 6 ml	100 µl acetonitril/ 55 mM NaAC in water pH 4.0
Tolbutamide	800 µM	DMSO	1 hr	25 µl (140mg/L) chloropropamide in MeOH/water 1:1	6 ml dichloromethane after acidification with 25 µl 4 N HCl/ml	200 µl acetonitrile/ water pH 2.8 (with phosphoric acid)
Testosterone	250 µM	MeOH	0.5 hr	100 µl (12.5 mg/l MeOH) 11β-hydroxy testosterone	6 ml dichloromethane	130 µl methanol/ Water (1:1)
Naphthol	1 mM	MeOH	30–60 min	[c]	[c]	[c]

[a]Phase I (CYP450) enzyme activity are best assayed using microsomal fractions. Phase II enzymes can easily be determined in primary cultured PT-cells as their expression is stable in time.

[b]Incubation times for the CYP450 enzymes (see Table 4.14.1) using microsomal fractions. When measured in primary cultured PT-cells optimal incubation times vary considerably.

[c]No extraction applied. Incubation medium directly analyzed by HPLC.

inhibitors of biotransformation enzymes is available online (*www.gentest.com*) allowing a problem-orientated selection of reagents. As an example, a selection of useful methods for the relevant enzymes expressed in the rat PT cells is provided in Table 4.14.1.

MEASURING BIOTRANSFORMATION ENZYME ACTIVITY IN PRIMARY CULTURED PT CELLS

BASIC PROTOCOL 1

In cultured cells, the activity of virtually all biotransformation enzymes expressed in the corresponding cell type can be measured. Determination is also possible after enzyme induction either in vivo (intact animal prior to cell isolation) or in vitro when intact cells are incubated with inducers.

Materials

Substrate stock solutions (Table 4.14.1)
Serum-free culture medium (see recipe)
Primary cultured rat proximal tubule cells (plated at 5×10^4 cells/cm^2 in. 60-mm dishes; see Support Protocol 2)
Phosphate buffered saline (PBS; *APPENDIX 2A*)
Rubber policeman

1. Prepare substrate solution by diluting the stock solution to the desired concentration in serum-free medium (for examples see Tables 4.14.1 and 4.14.2).
2. Rinse the primary cultured rat proximal tubule cell cultures two times with sterile PBS.
3. Incubate cells with 3 ml fresh serum-free medium containing the substrate (from step 1) at 37°C.

   Incubation times and linearity of product formation vary with substrate and need to be predetermined in an initial experiment.

4. Collect medium and store at –20°C until analysis (see Table 4.14.2).
5. Scrape cells using a rubber policeman, suspend in 1 ml PBS, and store at −20°C until determination of protein content and Westerm blotting.

   Protein concentration can be determined using commercially available assay kits (e.g., Pierce, Bio-Rad; also see Support Protocol 3) and Western blotting can be conducted using standard procedures.

BASIC PROTOCOL 2

MEASURING CYP450 ACTIVITY USING SUB-CELLULAR PT CELL FRACTIONS

The general protocol describes the principles of the methods applied to determine the activity of individual CYP450 enzymes as exemplified by the method for determining the tolbutamide 4-hydroxylation rate. The suggested volumes and incubation time are based on the experiments as described by Schaaf et al. (2001). Several methods for the determinations of other CYP450s can be found in the published literature (see Table 4.14.1).

Materials

2× concentrated cofactor mixture (see recipe)
Subcellular fractions (microsomal suspension containing ∼100 μg protein; see Support Protocols 1 and 3)
Incubation buffer (see recipe)
Substrate stock solution
Internal standard (see Table 4.14.2)
Extraction fluid (see Table 4.14.2)
Nitrogen source

10-ml glass tubes with caps
37°C water bath

NOTE: The substrate stock should preferably be prepared in incubation buffer. If the selected substrate is insoluble in buffer, DMSO, alcohol, or other solvents can be added. These solvents may have a direct effect on CYP450 activity (Hickman et al., 1998) so include solvent-only controls when solvents are used.

Prepare incubation mixture

1. Dilute 10 μl of 1000× substrate stock solution in 990 μl incubation buffer. Prepare the reaction mixture by mixing the following on ice in 10-ml glass tubes:

   500 μl 2× concentrated cofactor mixture
   100 μl microsomal suspension containing ∼100 μg protein
   Incubation buffer to achieve a total final volume of 1 ml (including substrate)
   40 μl substrate (add last to prevent initiation of the reaction).

   The volume of substrate is part of the total 1 ml.

2. Initiate the reaction by placing the incubation mixture in a 37°C water bath. Incubate for 30 min and then terminate the reaction by placing the sample on ice.

   The incubation period depends on the purity of the microsomal preparation and substrates used. Test several incubation periods and substrate concentrations to check linearity of product formation.

Analyze biotransformation products

3. Add an appropriate internal standard to the incubation mixture (see Table 4.14.2).
4. Add extraction fluid. Cap the tubes and mix (vortex) for 30 sec (see Table 4.14.2).

5. Centrifuge the samples 10 min at 3000 × *g*, 10°C, (this usually results in a satisfactory phase separation).
6. Collect the organic phase and evaporate to dryness under a gentle stream of nitrogen.
7. Resuspend the residue in the appropriate mobile phase for HPLC analysis (see Table 4.14.2). Analyze by HPLC (see CP Molecular Biology *UNITS 10.12 & 10.13*).

ISOLATION OF RAT PROXIMAL TUBULE CELLS

SUPPORT PROTOCOL 1

The procedure described below yields a more than 70% pure population of proximal tubule cells and usually 20–40 × 10^6 viable cells from one rat.

Materials

70% ethanol
10× HH buffer (see recipe)
50× EGTA stock solution (see recipe)
Collagenase B (Boehringer Mannheim)
Bovine serum albumin (BSA, fraction V; Sigma)
0.5 M $CaCl_2$ (see recipe)
Wistar Hannover rats with an average body weight of 225 g (Charles River)
100 mg/kg sodium pentobarbital solution, 60 mg/ml Nembutal, or any other anaesthetic drug
Heparin (5000 IE/ml)
36% (w/v) Nycodenz stock solution (see recipe)
PBS (sterile, GIBCO)
Complete cell culture medium (see recipe)

Perfusion apparatus (see Fig. 4.14.1) consisting of:
  37°C water bath
  Electric pump
  Bubble trap
  Organ bath
  Tubing
100-ml cylinder
250-ml bottles
100-ml bottles
50-ml bottle
250- and 100-ml beakers
0.22-μm sterile filters
Animal surgery table
Small set of surgical instruments including scissors, forceps, and clamps
18 G, 51 mm Abbocath T canula (Venisystems)
100-mm petri dish
Nylon gauze filters (80-μm)
12-ml tubes

Prepare perfusion apparatus and solutions

1. Rinse the perfusion apparatus (see Fig. 4.14.1) for 15 min with 70% ethanol to obtain sterile conditions, and then rinse with sterile water for 20 min. Prewarm the water bath to 37°C.
2. Collect the following sterile glassware (with lids):

   100-ml cylinder
   250-ml bottles

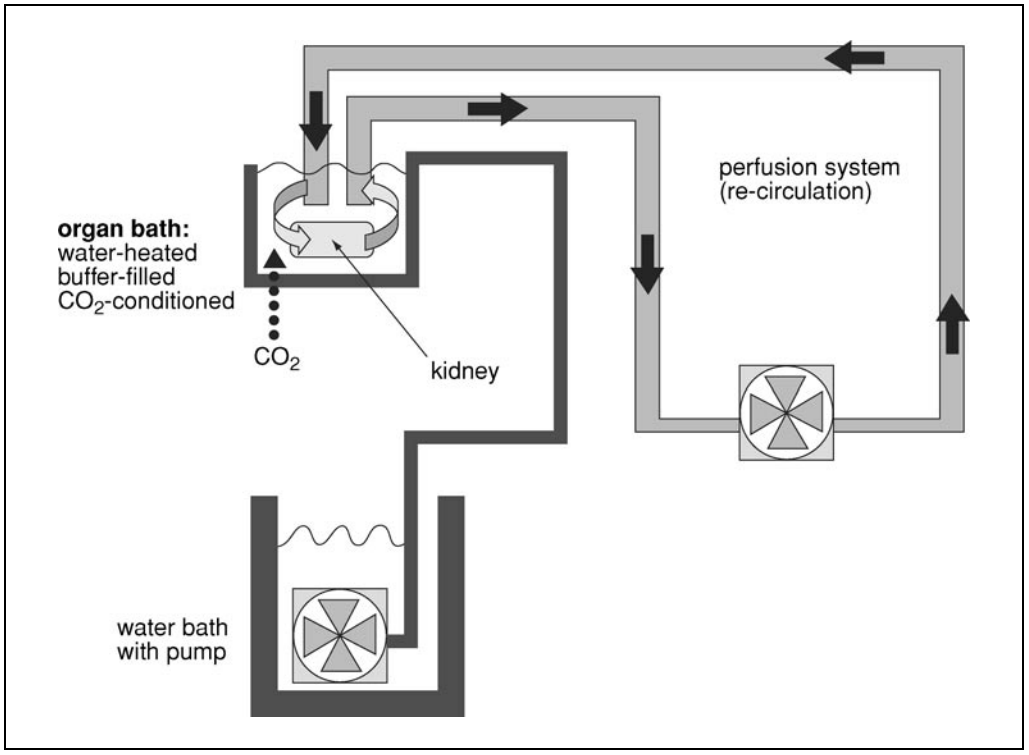

Figure 4.14.1 Kidney perfusion system.

100-ml bottles
50-ml bottle
250- and 100-ml beaker.

3. Prepare two 100-ml solutions of 1× HH buffer by diluting 10× HH stock buffer 1:10 with sterile double-distilled water. Transfer the first HH buffer solution (basis for BSA-HH buffer) into a 250-ml beaker and the second into a 200-ml bottle (basis for perfusion buffer II).
4. Prepare 30 ml of 10× HH buffer (basis for perfusion buffer III) into a 100-ml beaker.
5. Prepare a 150 ml HH-EGTA buffer (basis for perfusion buffer I) in a 250-ml bottle by mixing 15 ml of 10× HH buffer, 3 ml 50× EGTA stock solution, and 132 ml sterile double-distilled. Circulate perfusion buffer I in the perfusion system for ~20 min at a maximum flow rate of 7.5 ml/min.
6. Deposit 2.5 g BSA on the surface of 100 ml HH buffer in the 250-ml beaker (prepared in step 3) and allow it to dissolve slowly (BSA-HH buffer).
7. Dissolve 40 mg collagenase B in 30 ml 1× HH buffer in the 100-ml beaker from step 4. Filter-sterilize directly through a 0.22-μm filter and add 240 μl of 0.5 M $CaCl_2$. Keep sterile collagenase solution on ice (perfusion buffer III).
8. Add 360 μl of 0.5 M $CaCl_2$ to the BSA-HH buffer (step 6) as soon as the BSA is completely dissolved and filter the solution through a 0.22-μm filter into a sterile 100-ml bottle. Keep solution on ice.

Perform surgery

9. Anesthetize a Wistar Hannover rat, e.g., with 100 mg/kg sodium pentobarbital or any other anesthetic agent. Wait until surgical anesthesia is reached.

This rat strain has the advantage to possess only small amounts of connective tissue in the kidneys compared to other commercially available rat strains, allowing easy cell separation.

10. Place the animal on an appropriate surgery table on its back and inject heparin solution (0.1 ml/100 g) i.v. either into the vena femoralis or into one of the tail veins.
11. Open abdominal cavity up to diaphragm but leave the diaphragm intact.
12. Expose aorta and kidneys by carefully repositioning the liver, stomach, and intestines, preferably to the right side of the animal. Cut connective tissues where appropriate avoiding extensive bleeding.
13. Ligate the mesenteric and coeliac arteries. Ligate aorta and inferior vena cava distal to the renal arteries, but leave these ligatures open.
14. Insert an 18-G canula into the aorta proximal to the renal arteries and secure.
15. Close the ligatures of the distal vena cava and aorta (see step 13) and, at the same time, incise the left renal vein to ensure spontaneous outflow.

Perfuse kidneys

16. Connect the aortic canula to the perfusion apparatus (avoid air bubbles) and start perfusion with 150 ml perfusion buffer I at a minimal flow rate. Gently increase flow rate to 7.5 ml/min.

    The kidneys should turn pale instantly. Remaining blood (red patches) can be released by gentle manual massage of the kidneys. Injection of heparin solution into the perfusion buffer aids to remove small thrombi and may be used as a fail-safe routine.

17. Entirely remove the liver, stomach, and intestines while taking care not to interrupt renal circulation.
18. Using small sharp scissors, cut the vena cava distal to the ligatures and lift the kidneys, dissecting all connective tissues. Then, cut the aorta proximal to the canula.

    The kidneys should now be completely liberated and can be transferred to the organ bath of the perfusion systems. The perfusion buffer flow should never be interrupted during the extirpation procedure.

19. Replace perfusion buffer I in the perfusion system with 100 ml prewarmed perfusion buffer II, avoiding flow interruption and/or air bubbles. Continue perfusion for an additional 10 min.
20. Replace perfusion buffer II with 30 ml prewarmed perfusion buffer III containing collagenase. Perfuse for 20 min at a flow rate of 7.5 ml/min in a recirculation system.

    As the collagenase-containing buffer exits the kidney, collect it and use it for recirculation.

21. Disconnect kidney from the perfusion system and transfer to a sterile 100-mm petri dish filled with 20 ml cold, sterile BSA solution and keep on ice.

Prepare cell suspensions

22. Separate kidneys from remaining connective tissue and transfer the individual kidneys to clean medium-containing dishes on ice.
23. Remove the renal capsules using small sterile forceps.

    The kidneys should have lost tissue integrity and cohesion by now.

24. Gently scrape the cortical cells from the medulla, which is the tighter matter with a lighter color. Discard remaining medulla and pelvic sections of the kidneys.

    The cortical cells should come off easily if the perfusion was successful.

25. Resuspend the cortical cells and filter the cell suspension over nylon gauze into a sterile beaker. Keep beaker on ice.
26. Add 20 ml complete fresh BSA-HH buffer to the cells, mix gently, and filter by applying aliquots of the suspension to nylon gauze.
27. Dispense the filtered cell suspension into six sterile 12-ml tubes and centrifuge 5 min at 80 × *g*, 4°C.
28. Discard the supernatant and collect the cell pellets in 10 ml BSA-HH buffer. Centrifuge the suspension 5 min at 80 × *g*, 4°C.

Purify PT cells

29. Prepare 1 ml ice-cold 9% Nycodenz solution by diluting the 36% Nycodenz stock solution with sterile BSA buffer.
30. Prepare 3 ml of 14% Nycodenz solution by diluting the 36% Nycodenz stock solution with sterile BSA buffer.
31. Resuspend the cell pellet in the 14% Nycodenz solution in a sterile 12-ml tube. Keep on ice.
32. Carefully layer 1 ml of 9% Nycodenz solution on top of the Nycodenz-cell mixture and then add 0.5 ml BSA-HH buffer. Do not shake the tube. Centrifuge the Nycodenz gradient-cell mixture 4 min at 2300 × *g*, 4°C.

    The band between the two Nycodenz layers (interface) contains the PT cells.

33. Transfer the PT cells from the interface to a clean sterile 12-ml tube containing 5 ml sterile PBS using a small sterile pipet.
34. Briefly centrifuge 5 min at 80 × *g*, 4°C, and wash cells two times by sequentially centrifuging 5 min at 80 × *g*, 4°C, to remove remaining Nycodenz.
35. Finally, resuspend cells in sterile culture medium (DMEM/F12), analyze viability and purity (see Support Protocols 4 and 5), and follow Support Protocol 2 to obtain primary PT cultures, *or* store cell pellet up to 3 months at –70°C until further use for the preparation of sub-cellular fractions.

SUPPORT PROTOCOL 2

ESTABLISHING PRIMARY PT CELL CULTURES

This protocol describes the procedure of bringing the isolated cells into primary culture. Primary rat PT cells typically grow in isolated colonies and retain an epithelial morphology for 1 week.

Materials

Cell suspension (Support Protocol 1)
Complete culture medium (see recipe)
Serum-free DMEM/F12 medium (see recipe)

Collagen-coated 60-mm dishes (see Support Protocol 6)
37°C, 5% CO_2 incubator

1. Determine concentration of viable cells in the individual isolate (see Support Protocol 4).
2. Dilute cell suspension to 0.25 × 10^6 cells/ml in complete culture medium and plate 4 ml cell suspension on collagen-coated 60-mm dishes.
3. Swirl the dishes gently to evenly distribute the cells

4. Incubate the cells in a 37°C, 5% CO_2 incubator.

5. Change to serum-free DMEM/F12 medium after 24 hr.

   Attachment of cells may not be complete after 24 hr. Careful aspiration of the culture supernatant followed by a brief centrifugation (e.g., 5 min at 80 × g) provides a cell pellet, which can be resuspended in fresh medium (without serum) and added to the original dish to improve the cell number in the primary culture.

PREPARATION OF MICROSOMAL AND CYTOSOLIC FRACTIONS FROM PT CELLS

SUPPORT PROTOCOL 3

This protocol describes a basic procedure for the preparation of microsomal and cytosolic fractions from PT cells obtained as described in Support Protocol 1.

The procedure can be applied to freshly isolated cell pellets or cells that have been cultured. For example, using the total cell yield from one isolation (20–40 × 10^6 cells), this procedure yields a cytosolic fraction with an average protein content of 5 mg and a microsomal fraction containing ~1.0 mg protein. Both fractions can subsequently be used to measure the activity of biotransformation enzymes.

As interference of protease inhibitors in subsequent assays cannot be excluded, they are not included in this general protocol. It is therefore essential to perform all individual steps at 4°C.

The protein content from the obtained subcellular fractions can be assayed with commercially available protein assay kits (e.g., Pierce), although high glycerol concentrations (see below) in microsomal fractions might interfere with some of those assay protocols.

Materials

Cell pellet, fresh or frozen
KCl/EDTA solution (see recipe)
Liquid nitrogen
Glycerol buffer (see recipe)

Refrigerated ultracentrifuge with fixed-angle rotor
Potter-Elvehjem homogenizer with PTFE pestle (5-ml working capacity)
8.5-ml ultracentrige tubes (e.g., Nalgene UltraBottle Assemblies)
Ultra Turrax T8 homogenizer equipped with an 8-mm diameter dispersing element

1. Prior to use, cool the ultracentrifuge and rotor to 4°C.
2. Slowly thaw the frozen cell pellet on ice.
3. Add 2.5 ml KCl/EDTA solution to the cell pellet.
4. Transfer to Potter-Elvejhem homogenizer and homogenize cell suspension on ice at 1100 rpm until a clear suspension is obtained (usually 4 to 8 strokes).
5. Transfer the homogenates to a 8.5-ml ultracentrifuge tubes and equilibrate.
6. Centrifuge 25 min at 10,000 × *g*, 4°C, to obtain a cell-free homogenate.
7. Carefully transfer the supernatant to clean ultracentrifuge tubes and centrifuge 75 min at 100,000 × *g*, 4°C.

   The obtained supernatant is the cytosolic fraction.

8. Separate the supernatant, snap-freeze appropriate aliquots (e.g., 250 µl) in liquid nitrogen, and store up to 3 months at –70°C until needed.

9. Resuspend the microsomal fraction in 1 ml glycerol buffer using the ultra-Turrax T8 homogenizer (or equivalent).
10. Snap-freeze 100-µl aliquots in liquid nitrogen and store up to 3 months at –70°C until needed.

    Thawed fractions cannot be refrozen.

SUPPORT PROTOCOL 4

DETERMINING CELL VIABILITY AND NUMBER OF ISOLATED PT CELLS

Cell viability should be >70% to ensure successful subsequent culturing. Cell viability needs to be determined for each isolation.

The most common method to assess cell viability is trypan blue exclusion analysis. The method is based on the principle that viable cells exclude the dye as a result of membrane integrity, while non-viable cells lose this capacity and become stained (i.e., turn blue). A detailed protocol is presented with manufacturer's instructions for trypan blue dye (Sigma-Aldrich; also see *APPENDIX 3B*). Certain steps (e.g., dilutions, volumes) need to be adapted for use with PT cells.

Materials

PT cell suspension (Support Protocol 1)
0.4% (w/v) trypan blue solution (Sigma) in PBS
1.5-ml microcentrifuge tubes
Hemacytometer with coverslips
Microscope

1. Transfer 50 µl of PT cell suspension into a 1.5-ml microcentrifuge tube.
2. Add 200 µl of 0.4% trypan blue solution to the cell suspension (creating a dilution factor of 5). Mix thoroughly and let stand for ~5 min at room temperature; do not exceed 15 min as trypan blue is toxic for cells at longer incubation periods.
3. Transfer a small amount of the trypan blue–cell suspension to a chamber on the hemacytometer and view under a microscope at 100× magnification.

   Non-viable cells will stain deep blue, viable cells remain unstained.

4. Count cells according to the manufacturer's instructions for the hemacytometer. Count both viable and non-viable cells

   If >10% of the cells appear clustered, repeat the entire procedure after having dispersed the original cell suspension by vigorous pipetting.

   If <20 or >100 cells are observed in the counted (25) squares, repeat the procedure after adjusting the concentration of the original cell suspension.

5. Retrieve a second sample and repeat the counting procedure to ensure accuracy.
6. Calculate cell number and percent viability by using the fact that 25 squares (each 0.04 mm^2) of the hemacytometer represent a total volume of 0.1 mm^3, and 1 cm^3 equal to 1 ml. The subsequent cell concentration per milliliter (and the total number of cells) can be determined.

   Total cell number = cells per milliliter × the number of milliliters in the original cell suspension
   Cell viability (%) = [total viable cells (unstained)/total cell (stained and unstained) number] × 100

DETERMINING THE PURITY OF PT CELL PREPARATION BY SELECTIVE UPTAKE OF FLUORESCEIN

SUPPORT PROTOCOL 5

This second quality control parameter, used to quickly assess the purity of the isolate, should be performed following each of the first few isolation attempts.

Proximal tubule cells, especially those from the S1 and S2 segments of the tubule and to a lesser extent those from the S3 segment, will accumulate fluorescein. After a maximum incubation time of 15 min, all viable PT cells will be fluorescent under the fluorescence microscope. Cells from the S2 segment can be observed after only a 2- to 3-min incubation period. Other cells originating from the renal cortex, which may contaminate the isolate, have a much lower capacity to accumulate fluorescein. These cells will be (almost) invisible under the microscope. Typically, a >70% pure PT cell population is obtained.

Materials

Cell suspension (Support Protocol 1)
Serum-free culture medium (see recipe)
50 μM sodium fluorescein reagent (see recipe)
200 mM sodium azide solution (see recipe)
PBS containing 5% (w/v) BSA
37°C water bath
Fluorescence microscope: excitation wavelength between 470 and 490 nm, emission wavelength between 520 and 555 nm

1. Determine cell concentration of the isolate using the trypan blue exclusion procedure (see Support Protocol 4).
2. Resuspend 2×10^5 freshly isolated cells into 100 μl of serum-free culture medium.
3. Pre-incubate cells for 5 min in a 37°C water bath.
4. Gently shake the cell suspension and add 4 μl sodium fluorescein reagent (final concentration of 2 μM). Incubate 15 min at 37°C.
5. Add 10 μl of 200 mM sodium azide solution (final concentration 20 mM).
6. Resuspend cells in 5 ml PBS/5% BSA. Centrifuge 5 min at 1000 rpm, room temperature, and resuspend the cell pellet in 100 μl serum-free medium.
7. View the cells under a fluorescence microscope using 40× magnification
8. Count at least 100 fluorescent cells under the microscope using a hemacytometer.
9. Determine total number of cells by counting cells the same area under standard phase-contrast conditions.
10. Calculate the purity (%) of the isolated cell suspension as follows: (fluorescent cells/total number of cells in the same area) × 100%.

COATING CELL CULTURE SURFACES

SUPPORT PROTOCOL 6

Coating cell culture dishes or plates is used to promote cell attachment and cell adherence, at the same time preventing rapid de-differentiation of cells.

Materials

Collagen solution (see recipe)
PBS (GIBCO)
60-mm culture dishes, culture flasks, or culture plates

1. Prepare a 20 μg/ml collagen rat tail type I solution by diluting the 2 mg/ml stock with 0.2 N acetic acid.
2. Cover the surfaces of the plates, dishes, or flasks with the collagen working solution.
3. Incubate for at least 30 min at room temperature.
4. Remove the collagen working solution.
5. Rinse with sterile PBS and use directly or store up to 2 weeks at 4°C with a layer of PBS to protect the coating.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or double-distilled or deionized water for all recipes and in all protocol steps. Water should have a resistance of 18 MOhm/cm. Cell culture medium and all other solutions for cell culture need to be sterile and should be handled in a laminar flow cabinet. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

$CaCl_2$, 0.5 M

For 100 ml: Dissolve 21.9 g $CaCl_2 \cdot 6\ H_2O$ (Aldrich) in 80 ml water. Adjust volume to 100 ml. Sterilize by autoclaving or filtering through a 0.22-μm filter. Store up to 6 months at room temperature.

Co-factor mixture, 2×

89.4 mg $MgCl_2 \cdot 7H_2O$ (Merck; 60 mM final)
15.3 mg NADP (Sigma; 4 mM final)
14.2 mg NADH (4 mM final)
14.1 mg of glucose-6-phosphate (10 mM final)
Bring to 5 ml with 50 mM phosphate buffer, pH 7.4
Add 26 μl glucose-6-phosphate dehydrogenase (Roche; 2 U fianl)
Prepare fresh

Collagen solution

Make up a stock solution of 20 μg/ml rat tail type I collagen in 0.2 M acetic acid by pipetting 10 mg from the collagen stock solution (BD Biosciences) into a 500-ml sterile bottle. Add ~400 ml sterile water and 500 μl concentrated acetic acid, then adjust to a volume of 500 ml with sterile water. Store up to 3 months at 4°C.

Complete cell culture medium

To 500 ml DMEM/F12 (phenol red–free; GIBCO), add:

50 ml heat inactivated FBS (GIBCO; 10% v/v final)
5 ml penicillin/streptomycin (GIBCO; 100 μg/ml final)
5 ml 200 mM L-glutamine (BioWhittaker; 2 mM final)
5 ml supplement G (GIBCO; 10 μg/ml insulin, 5.5 μg/ml transferrin, and 6.7 ng/ml sodium selenite final)
Store up to 2 weeks at 4°C

EGTA solution, 50x

For a 100-ml solution, dissolve 0.951 g EGTA (Sigma; 25 mM final) in 80 ml water. To completely dissolve EGTA, add a few drops of 4 M NaOH. Adjust the volume to 100 ml with water. Sterilize by autoclaving or filtering through a 0.22-μm filter. Store up to 3 months at room temperature.

Glycerol buffer

2.8 g KH_2PO_4 (Merck; 50 mM final)
4.2 g Na_2HPO_4 (Sigma; 50 mM final)
33.6 mg Na_2-EDTA·$2H_2O$ (Sigma; 0.1 mM final)
500 ml H_2O
Add 200 ml glycerol (Sigma; 20% v/v final)
Adjust pH to 7.4 with 4 N NaOH and 4 N phosphoric acid
Bring to 1 liter with H_2O
Store up to 2 months at 4°C

HH buffer, 10x (pH 7.4)

20.02 g NaCl (Sigma; 1.37 M final)
0.932 g KCl (Merck; 50 mM final)
0.493 g $MgSO_4·7H_2O$ (Merck; 8 mM final)
0.117 g Na_2HPO_4 (Sigma; 3.3 mM final)
0.599 g KH_2PO_4 (Merck; 4.4 mM final)
5.46 g $NaHCO_3$ (Sigma; 260 mM final)
14.98 g HEPES (Sigma; 250 mM final)
240 ml H_2O
Adjust pH to 7.4 with 4 N HCl
Bring to 250 ml with H_2O
Sterilize by autoclaving for 15 min at 121°C at 1 bar or filter through a 0.22-μm filter
Store up to 6 months at 4°C

Incubation buffer

2.8 g KH_2PO_4 (Merck)
4.2 g Na_2HPO_4 (Sigma)
800 ml H_2O
Adjust pH to 7.4 with 4 N NaOH and 4 N phosphoric acid
Bring volume to 1 liter with H_2O
Store up to 1 month at 4°C

KCl/EDTA solution

11.5 g KCl (Merckl 1.15% w/v final)
33.6 mg Na_2-EDTA·$2H_2O$ (Sigma; 0.1 mM final)
900 ml H_2O
Bring volume to 1.0 liter
Store up to 3 months at 4°C

Nycodenz stock solution, 36% (w/v)

Deposit 36 g of analytical-grade Nycodenz (Nycomed Pharma) on the surface of 80 ml HH biffer (see recipe). Allow Nycodenz to dissolve in the HH buffer at 4°C. Adjust volume to 100 ml with deionized water. Sterilize by filtration through a 0.22-μm filter into a sterile 100-ml bottle. Store up to 1 month at 4″C.

Serum-free cell culture medium

Make up complete cell culture medium (see recipe) without 10% FBS.

Sodium azide solution

Dissolve 65.01 mg sodium azide in 5 ml PBS (GIBCO; 200 mM final). Prepare fresh on the day of use, protect from UV light using aluminium foil.

Sodium fluorescein reagent

Dissolve 18.8 mg sodium fluorescein in 10 ml of PBS (5 mM final concentration). Prepare fresh. Dilute 100 times to prepare a 50 μM solution.

COMMENTARY

Background Information

The cells of the proximal tubule are considered to be the main target for nephrotoxic substances. This vulnerability is explained by the presence of a variety of cellular transport mechanisms resulting in the active uptake and accumulation of numerous (toxic) substances, as well as the expression of biotransformation enzymes, which may activate (or deactivate) accumulated compounds.

Model systems consisting of enriched PT cells in primary culture have considerable advantages over "mixed" model systems (such as kidney slices), for they allow studies of cell-specific transport mechanisms as well as biotransformation-dependent effects of drugs and xenobiotics. PT cells in primary culture retain, at least for several days, their differentiated traits and, therefore, are superior to most immortal cell lines (e.g., LLC-PK_1), which have lost their biotransformation activity (Schaaf et al., 2001) and do not express renal-specific transporters including the organic anion transporters (Boom et al., 1992; Cox et al., 1993).

Various methods for the isolation of PT cells have been described previously (Stanton et al., 1986; Baer et al., 1997). The techniques described in this unit make use of standard laboratory equipment, and the surgical procedure requires minimal training. The use of a Nycodenz gradient for cell separation is supported by the observation that it is relatively inert to the PT cells compared to other widely used sucrose gradients including Percoll and Ficoll. Following isolation, for each cell preparation, the cell viability of the isolate needs to be carefully checked. Moreover, as the proximal tubule cell has very distinct features, the purity of the isolate should be quickly assessed by immunohistochemical and biochemical means (sodium-fluorescein transport).

The presented protocol for cell isolation was established for rats but may be applied to other animal species with minor modifications. It is worthwhile to mention that within a given animal species like rats, small physiological or anatomical differences might exist. The authors selected, for example, the Wistar Hanover strain (Charles River), as these animals have a smaller amount of connective tissue in the kidneys compared to other Wistar (outbreed) strains, renal perfusion is more easily performed, and digestion with collagenase results in the a sufficient number of free viable cells.

The isolated cells can be used for a variety of applications, including basic toxicity studies, biotransformation-dependent toxicity studies, and experiments to study transport and cellular distribution of drugs and xenobiotics.

Critical Parameters

The protocols are established to obtain a reproducible yield of cells, representing a highly pure population of rat proximal tubule cells. In turn, the preparation involves many steps, and the total preparation time is rather long (~4 hr). The most critical steps are the rapid and complete perfusion of the kidneys, the generation of a homogeneous single-cell suspension (prior to Nycodenz centrifugation), and the accurate preparation of the Nycodenz gradients.

Troubleshooting

Low yield

Insufficient perfusion of the kidneys due to surgical errors will considerably decrease cell yield. This includes incomplete separation of the renal perfusion system from the main body circulation (insufficient buffer flow) and obstruction by intra-renal thrombi. These thrombi can sometimes be removed by manually massaging the kidneys, or they should be avoided by injecting heparin during anesthesia or adding a heparin solution to the perfusion buffer I.

Ineffective separation

The renal cortex is comprised of 80% PT cells. Therefore, a significant fraction (>60%) of the original cell suspension should reside in the interface of the Nycodenz gradient, while the remaining cells (including distal tubule cells) are a pellet at the bottom of the tube. Any other distribution of the cell suspension indicates that the optimal Nycodenz gradient was not established and the two Nycodenz fractions have mixed during preparation. Thus, the correct density of the stock solution should be controlled (spectrophotometrically according to the manufacturer's recommendations),

and the technique to prepare the cell-Nycodenz gradient mixture (preventing mixing of the individual layers) monitored. Finally, the centrifugation step might impair the outcome if abrupt acceleration and deceleration disturb the gradient.

An ineffective separation results in impure cell populations and attempts toward reseparation usually result in a considerable decrease in cell viability. Moreover, at longer culture periods, fibroblast overgrowth serves as an indication of inefficient separation.

Low cell viability

Several reasons may contribute to a low cell viability of the plated cells (<70%). The most frequently observed difficulties are: an extended preparation and perfusion period, lack of oxygen, and mechanical injuries during the isolation steps. A possibility, which is often overlooked, is the presence of trace amounts of cleaning detergents in the glassware and tubings.

Low attachment efficiency

Directly related to low cell viability, is the fact that the plated cells may appear to have not efficiently attached as indicated by the absence of cell colonies (typical growth pattern for this type of cells) following an overnight culture. All factors described in the previous paragraphs can contribute to this. In particular, the washing steps following Nycodenz-gradient centrifugation are of importance for cell viability and performance in culture. Cells that have not attached in the first 24-hr culture period can be collected, washed by centrifugation (5 min at 80 × *g*, 4°C), resuspended in (serum-free) culture medium, and re-plated in the same dishes from which they were collected.

Biotransformation assays

The most critical step in the biotransformation experiments with intact cells is the intrinsic cytotoxicity of many model substrates, the uncontrollable cellular uptake (unless monitored with radiolabeled substrates), and the possible non-linearity of the enzymatic reactions, particularly in the presence of enzyme inducers or inhibitors. A thorough examination of all confounding factors should precede any major experiment.

Anticipated Results

Starting with a young adult rat weighing 250 to 300 g, the described procedure will routinely yield 20–40 × 10^6 PT cells. The purity of the isolated cell population is >80% and the viability of the cells exceeds 70%. When PT microsomes are prepared, ~1 mg microsomal protein should be obtained. The primary cultured cells should retain the typical epithelial-like morphology for 1 week, more specific differentiated functions will decrease significantly within the first days of culture.

Time Considerations

A typical isolation, including all preparative steps, usually takes 3 to 6 hr. Total preparation of the buffers and solutions take 30 to 45 min. Rinsing the perfusion system requires 60 min, the surgical procedure requires 60 to 90 min (including the perfusion step), and the preparation of the cell suspension takes ~90 min. Whenever possible, basic buffers and solutions should be prepared in advance.

TaqMan Real Time–Polymerase Chain Reaction Methods for Determination of Nucleotide Polymorphisms in Human *N*-Acetyltransferase-1 (*NAT1*) and -2 (*NAT2*)

N-acetyltransferase 1 (*NAT1*) and *N*-acetyltransferase 2 (*NAT2*) exhibit allelic variation and genetic polymorphism associated with increased susceptibility towards drug toxicity and environmental disease (Hein et al., 2000a; Butcher et al., 2002). The variant *NAT1* (Table 4.15.1) and *NAT2* (Table 4.15.2) alleles possess various combinations of single nucleotide polymorphisms (SNPs), deletions, and/or insertions compared to the reference alleles, that are sometimes inappropriately termed "wild-type." Combinations of nucleotide polymorphisms define alleles. The consensus listing of *NAT1* and *NAT2* alleles is maintained by an international committee and published at: *http://www.louisville.edu/medschool/pharmacology/NAT.html* (Hein et al., 2000b).

REAL-TIME TAQMAN ANALYSIS OF *NAT1* AND *NAT2*

BASIC PROTOCOL

TaqMan allelic discrimination methods have been developed to rapidly determine *NAT1* (Doll and Hein, 2002) and *NAT2* (Doll and Hein, 2001) genotypes. The SNPs selected for *NAT1* genotype determinations are: $C^{97}T$ (R^{33}Stop), $C^{190}T$ ($R^{64}W$), $G^{445}A$ ($V^{149}I$), $C^{559}T$ (R^{187}Stop), $G^{560}A$ ($R^{187}Q$), $A^{752}T$ ($D^{251}V$), $T^{1088}A$ (3′UTR), and $C^{1095}A$ (3′UTR). The SNPs selected for *NAT2* genotyping determinations are: $G^{191}A$ ($R^{64}Q$), $C^{282}T$ (silent), $T^{341}C$ ($I^{114}T$), $C^{481}T$ (silent), $G^{590}A$ ($R^{197}Q$), $A^{803}G$ ($K^{268}R$), and $G^{857}A$ ($G^{286}E$). All *NAT2* and *NAT1* alleles, except very rare ones, are detected with these SNP determinations.

The authors provide detailed methods and materials for using the 7700 Sequence Detector from Applied Biosystems. These methods can be adapted for other instruments from Applied Biosystems or other manufacturers.

The specific primers and probes for *NAT1* and *NAT2* genotype determinations are listed in Tables 4.15.3 and 4.15.4, respectively.

Materials

2× TaqMan Universal PCR Master Mix (Applied Biosystems)
3 μM primers (see Tables 4.15.3 and 4.15.4; Applied Biosystems)
4 μM fluorescent probes: normal, turbo, and MGB (see Tables 4.15.3 and 4.15.4; Applied Biosystems)
5 to 25 ng/μl high-quality genomic DNA samples
Optical 96-well plates (Applied Biosystems)
Optical caps (Applied Biosystems)
Sequence detector (e.g., 7700 Sequence Detector, Applied Biosystems) and computer

Prepare reagents

1. Thaw an aliquot of 2× TaqMan Universal PCR Master Mix, primers, and probes at 37°C.

   TaqMan Universal PCR Master Mix (Applied Biosystems) is optimized for TaqMan reactions and contains AmpliTaq Gold DNA polymerase, AmpErase, dNTPs with UTP, and a passive reference to correct for well-to-well variation. None of the above reagents are toxic or require special care. All reagents should be aliquoted, to minimize freezing and thawing, and stored at −20°C.

   Primers and probes for each SNP are listed in Tables 4.15.3 and 4.15.4. The primers and probes are diluted, in sterile DNAse-free water, to a concentration of 3 μM and 4 μM respectively prior to being aliquoted and stored at −20°C.

   Fluorescent probes should be kept out of direct sunlight to avoid degradation.

Table 4.15.2 Human *NAT2* Alleles[a]

NAT2 allele	Nucleotide change(s)	Amino acid change(s)
*NAT2*4*	None	None
*NAT2*5A*	$T^{341}C$, $C^{481}T$	I114T

[a] Adapted from Doll and Hein, 2002. Nucleotide positions are indicated in parentheses. PCR product size is indicated in square brackets. Nucleotide-specific polymerase chain reaction (PCR) primers and fluorogenic probes were designed using Primer Express (version 1.5; Applied Biosystems). The fluorogenic MGB probes were labeled with a reporter dye (either FAM or VIC or TET) specific for one of the possible nucleotides identified at eight polymorphisms in the *NAT1* coding region or 3′ UTR. The fluorogenic probes for the 559/560 and the 1088/1095 are distinguished using a three-probe system that has both nucleotide polymorphisms in the same probe. This is necessary because the 559/560 and 1088/1095 are too close together to use the conventional two-probe TaqMan assay. The nucleotide-specific primers amplify a segment of the *NAT1* gene flanking the probes.

[b] Abbreviations: bp, base-pair; FAM, 6-carboxyfluorescein; MGB, minor groove binder; *NAT1*, *N*-acetyltransferase 1; PCR, polymerase chain reaction; SNP, single-nucleotide polymorphism; TET, tetrachloro-6-carboxyfluorescein; UTR, untranslated region; VIC, a proprietary dye from Applied Biosystems.

2. Prepare a master solution of 2× TaqMan Universal PCR Master Mix, primers, and probes to have 12 µl solution/sample. Make up the solution with the following composition:

   50% 2× TaqMan Universal PCR Master Mix
   10% each appropriate primer
   2.5% each of two or three appropriate probes
   25% sterile, DNAse-free H_2O.

Table 4.15.4 Primers and Fluorogenic Probes for *NAT2* SNP Determinations[a]

191-Forward primer (131-149)	5′-gtgggcaagccatggagtt-3′
191-Reverse primer (242-220) [112 bp]	5′-gtggtcagagcccagtacagaag-3′
191A-TaqMan probe (204-179)	FAM-acaccacccacccTggtttcttctta- TAMRA

857-Forward primer (768-792)	5′-aactctcactgaggaagaggttgaa-3′
857-Reverse primer (912-888) [146 bp]	5′-tgggtgatacatacacaagggtttat-3′
857G-TaqMan probe (842-870)	FAM-ccaaacctggtgatgGatcccttactatt-TAMRA
857A-TaqMan probe (841-869)	VIC-cccaaacctggtgatgAatcccttactat-TAMRA

[a] Adapted from (Doll and Hein, 2001). Nucleotide positions are indicated in parenthesis. PCR product sizes are indicated in brackets. SNP-specific polymerase chain reaction (PCR) primers and fluorogenic probes were designed using Primer Express (Applied Biosystems). The fluorogenic probes are labeled with a reporter dye (either FAM or VIC) and are specific for one of the two possible bases identified at seven SNPs in the *NAT2* coding region.

[b] Abbreviations: bp, base-pair; FAM, 6-carboxyfluorescein; *NAT2*, *N*-acetyltransferase 2; PCR, polymerase chain reaction; SNP, single-nucleotide polymorphism; TAMRA, 6-carboxytetramethylrhodamine; VIC, a proprietary dye from Applied Biosystems.

Once all the components have been added, mix briefly by vortexing.

Aerosol-free tips should be used for all pipeting to minimize risk of cross-contamination.

3. Pipet 10 µl of the mix into the appropriate number of wells of an optical 96-well plate.
4. Add 1 µl of genomic DNA (5 to 25 ng) to the appropriate wells (one DNA sample/well). Place optical caps on wells.

   Make sure not to damage the caps when putting them on the 96-well plate.
5. Vortex plate to mix the genomic DNA into the mixture. Transfer the 96-well plate to the 7700 sequence detector.

Prepare the 7700 Sequence Detector

6. Turn on the 7700 Sequence Detector and computer.

   Turn on the 7700 Sequence Detector at least 30 min in advance.

7. Open the sequence detector software and close the screen that appears by clicking the upper left-hand corner.

8. Click on File and scroll to New Plate. Select Single Reporter, 7700 Sequence Detector, and Real-time, and click OK.

9. Highlight the wells that are being used in the run, click on Sample Type, and scroll to Unknown.

10. Change the dye layer to VIC, click on Sample Type, and scroll to Sample Type Setup. Click the Add button and scroll down to bottom row where New Control in the name column is indicated. Change the acronym to Unknown, change the name to Unknown, pick a color, change the reporter to VIC, and click OK when finished.

11. Click on Sample Type and scroll to Unknown.

12. If using either the 559/560 or 1088/1095-primer/probe combination for *NAT1* genotype determination, repeat steps 10 and 11 using TET as the dye layer and reporter.

13. Click on Thermocycler conditions and in stage 3 of the program, change 95°C to 92°C for *NAT1* genotype assays, change 60°C to 62°C for *NAT2* genotype assays, and click OK.

    The NAT1 PCR reactions begin with two initial hold steps (50°C for 2 min, followed by 95°C for 10 min) and 40 cycles of a two-step PCR (92°C for 15 sec, 60°C for 1 min). The NAT2 PCR amplification reactions begin with two initial hold steps (50°C for 2 min, followed by 95°C for 10 min) and 40 cycles of a two-step PCR (95°C for 15 sec, 62°C for 1 min).

14. Click on File, assign a name, and click Save.

15. Click the Show Analysis button and then the Run button.

    The run will be completed in ~2 hr.

    The fluorescence intensity of each sample is measured at each temperature change to monitor amplification of the NAT1 or NAT2 gene. The nucleotide present at each SNP is determined by the fluorescence ratio of the two SNP-specific fluorogenic probes. The fluorescence signal increases when the probe with the exact sequence match binds to the single-stranded template DNA and is digested by the 5′-3′ exonuclease activity of AmpliTaq-Gold DNA polymerase (Applied Biosystems). Digestion of the probe releases the fluorescent reporter dye (FAM, VIC, or TET) from the quencher dye (TAMRA).

Analyze completed run

16. Once the run is complete, click on Analysis and scroll to Analyze. Click OK.

    This screen informs whether or not the samples were amplified by polymerase chain reaction (PCR). Amplification is evident by an increase in the relative number (ΔRN).

17. Click on File and scroll to Save. Close this run by clicking in the upper left-hand corner.

18. Click on File and scroll to New Plate. Change the plate type to Allelic Discrimination and click OK.

19. Highlight the wells that were used in the run. Click on Sample Type and scroll to Unknown.

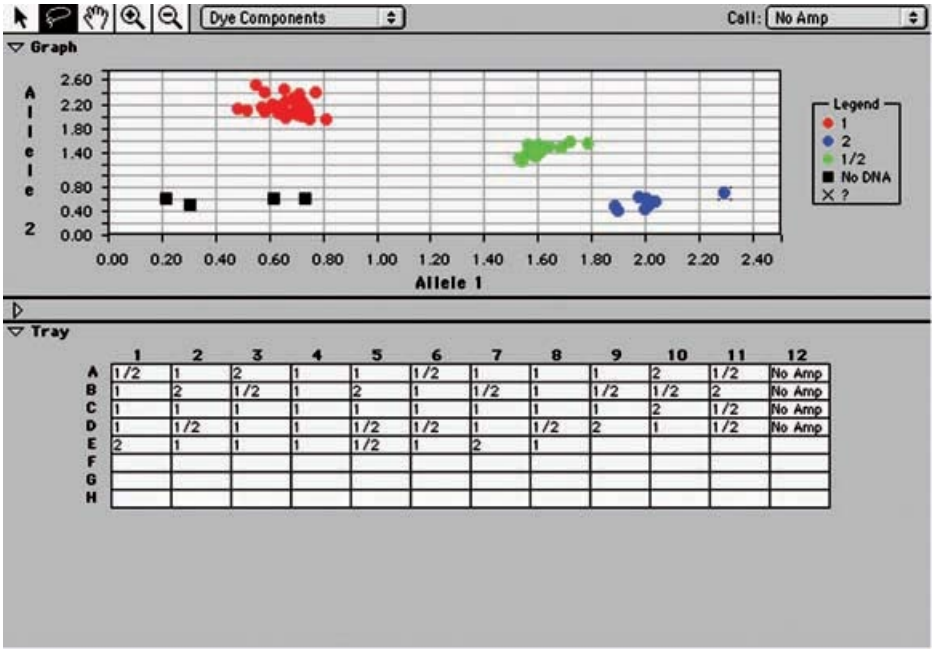

Figure 4.15.1 SNP data from the 7700 Sequence Detector. The top graph illustrates SNP fluorescence data for individual samples in the 96-well plate. The red circle cluster at upper left shows samples that are "1" or homozygous for one nucleotide (usually the more frequent one). The green circle cluster in the center shows samples that are "1/2" or heterozygous for the SNP. The blue circle cluster at lower right shows samples that are "2" or homozygous for the other nucleotide (usually the less frequent one). These values are imported into the bottom spreadsheet as described in the Basic Protocol. Thus, as shown in the database, the sample in well A-1 is in the green center cluster and is heterozygous for the two nucleotides; the sample in well A-2 is in the red upper left cluster and is homozygous for the common nucleotide; and the sample in well A-3 is in the blue cluster at lower right and is homozygous for the less common nucleotide. All cells in the 12th column (data illustrated as black squares) were negative controls (no DNA template). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.currentprotocols.com/colorfigures*.

20. Click on the Show Analysis button.
21. Click on Post-PCR Read and let the instrument proceed until it is done.
22. Click on Analysis and scroll to Analyze.
23. Click on Analysis and scroll to Allelic Discrimination. Click on Normalize button and scroll to Dye Components.
24. Click on the magnifying glass and then click on the graph to bring the graph to scale.

    There should be at least three identifiable groups as illustrated in Figure 4.15.1.

25. Click on the lasso and circle the grouping in the upper left. Change the call to allele 1. Circle the grouping of Xs that are in the bottom right and change the call to allele 2. Circle the grouping of Xs that is in the middle and change the call to allele $^1/_2$.
26. Print the graph and the corresponding 96-well tray that contains the results. Click on File and scroll to Save As. Give the post-PCR read a name and click Save.

    The results can be exported or copied to Excel or other programs for further analysis.

    The process of preparing the samples, preparing the 7700 Sequence Detector, and analyzing the run must be repeated for each SNP in human NAT1 and NAT2.

COMMENTARY

Background Information

NAT1 and *NAT2* encode *N*-acetyltransferase isozymes that catalyze the acetylation of many aromatic and hydrazine drugs as well as many aromatic and heterocyclic amine carcinogens present in the environment, industry, and the diet (Hein et al., 2000a; Butcher et al., 2002). Both *NAT1* and *NAT2* possess intronless, protein-coding, 870-bp exons. A related pseudogene, *NATP*, also has been identified (Vatsis et al., 1995). These *NAT* loci are separated by <500 kb in the orientation *NAT1:NATP:NAT2* in the 8p22 region of chromosome eight (Upton et al., 2001). *NAT1* and *NAT2* share 87% nucleotide identity in the coding region, translating to only 55 amino acid differences (Vatsis et al., 1995; Hein et al., 2000a).

*NAT1*4* is defined as the reference allele and over 25 variant alleles have been identified in human populations (Table 4.15.1). The *NAT1* alleles have genetic polymorphisms in both the coding and untranslated regions. The *NAT1*10* allele, a common allele associated with rapid acetylator phenotype in some but not all studies (Hein et al., 2000a; Upton et al., 2001), possesses SNPs in the 3′-untranslated region. Many published genotype methods are designed only to distinguish a small subset of SNPs and do not distinguish *NAT1*10* from *NAT1*14A* and other *NAT1* alleles. Since *NAT1*10* is often associated with environmental disease, it is particularly important that the *NAT1*10* allele frequency be determined accurately. Several *NAT1* alleles (*NAT1*14, *15, *17, *19*, and **22*) are associated with reduced *NAT1* catalytic activity and slow acetylator phenotype (Butcher et al., 1998; Hughes et al., 1998; Lin et al., 1998; Fretland et al., 2001b). Frequencies for some of the *NAT1* and *NAT2* alleles are rare reflecting nucleotide diversity rather than genetic polymorphism (defined as frequency of at least 1%).

*NAT2*4* is defined as the reference allele and >30 *NAT2* allelic variants have been identified in human populations (Table 4.15.2). The *NAT2* variant alleles possess one or a combination of nucleotide substitutions in the *NAT2* coding region. Seven of these: $G^{191}A$ ($R^{64}Q$), $C^{282}T$ (silent), $T^{341}C$ ($I^{114}T$), $C^{481}T$ (silent), $G^{590}A$ ($R^{197}Q$), $A^{803}G$ ($K^{268}R$), and $G^{857}A$ ($G^{286}E$) have frequencies in human populations exceeding 1% depending upon the ethnic group (Hein et al., 2000a; Butcher et al., 2002). For example, the $G^{191}A$ substitution common to the *NAT2*14* gene cluster is relatively frequent in African populations (Delomenie et al., 1996; Loktionov et al., 2002), but it is virtually absent in Caucasian populations. *NAT2* alleles possessing the $C^{190}T$ ($R64W$), $G^{191}A$ ($R64Q$), $T^{341}C$ ($I114T$), $G^{364}A$ ($D122N$), $A^{411}T$ ($L137F$), $A^{434}C$ ($E145P$), $G^{590}A$ ($R197Q$), and/or $G^{857}A$ ($G286E$) missense SNPs are associated with slow acetylator phenotypes (Leff et al., 1999; Fretland et al., 2001a; Hein, 2002; Svensson and Hein, in press). The *NAT2* slow acetylator phenotypes are most likely not homogenous, but rather reflect varying levels of slow acetylator phenotype due to different mechanisms among the various SNPs (Leff et al., 1999). The original *NAT1* and *NAT2* genotyping methods were designed to detect the most frequent SNPs (usually three or four) by polymerase chain reaction (PCR) restriction fragment length polymorphism (RFLP) analysis. These assays had the potential for genotype misclassifications (Hein et al., 2000a; Deitz et al., 2004). Several improved PCR-RFLP genotyping assays for *NAT1* and *NAT2* polymorphism assay have been developed subsequently (Doll et al., 1995; Delomenie et al., 1996; Deitz et al., 1997; Lo-Guidice et al., 2000; Cascorbi et al., 2001; Vaziri et al., 2001; Loktionov et al., 2002). Although these assays are still frequently utilized for *NAT1* and *NAT2* genotyping, they are very labor intensive and incomplete digestion of the PCR products can lead to misinterpretation of the results (Cascorbi and Roots, 1999).

Major advantages of the methods described here are that they do not require post-PCR processing (such as enzyme digestion) or the use of radioactivity. Since the methods amplify relatively small segments of *NAT1* or *NAT2*, they are effective for human DNA samples derived from buccal cells or paraffin-embedded tissues.

In addition to other real-time PCR–based assays, alternative methods for determining *NAT1* and *NAT2* nucleotide polymorphisms include automated DNA sequencing, allele-specific oligonucleotide and enzyme-linked immunosorbent assay (ELISA)-based oligonucleotide ligation assays (reviewed in Hein et al., in press).

Critical Parameters

Since *NAT1*, *NAT2*, and *NATP* are highly homologous, PCR primers must be specific for *NAT1* or *NAT2*. Since most *NAT1* and *NAT2* alleles have multiple nucleotide

substitutions, it is important to phase their location on one or the other of the homologous chromosomes in the diploid genome (Cascorbi and Roots, 1999). Genotype misclassification also occurs when variant *NAT* alleles sharing a common nucleotide polymorphism are not distinguished. This should be avoided or minimized since it causes substantial bias in epidemiology investigations, particularly if gene-environmental interactions are considered.

All assays should be set up in a place that is clean and free of any plasmid or genomic DNA contamination. This method is very sensitive and will amplify even the smallest quantities of template DNA, so care must be taken to prevent contamination of foreign DNA. The 96-well plate can be cut to size if <96 samples are run in a single run. As soon as the DNA samples have been added to the appropriate wells, the optical caps should be placed on the optical tubes. When placing the optical caps on the optical tubes, make sure not to damage the optical caps in any way or it will affect the result of that sample. No-DNA-template amplification controls should be carried out to demonstrate no contamination of foreign DNA. Other controls that should be included are positive controls for each SNP. It is important that the DNA concentration be in the range of 5 to 25 ng/assay, however, much less DNA can be used for plasmid controls.

The nucleotide substitutions at 559/560 and 1088/1095 are distinguished using a three-probe system that has both nucleotide polymorphisms in the same probe. This is necessary because the 559/560 and the 1088/1095 substitutions are too close together to use the conventional two-probe TaqMan assays. The 559/560 and 1088/1095 polymorphisms are not analyzed the way the other polymorphisms are analyzed. To determine whether and how many polymorphisms exist in a sample, look at the increase in fluorescence of the three probes. If only the FAM signal increases, then the sample is homozygous for 559C/560G or 1088T/1095C depending on which primer/probe set is used. If only the VIC signal increases, then the sample is homozygous for 559C/560A or 1088A/1095A depending on the primer/probe set used. If only the TET signal increases, then the sample is homozygous for 559T/560G or 1088T/1095A depending on which primer/probe set was used.

Assignment of haplotype or allele requires phasing the SNPs. This may be ambiguous due to the overlapping nature of the nucleotide substitutions that occur among the allelic variants. In these instances, the entire *NAT1* or *NAT2* sequence should be amplified by PCR as previously described (Doll et al., 1995; Deitz et al., 1997). The PCR product is then cloned directly into pCR-TOPO (Invitrogen) following manufacturer's instructions. This vector takes advantage of the 3′-A overhang added there by the *Taq* DNA polymerase during PCR. It also takes advantage of the topoisomerase gene that is covalently bound to the 3′-T overhang of the pCR-TOPO vector. This topoisomerase enzyme facilitates the direct ligation of the PCR product into the vector. Colonies possessing a single *NAT1* or *NAT2* allele can be used as a template for the genotyping assay or sequencing. A method to unambiguously assign the *NAT2* genotype using allele-specific PCR combined with RFLP has been described (Delmonie et al., 1996).

Anticipated Results

Figure 4.15.1 illustrates the data generated by the 7700 Sequence Detector and its transfer to a database. The frequency of *NAT1* and *NAT2* SNPs, alleles, genotypes, and phenotypes differs markedly between ethnic groups (e.g., Delomenie et al., 1996; Upton et al., 2001; Doll and Hein, 2002; Loktionov et al., 2002).

Time Considerations

It is most efficient to test all samples for one SNP before proceeding on to the next SNP. However, when processing small numbers of samples, different SNPs can be done in a single run. It requires ~2.5 hr for experienced users to assess one SNP in 96 samples. Preparation for each run can be accomplished in ~15 min with use of master mixes and multi-channel pipets. Setting up the sequence detector takes ~5 min. Once set up, each run takes ~2 hr of instrument time. Following completion of the run, data transfer to the database can be accomplished in ~10 min. For large experiments, economy of time and expense is achieved with instruments that can incorporate 384-well plates.

Evaluation of the Cytochrome b_5/ Cytochrome b_5 Reductase Pathway

This unit provides protocols for measuring the activity of the cytochrome b_5/cytochrome b_5 reductase pathway ex vivo using the reduction of ferrihemoglobin in erythrocytes (see Basic Protocol 1) or leukocytes (see Alternate Protocol), for evaluating mRNA expression of cytochrome b_5 and cytochrome b_5 reductase in leukocytes using qRT-PCR (see Basic Protocol 2), and for obtaining heterologous expression of the soluble forms of each protein in *E. coli* (see Basic Protocol 3). A method for preparing red blood cell lysate is described in Support Protocol 1; a method for preparing peripheral blood mononuclear cells is described in Support Protocol 2.

Cytochrome b_5 and its reductase can directly detoxify arylhydroxylamine compounds and bioactivate amidoxime prodrugs. Although factors that affect the expression of this pathway have not been well studied, ascorbate deficiency, malarial infection, and antithyroid and neuroleptic drugs have been reported to affect the expression and/or activity of this pathway.

FERRIHEMOGLOBIN REDUCTION AS A MARKER OF CYTOCHROME b_5 REDUCTASE ACTIVITY IN ERYTHROCYTES

BASIC PROTOCOL 1

Methemoglobin (Hb^{3+}) is a natural substrate for cytochrome b_5 reductase. However, the reduction of methemoglobin (Hb^{3+}) to hemoglobin (Hb^{2+}) is too slow to determine the in vitro activity of the enzyme in clinical samples. Alternatively, the rate of NADH-dependent reduction of a methemoglobin-ferrocyanide complex can be used as a marker for cytochrome b_5 reductase activity. An increase in optical density due to the reduction of this complex is monitored spectrophotometrically at 575 nm. For red blood cells, activity is normalized to hemoglobin content, while for other cell types (see Alternate Protocol) activity is normalized to milligram of protein added to the reaction mixture.

Materials

0.027 M disodium EDTA, pH 7.0: dissolve 392 mg Na_2EDTA in 50 ml H_2O; adjust pH to 7.0 using 1 M NaOH
50 mM sodium citrate buffer, pH 4.7 (see recipe)
0.5 mM potassium ferricyanide: dissolve 3.292 mg $K_3Fe(CN)_6$ in 20 ml H_2O (prepare fresh; protect from light)
1.224% (w/v) human hemoglobin (see recipe)
RBC lysate from subject of interest, diluted 1:20 (see Support Protocol 1)
2 mM NADH: dissolve 2.836 mg NADH in 2 ml H_2O (degrades in solution at room temperature; prepare fresh within 1 hr of use.)
1.5-ml amber microcentrifuge tubes
Quartz spectrophotometer cuvettes
Spectrophotometer

Prepare reaction mixture

1. To a 1.5-ml amber microcentrifuge tube, add the following reagents, prewarmed to 37°C, in the order given:

   19 µl 0.027 M EDTA, pH 7.0
   98 µl 50 mM sodium citrate buffer, pH 4.7
   294 µl 0.5 mM potassium ferricyanide

Contributed by Lauren A. Trepanier, Sunil U. Bajad, and Joseph R. Kurian
Current Protocols in Toxicology (2005) 4.16.1-4.16.17

196 µl 1.224% human hemoglobin
323 µl distilled water.

Prepare two reaction mixtures per sample, one for a control reading (which will receive no NADH in step 7) and one for an experimental reading.

2. Mix well by vortexing for 1 min.

   The reaction mixture should be amber colored (confirm by drawing up a small aliquot in a glass Pasteur pipet).

3. Add 20 µl of diluted (1:20) red blood cell lysate.

Take readings

4. Transfer to a quartz spectrophotometer cuvette.
5. Incubate 10 min at 37°C. During the incubation period, turn on the visible light source and allow the lamp to warm up.
6. Transfer cuvette to spectrophotometer.
7. Add 50 µl water (for control reading) or 50 µl 2 mM NADH (for experimental reading) to cuvette.
8. Read optical density (OD) at 575 nm at 1-min intervals for 12 min.

Calculate results

9. Discard data for first 2 min.

   For the first 2 min, the reaction rate is nonlinear.

10. Calculate ΔOD (i.e., $OD_{12\ min} - OD_{2\ min}$) for control and NADH-treated samples.
11. Determine enzyme activity using the following formula:

$$\mu\text{mol ferriHb reduced/min/g Hb} = \frac{\Delta\ \text{OD sample} - \Delta\ \text{OD control}}{[\text{Hb}]} \times 238$$

[Hb] is the hemoglobin concentration (in g/dl from co-oximeter measurement; see Support Protocol 1) in the stock RBC lysate. The factor 238 is obtained from the optical density difference between ferrohemoglobin and ferrihemoglobin (1/42), the time over which readings are made (1/10 min), conversion from g/dl to g/ml (100×), and the dilution factor for the stock RBC lysate (1/20 dilution of stock, and diluted again 50-fold in reaction, so 1000×).

SUPPORT PROTOCOL 1

PREPARATION OF RBC LYSATE

Red cell lysates can be used to measure various cytosolic enzyme activities in erythrocytes. This method uses ice-cold distilled water to osmotically disrupt washed red cells.

CAUTION: Human blood should be considered a biohazard; be sure to wear gloves when carrying out this protocol.

Materials

Heparinized blood
Phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A* or purchase from Sigma)
Stabilizing solution (see recipe)

Tabletop centrifuge
1.5-ml amber microcentrifuge tubes
Co-oximeter (Instrumentation Laboratory; *http://www.ilus.com/*)

1. Centrifuge 2 to 10 ml heparinized blood 10 min at 650 × *g*, room temperature, and discard plasma.
2. Add 10 vol PBS to the RBCs, centrifuge 8 min at 1450 × *g*, room temperature, and discard supernatant. Repeat this wash procedure two more times. After final wash, remove as much PBS as possible.
3. Transfer 200 µl of the washed RBCs to a 1.5-ml amber microcentrifuge tube, add 200 µl ice-cold distilled water, and vortex vigorously for 1 min to lyse RBC. Use this RBC lysate immediately (diluting as in step 5) or store up to 2 months (may retain optimal activity longer) at −80°C.
4. Determine hemoglobin (Hb) concentration of 200 µl of the stock lysate (in g/dl) using a co-oximeter in microsample mode, according to manufacturer's instructions.
5. For the ferrihemoglobin reduction assay (see Basic Protocol 1), dilute stock lysate from step 3 1:10 by adding 360 µl stabilizing solution to 40 µl lysate, then centrifuge 20 min at 11,000 × *g*, room temperature, to remove cell debris. Collect the supernatant and further dilute by adding an equal volume of stabilizing solution.

   Thus, the final dilution of the lysate for use in Basic Protocol 1 will be 1:20.

FERRIHEMOGLOBIN REDUCTION ACTIVITY IN MONONUCLEAR LEUKOCYTES

ALTERNATE PROTOCOL

Mononuclear leukocytes predominantly express the membrane-bound forms of cytochrome b_5 reductase and cytochrome b_5. Like soluble forms in RBCs, membrane-bound forms can also reduce the ferrihemoglobin complex. Hence, the same method can be used to determine the level of activity of these enzymes in mononuclear leukocytes. The only difference is that the activity is normalized to the total protein concentration in the cell lysate instead of hemoglobin content.

Additional Materials *(see Basic Protocol 1)*

Leukocytes (PBMC; see Support Protocol 2)
Bath sonicator
Bradford protein assay kit (Bio-Rad)

Prepare PBMC lysate

1. Aliquot 2 × 10^6 leukocytes in a 1.5-ml microcentrifuge tube (amber tubes not necessary).

   Peripheral blood mononuclear leukocytes can be isolated from human blood using any reported protocol. Final cell suspension should be brought up in 100 µl or less, in order to get high protein concentration.

2. Sonicate cells in a bath sonicator for 30 sec, place on ice for 2 min, and repeat two times.
3. Freeze lysate at −80°C for 10 min, then thaw at room temperature.
4. Sonicate again for 30 sec to fully lyse cells.
5. Determine protein concentration of a small aliquot diluted 1:10, using a Bradford assay kit.

   When using the Bio-Rad protein assay kit, use 1 µl lysate plus 9 µl sterile water plus 200 µl Bio-Rad protein assay dye and read OD at 570 nm. Use human albumin, up to 1.0 mg/ml, for the standard curve.

Determine enzyme activity

6. Perform the enzyme assay (see Basic Protocol 1) except use PBMC lysate in place of RBC lysate.

   If more than 20 μl of cell lysate is needed to provide 50 μg protein, the volume of water included in the reaction mixture can be reduced accordingly to maintain a total final reaction volume of 1 ml.

7. Calculate enzyme activity based on the following formula (modified from that used in Basic Protocol 1):

$$\mu\text{mol ferriHb reduced/min/mg protein} = \frac{\Delta \text{ OD sample} - \Delta \text{ OD control}}{420} \times 20$$

   The factor 420 reflects the optical density difference between ferrohemoglobin and ferrihemoglobin (1/42) and the time over which the readings are made (1/10 min). The factor 20 converts 50 μg of added protein to 1 mg.

SUPPORT PROTOCOL 2

ISOLATION OF PERIPHERAL BLOOD MONONUCLEAR CELLS

The method below may be used to prepare leukocytes (peripheral blood mononuclear cells; PBMC) used in the Alternate Protocol and Basic Protocol 2.

CAUTION: Human blood should be considered a biohazard; be sure to wear gloves when carrying out this protocol.

Materials

Heparinized whole blood from subject of interest, freshly obtained
Hanks' Balanced Salt Solution (HBSS; *APPENDIX 2A*) containing 5 mM EDTA, pH 7.4
Lymphocyte Separation Medium (LSM; Mediatech Inc.)
ACK lysis buffer (Cambrex Biosciences; *http://www.cambrex.com*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

50-ml conical centrifuge tubes
Tabletop centrifuge

Perform density gradient separation

1. Place 10 ml heparinized whole blood from subject of interest in a 50-ml conical centrifuge tube. Dilute blood to a total volume of 30 ml with HBSS containing 5 mM EDTA, pH 7.4.

   Smaller volumes of blood can be used, but do not scale down the other reagents.

2. Underlay blood slowly with 10 ml Lymphocyte Separation Medium.
3. Centrifuge 18 min at 600 × *g*, room temperature.
4. Remove plasma layer to within 1 cm of the white buffy coat containing mononuclear leukocytes.
5. Transfer the buffy coat gently into a fresh 50-ml conical tube.

   Inclusion of some red blood cells and plasma is not detrimental.

Lyse red blood cells

6. Dilute the buffy coat to 50 ml with HBSS containing 5 mM EDTA, pH 7.4.
7. Centrifuge 7 min at 250 × *g*, room temperature, to pellet the leukocytes. Discard the supernatant.

8. Add 2 ml of AKC lysing buffer to the cell pellet to lyse any residual red blood cells. Resuspend by gentle manual rocking. Incubate 3 min at room temperature.

Isolate PBMC

9. Dilute cell pellet to 50 ml with HBSS containing 5 mM EDTA, pH 7.4.

10. Centrifuge 7 min at 250 × *g*, room temperature. Discard supernatant. Resuspend cells in any buffer as required for subsequent use. For ferrihemoglobin reduction (Alternate Protocol), resuspend PBMC in 100 ml PBS, pH 7.4.

QUANTITATIVE REVERSE TRANSCRIPTASE POLYMERASE CHAIN REACTION FOR EXPRESSION OF CYTOCHROME b_5 REDUCTASE AND CYTOCHROME b_5

BASIC PROTOCOL 2

Quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) is the most sensitive technique for the detection and quantification of mRNA expression. Quantification of mRNA using qRT-PCR can be performed using several different methodologies, and many kits are available. For this protocol, mRNAs for cytochrome b_5 reductase (b_5R) and cytochrome b_5 (cyt b_5) are quantified using SYBR Green dye (Molecular Probes) as a reporter, because it is simple to use, sensitive, and inexpensive. To compensate for variations in pipetting, RNA quality, or efficiency of reverse transcription, an endogenous control must also be amplified, such as 18S rRNA used in this protocol. For final calculation of the amount of mRNA in original samples, the relative standard curve method is used.

Materials

Source for RNA: e.g., peripheral blood mononuclear cells (PBMC; see Support Protocol 2)
RNA-preserving solution: e.g., RNA*later* (optional; Ambion)
Phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*)
RNA isolation kit: e.g., RNAqueous-4PCR (Ambion)
DNase/RNase-free H_2O
cDNA preparation kit: e.g., SYBR Green PCR/RT-PCR kit (Applied Biosystems)
Primers (prepare in DNase/RNase-free H_2O; store in aliquots at −20°C):
  6.66 μM 18S rRNA forward primer: 5′-CGCCGCTAGAGGTGAAATTCT-3′
  6.66 μM 18S rRNA reverse primer: 5′-CGAACCTCCGACTTTCGTTCT-3′
  10.0 μM b_5R forward primer: 5′-AGGGCAAAGGGAAGTTCGCCAT-3′
  10.0 μM b_5R reverse primer: 5′-ACAGACTTCACTGTCCTGATGATA-3′
  10.0 μM cyt b_5 forward primer: 5′-CTGCACCACAAGGTGTACGA-3′
  10.0 μM cyt b_5 reverse primer: 5′-ACCTCCAGCTTGTTCCCTTA-3′
UV spectrophotometer
DNase/RNase-free pipet tips with filters
250-μl clear DNase/RNase-free tubes
Standard thermal cycler (for reverse transcription)
96-well PCR plates (e.g., Bio-Rad)
Real time PCR cycler (e.g., Bio-Rad iCycler)
Optical quality sealing tape (e.g., Bio-Rad)
Tabletop centrifuge with microtiter plate carrier

Isolate mRNA prepare cDNA

1. Isolate cells of interest (see Support Protocol 2).

   If RNA is not to be used on the same day, cells can be stored in an RNA-preserving solution such as RNAlater (Ambion) using the kit protocol (i.e., resuspend cells of interest in small volume of PBS and add 5 to 10 volumes of RNAlater). Store cells at 4°C for use within 1 month, or at −20°C or −80°C for longer periods.

2. Isolate total RNA using RNAqueous-4PCR kit according to the manufacturer's instructions.
3. Dilute an aliquot of the isolated RNA such that the concentration will be appropriate for measuring the OD_{260}/OD_{280} ratio, e.g., if the volume of isolated RNA in solution is 100 µl, dilute 30 µl to a volume of 600 µl with DNase/RNase-free water.
4. Using a UV spectrophotometer, read the OD of the diluted sample at 260 nm and then at 280 nm.

   The ratio OD_{260}/OD_{280}, indicating the purity of nucleic acid relative to protein contamination, should be between 1.8 and 2.1.
5. Calculate concentration of RNA in microgram/milliliter as:

   $OD_{260} \times$ dilution factor (see step 3) $\times$ 40.

   Nucleic acid at a concentration of 40 µg/ml gives an OD of 1 at 260 nm.
6. On the same day that the RNA is prepared, prepare cDNA using 250 ng RNA and the SYBR Green PCR/RT-PCR kit, according to the manufacturer's instructions. Store cDNA (in 20-µl aliquots) at −20°C until further use. Prepare negative-control cDNA using either no reverse transcriptase or no RNA.

Perform real-time quantitative PCR

7. Place the SYBR Green master mix (stored at 4°C) from the PCR/RT-PCR kit on ice. Calculate the total volume required for the experiment by multiplying the number of samples in duplicate/triplicate by 13 µl. Transfer this volume (plus ~10% extra) to a transparent 250-µl DNase/RNase-free tube on ice.

   The SYBR Green master mix contains buffer, nucleotides, and Taq DNA polymerase for the PCR reaction. Transferring the needed amount of master mix to a separate tube allows one to avoid contamination of the stock solution, and will also allow closer observation during pipetting to avoid bubble formation.
8. Place a 96-well PCR plate on a 96-well plate stand or a clean surface within a biosafety hood.

   If there are very few samples, it is possible split the PCR plate along the perforations and keep the remaining part for future use. Because the outer wells give variable results due to sample evaporation, select the inner wells to load the samples. Try to keep the layout simple by selecting one row for one gene.

   The PCR plate should be prepared in a biosafety hood to avoid aerosolized contamination.
9. Thaw primer stocks and dilute 1:10 with DNase/RNase-free water (e.g., 10 µl primer stock plus 90 µl water). Thaw cDNA (from step 6) and dilute 20 µl cDNA sample with 20 µl DNase/RNase-free water.
10. Add the following reagents to each well in the order indicated:

    12.5 µl SYBR Green master mix
    3.75 µl forward primer (diluted per step 9)
    3.75 µl reverse primer (diluted per step 9)
    5.00 µl diluted cDNA (from step 9).

    Adding reagents in the order indicated will help preserve the valuable cDNA sample in case of pipetting error while adding other reagents.

    The volume of cDNA solution added here (5.00 µl) should contain ~12.5 ng of cDNA if reverse transcription from 250 ng RNA was complete.

    Include controls with water, or with "cDNA" prepared using no reverse transcriptase or no RNA (see step 6).

11. Cover all wells in the plate with optical tape as follows. Carefully peel off white paper backing from the optical tape while holding the backing tabs on each end of the tape. Save the paper backing. Hold the outer tabs of the transparent tape with the sticky side facing down. Place the sticky side of the tape on the plate while stretching it slightly, so that the whole plate is covered.

    Do not touch the inner surface of the tape (fingerprints will obstruct the fluorescence signal that passes through it during data acquisition). The backing tabs should be outside the plate. Do not touch the covered plate.

12. Use the peeled-off paper backing to press the film down over the surface of the plate by smoothing the shiny side of the backing against the plate surface. Press firmly with fingers so that all wells are smoothly covered.

13. Centrifuge 5 min at 270 × *g*, room temperature, then transfer the plate to the thermal cycler.

14. Perform PCR using the following cycling parameters:

1 cycle:	3 min	95°C	(initial denaturation)
40 cycles:	30 sec	95°C	(denaturation)
	60 sec	60°C	(annealing).

    These parameters have been optimized for 18S, b_5R, and cyt b_5 in order to increase sensitivity, reduce primer dimers, and obtain reproducible results.

    Real time PCR measures RNA message levels indirectly by determining the number of cycles a sample requires to exceed an arbitrary threshold of fluorescent PCR product. The number of cycles (C_t) is related to original copy number (RNA after conversion to cDNA) by means of a standard curve of C_t at various dilutions of known quantities of cDNA.

Prepare standard curves for 18S, b_5R, and cyt b_5

15. Use 500 ng of RNA to prepare cDNA (see step 6).

    More starting RNA is used to make cDNA for a standard curve than for a single subject assay.

16. Perform serial dilutions of the cDNA sample to have at least six concentration points on each standard curve, covering the expected range of message in the samples (for example, 1:1, 1:2, 1:4, 1:8, 1:16, and 1:32).

17. Perform quantitative real-time PCR on the serial dilutions using the cycling parameters in step 14.

18. Plot log total RNA on the *y* axis and C_t values (number of cycles until copy number exceeds an arbitrary threshold, set by the cycler software) on the *x* axis.

    For individual samples, plug C_t for that sample into the standard curve to quantitate original amount of RNA in ng. To normalize for the efficiency of reverse transcription, divide ng of target RNA by ng of 18S RNA. The resulting data is a dimensionless ratio that reflects relative expression among subjects, tissues, or conditions.

Check for specificity of primers

19. Determine melting curve as programmed into cycler to control for contamination by unrelated amplicons or primer dimers.

    Determination of a melting curve usually involves a gradual increase in temperature in 0.5°C increments from 50° to 100°C. PCR product is monitored for loss of fluorescence, indicating denaturation of double-stranded DNA.

    When change in fluorescence is plotted over time, a single peak should be seen. Additional peaks indicate more than one product, or primer dimers, in the reaction mix.

BASIC PROTOCOL 3

EXPRESSION OF HUMAN RECOMBINANT SOLUBLE CYTOCHROME b_5 REDUCTASE OR CYTOCHROME b_5 IN *E. COLI*

This protocol describes a facile method for expressing and purifying the soluble forms of cytochrome b_5 reductase (b_5R) or cytochrome b_5 (cyt b_5), which have been successfully utilized in reconstitution assays for xenobiotic metabolism in vitro and in the production of polyclonal antibodies in vivo. The following protocol was established using pCR T7 TOPO TA expression vectors with ampicillin resistance. These systems are recommended for b_5R (pCR T7/NT TOPO) and cyt b_5 (pCR T7/CT TOPO) expression. The purification described uses 6×-histidine tags and nickel affinity chromatography. No activity differences were observed with the use of tagged versus untagged proteins in xenobiotic metabolism assays. The following protocol may be used for expression and purification of either b_5R or cyt b_5. Some steps are specific to one or the other protein; these are clearly noted.

Materials

b_5R and cyt b_5 cDNA, human soluble forms (contact the authors at *latrepanier@svm.vetmed.wisc.edu*)
pCR T7 TOPO TA expression vector (Invitrogen): NT or CT
Chemically competent *E. coli*: e.g., One Shot Chemically Competent Cells [BL21(DE3) cells] from Invitrogen
SOC medium (supplied with the One Shot Chemically Competent Cells from Invitrogen)
LB broth (see recipe)
100 mg/ml ampicillin stock solution (see recipe)
10 mM IPTG (see recipe)
Binding buffer, pH 8.0 (see recipe)
Complete Mini Protease Inhibitor Cocktail tablets (Roche Diagnostics; optional)
Lysozyme (Sigma; optional)
Ni-NTA agarose resin (25 ml ethanol suspension; Invitrogen)
Elution solutions 1, 2, and 3 (see recipe)
SDS-PAGE loading buffer: add 50 µl 2-mercaptoethanol (Sigma) to 950 µl Laemmli sample buffer (Bio-Rad); prepare fresh for each purification
Tris-HCl precast polyacrylamide gels (Bio-Rad) compatible with Mini PROTEAN 3 Electrophoresis Cell: 12% gel (for b_5R expression) or 15% (for cyt b_5 expression)
1× Tris-glycine electrode buffer (see *UNIT 2.2* for 10× buffer)
Phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A* or purchase from Sigma)
Bradford protein assay kit (Bio-Rad)
2 mM hemin (see recipe)
QIAprep Plasmid Prep kit (Qiagen)
42°C water bath
37°C warm room with rotary shakers
100- and 2000-ml Erlenmeyer flasks, sterile
250-ml culture tubes
Refrigerated centrifuge capable of holding 250-ml culture tubes, capable of 12,000 × *g*
Safety goggles and ear plugs
Sonic Dismembranator with microtip attachment (Fisher)
15- or 50-ml conical polypropylene centrifuge tubes
10-ml Poly-Prep columns (Bio-Rad)
0.5-ml microcentrifuge tubes
Mini PROTEAN 3 Electrophoresis Cell (Bio-Rad)
95°C heating block

Dialysis cassettes (Pierce): 10,000 MWCO (for b_5R expression) or 3,500 MWCO (for cyt b_5 expression)
1000-ml beaker
15-ml Centriplus centrifugal concentrators (Millipore): 10,000 NMWL (for b_5R expression) or 3,000 NMWL (for cyt b_5 expression)
Additional reagents and equipment for protein electrophoresis and gel staining (*APPENDIX 3F*) and dialysis and concentration of protein solutions (*APPENDIX 3H*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

Prepare plasmid

1. Insert b_5R or b_5 cDNA into the appropriate pCR T7 TOPO TA expression vector (NT for b_5R and CT for b_5) according to the protocols provided by the supplier of the vector. Purify the plasmid using a QIAprep Plasmid Prep kit.

   The b_5R construct should have a N-terminal histidine tag; the cyt b_5 construct should have a C-terminal histidine tag.

   NT is used for b_5 reductase and CT for cyt b_5. The authors chose these empirically because the noncatalytic hydrophobic tail for membrane bound b_5 reductase is N-terminal, and they predicted that a His tag (or any extra tag) on the N-terminus of soluble b_5R would therefore be less likely to interfere with function; conversely, the hydrophobic tail for membrane-bound cyt b_5 is on the C-terminus.

Transform E. coli

2. Add 7 µl of the b_5R– or cyt b_5–containing plasmid preparation to the tube provided with the One Shot Chemically Competent Cells containing 50 µl SOC medium and chemically competent *E. coli*. Mix gently, then incubate on ice 5 to 10 min.

   Do not vortex or pipet up and down.

   There are several chemically competent cell preparations available; for this protocol, BL21(DE3) cells are recommended.

3. Heat-shock the cells for 30 sec in a 42°C water bath, taking care not to shake the tube. Immediately transfer the tube to ice.

4. Add 250 µl of room temperature SOC medium. Cap the tube tightly and shake horizontally on a rotary shaker at ~200 rpm for 45 min at 37°C.

Inoculate bacteria

5. To a sterile 100-ml Erlenmeyer flask, add 10 ml of LB broth, 10 µl of 100 mg/ml ampicillin stock (final concentration in broth, 100 µg/ml), and the transformed *E. coli* cells from the transformation steps (see step 4). Shake at ~200 rpm on the rotary shaker for 18 hr at 37°C.

   The culture will become cloudy. This step may be extended if the culture has not become cloudy.

6. After 18 hr, increase the culture size by adding the entire culture from step 5 to a sterile 2000-ml Erlenmeyer flask containing 1000 ml LB broth and 1 ml of 100 mg/ml ampicillin stock.

   After autoclaving the medium, culture and ampicillin can be added when the outside of the flask is cool enough to be touched.

7. Shake on rotary shaker at ~175 rpm for 4 to 8 hr at 37°C or until the culture becomes cloudy and reaches an optical density of 0.8 at 600 nm. Measure the optical density periodically by sampling 1 ml from the culture and analyzing on a spectrophotometer.

Be careful not to allow the culture to proceed beyond an optical density of 0.8. Protein overexpression and sequestration through lipid vacuolization might otherwise occur during the expression step, which ultimately leads to low protein recoveries.

Express protein

8. Induce expression by adding 10 ml of 10 mM IPTG stock solution (final concentration 100 μM). Shake on rotary shaker at ~200 rpm for 16 hr at room temperature.

   Culture with b_5R will become pale yellow; culture with cyt b_5 will become orange.

9. Transfer cultures to 250-ml culture tubes. Centrifuge 10 min at 9000 × *g*, room temperature.

   Cells expressing b_5R will be yellow; cells expressing cyt b_5 will be red.

10. Discard supernatant and resuspend pelleted cells in a minimal amount (e.g., as little as 5 ml per pellet) of binding buffer, pH 8.0. Freeze cells at −80°C.

    Cells may be kept at −80°C for up to 60 days.

    A protease inhibitor cocktail tablet (e.g., Complete Mini Protease Inhibitor Cocktail from Roche Diagnostics) may be added here to protect the overexpressed enzyme from degradation during lysate preparation. Follow manufacturer's suggested protocol for protease inhibition.

Prepare lysate

11. After 10 min (or after storage), thaw the cell suspension by placing tube in a 37°C water bath for 10 min. Freeze cells ≥10 min at −80°C, then thaw again as before to lyse cells.

    Lysozyme may be added to a final concentration 1 mg/ml after thawing to enhance lysis. After lysozyme addition, incubate on ice for 30 min with frequent mixing, then proceed to the next step.

12. Put on safety goggles and ear plugs. Sonicate the cell suspension using a Fisher Sonic Dismembranator with a microtip adaptor, at 30% power. Perform ten repetitions of a cycle of 30-sec sonication bursts followed by 30 sec on ice.

    The microtip should be fully immersed in the lysate but not touching the bottom of the culture tube.

13. Clear the lysates by centrifuging for 20 min at 12,000 × *g*, 4°C, to bring down the cellular debris. Collect supernatant and proceed directly to affinity purification.

    The supernatant with b_5R should be yellow and with cyt b_5 should be red. The pellet usually retains some of its color.

Carry out Ni-NTA batch binding affinity purification

14. Pour an appropriate amount of the ethanol suspension of Ni-NTA agarose resin into a 15- or 50-ml conical polypropylene centrifuge tube.

    A suggested starting point is 1 ml of resin per 5 ml of cleared lysate. The binding capacity of Ni-NTA is 5 to 10 mg of protein per ml of resin. The resin accounts for ~35% of the Ni-NTA/ethanol mixture. If, for example, 3 ml of resin is required, use 3/0.35, or ~8.6 ml, of the Ni-NTA/ethanol mixture.

15. Remove the ethanol by centrifuging the resin 30 to 60 sec at 9000 × *g*, room temperature. Pour off the supernatant (ethanol) and resuspend the resin in an equal volume of water. Repeat this wash step three to five times.

16. Equilibrate the resin with binding buffer by centrifuging the resin as described in step 15 pouring off the supernatant (water), and resuspending in an equal volume of binding buffer, pH 8.0. Repeat this step three to five times, then centrifuge the resin, discard the supernatant (binding buffer), and proceed to step 17.

17. Add 5 ml of cleared lysate (from step 15) per 1 ml of resin and mix thoroughly. Slowly agitate the mixture on a rotary shaker 1 hr at 4°C to allow the His-tagged protein to bind to the nickel resin.

18. Centrifuge the resin as described in step 15 and collect the supernatant. Save a portion of the supernatant to determine binding efficiency at a later point.

    At this point the resin should be yellow to green for b_5R and red to purple for cyt b_5.

19. Remove residual (unbound) lysate by resuspending the resin in binding buffer, centrifuging the resin as in step 15, and discarding the supernatant. Repeat this step five times.

20. Resuspend resin in 2 vol elution solution 1 (containing 20 mM imidazole). and transfer suspension to a 10-ml Poly-Prep column for elution.

    For example, if resin is 5 ml, resuspend with 10 ml binding buffer.

21. Allow the resin to fall by gravity to form a packed column with the elution solution on top. Begin collecting 1-ml fractions in numbered glass tubes by opening the bottom of the Poly-Prep column.

22. Continue to pour elution solution 1 onto the column as fractions are being collected. For each milliliter of resin, pour a total of 5 ml of elution solution 1 over the column.

    For example, pour a total of 25 ml of elution solution over 5 ml of packed resin.

23. After a sufficient amount of elution solution 1 has been poured over the column, continue releasing contaminants by switching to elution solution 2 (containing 40 mM imidazole). For each milliliter of resin, pour 3 ml of elution solution 2 over the column.

    For example, pour a total of 15 ml of elution solution 2 over 5 ml or packed resin.

24. Begin eluting the b_5R or cyt b_5 off the resin with elution solution 3 (containing 125 mM imidazole). Continue pouring this solution over the column until the protein is entirely eluted and the resin returns to a light blue color. Store eluted 1-ml fractions at 4°C.

Perform SDS-PAGE purity analysis

25. In separate, numbered 0.5-ml microcentrifuge tubes, add 10 µl of each eluted fraction and 10 µl of SDS-PAGE loading buffer. Vortex each tube and heat at 95°C for 5 min.

26. Load 10 µl of each sample into a separate well of a Tris-HCl precast polyacrylamide gel.

    b_5R samples should be run on a 12% gel; cyt b_5 samples should be run on a 15% gel.

27. Run the gel in a Mini PROTEAN 3 Electrophoresis Cell at 150 V for 90 min, with 1× Tris-glycine electrode buffer as the running buffer.

    APPENDIX 3F provides additional details concerning protein electrophoresis.

28. Stain the gel using a method of choice (*APPENDIX 3F*).

    Coomassie stain (e.g., Bio-Safe Coomassie from Bio-Rad) is recommended for ease of use.

29. Identify the bands of desired purity on the gel. Pool the corresponding eluted fractions from step 24.

    His-tagged soluble b_5R is 36 kDa; His-tagged soluble cyt b_5 is 16.5 kDa.

    The amount of contamination can be estimated as a percentage of total band staining within a specific row of the gel. Usually when contamination bands comprise 10% or less of the total staining in a particular lane, it is determined to be acceptably pure.

30. If b_5R and or cyt b_5 samples are of adequate purity, proceed with the remainder of the protocol. If increased purity is desired, continue with the dialysis steps (through step 35, then repeat Ni-NTA affinity purification (steps 14 to 24).

Repeating affinity purification a second time should result in samples with ≥99% purity as determined by silver staining.

Dialyze and concentrate the purified material

31. Load the pooled eluted samples into a dialysis cassette and equilibrate cassette according to the manufacturer's instructions.

b_5R samples should be dialyzed in 10,000-Da molecular weight cutoff (MWCO) cassettes; cyt b_5 samples should be dialyzed in 3,500-Da MWCO cassettes. Different cassette volumes are available (e.g., 1 to 3 ml or 3 to 12 ml) depending on the sample size.

32. Place the cassette in 900 ml of PBS, pH 7.4, in a 1000-ml beaker. Add a magnetic stir bar, place the beaker on a magnetic stirring plate at 4°C and allow the cassette to rotate for 3 hr.

33. Remove the cassette and place it in a fresh 1000-ml beaker with 900 ml of PBS, pH 7.4. Continue stirring for 3 hr.

34. Remove the cassette and place it in a fresh 1000-ml beaker with 900 ml of PBS, pH 7.4. Continue stirring for 12 hr.

This step can exceed 12 hr and may be done overnight.

35. Collect the sample from the cassette.

36. Concentrate the sample using a Centriplus centrifugal concentrator and refrigerated centrifuge according to the manufacturer's recommendations for the concentrator. Do not concentrate beyond 3 mg/ml protein. Also see *APPENDIX 3H*.

Use a 10,000-Da nominal molecular weight limit (NMWL) device for b_5R, and a 3,000-Da NMWL device for cyt b_5. Manufacturers' rotation force recommendations may vary. Centrifuge the 15-ml Centriplus devices 15 min at 8000 to 9000 × g, 4°C.

37. Collect the supernatant and determine the sample concentration. (e.g., using the Bio-Rad kit for the Bradford method).

38a. *For b_5R:* Store purified b_5R at 4°C (will retain optimal activity up to 3 weeks) or up to 6 months at −80°C. Avoid multiple freeze-thaw cycles.

38b. *For cyt b_5:* Load with hemin as described in the remaining steps.

Load cyt b_5 with hemin

39. Add 2 mM hemin solution to the cyt b_5 sample at a molar ratio of 4:1 hemin/cyt b_5.

Before using cyt b_5 in xenobiotic metabolism assays, it is essential to load the E. coli–expressed protein with the metalloporphyrin that is present in human hemoproteins. Hemin, or chloroprotoporphyrin IX iron (III), is an iron-containing protoporphyrin IX complex with a chloride ion disturbing full coordination of the iron. It is a precursor to the endogenously active heme, which is the moiety responsible for hemoprotein activity. The hemin chloride ion is lost during incorporation into cyt b_5, resulting in full coordination of the iron and conversion of hemin to heme. This conversion is the ultimate step in activating E. coli–expressed human cyt b_5.

40. Lightly vortex the mixture, then place it on a rotary shaker at 4°C overnight.

41. Remove excess hemin with a 15-ml 3,000 NMWL Centriplus concentrator and refrigerated centrifuge according to the manufacturer's recommendations for the concentrator, centrifuging 10 min at 8000 to 9000 × g, 4°C.

Alternatively, dialysis may be performed as described in steps 31 to 35 to remove excess hemin. However, the time allowed for dialysis should be doubled in each step (i.e., 3 hr becomes 6 hr and 12 hr becomes 24 hr).

42. Determine concentration of cyt b_5 again as in step 37.

43. Store purified cyt b_5 at 4°C; it will retain optimal activity for 3 weeks. Alternatively, store up to 6 months at −80°C. Avoid multiple freeze-thaw cycles.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ampicillin stock solution, 100 mg/ml

Dissolve 0.5 g ampicillin in 5 ml distilled water to prepare 100 mg/ml stock. Store in 1-ml aliquots up to 6 months at −20°C.

Binding buffer, pH 8.0

Dissolve 2.4 g NaH_2PO_4 and 23.376 g NaCl in 1 liter of distilled water. Adjust pH to 8.0. Store up to 60 days at 4°C.

Final concentrations are 20 mM NaH_2PO_4 and 400 mM NaCl.

Elution solutions

Elution solution 1 (20 mM imidazole): Add 667 µl of 3 M imidazole stock (see recipe) to 100 ml binding buffer, pH 8.0 (see recipe).
Elution solution 2 (40 mM imidazole): Add 1.33 ml of 3 M imidazole stock (see recipe) to 99 ml of binding buffer, pH 8.0 (see recipe).
Elution solution 3 (125 mM imidazole): Add 4.17 ml of 3 M imidazole stock (see recipe) to 96 ml of binding buffer, pH 8.0 (see recipe).
Elution solutions 1, 2, and 3 may be stored up to 60 days at 4°C.

Hemin, 2 mM

Dissolve 0.130 g hemin (>99% purity; Sigma) in 10 ml dimethyl sulfoxide (DMSO). The solution will be dark blue. Prepare fresh for each purification.

Human hemoglobin, 1.224% (w/v)

Dissolve 0.1224 g purified human hemoglobin (Sigma) in 10 ml warm water and vortex for 10 min. Do not keep on ice, as a precipitate may form. Prepare fresh.

Imidazole stock solution, 3 M

Dissolve 20.424 g imidazole in 100 ml distilled water. Adjust pH to 8.0 using 1 M NaOH. Store up to 60 days at 4°C.

The solution will be light yellow at this concentration.

Isopropyl β-D-thiogalactopyranoside (IPTG), 10 mM

Dissolve 0.119 g IPTG in 50 ml distilled water. Store in 11-ml aliquots up to 6 months at −20°C, protected from light.

Luria Bertani (LB) Broth

Dissolve one LB broth tablet (Sigma) per 50 ml distilled water and sterilize by autoclaving. Add ampicillin solution after flask has cooled to touch as described in Basic Protocol 3. Use broth within 24 hr of preparation.

Alternatively, make the broth by combining 10 g tryptone, 5 g yeast extract (both available from Fisher), 10 g NaCl, 200 µl of 5 N NaOH, and 1 liter of water. Sterilize the broth and add ampicillin solution as described above. Use within 24 hr of preparation.

Sodium citrate buffer, pH 4.7 (50 mM)

Dissolve 2.1 g citric acid (anhydrous) and 2.94 g sodium citrate dihydrate in 990 ml water. Adjust the pH to 4.7 using 10 M HCl, and bring the volume to 1 liter with distilled water. Store up to 1 week at 4°C.

Stabilizing solution

0.01 ml 2-mercaptoethanol
2 ml of 10% (w/v) disodium EDTA, pH 7.0
198 ml H_2O
Store up to 1 week at 4°C

Prepare the 10% EDTA stock solution by combining 10 g disodium EDTA with 100 ml distilled water and adjusting the pH to 7.0 using 1 M NaOH.

COMMENTARY

Background Information

NADH cytochrome b_5 reductase (b_5R; EC 1.6.2.2; diaphorase I; NADH:ferricytochrome b_5 oxidoreductase) is a FAD-containing protein with soluble and membrane-bound forms, each the product of the same gene through alternative promoters and alternative splicing (Tomatsu et al., 1989; Leroux et al., 2001). The hemoprotein cytochrome b_5 (cyt b_5) is also expressed in soluble and membrane-bound forms and is also the product of a single gene (Giordano and Steggles, 1991). The cyt b_5 and b_5R proteins together mediate electron transfer from NADH to fatty acid desaturases (Oshino et al., 1971) and P450 oxidases (Hildebrandt and Estabrook, 1971). In erythrocytes, these enzymes play a primary role in maintaining hemoglobin in its reduced state (Hultquist and Passon, 1971). In addition, b_5R mediates the reduction of the partially oxidized form of ascorbate, ascorbyl free radical, back to ascorbate (Ito et al., 1981; Shirabe et al., 1995). The cyt b_5 and b_5R proteins also appear to directly catalyze the reduction of hydroxylamine and amidoxime metabolites (Kurian et al., 2004). The described techniques can be used to evaluate variability in the expression and/or activity of this pathway.

Critical Parameters and Troubleshooting

Ferrihemoglobin reduction as a marker of cytochrome b_5 reductase activity

If poor activity is seen overall in Basic Protocol 1 or the Alternate Protocol, consider the following measures.

1. Prepare fresh potassium ferricyanide.
2. Prepare fresh NADH. NADH degrades in solution at room temperature and should not be used more than 1 hr after preparation.
3. Warm all the solutions to 37°C.
4. Make sure that the purified hemoglobin is not kept on ice.

qRT-PCR for expression of cytochrome b_5 reductase and cytochrome b_5

Quality of RNA is of the utmost importance in carrying out Basic Protocol 2, as contamination by genomic DNA leads to inaccurate results. The RNA elution solution (a component of the RNA isolation kit) should be heated to 95° to 100°C prior to use. For pipetting the DNase-inactivating agent (another component of RNA isolation kit used in step 2 of Basic Protocol 2), use a pipet tip with a broad opening (such as a 10- to 20-µl tip, as opposed to a 1- to 10-µl tip; the tip may be trimmed to widen the end). It is important that the white slurry be uniformly suspended during pipetting.

Because small volumes of reagents must be pipetted, pipettors should be calibrated regularly. Also, tips should be changed whenever residual volume is noted between samples; a small change in pipetting volume can result in variable data due to the high sensitivity of the assay.

If the C_T values become higher than those originally obtained with fresh reagents, the reverse transcriptase used for cDNA preparation may be degraded. Repeat cDNA preparation with fresh RT enzyme.

Expression of human recombinant soluble cytochrome b_5 reductase or cytochrome b_5 in E. coli

For problems that may arise in purification (Basic Protocol 3), along with their possible causes and solution, see Table 4.16.1.

Table 4.16.1 Troubleshooting Guide for Cytochrome b_5 Reductase or Cytochrome b_5 Expression

Problem	Possible cause	Solution(s)
Culture did not become cloudy (E. coli cell population has not grown)	Cells may have been too violently disturbed during transformation	Be gentle while introducing the plasmid to the cells.
	Ampicillin concentration may be too high	Make sure the final concentration of ampicillin in the LB broth is 100 μg/ml.
	Rotary shaker may have been turned off for extended periods (e.g., in a common equipment room)	Resume incubation with shaking.
	Incubation times may be too short or temperatures may be too high or too low	Confirm suggested time and temperature ranges for incubation from the protocol.
Pelleted cells are not expected color (expression has not occurred)	IPTG solution not optimal	Check IPTG concentration. Make sure IPTG has not expired. Make sure IPTG was not exposed to light prior to induction.
	Induction was not optimal	Make sure induction time, temperature, and IPTG concentrations were as specified.
		Make sure culture optical density was between 0.6 and 0.8. Low expression may be a result of too few cells containing the expression plasmid.
Lysate supernatant is not expected color	*E. coli* cells were not fully lysed	Increase the number of cycles of sonication with the microtip sonicator. Also, try adding lysozyme during lysate preparation.
	Overexpressed proteins were liposome-encapsulated and therefore inaccessible	Do not allow cultures to grow beyond an optical density of 0.8 and do not allow induction to proceed beyond 16 hr. Also, do not induce at temperatures >25°C.
Resin not expected color after batch binding (protein does not bind resin)	Resin is not equilibrated to the binding buffer (pH 8)	Optimal histidine tag in nickel affinity chromatography is at pH 8.0 (due to the pK_a of histidine). Be certain to follow the protocol for Ni-NTA resin equilibration.
	b_5R or cyt b_5 histidine tag is not accessible	b_5R should be N-terminally histidine tagged and cyt b_5 should be C-terminally tagged
b_5R or cyt b_5 do not elute	Imidazole concentration is too low in elution buffer	Make sure that the imidazole stock solution is 3 M, not expired (past 60 days), and not precipitated. If precipitated, warm the solution slightly and stir until the precipitate is dissolved. Follow suggested protocol for preparing elution solution.

continued

Table 4.16.1 Troubleshooting Guide for Cytochrome b_5 Reductase or Cytochrome b_5 Expression, continued

Problem	Possible cause	Solution(s)
b_5R or cyt b_5 elute with contaminants, before final elution buffer is poured over column	Less than optimal conditions; binding buffer may not be exactly at pH 8.0; elution solutions may not be the specified concentration or pH; and fewer than normal contaminants may interfere with expected imidazole-to-column interaction[a]	Make sure that buffers and elution solutions are at correct pH values. Use elution solution concentrations as relatively firm guidelines. Adjust imidazole concentrations as necessary.
		Decrease lysate:resin ratio (e.g., to 2:1).
Protein has lost activity	Protein's active life has expired	Both proteins should maintain optimal activity for 3 weeks when stored at 4°C; do not use beyond this point.
	Proteins stored at too high a concentration may precipitate	Store proteins at ≤3 mg/ml (between 0.5 and 3 mg/ml is optimal).

[a]Fewer than normal contaminants mean that the lysate may not contain the expected amount of contamination and consequently contains significantly more b_5 or b_5R. Less contaminants mean that the column can overload with the protein of interest and leave fewer sites for excess protein of interest to interact with the column. Also, the interactions tend to be less specific, as many single proteins converge on one column bead. As a result, when contamination should be eluted, the desired protein may actually begin to elute. This is actually a very rare situation.

Anticipated Results

Ferrihemoglobin reduction as a marker of cytochrome b_5 reductase activity

Reported normal values for NADH cytochrome b_5 reductase activity in adults are 3.4 ± 0.5 μmol FerriHb reduced/min/g Hb (Beutler, 1975). However, when using pure hemoglobin (see Basic Protocol 1), the mean activity that the authors have obtained is 4.6 ± 1.0 μmol FerriHb reduced/min/g Hb. For mononuclear leukocytes (see Alternate Protocol), preliminary data suggest a range of 10 to 20 nmol FerriHb reduced/min/μg protein in normal human subjects.

Although factors that affect the expression of cytochrome b_5 and its reductase have not been well studied, ascorbate deficiency, malarial infection, and antithyroid and neuroleptic drugs have been reported to affect the expression and/or activity of this pathway.

qRT-PCR for expression of cytochrome b_5 reductase and cytochrome b_5

Using the method described in Basic Protocol 2, the efficiency of the PCR reaction for all the three genes [efficiency = $10^{(-1/\text{slope})}$–1] is between 90% and 100% (where slope is that of the standard curve). The standard curves (log total RNA on *y* axis and C_T values on *x* axis) for all three genes are also linear up to a 32-fold dilution.

The range of C_T values obtained for different genes in experimental samples is: 10 to 15 for 18S RNA, 28 to 35 for b_5R, and 30 to 40 for cyt b_5.

Using the C_T value for a given sample, determine the corresponding log RNA concentration from the appropriate standard curve equation. Calculate the inverse log to obtain an RNA value. Finally, divide the values obtained for b_5R or cyt b_5 RNA by the values obtained for 18S rRNA for normalization. Report the values as RNA normalized for 18S rRNA.

Melting curve analysis is performed to check the specificity of the reaction; most instruments have protocols installed in the software for doing this. Melting curve analysis should indicate only one peak for each gene.

Expression of human recombinant soluble cytochrome b_5 reductase or cytochrome b_5 in E. coli

Average amounts of purified enzyme recovered per liter of initial culture are 8 to 10 mg for b_5R and 10 to 12 mg for cyt b_5. The lower value in this range refers to the amount expected after repeating the Ni-NTA affinity purification a second time to achieve a >99% pure enzyme. The higher value in the range is expected after one column purification, which results in a >95% pure enzyme.

Time Considerations

Ferrihemoglobin reduction as a marker of cytochrome b_5 reductase activity

Isolation of RBCs, and preparation of lysate (Support Protocol 1) and reagents takes ∼1 hr. Analysis of each patient sample (with and without NADH; Basic Protocol 1) takes 30 to

35 min. overall. To save time, start preparing another sample while the previous one is being read in the spectrophotometer.

qRT-PCR for expression of cytochrome b_5 reductase and cytochrome b_5

Basic Protocol 2 as a whole takes 1.5 days. On day 1, isolate PBMCs, isolate RNA, and prepare cDNA. On day 2, prepare PCR plate and perform the run. The protocol for PCR cycling takes ~2.5 hr. Additional time is required if a melting curve is also being performed. If the qRT-PCR instrument is a shared facility, a total of 3 to 4 hr should be booked.

Expression of human recombinant soluble cytochrome b_5 reductase or cytochrome b_5 in E. coli

Basic Protocol 3 in its entirety may be comfortably completed over 5 to 6 days. Ideally the protocol should be carried out according to the following timeline.

Day 1: Proceed through inoculation (step 5).

Day 2: Proceed through expression (step 8).

Day 3: Proceed through Ni-NTA Affinity Purification (step 24).

Day 4: Proceed through dialysis and concentration (through step 34).

Day 5: Finish the protocol for b_5R purification (through step 38a), or proceed to hemin loading (see Basic Protocol 3, steps 39 to 42) for the cyt b_5 purification.

Day 6: Finish the protocol for cyt b_5 purification.

After gaining experience with specific techniques, it may be possible to increase efficiency and combine steps from separate days. Alternatively, listed below are several intervals in the protocol where it is possible to pause without adversely affecting results.

1. The pelleted cells obtained after completing expression may be kept at −80°C for up to 60 days before proceeding to lysate preparation.

2. The fractions collected in Ni-NTA affinity purification may be stored at 4°C for up to 7 days before proceeding to dialysis and concentration. However, be aware that if fractions contain purified enzyme at a concentration above 3 mg/ml, precipitation may occur and disturb ultimate recovery.

3. Hemin loading of cyt b_5 is not immediately necessary. Cyt b_5 samples may be stored at 4° or −80°C before hemin loading. However, keep in mind the considerations regarding storage and activity of purified enzymes when deciding whether or not to delay hemin loading.

Measurement of Xenobiotic Carbonyl Reduction in Human Liver Fractions

This unit describes procedures for studying the metabolism of a xenobiotic by human liver carbonyl reducing enzymes. In the body, these enzymes catalyze the phase I reduction of potentially toxic aldehyde and ketone moieties to their respective alcohols, facilitating conjugation and/or excretion. In addition to detoxification, carbonyl reducing enzymes participate in steroid and prostaglandin metabolism, housekeeping, stress response, neurotransmission, mutagenesis, and carcinogenesis. The enzymes that catalyze carbonyl reduction are divided into four superfamilies: medium-chain dehydrogenases/reductases (including alcohol dehydrogenases), aldo-keto reductases, quinone reductases, and short-chain dehydrogenases/reductases (including microsomal and cytosolic carbonyl reductases).

Carbonyl reducing enzymes differ in subcellular location, cofactor dependence, and susceptibility to chemical inhibitors, enabling their characterization with simple in vitro experiments. Generally, the xenobiotic is incubated with pooled human liver microsomes or cytosol in the presence or absence of cofactors. Experimental methods for carbonyl reducing enzymes are similar to approaches for cytochrome P450 enzymes, except for the availability of isoform-specific reagents. Purified enzymes, heterologously-expressed isozymes, and isoform-selective inhibitors are well-characterized and commercially available for cytochrome P450 studies. Analogous protein preparations and reagents are not yet widely available for carbonyl reducing enzymes. Without these materials, it is impossible to identify the specific isoform within a family of carbonyl reducing enzymes responsible for metabolism. A more practical objective is to determine which carbonyl reducing enzyme(s) participates in metabolism, and this is the chief objective of the protocols described in this unit. More definitive studies require recombinant or purified carbonyl reducing enzymes along with detailed enzyme kinetic and inhibition experiments with precise analytical methods for quantitation of metabolites.

NADPH-dependent reactions in microsomes include carbonyl reduction and/or other pathways, including the oxidative pathways catalyzed by cytochrome P450 enzymes. Some of the methods outlined in this unit include conditions for examining P450-mediated reactions concurrently with carbonyl reduction. These experiments incorporate differences in the properties of P450 and carbonyl reducing enzymes in order to evaluate their roles in metabolism, and they include the use of inhibitors, recombinant P450 preparations, and pH dependence.

Basic Protocol 1 outlines preliminary experiments to characterize the cofactor dependence and subcellular location of enzymes involved in metabolism and to optimize reaction conditions. Once metabolism by carbonyl reducing enzymes has been established, chemical inhibitors selective for a family of carbonyl reducing enzymes can aid in distinguishing among their activities (see Basic Protocol 2). Determining the effect of pH on metabolism can help to characterize reactions catalyzed by carbonyl reducing enzymes (see Basic Protocol 3). Finally, recombinant P450 enzyme preparations can be employed to examine cytochrome P450–mediated reactions independently from carbonyl reduction (see Basic Protocol 4).

NOTE: To examine the metabolism of a xenobiotic with the protocols outlined in this unit, an analytical method is required for measurement of the metabolite(s) produced. Most commonly, the xenobiotic (parent) and metabolites are separated chromatographically

Contributed by M. Jane Cox Rosemond
Current Protocols in Toxicology (2005) 4.17.1-4.17.25

by HPLC with UV, radiochemical, or mass spectrometric (MS) detection. Ideally, the identity of the carbonyl reduced product is confirmed by mass spectrometry at some point during the investigations. Analysis of metabolites by HPLC with MS detection is covered in *UNIT 4.4*. Additional HPLC references are provided in the Commentary.

NOTE: The reduction of unsymmetrical ketones to their respective alcohols generates chiral centers. References on the subject of stereochemistry and metabolism are provided in the Commentary, and published investigations in which the stereochemistry of carbonyl reduction was monitored are noted in Table 4.17.7.

BASIC PROTOCOL 1

DETERMINATION OF SUBCELLULAR LOCATION AND COFACTOR DEPENDENCE OF A CARBONYL REDUCING ENZYME

Conduct these preliminary experiments to assess the involvement of particular carbonyl reducing enzymes in metabolism and to establish optimal reaction conditions. Test cytosol with the cofactors NADH or NADPH, and microsomes with NADPH. Most carbonyl reducing enzymes of human liver are active in these conditions (Table 4.17.1). Run, in parallel, control incubations in the absence of added cofactor. Some suggested initial parameters are listed in Table 4.17.2. Once the results from initial experiments are evaluated, adjust parameters (e.g., reaction time and protein concentration) to maximize turnover.

NOTE: Some residual cofactor may be present in subcellular fraction preparations; thus, a small amount of background metabolism may be observed.

NOTE: Wear personal protective equipment (e.g., laboratory coat, safety glasses, gloves) when working with materials derived from human tissue such as human liver subcellular fractions.

Table 4.17.1 Cofactor Dependence and Subcellular Location of Carbonyl Reducing Enzymes[a,b]

Subcellular location	Enzyme superfamily	Enzyme	Cofactor[c]
Cytosol	Medium-chain dehydrogenase/reductase	Alcohol dehydrogenase (ADH)	NAD(H)
	Aldo-keto reductase (AKR)	AKR1A, AKR1B, AKR1C, AKR1D, AKR6, AKR7[d]	NADPH[e]
	Quinone reductase	NAD(P)H:quinone oxidoreductase 1 (NQO1)	NADPH or NADH, interchangeably
		NRH:quinone oxidoreductase (NQO2)	NRH
	Short-chain dehydrogenase/reductase (SDR)	Carbonyl reductase (CR,CBR)	NADPH
Microsomes	SDR	11β-Hydroxysteroid dehydrogenase (11β-HSD)	NADPH

[a] Abbreviation: NRH, dihydronicotinamide riboside.

[b] A general reference for Table 4.17.1 is Oppermann and Maser (2000).

[c] The predominant cofactor for each enzyme system is given.

[d] The following human liver AKR isoforms have been the subjects of some published studies of xenobiotic metabolism: AKR1A1 (aldehyde reductase), AKR1B (aldose reductases), AKR7 (aflatoxin aldehyde reductase), and AKR1C1, 1C2, and 1C4 (dihydrodiol dehydrogenases).

[e] One member of the AKR1C family, AKR1C4, utilizes NADH or NADPH (Atalla et al., 2000).

Table 4.17.2 Suggested Assay Parameters for Preliminary Experiments[a,b]

Component	Conditions
Buffer	100 mM potassium phosphate, pH 7.4
Protein	1 mg/ml
Substrate	1, 10, 100 μM
Cofactor	2 mM NADPH, 2 mM NADH (cytosol) 2 mM NADPH (microsomes) 2 mM NADPH-regenerating system (for reaction times >30 min) 2 mM NADPH (microsomes)
Incubation time	30 min
Temperature	37°C
Controls	0 min, no cofactor

[a]Final concentrations of reaction components are given in the table.
[b]Consult the Commentary section for alternative assay conditions that have been reported in the literature (Table 4.17.7).

Materials

Pooled human liver subcellular fractions (cytosol, microsomes; BD Biosciences, In Vitro Technologies, Xenotech), −80°C
1 M potassium phosphate buffer, pH 7.4 (see recipe)
Cofactors:
2 mM NADH (see recipe)
2 mM NADPH (see recipe)
For NADPH-regenerating system:
Glucose 6-phosphate dehydrogenase (see recipe)
Regenerating system cofactor mixture (see recipe)
1000× xenobiotic substrate solutions (see recipe)
Reagents for stopping reactions (Table 4.17.7)
Chromatography buffers and solutions
Thermomixer or shaking water bath, 37°C
1.5-ml microcentrifuge tubes
Additional reagents and equipment for HPLC and analysis (*UNIT 4.4*)

1. Turn on shaking water bath or Thermomixer and warm to 37°C.
2. Thaw pooled human liver subcellular fractions by gently warming them by hand. Place on ice immediately upon thawing.

   Keep the protein preparations on ice when not in use.

3. Add the following reagents, in order, to a 1.5-ml microcentrifuge tube for a final reaction volume of 1 ml. Minimally, run samples in duplicate; include more replicates depending on reproducibility.

   a. For cytosolic incubations, add:
   789 μl H_2O (779 μl with regenerating system)
   100 μl 1 M potassium phosphate, pH 7.4
   100 μl 10 mg/ml cytosol
   (10 μl 100× glucose-6-phosphate dehydrogenase, with regenerating system)
   1 μl 1000× xenobiotic substrate solution.

   b. For microsomal incubations, add:
   839 μl H_2O (829 μl with regenerating system)
   100 μl 1 M potassium phosphate, pH 7.4

50 µl 20 mg/ml microsomes
(10 µl 100× glucose-6-phosphate dehydrogenase, with regenerating system)
1 µl 1000× xenobiotic substrate solution.

The final volumes of reagents will vary depending on the concentration of protein in the subcellular fraction preparation and the concentration of the xenobiotic substrate achievable based on solubility. Adjust the amount of water for a final volume of 1 ml.

Prepare samples on the laboratory bench at room temperature. If desired, pre-warm samples 5 min at 37°C before initiating reactions.

4. Initiate reactions by the addition of cofactor (10 µl of 0.2 M stock or 10 µl of regenerating system cofactor mixture). For control samples without cofactor, add a 10-µl aliquot of buffer only. Start a timer.

   Add the cofactor droplet to the inside lid of the microcentrifuge tube to control the timing of reactions. To start reactions, close the cap and gently mix the contents by inverting the tube two to three times.

   Alternative ways to start reactions are: (1) initiate reactions with substrate instead of cofactor, or (2) initiate reactions with enzyme if the substrate is sufficiently soluble in the absence of protein and there is no lag in enzyme activity based on temperature.

5. Prepare 0-min control samples. Remove an aliquot (e.g., 100-µl) immediately after adding cofactor. Without delay, add stopping reagent to the 0-min samples and mix.

   Details about stopping reagents are provided in step 7.

   For a rapidly metabolized substrate, remove the 0-min aliquot, then add the stopping reagent followed by the appropriate volume of cofactor (1:100 dilution of cofactor). As an example: remove 100 µl from the 1-ml incubation mixture and place into a 1.5-ml microcentrifuge tube on ice. Add 100 µl of acetonitrile and mix. Then, add 1 µl of cofactor.

6. Incubate the tubes with gentle shaking at 37°C, either in a water bath or Thermomixer (set at 500 rpm). For time-point samples, remove an aliquot (e.g., 100-µl) at the appropriate interval following the initiation of reactions.

   Until the degree of turnover is assessed, extensive sampling at multiple time-points is unnecessary. As an alternative, sample a small number of time-points in addition to the 0-min control (e.g., 5, 30 min).

   Adjust the volume removed at each time-point based on the amount of sample required for analysis. Ensure that the overall incubation volume is sufficient to allow for removal of all time-point samples.

7. Terminate the reactions with an appropriate stopping method, taking into consideration the solubility and stability of the xenobiotic/metabolites (analytes) and the analytical method.

   Common methods for stopping reactions include the addition of organic solvent or rapid acidification or alkalinization, followed by placing the samples on ice. Examples of methods for stopping reactions are provided in the Commentary, Table 4.17.7. In general, the best conditions for stopping reactions will depend on the analytes; usually some optimization is required.

   A suggested stopping procedure is as follows: remove a 100-µl aliquot at each time-point (e.g., 0, 5, 30 min). Add 0.5 to 1× volume of organic solvent (e.g, acetonitrile), vortex to mix, and then incubate for 10 to 15 min at room temperature. Proceed to step 8.

   Increase the volume of organic solvent (up to ~ 3× reaction volume) if a 0.5 to 1× dilution is insufficient to recover analytes. Ensure that the amount of stopping reagent does not excessively dilute the samples and interfere with detection of analytes. Develop an alternative stopping procedure if samples become too dilute.

   In some cases, a solvent extraction procedure may be required to concentrate the analytes. Include an internal standard in the stop solution for samples requiring extraction before

analysis (refer to Table 4.17.7 for examples). An internal standard should have properties distinct from the parent or metabolites to enable its detection independently from other analytes.

Although it is a common practice, placing terminated reactions on ice need not be routine. Some analytes may be insoluble at low temperature, reducing recovery.

Have an appropriate sample processing method in place that allows for optimal recovery of analytes before conducting large-scale experiments. Aim for reproducible recovery of >80%.

8. Centrifuge the terminated reactions 5 min at 17,000 × *g*, room temperature, to remove any precipitate. Remove an aliquot of the supernatant for analysis.

   For radiolabeled substrates, remove two aliquots of supernatant, one aliquot for liquid scintillation counting (for calculation of recovery), and one aliquot for HPLC analysis. For HPLC, inject 10,000 to 15,000 dpm per sample.

9. Repeat experiments, varying parameters such as protein concentration and incubation time, to optimize reaction conditions, achieve maximal turnover and, if preferred, establish conditions for linearity of the reaction rate with respect to protein concentration and time. For example, conduct incubations with protein concentrations ranging from 0.01 to 2 mg/ml. Vary the incubation times from minutes to several hours, depending on turnover. Substitute NADPH-regenerating system for NADPH if reaction times are >30 min due to the instability of NADPH in solution.

   If non-enzymatic substrate conversion is suspected, include the following controls: (1) incubations without protein, and (2) incubations with heat-inactivated enzymes. Heat-inactivate protein preparations by heating 30 min at 60°C (Breyer-Pfaff and Nill, 1995).

USE OF CHEMICAL INHIBITORS IN THE STUDY OF CARBONYL REDUCING ENZYMES

BASIC PROTOCOL 2

Carbonyl reducing enzymes differ in their sensitivity to chemical inhibitors, providing a convenient means of distinguishing between the activities of different enzyme families.

Ideally, conduct inhibition experiments with the substrate concentration at or near the apparent K_m of the reaction. In the absence of a K_m value, select a range of concentrations (e.g., 1, 10, 100 μM). For a xenobiotic in drug development, select a substrate concentration based upon the clinical C_{max}, if known. References about conducting kinetic experiments and K_m determinations are provided in the Commentary.

For convenience, initially test inhibitors at a single concentration (e.g., 100 μM). After assessing the data from preliminary experiments, plan to test at least two different inhibitors of each enzyme family, at two concentrations. Include inhibitors of cytochrome P450 enzymes alongside inhibitors of carbonyl reducing enzymes if P450-mediated metabolism is suspected. As a guide, a list of selected chemical inhibitors of carbonyl reducing enzymes and concentrations is provided in Table 4.17.3. An expanded list of inhibitors with kinetic data provides more choices (Rosemond and Walsh, 2004).

Conduct incubations at the optimal conditions established in preliminary experiments (see Basic Protocol 1, parameters listed in Table 4.17.2). Reagents and procedures are the same as Basic Protocol 1; the only differences are the inclusion of chemical inhibitors and corresponding vehicle controls. For the purpose of illustration, a sample method for a xenobiotic having cytosolic and microsomal NADPH-dependent metabolism is described in this protocol. Carbonyl reducing enzymes of both subcellular fractions can be probed with the inhibition experiments in this protocol. In this example, the K_m of the substrate is 20 μM, incubation time is 15 min, and protein concentration is 1 mg/ml.

Table 4.17.3 Chemical Inhibitors for Studies with Carbonyl Reducing Enzymes[a]

Subcellular location	Enzyme	Selected inhibitors	Suggested concentration range[b]	Suggested vehicle[c]	Selected references
Cytosol	ADH	4-Methylpyrazole[d]	0.6–1 mM	Water	Stone et al., 1995; Shimoda et al., 1998; Walsh et al., 2002

		Proadifen (SKF525A)	0.1–1 mM	Water	
		Metyrapone	0.2–2 mM	Water	

[a] Abbreviations: ADH, alcohol dehydrogenase; AKR, aldo-keto reductase; CR, carbonyl reductase; 11β-HSD, 11β-hydroxysteroid dehydrogenase; NQO1, NAD(P)H:quinone oxidoreductase 1; NQO2, NRH:quinone oxidoreductase; SDR, short-chain dehydrogenase/reductase.

[b] A wide range of inhibitor concentrations is proposed where specific references for human liver enzymes were not found.

[c] The suggested vehicle is based on information from The Merck Index (Budavari, 1996) or the listed reference.

[d] 4-Methylpyrazole inhibits class I ADH isozymes only.

[e] CAUTION: Benzo(a)pyrene is a suspected carcinogen (Budavari, 1996).

[f] Monoclonal antibodies have been employed as inhibitors of cytochromes P450. For reference, see Gelboin et al. (1999) and Donato and Castell (2003).

NOTE: Some inhibitors (e.g., quercetin) and substrates of carbonyl reducing enzymes (e.g., warfarin, haloperidol, and metyrapone) are also inhibitors of P450. Consider the possibility of coincident P450 inhibition when evaluating experimental results from microsomes.

Materials

Pooled human liver subcellular fractions (cytosol, microsomes; BD Biosciences, In Vitro Technologies, Xenotech)
1 M potassium phosphate buffer, pH 7.4 (see recipe)
1000× inhibitor solution (see Table 4.17.3 and recipes):
For cytosol:
Phenolphthalein, flufenamic acid (AKR probes)
Menadione, quercetrin (CR probes)
For microsomes:
Glycyrrhetinic acid, chenodeoxycholate (11β-HSD probes)
Aminobenzotriazole (P450 probe)
Vehicle solutions (solvent for dissolving inhibitors, to be tested as controls):

1000× xenobiotic substrate solution (see recipe)
Reagents for stopping reactions (see Table 4.17.7)
Chromatography buffers and solutions
Cofactors: 2 mM NADPH (see recipe)

Thermomixer or shaking water bath, 37°C
1.5-ml microcentrifuge tubes

Additional reagents and equipment for HPLC and analysis (*UNIT 4.4*)

1. Turn on water bath or Thermomixer and warm to 37°C.
2. Thaw pooled human liver subcellular fractions by gently warming them by hand. Place on ice immediately upon thawing.

   Keep the protein preparations on ice when not in use.

3. Add the following reagents, in order, to a 1.5-ml microcentrifuge tube for a final reaction volume of 1 ml. Minimally, run samples in duplicate; include more replicates depending on reproducibility.

   a. For cytosolic incubations, add:
   788 µl H_2O
   100 µl 1 M potassium phosphate buffer, pH 7.4
   100 µl 10 mg/ml cytosol
   1 µl 1000× inhibitor or vehicle
   1 µl 1000× xenobiotic substrate solution (20 mM stock, in this example).

   b. For microsomal incubations, add:
   838 µl H_2O
   100 µl 1 M potassium phosphate buffer, pH 7.4
   50 µl 20 mg/ml microsomes
   1 µl 1000× inhibitor or vehicle
   1 µl 1000× xenobiotic substrate solution (20 mM stock, in this example).

   If preferred, preincubate samples with the inhibitor by warming samples for 5 min at 37°C after the addition of inhibitor. Then, add the substrate followed by cofactor.

4. Perform Basic Protocol 1, steps 4 to 9. Initiate the reactions with cofactor or buffer (for controls) and incubate samples. After a 15-min incubation (in this example), terminate reactions, then process and analyze the samples.

   If inhibitor stock solutions are prepared in several solvents, the total number of vehicle controls can be reduced by running the vehicle solution containing the highest concentration of organic solvent. For example, if one inhibitor is dissolved in DMSO/water (1:1), and another inhibitor is dissolved in 100% DMSO, then run only the 100% DMSO control. There should be no interference from solvent alone if the overall concentration of organic solvent from the addition of substrate and inhibitor is in the range of 0.1% to 0.2%.

DETERMINING pH DEPENDENCE OF CARBONYL REDUCING ENZYMES

BASIC PROTOCOL 3

Many cytosolic carbonyl reducing enzymes have acidic pH optima in the range of pH 5.5 to 6.5 (Table 4.17.4). Also, many carbonyl reducing enzymes function reversibly as oxidoreductases, or dehydrogenases. NADPH-dependent carbonyl reducing enzymes function in the reductive direction at physiological pH but will function oxidatively at alkaline pH (>10) and high substrate concentration (Felsted and Bachur, 1980). References for studies in which both reactive directions were investigated are noted in the Commentary (Table 4.17.7).

Table 4.17.4 Comparison of pH Optima and Reactions Catalyzed by Human Liver Carbonyl Reducing Enzymes[a]

Subcellular location	Enzyme	Cofactor[b]	pH optimum[c]	Function[d]	Selected references[e]
Cytosol	ADH	NAD^+	7.5–10.5	Oxidation of alcohols; reduction of quinones	Blair and Vallee, 1966
	AKR	NADPH	5.5–6.5	Reduction of endogenous and xenobiotic carbonyls, C-C double bonds	Felsted and Bachur, 1980; Atalla et al., 2000
	NQO1	NAD(P)H	7.0–7.4	Two-electron reduction of quinones	Ross et al., 2000
	NQO2	NRH	7.0–7.4	Two-electron reduction of quinones	Long and Jaiswal, 2000
	CR	NADPH	5.5–6.5	Reduction of endogenous and xenobiotic carbonyls	Felsted and Bachur, 1980; Forrest and Gonzales, 2000
Microsomes	11β-HSD	NADPH	7.4	Reduction of endogenous and xenobiotic carbonyls	Maser et al., 2003
	P450 (for comparison)	NADPH	7.4	Several types of oxidative reactions; endogenous and xenobiotic substrates	Guengerich, 2004

[a]Abbreviations: ADH, alcohol dehydrogenase; AKR, aldo-keto reductase, CR, carbonyl reductase; 11β-HSD, 11β-hydroxysteroid dehydrogenase; NQO1, NAD(P)H:quinone oxidoreductase 1; NQO2, NRH:quinone oxidoreductase 2; NRH, dihydronicotinamide riboside.

[b]The predominant cofactor is given.

[c]The pH ranges come from the listed references or from typical assay conditions reported in the literature.

[d]Several of these enzymes function reversibly as oxidoreductases. NADPH-dependent enzymes function mainly in the reductive direction while NADH-dependent enzymes function mainly oxidatively.

[e]A general reference for Table 4.17.4 is Oppermann and Maser (2000).

Follow this protocol for a cytosolic, NADPH-dependent enzyme system functioning in the reductive direction. Run reactions at the optimum conditions established during initial experiments (see Basic Protocol 1, parameters listed in Table 4.17.2), and evaluate the pH dependence over the range of pH 5.0 to 7.4 with phosphate buffers.

NOTE: The oxidation of carbonyl reduced products in microsomes can be catalyzed by cytochrome P450 enzymes. For example, haloperidol undergoes reduction by cytosolic carbonyl reductase and aldo-keto reductases, producing reduced haloperidol. Reduced haloperidol is oxidized by cytochrome P450, regenerating haloperidol (Kudo and Ishizaki, 1999). The interconversion of haloperidol and reduced haloperidol was observed in clinical studies (Chakraborty et al., 1989).

Materials

Pooled human liver cytosol subcellular fraction (BD Biosciences, In Vitro Technologies, Xenotech)
1M potassium phosphate buffer, pH 5.0, 5.5, 6.0, 6.5, 7.0, 7.4 (see recipes)
1000× xenobiotic substrate solution (see recipe)
Reagents for stopping reactions (Table 4.17.7)
Chromatography buffers and solutions
Cofactor: 2 mM NADPH (see recipe)

Thermomixer or shaking water bath, 37°C
1.5-ml microcentrifuge tubes

Additional reagents and equipment for HPLC and analysis (*UNIT 4.4*)

1. Turn on water bath or Thermomixer and warm to 37°C.
2. Thaw pooled human liver cytosol subcellular fraction by gently warming by hand. Place on ice immediately upon thawing.

   Keep the protein preparation on ice when not in use.

3. Add the following reagents, in order, to a 1.5-ml microcentrifuge tube for a final reaction volume of 1 ml. Minimally, run samples in duplicate; include more replicates depending on reproducibility.

   789 µl H_2O
   100 µl 1 M potassium phosphate, replicates at each pH 5.0, 5.5, 6.0, 6.5, 7.0, 7.4
   100 µl 10 mg/ml cytosol
   1 µl 1000× xenobiotic substrate solution

4. Perform Basic Protocol 1, steps 4 to 9. Initiate reactions with NADPH (10 µl of 0.2 M stock or buffer, for controls) and incubate samples. Follow with termination of reactions, sample processing, and analysis.

DISCRIMINATING BETWEEN CYTOCHROME P450 AND CARBONYL REDUCING ENZYMES WITH RECOMBINANT P450 PREPARATIONS

BASIC PROTOCOL 4

These experiments can help to distinguish between reactions mediated by carbonyl reducing enzymes (or other non-P450 enzymes) and cytochromes P450. Recombinant P450 isoforms (1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, and 3A4) are combined into a single preparation containing human P450 enzymes but no human carbonyl reducing enzymes. This preparation is run in parallel with pooled human liver microsomes, which contain P450 in addition to carbonyl reducing enzymes. As a control, microsomes prepared from cells untreated with recombinant P450 vectors are included. These background control preparations contain no human P450 or carbonyl reducing enzymes, though they may contain carbonyl reducing enzymes endogenous to the expression system (Table 4.17.5).

Table 4.17.5 Suggested Assay Parameters for Recombinant P450 Experiments

Component	Conditions
Pooled human liver microsomes (human carbonyl reducing enzymes, human P450)	Run at the optimal protein concentration established in initial experiments[a]
Recombinant P450 mixture (no human carbonyl reducing enzymes, human P450)	Run at the optimal protein concentration established in initial experiments[a]
Recombinant control protein (no human carbonyl reducing enzymes, no human P450)	Run at the optimal protein concentration established in initial experiments[a]
Buffer, substrate concentration, incubation time	Run at the optimal conditions established in initial experiments
Cofactor (2 mM final)	NADPH or NADPH-regenerating system
Temperature	37°C
Controls	0 min, no cofactor

[a]In this protocol, the protein concentration was based on the sample recipe in Table 4.17.6.
[b]If possible, test all three protein preparations at the same protein concentration.

Table 4.17.6 Sample Recipe for a Recombinant P450 Mixture[a,b]

Initial product concentrations (from vendor)			Recombinant mixture preparation					Final concentrations in incubations	
P450	Initial protein concentration (mg/ml)[c]	Initial P450 content (pmol/ml)	Volume per P450 (ml)	Total volume of protein	Protein (mg/ml)	P450 (pmol/ml)	Amount recombinant mix per 1 ml incubation (ml)	Protein (mg/ml)	P450 (pmol/ml)
1A2	6	1000	0.5	3.75 ml of 5.83 mg/ml	0.80	133	0.254	0.20	30
2A6	10	1000	0.5		1.3	133		0.33	30
2B6	7	1000	0.5		0.93	133		0.24	30
2C9	3	1000	0.5		0.40	133		0.11	30
2C19	3	1000	0.5		0.40	133		0.11	30
2D6	6	1000	0.5		0.80	133		0.20	30
2E1	4	2000	0.25		0.27	133		0.07	30
3A4	7	1000	0.5		0.93	133		0.24	30
								Final total protein concentration in incubations = 1.5 mg/ml	

[a]The recombinant P450 mixture helps to discriminate between P450- and non-P450-mediated metabolism. Aliquots of each recombinant cytochrome P450 isoform are combined to create an artificial human microsomal preparation with P450 and no other human microsomal enzymes. The quantities of each isoform will vary depending on the concentration of protein and P450 in each product. These characterizations are typically performed by the supplier (e.g., BD Biosciences, Invitrogen). P450 isoforms are mixed so that the final concentration of each P450 in the incubation mixture is 30 pmol/ml.

[b]The use of recombinant P450 mixtures is discussed in Crespi and Miller (1999).

[c]A typical protein concentration for control recombinant microsomal preparations is 5 mg/ml.

Materials

Pooled human liver microsomes (BD Biosciences, In Vitro Technologies, Xenotech), gently thawed and placed on ice
1 M potassium phosphate buffer, pH 7.4 (see recipe)
1000× xenobiotic substrate solution (see recipe)
Recombinant P450 mixture (see Table 4.17.6), gently thawed and placed on ice
Recombinant control preparation, gently thawed and placed on ice
Cofactor:
2 mM NADPH (see recipe)
For NADPH-regenerating system:
Glucose 6-phosphate dehydrogenase (see recipe)
Regenerating system cofactor mixture (see recipe)
Reagents for stopping reactions (Table 4.17.7)
Chromatography buffers and solutions
Thermomixer or shaking water bath, 37°C
1.5-ml microcentrifuge tubes
Additional reagents and equipment for HPLC and analysis (*UNIT 4.4*)

1. Turn on water bath or Thermomixer and warm to 37°C.
2. Thaw microsomes by gently warming by hand. Place on ice immediately upon thawing.

   Keep the protein preparations on ice when not in use.

3. Add the following reagents, in order, to a 1.5-ml microcentrifuge tube for a final reaction volume of 1 ml. Minimally, run samples in duplicate; include more replicates depending on reproducibility.

   a. For microsomal incubations, add:

      814 µl H_2O (804 µl with regenerating system)
      100 µl 1 M potassium phosphate buffer, pH 7.4
      75 µl 20 mg/ml microsomes
      (10 µl 100× glucose-6-phosphate dehydrogenase, with regenerating system)
      1 µl 1000× xenobiotic substrate solution.

   b. For recombinant P450 incubations, add:

      635 µl H_2O (625 µl with regenerating system)
      100 µl 1 M potassium phosphate buffer, pH 7.4
      254 µl 5.83 mg/ml recombinant P450 mixture
      (10 µl 100× glucose-6-phosphate dehydrogenase, with regenerating system)
      1 µl 1000× xenobiotic substrate solution.

   c. For recombinant control incubations, add:

      593 µl H_2O (583 µl with regenerating system)
      100 µl 1 M potassium phosphate buffer, pH 7.4
      296 µl 5 mg/ml control recombinant microsomes
      (10 µl 100× glucose-6-phosphate dehydrogenase, with regenerating system)
      1 µl 1000× xenobiotic substrate solution.

      If the enzymatic activity of the recombinant P450 mixture is in doubt, confirm the viability of the mixture with a P450 probe substrate (positive control). Methods for traditional HPLC-based assays in addition to fluorescent probe substrate assays may be found in Donato et al. (2004). More fluorescent P450 methods may be found at http://www.gentest.com (website for BD Biosciences).

4. Perform Basic Protocol 1, steps 4 to 9. Initiate reactions with cofactor (or buffer, for controls) and incubate the samples. Collect multiple time-point samples if desired. Follow with termination of reactions, sample processing, and analysis.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Glucose 6-phosphate dehydrogenase (50 U/ml)

Dissolve 250 U glucose 6-phosphate dehydrogenase in 5 ml of 0.1 M potassium phosphate buffer, pH 7.4 (see recipe). Freeze in 0.2-ml aliquots. Store up to 1 year at −20°C.

The premeasured vials of lyophilized glucose 6-phosphate dehydrogenase are convenient since the enzyme powder is electrostatic and difficult to weigh accurately. Purchase vials containing a known amount (units) of dehydrogenase.

NADPH-regenerating system cofactor mixture, 100×

Combine the following:
765 mg $NADP^+$ (mol. wt. 765.4)
238 mg $MgCl_2$ (mol. wt. 95.21)

continued

705 mg glucose 6-phosphate (mol. wt. 282.1)
5 ml 0.1 M potassium phosphate, pH 7.4 (see recipe for 1 M)
Freeze in 0.2-ml aliquots
Store up to 1 year at −20°C

Nicotinamide adenine dinucleotide phosphate (reduced NADPH), 0.2 M

Dissolve 166.7 mg reduced NADPH (mol. wt. 833.4) into 1 ml of 0.1 M potassium phosphate buffer, pH 7.4 (see recipe for 1 M). Prepare fresh on each experimental day and keep on ice except during use.

Nicotinamide adenine dinucleotide (reduced NADH), 0.2 M

Dissolve 148.3 mg reduced NADH (mol. wt. 741.6) into 1 ml of 0.1 M potassium phosphate buffer, pH 7.4 (see recipe for 1 M). Prepare fresh on each experimental day and keep on ice except during use.

Potassium phosphate buffer, 1 M (pH 7.4)

Prepare a 1 M solution of monobasic potassium phosphate by adding 136.1 g anhydrous KH_2PO_4 to 1 liter water. Prepare a 1 M solution of dibasic potassium phosphate by adding 174.2 g anhydrous K_2HPO_4 to 1 liter water. Combine 1 part monobasic with 3 parts dibasic and check the pH. Continue to mix monobasic and dibasic buffers to pH 7.4. Store up to 6 months at 4°C.

To make 0.1 M potassium phosphate buffer, pH 7.4:

Dilute 10 ml of 1 M potassium phosphate buffer, pH 7.4, into 90 ml of water. Check pH and readjust to pH 7.4 with concentrated acid (H_3PO_4 or HCl) or base (KOH or NaOH) if necessary. Store up to 6 months at 4°C.

Potassium phosphate buffers, 1 M (pH 5.0, 5.5, 6.0, 6.5, 7.0)

Prepare a 1 M solution of monobasic potassium phosphate by adding 136.1 g anhydrous KH_2PO_4 to 1 liter water. Prepare a 1 M solution of dibasic potassium phosphate by adding 174.2 g anhydrous K_2HPO_4 to 1 liter H_2O. Combine 1 part monobasic with 3 parts dibasic and check the pH. Continue to mix monobasic and dibasic buffers as needed to the desired pH value (5.0, 5.5, 6.0, 6.5, or 7.0). Prepare ∼100 ml at each pH. Store up to 6 months at 4°C.

For brief periods (up to 1 week), store buffers at room temperature. To prevent microbial contamination, buffers may be sterile-filtered prior to storage. For example, 1 liter of buffer can be sterile-filtered into four 250-ml filter units to protect the integrity of the bulk buffer stock. Recommended filtering units include vacuum filter/storage systems with 0.22-μm cellulose acetate filters (Corning and Nalgene).

Xenobiotic substrate or inhibitor solution, 1000×

Prepare in aqueous solution if possible. Minimize the amount of organic solvent in reaction mixtures; for example, if the substrate or inhibitor is soluble only in DMSO, prepare the solution as concentrated as possible.

A convenient stock concentration is 1000× the final test concentration. If initial test concentrations are 1, 10, and 100 μM, then the corresponding stock solutions should be 1, 10, and 100 mM, respectively. Dilute the substrate or inhibitor 1:1000 by adding 1 μl per 1 ml incubation.

The basic protocols call for the addition of 1 μl of 1000× substrate or inhibitor stock per 1 ml incubation. If desired, adjust the concentration of stock solution to avoid pipetting this small volume, as long as the final concentration of organic solvent is kept to a minimum (e.g., 10 μl of 100× substrate). Include controls with organic solvent to ensure that the solvent alone is not inhibitory. With radiolabeled substrates, ensure that the correct amount of radioactivity is included in incubations. If necessary, combine radiolabeled and unradiolabeled (cold) substrate to reach the proper final substrate concentration and to detect metabolites with sufficient radiochemical signal.

COMMENTARY

Background Information

Carbonyl reducing enzymes catalyze the reversible phase I oxidoreduction of ketone and aldehyde moieties of xenobiotic and endogenous substrates to their respective alcohol moieties. Catalysis by carbonyl reducing enzymes is accomplished via two-electron hydride transfer from the nicotinamide cofactor to the carbonyl carbon. In detoxification, carbonyl reduction facilitates xenobiotic elimination by generating hydroxyl metabolites that become substrates of conjugative enzymes and/or undergo excretion. Carbonyl reducing enzymes are widely distributed in tissues including liver, lung, brain, heart, kidney, spleen, testis, and blood. Both soluble and membrane-bound forms exist. Some endogenous substrates are steroid hormones, glucocorticoids, monosaccharides, prostaglandins, and fatty acids. Carbonyl reducing enzymes are known more for their physiological roles than their roles in xenobiotic metabolism. Some examples of xenobiotic substrates include NSAIDS, quinones, anthracycline antiobiotics, fenofibrate, haloperidol, menadione, metyrapone, naltrexone, warfarin, and tobacco-related nitrosamines. General review references for carbonyl reducing enzymes include: Maser (1995), Forrest and Gonzales (2000), Oppermann and Maser (2000), and Rosemond and Walsh (2004).

There are more than 60 different isoforms of carbonyl reducing enzymes in humans. These enzymes can be grouped according to gene sequence, active site components, enzyme mechanism, and three-dimensional structural features of the cofactor binding site (for an overview, see Oppermann and Maser, 2000). The four superfamilies of carbonyl reducing enzymes are: medium-chain dehydrogenases/reductases (including alcohol dehydrogenases), aldo-keto reductases, quinone reductases, and short-chain dehydrogenases/reductases (including microsomal and cytosolic carbonyl reductases).

With the in vitro experiments described in this unit, the number of carbonyl reducing enzymes contributing to metabolism of a particular xenobiotic substrate can be condensed to an enzyme family or families. These experiments exploit the differences in subcellular localization, cofactor dependence, and susceptibility to chemical inhibitors among carbonyl reducing enzymes, and are conducted with subcellular fractions available commercially or prepared experimentally.

Examples of experimental methods for carbonyl reducing enzymes taken from published literature are given in Table 4.17.7, including references for purification and recombinant protein expression. Historically, liver has been the major source of carbonyl reducing enzymes, particularly the cytosolic aldo-keto reductases and carbonyl reductases. The major microsomal xenobiotic-metabolizing carbonyl reductase, 11β-HSD, has been the subject of some recent investigations (Bannenberg et al., 2003; Maser et al., 2003; Wsól et al., 2004).

Procedures for investigating carbonyl reducing enzymes typically include spectrophotometry, TLC, and HPLC. Spectrophotometric methods (monitoring the disappearance of absorbance at 340 nm due to consumption of NADPH or NADH) have been employed to follow cofactor-dependent carbonyl reducing activity during protein purification or subcellular fraction preparation. TLC has been utilized for separation and identification of carbonyl reduced products. HPLC with radiochemical, UV, or mass spectrometric detection is the most frequently cited analytical approach. The pesticide metyrapone can serve as a positive control (probe) substrate in an HPLC-based assay for carbonyl reduction. Metyrapone undergoes ketone reduction to metyrapol by carbonyl reducing enzymes of cytosol and microsomes. Incubation conditions and HPLC analytical methods for metyrapone have been published (Maser et al., 1991; Maser and Bannenberg, 1994; Bannenberg et al., 2003).

The experiments described in this unit cover all of the currently known carbonyl reducing enzymes of human liver. Subcellular fraction-cofactor combinations not included in this unit can be tested in case the xenobiotic is a superior substrate for an unidentified enzyme system. For example, no carbonyl reducing enzymes of human liver mitochondria have been described in the published literature, although a mitochondrial NADPH-dependent carbonyl reducing enzyme of mouse, guinea pig, and pig lung has been described (Forrest and Gonzales, 2000). New carbonyl reducing enzymes remain to be discovered; so, for certain substrates, it may be worthwhile to test combinations that cover all of the possibilities in vitro.

Table 4.17.7 A Sampling of Methods for Human Liver Carbonyl Reducing Enzymes from Published Literature[a]

Substrate (K_m)[b] (Ref.)	Experimental details[c]	Comments	Analysis
Acetohexamide, befunelol, 4-benzoylpyridine, daunorubicin, ethacrynic acid, haloperidol, ketoprofen, loxoprofen, metyrapone, naloxone, naltrexone, 4-nitrobenzaldehyde (Ohara et al., 1995)	100 mM potassium phosphate, pH 6.5 0.04 mg/ml enzyme (purified AKR1A1, AKR1C1, AKR1C2, AKR1C4, CR) NADPH-regenerating system 1 mM substrate 2 ml/sample, 1 hr, 30°C Stop: 1 ml 1 M sodium carbonate, pH 10.0 Organic extraction	—	TLC
Benfluron (Skálová et al., 2002)	100 mM sodium phosphate, pH 7.4 3 mg/ml microsomes or cytosol 2 mM NADPH-NADH mixture 1.5 mM benfluron 0.3 ml/sample, 30 min Stop: 0.1 ml 26% aqueous ammonia solution or 1 M NaOH, ethyl acetate extraction.	Anaerobic conditions investigated (argon)	HPLC, TLC
Benfluron (Skálová et al., 2002)	100 mM sodium phosphate, pH 7.4 71 μg/ml purified 11β-HSD; or 47 μg/ml purified CR NADPH-regenerating system 0.2 mM benfluron 0.05 ml/sample, 30 min Stop: cool to 0°C, 0.02 ml 26% aqueous ammonia solution, ethyl acetate extraction	—	HPLC, TLC
Cortisone (4 μM); ketoprofen (20 μM); metyrapone (370 μM)[d] (Hult et al., 2001)	15 mM Tris·Cl, pH 7.4 10–2000 μg microsomes, S9[e] or purified recombinant 11β-HSD 0.5 mM NADPH or regenerating system 2–2500 μM substrate, 10–60 min Stop: 3× vol acetonitrile	Reductive enzymatic activity of recombinant 11β-HSD not maintained during purification	HPLC
Cortisone (14 μM) (Maser et al., 2002)	10 mM sodium phosphate, pH 7.4 2–5 mg/ml purified 11β-HSD NADPH-regenerating system 2–75 μM substrate 0.05 ml/sample, 3 hr Stop: 0.15 ml acetonitrile	Reverse reaction investigated (pH 9.0, $NADP^+$)	HPLC
Doxorubicin (0.28 mM); daunorubicin (0.31 mM) (Loveless et al., 1978)	20 mM potassium phosphate, pH 7.4 1–2 mg/ml protein 1 mM NADPH 0.05–1 mM substrate 0.5 ml/sample, 15 min Stop: equal volume of ice-cold isopropanol, then ammonium sulfate to saturation	—	TLC

Table 4.17.7 A Sampling of Methods for Human Liver Carbonyl Reducing Enzymes from Published Literature[a], *continued*

Substrate (K_m)[b] (Ref.)	Experimental details[c]	Comments	Analysis
E-10-oxo-nortriptyline *Z*-10-oxo-nortriptyline (R)- and (S)-ketotifen For AKR1C1 and 1C2, K_m values: 2.6–53 μM (Breyer-Pfaff and Nill, 2000)	100 mM Tris·Cl, pH 7.4, 8 mM $MgCl_2$, 25 mM KCl 0.6–12 μg purified AKR1C1, AKR1C2, or CR NADPH-regenerating system 6–10 substrate concentrations (5× below to 5× above K_m) 0.36 ml/sample, 4–20 min Stop: 0.04 ml 2 N perchloric acid, put on ice	Reverse reactions and stereochemistry examined. Enzyme isolation described	HPLC
Rofecoxib (100–200 μM, cytosol) (Slaughter et al., 2003)	100 mM sodium phosphate, pH 7.4, 3 mM $MgCl_2$ 5–6 mg/ml S9 or cytosol 1 mM nicotinamide cofactor (10 mM malate, cytosol) 100 μM substrate 0.5 ml/sample, up to 24 hr Stop: 2:1 acetonitrile:methanol (3× volume)	Complex metabolic pathways; malic acid-based regenerating system for cytosol; NAD^+-regenerating system. Reverse reactions investigated	HPLC
Warfarin (Hermans and Thijssen, 1989)	20 mM Tris·Cl, pH 7.4, 150 mM KCl 6 mg/ml cytosol or microsomes NADPH-regenerating system 0.2 mM substrate 0.36 ml/sample, 10 min Stop: 0.5 ml ice-cold acetonitrile (Stop solution contained internal standard, acenocoumarol), organic extraction	Stereochemistry examined	HPLC
Warfarin (1.55 mM) (Moreland and Hewick, 1975)	100 mM potassium phosphate, pH 7.4 3–6 mg/ml cytosol 1.3 mM substrate (0.13–2.08 mM) NADPH-regenerating system 2.5 ml/sample, 50 min Stop: 0.5 vol 3 N HCl, organic extraction	—	TLC
Wortmannin (119 μM) (Holleran et al., 2004)	100 mM potassium phosphate, pH 6.0 1:20 dilution of purified recombinant CR 0–300 μM wortmannin 1.5–3 mM nicotinamde cofactor, 25 μM FAD, 0.1% BSA 0.2 ml/sample, 5 min Stop: 5× volume ethyl acetate, organic extraction	Expression and purification of human CR	HPLC

[a] Abbreviations: AKR, aldo-keto reductase; CR, carbonyl reductase; 11β-HSD, 11β-hydroxysteroid dehydrogenase; 3,7-DMX, 3,7-dimethyl-1-(5-oxohexyl)-xanthine; NNK, 4-methylnitrosamino-1-(3-pyridyl)-1-butanone.

[b] Most substrates are available from standard commercial sources, such as Sigma-Aldrich. Some nonstandard sources for other chemicals are: NNK, Midwest Research Institute; (R)-warfarin, Ultrafine Chemicals; timiperone, Pharm Chemical Shanghai/Lansheng. Commercial sources for benfluron and nortryptyline metabolites are not known.

[c] Incubations were performed at 37°C unless indicated otherwise.

[d] The K_m values for cortisone, ketoprofen, and metyrapone were determined with yeast S9 or microsomal fractions containing recombinant human 11β-HSD (Hult et al., 2001).

[e] S9 is a subcellular fraction preparation (supernatant) from a 9000 × *g* centrifugation of homogenized liver tissue. The S9 fraction contains microsomes and cytosol.

Table 4.17.8 Troubleshooting Guide to Analysis of Carbonyl Reductase Enzymes

Problem	Possible cause	Solution
No or low turnover	Incubation time too short	Extend incubation time
	Cofactor depleted	Utilize regenerating system; prepare fresh solutions of NADH, NADPH daily
	Suboptimal pH	Test other pH
	Concentration of organic solvent too high	Reduce amount of solvent to <0.2% if possible, or try a different solvent
	Xenobiotic test compound precipitating out of solution	Start at lower concentration; add compound after adding protein to samples
	Incubation time too long (products either precipitate out of solution or are unstable)	Shorten incubation time; monitor stability of parent, products
	Conditions unsuitable	Test alternate subcellular fraction/cofactor combinations; test known substrate (i.e., positive control) to ensure viability of the test system
	Too vigorous mixing of samples	No vortexing; mix gently by hand; reduce Thermomixer mixing speed
Inconsistent results	Substrate insoluble	Check samples closely for precipitated test compound
	Inefficient sample processing	Revise sample processing methods
No detection (radiolabeled substrate)	Error in calculation	Review calculations
	Inefficient sample processing	Revise sample processing methods

Critical Parameters and Troubleshooting

It is imperative to determine the optimal conditions for performing the incubations, for processing the samples to achieve maximal recoveries, and for analyzing the products of reactions. Guidance for optimization of experimental parameters is incorporated in the Basic Protocols. A troubleshooting guide is provided in Table 4.17.8.

Anticipated Results

The results may be easily interpreted in the case of a single carbonyl reducing enzyme mediating the metabolism of a xenobiotic. As an illustration: ketone reduction occurs only in cytosol with NADPH, is inhibited by flufenamic acid and phenolphthalein, is not inhibited by menadione, and has an optimal pH 6.0. These data clearly implicate aldo-keto reductases and rule out other enzymes.

A more likely outcome is that the xenobiotic is metabolized by multiple enzymes. These studies are complicated by the fact that subcellular fractions are crude enzyme sources, unlike purified or recombinant preparations. But, even with crude fractions, it is possible to eliminate some of the potential enzymes contributing to metabolism with the experiments described in this unit.

The investigation of carbonyl reducing enzymes may be carried a step further by estimating kinetic parameters. For example, an apparent K_m value of 2 μM (cytosol) versus 1 mM (microsomes) indicates that the xenobiotic is a much better substrate for cytosolic than microsomal carbonyl reducing enzymes. Chemical inhibition experiments may be conducted at the substrate concentration approximating the apparent K_m value. The relative potency of chemical inhibitors can help to further assess the roles of different carbonyl reducing enzymes. Finally, a pH dependence study and characterization of cytochrome P450 involvement help to complete the overall metabolic picture.

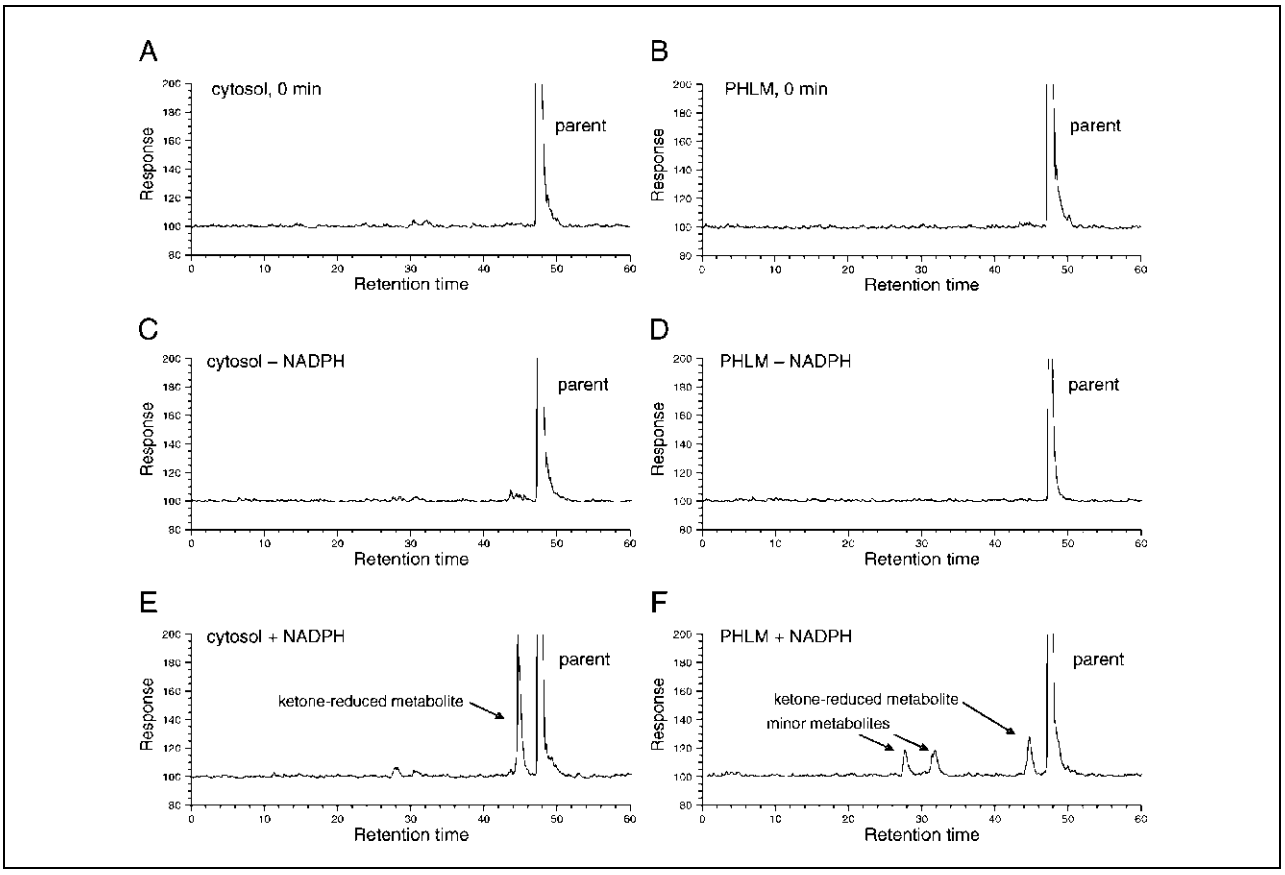

Figure 4.17.1 Representative radiochemical profiles from experiments with human liver subcellular fractions. Reaction mixtures included 100 mM potassium phosphate buffer, pH 7.4, 1 mg/ml pooled human liver subcellular fractions, and 2 μM [^{14}C]-radiolabeled substrate (parent). Reactions were initiated with 2 mM NADPH cofactor or buffer (control), followed by incubation for 30 min at 37°C and analysis by HPLC with radiochemical detection. Results from experiments with cytosol are shown in **A, C**, and **E**; results with microsomes (PHLM) are shown in **B, D**, and **F**. (**A,B,C,D**) No metabolism was detected in the control samples (0-min time point, no-cofactor control). In the presence of NADPH, the ketone-reduced metabolite (identity confirmed by mass spectrometry) was the major product in cytosol and microsomes (**E** and **F**). Thus, the xenobiotic is a substrate of NAPDH-dependent carbonyl reducing enzymes of both subcellular fractions. Some additional minor metabolites were detected in microsomal samples (**F**).

Examples of results illustrate how, in practice, the different methods generate information about carbonyl reduction pathways (Figs. 4.17.1 to 4.17.4). In these examples, the substrate is a [^{14}C]-radiolabeled benzophenone derivative in which reduction of the diphenyl ketone moiety is the major route of metabolism. The xenobiotic is a substrate of cytosolic and microsomal carbonyl reducing enzymes, and metabolites are analyzed by HPLC with radiochemical detection. Some representative radiochemical profiles comparing metabolism in cytosol and microsomes are shown in Figure 4.17.1. Some results with inhibitors of carbonyl reducing enzymes are shown in Figures 4.17.2A (cytosol) and 4.17.2B (microsomes). Figure 4.17.3 shows a pH-dependence study, and Figure 4.17.4 shows a comparison of metabolism in pooled human liver microsomes and recombinant P450 enzymes.

Time Considerations

Allow time for ordering (1 to 2 hr) and obtaining (up to 1 week) reagents. Prepare buffers and stock solutions of substrate and inhibitors ahead of time (1 to 2 days).

Gather supplies for HPLC analysis, such as the analytical column and solvents or buffer components. Set up the HPLC instrument ahead of time. Make sure the column is ready for samples and that the separation conditions are appropriate. Allow 1 to 3 days or more depending on the availability of a chromatographic method. References are provided at the end of this section for HPLC analytical method development (see Key References).

For a substrate that is radiolabeled, allow extra time for calculating stock concentrations, amounts for HPLC analysis and radiochemical detection, and amounts deposited in waste. When calculating the correct amount for HPLC analysis, remember to incorporate

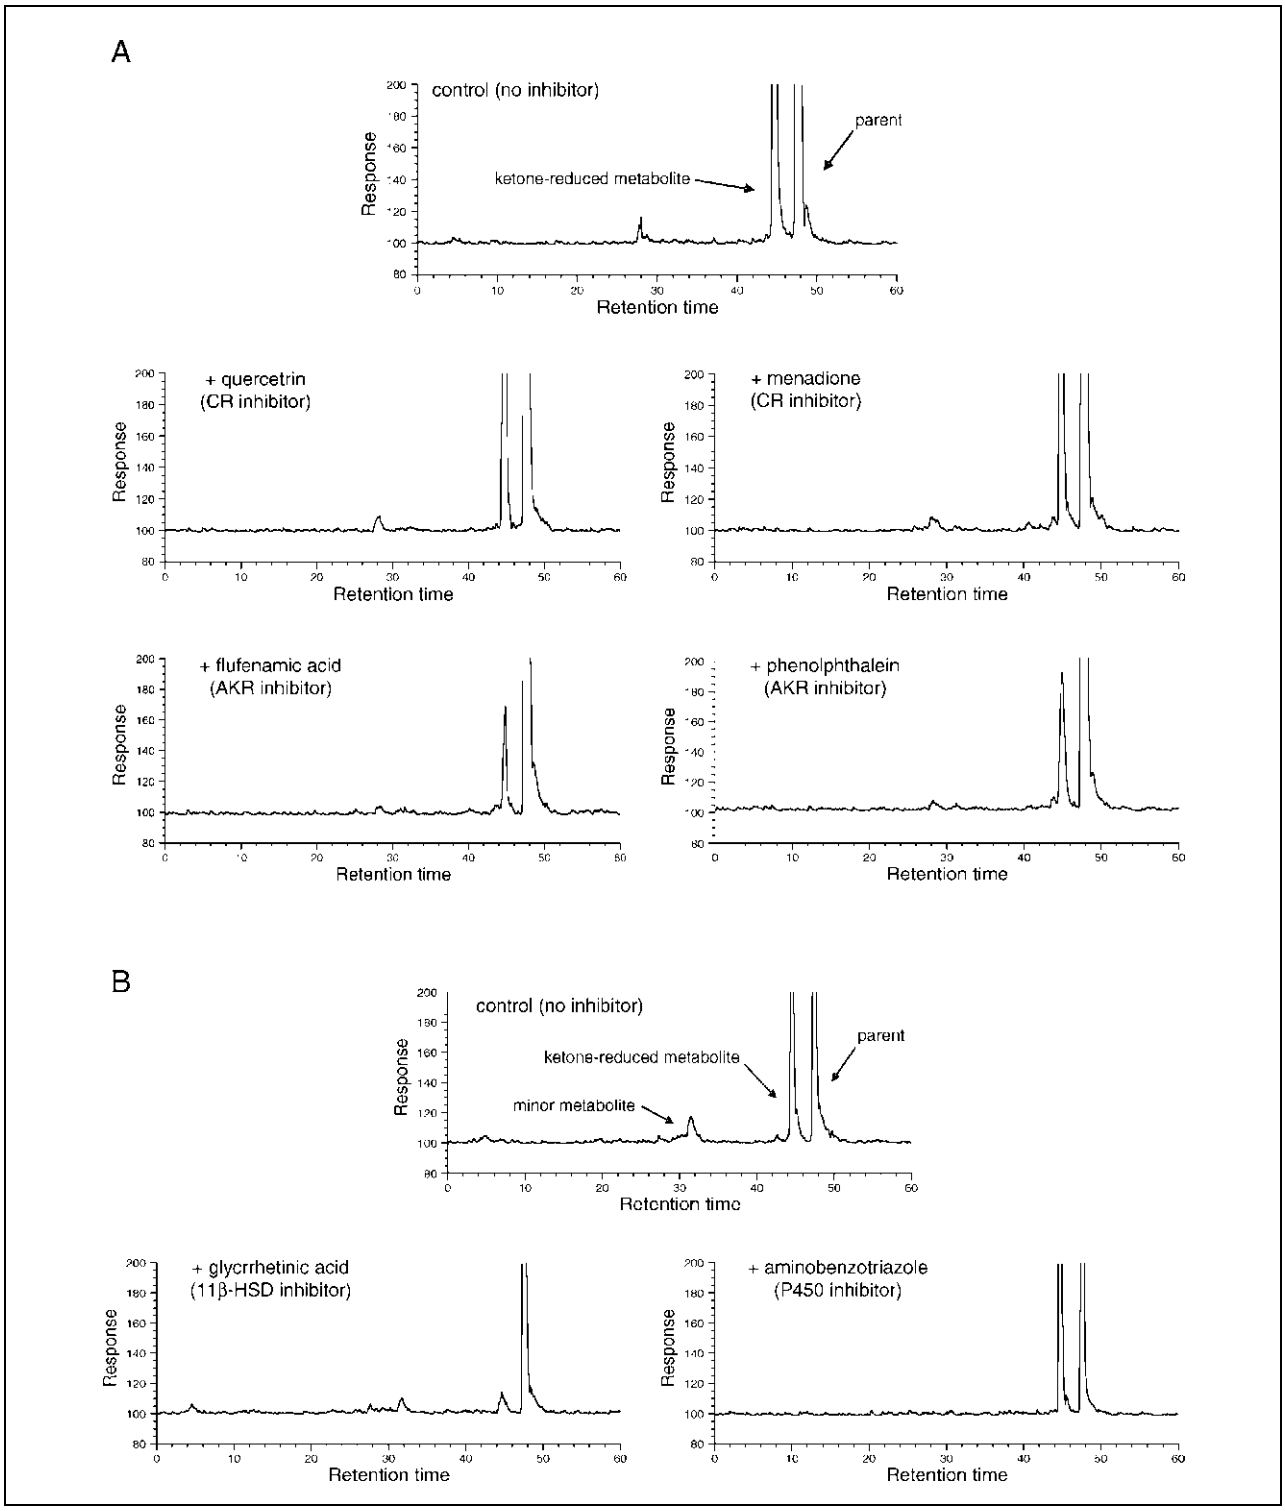

Figure 4.17.2 Legend at right.

Figure 4.17.2 *(at left)* (**A**) Representative radiochemical profiles from experiements with inhibitors of cytosolic carbonyl reducing enzymes. Reaction mixtures included 100 mM potassium phosphate buffer, pH 6.0, 1 mg/ml pooled human liver cytosol, 100 μM inhibitor, and 2 μM [^{14}C]-radiolabeled substrate (parent). Control samples without inhibitor contained vehicle only (<0.2% solvent). Reactions were initiated with NADPH-regenerating system, followed by incubation for 4 hr at 37°C and analysis by HPLC with radiochemical detection. The inhibitors selected for these experiments were: quercetrin and menadione (targeting carbonyl reductase, CR); flufenamic acid and phenolphthalein (targeting aldo-keto reductases, AKR). Ketone reduction was impacted more by the AKR probes (70% to 80% inhibition, calculated from peak areas) than the CR probes (15% to 20% inhibition), suggesting that the xenobiotic is a better substrate of AKRs than CRs. (**B**) Representative radiochemical profiles from experiments with inhibitors of microsomal carbonyl reducing enzymes. Reaction mixtures included 100 mM potassium phosphate buffer, pH 7.4, 1 mg/ml pooled human liver microsomes, and 2 μM [^{14}C]-radiolabeled substrate (parent). Control samples without inhibitor contained vehicle only (<0.2% solvent). Reactions were initiated with NADPH-regenerating system, followed by incubation for 2 hr at 37°C and analysis by HPLC with radiochemical detection. The inhibitors selected for these experiments were: 18β-glycyrrhetinic acid (targeting 11β-hydroxysteroid dehydrogenase, 11β- HSD) and aminobenzotriazole (targeting cytochrome P450). Only a trace amount of ketone-reduced metabolite formed in the presence of 10 μM 18β-glycyrrhetinic acid, implicating 11β-HSD in metabolism. In the presence of the non-specific P450 inhibitor, 1 mM ABT, minor metabolites were not detected, and there was an increase (+25%) in the amount of ketone-reduced metabolite compared to vehicle controls (calculated from peak areas). One interpretation is that ABT inhibited the formation of minor metabolites, allowing the carbonyl reduction pathway to predominate.

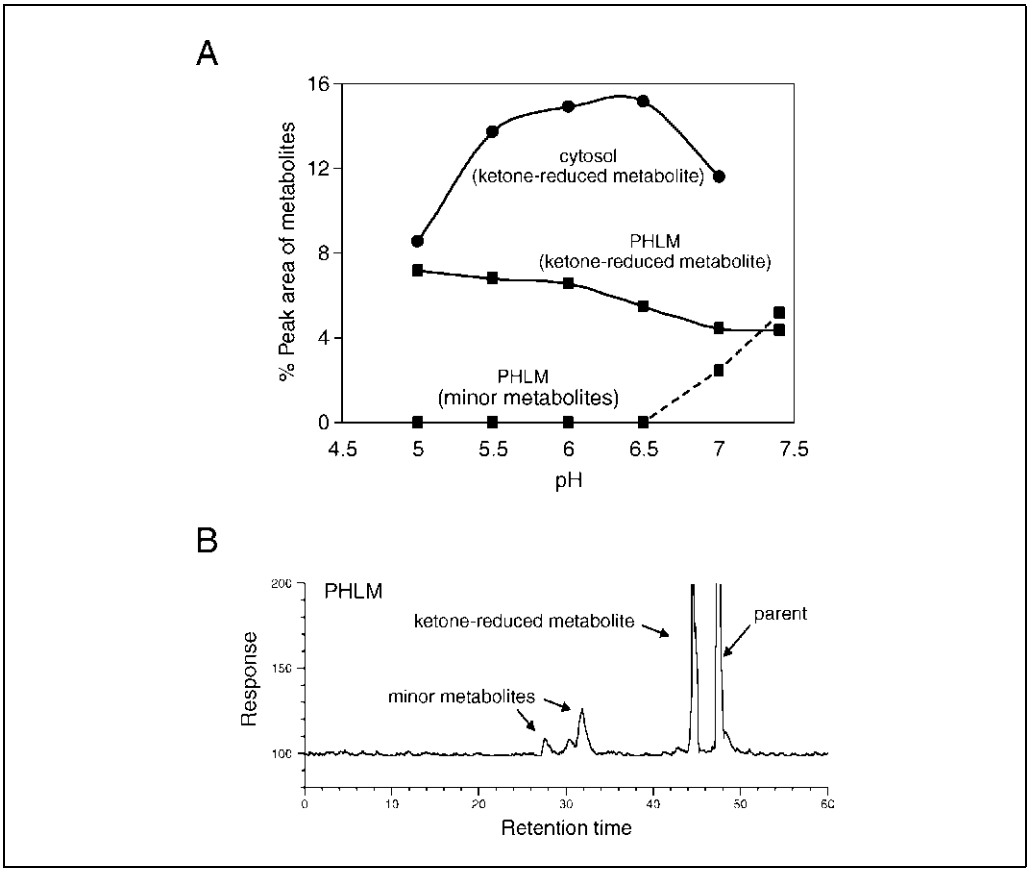

Figure 4.17.3 pH dependence of metabolism in cytosol and microsomes. Reaction mixtures contained 100 mM potassium phosphate buffer, pH 5.0 to 7.4, 1 mg/ml pooled human liver cytosol or microsomes, and 1 μM [^{14}C]-radiolabeled substrate (parent). Reactions were initiated with 2 mM NADPH, followed by incubation for 30 min at 37°C and analysis by HPLC with radiochemical detection. (**A**) Results from the pH dependence study. (**B**) A representative radiochemical profile of microsomal metabolites. To produce the plot in **A**, the % peak areas were calculated: (metabolite peak area/total peak area in chromatogram) × 100. The ketone-reduced product formed preferentially at pH 5.5 to 6.5, consistent with carbonyl reducing enzymes. Minor metabolites formed only in microsomes and at pH >6.5, consistent with P450 enzymes.

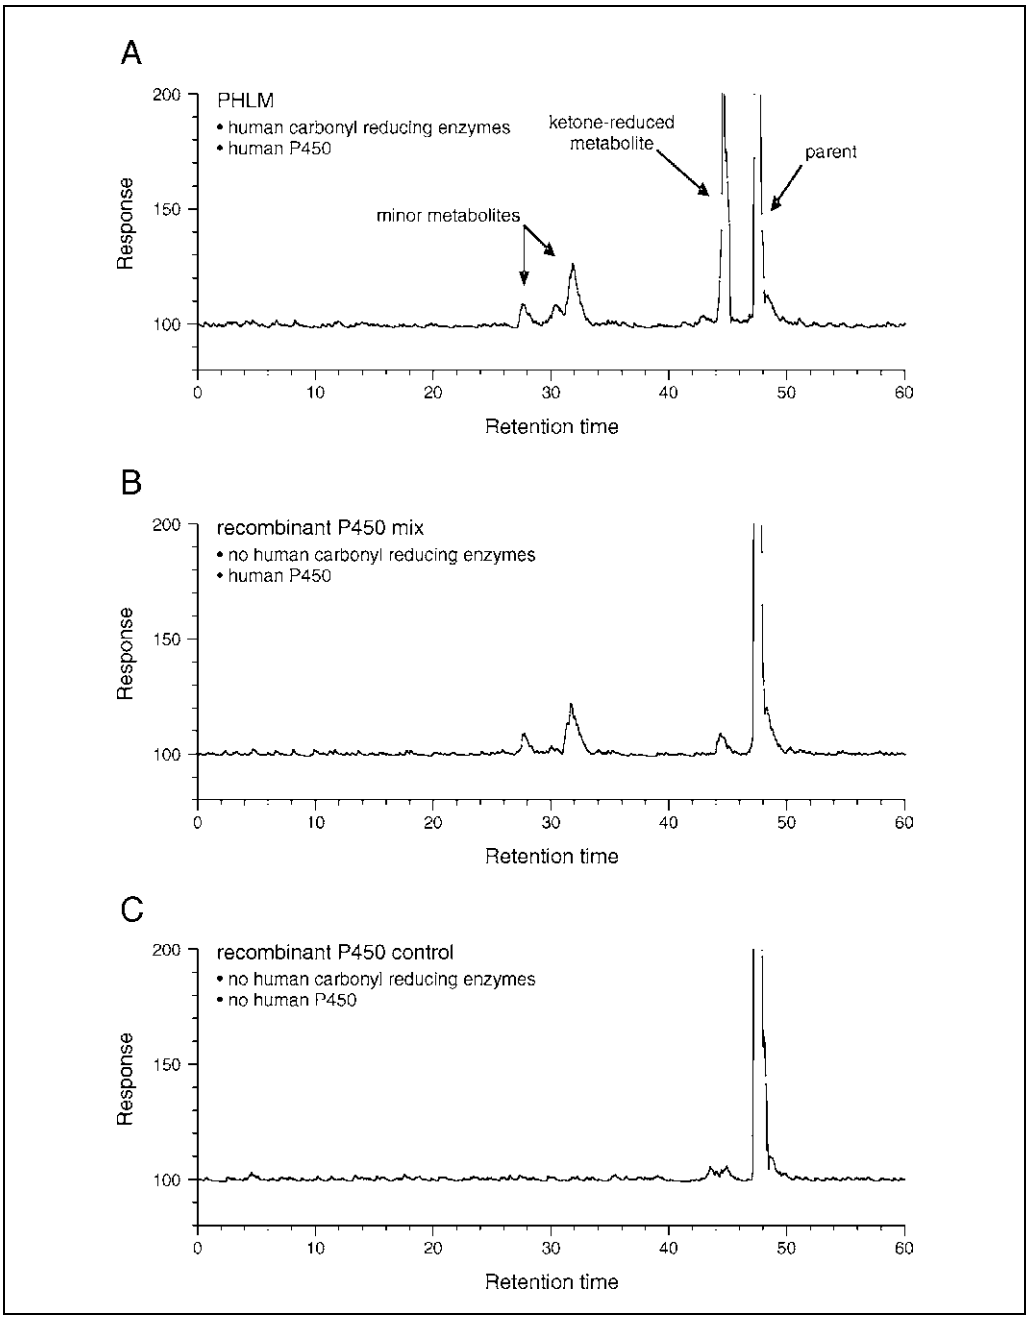

Figure 4.17.4 Representative radiochemical profiles from experiments with pooled human liver microsomes and recombinant cytochrome P450 preparations. Reaction mixtures included 100 mM potassium phosphate buffer, pH 7.4, 1.5 mg/ml protein, and 1 μM [^{14}C]-radiolabeled substrate (parent). Reactions were initiated with NADPH-regenerating system, followed by incubation for 2 hr at 37°C and analysis by HPLC with radiochemical detection. (**A**) In pooled human liver microsomes (PHLM), the ketone-reduced metabolite and minor metabolites formed (peak labels). (**B**) The minor metabolites were also detected in incubations with the recombinant P450 mixture (pool of heterologously expressed P450 enzymes: 1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, 3A4). (**C**) None of the metabolites were detected in incubations with recombinant control microsomes (microsomes lacking native human P450 activity, prepared from insect cells infected with wild-type virus). These results implicate P450 enzymes in the formation of the minor metabolites and indicate that the non-P450 enzyme(s) responsible for ketone reduction reside in pooled human liver microsomes.

volume changes that occur upon stopping reactions and processing samples.

After the initial preparation of HPLC equipment, buffers, protein reagents, inhibitor, and substrate stock solutions, the time for setting up assays is minimal (allow ~1 hr for thawing enzymes, preparing cofactor solutions, and labeling tubes for samples and tubes for stopping reactions).

In preliminary experiments, minimize the number of samples until analytical techniques and sample processing methods are in place. Increase the number of samples as appropriate; for example, a convenient experiment size for 1 day of incubations (with short incubation times, <30 min), sample processing (with simple procedures), preparation for analysis, and HPLC instrument setup can range from 30 to 45 samples. In experiments with long incubation times (hours) or elaborate sample processing steps, plan for a smaller number of samples. Preferably, analyze the samples as soon as they are prepared. Store (i.e., freeze or refrigerate) samples only if analytes are stable in the storage conditions. Confirm the stability by directly comparing the contents of freshly prepared with stored samples. Ensure that the contents of stored samples are representative of the contents of freshly-prepared samples.

Acknowledgments

The author gratefully acknowledges John S. Walsh for advice and direction in conducting studies of carbonyl reducing enzymes, and Cosette Serabjit-Singh for critical review of the manuscript.

CHAPTER 5
Toxicokinetics

INTRODUCTION

Toxicokinetics is a specialized area of toxicology that blends pharmacokinetic procedures with those of toxicology. It involves understanding the processes that govern the absorption, distribution, metabolism, and excretion of chemicals by the body. In general, these processes can be referred to as input (absorption), translocation (distribution), and output (metabolism, excretion). The rates of each process can be derived and used to describe in mathematical terms the time course for chemical and metabolite disposition in the body. Each process is governed by a number of physicochemical, biochemical, and physiological factors that profoundly affect how the body handles a particular chemical. For example, the state of hydration of the skin is an important physicochemical factor that influences chemical absorption by that route. Also, metabolic enzymes can have a profound effect on the input and output processes for a chemical. Thus, factors that increase the rate of biotransformation (enzymatic metabolism) of a chemical can profoundly affect input (increased formation of a toxic metabolite) or output (increased detoxification) processes that govern the temporal patterns of response to a particular chemical. These factors include induction and/or inhibition of xenobiotic-metabolizing enzymes, and interindividual variations may result from the presence of polymorphisms in these enzymes. Reduction of adipose tissue mass reduces a storage compartment for lipophilic chemicals and thus can alter their rate of elimination from the body. Since toxicants are frequently present as complex mixtures, the way in which one toxicant can affect the toxicokinetics of another is important and will be considered in subsequent units.

This chapter presents a series of methods for determining rates of absorption, distribution, and elimination of chemicals. In addition, mathematical approaches for determination of toxicokinetic parameters are discussed. As the chapter evolves, more complex modeling approaches will be presented. Since toxicokinetic models provide effective means of extrapolating animal data to the human situation, methods for obtaining human data will be presented. Chapter 4, which focuses on techniques for determining rates and routes of biotransformation of chemicals, should be considered a companion chapter to this one. Such information is critical in understanding chemical toxicity and in comparing animal and human data.

UNIT 5.1 describes an in vitro system for assessing percutaneous absorption of chemicals that can be applied to skin from a variety of animal species, including humans. The system can also provide information on the metabolism of chemicals by the skin.

UNIT 5.2 covers in vivo approaches for measuring absorption through the skin. The basic procedure uses rats, but is applicable to other species; modifications for assessing absorption of volatile compounds are also provided. A second approach presented is a procedure for assessing dermal absorption of chemicals by humans. Discussion of the legal and ethical aspects of the use of human volunteers in such studies is included.

UNIT 5.3 is an introductory unit that provides basic information on the processes that govern pharmacokinetics/toxicokinetics. It provides definitions and formulas that describe

Contributed by I. Glenn Sipes and Ernest Hodgson
Current Protocols in Toxicology (2005) 5.0.1-5.0.2

various output processes.The author stresses the importance of interrelationships among the various physiological and biochemical parameters that ultimately determine plasma half-life, clearance, tissue retention, etc. Important information is presented with respect to the experimental design for toxicokinetic studies as well as complicating factors that need to be considered in the design and analysis of such studies. The unit concludes with data analysis of an example study.

UNIT 5.4 provides a protocol for the establishment and use of the isolated perfused porcine skin flap (IPPSF). The IPPSF is used to measure the rate and extent of absorption of chemicals through skin. It involves an ex vivo preparation with intact anatomical structure and microcirculation. Metabolism of toxicants during transit through the skin can also be measured. Not only can the external environment and internal factors be controlled in this system, but porcine skin is also more closely related, anatomically and physiologically, to human skin than the skin of any other available experimental animal. The IPPSF has proven to be an invaluable model of toxicant uptake by human skin.

UNIT 5.5 describes another method for the measurement of skin penetration of toxicants or other xenobiotics, namely the flow-through diffusion cell system. The present protocol emphasizes porcine skin and thus provides a precise alternative to *UNIT 5.4*, the isolated perfused porcine skin flap (IPPSF). The diffusion cell enables the experimenter to isolate and focus on the role of the stratum corneum and the viable epidermis rather than the complex in vivo-like model represented by the IPPSF. Although porcine skin is utilized because it is the best known surrogate for human skin, this method has also been used for investigations of skin penetration in rodent, humans, and other primates.

UNIT 5.6 on toxicant transport by P-glycoprotein concerns events at the cellular level that are important to toxicokinetics. Transporter proteins are currently of considerable interest and P-glycoprotein is one of the best known. This transporter is widely distributed, generally on the apical side of cells in organs of elimination; it is found in hepatocytes, in enterocytes, in the brush border of proximal tubule cells of the kidney, as well as in other tissues. It brings about the efflux from these cells of many xenobiotics, including therapeutic drugs and many toxicants.

Although collection of urine and bile has been carried out for several decades, it is nevertheless still critically important in toxicokinetic studies. *UNIT 5.7* is particularly timely as it deals with continuous collection of urine and bile from the mouse rather than from the rat or larger mammals normally used. Because the mouse is the animal of choice for genetic manipulation, careful and accurate collection of body fluids is essential to determine toxicokinetic parameters in such genetic constructs as humanized and knockout mice.

I. Glenn Sipes and Ernest Hodgson

Measurement of Bioavailability: Measurement of Absorption Through Skin In Vitro

BASIC PROTOCOL

Measurement of skin absorption is essential for all new drugs intended for skin application (those for use in treating skin conditions and those aimed to penetrate the skin for the treatment of systemic diseases), as well as agrochemicals not intended for direct skin application, but to which there may be accidental skin exposure during occupational use. In studying skin bioavailability, both in vitro and in vivo (*UNIT 5.2*) techniques can be employed. In vitro methodologies have certain advantages over their in vivo counterparts in that they are simpler, faster, more reproducible, and more economical. By employing human skin, in vitro methods reduce the use of animals and overcome the necessity for extrapolation between species. In addition, they allow the study of skin absorption in isolation from systemic events. The use of fresh skin (maintained under conditions that ensure continuous viability of the tissue) provides a barrier that is representative of the in vivo situation. The most valuable in vitro techniques are those employing freshly excised animal or human skin in flow-through diffusion cells, since this ensures that the skin remains metabolically active throughout the course of the experiment, allowing skin absorption and skin metabolism to be studied simultaneously.

This protocol describes one particularly useful in vitro method, the flow-through diffusion-cell skin absorption model (SAM), which can be utilized to investigate the percutaneous absorption of chemicals following topical application. Skin from various species can be employed (e.g., human, rat, mouse, guinea pig, pig), and freshly obtained skin remains metabolically active in the flow-through diffusion cell for ≥24 hr, allowing skin metabolism to be assessed at the same time as skin bioavailability. For accurate assessment of skin absorption and metabolism, it is advisable to use radiolabeled compounds, although unlabeled compounds may be used if a suitably validated analytical technique is available. Either full-thickness skin or thinner sections (isolated epidermis or epidermis plus a little upper dermis) may be used. Following application of the compound to the skin surface for the desired length of time, it is possible to assess uptake into the skin, passage across the skin into the receptor fluid bathing the underside of the tissue, and residual material remaining on the skin surface, enabling a full mass balance to be achieved. A diagram of the diffusion cells (both occluded and unoccluded versions) and a photograph of the SAM system are presented in Figure 5.1.1.

The key to success with this procedure is to prepare the skin adequately prior to placing it in the diffusion cells. This involves removing all subcutaneous fat and tissue carefully. When epidermal membranes or epidermis plus a little dermis are employed, it is advisable to establish the integrity of the membrane prior to absorption studies (for example, by measuring electrical resistivity or the permeation of a marker substance such as tritiated water). It is not necessary to establish the integrity of full-thickness skin, since this tissue is generally not subjected to any potentially damaging treatment prior to experimentation.

CAUTION: Human skin is a biohazard and should be handled with caution. Gloves, goggles, and a face mask should be used throughout. Perform as much of the procedure as possible in a safety cabinet, handling samples with care so as to prevent aerosol generation. Ensure surgical samples are pathogen free. All persons handling human and animal tissue should be vaccinated against hepatitis B virus; other precautions may be required, depending on the source of the skin. Ethical approval for use of human skin should be obtained from the local hospital ethics committee, and patients' consent to donate their skin for research should be obtained.

Contributed by Sharon A.M. Hotchkiss

Current Protocols in Toxicology (1999) 5.1.1-5.1.14

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

Receptor fluid: HHBSS (see recipe) or tissue culture medium
Skin sample (human or animal)
70% and 100% (v/v) ethanol
Enzyme solution (e.g., Dispase, Sigma; optional)

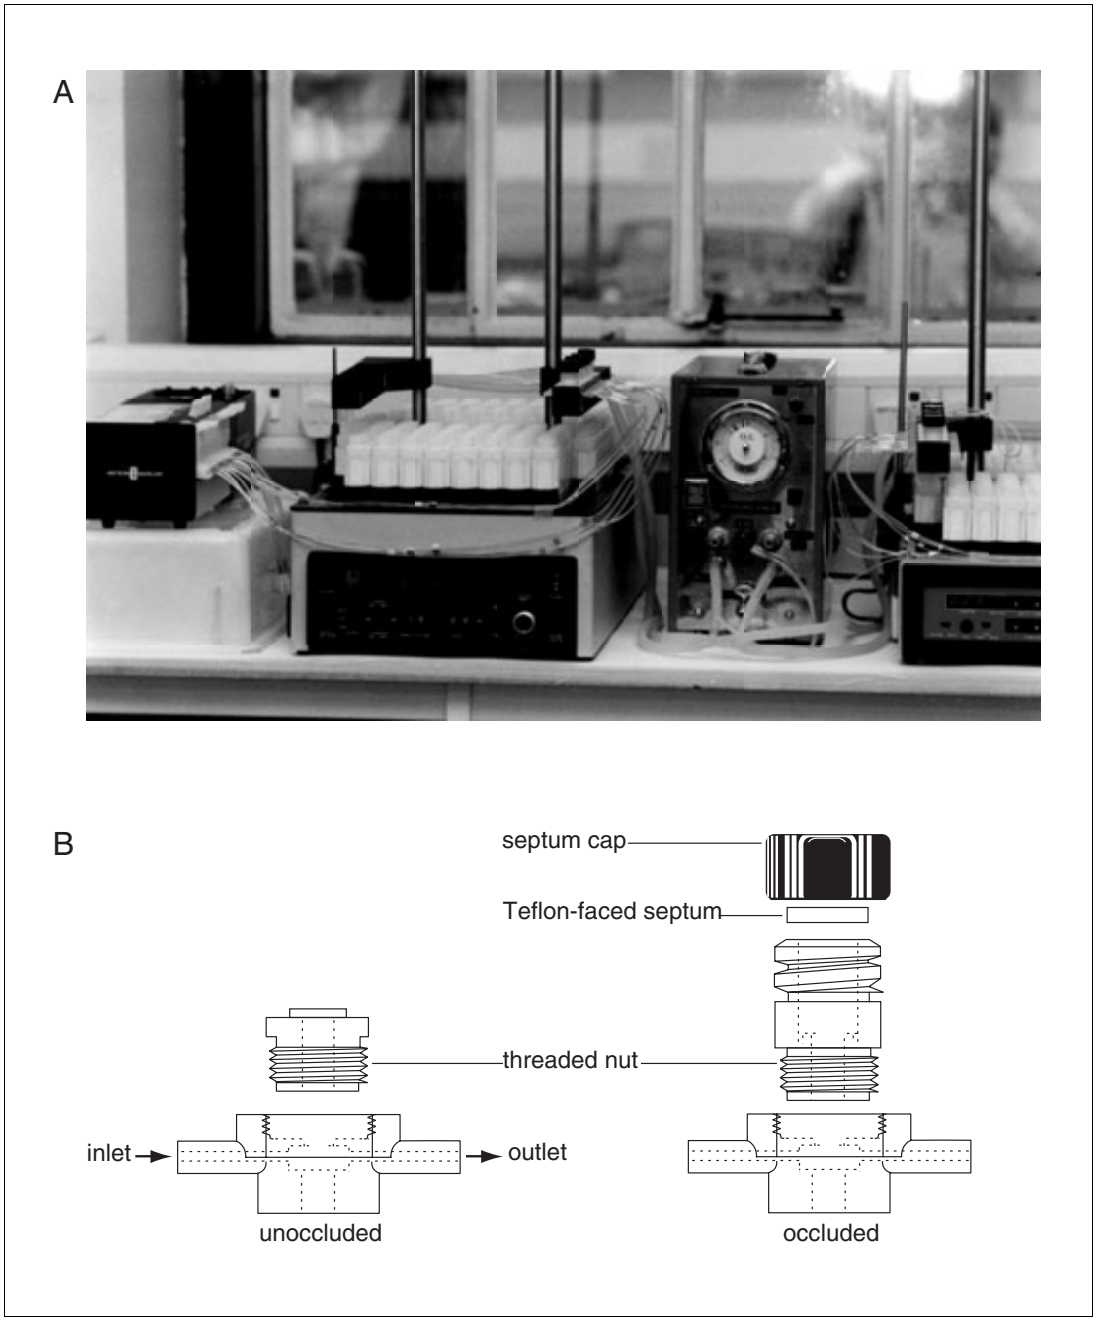

Figure 5.1.1 (**A**) Complete SAM system (1, pump; 2, fraction collector; 3, diffusion cells; 4, water circulator). The second fraction collector (at the right) is not needed. (**B**) Diagrammatic representation of in vitro flow-through diffusion cells, shown for both occluded and unoccluded systems.

Test compound (usually radiolabeled; >98% pure)
Vehicle: e.g., dimethyl sulfoxide (DMSO), ethanol, or water
Scintillation fluid (e.g., Ecoscint, National Diagnostics)
2% (v/v) aqueous soap solution (liquid hand soap, e.g., Labguard microbial hand soap, Day Impex; optional)
Decontamination liquid (e.g., Decon from Decon Laboratories)
Skin digest solution (see recipe)
4.4 M nitric acid (HNO_3)

Skin absorption model (SAM) system (Fig. 5.1.1), including:
Fraction collector (Crown Glass)
Flow-through diffusion cells (Crown Glass)
Receptor fluid reservoir
Heated water circulator set at 36°C (Churchill)
Peristaltic pump (Watson-Marlow)
Teflon septa and caps (for occluded skin experiments; Crown Glass)
20-ml plastic and glass scintillation vials
Heated mantle blocks (Crown Glass)
Vacuum filtration system with 0.45-µm filter
Dermatome (e.g., Padgett electric model; optional)
Surgical tools (scissors, scalpel, forceps)
Rubber mat or cork board
Circular steel cutter with 1.7-cm-diameter circular cutting edge (custom made at the Imperial College School of Medicine)
Hammer
0.63-µm-bore orange-white marprene or polyvinyl chloride (PVC) tubing (Watson-Marlow)
10-µl Hamilton syringe and blunt-ended needle
Gauze swabs cut into ~1.5-cm^2 pieces
70°C shaking water bath
Spreadsheet software (e.g., Microsoft Excel)

Set up equipment

1. Prepare the fraction collector of a SAM system by ensuring that all racks are filled with 20-ml plastic scintillation vials. Set digital settings for the collection interval (e.g., hourly) and the duration of the experiment (e.g., 24 hr).

2. Place seven flow-through diffusion cells of the SAM system in a heated mantle block and ensure that they are correctly oriented. Position the heated mantle block such that all drops of liquid from underneath the cells fall into the scintillation vials.

   Seven or fourteen diffusion cells can be run concurrently. Doubling the procedure requires a second heated mantle block (one for each seven cells).

   The side arms of the diffusion cells are of two types: the biggest aperture is in the inlet arm (which connects via tubing to the pump) and the smallest aperture is in the outlet arm (from which the receptor fluid flows out into the vials). The outlet hole is designed to be smaller to ensure a slight back pressure in the diffusion cell, to aid mixing, and to reduce bubble formation under the skin.

3. Prepare the receptor fluid.

   HHBSS has been determined to be the most acceptable receptor fluid for most purposes. If the compound is highly lipophilic, a solvent (e.g., 50% aqueous ethanol) or supplements (e.g., PEG or BSA) may be required (see Critical Parameters).

HHBSS or a tissue culture medium are essential when skin metabolism is to be studied, as these receptor fluids maintain the skin in a metabolically viable condition for ≥24 hr. An ethanolic receptor fluid will not support skin viability for more than a few minutes.

4. Filter the receptor fluid by vacuum filtration using a 0.45-µm filter (to remove air bubbles) and transfer the liquid to the SAM receptor fluid reservoir.

5. Switch on the heated water circulator of the SAM system (set at 36°C) and allow the heated mantle block and diffusion cells to warm up.

   Setting the water circulator to 36°C results in a skin surface temperature of ~32° to 33°C.

Prepare skin circles

6. Obtain a fresh skin sample, rinse with 70% ethanol, and place in a petri dish on ice.

   Human skin should be obtained as fresh as possible from donors. Typically, large regions of tissue are required (e.g., breast reduction, apronectomy).

   Animal skin (e.g., male Fischer 344 rat, body weight ~175 to 250 g) should be obtained following light anesthesia (with ether or halothane) and appropriate euthanasia (any humane form, e.g., cervical dislocation). The dorsal region should be clipped with animal clippers and removed using a sharp scalpel and scissors, taking care not to nick the skin.

7. Cut away as much subcutaneous tissue as possible with scissors and scalpel. If a thinner membrane is required, remove dermis as appropriate, using a dermatome (for samples consisting of epidermis and upper dermis) or an enzyme solution (for epidermis only).

   For further details, see Critical Parameters discussion of skin membrane.

8. Place the skin epidermal side up on a rubber mat or corkboard.

9. Cut out circles of skin, 1.7 cm in diameter, using a circular steel cutter and hammer. Place each skin circle in a petri dish (epidermal side down), and cover lightly with tissue paper or foil.

10. Place a circle of skin epidermal side up into each diffusion cell body, gently easing the tissue with forceps to allow the tissue to meet the edges of the cell. Secure the threaded nut in each diffusion cell.

Attach receptor fluid reservoir

11. Start the peristaltic pump of the SAM system and prime the tubes from the receptor fluid reservoir. Run the flow at maximum speed (75 ml/hr) for ~1 min and ensure that there are no air bubbles in the lines.

12. Attach a 0.63-µm marprene or PVC tube from the receptor fluid reservoir to the inlet arm of each diffusion cell, taking extreme care not to introduce any air bubbles into the system.

13. Run the peristaltic pump at maximum speed until the receptor fluid is flowing under all the skin circles and the eluent drips into the 20-ml scintillation vials.

14. Allow the receptor fluid to bathe the underside of the skin for 20 to 30 min at the required flow rate (1.5 ml/hr is suitable for most experiments).

Apply test chemical

15. While the skin and receptor fluid are equilibrating, make up a test compound solution in a suitable vehicle.

    Doses can range from a few ng/cm^2 skin to mg/cm^2 skin, depending on the compound under study and its likely level of contact with human skin.

    It is preferable to use a radioactive chemical (usually ^{14}C- or ^{3}H-labeled). For example, depending on the absorption properties of the compound, ~0.2 µCi of ^{14}C per skin circle will usually suffice.

16. Measure the specific activity of the test compound solution accurately and in triplicate by liquid scintillation spectrometry.

17. Following equilibration of the skin in the SAM system for 20 to 30 min, move the fraction collector rack (containing 20-ml vials) into position. Gently apply 5 to 10 µl test compound solution to each skin circle using a 10-µl Hamilton syringe with a blunt-ended needle.

    Apply the dose solution to the center of the exposed area of the skin, only lightly touching the skin to remove the last drop of the dose solution from the needle.

18. *Optional:* If the diffusion cells are to be occluded, cover each cell with a Teflon septum and cap (Fig. 5.1.1B), making sure the cap is finger tight.

    This is done if the experiment aims to investigate the effect of occlusion on skin penetration (see Critical Parameters).

19. Collect receptor fluid for the desired length of time (e.g., every 2 hr for up to 72 hr). Throughout the experiment, add 15 ml scintillation fluid to each collected fraction, mix, and measure the radioactivity.

Disassemble equipment and measure radioactivity

20. At the end of the experiment, switch off the water circulator, fraction collector, and pump, and disconnect the tubing from the cells. Rinse out the reservoir flask, thoroughly, and replace the liquid with 70% ethanol, leaving this to pump through the tubes for ~15 min.

21. If cells were occluded, unscrew each cap and place it with its septum in a beaker containing 10 ml of 100% ethanol (one beaker per cap and septum). Unscrew each threaded nut and place in a beaker containing 50 ml of 100% ethanol (one per nut).

    In addition to the receptor fluid measured above, four separate radioactivity measurements will be made for each sample: from the cap, the cell and matching threaded nut, a skin swab, and the skin circle.

22. Swab the skin at least twice (sometimes up to ten times) with 1.5-cm^2 gauze swabs soaked in 2% aqueous soap solution or 100% ethanol (depending on the chemical's solubility) and place the swabs in 20-ml plastic scintillation vials, each containing 10 ml of 100% ethanol.

23. Place each skin circle into a separate 20-ml scintillation vial and freeze at −20°C for later analysis of residual radioactivity in the skin. Place each diffusion cell body in the appropriate beaker with its matching threaded nut.

24. Cover the beakers with Parafilm/nescofilm and leave the caps, swabs, and cells/threaded nuts to soak overnight.

25. The next day, place triplicate 1-ml aliquots of all liquid samples (i.e., swabs, caps, cells/threaded nuts) into 20-ml scintillation vials, add 10 ml scintillation fluid, and count for residual radioactivity.

26. Clean the diffusion cells and caps by placing each cell body, threaded nut, cap, and septum into a plastic beaker containing ~800 ml of a weak solution of decontamination liquid (e.g., ~1% Decon solution). Leave to soak overnight. The next day, rinse each cell unit thoroughly with tap water followed by distilled water and leave to soak in distilled water overnight. Dry the cells thoroughly with tissue, paying special attention to the side arms.

Figure 5.1.2 Sample spreadsheet for analysis of skin absorption data. Data are shown for receptor fluid (at 2-hr intervals from 0 to 24 hr), swabs, cell wash (C. Wash), Teflon cap wash (T. Cap), and skin circles. Cumulative (cum.) % dose is absorption as a percent of the applied dose. The rate of absorption per diffusion cell is given in ng/hr, and the rate of absorption per cm^2 of skin is given in ng/cm^2/hr.

27. When the skin sample analysis is to be conducted, remove the skin circles from the freezer and allow to thaw at room temperature. Transfer the tissue to a tared glass scintillation vial and weigh.

28. Add an aliquot of skin digest solution to each skin circle (1.5 ml to human skin, 1 ml to rat skin), cap the vial, and place in a shaking water bath at 70°C for 1 to 2 hr.

29. Remove the vial, allow to cool to room temperature, and add 0.5 ml of 4.4 M HNO_3. Check that the pH is neutral (pH 7 exactly).

30. Add 10 ml scintillation fluid, mix well, and count for radioactivity against a quench curve made up using untreated human or rat skin spiked with a known amount of radioactivity.

Analyze results

31. Prepare a computer spreadsheet (e.g., using Microsoft Excel; see Fig. 5.1.2) and enter dpm data to determine the recoveries on the skin surface, within the skin, in the receptor fluid, on the diffusion cells, and on the caps.

32. Calculate total recovery and absorption. Calculate absorption as a percent of the applied dose and also in absolute amounts (e.g., $\mu g/cm^2$).

Absorption is defined as recovery in the receptor fluid. Skin levels may also be considered as "absorbed" in terms of dermal exposure, although these skin residues may not necessarily be systemically available.

Total recoveries (the sum of all assayed compartments) should be >90% unless the compound is volatile.

Further analyses may involve calculation of steady-state flux, permeability constants (K_p), and lag times (see Background Information). Where appropriate, statistical analysis may be conducted (for example, to compare absorption of a given compound under both occluded and unoccluded conditions).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HHBSS (HEPES-buffered Hanks' balanced salt solution)

Weigh 19.6 g Hanks' balanced salt solution (HBSS; premade powder, Sigma), 11.9 g HEPES acid, and 0.7 g sodium bicarbonate into a conical flask and add ~800 ml Milli-Q-purified water (or equivalent). Add 10 ml of 10 mg/ml gentamicin solution and stir using a magnetic stirrer. Adjust pH to 7.3 using 1 M NaOH and adjust volume to two liters with water. Prepare fresh for each experiment.

Skin digest solution

Add 20 g sodium hydroxide to 150 ml Milli-Q-purified water and cool on a bucket of ice. Add 75 ml methanol and 25 ml Triton X-405, and mix thoroughly with a magnetic stirrer. Prepare fresh on the day of use.

COMMENTARY

Background Information

Brief review of other techniques

A wide variety of in vitro techniques are available for the study of skin bioavailability (absorption and metabolism; Table 5.1.1). The most commonly used approaches employ animal or human skin in diffusion chambers, either static or flow-through, where the skin is placed horizontally and exposed to the atmosphere to separate the donor and receptor compartments (Franz, 1975; Bronaugh et al., 1982; Bronaugh and Stewart, 1985; Hotchkiss et al., 1990, 1992a,b, 1993). Skin absorption, and metabolism if desired, is determined by the analysis of the parent compound and/or metabolites (e.g., by high-performance liquid chromatography or by gas chromatography/mass spectrometry) appearing in the receptor fluid under the skin, and the skin may also be analyzed to determine any parent compound and metabolites within the tissue. Where radiolabeled compounds have been applied, microautoradiographic techniques may be used to visualize the compound in the skin and determine the precise anatomical location of the absorbed chemical.

Other in vitro techniques have proven to be of some value for skin absorption studies, including fresh skin explants in short-term organ culture (Kao and Hall, 1987) and an elaborate isolated, perfused porcine skin-flap model (Riviere et al., 1986). Isolated human skin (Kreidstein et al., 1991) and pig ears (de Lange et al., 1994) have also been perfused. These perfused skin preparations have the advantage of using the skin's own microcirculation to carry nutrients to the cells and remove the penetrant compounds. However, they are also time consuming to perform and require competent technical skills.

So-called reconstructed human skin or human skin equivalents have been recently developed, fueled by the difficulties encountered in obtaining fresh human skin, and are currently under investigation as skin absorption models. These skin equivalents are essentially collagen matrices containing skin fibroblasts with an overlaid layer of epidermal keratinocytes. Sev-

Table 5.1.1 In Vitro Methods for the Evaluation of Percutaneous Absorption/Metabolism in Different Samples

Organs/tissue	Cells	Subcellular fractions
Diffusion chambers (static and flow-through)	Isolated cells (e.g., keratinocytes, melanocytes, fibroblasts,, Langerhans cells)	Homogenates (whole skin, epidermis, or dermis)
Short-term organ culture		Microsomes
Isolated perfused porcine skin flap	Cell lines	Cytosolic fraction
Skin slices/chopped skin	Epidermal keratinocyte cultures	Purified enzymes
Whole human hair follicles	Hair follicle keratinocyte cultures	
Human skin punch biopsies		
Reconstructed human skin		
Human skin equivalents		

eral skin equivalents have been tested to determine percutaneous absorption and, although the stratum corneum is not properly formed in these systems and absorption is often orders of magnitude higher than human skin, some are now commercially available.

In vitro/in vivo correlations

Some in vitro systems have been shown to provide predictive models for in vivo absorption. Franz (1975) reported good correlations between the in vitro absorption of hippuric acid, benzoic acid, and chloramphenicol through human skin in a static diffusion cell and previously published in vivo data. Bronaugh et al. (1982) also reported that the static cell provided a good model for the percutaneous absorption of benzoic acid, urea, and acetylsalicylic acid through rat skin. The use of skin in flow-through diffusion cells has significant advantages over its use in static cells. For one, it more closely resembles the true skin barrier as it exists in vivo, due to the continuous flow of a physiological receptor fluid across the underside of the skin, which mimics dermal blood flow, maintains skin viability by providing nutrients and oxygen and by carrying away waste products, aids in the partitioning of lipophilic compounds into the receptor fluid, and minimizes sample collection problems. Various studies have shown that the flow-through diffusion cell system provides a good model for predicting the in vivo percutaneous absorption of a wide range of compounds in human and animal skin (Bronaugh and Stewart, 1985; Hotchkiss et al., 1990, 1992a,b; Mint et al., 1994; Beckley-Kartey et al., 1997).

Skin reservoir

There is considerable debate over whether one should consider the material present within the skin, in an in vitro percutaneous absorption experiment, as absorbed compound. In theory, residual chemicals within the skin are available for subsequent systemic absorption and will not be removed by conventional washing procedures. In support of this, a linear relationship has been shown to exist between the amount of a chemical present in rat stratum corneum 30 min following application in vivo and the total amount absorbed (excreted and in epidermis and dermis) in 4 days (Rougier et al., 1985), indicating that measurement of the amount of chemical in the stratum corneum reservoir may allow the prediction of total systemic absorption. Conversely, the kinetics of absorption of some topically deposited chemicals from the skin into the systemic circulation may be so slow that skin desquamation may remove the stratum corneum reservoir layers before further systemic absorption may occur. The presence of a cutaneous reservoir for potentially hazardous or pharmacologically active compounds may result in continued systemic exposure, even after topical contact has ceased.

Quantification of absorption: permeability constant, flux, and lag time

In simple terms, the absorption of a chemical through the skin can be regarded as a diffusion process and is therefore governed by Fick's first law of diffusion at steady state. There is a period immediately after skin exposure where diffusion increases to reach steady state. This lag time is compound specific and ranges from minutes to days.

Once the system reaches steady state, the rate of absorption of a chemical across a membrane is proportional to the applied concentration and can be represented by $J = K_p \times DC$, where J is the steady-state rate of absorption (flux), K_p is the permeability constant, and DC is the concentration difference of the penetrant across the membrane. The permeability con-

stant is in turn defined by $K_p = (K_m \times D)/\delta$, where K_m is the partition coefficient of penetrant between tissue (stratum corneum) and vehicle, D is the diffusion constant, and δ is the diffusion path length (stratum corneum thickness). Thus, the permeability constant (cm/hr) increases with the solubility of the penetrant in the stratum corneum and decreases with increasing skin thickness. Combining these equations gives $J = (K_m \times D \times DC)/\delta$. These equations may be applied to most percutaneous absorption studies and, with certain exceptions, will give reasonable approximations.

In vitro studies can be carried out using two types of dosing conditions: either infinite dose or finite dose. An infinite dose of topically applied compound will ensure that steady-state kinetics are maintained over the entire time course, enabling the true permeability coefficient (K_p) to be calculated. A finite dose will more likely represent the in vivo situation, whereby only small amounts of chemical are applied to the skin and apparent steady-state kinetics are only reached for a brief period of time.

Critical Parameters

A number of factors appear to be important in determining how well a chemical penetrates into the skin, and should therefore be considered as potential influencing factors in an in vitro experiment. These include the chemical's physicochemical properties (e.g., solubility, molecular volume, volatility), the amount applied, whether any other chemical is applied at the same time, the duration of skin exposure, whether the surface of the skin is covered, skin temperature and moisture content, and whether the skin is damaged or diseased. The precise site of application is also a factor determining the rate and extent of skin absorption, as is the age of the skin, the species, and structural differences such as skin thickness and the number of hair follicles (Hotchkiss, 1995).

The critical parameters, in terms of obtaining good in vitro percutaneous absorption data that is representative of the in vivo situation, fall into two main categories: choice of skin membrane and choice of receptor fluid.

Skin membrane

The single most important factor to ensure good in vitro data is to prepare the skin very carefully by removing all subcutaneous tissue prior to placing it in the diffusion cell. The simplest skin membrane type is full-thickness skin, which is easy to handle and prepare and is routinely employed (Frantz et al., 1990; Hotchkiss et al., 1990, 1992a,b, 1993). It is quite in order to commence any new study using full-thickness skin; however, it should be remembered that for highly lipophilic compounds (e.g., those with an octanol-water partition coefficient [$P_{o/w}$] > 4) the dermis of the skin is hypothesized to act as an additional barrier to skin penetration in vitro. This may limit the chemical's partitioning from the skin into the receptor fluid in an in vitro system and, hence, the in vitro system may underestimate the true in vivo absorption. The dermal barrier is not present in vivo because the cutaneous blood supply lies in the upper dermis, close to the epidermal-dermal junction, insuring that the chemical can diffuse into the bloodstream without having to traverse the entire thickness of the dermis.

One cannot always predict, from lipophilicity alone, if the dermis will present a problem for a particular compound, because certain highly lipophilic molecules are metabolized in the skin to more polar metabolites that may readily partition out from the tissue into the receptor fluid. When a problem is anticipated, it is wise to remove the dermis, or as much of it as possible, prior to conducting the percutaneous absorption study. This should preferably be done by mechanical means with a dermatome, but can also be done thermally by immersion in hot water, enzymatically by Dispase separation, or chemically by sodium bromide treatment. Bear in mind, though, that heat and chemical treatment will deactivate xenobiotic metabolizing enzyme activity in the skin. In addition, preparation of epidermal sheets is difficult in hairy skin, since the hair follicles penetrate deep into the dermis and can compromise the barrier properties of these epidermal sheets. The dermatome method removes the majority of the dermis and can give skin samples of accurate thickness. The typical thickness of dermatomed tissue used in in vitro experiments is 200 to 300 μm for rat skin, and 300 to 1000 μm for human and pig skin (Bronaugh and Stewart, 1985; Potts et al., 1989; Storm et al., 1990).

If epidermal membranes rather than full-thickness skin are to be used, great care with handling the fine epidermal sheets is required. Typically, these sheets of skin are very thin (~100 μm) and delicate, and therefore should not be transferred to the diffusion cells using forceps (as one does for full-thickness skin). Instead, they should be floated on water and the diffusion cells should be submerged underneath to allow the membrane to settle in the cell.

Skin freshness. Where metabolism is to be studied, the skin must be obtained as fresh as possible, ideally within 1 hr of excision from either the human individual or animal. This is important because the enzymes in the skin may decline rapidly following excision. At present, the viability of skin in the SAM system has only been assessed up to 24 hr and cannot be guaranteed for longer periods. Of course, the viability of the tissue should be specifically defined in terms of the enzymes involved: cytochrome P-450 enzymes may decline very rapidly post excision (e.g., within 8 hr), whereas esterase enzymes may be active for considerably longer (e.g., >24 hr).

Nonviable tissue. Some experimenters elect to use nonviable skin—e.g., previously frozen tissue or human autopsy specimen—for skin bioavailability studies. The argument in support of this approach is that the stratum corneum, the major barrier to skin penetration, is comprised of nonliving keratinocytes and therefore it is not essential to have viable tissue for in vitro studies. There is some value to this approach in cases where fresh skin is in short supply, but by far the most appropriate skin membrane is one where the epidermal tissue is metabolically active, so that a true picture of the bioavailability, including any metabolites produced during skin penetration, may be obtained. In the author's experience, the absorption of chemicals through previously frozen skin is not always the same as through fresh skin, and therefore this membrane type should not be used unless there is no viable alternative.

Inter-individual variation. There is widespread inter-individual variation between humans in the percutaneous absorption of chemicals. For instance, the inter-individual variation in percutaneous absorption of 4,4′-methylenebis(2-chloroaniline) (MbOCA) and 4,4′-methylene dianiline (MDA) between ten different human subjects is large, with a three- to four-fold range in absorption (Hotchkiss et al., 1993). Similarly, a four-fold variation in diethyl phthalate absorption through eight subjects' skin has been observed in vitro (Mint et al., 1994). Thus, care should be taken when drawing conclusions from data in a single individual, as absorption may be considerably higher or lower in another subject. For this reason, it is recommended that skin samples from at least three different individuals (or animals) be used.

Species. Species differences in absorption are a particularly important consideration. Where human skin is not readily accessible, rodent (typically rat and mouse) skin can be employed, and both haired and hairless varieties are available (Bartek et al., 1972; Kao et al., 1988; Hotchkiss et al., 1990, 1992a,b; Beckley-Kartey et al., 1997). In general, human skin is less permeable to xenobiotics than the skin of laboratory animals (Bartek et al., 1972; Mint et al., 1994). Skin absorption would appear to be relatively high in the rat and rabbit and lower in the pig and monkey, with the latter two species providing a closer approximation than rodents to human skin. The lower percutaneous absorption (increased barrier properties) in human skin compared with rat tissue is possibly due to a combination of the increased skin thickness (3 mm compared with 2 mm) and decreased hair follicle density (10/cm^2 compared with 300/cm^2). However, on occasion, and particularly under occlusive conditions, the percutaneous absorption of some chemicals (e.g., phenol and MDA) is greater through human skin than through rat tissue, which may, in part, be due to the increased thickness of (male) rat stratum corneum (~35 μm thick) compared with that of human (~20 μm thick; Hotchkiss et al., 1993). Since rodents are typically employed for skin absorption studies, and marked species differences in percutaneous absorption between rat and human skin have been observed, care should be taken when relying upon animal data to provide a model for extrapolation to the human exposure situation. Other species' skin have been utilized in in vitro models, including monkey, rabbit, guinea pig, pig, snake, and frog. Pig skin appears to be particularly useful since it is similar in structure to human skin. However, as a general rule, there is no substitute for human skin.

Anatomical region. The anatomical region of skin exposed to a chemical in the in vitro system may have a profound effect on its absorption. Although the rank order of skin site permeability would appear to be compound specific, scrotal skin appears to be the most permeable, scalp and face are intermediate, and palms, soles, and arms are the least permeable (Maibach et al., 1971). These data are in broad agreement with site-dependent differences in stratum corneum thickness: the stratum corneum thickness is thinnest on the eyelids and scrotum (10 μm) and thickest on the palms and soles (1 mm; Scheuplein and Bronaugh, 1983; Scott et al., 1991).

Dose. The dose of a chemical applied to the skin in the in vitro system will have an effect on the extent of percutaneous absorption (Hotchkiss et al., 1990a,b). In general, increasing the dose will increase absorption, because

the rate of diffusion is proportional to the amount of diffusant (Fick's law).

Occlusion. Occlusion of the skin surface in an in vitro experiment may enhance the percutaneous absorption of some chemicals, although not of others (Bucks et al., 1989; Hotchkiss et al., 1990, 1992a,b, 1993; Mint et al., 1994). For example, the absorption of MDA through human skin in vitro is significantly increased by occlusion (from 13% to 32%; Hotchkiss et al., 1993). Occlusion blocks evaporation of water from the skin surface (transepidermal water loss), which results in an increase in skin hydration. Under normal circumstances, the stratum corneum contains 5% to 15% water, but this can be enhanced to 50% by occlusion. Occlusion may also increase skin temperature—with increases up to 5°C being observed—by preventing the cooling evaporation of water, which may further enhance percutaneous absorption (Bucks et al., 1989).

Skin temperature. Under normal conditions, skin temperature is ~32°C, although this varies with factors such as external air temperature, clothing, occlusion, rubbing, and exercise. A number of authors have reported the enhanced absorption of a wide range of chemicals (including levamisole, salicylate, and phenols) through animal skin as its temperature is increased. This may result from enhanced diffusion and/or increased cutaneous blood flow. However, absorption is not always enhanced by increasing skin temperature (Blank et al., 1967).

Vehicle. The vehicle or formulation in which a chemical is applied to the skin may affect its in vitro absorption. For example, *N*-nitrosodiethanolamine penetrates the skin 200 times faster from a lipophilic vehicle (olive oil) than from an aqueous vehicle (water; Scheuplein and Bronaugh, 1983). Ethanol, 2-phenylethanol, and DMSO vehicles have been shown to enhance the absorption of benzyl acetate through rat skin in vitro (Hotchkiss et al., 1992b).

Skin metabolism. For any in vitro percutaneous absorption study, it is important to consider the potential impact of cutaneous metabolism on the bioavailability of the chemical. The degree of cutaneous metabolism will determine whether a chemical is absorbed across the skin barrier intact or as one or more metabolites. The skin contains many of the xenobiotic metabolizing enzymes identified in the liver (Hotchkiss, 1998). Skin absorption may potentially be affected by skin metabolism, since the metabolites may be absorbed at different rates owing to their different physicochemical properties. Vice versa, skin metabolism may potentially be affected by skin absorption, since the slower a chemical is absorbed the greater the chance it will be metabolized. Cutaneous enzymes have been shown to inactivate toxic chemicals such as the organophosphorous pesticides, and indeed cutaneous esterase enzyme activity may be so efficient that topically applied esters may be completely metabolized during skin absorption (see review, Hotchkiss, 1998). In contrast, other skin enzymes may activate relatively harmless substances into toxic metabolites, including cutaneous cytochrome P4501A (CYP1A)–mediated activation of the polycyclic aromatic hydrocarbons benzo(a)pyrene and dimethylbenz(a)anthracene to toxic compounds sufficiently reactive to bind to cellular DNA and cause skin cancer (see review, Hotchkiss, 1998).

Receptor fluid

The choice of receptor fluid is the second critical consideration. Ideally, one would select a receptor fluid that maintains skin viability (e.g., HHBSS or tissue culture medium) and thus allows skin metabolism to proceed during percutaneous absorption. In addition, the receptor fluid should not be a limiting factor in terms of the solubility of the penetrant. Once again, a problem may arise with highly lipophilic compounds as these will have difficulty partitioning out from the lipid skin into the relatively aqueous receptor fluid (although skin metabolism may generate polar products that can partition more readily). In these cases, one can consider substituting the typical receptor fluid with 50% aqueous ethanol or supplementing the existing receptor fluid with up to 6% (w/v) PEG (polyethylene glycol-20 oleyl ether) or up to 4% (w/v) BSA (Bronaugh and Stewart, 1985; Suber et al., 1991). However, 50% ethanol and PEG will not maintain tissue viability, and therefore metabolism cannot be studied using these receptor fluids. The addition of albumin has its limitations in studies where skin metabolism is to be investigated, because albumin has been shown to have intrinsic hydrolytic activity with the potential for interference in the measurement of the bioavailability of esters. In general, the flow rate of the receptor fluid is set between 1.5 and 3 ml per hour, with faster flow rates having no effect on the absorption of benzoic acid or caffeine (Bronaugh and Stewart, 1985; Frantz et al., 1990).

Troubleshooting

A number of factors may lead to poor recoveries of radioactivity following an in vitro skin

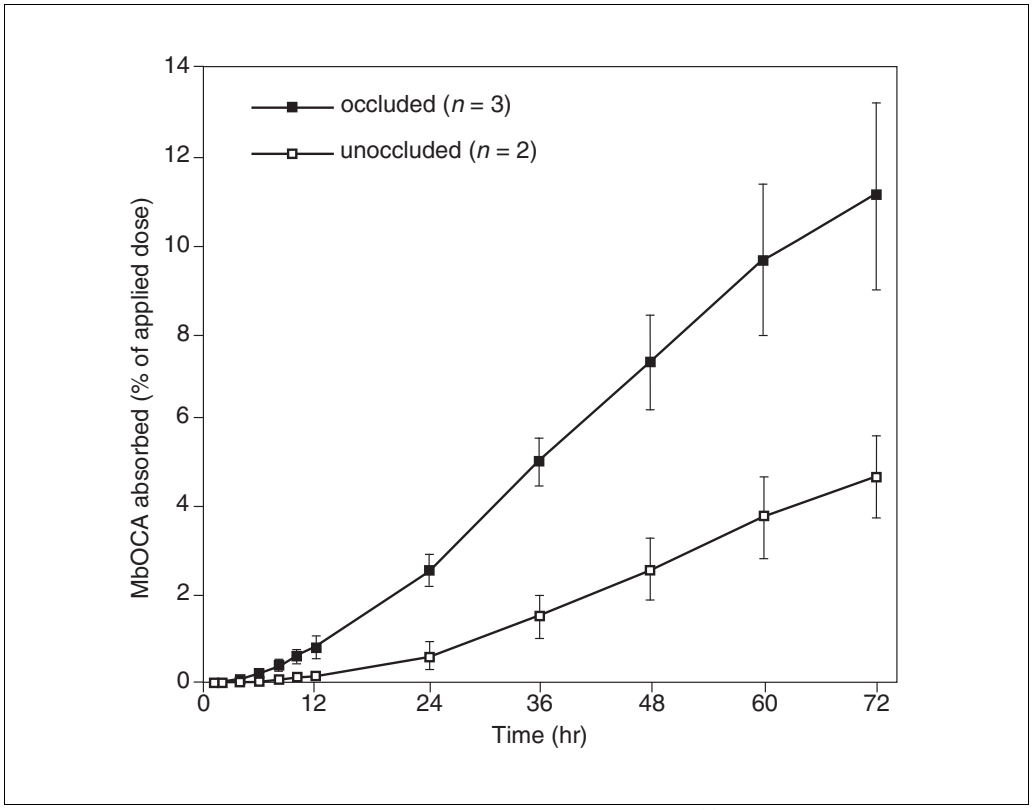

Figure 5.1.3 Typical in vitro percutaneous absorption profile of ^{14}C recoveries in receptor fluid following topical application of [^{14}C]4,4′-methylene-bis(2-chloroaniline) (MbOCA) to human skin. Mean ±SD.

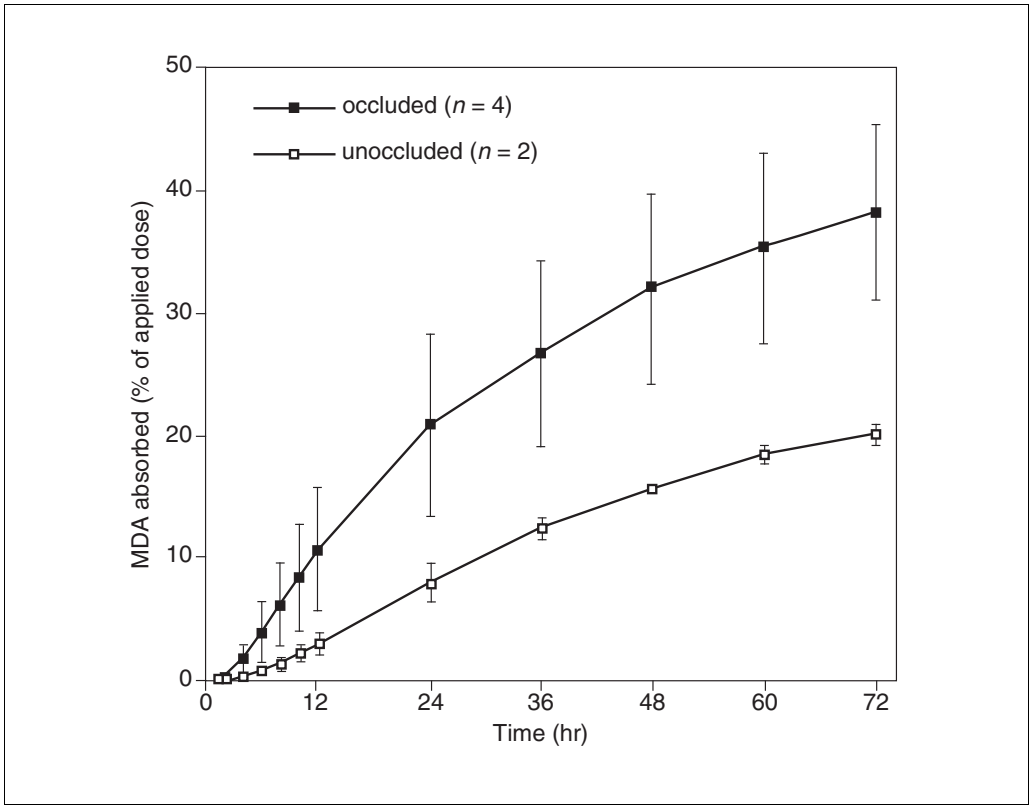

Figure 5.1.4 Typical in vitro percutaneous absorption profile of ^{14}C recoveries in receptor fluid following topical application of [^{14}C]4,4′-methylene dianiline (MDA) to human skin. Mean ±SD.

penetration study. Volatile compounds may be lost to the atmosphere at a variety of stages in the process, including evaporation from the needle or skin at the time of application, evaporation from the skin during the course of the experiment, and evaporation from the vials of receptor fluid in the fraction collector. For volatile compounds, it is advisable to apply the compound to the skin surface quickly and then immediately occlude the skin. Vials of receptor fluid should be capped immediately, rather than allowing them to sit on the faction collector for long periods of time. Conversely, if recoveries of radioactivity are unexpectedly high, consider whether the apparatus has been contaminated in some way or inadequately cleaned following a previous experiment. Always wash the diffusion cells, caps, and tubing thoroughly between experiments. Particular care should be taken when using tissue culture medium as a receptor fluid, as this may provide an ideal growth medium for bacteria and fungi in the nonsterile conditions of the open laboratory, resulting in buildup and eventual blockage of the tubing.

Anticipated Results

In vitro experiments using the SAM system are anticipated to generate percutaneous absorption profiles for the compounds under study analogous to those shown for the aromatic amines MbOCA (Fig. 5.1.3) and MDA (Fig. 5.1.4). In the case of MbOCA, the in vitro absorption through unoccluded human skin into the receptor fluid is very low, reaching only 4% (11% if occluded), and a typical absorption profile shows a lag phase of ~10 hr before an approximately linear increase in absorption that lasts for up to 72 hr. The apparent permeability constant (K_p) for the percutaneous absorption of MbOCA is 0.30×10^{-5} cm/hr (unoccluded) and 1.02×10^{-5} cm/hr (occluded). In the case of MDA, the absorption through human skin is more extensive than for MbOCA, reaching 20% (38% if occluded), and a typical absorption profile shows a lag phase of ~2 hr before a rapid increase in absorption approaching an equilibrium at 72 hr. The apparent permeability constant (K_p) for the percutaneous absorption of MDA is 3.09×10^{-5} cm/hr (unoccluded) and 8.34×10^{-5} cm/hr (occluded; Hotchkiss et al., 1993).

The graphically displayed profiles of absorption for most chemicals fall into two types. *Infinite dose* profiles have approximately steady-state absorption over the entire time course, where either the dose is high or the absorption through the skin is very slow and does not result in a significant depletion of the material remaining to be absorbed. *Finite dose* profiles show a decreasing rate of absorption, where either the dose is low or the rate of absorption is so rapid that there is depletion of the compound on the skin surface.

Time Considerations

The time taken to prepare the skin and to equilibrate the SAM system is usually on the order of 1 to 2 hr. The duration of the percutaneous absorption experiment depends on the desired exposure or collection time—ranging from relatively short-term (e.g., 8 hr) to long-term (e.g., 5 days)—but most bioavailability experiments will be of 24 or 72 hr duration. During this time, the procedure is fairly labor intensive, as the vials must be constantly removed and counted for radioactivity. Alternatively, fluor must be added and vials capped continuously; however, counting is lengthy so it is best not to count them all at the end. Once the experiment has been performed, allow extra time for data entry onto the computer spreadsheet and further analysis. Samples of skin for digestion can be collected from a number of experiments, stored in the freezer, and digested together at a later date, hence saving time and reagents.

Measurement of Bioavailability: Measuring Absorption Through Skin In Vivo in Rats and Humans

Humans are exposed dermally to various chemicals, either voluntarily in the case of therapeutic agents for treatment of local conditions or as a route of administration for systemic effects, or involuntarily in the case of occupational or environmental exposure. In either case a knowledge of the systemic exposure resulting from dermal exposure plays a key part in evaluating either pharmacological or toxicological effects.

A protocol design for rats is discussed here (see Basic Protocol 1), with the recognition that it will generate data that probably overestimate absorption in humans and therefore represent a worst case. A similar protocol can be used for other species such as pig, a species recognized as being a closer model to human, but with some practical limitations imposed by the greater size of the animal. An Alternate Protocol is discussed which would be applicable for volatile compounds.

Studies to assess dermal absorption in humans (see Basic Protocol 2) are invaluable to assist in extrapolating toxicological data from animals to humans as part of the risk assessment process. There are special considerations to be taken into account, namely a general reluctance to perform such studies for compounds other than human pharmaceuticals. Given a formal ethical review process, however, there is no logical reason why appropriately designed and controlled studies should not be undertaken (Hayes, 1983; Wilks and Woolen, 1994). Some practical limitations will of course restrict the type of data that can be obtained in studies with humans as opposed to animals.

Laboratory workers performing these protocols should be adequately experienced and trained and fulfill the necessary regulatory and safety requirements for working with radiochemicals and laboratory animals. It is likely that such laboratories will already be performing animal metabolism studies with radiolabeled materials, and hence have access to, and be trained in the use of, liquid scintillation counters and animal metabolism cages.

Where radiolabeled compounds are used, the radiolabel (normally carbon 14) should be situated in a metabolically stable position(s) such that there is minimal formation of $^{14}CO_2$. The radiochemical purity should be as high as possible, preferably >98%. The specific activity of the test compound required will depend upon the dose level used.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by local radiation safety officers (also see *APPENDIX 1A*).

MEASUREMENT OF DERMAL ABSORPTION IN THE RAT

BASIC PROTOCOL 1

The rat strain should be the same as that used in toxicology and metabolism studies. In general, particularly if rat metabolism data are already available, the use of one sex is sufficient. While there may be sex differences in metabolism, distribution, and excretion, such differences in dermal absorption are not expected. It is common either to use males

Contributed by Stephen V. Bounds and David R. Hawkins
Current Protocols in Toxicology (1999) 5.2.1-5.2.10

or to use the more sensitive sex based on toxicological data. The radiolabeled test material is applied to a protected area of the skin and absorption is measured by analyzing the material remaining in the skin and tissues and excreted by the animal.

Materials

Radiolabeled test compound (labeled with ^{14}C or ^{3}H) at >98% purity
Adult male rats, 8 to 12 weeks old, 225 to 250 g (at least four per data point)
Solvents such as acetone or methanol
Oxidizer
Sodium hydroxide
Triton X-405

Animal clippers
Spacer: saddle (silicon rubber) or O-ring (Teflon, or nonabsorbent rubber)
Adhesive (cyanoacrylate: e.g., Superglue)
Gauze (metal mesh or plastic) to fit above spacer
Application device, e.g., syringe or calibrated pipet (Gilson or equivalent)
Metabolism cages (Jencons)

1. Prepare the test compound formulation.

   The test compound should be applied in a vehicle that is appropriate to the nature of the exposure being assessed. Ideally the compound should be a solution in a liquid formulation that can be applied uniformly to the skin surface. In the case of pesticides, this may mean standard formulations developed for their use. For pharmacological products this may mean creams or emulsions representative of likely in-use preparations. A realistic application volume for liquid formulations would be 10 µl/cm^2; for a study using a radiochemical, the specific activity should be sufficient to allow application of ~0.5 MBq (~14 µCi) to a 12-cm^2 area of skin. This will allow detection of a dermal absorption of <0.5% of the dose.

2. The day prior to dosing, prepare the application site by shaving an area of each animal's dorsal skin, being careful to avoid abrading the skin surface.

3. Immediately prior to dosing, apply a spacer (part of a protective device, see below), such as a silicone rubber saddle or O-ring, to the back of the animal, enclosing the application site. Secure the spacer with cyanoacrylate adhesive.

   As an example, Figure 5.2.1 shows a protective device consisting of a spacer (e.g., rubber ring or rectangle) to which is secured a metal or plastic gauze.

   The entire protective device should be of sufficient height and robustness that when the animal arches its back or moves around, no part of the device is in direct contact with the application area. The device should allow air circulation (for semi-occluded) but should not allow the animal to lick or rub the dose site against the holding cage. It should also

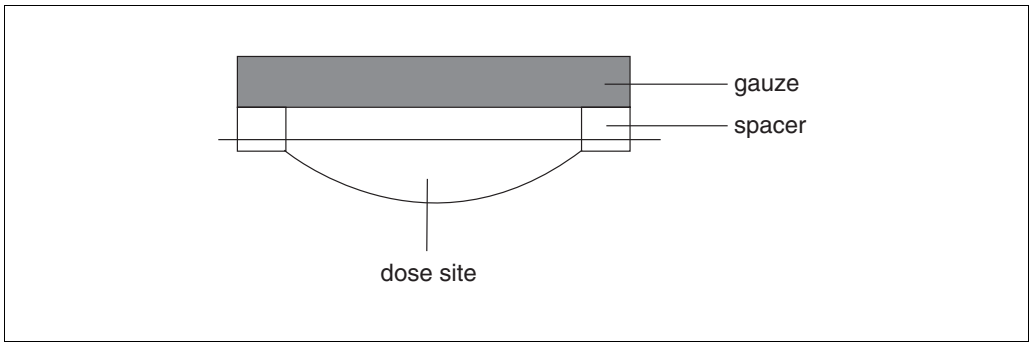

Figure 5.2.1 Schematic of saddle arrangement used to protect the dose application site (cross-section).

allow the animal sufficient movement to be able to eat and drink within the metabolism cage. An alternative is to use a collar that restricts the animals' movement. Semi-occlusion allows the skin to be equilibrated with the surrounding air and hence maintained in a normal hydration state.

4. Apply the formulation with a pipet to ~12 cm^2 of skin within the spacer. Ensure that the dose is aspirated without air bubbles and that it is spread as evenly as possible over the dose area. The pipet tip can be used as a dose spreader and retained for analysis.

   For example, for an application area of 3 × 4 cm (12 cm^2) and an application volume of 10 µl/cm^2, a total dose of 120 µl would be required.

5. After application, glue the gauze to the spacer, covering the treated area. Ensure that it does not touch the dose site, that it cannot be removed by the animal, and that it does not restrict the animal's movement.

6. For a liquid formulation, perform dose assays with the same calibrated pipet used for dosing. Pipet the dose assay aliquots directly into a volumetric flask and dilute to volume with an appropriate solvent such as acetone or methanol, prior to taking further aliquots of this solution for liquid scintillation counting. Assay the dose assays taken prior to dosing immediately to check that the radioactivity concentration was correct prior to dosing. Measure the remaining dose assays as soon as possible after dosing. Calculate the applied dose from the mean of these assays minus the residual activity remaining on the dose spreader for each animal.

   The purpose of these assays is to be able to determine the actual dose delivered using, where possible, the same dosing apparatus (syringe or pipet) and to keep a check on the homogeneity of the dose formulation. The number and frequency of the dose assays will vary from formulation to formulation depending on the formulation type. For example, for a well-mixed solution, three dose assays may be taken immediately prior to dosing, three after dosing is complete, and additional dose assays during the dosing procedure between each group of animals. For a less homogenous dose formulation, such as an emulsion, more frequent dose assays would need to be taken.

Collect samples

7. Immediately after test compound application, house the rat in an individual metabolism cage that allows separate collection of urine and feces, and volatile metabolites or $^{14}CO_2$ in expired air. When the exposure period to the applied dose is 8 hr (i.e., excess dose washed off after 8 hr), urine and feces should be collected separately from animals over the intervals 0 to 8 hr and 8 to 24 hr, and over 24-hr intervals thereafter until the experiment is terminated.

   Termination times for groups of animals can vary according to the objectives and nature of the test compound, but possible times are 8, 24, 48, and 72 hr. It is necessary to collect volatile metabolites or $^{14}CO_2$ in expired air when any absorbed material is excreted as $^{14}CO_2$ or other volatile metabolites.

8. Wash the metabolism cages with water or other suitable solvent, such as acetone or methanol, at the end of the collection. Retain the washes for measurement of radioactivity.

9. At 8 hr (or other defined time), remove the gauze from the spacer and wash the treated area five times with cotton wool swabs moistened with soap solution or other cleansing agent, such as aqueous ethanol, that would have minimal effect on the dermal uptake of the test compound. Dry the area with cotton wool and then resecure gauze to the spacer.

   During the washing period the animal should be held over the metabolism cage to collect any excreta voided during this process.

10. At each of the selected times, euthanize the animals by an overdose of anesthetic (i.e., halothane:oxygen). Remove blood by cardiac puncture. Remove the spacer and gauze (retaining them for analysis) and dissect the treated skin—including a 1-cm border surrounding the dose site—from the carcass. Remove the gastrointestinal tract and other tissues of specific interest for separate measurement.

Analyze samples

11. Measure the total radioactivity in all samples (dose assays, dose spreader, urine, feces, cage washes, tissues and organs, carcass, dose site swabs, rubber spacer, and gauze) by liquid scintillation spectrometry either by direct addition of liquid sample aliquots to a suitable scintillation fluid or after pre-treatment. Extract the saddle, gauze, and cotton wool swabs with an organic solvent (such as acetone or methanol) suitable for dissolution of the test compound and analyze extracts.

    It is expected that the recovery of the applied dose from all sources will be in the range of 90% to 110%.

    Pretreatment consists of either combustion in an oxidizer followed by trapping of the carbon dioxide or solubilization with a suitable reagent, such as a solution of 80 g sodium hydroxide in 600 ml water, 300 ml methanol, and 100 ml Triton X-405.

12. In some cases significant amounts of the applied dose may be present in the treated skin sample taken at the termination of the experiment. Assess the localization of this material within the skin using microautoradiography or by skin-stripping.

    Without experimental evidence, it is not possible to state whether this material will be absorbed or whether it will be lost externally by exfoliation of skin cells. To obtain more definitive data on the ultimate fate of this material, dose and treat additional groups of animals in the same way as the main groups, but using extended collection times. Assess the quantity of material excreted and remaining in the treated skin at times such as 5, 10, and 15 days. If absorbed, the depletion of material from the skin should correlate with material excreted.

ALTERNATE PROTOCOL

MEASUREMENT OF ABSORPTION OF VOLATILE COMPOUNDS

Dermal penetration of volatile compounds can be assessed in much the same way as described above by including carbon filters under the gauze above the dose site (Susten et al., 1986; Winter and Sipes, 1993). Perform a preliminary in vitro test to check the efficiency of the carbon filters and saddle arrangement: secure the saddle to some excised rat skin (or a glass plate), dose, then secure the gauze and filters. Place this in vitro apparatus in a metabolism cage or glass chamber within an incubator set at the rat body temperature (37.8°C). Pass air through the apparatus and through a series of traps; collect any volatile material that has passed the filter. At 8 hr after dosing, determine the distribution of dose from analysis of the dose site, saddle, gauze, filters, cage wash, and volatile traps.

If the carbon filter arrangement is efficient, then very little dose (e.g., <1%) is recovered from the cage wash and volatile traps, while quantitative recovery of radioactivity (>90%) is still maintained. It is very important to confirm the efficiency of the carbon filter arrangement, as otherwise the rat could absorb dose from inhalation rather than dermal penetration. Also, any radioactivity collected from the volatile traps connected to the metabolism cages for the in vivo experiment is assumed to have originated from expired air and hence included as absorbed dose. In order to minimize the time taken to dose the rats and secure the saddle and filters, the use of a light anesthetic at dosing can be useful.

MEASUREMENT OF DERMAL ABSORPTION IN HUMAN VOLUNTEERS

Information on dermal absorption in humans can be obtained either from routine occupational or environmental exposure monitoring (although these may include more than one route of exposure) or from controlled dose administration studies to human volunteers. Only the latter will give information on the quantitative relationship between a dose (exposure) and absorbed material circulating in blood or excreted. This information provides the basis for routine monitoring in workplace populations, the general population, or—in the case of medicinal products—in patients. Conducting human volunteer studies as part of drug development is a widely accepted practice, but the justification and ethical acceptability for performing studies with other chemicals are subject to more debate. However, the scientific value is indisputable, because volunteer studies can provide accurate and reliable information that has a practical value for the assessment of the safety of chemicals resulting from human exposure.

Legislation governing the use of human volunteers exists in most countries, although there are some inherent differences due to cultural or legal considerations. Any study must take into account the ethical aspects, particularly where there is no direct benefit to the subject—which is the case for all nonpatient volunteer studies, whether drug or chemical. The guidelines most universally adopted are in the World Medical Association Declaration of Helsinki (Recommendations Guiding Physicians in Biomedical Research Involving Human Subjects) which was first adopted in 1964 and has undergone subsequent modifications. Some of the general conditions that need to be met are as follows: a formal risk-benefit analysis has been carried out, the objectives are scientifically sound, the responsible investigators are appropriately qualified, informed consent of volunteers has been obtained, there is a detailed experimental protocol, and all studies have been approved by an independent ethics committee consisting of medical and nonmedical scientific and lay persons who act independently of the study sponsor. The key information required in the submission for ethical committee approval is toxicity data, to allow an assessment of the risk to the volunteers. The extent of toxicity data required will depend on the nature of the compound and may vary between countries. In general, for pharmaceutical development, there is a desire to obtain human data very early in the development process, and single low-dose studies can be conducted after limited toxicity data in two nonhuman species. For other chemicals, such as pesticides, studies are only likely to be conducted at later stages of development when chronic toxicity data are available. It is to be expected that more support data will be required for nonpharmaceuticals, but something less than chronic toxicity data should be acceptable.

Studies should be performed in a clinic under medical supervision by suitably qualified personnel, while analysis of samples should be laboratory based. Many of the details of test compound information and application, samples collected, and times will depend on the nature of the compound, its biological properties, and the situation in which human exposure would occur. Similar studies in animals should be carried out initially as described in Basic Protocol 1 and Alternate Protocol, and the results taken into account in designing the human study. Clinical investigations also have particular requirements for treatment of the volunteers, and for all these reasons, it is not possible to describe in detail a definitive protocol. The key stages and suggested procedures are described.

NOTE: All studies with human subjects must be approved by the Institutional Review Board (IRB), which must adhere to the Office for the Protection from Research Risk (OPRR) guidelines or other applicable governmental regulations for using human subjects.

Selection of Volunteers

Studies should be restricted to normal healthy males (three to six subjects), age range 30 to 60 years, and body weight ±15% of ideal for height/frame size. Various exclusion criteria should be applied by the clinical unit, such as subjects receiving any medication, participation in any clinical trial in the previous 3 months or in a study involving radioisotopes during the previous 12 months, known allergy or intolerance to related compounds, and any active skin condition or excessive hair in the area designated for dose application.

Subjects should undergo a pre-study screening within 14 days prior to administration; this should include a full medical history, physical examination, and laboratory tests including hematology screen, plasma biochemistry screen, plasma virology screen, urinalysis, and screening for drugs in urine. Subjects should normally be resident in a controlled clinical unit for the duration of the study and no alcohol or medication should be permitted. Standard meals should be provided in amounts commensurate with the individual. To encourage urine production, subjects should be asked to drink 200 ml of water at intervals such as pre-dose and 2, 4, 6, and 8 hr after dosing. The physiological condition of the subjects should be observed throughout the study, and blood pressure, respiration rate, and pulse rate monitored.

A post-study screening, performed at discharge after completion of the study, should include a physical examination and laboratory investigation of blood, plasma, and urine. Subjects should be requested to report any adverse events to the principal clinical investigator or his/her deputy.

Treatment Area

Select an area of skin representative of the area likely to be exposed and that allows controlled uniform application of the test compound and convenient maintenance of the integrity of the treated area post-application: e.g., the forearm or (most preferable) the back. Mark an area of ~100 cm^2 on the selected site using indelible ink and surround it with adhesive tape. Apply ~0.5 ml of the test compound, preferably in a suitable liquid formulation such as dissolved in 70% (v/v) aqueous ethanol. Use a syringe with a pipet tip to distribute the solution evenly over the area, allowing time for natural drying. Expose the treated area to air to dry for 30 min from the start of application. At this time cover the area with a gauze dressing (semi-occlusion) secured externally to the treated area to provide protection during the exposure phase. The duration of exposure will be determined by the compound, its usage, and the objective of the experiment. A typical exposure period is 6 to 8 hr; when a radiolabeled compound is used, that is usually the maximum time allowed based on assessment of radiological exposure. After the specified time, wash off unabsorbed material on the skin using cotton wool swabs and a solvent. The solvent will depend upon the objectives of the experiment but could be any solvent suitable for the compound, such as aqueous ethanol, or soapy water to simulate washing. It is possible to obtain some assessment of material remaining on the skin or in the stratum corneum by using transparent adhesive tape to take successive skin strips (~10 to 15) of a small part of the treated area (e.g., 2.5 cm^2). After washing, cover the area with a gauze dressing until the end of the experimental period (e.g., 3 to 5 days). At this stage, take further skin strips from a different treated area.

Sample Collection

The samples collected will depend upon the objectives of the study and the analytical methodology being used. When a radiolabeled compound is used, the intention is to collect all samples that can be measured to obtain information on the fate of the dermal dose, the rate and extent of absorption, rates and routes of excretion, and blood/plasma kinetics.

The samples should therefore consist of (1) urine collected in labeled pre-weighed containers at appropriate intervals, such as a pre-dose urine void and then periods of 0 to 2, 2 to 4, 4 to 6, 6 to 12, and 12 to 24 hr, and then 24-hr intervals until the end of the experiment; (2) feces, such as pre-dose, 12-hr, and then daily samples; and (3) blood samples (~9 ml) withdrawn by syringe or indwelling cannula from a suitable forearm vein into labeled lithium heparin tubes. The total blood withdrawal should be limited so as to be without impact on the subject volunteer or the integrity of the study: a total of ~150 ml over 5 days is suggested. Exact sampling times may vary according to the compound, but a possible regimen consists of pre-dose and the following times after the start of the application: 0.5, 1, 2, 4, 6, 8, 10, 12, 24, 36, 48, 72, 96, and 120 hr. The packed cell volume can be determined using a microhematocrit technique at pre-dose and at other selected sampling times, such as 2 and 24 hr post-dose. If analysis of plasma samples as well as or instead of whole blood is desired, centrifuge blood samples 10 min at $1200 \times g$, 4°C, and transfer the separated plasma to polypropylene vials.

Sample Analysis

Total radioactivity should be determined in all biological samples, skin washes, protective gauze dressings and skin strippings using standard procedures as indicated for the rat protocol. The results can be expressed as percentage of the administered dose and milligram (or microgram) equivalents either as amount in the total sample or as a concentration. If sufficient radiolabel is absorbed, other analytical techniques can be used to determine the nature of absorbed or excreted radiolabel (i.e., parent molecule/metabolites).

COMMENTARY

Background Information

Because animal models are used to assess toxicological potential, a knowledge of dermal absorption is invaluable, more particularly since dose-response relationships in systemic toxicity are often assessed using oral administration. It is well known that dermal absorption in animals exhibits large interspecies differences (Wester and Noonan, 1980). Absorption in rats, in particular, is often much higher than in humans. However, the rat is relevant as the rodent species most commonly used for toxicological assessment. Rats are also convenient to use due to availability, ease of handling for dose application, the feasibility of ensuring quantitative collection of excreta samples, and a size that provides a suitable skin area for application.

Measurement of bioavailability is being interpreted here as the extent of absorption of a dermally applied dose. It is not being interpreted as the systemic availability of the dermally applied compound, which is the strict interpretation of bioavailability in the context of pharmaceuticals, where interest is often more specifically focused on systemic exposure to the pharmacologically active compound. In this latter case, bioavailability is a function of both absorption and metabolism of the compound before it reaches the systemic circulation and may often be compared to a reference intravenous dose. However, the protocols described here could also be used to obtain this type of information.

Some aspects of a protocol design will depend upon the type of analysis being performed on collected samples. The definitive approach to assessing dermal absorption is to use radiolabeled compounds because this facilitates measurement of compound-related material (including metabolites) in the biological samples. Hence, in this case, it is not necessary to know the identity of metabolites in order to establish what proportion of a topically applied dose is absorbed. Alternatively, if the compound is excreted unchanged or the identity of a major excreted metabolite and its relationship to total excretion are known, specific analytical methods [e.g., high-performance liquid chromatography (HPLC), gas chromatography (GC), or gas chromatography/liquid chromatography–mass spectrometry (GC/LC-MS)] could be used. The protocol designs described here apply to studies using radiolabeled compound, although the technical aspects of compound application, maintenance of the test system, and sample collection would also apply to alternative analytical approaches.

Critical Parameters

For studies where radiolabeled compounds are being used in humans, separate authorization is required for the administration of a specified amount of radioactivity in terms of total dose and amount per unit area of skin. In the UK the approval process is governed by the Administration of Radioactive Substances Advisory Committee (ARSAC). The approval process requires submission of data obtained from equivalent experiments in animals that include measurement of the time-course of radioactivity concentrations in treated skin and tissues that allows an assessment of radiological exposure. The guideline is that the exposure of the human volunteer resulting from the experiment should be less than that occurring from exposure to natural sources of radioactivity during a year. These procedures are country-specific; in the USA, experiments must be conducted in accordance with the Atomic Energy Commission's guidelines.

The key specific issues pertinent in human volunteer studies can be summarized as follows:

1. Good Clinical Practice (GCP)

Compliance with the following as appropriate:

a. Declaration of Helsinki (1964), as amended Tokyo (1975), Venice (1983), and Hong Kong (1989).

b. EEC Note for Guidance: Good Clinical Practice for Trials in Medicinal Products in the European Community (approved by Committee for Proprietary Medicinal Products, July 1990, operative July 1991).

c. Current GCP documentation (21CFR parts 50, 56, and 312) issued by Food and Drug Administration (FDA), U.S.A.

d. Good Clinical Practice for Trials on Drugs issued by Pharmaceutical Affairs Bureau, Ministry of Health and Welfare, Japan (1989).

2. Good Laboratory Practice (laboratory investigation)

Performance of laboratory investigations in compliance with regulations pertaining to the country where the study is conducted and which has international acceptance.

3. Ethics Approval

Approval of study protocol by Independent Ethics Committee.

4. Approval to Administer Radioactivity (where appropriate)

In the UK, conducted through ARSAC: Administration of Radioactive Substances Advisory Committee, Department of Health, Alexander Fleming House, Elephant & Castle, London, SE1 6BY.

5. Informed Consent

Requirement that, prior to enrollment, all subjects give written informed consent to participate in the study, after the purpose, nature, and risks of the study have been fully explained both verbally and in writing. Each subject is advised that he or she is free to withdraw from the study at any time without any obligation to disclose reason for doing so.

6. Medical Cover

Availability of medical cover by a principal clinical investigator or his/her deputy.

Troubleshooting

The single most problematic aspect of human studies concerns the significance of less-than-quantitative accountability of the applied dose when a radiolabeled compound is used. Besides inaccuracies in measurement of the dose, there are essentially three possible reasons, namely, (1) errors in collection and analysis of samples, (2) incomplete recovery such as retention in the treated skin, and (3) incomplete excretion from the body and loss by volatilization from the treated site. These problems may have been encountered in the animal studies where it is possible to make the necessary checks and measurements, but data in animals do not always predict what may occur in a human study. Some indication of the problem might be obtained by comparison of data from individual subjects. Anomalous data from one subject might indicate a problem with sample collection or analysis. Incomplete excretion of absorbed material might be reflected in data on rates of excretion during the various collection periods. If substantial amounts of the dose were measured in the last samples collected, it is possible that further amounts would have been measured in subsequent samples.

However, volatilization from the skin is likely to be a main factor when recoveries are substantially less than 90% of the applied dose. Losses may occur even for compounds not considered to be highly volatile. If this phenomenon is suspected, some additional investigations, possibly simulated in vitro experiments, should be considered to provide supporting data. Such experiments could consist of application of a known amount of material to a skin sample and measurement of losses of compound from the surface.

Anticipated Results

Assessments of total dermal absorption and hence the total body burden require measurements of the compound and all its metabolites

in excreta. In the case of rodent studies using a radiolabeled compound, a complete balance of material can be obtained by taking measurements on treated skin and carcass at the end of the experiment. In this case it is expected to be able to obtain a total recovery of >90% of the administered dose. Summation of the amounts of the dose in urine, feces, and the carcass provides a value for the total absorption. An ambiguity exists if material was retained in the treated skin and was not removable by washing. The question raised is whether this material would eventually have been absorbed. It is unreasonable to assume that all this material will be absorbed, and its fate may vary from case to case, but depletion by external exfoliation may well be a major route. This phenomenon is likely to be a function of the physicochemical properties of the test compound and may be caused through some physical or covalent binding to the skin structures that effectively makes the materials unavailable for absorption. Even if the material was absorbed, this is clearly a very slow process and would provide only a very low systemic exposure concentration. An extended experimental collection period can provide an indication of the fate of this material, as described above in the rat protocol (see Basic Protocol 1).

Data obtained from human studies are of necessity more limited in providing opportunities for a complete recovery of the applied dose. The nonaccountable aspects are volatilization from the skin after application and retention in tissue or treated skin. The protocol described here is primarily one to assess human systemic exposure under simulated use conditions, and clearly enables a comparison of this exposure with laboratory animals used in toxicology studies. Some human studies using radiolabeled compounds to assess dermal absorption have been reported for diazinon (Wester et al., 1993) and pyrethrin and piperonyl butoxide (Wester et al., 1994).

For both laboratory animals and human studies, chromatographic analysis of samples (blood, urine, etc.) will provide information on the proportions and amounts of the parent compound and its metabolites. The study then becomes a metabolism investigation by the dermal route. The importance of these data is that they give the relationship between extent of absorption and the concentration-time profile or amounts of a specific component. This information can then be used in the design of further experiments to compare bioavailability using different formulations or dose rates. It also provides the means to make a transition from using radiolabeled compound to using unlabeled compound and conventional specific analytical methods.

Time Considerations

The largest amount of time required for a human study is the planning phase, which involves obtaining ethical approval, screening and selection of volunteers, and scheduling the study in a clinical unit. This process will depend upon the organizations involved but could take 2 to 3 months. The in-life phase of study will take 5 to 7 days and subsequent analysis of samples and collation of data will take a few weeks depending on the scale of the experiment. For an animal study, planning and organization may take about one month, the in-life phase about 7 days, and subsequent sample analysis etc. a few weeks.

Measurement of Disposition Half-Life, Clearance, and Residence Times

AIMS AND OBJECTIVES

The interaction of an exogenous compound, drug, or toxicant with a biological system involves at least three general processes that can be characterized as input (absorption), translocation (distribution), and output (elimination). The latter two events are often referred to as disposition. An additional and critical characteristic of such an interaction is the pharmacologic response or toxic effect. This unit is concerned with the former processes, and especially with output or elimination, which comprise the study area referred to as pharmacokinetics or toxicokinetics.

The approach taken in developing this unit will first involve providing an understanding of the process, along with definitions. This will be followed by discussion of experimental design issues, complicating factors to consider, and data analysis with a completely worked-out example. Because of the relatively limited space available here, not all concepts can be thoroughly developed; the reader will be referred to appropriate references. It will also be useful to keep in mind, when reading through this unit, the interrelationships among the parameters discussed. These interrelationships will be emphasized as the concepts are developed.

CHARACTERIZING THE ELIMINATION/DISPOSITION PROCESS (OUTPUT)

Loss of a substance from the body, generally referred to as elimination and assumed to be an irreversible process, may be quantified by three fundamental measures: rate of loss, a rate constant or associated term (e.g., half-life or residence time), and clearance. Rate of loss is not typically useful, because it is usually directly related to the plasma concentration of the substance, which is most often changing with time. Rate of loss may have some utility if the substance is at steady state (a good example is an endogenous substance such as creatinine, or an exogenous compound where steady state has been achieved with long-term intravenous infusion) or if the loss process is constant. The latter behavior is seen with some substances (e.g., ethanol, salicylate, and phenytoin) above a certain plasma concentration. In the vast majority of instances, however, the loss process for exogenous substances has been shown (or is assumed) to adhere to the principles of *first-order kinetics*. The latter principle is simply stated as: rate of loss from the body is directly proportional to the concentration (C) or amount (X) of the substance in the body (concentration is raised to the power of one and, thus, "first-order")—i.e., rate of loss $\propto C$. The proportional relationship is represented by a constant, the apparent overall first-order elimination rate constant, K, which has units of reciprocal time (t^{-1} or $1/t$)—i.e., rate of loss = $-K \times C$. The minus sign indicates loss of substance. For simplicity, the preceding and subsequent discussions will assume that dosing is achieved with an intravenous (i.v.) bolus dose (i.e., the entire dose is given at once). There is need to make an assumption concerning the model that best describes the display of concentration-time data. It is easiest to begin by assuming the simplest possible model, a one-compartment model. The meaning of this is discussed below.

Since rate per se is not particularly useful, the rate expression needs to be integrated over time (from time zero to infinity) to obtain a relationship that describes the elimination process in the form of C as a function of time, t. The integration of a first-order process results in an exponential equation:

$$C = C^0 e^{-K \times t}$$

Equation 5.3.1

where e is the base of natural logarithms and C^0 is the value of the hypothetical initial concentration at time zero. Most scientists will do almost anything to be able to present data in the form of a straight line, $y = (m \times x) + b$, where m is the slope and b is the intercept. This is easily accomplished by taking natural logarithms (ln, base e) or common logarithms (log, base 10) of both sides of Equation 5.3.1:

$$\ln C = \ln C^0 - k \times t$$

$$\log C = \log C^0 - \frac{k}{2.3} \times t$$

$$\Downarrow \quad \Downarrow \quad \Downarrow \quad \Downarrow$$

$$y = b - m \times x$$

Equation 5.3.2

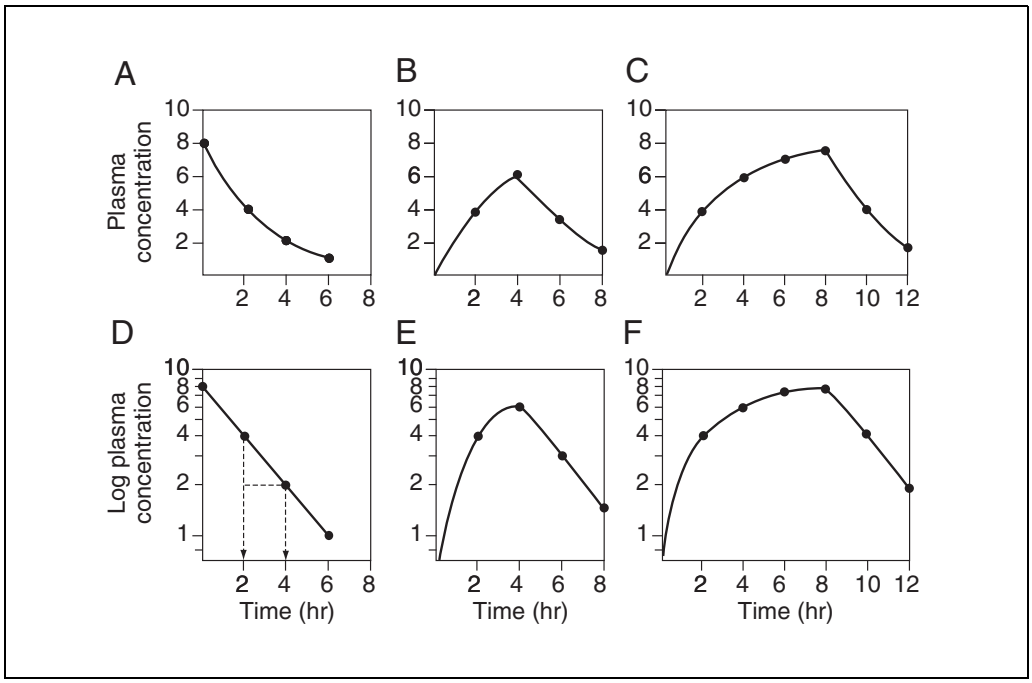

Figure 5.3.1 Plasma drug concentration–time profiles plotted on regular (Cartesian) coordinates following: (**A**) an intravenous (i.v.) bolus; (**B**) a short infusion; and (**C**) a long-term infusion. (**D-F**) The same data shown in A-C, respectively, have been re-plotted onto semilogarithmic axes in panels D-F. Used with permission of Saguaro Press.

Plots of plasma concentration versus time following an i.v. bolus dose, short-term i.v. infusion, and a long-term i.v. infusion are illustrated in Figure 5.3.1 (panels A to C). Concentrations decline in an exponential fashion, described by Equation 5.3.1. In contrast, if the same data are plotted on semilogarithmic axes, as represented by Equation 5.3.2, graphs D to F are obtained. The latter graphs contain more information than the former, and such semilogarithmic plots are the starting point for almost any pharmacokinetic analysis. In a semilog plot of plasma concentration (C; y-axis) versus time (t; x-axis), the slope of the line is given by $-K/2.3$, and the intercept is equal to C^0 following an i.v. bolus dose.

(It is of interest to note that semilogarithmic graph paper used to be called "ratio paper" and is best suited to the plotting of data that change in an exponential fashion. The term "ratio" was used to indicate that numbers in the same ratio to each other are the same distance apart on the logarithmic scale. Thus, the following pairs of numbers that are in the same ratio [of 5 to 1] are separated by the same distance: 10/2; 100/20; 600/120. Similarly, numbers that represent the same percentage increase or decrease are separated by the same distance on the logarithmic scale. Thus, the following pairs of numbers, which represent a 10% decrease, will be separated by the same distance: 100/90; 10/9; 20/18. Another characteristic of semilog graph paper is the number of "cycles" represented. Each cycle is an order of magnitude or a factor of 10. Two-cycle semilog paper will encompass a 100-fold range from, for example, 1 to 10 to 100 or 0.01 to 0.1 to 1.0.)

The first-order rate constant, K, which has units of reciprocal time, represents a fractional rate of loss of drug from the body. Thus, if K had a value of 0.05 hr^{-1}, it would be approximately correct to say that, after 1 hr, ~5% of what was in the body at the beginning of that hour was eliminated. One hour later, another 5% would be lost (but 5% of a smaller quantity). A K value of 0.1 hr^{-1} indicates that there would be a 10% loss of the starting quantity per hour. This is an approximation only, since K really represents an instantaneous rate of loss. For example, assume an initial amount in the body of 100 units and $K = 0.1$ hr^{-1}. After 1, 2, and 3 hr, the amount remaining in the body would be ~90, 81, and 73 units.

A more useful and easily understood parameter, which is inversely related to K, is referred to as *half-life* ($t_{1/2}$). Half-life is the time needed for plasma concentration or the amount of drug in the body to decline by 50%. There are several qualifications to this definition, as will be discussed. The estimation of $t_{1/2}$ is shown in Figure 5.3.1D. The concentrations of 8 and 4 units intersect the log-linear line at times

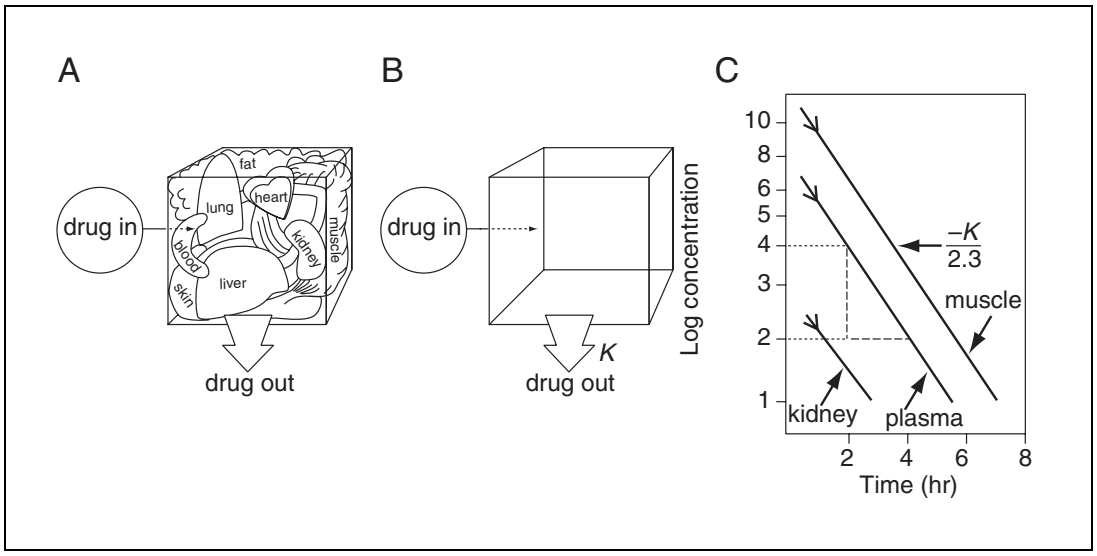

Figure 5.3.2 Schematic representation of the one-compartment model showing i.v. bolus input and drug output. (**A**) All body organs and tissues are scrunched into a single box (compartment) to indicate that these are lumped together because of similar kinetic behavior (kinetic homogeneity). Please note that there is no anatomical reality to this figure. (**B**) Typical representation of a one-compartment model. (**C**) Semilogarithmic plot of drug concentrations versus time in plasma and other selected tissues. Note that all lines are log-linear and parallel to each other (kinetic homogeneity), do not increase with time immediately after dosing, and do not superimpose (lack of concentrational homogeneity). Used with permission of Saguaro Press.

corresponding to 2 and 4 hr, respectively. The difference, 2 hr, is the half-life for that drug. The relationship between K and $t_{1/2}$ is given by $t_{1/2} = 0.693/K$. One can either calculate K from the slope of the line (by regression analysis) to estimate $t_{1/2}$, or else estimate $t_{1/2}$ from the graph and calculate K. One important point to note about this relationship is that dose does not appear; $t_{1/2}$ *is independent of dose* of drug for a first-order kinetic process.

Before applying the above analysis, it is useful to have an understanding of the model that is being depicted. A *one-compartment model* will accurately describe plasma concentration–time data if one basic assumption about the drug is met—following administration, the drug is immediately distributed throughout the body. This instantaneous distribution essentially means that drug distribution from the blood to other tissues occurs so rapidly that typical blood-sampling protocols will not permit it to be seen. Figure 5.3.2 illustrates one way to visualize such a model with drug input and output. Many, but not all, body organs and tissues have been scrunched into a large box (Fig. 5.3.2A); clearly, no attempt has been made to be anatomically correct in this depiction. This rendering is presented as a reminder that our models, no matter how simple, must reflect the existence of real body organs and tissues. The model, shown in 5.3.2B, appears as a simple box or as a single compartment not cluttered with body components and with no concern for anatomy. This model simply reflects the assumption underlying its creation; all parts of the body behave the same kinetically and, therefore, can be lumped together. Figure 5.3.2C, which is a semilog plot of plasma and other tissue concentrations with time, indicates several important aspects of the behavior of the model. First, concentrations in all sampled tissues are described by a log-linear straight line; this follows from our assumption of first-order elimination kinetics. The half-life calculation is illustrated for the plasma data; $t_{1/2}$ is equal to 2 hr. Second, all lines are parallel to each other. In other words, these tissues behave in a *kinetically homogenous* manner. In contrast, the concentrations do not superimpose, and therefore there is no concentrational homogeneity. The latter occurs because of differences in tissue binding of drug (in this instance the order of binding is: muscle>plasma>kidney). Finally, since we have assumed instantaneous distribution, all concentrations decline with time following dosing (i.e., there is no increase immediately following i.v. bolus dosing; even though we know that this must happen, it happens so quickly that we cannot see it using traditional blood sampling). *The one-compartment model*

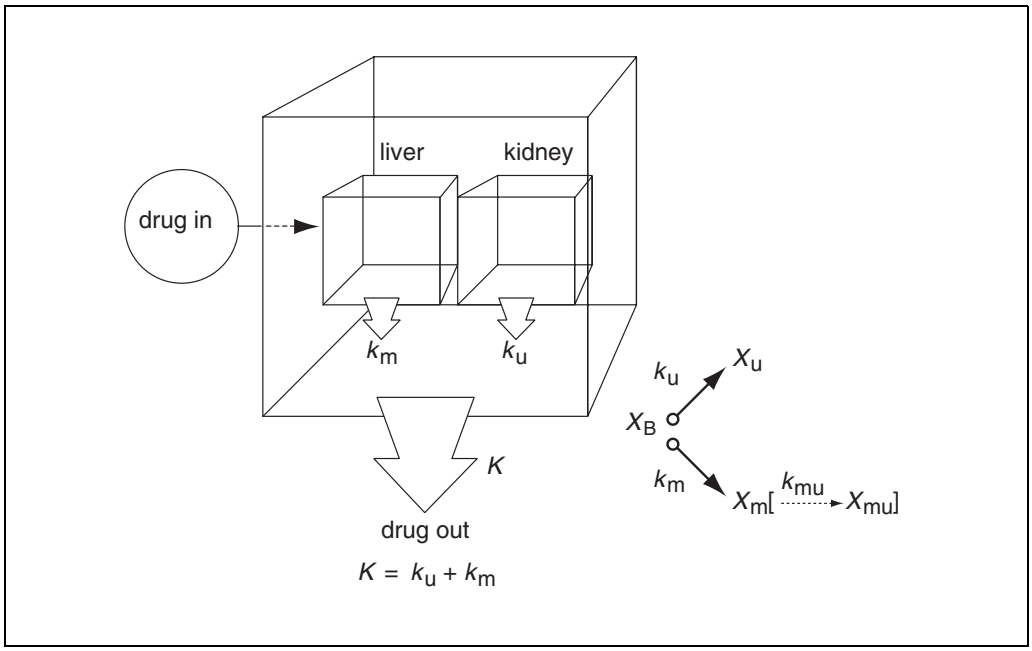

Figure 5.3.3 Schematic representation of elimination from a one-compartment model (left). The kidney and liver independently contribute to the overall elimination of drug. The apparent overall first-order elimination rate constant (K) is the sum of the rate constants for urinary excretion of drug by the kidney (k_u) and enzymatic metabolism by the liver (k_m). A simple symbolic scheme is shown on the right. Also shown by dashed line is the excretion of metabolite into the urine (k_{mu}). The latter process has no bearing on drug elimination. Used with permission of Saguaro Press.

lumps all body regions together, into a single space, since all regions behave the same way kinetically.

Reexamining Figure 5.3.2C, the only data that we will likely have generated are those from blood sampling and not from sequential tissue sampling. The fluid sampled is always blood (unless microdialysis is being applied) from which we can assay blood, plasma, or serum. For now, it is not necessary to distinguish among these different biofluids. The plasma concentration–time data are plotted on semilog graph paper (or using a software program, whereupon the data will be seen on a computer screen) and an estimate of the slope is obtained (using linear regression). From the slope, values for the apparent, overall first-order elimination rate constant (K) and $t_{1/2}$ are obtained. This overall rate constant is the sum of all individual eliminating organ rate constants.

The latter point is noted in Figure 5.3.3. The model shown is a representation of a one-compartment model with renal excretion and hepatic metabolism. The symbolic notation (right side of figure) indicates that these two kinetic processes are parallel (or competitive) and that the overall rate constant, K, is the sum of the individual rate constants for urinary excretion (k_u) and hepatic metabolism (k_m). It should be noted that half-lives are not additive. It is also important to recognize that subsequent (or "downstream") events, such as urinary excretion of a metabolite (represented by k_{mu}), have nothing to do with elimination of parent drug. The downstream process may be important because the metabolite is active or toxic, but its existence has no bearing on the disposition of parent drug or the value of K.

The meaning, but not the calculation of half-life, becomes more complicated when it is necessary to describe the disposition of a drug with a more complex model. Whenever drug distribution from the blood to body tissues following an i.v. bolus dose is not instantaneous but occurs at a measurable rate, the drug is said to have *multicompartmental* characteristics. We can no longer lump all body tissues and organs into one compartment. It is necessary to separate one group of tissues from another group—one rapidly receiving drug and the other receiving drug at a slower, measurable rate. This is illustrated in Figure 5.3.4A where there are two connected boxes (compartments) each with a different group of tissues. The group of tissues on the left, which includes blood, receives the compound rapidly (e.g., liver and kidney). The other group of tissues on the right, including muscle, skin, and fat, receives the compound more slowly. This two-

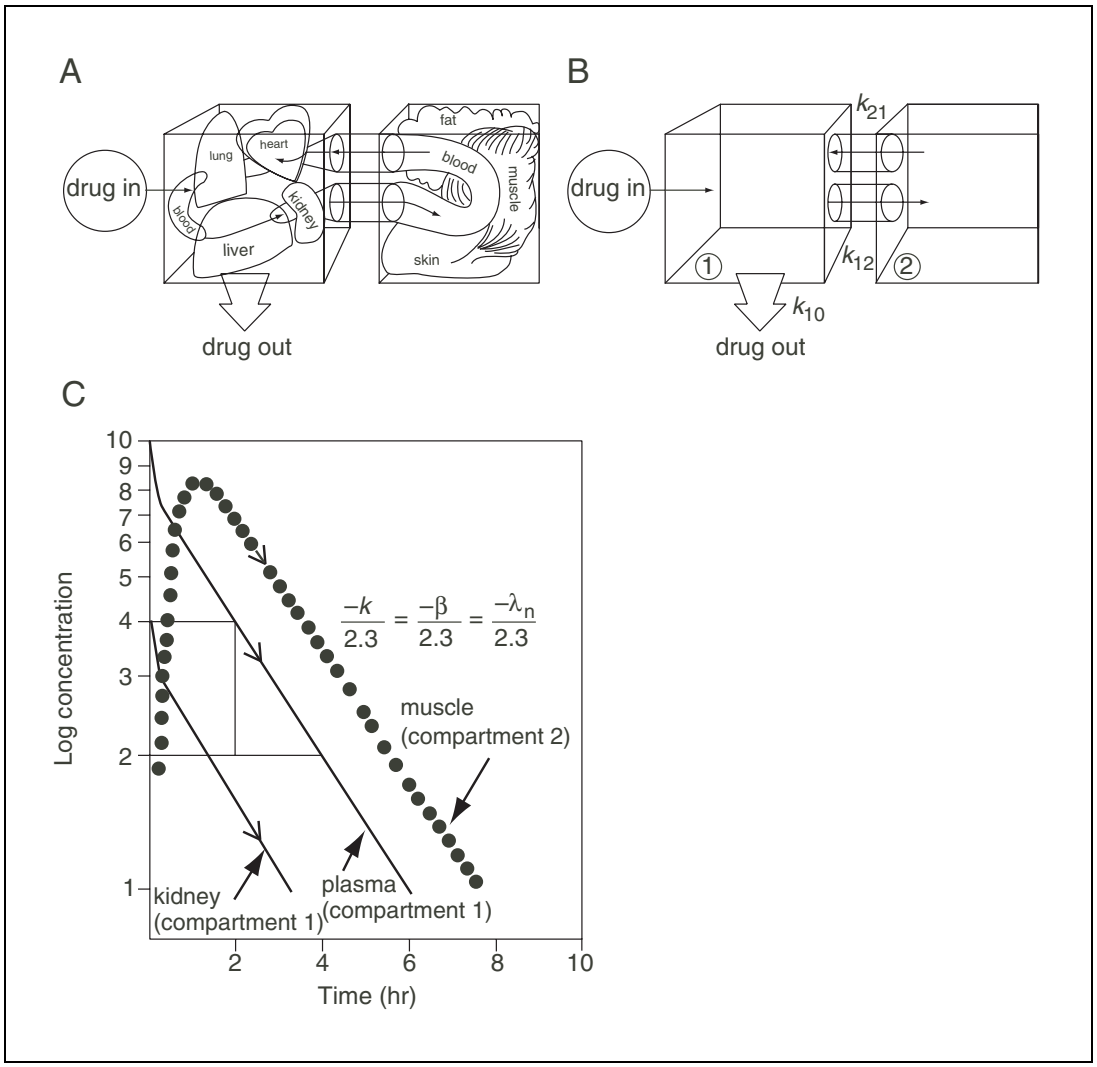

Figure 5.3.4 (**A**) An "anatomical" version of a two-compartment model illustrating the presence of specific organs and tissues in each of the two compartments connected by the blood stream. Tissues lumped together in the compartment on the left receive drug rapidly, whereas tissues lumped into the compartment on the right receive drug slowly. (**B**) Hypothetical two-compartment model devoid of any consideration of tissues. Compartment 1 ("central") receives and eliminates drug, whereas, compartment 2 ("peripheral") receives drug slowly. The intercompartmental first-order rate constants are shown (i.e., k_{12} and k_{21}) as well as the elimination rate constant (k_{10} or k_{el}). (**C**) Concentration-time profiles (semilog axes) of plasma and tissues in rapid equilibrium with plasma (e.g., kidney; compartment 1) and tissues in slow equilibrium with plasma (e.g., muscle; compartment 2). Used with permission of Saguaro Press.

compartmental representation in Figure 5.3.4B ignores the tissues contained in each box but their presence is assumed. The compartment receiving and eliminating drug is referred to as compartment 1 (or "central") and the other compartment is referred to as compartment 2 (or "peripheral"). The intercompartmental first-order rate constants, k_{12} and k_{21} and the rate constant associated with drug elimination, k_{10} (or k_{el}), are shown in the model. The corresponding concentration-time data are illustrated in Figure 5.3.4C. The concentrations of drug in those tissues represented in compartment 1, which receive drug rapidly (plasma and kidney are shown), initially decline rapidly (the distributive phase), and then in a log-linear manner (post-distributive phase). In contrast, drug concentrations in those tissues that receive drug more slowly (compartment 2; muscle is shown) initially rise and then decline in a log-linear manner in parallel with plasma.

The estimation of half-life is shown in Figure 5.3.4C and it is determined in the same way as outlined previously. The only qualification is that the data must be in the log-linear or post-distributive or terminal phase. It is for this reason that half-life is best referred to as a "terminal" $t_{1/2}$ or a "disposition" $t_{1/2}$. The for-

mer term indicates which data are being used for the estimation of half-life and the latter term makes clear that half-life depends upon distribution as well as elimination. The term "elimination" half-life is less descriptive and "biological" half-life is likely to be confused with response and, for that reason, use of the two latter terms is not encouraged.

The slopes noted in Figure 5.3.4C incorporate one of several symbols: K, β, or λ_n. The two latter terms arise from the equation describing the plasma concentration-time profiles of a multicompartmental model, in this case a two-compartment model:

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

Equation 5.3.3

$$C = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$$

Equation 5.3.4

By definition, $\alpha > \beta$ (or $\lambda_1 > \lambda_2$), and the terminal slope, which always represents the slowest process, is given by β or λ_n (in this case, λ_2). The rate constants, α and β, are hybrid constants in that they depend upon other constants in the model (i.e., k_{12}, k_{21}, and k_{10}). The coefficients (A's and B's) represent intercepts on the y-axis.

An important point to appreciate about $t_{1/2}$ is that it is not an independent parameter, but rather $t_{1/2}$ depends upon two other parameters: apparent volume of distribution (V) and clearance (CL):

$$t_{1/2} = \frac{0.693\,V}{\mathrm{CL}}$$

Equation 5.3.5

The *apparent volume of distribution* is an abstract concept made more difficult by the variety of different volume terms that may be estimated. This volume is rarely a real physiological space and, for that reason, its meaning causes confusion. Volume serves as a proportionality constant between blood concentration and the amount of substance in the body, and it gives an indication of the magnitude of distribution (or movement) out of the vascular system (i.e., the greater the apparent volume, the more extensive is the distribution). Fundamentally, the apparent volume represents the space that a substance occupies if it is uniformly present throughout the body at the same concentration as in blood or plasma. The latter is the reference fluid used for calculation of volume. That is, the apparent volume is a "volume equivalent" of plasma. For example, if plasma and liver concentrations of a substance were 1 and 10 mg/liter, respectively, every liter of liver would be equivalent to 10 liters of plasma. This disparity in concentration among tissues and the consequent value of apparent volume is a function of tissue binding. Apparent volumes in the rat may be as small as ~0.2 liter/kg (gentamicin) or as large as ~30 liter/kg for chlorpromazine and even higher for other compounds, such as insecticides.

Why should apparent volume of distribution or movement of a substance out of the bloodstream into tissues affect $t_{1/2}$? In order for a drug to be eliminated from the body it must be in the blood stream and carried to the eliminating organs (primarily the liver and kidney). If most of the compound in the body resides in tissues and not in the blood stream, that compound is not readily accessible to the organs of elimination and will, as a consequence, be slowly eliminated. The greater the apparent volume, the slower this process and the longer the $t_{1/2}$.

The other part of the half-life relationship noted in Equation 5.3.5 involves a term referred to as *clearance*. This idea of clearance is perhaps the most important concept in pharmacokinetics, and it has numerous applications. Clearance determines concentrations at steady state (resulting from multiple dosing) and it permits the evaluation and prediction of drug disposition in the body. Although clearance is used to characterize elimination, it differs from $t_{1/2}$ in that it reflects the efficiency of removal by an eliminating organ. Clearance (CL) has units of flow, i.e., volume per time, and it is defined as that volume of blood (or plasma) from which the substance is completely removed per unit of time to account for the rate at which the material is being eliminated. On the assumption of first-order kinetics, the basic relationship that defines clearance is

$$\mathrm{CL} = \frac{\text{rate of elimination}}{\text{plasma concentration}} = \frac{\dfrac{d\ (\text{amount})}{dt}}{C}$$

Equation 5.3.6

This relationship is virtually identical in form to an equation noted previously in describing first-order kinetics: $dC/dt = K \times C$ versus $d(\text{amount})/dt = \mathrm{CL} \times C$. The proportionality

constant in the former case, K, has units of reciprocal time, whereas the proportionality constant in the latter case, CL, has units of flow. The former constant depends upon apparent volume (as noted in Equation 5.3.5); clearance does not. Each eliminating organ has its own value for clearance and the sum of all such clearances is referred to as *systemic clearance*, CL_S, or total body clearance. In order to measure organ clearance experimentally in the whole animal, one has to be able to quantitate the mass of compound appearing in a terminal compartment with time. For example, clearance into urine (renal clearance), bile (biliary clearance), and expired breath (pulmonary clearance) can be measured since the compound under study can be completely collected. This is not the case for systemic or metabolic clearance. Another relationship, therefore, needs to be used in order to calculate those clearances, as well as any other organ clearance. The integral of Equation 5.3.6 for systemic clearance is:

$$CL_s = \frac{\frac{d\ (\text{amount})}{dt}}{C} = \frac{\int_0^\infty \frac{d\ (\text{amount})}{dt}}{\int_0^\infty C \times dt} = \frac{\text{dose}}{AUC_0^\infty}$$

Equation 5.3.7

where dose is the i.v. bolus dose (or the dose actually absorbed by some nonvascular route) and AUC_0^∞ is the area under the plasma concentration–time curve from time zero to infinity (i.e., area under a curve is the mathematical equivalent of integrating the equation that describes that curve). (The area may be estimated two ways: by fitting the data to an appropriate equation from which the parameters of the equation are obtained and used to calculate area, or via an area-approximation method such as the trapezoidal rule or spline function, among others. Some investigators like to look upon an area as an index of exposure to that substance; the greater the area, the greater the exposure. The latter will typically vary with dose or it may be different among subjects.) Multiplying the numerator by the fraction of the dose metabolized or excreted unchanged into the urine will provide corresponding estimates of metabolic or renal clearances, respectively.

Clearance is best understood with reference to Figure 5.3.5. In-flowing (i.e., arterial) blood enters an organ with a flow of Q_{in} and a substrate concentration of C_{in}. Out-flowing (i.e., venous) blood exits the organ with a flow Q_{out} ($Q_{in} = Q_{out}$) and a substrate concentration of C_{out}. If the organ is responsible for elimination of that substance, $C_{out} < C_{in}$. The relationship between these concentrations is embodied in the extraction ratio (ER):

$$\text{extraction rate} = ER = \frac{C_{in} - C_{out}}{C_{in}}$$

Equation 5.3.8

If $C_{in} = C_{out}$, this is a noneliminating organ and ER = 0. If $C_{out} = 0$, then ER = 1 (i.e., all of the substance has been removed from the in-flowing blood, the most efficient removal process possible). A compound with an intermediate ER value (0.5) is illustrated in Figure 5.3.5. Flow to this hypothetical organ is 10 ml/min. During a short interval of time, say, 1 min, the concentration entering the organ is 10 units/ml, and upon exit the concentration is reduced to 5 units/ml. The value for ER is (10 − 5)/10, or 0.5 The organ has removed 50% of the substance entering the in-flowing blood. The amount extracted or eliminated by the organ is one-half of the amount entering: 0.5 × 10 ml × 10 units/ml = 50 units. This is shown in Figure 5.3.5 as the material retained in the organ. Since that amount of substance (50 units) is contained in 5 ml of blood, the organ clearance is 5 ml per unit of time, in this instance, 1 min. Another way to state that calculation is that clearance is the product of ER and Q (i.e., 0.5 × 10 ml/min = 5 ml/min). According to Equation 5.3.6, clearance may be calculated as the rate of elimination divided by the corresponding blood concentration. The rate of elimination is 50 units/min, divided by the incoming concentration of 10 units/ml, giving a clearance of 5 ml/min.

The relationship between extraction ratio and clearance is illustrated with the "double rainbows" shown in Figure 5.3.6. The organ extraction ratio is often arbitrarily divided into three equal segments: low (ER < 0.33), intermediate (ER, 0.33 to 0.67), and high (ER > 0.67) extraction. The corresponding organ clearances, behind the ER rainbow, are related to the latter via blood flow, since CL = ER × Q. The clearance rainbow is divided into three comparable regions: low (or restrictive), intermediate, and high (or nonrestrictive) clearance.

Notice that organ clearance can never exceed organ blood flow following i.v. dosing: a substance cannot be cleared any faster than it is delivered (via blood flow) to the eliminating organ. Indeed, the clearance of high-ER compounds (ER ≈ 1) essentially measures organ blood flow (e.g., *p*-aminohippurate for measuring renal blood flow; indocyanine green for measuring liver blood flow). If we consider two specific eliminating organs, the liver and kid-

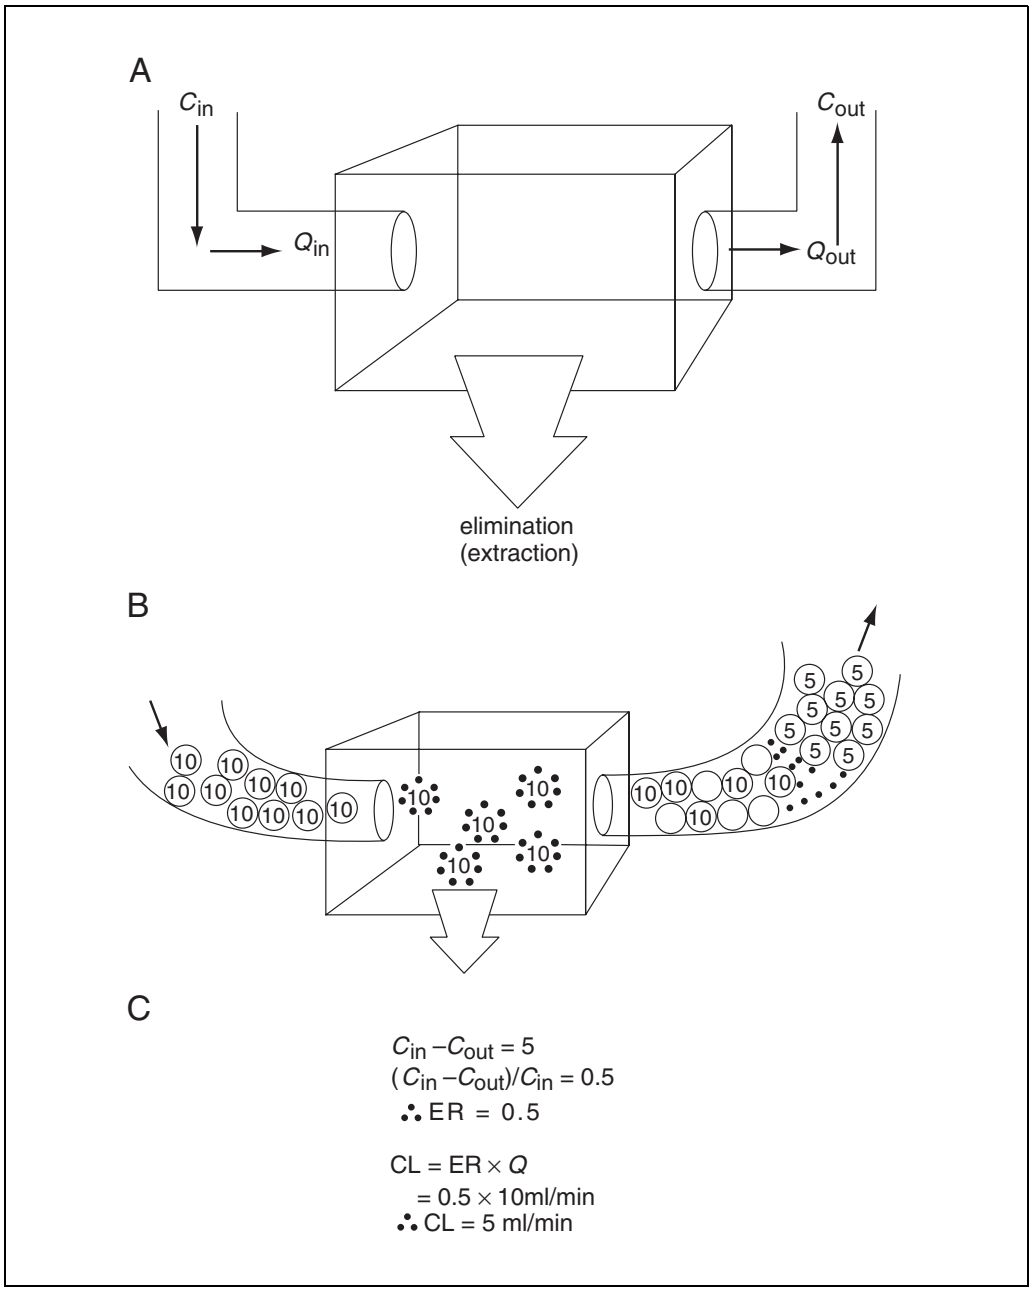

Figure 5.3.5 (**A**) Representation of blood flowing through an organ that eliminates or extracts a substrate from the in-flowing blood (Q_{in}) at an entering concentration of C_{in}. The resulting out-flowing blood ($Q_{out} = Q_{in}$) and concentration, C_{out}, allow determination of extraction ratio. (**B**) A hypothetical eliminating organ receiving 10 ml blood/min (each circle = 1 ml) at an initial concentration of 10 units/ml. The exiting concentration is 5 units/ml, the equivalent of 5 ml of blood has been extracted and the corresponding mass of substrate remains in the eliminating organ. (**C**) The extraction ratio, ER, is determined as the difference between the in and out concentrations divided by the in concentration. ER is equal to 0.5. Organ clearance, CL, is then determined from the product of ER and blood flow, Q, to be 5 ml/min. Used with permission of Saguaro Press.

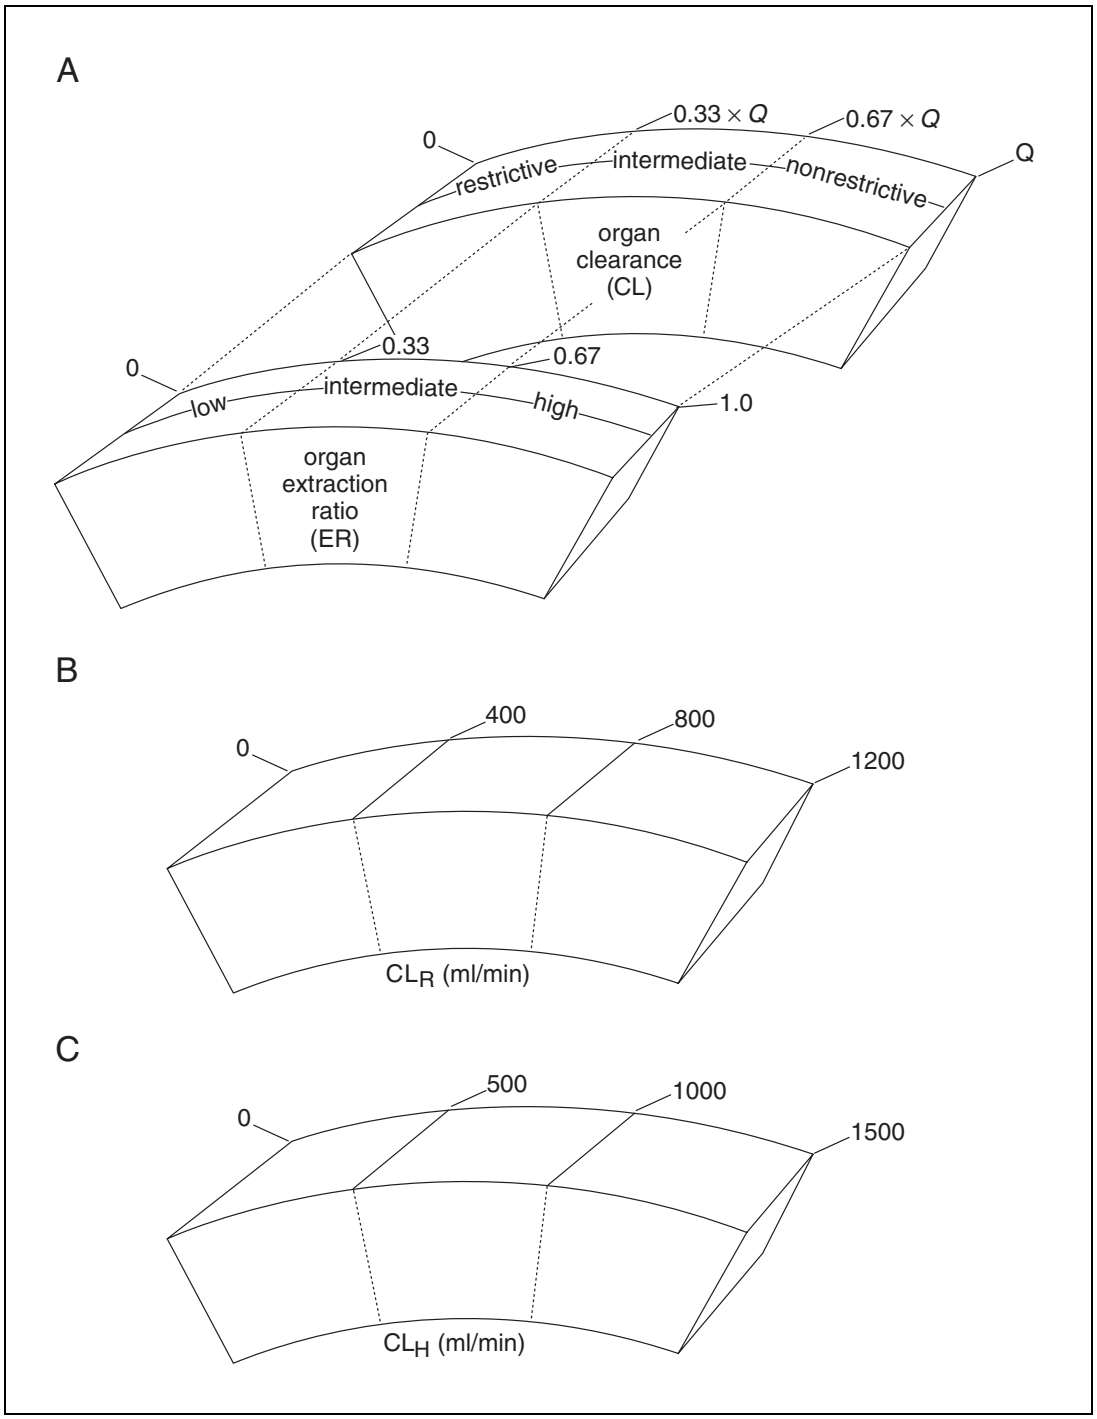

Figure 5.3.6 A "double rainbow" illustrating the range of values and the relationship between extraction ratio and organ clearance. The extraction ratio (ER) rainbow is divided into three equal parts: low, intermediate, and high extraction. Organ clearance, CL, is related to ER by organ blood flow and values range from 0 to organ blood flow. The clearance rainbow is divided into equal parts: low or restrictive ($<0.33 \times Q$), intermediate [$(0.33 \times Q)$ to $(0.67 \times Q)$] and high or nonrestrictive ($>0.67 \times Q$) clearance. The actual clearance values for two eliminating organs in humans, the kidney (**B**) and the liver (**C**), are illustrated at the bottom of the figure. The maximum hepatic and renal clearance values will not exceed blood flows to those organs, 1500 and 1200 ml/min, respectively. Used with permission of Saguaro Press.

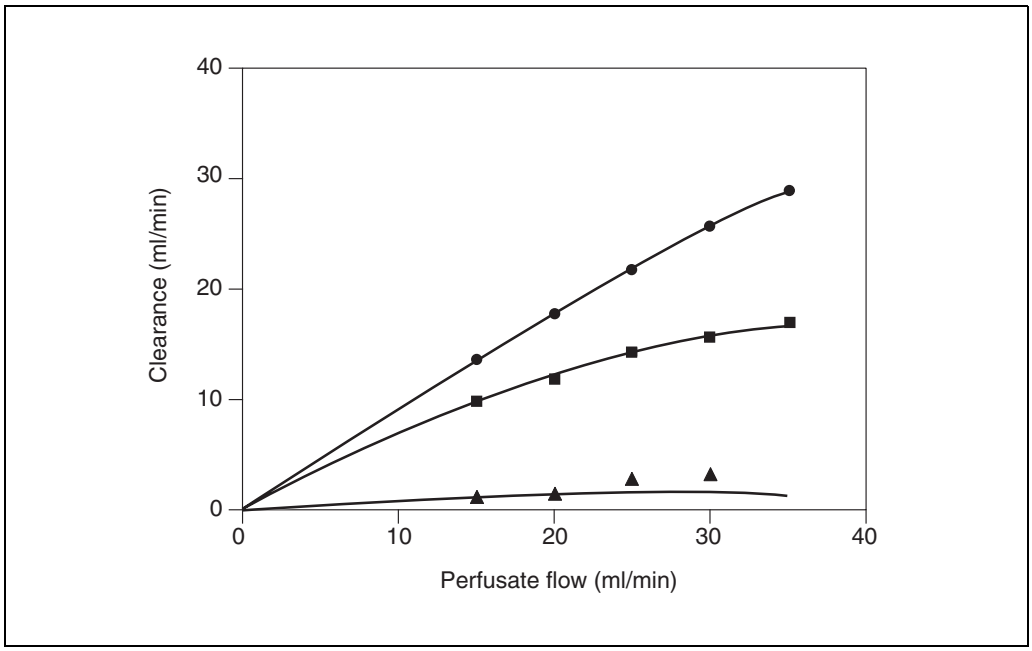

Figure 5.3.7 Clearance as a function of perfusate flow as determined in an isolated perfused rat liver. Note the dependence of clearance on flow for lidocaine (circles) and ethanol (squares) which have high and intermediate extraction ratios (0.91 and 0.65), respectively. In contrast, the clearance of antipyrine (triangles), which has a low extraction ratio (0.07), is independent of flow. Data taken from Sinha et al. (2000). Used with permission of Saguaro Press.

ney, the corresponding clearance "rainbows" are illustrated at the bottom of the figure. The average blood flows to the liver and kidney in humans are ~1500 and 1200 ml/min, respectively, as noted on the extreme right of the "rainbows." Figure 5.3.7 illustrates the relationship between clearance and perfusate flow for high (lidocaine), intermediate (ethanol), and low (antipyrine) clearance compounds as determined in an isolated perfused rat liver (Sinha et al., 2000).

A particularly useful expansion of the ER relationship, based upon a simple model of an eliminating organ (Wilkinson and Shand, 1975) is known variously as the venous equilibrium, blood flow-limited, or well-stirred model:

$$ER = \frac{CL_{int}}{CL_{int} + Q}$$

Equation 5.3.9

Since clearance is the product of ER and Q:

$$CL = \frac{CL_{int} \times Q}{CL_{int} + Q} = \frac{f_U \times CL_{U,int} \times Q}{f_U \times CL_{U,int} + Q}$$

Equation 5.3.10

The above relationship embodies all of the factors that can possibly influence organ clearance: f_U, unbound fraction of compound in plasma; CL_{int}, intrinsic clearance; $CL_{U,int}$, unbound intrinsic clearance; and Q, blood flow. Any change in clearance must be mediated through one or more of the parameters in Equation 5.3.10. Intrinsic clearance, CL_{int}, is the inherent ability of the organ to clear the compound in the absence of any blood flow restrictions. For example, a measure of intrinsic metabolic clearance could be obtained by adding the substrate to a test tube containing an enzyme or homogenized liver preparation. Since the latter value may be affected by substrate binding in the preparation, another term, unbound intrinsic clearance, $CL_{U,int}$, is defined. Unbound intrinsic clearance represents the intrinsic ability to metabolize in the absence of any substrate binding in the test tube. Having some knowledge of the clearance of the compound, i.e., whether it is low or high, permits simplification of the relationships above, which in turn provides insight into those factors that may influence clearance (and, therefore, half-life). Therefore, for a compound with low clearance (low ER),

$$CL_{int} = f_U \times CL_{U,int} << Q, \text{ and}$$
$$CL \approx f_U \times CL_{U,int}$$

Equation 5.3.11

For such a compound, only changes in plasma protein binding or unbound intrinsic clearance will affect clearance. An example is antipyrine, whose clearance is small and therefore independent of flow (see Fig. 5.3.7). In contrast, for a compound with a high clearance (high ER),

$$CL_{int} = f_U \times CL_{U,int} >> Q, \text{ and}$$
$$CL \approx Q$$

Equation 5.3.12

For such compounds, only a change in organ blood flow will affect clearance. An example is lidocaine, whose clearance depends only upon flow (see Fig. 5.3.7). (These simplifying concepts and the resulting approximate relationships provide invaluable insight and predictions with respect to the effect on drug disposition of such factors as drug-drug interactions, disease states, and physiological disorders.) Several excellent reviews have been published which present these clearance concepts (Wilkinson and Shand, 1975; Wilkinson, 1987; Rowland and Tozer, 1995a).

Another approach to the characterization of the rate of elimination (and other processes) which has received considerable attention in recent years is referred to as *statistical moment theory*, *residence time analysis*, or *noncompartmental analysis*. The acronym SHAM has been used to describe this approach; the acronym is derived from the following abbreviations: *S*, slope; *H*, height; *A*, area; and *M*, moment. Each of these measures, which describes attributes of a plasma concentration-time curve, may be used by themselves or in combination to completely characterize various aspects of the disposition process (e.g., *M*/*A* = mean residence time; Lassen and Perl, 1979). The use of slope (to get K and $t_{1/2}$), height (to get certain volumes), and area (to get clearance and volume) have already been discussed. The idea of a *moment* is applied to concentration versus time data and is normalized in order to obtain additional information about disposition, as noted below. Many biological sciences such as biochemistry and physiology (and physical sciences such as chemical engineering) have traditionally characterized elimination processes in a manner different from the way that it has developed in pharmacokinetics (as outlined previously). Those fields are more likely to employ one of the following (generally interchangeable) terms to characterize elimination: *time constant*, *turnover time*, or *mean residence time* (MRT). The time constant is the time necessary for the plasma concentration to decline to 37% of its initial value (i.e., 63% loss versus 50% for $t_{1/2}$). That time can be calculated from $1/K$ (versus $0.693/K$ for $t_{1/2}$), where K is the same first-order overall elimination rate constant discussed previously, and if a one-compartment model applies. Another way to look at this value is that it represents the amount of time necessary for an endogenous pool of substance (e.g., albumin) to completely replenish itself or "turn over." Finally, this time represents the average amount of time that molecules of an exogenous substance spend in the body after gaining access to the body, which corresponds to the mean residence time, MRT. In a simple (i.e., one-compartment) system, the time constant and MRT are easily related to half-life; $MRT = 1.44 \times t_{1/2}$. The relationship is more complex for a multicompartment system (Mayersohn and Hamilton, 1993). In physiological or biochemical terms, MRT is the relationship between some mass and a corresponding flux (rate) or between some volume and a corresponding flow. For example, the mean circulation time of blood in an adult human male is governed by total blood volume (~5 liters) and total blood flow (or cardiac output; ~5 liters/min). Mean circulation time is ~1 min (i.e., 5 liters/5 liters/min). The turnover time of the endogenous albumin pool in an adult human is determined by the mass of the pool (~300 g) and its elimination (or catabolic) rate (~10 g/day). The turnover time for the albumin pool is ~30 days (i.e., 300 g/10 g/day).

In analogy to the preceding relationships, a mean residence time for an exogenous i.v. bolus dose of drug or toxicant is given by the ratio of an apparent volume term (referred to as the steady-state volume) and the corresponding systemic clearance of the compound:

$$\text{mean residence time} = MRT = \frac{V_{ss}}{CL_s}$$

Equation 5.3.13

Note that the dependence of MRT upon volume and clearance is identical to that for $t_{1/2}$ (Equation 5.3.5); however, different volume terms are involved. The major advantage of expressing elimination in terms of MRT rather than $t_{1/2}$ is that the former is nonparametric and may be calculated directly from the data (it also

offers a method to calculate V_{SS}; Benet and Galeazzi, 1979; Perrier and Mayersohn, 1982a,b). In general, moments are easier to estimate; the parameters may not be. In addition, we generally need more data to estimate parameters compared to moments.

Moment analysis has other uses which include, for example, the characterization of movement within and through compartments (McNamara et al., 1987; Kong and Jusko, 1988), estimation of metabolite residence time after parent administration (Veng-Pedersen, 1986), and estimation of mean absorption time in conjunction with i.v. and non-i.v. data (Riegelman and Collier, 1980).

A statistical view of a mean residence time can be illustrated by analogy to i.v. drug dosing (e.g., Karol, 1989). Envision 100 people simultaneously entering a large room that you rented for a New Year's Eve party. These people all enter at time = 0, linger in the room, and leave the party by exiting at different times. Beginning at time zero, a record is kept of the time of exit and how many people exit at that time (this is how you discover who your friends really are). Table 5.3.1 summarizes the data.

We want to calculate from these data the average amount of time your friends spend at the party by being in the room (in analogy to a substance's MRT in the body). A calculation similar to a weighted mean is done: add the product of time of exit (t) and the number exiting at that time (n) and divide that product by the sum of all those exiting (N):

$$\text{mean time} = \frac{(10\times17)+(12\times23)+\ldots+(35\times14)}{(17+23+\ldots+14)} = 20.9 \text{ min}$$

Equation 5.3.14

Your friends spend an average of 20.9 min at the party (this does not appear to have been a very successful party!).

In general:

$$\text{MRT} = \frac{\sum_{i=1}^{n} t_i \times N_i}{\sum_{i=1}^{n} N_i}$$

Equation 5.3.15

When dealing with drug or toxicant elimination, we do not consider discrete events (such as people leaving a room) because there are billions of molecules and an infinite number of corresponding events (i.e., times of exit). Rather than summing as in Equation 5.3.15, the relationship is integrated over time zero to infinity. Since the molecules will exit the body according to some explicit relationship (which need not be known, e.g., $C = C^0 \times e^{-Kt}$), the term N_i may be replaced by some appropriate expression for plasma concentration as a function of time. Assuming constant clearance:

$$\text{MRT} = \frac{\int_0^\infty t \times C \times dt}{\int_0^\infty C \times dt} = \frac{\text{AUMC}_0^\infty}{\text{AUC}_0^\infty}$$

Equation 5.3.16

The denominator is the area under the concentration-time curve discussed previously. The numerator is the area under the first moment of the concentration-time curve, AUMC, which is obtained from a plot of $t \times C$ versus t. The ratio, AUMC/AUC, is called the "normalized first moment," which gives information about a

Table 5.3.1 Data Used for the Estimation of a "Mean Residence Time"

Time of exit (min): t	Number exiting: n	Cumulative number exiting
10	17	17
12	23	40
18	6	46
22	19	65
30	21	86
35	14	100

mean value. The subsequent normalized moments (2nd, 3rd, etc.) give additional information about, for example, the variance around the mean, measure of skewness or symmetry, measure of peakedness (kurtosis), etc. The latter moments tend to be unstable and are not often calculated. The terminal area for the AUMC plot is not determined in the same way as for the C versus t curve (i.e., $AUC_0^\infty = C_{last}/K$) but rather with use of the following relationship:

$$AUMC_0^\infty = \frac{C_{last}}{K^2} + \frac{t \times C_{last}}{K}$$

Equation 5.3.17

There are numerous other mean residence and transit times that may be calculated and which help to define certain properties of disposition and more completely characterize the system, but a discussion of these is beyond the scope of this chapter (see, e.g., Lassen and Perl, 1979; Kong and Jusko, 1988).

EXPERIMENTAL DESIGN ISSUES

The design of any experiment must be appropriate in order that unequivocal answers will be obtained to the questions being asked. Anything less is a waste of time, effort, and money. We will assume here that the question being asked is how can we best describe the disposition kinetics of a substance as a function of one or more variables (e.g., dose and route of administration)? A fairly consistent list of experimental design issues needs to be addressed, regardless of the nature of the substance.

Preliminary Considerations

Before beginning any animal experiment, consideration of two issues will assist in making the study successful. First, the analytical method must be in place. The analytical validation should provide answers to the questions: how sensitive, how selective, how reproducible, and how robust. The results of any pharmacokinetic study are only as meaningful as the quality of the analytical method. This point cannot be over-emphasized. Sensitivity will help establish the minimum dose (and resulting plasma concentrations) and the duration of sampling. The selectivity will ensure that the data, subsequent analysis, and parameter values are uniquely associated with the parent compound administered (and not, for example, a metabolite). Reproducibility makes the data and subsequent analysis more reliable and meaningful. Robustness ensures that the assay is sufficiently rugged so that it is not overly influenced by changes in day-to-day conditions and environment. The person who is expected to assay the authentic samples should be given unknown samples spiked with the compound of interest (in the appropriate fluid matrix), prepared by another member of the laboratory, to assure the reliability of the results.

A second essential step to a successful study, often neglected but well worth the effort, is to conduct a preliminary experiment. This one experiment or series of experiments will answer one very fundamental question: is it possible to perform the study and can the questions posed be answered? If not, this is the time to rethink the study and the experiments. The data obtained from this preliminary experiment will permit optimization of virtually all of the important experimental variables, such as: dose, sample volume, times and duration of sampling, and animal response. What constitutes a "preliminary" experiment will vary from investigator to investigator. Basically, it represents the minimal experimental effort necessary to approximately characterize the variables. Those variables, when known, will result in the design of an experiment that will provide the data necessary to answer the questions posed or hypothesis to be tested. Typically, this preliminary experiment will indicate, among other things, most of the following—(1) if the assay is working properly; (2) the type of pharmacokinetic model and kinetics of elimination involved; (3) the duration of blood sampling and the best times of sampling; (4) the minimum blood volume needed to provide reliable analytical data; (5) the need to change dose; and (6) the safety to the animal of the dose chosen Other issues that may be addressed in this preliminary experiment, but which require additional effort, would include the degree of plasma protein binding, presence of metabolites, and recovery of the compound in urine, bile, feces, or expired air.

The results of the preliminary experiment will provide useful information that will then permit optimization of the experimental design. Alternatively, the preliminary experiment may be only partially successful, in the sense that not all of the needed information is obtained. Finally, the preliminary experiment may be a "failure," in the sense that, for example, no measurable plasma concentrations are observed. If either of the two latter situations arises, additional preliminary experiments need to be conducted. However, preliminary

experimental results like these should not be considered failures, because such results clearly indicate the need to revise the initial experimental design. This information, while perhaps not what was anticipated, could save great effort, time, and expense.

Some investigators will go one step further and perform a "positive control" experiment, whose results are, from experience, completely predictable. For example, a dose of a compound with which there is considerable experience in that laboratory will be given to an animal and the data analyzed and compared to previous results. This is done to determine if critical aspects of the experiment are working properly. Such an experiment will allow, among other things: (1) assessment of the student's or technician's ability to prepare and administer the compound, obtain samples, and perform the assay properly; (2) evaluation of the analytical instruments to be certain that they are working properly; and (3) evaluation of the ability to properly analyze the resulting data. There is much to be said for this type of experimental control, but in the author's experience it is a seldom-used safeguard.

General Design

Characterizing the disposition kinetics of a substance is generally accomplished using one of three sampling strategies: (1) intense sampling of single animals; (2) less intense sampling of several animals; (3) sparse sampling of many animals. The two former designs, especially the first, are most often used, but the last approach has gained considerable attention in recent years, especially within the pharmaceutical industry. In the first design, three to six individual animals are separately dosed with compound and intensive blood sampling proceeds according to some regimen. Data from each animal are analyzed and parameters obtained. The parameters are averaged and a measure of variance expressed (e.g., standard deviation). Individual plasma concentration–time curves can be prepared to describe disposition. The within-animal data generally provide a good description of the disposition of the compound, and comparisons among animals give some estimate of inter-animal variation (albeit limited information about the population). A disadvantage to this approach is that surgery is generally required in order to place a permanent catheter, which permits multiple sampling over time. The second design follows the same sampling scheme as the first, but blood samples are taken from among a number of different animals and at different times; thus, complete concentration-time curves are not obtained in individual animals. For example, samples 1 through 3 are taken from animals A and B; samples 4 through 6 are taken from animals C and D, etc. One obtains a single concentration-time curve with some estimates of variance at each time, depending upon the number of animals sampled per time. The analysis of these data results in a single set of parameter values with no estimation of variance. An advantage to this approach is that a limited number of blood samples (and limited blood volume) is taken and, therefore, surgical placement of a catheter is generally not necessary.

Another design, used in recent years in the pharmaceutical industry, which is less suited for an academic environment, is similar to the previous approach but involves fewer samples from even larger numbers of animals. This design relies on a sparse amount of data per animal but a sufficiently large number of animals that a good estimation of population parameters is obtained. The study groups are generally those associated with long-term toxicity testing (i.e., the study group per se or a parallel "satellite" group). Since one wants to interfere with the animals as little as possible, only a limited number of blood samples will be taken from any one animal (perhaps only one). The resulting data are then treated with specialized computer-based fitting programs (e.g., NONMEM; Beal and Sheiner, 1992), which permit development of both pharmacokinetic and error models to describe disposition of the compound. This approach maximizes the use of animals and provides unique population information. The sampling design strategies for such studies can become quite complicated and will not be discussed here. The readers are referred to several publications that address these issues (Nedelman et al., 1993; Ette et al., 1994; Tanigawara et al., 1994; Van Bree et al., 1994; Nedelman and Gibiansky, 1996; Tse and Nedelman, 1996; Gething and Daley-Yates, 1997; Mahmood, 1997).

Blood Sampling Protocol

A critical issue in the design and ultimate success of any pharmacokinetic study, in terms of obtaining accurate and useful parameter values, is the frequency and duration of blood sampling. These decisions are never arbitrary but should be based upon the results of preliminary studies. The final design will primarily be governed by issues of analytical sensitivity and how much blood volume can be withdrawn; we

Table 5.3.2 Approximate Number of Blood Samples That May Be Obtained from Rats of Different Weights

Blood volume removed (%)	100-g rat				200-g rat			
	Sample volume (µl)							
	100	200	300	500	100	200	300	500

30%	18	9	6	3[a]	36	18	12	7

[a]Too few samples, indicating unacceptable protocol.

want to maximize the former and minimize the latter. Clearly the choice of animal species will have a significant impact upon such design issues; the smaller the animal the more critical the concerns. Mice offer a considerable challenge because of the limited blood volume and, most often, several animals undergo limited (e.g., 1 or 2) sampling at selected times (as described above) in order to obtain a composite description of concentration versus time. Blood volume and number of samples are less an issue in larger animals such as rabbits and dogs. However, in a practical sense, especially in the pharmaceutical industry, there is only a limited quantity of a new chemical entity that would be available early in the preclinical discovery process, and this limits the size of the dose and therefore the selection of animal species. It is essential in that situation that only a rodent be selected for initial experiments.

The author assumes here that the majority of investigators study rats rather than mice or animals larger than rats. Furthermore, it is assumed that serial blood samples are obtained from individual unanesthetized, free-moving animals, either from a previously placed indwelling venous (or arterial) catheter or via another technique that permits multiple sampling (e.g., tail cutting; Tse and Jaffe, 1991). The former approach has become so popular that many companies now provide a service whereby the animals can be purchased with an indwelling venous catheter (at considerable cost, of course). However, the general principles outlined here will apply to serial sampling of individual animals or to cases where sampling does not involve individual animals, but rather select samples from different animals. In general, the basic aim of the study is to obtain sufficient information to completely characterize the disposition kinetics of the compound of interest. When this is not the case, then other concerns need to dictate the sampling protocol (e.g., an estimate of $t_{1/2}$ only will require limited sampling and an estimate of plasma protein binding will require only several selected samples).

The total number of blood samples and the volume per sample will be limited by what the investigator believes to be an acceptable volume of total blood removal. Blood volume per sample is generally determined by assay sensitivity. The more sensitive the assay, the less blood needs to be removed per sample and the less invasive and disruptive the procedure. Another issue here is the duration of time during which blood is removed—i.e., is the total volume removed over a short time or during an experiment that lasts for several days? The effect of blood loss on the disposition kinetics of a substance needs to be considered, but with the exception of alteration in plasma protein binding (Hulse et al., 1981), little is known about this issue. One experimental technique used by some investigators, to minimize the effect of blood loss, is to replace the blood removed with saline or blood from a donor animal. Table 5.3.2 gives some indication of the approximate number of blood samples that can be taken, assuming a certain level of total blood loss and and a given volume per sample. These calculations are done for animals of 100 and 200 g and assumes that blood volume represents ~6% of total body weight. It should be stressed that if the fluid being assayed is serum or plasma, the numbers in the table need to be cut in half (assuming a hematocrit of ~0.5).

The numbers marked with the superscript letter "a" represent too few samples and an unacceptable protocol. Seldom can one obtain sufficiently reliable information from <6 blood samples. Generally, one tries to obtain ~10 blood samples per animal; more is always better. As a general rule, blood sampling should

proceed for at least 3 to 4 terminal half-lives; the longer the better. However, the latter issue is governed by the sensitivity of the assay. Using this guideline will minimize the need to rely upon extensive (and potentially incorrect) extrapolation of the data. This rule refers to parent compound. If there is interest in formed metabolite(s) with a longer terminal half-life than the parent drug, then sampling needs to be extended appropriately.

At what times should the samples be obtained? The answer to this question is determined by the results of the preliminary experiment, the purpose of the study, and some practical issues (such as normal working hours). Ideally, one has good estimates of the parameters of the model describing the concentration-time curve, but this is seldom the case. If that is indeed the case, the samples are chosen as a function of the distributive and terminal half-lives. To obtain a good estimate of terminal half-life, more samples need to be taken after distribution is complete. In order to best describe the model, especially if it is multi-compartmental, early time samples need to be obtained. Early, intensive sampling would likely also be necessary for obtaining pharmacodynamic data as part of the experimental design (assuming rapid response). If the purpose of the experiment is to describe completely the concentration-time curve in order to obtain a reasonable model and good estimates of half-life and area, the times need to be spread out over the entire duration of sampling. Assuming that a maximum of ten samples can be obtained and an i.v. bolus dose is given, the earlier sample times might include: 5 min (seldom earlier) or 10 min, 0.25 hr, 0.5 hr, 0.75 hr, and 1 hr. The remaining samples would be used to best define the terminal half-life. The latter sample times may be described relative to half-life: i.e., 1, 2, 3, 4 and 5 × $t_{1/2}$. The exact sample times are adjusted and a compromise reached based upon assay sensitivity and the actual clock time. In practice, the most difficult sample times are between 8 and 24 hr, since few experimenters want to remain in the laboratory around the clock. A cursory examination of the literature will indicate this sample void for compounds with half-lives greater than ~3 or 4 hr. If, for example, the compound had a distributive phase (but not defined well) and a terminal half-life of ~2 hr, the following sample times would be reasonable: 0.0833, 0.167, 0.25, 0.5, 1, 2, 4, 6, 8, and 10 hr. The choice becomes more complicated if fewer samples are allowed. If only six samples can be obtained, the following schedule would be reasonable: 0.167, 0.5, 1, 2, 6, and 8 hr. The fewer samples the less precise the model and the less accurate will be all parameters (e.g., $t_{1/2}$, V, and CL).

The above is a guideline only and is not inscribed in stone. One needs to exercise reasonable flexibility in choice of sample design based upon preliminary results. Some compounds have very short half-lives (e.g., cocaine, ~20 min), while others have long half-lives in rats (e.g., the dioxin derivative, TCDD, ~20 days).

How many animals should be included in a study? The answer to this question depends upon the purpose of the study and the variance associated with the parameters of interest. If the study is designed to compare the effect of one or more variables on the disposition of the compound (e.g., effect of another drug or influence of disease or age), then a sufficient number of animals needs to be used to provide a reliable statistical answer having the necessary power to detect differences. The actual number of animals will depend upon the variance in the parameters that will be compared (e.g., $t_{1/2}$ or CL). The appropriate statistical considerations need to be made, keeping in mind the assumptions behind the statistical tests that will be used (e.g., see Bolton, 1997). In contrast, there are no statistical guidelines if the purpose of the study is not to make comparisons but rather to define the disposition kinetics of the compound. Useful information will be obtained from three or six or more animals; the more animals the more reliable the population estimates become. It is fairly common to conduct a study to characterize the pharmacokinetics of a compound in four to six animals and, for the most part, with the typical variance found, this seems a reasonable number for providing reliable initial estimates.

What Fluid to Sample?

Although it is always a blood sample that is taken from an animal, the question arises, which fluid should be assayed—whole blood, plasma, or serum? While blood may be the preferred fluid, it is seldom assayed, generally for reasons of analytical cleanliness (a notable exception is determination of "blood alcohol" concentrations, but most often a head space gas chromatographic assay is used). Plasma and serum are essentially the same fluid; the only difference is that serum, which is obtained from coagulated blood, is devoid of fibrinogen. Since

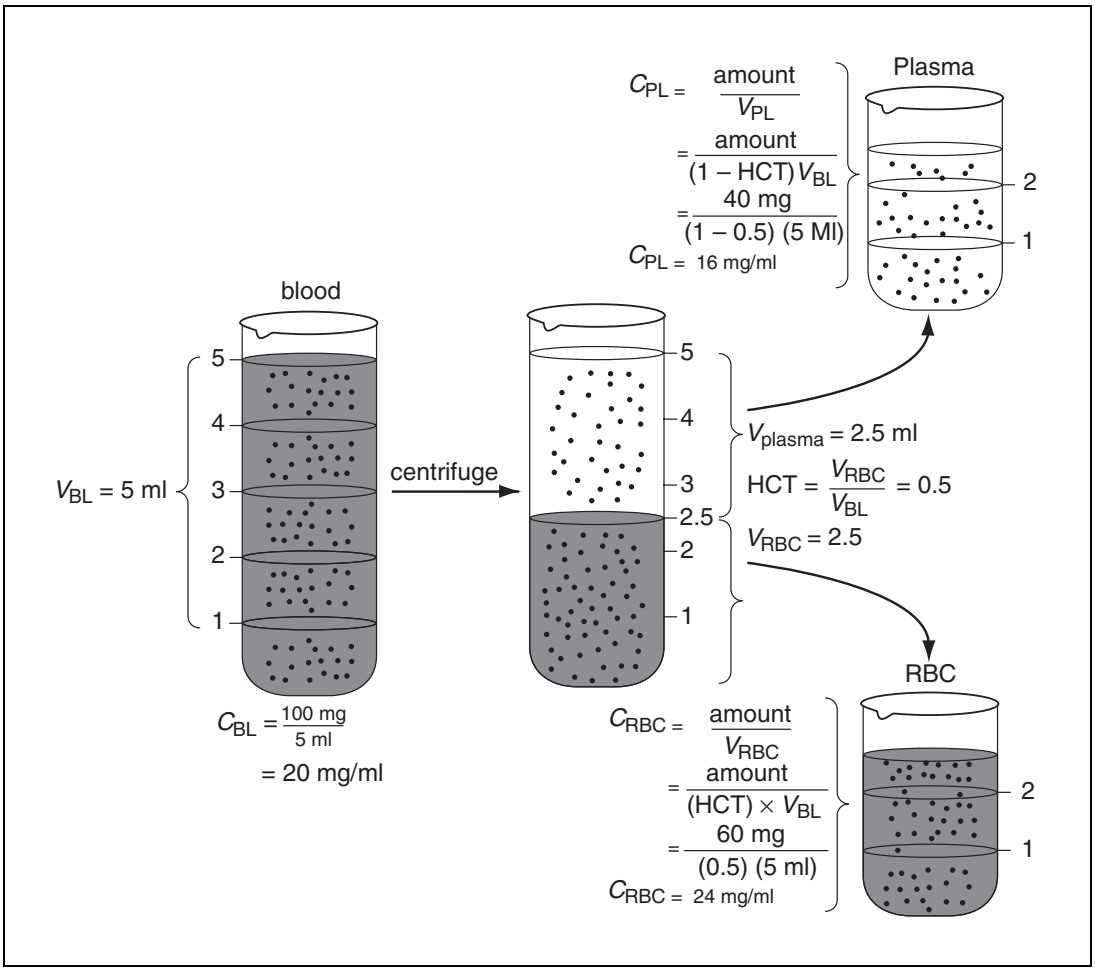

Figure 5.3.8 Illustration of the experimental determination of blood, plasma, and red blood cell concentrations of a drug. A 5-ml blood sample is determined by assay to have a drug concentration of 20 mg/ml (left). After centrifugation, the red blood cells (RBC) occupy a volume of 2.5 ml as does the plasma volume. The hematocrit, therefore, is 0.5 (2.5/5.0). The RBCs are assayed and found to have a drug concentration of 24 mg/ml (bottom right). The plasma is assayed and determined to have a drug concentration of 16 mg/ml (top right). The blood-to-plasma concentration ratio is 1.25 (viz., 20/16). HCT represents hematocrit. Used with permission of Saguaro Press.

it is blood that carries the compound to eliminating organs, all expressions of organ extraction and clearance should be made in reference to blood concentrations of the compound. This is seldom the case, however, as it is plasma concentrations that are virtually always measured and reported in the literature. While for most applications plasma clearance remains a useful and meaningful measure, it may on occasion be necessary to relate plasma clearance to blood clearance. The latter requires determination of the blood-to-plasma concentration ratio. That ratio is most easily determined experimentally with use of a radioactive form of the compound, but any selective assay should suffice. The blood (an authentic sample or one with added unlabeled compound) is spiked with sufficient radiolabeled compound. After equilibration at 37°C, the blood is counted and an aliquot of the blood is centrifuged, plasma obtained, and this plasma is also counted. Knowing the hematocrit of the blood, concentrations in each fluid are calculated and the resulting ratio determined. This is illustrated in Figure 5.3.8. Since rate of elimination is the product of either blood or plasma concentration and the corresponding clearance term, plasma clearance can be converted into blood clearance (Rowland and Tozer, 1995b).

$$\text{rate of elimination} = \mathrm{CL}_{\text{blood}} \times C_{\text{blood}} = \mathrm{CL}_{\text{plasma}} \times C_{\text{plasma}}$$

Equation 5.3.18

$$CL_{blood} = CL_{plasma}\left(\frac{C_{plasma}}{CL_{blood}}\right)$$

Equation 5.3.19

Ideally, the blood-to-plasma concentration ratio should be determined as a function of concentration over the expected or measured concentration range in the study. In this way, any concentration dependence in red blood cell partitioning can be detected. Such a study can be easily combined with evaluation of plasma protein binding. The blood samples are spiked with radioactive compound over the appropriate concentration range (achieved by adding unlabeled compound or using authentic blood samples). An aliquot of blood is counted. The blood is centrifuged and an aliquot of plasma is counted. Assuming there is sufficient plasma, the remainder may be used to assess plasma protein binding by any appropriate method (e.g., ultrafiltration). This optimal approach minimizes the need for extra blood samples and both concentration ratios and plasma protein binding are determined from the same samples, minimizing the variance associated with using different sets of blood samples.

There are a number of experimental issues here that are of concern. The first involves use of indwelling catheters for short or long-term blood sampling. While this is the most practical means of serial sampling in the free-moving animal, placement of such catheters have been associated with short-term weight loss (greatest with carotid artery and least with jugular vein placement; Yoburn et al., 1984) and changes in corticosterone plasma concentrations (Fagin et al., 1983; Tsukamoto et al., 1984). Perhaps more relevant are the direct changes noted in the pharmacokinetics of several compounds as a consequence of catheter placement. Terao and Shen (1983) noted that long-term placement of a venous catheter resulted in a substantial increase in the plasma concentrations of the acute-phase protein, α_1-acid glycoprotein (AGP), which primarily binds basic compounds, and a decrease in albumin concentrations, which primarily binds acidic compounds. These protein changes resulted in increased binding of l-propranolol to AGP and decreased binding of phenytoin to albumin and consequent changes in several pharmacokinetic parameters. The results of Chindavijak et al. (1988) and Torres-Molina et al. (1992) suggest not only changes in plasma protein binding but alterations in hepatic metabolism which may affect both low and high extraction ratio compounds. These time-dependent changes, which occur over several days, may argue against a cross-over design for those compounds whose disposition may be affected by the presence of a catheter.

Another potential problem associated with the use of indwelling catheters is related to the use of anticoagulants, especially heparin, to maintain catheter patency. Heparin, upon systemic administration, is known to mobilize free fatty acids, which in turn compete for binding sites on proteins, especially albumin (Brown et al., 1981). The consequent alteration in plasma protein binding may cause changes in the pharmacokinetic parameters (e.g, V, CL, and $t_{1/2}$) of certain drugs. Therefore, when flushing an indwelling catheter it is best to minimize the volume of anticoagulant used and try to restrict injection to the end of the catheter only. Alternatively, one can instill and use normal saline for flushing the catheter.

Often the indwelling venous catheter is used for i.v. dosing as well as for blood sampling. Following the i.v. dose, the catheter should be flushed with normal saline (~0.5 ml) to be certain that the dose is actually delivered to the systemic circulation and to wash the surface of the catheter. There is some concern about assuming that the compound given does not adsorb to the surface of the catheter. This potential for adsorption (and, therefore, overestimation of the actual dose injected) should be evaluated from simple in vitro experiments. The dosing solution should be passed through an appropriate length of catheter into a test tube. The catheter is then flushed with normal saline, as is done in vivo, and the washings combined with the dosing solution in the test tube. The total dose recovered in the test tube should be determined by assay and compared to the actual dose. If there is substantial loss of compound by adsorption, the dose needs to be accurately estimated or administered into another vein (e.g., tail vein).

A final concern is with the use of anesthetics which, depending upon the animal preparation, may be a significant issue. The anesthetic choice is of less concern when an indwelling catheter is placed and the experiment proceeds 2 or more days after the exposure to the anesthetic. The latter assumes, of course, that there are no residual effects of the anesthetic on, for example, hepatic function, which might interfere with metabolic processes. In contrast, if the animal is maintained anesthetized throughout the entire experiment during which time blood

samples are obtained, then the choice of anesthetic may be a critical one. Several investigators have compared anesthetic effects on the pharmacokinetics of antipyrine, a compound often used to assess hepatic oxidative metabolism. If the animals are maintained under anesthesia with parenterally administered anesthetics such as pentobarbital, urethane, or ketamine/xylazine, the clearance of antipyrine decreases and half-life increases. The change in antipyrine kinetics is very substantial for several of those agents, (e.g., CL, 3.20 versus 6.21 ml/min × kg for ketamine and control, respectively; Gumbleton and Benet, 1991). Similar observations were made by Tse et al. (1992), who found that the gaseous anesthetic isoflurane is the preferred agent, although long-term use of almost any anesthetic, including isoflurane, is to be avoided. A more complete review of anesthetic effects on pharmacokinetics and pharmacodynamics may be found in an especially thorough and useful text concerned with numerous experimental issues in animal pharmacology (Claassen, 1994).

Dosing Methods and Sites

There are numerous issues related to the "how" and "where" of dosing that have an impact on estimation of half-life, clearance, and residence times. Unequivocal data and meaningful disposition parameter values are only obtained following intravenous or intra-arterial dosing. The method of dosing may include bolus as well as short- and long-term infusions (as seen in Fig. 5.3.1). There are basically two issues that need to be considered when a non-vascular route of administration is used. The first is the rate of absorption, which, if very slow, will result in an incorrect estimate of disposition half-life. If the absorption process, expressed with an apparent first-order rate constant, k_a, is slower than the disposition rate constant, K ($k_a << K$), then the terminal slope will reflect absorption (or input) and not disposition. The slowest (or rate-limiting) process in a sequence of steps (e.g., absorption site → compound in body → compound eliminated) will always determine the value of the terminal slope. This situation is sometimes referred to as a "*flip-flop*" model. Plasma concentrations resulting from absorption will be described by the following relationship:

$$C = A \times (e^{-K \times t} - e^{-K_a \times t})$$

Equation 5.3.20

where A (units of concentration) is a constant given by a value on the y axis. The concentration-time data will rise and then fall with a terminal slope representing either k_a or K, depending upon which is smaller. It does not matter how sophisticated the analysis of this curve is—a nonvascular dose may or may not give rise to the correct value for disposition half-life. The only way to know for certain is to give an i.v. or intra-arterial dose whose slope, by definition, will be that of disposition. Therefore, frequently used routes of administration such as subcutaneous (s.c.), intramuscular (i.m.), or oral will either give the correct value or an overestimate of disposition half-life. An example of this phenomenon is illustrated in Figure 5.3.9, which is a plot of cocaine plasma concentrations following an i.v. bolus and s.c. dose of 7.5 mg/kg in rats (Sukbuntherng et al., submitted). Absorption following the s.c. dose is slow and the concentration-time data appear to provide a half-life much greater than that seen following i.v. dosing. This type of temporal profile is also expected to affect the response-time relationship, and this should be kept in mind when such measurements are being taken. The most likely explanations for the occurrence of a "flip-flop" situation include: compounds with poor membrane permeability (e.g., very polar or large molecule); compounds with very limited aqueous solubility; formulations that release compound slowly (e.g., oily vehicle or suspension placed s.c. or i.m.); or limited or altered blood flow to the site of absorption. The last factor might explain the slow absorption of cocaine following s.c. dosing—the compound causes constriction of blood vessels and reduces blood flow.

Moment analysis can be applied here for the estimation of a mean absorption (or input) time (MAT), which is the average amount of time that the compound spends at the absorption site. For an i.v. infusion, the mean absorption time is simply the infusion time divided by 2 (e.g., if infusion lasts for 60 min, MAT = 60/2 = 30 min). The calculation of a MAT requires knowledge of MRT (from i.v. dosing; see Equation 5.3.13 and related discussion above):

$$\text{MAT} = \left[\frac{\text{AUMC}_0^\infty}{\text{AUC}_0^\infty}\right]_{\text{non-i.v.}} - \text{MRT}$$

Equation 5.3.21

In a simple system, MAT and k_a are related (MAT = $1/k_a$). Mean absorption time offers a

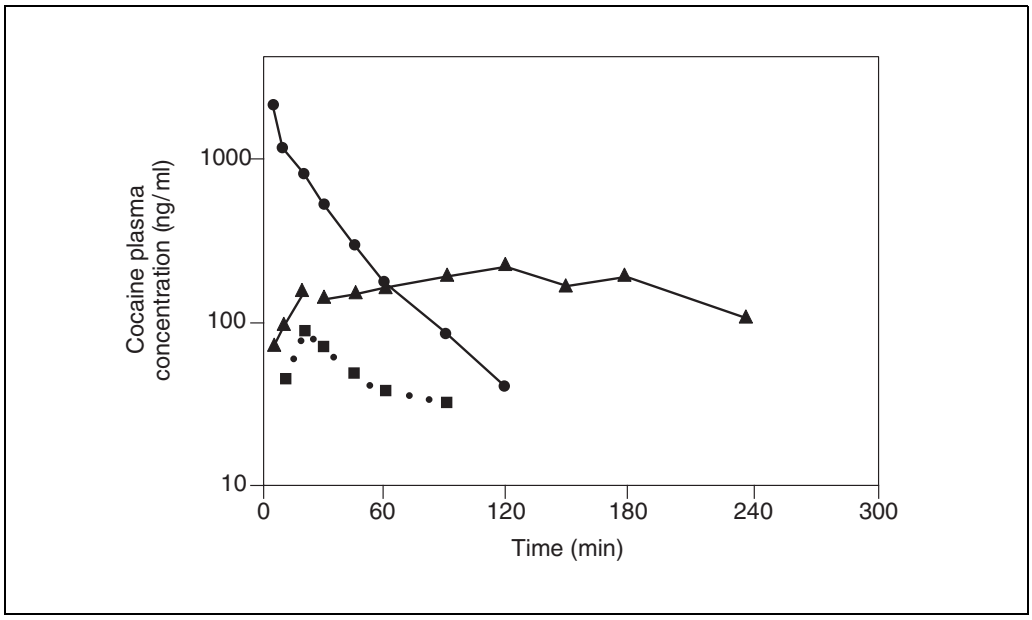

Figure 5.3.9 Average cocaine plasma concentrations as a function of time following an i.v. bolus dose of 7.5 mg/kg (circles) and a subcutaneous dose (triangles) of 7.5 mg/kg cocaine given to three rats. An oral dose of cocaine (17.9 mg/kg) was given to one rat (squares). Based upon the data in Sukbuntherng et al. (submitted). Used with permission of Saguaro Press.

measure of the rate of absorption, which complements that of an absorption rate constant.

Another approach that may also be taken, but which will not be discussed here, is to perform a *deconvolution* analysis, which provides a means of viewing the rate of absorption as a function of time. Deconvolution, which means "uncurling," is a mathematical attempt to separate (or "uncurl") the absorption process from the sum of input and disposition processes, which are represented in the concentration-time data following nonvascular dosing. The latter approach graphically illustrates the input process as the compound continues to be absorbed.

The second issue with regard to site of administration is with respect to the completeness of absorption. Estimates of completeness of absorption are often expressed as the *fraction of the dose absorbed or systemic bioavailability* (F). Expressing a previous relationship (Equation 5.3.7) in a more general manner, taking into consideration an absorption process:

$$\mathrm{AUC}_0^{\infty} = \frac{F \times \mathrm{dose}}{\mathrm{CL_s}}$$

Equation 5.3.22

For an i.v. dose, $F = 1$, so this factor does not appear in the numerator of Equation 5.3.7. Clearly, if $F < 1$, which it may be for a variety of reasons, the resulting AUC_0^{∞} will not provide a correct estimate of clearance (or apparent volume). The ratio of areas following nonvascular and i.v. dosing is often used to calculate the *absolute bioavailability* (after adjusting for any differences in doses), which is simplified by assuming constant clearance:

$$F_{\mathrm{absolute}} = \frac{(\mathrm{AUC}_0^{\infty})_{\text{non-i.v.}} \times (\mathrm{CL_s})_{\text{non-i.v.}}}{(\mathrm{AUC}_0^{\infty})_{\text{i.v.}} \times (\mathrm{CL_s})_{\text{i.v.}}} \times \frac{(\mathrm{dose})_{\text{i.v.}}}{(\mathrm{dose})_{\text{non-i.v.}}}$$

$$\cong \frac{(\mathrm{AUC}_0^{\infty})_{\text{non-i.v.}}}{(\mathrm{AUC}_0^{\infty})_{\text{i.v.}}} \times \frac{(\mathrm{dose})_{\text{i.v.}}}{(\mathrm{dose})_{\text{non-i.v.}}}$$

Equation 5.3.23

Figure 5.3.9 illustrates this issue following the oral administration of cocaine. The absolute oral bioavailability of cocaine is estimated to be only ~5% ($F = 0.05$). This is in marked contrast with s.c. dosing which, while slow, is essentially complete ($F = 1$). Low, incomplete nonvascular absorption may occur for a variety of reasons, including limited aqueous solubility, limited membrane permeability, saturable (dose-dependent) transport process, or presys-

temic (first-pass) elimination (e.g., degradation in gut fluid or metabolism by the intestinal membrane, liver, or bacterial flora). The low oral absorption of cocaine is probably attributed to the latter effect, which can be summarized in the following way:

$$F = f_{\text{released}} \times (1 - \text{ER}_{\text{gut fluid}}) \times (1 - \text{ER}_{\text{gut wall}}) \times (1 - \text{ER}_{\text{liver}})$$

Equation 5.3.24

The terms in parentheses, (1 − ER), represent the fractions that survive that particular metabolic process and f_{released} is the fraction of the dose released by the oral dosage form into the gut fluids.

There are numerous experimental factors which can affect the rate and completeness of absorption from a nonvascular site and which in turn will affect the concentration-time data and the correctness of many derived pharmacokinetic parameters including $t_{1/2}$, V, and CL_S. Such issues include the solubility of the compound in the formulation used for dosing, the pH and volume of the vehicle administered, and the tissue site chosen for dose administration. These should not be considered trivial issues, as they can have a major impact on the interpretation of the experiment. There is a fairly rich (generally, older) literature concerned with these experimental variables, which the investigator needs to consider in the proper design of an optimal experiment. Many of these are issues discussed elsewhere (Claassen, 1994).

COMPLICATING FACTORS AND OTHER ISSUES TO CONSIDER

The following discussion reviews several complicating issues, which need to be considered in the design and analysis of pharmacokinetic studies. Only a limited discussion of these issues will be presented here.

Dose-Dependencies (Nonlinearities)

All of the preceding discussions have made one important assumption, that of first-order kinetics, sometimes referred to as *linear or dose-independent kinetics*. A broad definition of a linear system is one in which output is directly related to input—double input results in double output. A complete definition of a linear system would include the *principle of superposition* and the idea of *time invariance*. The principle of superposition states that following dosing, concentration-time data divided by dose will superimpose onto one curve when plotted as a function of time. Time invariance states that the system will behave the same way regardless of time. With a linear system, the values for the input and output parameters will not change with dose. This condition does not always apply, and it is less likely to apply in toxicokinetic studies where very often unusually large, toxic doses are examined.

Any process of absorption, distribution, and elimination may become nonlinear as a function of dose, and there are numerous examples from the drug literature to indicate this (e.g., for a thorough discussion, see Rowland and Tozer, 1995c). The classic example of this type of process is given by the oxidative metabolism of ethanol by alcohol dehydrogenase, which may be described by the Michaelis-Menten enzyme kinetics equation:

$$\text{rate of metabolism} = v = \frac{V_{\max} \times C}{k_m + C}$$

Equation 5.3.25

where v is velocity or rate, $V_{\max}$ is the maximal rate, C is plasma concentration, and k_m is the Michaelis constant. The Michaelis constant has units of concentration, and it represents the concentration needed to obtain one-half of the maximal rate (i.e., one-half of $V_{\max}$). That symbol, k_m, should not be confused with a metabolic rate constant (with units of 1/time). The above equation takes the form of a hyperbola, a relationship frequently seen in biology, describing a nonlinear system or saturable process (often related to binding). We can simplify this relationship by considering the two extremes of concentration, low and high. At low concentrations, $C << k_m$, and the denominator can be approximated by k_m. Therefore, the rate of metabolism will be described as follows:

$$\text{rate of metabolism} \cong \left(\frac{V_{\max}}{K_m} \right) \times C$$

Equation 5.3.26

The ratio of constants in parentheses is also a constant and can be represented by the rate constant discussed previously, K (or a metabolic rate constant). In other words, at low plasma concentrations, rate is directly related to concentration, which is a statement of first-order kinetics. When concentrations get large, such that, $C >> k_m$, the k_m in the denominator can be ignored and the concentration terms cancel. At high concentrations, rate may be expressed as:

$$\text{rate of metabolism} = V_{max}$$

Equation 5.3.27

The above relationship indicates that no matter how concentration (or dose) increases, the rate will not change; it remains constant. This is a statement of *zero-order kinetics*. At concentrations in between the two extremes, there is mixed kinetics.

The above situation can be simply related to clearance, since clearance is the expression of rate relative to plasma concentration:

$$CL = \frac{\text{rate}}{C} = \frac{V_{max} \times C}{(k_m + C) \times C} = \frac{V_{max}}{k_m + C}$$

Equation 5.3.28

Thus, when, $C << k_m$, ignore C in the denominator and CL will be a constant given by V_{max}/k_m. In contrast, at high concentrations, $C >> k_m$, the denominator in Equation 5.3.28 becomes larger and larger as C increases. This results in a decrease in CL as concentration (or dose) increases, which in turn results in an increase in half-life (recall that $t_{1/2} = 0.693 \times V/CL$). This happens for ethanol and at least two other drugs, phenytoin and salicylate, and for numerous toxic chemicals such as dioxane. There are significant implications to this saturable process, especially in the clinical and toxicological response to the compound. The above analysis represents a very general treatment of any process of elimination, and is not limited to enzyme metabolism but includes renal excretion and biliary excretion, among other processes.

In order to detect nonlinear behavior in elimination, it is necessary to administer ≥3 different doses and to cover as wide a range of plasma concentrations as possible. An indication of nonlinear elimination can be inferred under the following circumstances: (1) when the concentration-time data divided by dose will not superimpose to form one curve; (2) when the concentration-time data are not strictly exponential (i.e., not log-linear) after distribution is complete; and (3) when the half-life appears to be changing with time (i.e., the terminal slope becomes more and more steep with time as concentrations decline). In addition, the areas under the curves will not increase in direct proportion to dose, but rather out of proportion. There are other ways to determine the existence of nonlinear elimination (in metabolism or renal excretion) that rely upon collection of urine metabolites and other experimental procedures (Levy, 1968). There are numerous other forms of nonlinearity in elimination such as, metabolite inhibition of metabolism.

Some care needs to be applied when interpreting a concentration-time curve whose data are relatively incomplete—that is, where only one or two half-lives of elimination have been examined. Virtually all data, whether adhering to first-order or zero-order elimination kinetics, will provide a log-linear relationship over a narrow concentration range, and, therefore, suggest first-order kinetics. This was noted in a report that examined the elimination kinetics of 4-methylpyrazole, which was shown to follow nonlinear elimination kinetics in the dog (Mayersohn et al., 1985). An illustration of the plasma concentration-time plot of the latter compound is shown in Figure 5.3.10, which illustrates several of the points noted above.

Measurement of Total Radioactivity or Use of a Nonselective Assay

We noted in a previous section how slow or incomplete absorption from the site of dosing could influence the estimation of parameter values and alter the interpretation of the experiment ("flip-flop" model and $F < 1$). There is an analogous situation that can occur on output rather than on input, but which reflects the identical principle; the slowest step in a sequence of steps will dictate the meaning and value of the terminal slope. The sequence of steps in this instance is: parent drug → metabolite → metabolite elimination. One of these two steps must be rate-limiting and, depending upon what chemical form is measured, will determine the meaning of the slope of concentration versus time. An incorrect value for the terminal disposition half-life may be obtained for a compound that undergoes metabolism when a radiolabled form of the compound is dosed and total radioactivity is measured, or, what is essentially the same issue, if a nonspecific chemical assay is used to quantify the parent compound. The terminal half-life obtained under either of the above circumstances will be equal to or will exceed the correct disposition half-life. The latter will occur if any of the metabolites being quantified are themselves lost from the body more slowly than the parent compound. In the case of a nonspecific assay, the metabolite may be measured along with parent compound. In the case of measurement of total radioactivity, the metabolite eliminated more slowly than the parent compound

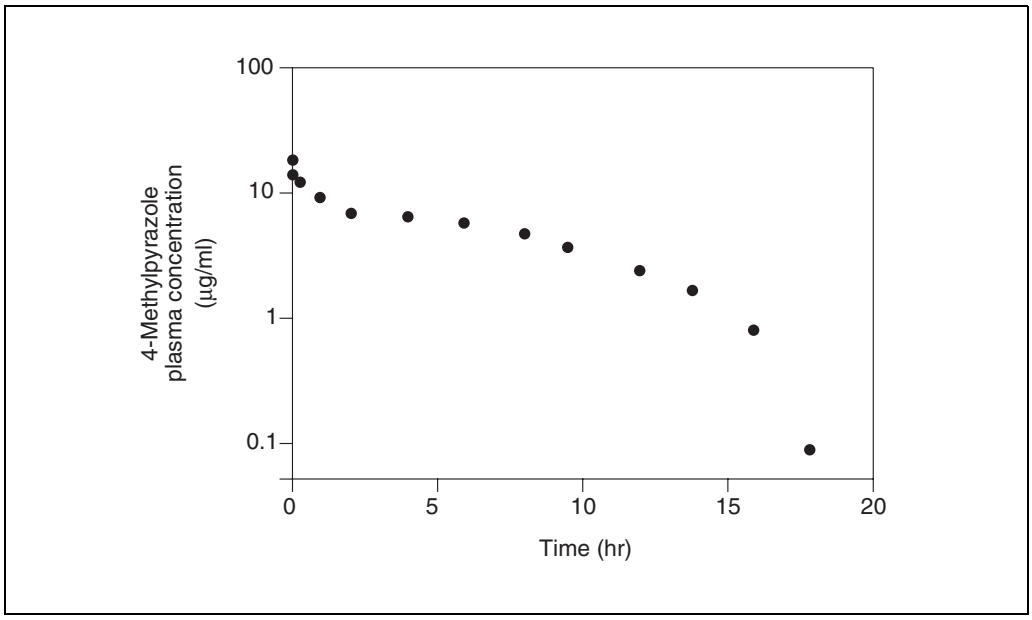

Figure 5.3.10 Plasma concentration-time profile of 4-methylpyrazole following an i.v. bolus dose of 10 mg/kg to one dog. Note that the shape of the curve suggests a nonlinearity in disposition. Based upon the experiment reported by Mayersohn et al. (1985), but data not provided in publication. Used with permission of Saguaro Press.

may contain the radiolabel in its structure, and contribute to the total radioactivity measured. An example of this disparity in terminal half-life based upon total radioactivity or that associated with the parent compound is illustrated in Figure 5.3.11. The compound, salmeterol, was given to rats as an i.v. dose (2 mg/kg) and radioactivity was measured—both total and that associated with parent compound (Manchee et al., 1993). There is obviously a very substantial discrepancy between total radioactivity and that related to parent compound, which would appear to reflect high plasma concentrations of formed radioactive metabolites. One or more metabolites are eliminated far more slowly than the parent compound.

An additional problem with radiolabeled compounds is the possibility of isotope exchange with, for example, water if the compound is tritium (^{3}H)–labeled, or where there is an exchange of ^{14}C with any of a myriad of endogenous carbon-containing molecules. The resulting apparent half-life will reflect the half-life of the slowest of all of the labeled compounds eliminated from the body. Unusually long elimination half-lives may be explained by the latter occurrence, but it is more difficult to attribute half-life to a metabolite per se if no specific information is available about the parent compound. This illustrates, once again, the critical need for a selective assay.

A similar analytical issue exists when there are enantiomeric forms of the parent compound (as well as subsequent metabolites). Unless an effort is made to develop an enantiomerically selective assay, the concentration measured will be that of the racemic mixture. Since enantiomers often behave differently in terms of pharmacokinetic and pharmacodynamic parameters (e.g., Tucker and Lennard, 1990; Eichelbaum and Gross, 1996), a selective assay is desirable. Alternatively, if the pure enantiomers are available for dosing, studies can be done on the individual forms.

"Effective" or "Accumulation" Half-Life

Advances in analytical chemistry, especially the now routine application in the pharmaceutical industry of high-performance liquid chromatography (HPLC) in conjunction with mass spectrometry (see *UNIT 4.4*), has resulted in exquisitely sensitive methods for quantitation of exogenous substances. These sensitive assays permit the evaluation of disposition for a longer time following dosing, which in turn has given rise to an apparent need for more complex multicompartmental models to describe the data. These models inevitably include a very long terminal half-life. While these long terminal half-lives may be correct, and most likely reflect slow redistribution from tissues to blood, they are often not a useful parameter.

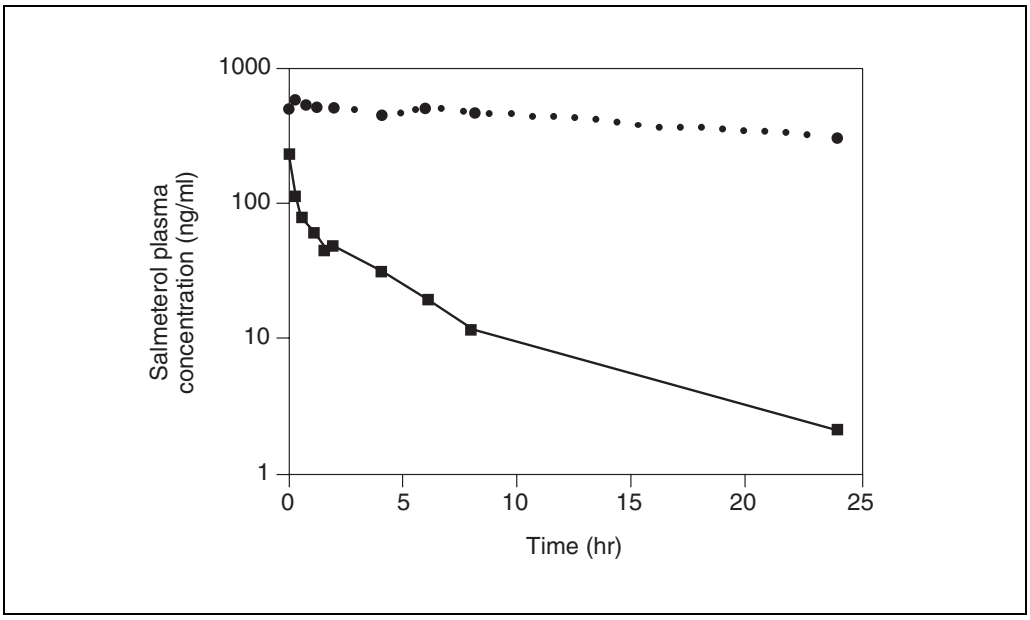

Figure 5.3.11 Salmeterol plasma concentrations as a function of time following the i.v. bolus administration of 2 mg/kg to rats. Concentrations are related to total radioactivity (circles) or that associated with parent compound (squares). Note the very large discrepancy in terminal half-life based upon the chemical form being quantified. The total radioactivity includes radiolabeled formed metabolite(s). Based upon recovery and replotting of graphical data in Manchee et al. (1993).

The reason for the latter statement is based upon the fact that the long terminal half-life occurs only after most of the dose of the compound has been eliminated from the body and because that long half-life does not determine how the drug *accumulates* in the body as a result of multiple dosing. The magnitude to which a compound accumulates in the body is a function of half-life and the dosing (or exposure) interval (τ, expressed in units of time); accumulation increases when half-life is long and when the dosing interval is short. For that reason there is need for a practical "accumulation" (or "effective") half-life that will actually determine the extent of accumulation upon multiple dosing. This effective half-life will always be less than the very long terminal half-life measured with a sensitive assay, and it is calculated on the basis of the actual accumulation of the compound (Kwan et al., 1984). Readers interested in multiple dosing and accumulation (not discussed in this unit) and effective half-life are referred to the previous reference.

DATA ANALYSIS: A WORKED EXAMPLE

The following section will provide a complete example of a fairly representative data set that would be obtained from the experimental designs discussed in preceding sections. The author has taken an actual literature example and used tabular data. Note, however, that it is possible to recover graphical data from publications using digitizing techniques that have been shown to be quite accurate (Mayersohn and Tannenbaum, 1998). The data have been treated by noncompartmental and compartmental (model-fitting) methods in order to illustrate how the final parameter values compare.

Example: Creatinine Disposition in the Dog Following an i.v. Bolus Dose

These data have been taken from an early publication (Dominguez et al., 1935). A dose of 6.6 g creatinine was given as an i.v. bolus to a dog (20.2 kg). The resulting plasma concentrations were corrected for the endogenous creatinine concentration. Table 5.3.3 provides a listing of the concentration-time data along with estimates of areas (AUC and AUMC). The areas were determined with use of the linear trapezoidal rule in a Microsoft Excel spreadsheet.

The area calculations for an i.v. bolus dose can be divided into three segments:

1. The first area is approximated by a rectangle: $C_1 \times t_1$; e.g., $812 \times 0.200 = 162.4$.
2. All of the remaining individual areas are estimated with use of the linear trapezoidal rule: $(1/2) \times (C_1 + C_2) \times (t_2 - t_1)$; e.g., $(1/2) \times (812 + 702) \times (0.292 - 0.20) = 69.4$.
3. The terminal (or remaining) area from the last measured time (t_n) to time infinity, is

Table 5.3.3 Creatinine Plasma Concentration-Time Data and Area Calculations

Time (hr)	Creatinine plasma conc. (μg/ml)	AUC (μg × hr/ml)	$C \times t$ (μg × hr/ml)	AUMC (μg × hr^2/ml)
0.200	812	162.4	162.4	16.2
0.292	702	69.4	204.8	16.8
0.567	422	154.6	239.1	61.0
0.783	411	90.2	322.0	60.8
1.025	316	87.8	323.9	78.0
1.542	242	144.2	373.1	180.1
2.042	205	111.8	418.5	197.9
3.042	169	187.0	514.0	466.3
4.033	125	145.8	504.2	504.9
5.033	86	105.5	432.9	468.5
6.058	77	83.5	466.5	460.9
7.042	66	70.3	464.8	457.9
8.075	50	59.9	403.8	448.7
Sum:		1472.4		3418.1

calculated from the last measured concentration (that is on a regression line, as noted below) divided by the terminal rate constant: C_n/β; e.g., 50/β.

The total area under the curve is the sum of the above areas:

$$\mathrm{AUC}_0^{\infty} = \mathrm{AUC}_0^{t_1} + \mathrm{AUC}_{t_1}^{t_n} + \mathrm{AUC}_{t_n}^{\infty}$$

Equation 5.3.29

The total area to time 8.075 hr is 1472.4 μg × hr/ml. An estimate needs to be obtained of the terminal rate constant, β. This is discussed below.

The same general process is used for determination of the area under the moment curve, AUMC, with some exceptions.

1. The first area is approximated by a triangle: $(1/2) \times C_1 t_1 \times t_1$; e.g., (1/2) × 162.4 × 0.200 = 16.2.

2. All of the remaining individual areas are estimated with use of the linear trapezoidal rule: $(1/2) \times (C_1 t_1 + C_2 t_2) \times (t_2 - t_1)$; e.g., (1/2) × (162.4 + 204.8) × (0.292 − 0.20) = 16.8.

3. The terminal (or remaining) area needs to be calculated differently from that for AUC. The terminal area is calculated from the two following terms: $C_{tn}/\beta^2 + C_n t_n/\beta$. Generally, the actual values for C_{tn} and $C_n t_n$ are used along with the estimate for β obtained from regression of the concentration-time data.

Figure 5.3.12 illustrates the results of the noncompartmental and compartmental analysis of the concentration-time data. A decision needs to be made, using the former approach, about which data points constitute the terminal phase (i.e., those points that form the terminal, log-linear phase). This is generally not a difficult decision if the data are reasonably uniform. In this instance, the data points from 2 hr and beyond were selected. The solid line illustrates the linear regression of those seven points. The equation of the line was:

$$C = 324\ \mu\mathrm{g/ml} \times e^{-0.235 \times t} \quad (r^2 = 0.98)$$

Equation 5.3.30

The terminal rate constant had a value of 0.235 hr^{-1}, which corresponds to a terminal half-life of 2.95 hr. That value is then used for estimation of the terminal areas of AUC and AUMC, as noted above. In the former case, the rate constant is divided into the last concentration value that lies on the regression line. The latter concentration needs to be calculated from the regression equation. In this instance, the value at 8.075 hr is 49 μg/ml. The terminal area, therefore, is equal to: 49 μg/ml ÷ 0.235 hr^{-1}, or 208.5 μg × hr/ml. The total area, therefore, is the sum of: 208.5 + 1472.4 = 1680.9 μg × hr/ml.

The terminal AUMC is given by:

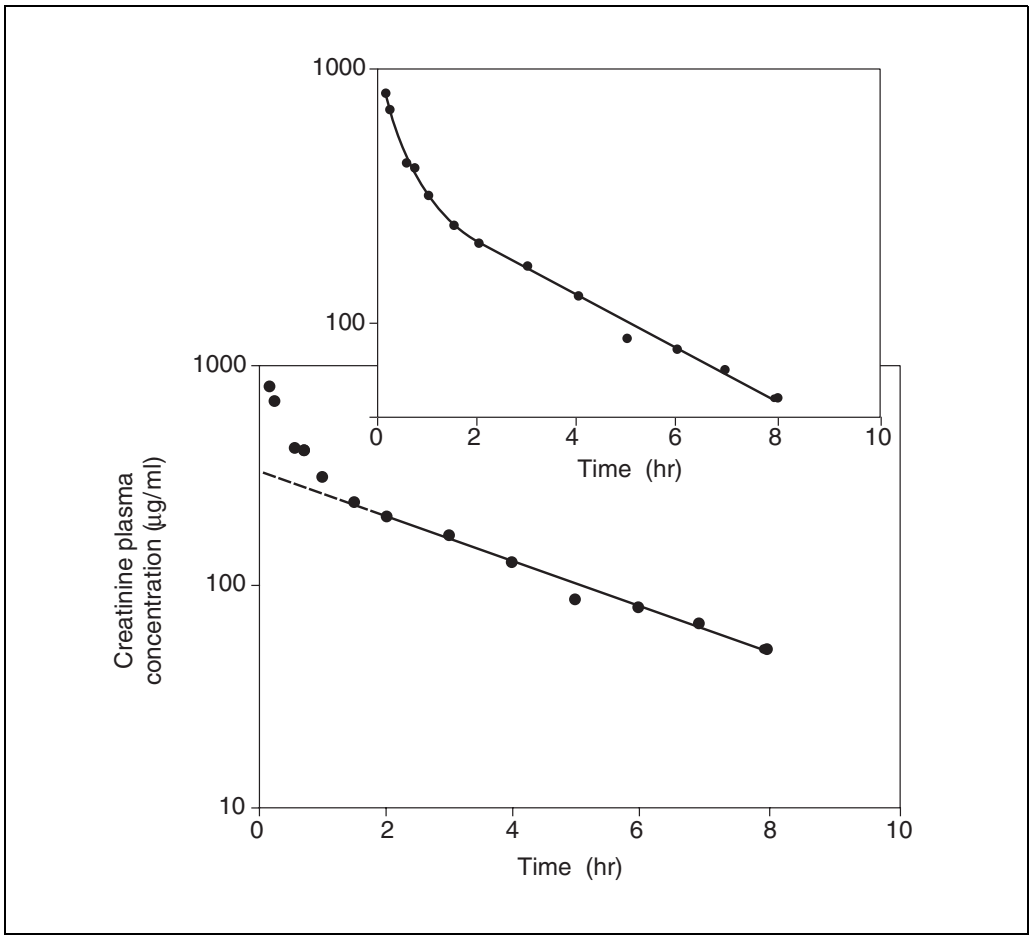

Figure 5.3.12 Semilog plot of creatinine plasma concentration as a function of time following an i.v. bolus dose of 6.6 g creatinine to one dog. The bottom graph illustrates the noncompartmental approach to data analysis. The solid line is the linear regression fit of the data points thought to represent the terminal phase. The terminal rate constant was determined to be 0.235 hr^{-1}. The inset graph illustrates a compartmental analysis of the data using the WinNonlin program. The solid line represents the nonlinear regression fit to the data. The terminal rate constant was determined to be 0.233 hr^{-1}. See text for discussion.

$$\begin{aligned}\mathrm{AUMC}_{\mathrm{terminal}} &= \frac{50\ \mu g/ml}{(0.235\ hr^{-1})^2} \\ &\quad + \frac{403.8\ \mu g \times hr/ml}{(0.235\ hr^{-1})} \\ &= 905.4 + 1718.3 \\ &= 2623.7\ \mu g \times hr^2/ml\end{aligned}$$

Equation 5.3.31

The total value for AUMC is the sum of: 3418.1 + 2623.7 = 6041.8 $\mu g \times hr^2/ml$.

We can now estimate several additional important pharmacokinetic parameters.

1. *Systemic clearance, CL_S:* This value is obtained from:

$$\frac{\text{i.v. dose}}{\mathrm{AUC}_0^{\infty}} = \frac{6600\ mg}{1680.9\ mg \times hr/liter}$$

Equation 5.3.32

A value of 65 ml/min is obtained. Since the compound is cleared only by renal pathways and, presumably, by glomerular filtration, the value calculated represents renal clearance, CL_R. If we assume that this plasma clearance is about equal to blood clearance, an estimate of renal extraction ratio can be obtained (i.e., the blood to plasma concentration ratio is about equal to 1). A literature value for renal blood flow in the dog is 21.6 ml/min × kg. CL_R in our dog is 65 ml/min × 20.2 kg or 3.22 ml/min × kg. The renal extraction ratio is given by, $CL_R/Q_R = 3.22/21.6 = 0.15$. This is a relatively

Table 5.3.4 Comparison of the Pharmacokinetic Parameters of Creatinine Obtained by Noncompartmental and Compartmental Analyses

Parameter	Compartmental	Noncompartmental
β (hr^{-1})	0.233	0.235
$t_{1/2}$ (hr)	2.97	2.96
AUC_0^∞ ($\mu g \times hr/ml$)	1701.2	1680.9
CL_S (ml/min)	64.7	65.0
V_β (liter)	16.7	16.6

small extraction ratio, indicating low or restrictive clearance of creatinine.

2. *Apparent volume of distribution: V_β or V_{area}*: this value is obtained from:

$$\frac{CL_s}{\beta} = \frac{(65\ ml/min) \times (60\ min/1\ hr)}{0.235\ hr^{-1}}$$
$$= 16.59\ liter = 0.82\ liter/kg$$

Equation 5.3.33

3. *Mean residence time, MRT:* This value is obtained from:

$$\frac{AUMC_0^\infty}{AUC_0^\infty} = \frac{6041.8\ \mu g \times hr^2/ml}{1680.9\ \mu g \times hr/ml} = 3.59\ hr$$

Equation 5.3.34

Mean residence time can also be used to estimate another apparent volume of distribution referred to as the steady-state volume (V_{SS}). [V_{SS} is determined from MRT $\times$ CL_S = 3.59 hr $\times$ (65 ml/min) (60 min/1 hr) = 14.0 liters or 0.69 liter/kg.] There are also a variety of other residence and transit times that may be of interest (see Lassen and Perl, 1979, for additional information). For this example, mean residence time in the central compartment (~1.5 hr); mean residence time in the peripheral compartment (~2.0 hr); mean transit time in the central compartment (~0.49 hr); mean transit time in the peripheral compartment (~1.0 hr); and the average number of times that creatinine returns to the peripheral compartment (~3).

How different would the results have been if the data were analyzed by compartmental methods using nonlinear regression? Not very different at all, as shown by the comparisons in Table 5.3.4.

Notice how similar the parameter values are; they are virtually identical. This is expected for data that are reasonably well behaved.

Isolated Perfused Porcine Skin Flap

The isolated perfused porcine skin flap (IPPSF) is used to determine the rate and extent of absorption of chemicals through skin. This ex vivo model system allows cutaneous toxicology and pharmacology studies to be conducted in viable skin that has a normal anatomical structure and intact microvasculature. The latter is a unique advantage of this system as other in vitro systems do not have this intact microvasculature. Porcine skin is also anatomically and physiologically similar to human skin (Fig. 5.4.1), therefore, data from studies utilizing this ex vivo model can, in some cases, be used to predict dermato-pharmacokinetics and dermatotoxicity of test chemicals in humans (Monteiro-Riviere, 1991). The porcine skin flap can be used to assess dermal metabolism and bioavailability as it eliminates the confounding influence of systemic metabolic processes.

This unit describes surgical preparation of the isolated perfused porcine skin flap and operation of the IPPSF system. Surgical preparation of the porcine skin flap (see Support Protocol) involves a two-stage surgical procedure under aseptic conditions after which the closed or tubed skin preparation is removed from the pig and the main arterial supply is cannulated. The operation of the IPPSF system (see Basic Protocol) is very labor intensive compared to most in vitro skin diffusion cell systems as it involves real time monitoring of flap viability and intensive sample collection during and at the end of these experiments.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

Current Protocols in Toxicology (2001) 5.4.1-5.4.9

BASIC PROTOCOL

OPERATION OF THE ISOLATED PERFUSED PORCINE SKIN FLAP

After Stage II as described in the Support Protocol, the flap is placed in a cradle where it is perfused with bovine serum albumin medium, and the effluent is collected at selected time points. The flap cradle is placed in a custom-designed temperature- and humidity-regulated chamber (Fig. 5.4.2) made specifically for this purpose. Flap viability, perfusate flow and pressure, and environmental temperature and humidity are also monitored during the course of the experiment.

Materials

Porcine skin flap (see Support Protocol)
Oxygenated Krebs-Ringer bicarbonate buffer
4.5% bovine serum albumin medium (see recipe)
Air supply: 95% oxygen/5% carbon dioxide
Skin Bond (e.g., Skin-Bond, Smith & Nephew)
Test chemical solution, with or without radiolabel
1% (v/v) soap solution (e.g., ivory soap)
Ethyl acetate
OCT Compound (Tissue-Tek, Miles)
Liquid nitrogen
10% (v/v) neutral buffered formalin

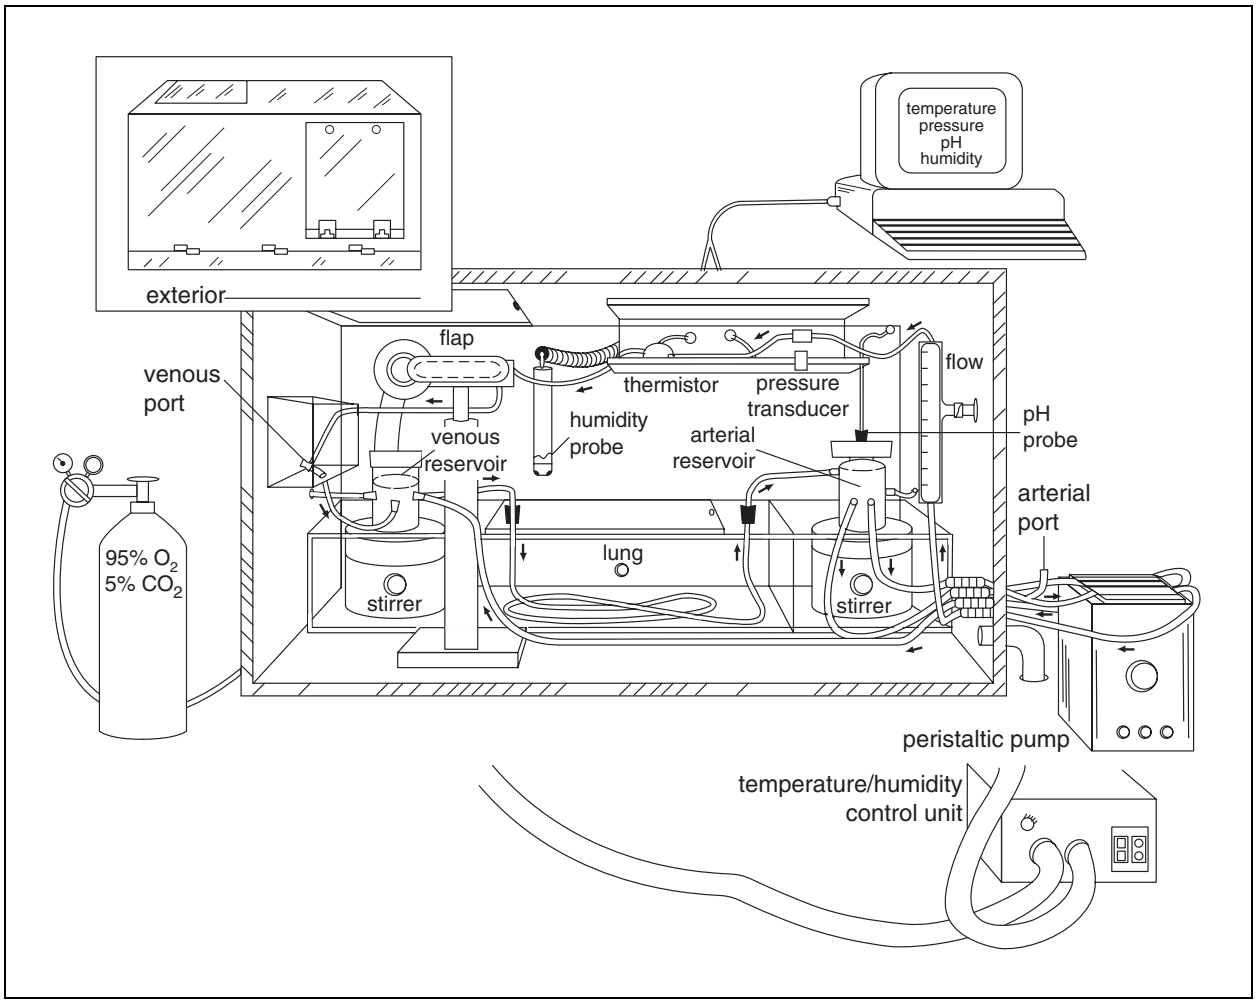

Figure 5.4.2 Schematic of the perfusion chamber used to maintain a viable IPPSF at controlled temperature, humidity, pressure, and perfusate flow.

Soluene 350 (Packard Instrument)
Sodium hypochlorite
Isopropyl alcohol

Custom-designed flap chamber made of 0.5-in thick Plexiglass and containing:
- Custom-designed humidifier
- Custom-designed media reservoirs
- Hygrometer
- Thermometer
- Peristaltic pump
- Silastic and tygon tubing
- Pressure transducer
- pH meter
- Magnetic stirers

3 × 7–cm flexible template (e.g., Stomahesive, ConvaTec-Squibb)
Glucose analyzer (e.g., Glucose Analyzer 2, Beckman)
5-ml and 20-ml capped scintillation vials (e.g., Sarstedt)
2 × 2–in. gauze
Cellophane tape
Razor blade or scalpel
Forceps
Aluminum foil boat

Perfuse porcine skin flaps

1. Perfuse porcine skin flaps via the cannula at ~1.0 ml/min (3 to 7 ml/min/100 g) with oxygenated (95% O_2/5% CO_2) Krebs-Ringer bicarbonate buffer and 4.5% bovine serum albumin medium. Add the prepared medium to the reservoir, and place the reservoir on a magnetic stirer positioned in the skin flap chamber. Maintain skin flaps at 37°C, 50% to 60% relative humidity, perfusate pH at 7.4, and mean arterial pressure ranging from 30 to 70 mmHg.

   These values are consistent with in vivo values reported in the literature.

2. Perfuse skin flap for 1 hr to equilibrate and to collect predose samples to determine glucose utilization and background levels.
3. After 1 hr of perfusion, disconnect flap from the perfusion system. Apply a 3 × 7–cm flexible template to the skin surface with Skin-Bond to provide a surface area of 5.0 cm^2 for applying dosing solutions.
4. Immediately reconnect the flap, and apply as much as 100 µl of the test chemical to the dose site within the stomahesive.

   Doses exceeding 100 µl may result in pooling and/or run off of the dose into the cradle and contamination of collected samples.

Collect venous perfusate samples

5. Collect venous perfusate samples at 30-min intervals for the first 2 hr post-dosing and then at 1 hr intervals for 6 hr for a total of 8 hr.

   Skin flap viability begins to decline after 8 hr.

6. Assess skin flap viability by monitoring vascular resistance (VR; perfusate pressure/flow) and cumulative glucose utilization (CGU). Monitor CGU by collecting arterial perfusate samples collected at hourly intervals and then compare with venous samples to determine arterial-venous glucose extraction. Use a glucose analyzer to measure glucose in both arterial and venous samples.

   VR is defined as the ratio of arterial pressure to perfusate flow rate.

Clean and process skin flap

7. At the end of the 8-hr perfusion, remove the stomahesive and save in a scintillation vial for further analysis. Rinse the suture line, which is the portion of skin in contact with the effluent, with ~10 ml distilled water to remove remnants of test chemical.
8. Swab the dose site with a single 2 × 2–in. gauze pad soaked with 1% soap solution and swab dry with a dry 2 × 2–in. gauze pad.

   The latter is important to ensure that the skin surface is dry for effective tape stripping.
9. Save swab pads in a scintillation vial for further analysis.

   This represents surface levels at 8 hr after perfusion.
10. Tape dose site 12 times with cellophane tape and store in a scintillation vial.
11. Solubilize cellophane tape with ~15 ml ethyl acetate and save for analysis.

    This sample represents the stratum corneum levels at termination.
12. Excise skin from the dose site with a razor blade or scalpel. Weigh tissue sample, and divide into three approximately equal weight portions.

Freeze tissue specimen

13. Using forceps, carefully place the central portion of the dose site, with cut surface facing up, in OCT compound in an aluminum foil boat. Ensure that entire epidermal surface is in contact with the bottom of the foil boat and freeze the contents in liquid nitrogen.

    This frozen section will be later placed in a cryostat to determine depth of penetration (~40-μm intervals) of the test chemical.
14. Of the two remaining portions of the dose skin, place one portion in 10% buffered formalin.

    The sample will be processed, and stained with hematoxylin and eosin for histological examination.
15. Place the other skin portion in OCT compound as described in step 13, except with cut surface facing down in the aluminum foil boat. Freeze remaining skin flap in liquid nitrogen and store at −80°C for further analysis.

    This skin sample can be saved for enzyme histochemical studies.
16. As these are mass balance studies, separate the frozen flap into skin and fat samples and solubilize the tissues in Soluene 350 for 48 hr at 50°C before further analysis.
17. Clean the skin flap chamber after removal of the flap, and perfuse lines with sodium hypochlorite for 12 min; isopropyl alcohol for 12 min; and water for 30 min.

SUPPORT PROTOCOL

SURGICAL PREPARATION OF PORCINE SKIN FLAP

IPPSFs are created from the ventral abdomen of the pig in two surgical stages. In Stage I (Fig. 5.4.3), two flaps per pig, each lateral to the ventral midline, are prepared but not removed from the pig. After careful dissection and suturing, the pig is allowed to recover for 48 hr to allow for granulation of the surgical area. After a recovery period of 48 hr, the flap is cannulated and then removed from the pig.

Materials

8-week-old weanling female Yorkshire pigs (Looper Farms, Hickory, NC)
Preanesthetic: 0.04 mg/kg atropine sulfate; 1.5 mg/kg xylazine hydrochloride; 11 mg/kg ketamine hydrochloride
Anesthesia: halothane
Betadine
Alcohol
Heparinized saline: 0.5 ml heparin in 50 ml physiological saline

Gowns and towels, disposable
Endotracheal tube (size 5.5 mm)
Hair clippers
Scalpels
Suture material (no. 0 and no. 2 chromic catgut; Prolene no. 3.0; Ethicon no. 3.0)
Surgical wrap and bandage (e.g., Teflon pad and elasticon)
Tygon tubing (0.023-in i.d., 0.038-in o.d.)
Hemostats

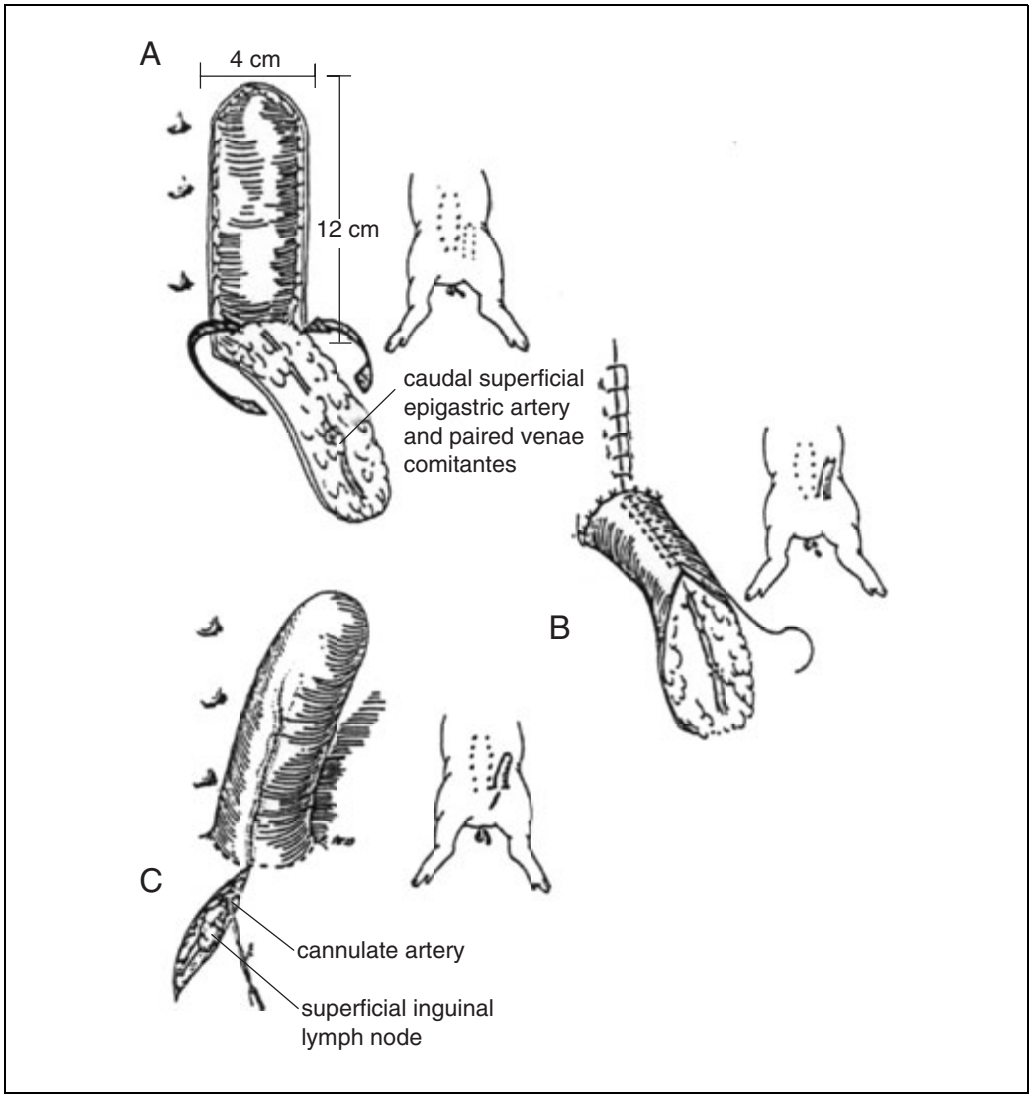

Figure 5.4.3 Surgical procedure for creating flaps. (**A**) A single pedicle axial pattern skin flap is raised and (**B**) tube completing the Stage I procedure. (**C**) Two days later, the caudal superficial epigastric artery is cannulated, and the flap is removed and transferred to the perfusion chamber in Figure 5.4.2.

Prepare pigs

1. Acclimatize and weigh pigs 1 to 2 weeks before surgical procedure.

   Acclimitization helps calm the animals and makes them easier to handle and restrain.

2. Premedicate with 1.5 mg/kg xylazine hydrochloride and 11 mg/kg ketamine hydrochloride prior to tracheal intubation; anesthetize with halothane using an anesthesia machine.

3. Place animal in dorsal recummbancy. Prepare each pig for routine aseptic surgery by clipping hair from the caudal abdominal and inguinal regions and surgically scrubbing three times each with betadine and alcohol. Don a disposable surgical gown. Use towel clamps to clamp disposable towels over the caudal region of the pig leaving the surgical area free for Stage 1 procedures.

   For surgical techniques see Knecht et al. (1987).

Stage I: Dissect flap

4. In Stage I, first mark an area 4 × 12–cm of skin on either side of the midline in the caudal abdominal and inguinal region.

   This demarcated area is perfused by the caudal superficial epigastric artery (CSEA) and its associated paired venae comitantes. For inexperienced individuals, prior trial dissection of this area may be required to ensure that the CSEA is located within the marked area.

5. Incise this marked area and use a scalpel with forceps to dissect the subcutaneous tissue while ensuring the CSEA is not compromised. Use gauze to remove excess blood.

   At the end of Stage I, only this artery and closely associated but limited subcutaneous tissues will be attached to the pig.

6. Appose the caudal incision area and suture. Trim remaining fat from skin flap edges, and suture the opposing edges with a simple interrupted suture pattern to form a tubed fold of skin. For suturing use 3.0 Proline to tube the flap; 0 catgut to close the abdomen, 2.0 catgut to close the subcuticular; and 3.0 Ethicon to close the sites of the flap.

7. Repeat steps 5 and 6 for the opposite marked area such that two sutured flaps are formed but remain attached to the pig.

8. Allow the two flaps to lie on the abdomen of the pig, and wrap with Teflon pad and elasticon before allowing the pig to recover from anesthesia.

Stage II: Cannulate and remove flap

9. Perform Stage II 48 hr after Stage I. Premedicate and anesthetize the pig as described in step 2.

10. Cannulate CSEA with 0.023-in Tygon tubing held in place with several sutures around the artery and tubing. Use a 10-ml syringe with a 21- or 23-G needle to flush the cannula with heparinized saline to ensure correct cannulation and that the CSEA is not blocked with blood clots.

11. After identifying the CSEA, remove surrounding tissue with scissors. Nick the artery with scissors to facilitate entry of the tubing. Clamp the artery with a hemostat before removing the flap from the pig, remove the flap, and then suture. Place the cannulated flap into the custom-designed skin flap cradle. Ensure that the suture line is facing down.

    The pig can be recovered for other research purposes or humanely euthanized.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Bovine serum albumin medium (2 liters)

13.78 g NaCl
0.71 g KCl
0.56 g $CaCl_2$
0.32 g KH_2PO_4
O.58 g $MgSO_4 \cdot 7H_2O$
5.50 g $NaHCO_3$
2.40 g dextrose
90.0 g BSA, Fraction V
Water to 2 liters

Add ~1700 ml water and a stir bar to a clean 4000-ml beaker. Add all reagents except BSA to beaker and mix well, adjusting pH to ~7.4 with NaOH and/or HCl. Add BSA slowly to beaker while stirring until all has gone into solution. It may take ~1 hr for all BSA to dissolve. Add 0.25 ml of 250 mg/ml amikacin (Gensia Laboratories, Ltd.). Bring volume up close to 2000 ml. Mix well and pH to 7.45 ± 0.03 with NaOH and/or HCl. Remove stir bar; pour solution into a 2000-ml volumetric flask. Bring volume to 2000 ml with water. Divide equally into six clean, autoclaved 500-ml plastic reagent bottles. Label and freeze immediately. Store up to 3 weeks. When thawing for use, add 10 ml of 1000 USP U/ml sodium heparin and 0.1 ml of 250,000 U/ml penicillin G sodium (note that this drug expires in 7 days).

COMMENTARY

Background Information

There have been numerous efforts to assess dermal absorption and cutaneous toxicity of chemicals using various in vitro and in vivo methods. The in vitro methods are limited largely because absorption is assessed in skin sections or whole skin without an intact microvasculature. In vivo models require companion intravenous studies to determine absolute dermal bioavailability, and they are usually unable to determine "first pass" cutaneous metabolism for topically applied drugs or pesticides. Isolated kidney, liver, and lung perfusion systems have been developed. However, very few isolated perfused skin systems have been developed because it has been difficult to identify a "closed" vascular system as observed with other organ systems. Isolated rabbit and pig ear systems have been developed (Behrendt and Kampffmeyer, 1989; Dick and Scott, 1992); however, the major disadvantages are that the arterial supply to tissues in the ear (e.g., cartilage, muscle) is very different from that in skin in other body regions, and the skin in the ear is structurally different (hair density and adnexial structures) compared to skin in other body regions.

Successful preparation of the isolated perfused porcine skin flap (IPPSF) depends primarily on identification, catheterization, and perfusion of the caudal superficial epigastric artery (CSEA), which directly supplies skin in the caudal abdominal region of weanling pigs. The IPPSF is strictly an ex vivo model that can be advantageous over most in vitro and in vivo systems in that there is an intact functional cutaneous microcirculation, and dermal absorption and cutaneous toxicity studies can be conducted simultaneously with the same skin flap.

Data generated from the IPPSF have been used to make predictions that have correlated well with in vivo absorption data for several drugs and insecticides (Riviere et al., 1986, 1995; Wester et al., 1998). IPPSFs can be used to study depth of penetration, skin distribution, transdermal drug delivery, and systemic targeting of anticancer drugs to tumor-bearing flaps (Chang et al., 1994; Vaden et al., 1994; Baynes et al., 1996). Iontophoretic delivery of various drugs (e.g., lidocaine, arbutamine) and hormones (e.g., LHRH) have also been demonstrated (Riviere et al., 1991, 1992; Heit et al., 1993). IPPSFs are physiologically and bio-

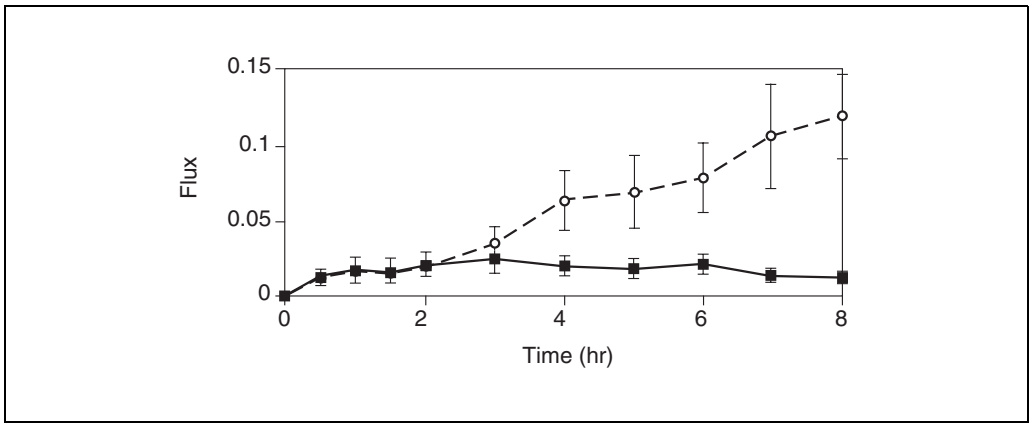

Figure 5.4.4 Flux-time profile for benzidine in acetone (solid line) and DMSO (dashed line) applied to IPPSFs.

chemically viable and have been used successfully to assess cutaneous toxicity of topically applied chemicals (King and Monteiro-Riviere, 1991; Spoo et al., 1992; Monteiro-Riviere, 1993; Zhang et al., 1995). This feature becomes relevant if the local effects of cytotoxic (e.g., solvents, fuels, surfactants) and vasoactive chemical (e.g., methyl nicotinate) components in chemical mixtures are to be assessed (Baynes et al., 1997; Allen et al., 2000).

In addition to the time and cost required to surgically prepare IPPSFs, the major drawback to IPPSFs is that systemic-mediated immunological or physiological, and neural feedback responses to topically applied toxicants cannot be observed. The other limitation is that IPPSF studies should not be conducted beyond 8 to 12 hr because IPPSF viability begins to decrease beyond this time point. In spite of these limitations, the IPPSF is more economical than animal and human in vivo studies. It has also been utilized by industry in preclinical drug development studies.

Critical Parameters and Trouble Shooting

It is important to develop a flap in a region where there are no gross morphological abnormalities in the skin. Using compromised skin can result not only in erroneous absorption profiles but also in blister formation on the dose site area during perfusion.

Cannulation of the CSEA during Stage II surgery is critical. It is possible that during Stage I surgery or during the healing process between Stage I and Stage II, that the artery may become compromised, making cannulation very difficult to almost impossible. One way to avoid this would be to adequately secure the flap after Stage I surgery.

Even after successful catheterization, high pressures may be observed in the flap. This may be due to blood clots in the CSEA. This can be corrected by first flushing the CSEA in the flap immediately after Stage II with heparinized saline and then immediately connecting the cannula to the perfusion system. High pressures can also result from a "kinked" vessel or tubing. Make certain that all tubing is free of kinks and that the cannula and vessel are straight.

Anticipated Results

This section gives an example of the kind of data that can be generated from use of the IPPSF and how absorption parameters can be calculated from a given data set. In this example, IPPSFs were exposed to benzidine for 8 hr to assess absorption in an acetone and DMSO vehicle. The plot in Figure 5.4.4 depicts the flux-time profile of benzidine diffusion through skin. At least 4 to 5 replicates are conducted per test chemical for IPPSF experiments. Systemic absorption is defined as the total amount of radioactivity detected in the perfusate for the entire 8-hr perfusion period. Skin surface penetration is defined as the sum of total absorption and total radioactivity in the tissues. The latter includes all skin and fat samples taken and analyzed after the 8-hr perfusion. Penetration into the stratum corneum layer at 8 hr is based on levels detected in the tape strips. The radioactivity remaining on the skin surface is defined as the amount of radioactivity detected in the skin swab samples. The following ratios can also be calculated to assess the relative disposition in skin: Relative Systemic Absorption (Absorption/Penetration); Relative Skin Surface Penetration (Penetration/Skin Surface); Stratum Corneum/Dosed Skin; and Stratum Corneum/Skin Surface.

Time Considerations

Surgical preparation of the IPPSF requires ~3 hr for Stage I and ~1 hr for Stage II. This time allows for restraint of the animal and for the anesthetics to take effect. Most of the IPPSF experiments do not last longer than 9 hr; 1 hr to equilibrate and to collect pre-dose samples and no longer than 8 hr to perfuse the flap. The cleaning process and collection of tissue samples at the end of the perfusion, which must occur immediately after completion of the perfusion, usually takes 1 to 2 hr.

Porcine Skin Flow-Through Diffusion Cell System

The flow-through diffusion cell system is used to determine the rate and extent of absorption of chemicals through skin in vitro. Skin from rats, mice, primates, and humans can be used in these experiments. However, porcine skin maybe preferred not only because of its availability but also because of its anatomical and physiological similarity to human skin (Fig. 5.4.1). It is often problematic finding disease-free fresh human skin, and if found, an unacceptably high degree of intersample variation may be introduced. The stratum corneum cell layer in humans (10 to 50 μm) and pigs (15 μm) is nonviable and is considered the rate-limiting barrier in percutaneous absorption of many compounds (Monteiro-Riviere, 1991). Much of the research has concentrated on stratum corneum, although the viable epidermis (80 μm in humans and 60 μm in pigs) and dermis are now thought to contribute significantly to the percutaneous penetration of compounds and ultimately their rate and extent of absorption. This in vitro system may be used for assessment of dermal metabolism and bioavailability without confounding contribution of the liver normally associated with in vivo methods.

This unit describes the surgical preparation of porcine skin sections and the operation of the flow-through diffusion cell system. Surgical preparation of porcine skin (see Support Protocol) involves specific humane procedures for removal of porcine skin and preparation for the diffusion cell. The operation of the diffusion cell system (see Basic Protocol) involves dosing and sample collection during and at the end of these experiments.

CAUTION: If radioactive test compounds are used, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

OPERATION OF THE FLOW-THROUGH DIFFUSION CELL SYSTEM

BASIC PROTOCOL

The flow-through diffusion cell system consists of three major components; namely, (1) the diffusion cell in specifically engineered heating blocks, (2) peristaltic pump and tubing, and (3) sample collecting apparatus. The artificial medium can vary but should be physicochemically similar to serum. Bovine serum albumin is added to the medium to mimic the oncotic pressure in serum in vivo. Saline and other fluids have been used as receptor fluids, but these media may interfere with the viability of the skin and may not truly represent partitioning into blood in vivo. The aim here is to perfuse the dermal surface of the prepared skin sections with the artificial medium, dose the epidermal surface with the test chemical, collect perfusate samples at desired time points after dosing, and finally obtain surface, stratum corneum, and skin samples at the end of the perfusion experiment. These experiments are usually not longer than 8 to 12 hr as dermal viability begins to be lost at about this time. The system described below allows for perfusion of 14 diffusion cells under desired environmental conditions.

Current Protocols in Toxicology (2001) 5.5.1-5.5.8

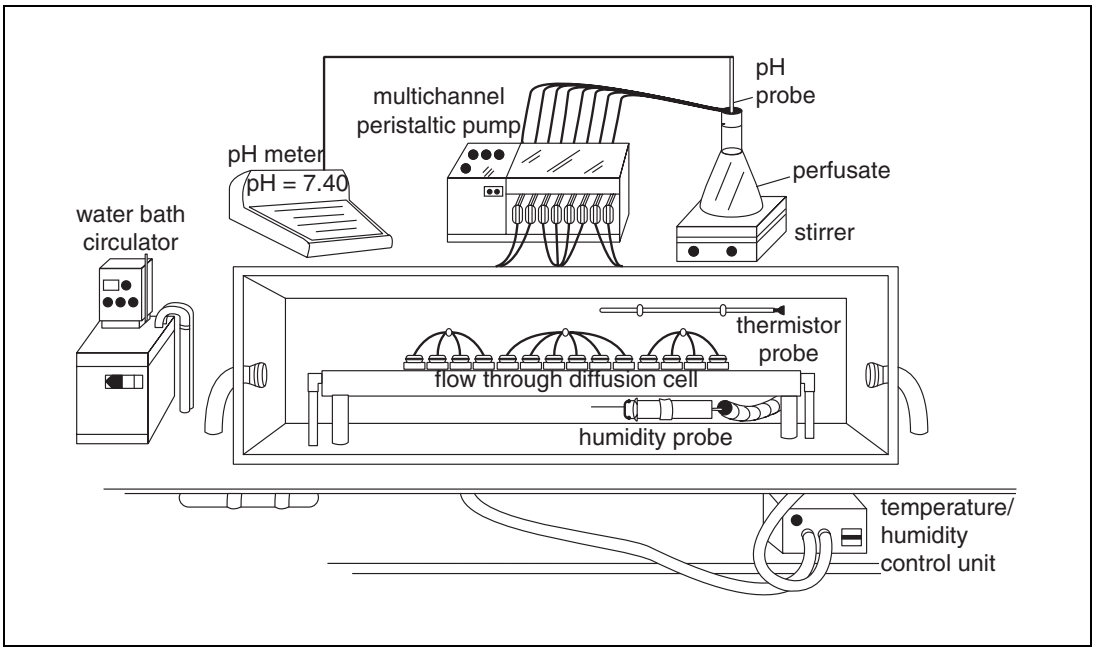

Figure 5.5.1 Illustration of the flow-through diffusion cell system in an environmentally controlled chamber.

Materials

Artificial medium
Skin punch biopsy sections (see Support Protocol)
Bovine serum albumin medium (*UNIT 5.4*)
Test compound
1% (v/v) soapy solution
Sodium hypochlorite
Isopropyl alcohol

Two-compartment Teflon flow-through diffusion cells (Crown Glass)
Heating blocks
Tygon tubing
Brinkmann constant-temperature circulator (Brinkmann)
Peristaltic pump
Fraction collector
Humidifier
Hygrometer and thermometer
pH meter
20-ml scintillation vials
Cotton swabs (e.g., Q-tips)
Cellophane tape
Magnetic stirrer

Set up flow-through diffusion cell apparatus

1. Set up a flow-through diffusion cell apparatus; an example is depicted in Figure 5.5.1.

   If the test substance is hazardous or a control of environmental conditions is desired, the flow-through diffusion cell system can be enclosed in an environmentally controlled chamber (Fig. 5.5.1). This chamber can be made of a light inert material such as plexiglass.

2. Load 7 diffusion cells into each heating block and connect inlet and outlet arms to tubing leading to the peristaltic pump and scintillation vials, respectively. Maintain temperature of the bovine serum albumin (BSA) medium and flow-through diffusion

cell at 37°C in both heating blocks using a Brinkmann constant-temperature circulator.

3. Prior to loading the skin sections in the cell, perfuse the entire system with the BSA medium to remove air bubbles from the inlet tubing connecting peristaltic pump to diffusion cells, the diffusion cells, and the outlet tubing from the diffusion cells.

   Rubber or other artificial membranes can be used at this time in place of skin sections to ensure removal of air bubbles and that BSA medium flow rates range from 4.0 to 5.0 ml/hr.

Load and perfuse skin sections

4. Load skin punch biopsy sections (see Support Protocol) into diffusion cells and ensure that there are no air bubbles at the dermis-medium interface. Perfuse skin sections with BSA medium, maintained between pH 7.4 and 7.5, at a flow rate of 4.0 to 5.0 ml/hr.
5. Maintain the heating block at 37°C.
6. Begin collecting BSA medium samples in scintillation vials for 15 to 30 min prior to dosing to obtain background levels, to ensure that there are no leaks in the system, and to ensure that flows are within range of desired flow rates.

Add test compound and collect medium samples

7. Dose skin surface with small volume of test compound.

   For example, use ~10 µl for a surface area of 0.32 cm^2. Excess volume may result in contamination and erroneous readings at early time points.

8. Collect BSA medium samples at short time points (e.g., 5, 10, 20, 30, and 45 min) for the first hour and longer time points thereafter.

   This is important if flux, permeability, and lag time are desired parameters.

Collect skin samples

9. At the end of the perfusion, obtain skin surface samples by swabbing each skin surface with one cotton swab soaked in 1% soapy solution and then with a second dry swab.
10. Obtain stratum corneum samples by tape stripping each skin section six times with cellophane tape. Save these samples along with the remaining skin section for further analysis by chromatographic or radiochemical analysis.

    Radiolabelled BSA medium and tissue samples can be combusted in a Packard Model 307 Tissue Oxidizer (Packard Chemical) and then analyzed by a Packard Liquid Scintillation Counter (Packard Chemical) for total [^{14}C or ^{3}H] determinations.

11. After tissue samples have been obtained, perfuse the entire system at maximum flow rates with the following liquids to remove remnants of the test chemical from the perfusion lines and diffusion cells: sodium hypochlorite solution for 30 min; isopropyl alcohol for 30 min; and water for 45 min. Discard the aqueous and alcohol waste appropriately, especially if the dosing compound was radiolabeled.

SURGICAL PREPARATION OF PORCINE SKIN

SUPPORT PROTOCOL

Skin can be obtained from any anatomical region of the pig's body. Skin from the dorsum (back) of the pig is preferred because the surrounding musculature and skeleton facilitates dermatoming and does not require prior excision of skin. Because of the nature of this procedure, euthanasia of the animal is required prior to dermatoming. After dermatoming skin to correct thickness, punch biopsies of the dermatome skin are then loaded into the diffusion cell system.

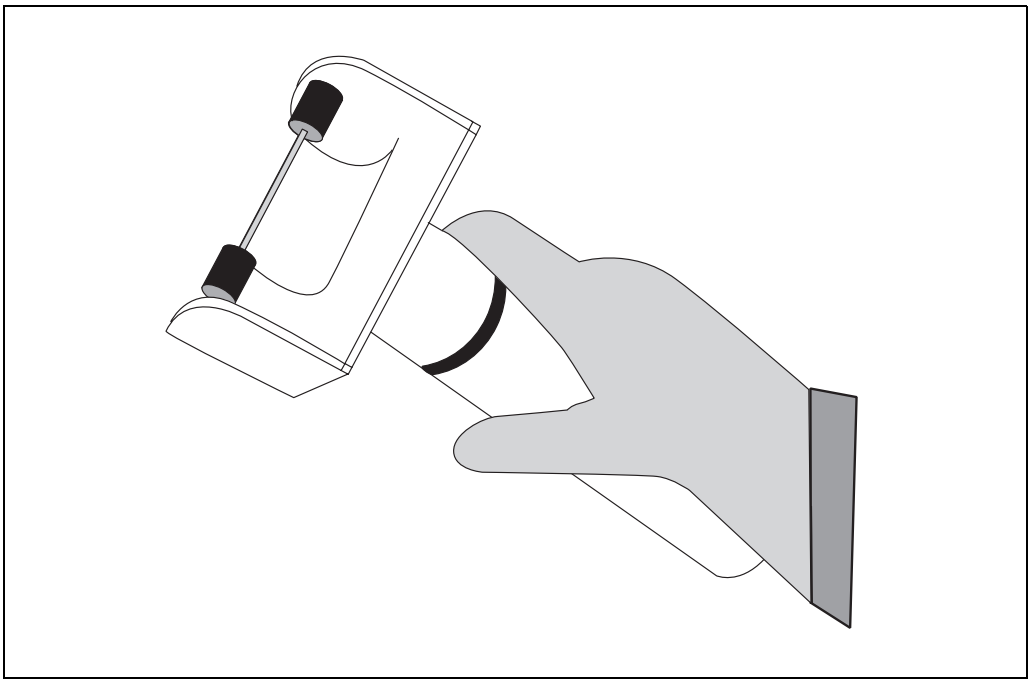

Figure 5.5.2 An illustration of the Padgett Electro Dermatome in removing sheets of skin.

Materials

8-week-old weanling female Yorkshire pigs (e.g., Looper Farms)
Preanesthetic: ketamine hydrochloride (11 mg/kg body weight); xylazine hydrochloride (1.4 mg/kg body weight)
Pentobarbitol sodium (100 mg/kg body weight)
Physiological saline

Gauze
Dermatome and blades (e.g., Padgett electric model; optional)
Scissors and forceps
16-mm steel biopsy punch
Micrometer

1. Acclimatize 8-week-old weanling female pigs 1 to 2 weeks before surgical procedure and clip the hair from the dorsum (back) of the pig 24 to 48 hr prior to dermatoming skin.
2. Tranquilize pig with ketamine (11 mg/kg body weight) and xylazine (1.5 mg/kg body weight) sequentially. Then euthanize with pentobarbitol solution (100 mg/kg body weight). Clean any debris from the back of the pig with dry gauze, and examine for gross morphological abnormalities in the skin.
3. Set dermatome to 200 to 300 μm prior to dermatoming skin.

   This setting should provide a thickness of ~200 μm, which is representative of stratum corneum, viable epidermis, and a small portion of the dermis. The aim here is to minimize the contribution of the dermis layer to diffusion of the test compound. Some individuals may use higher or lower dermatome settings to obtain a skin thickness within the 200- to 300-μm range.

4. Dermatome the skin as shown in Figure 5.5.2 applying constant pressure and utilizing a forceps to help guide the dermatomed skin through the dermatome.

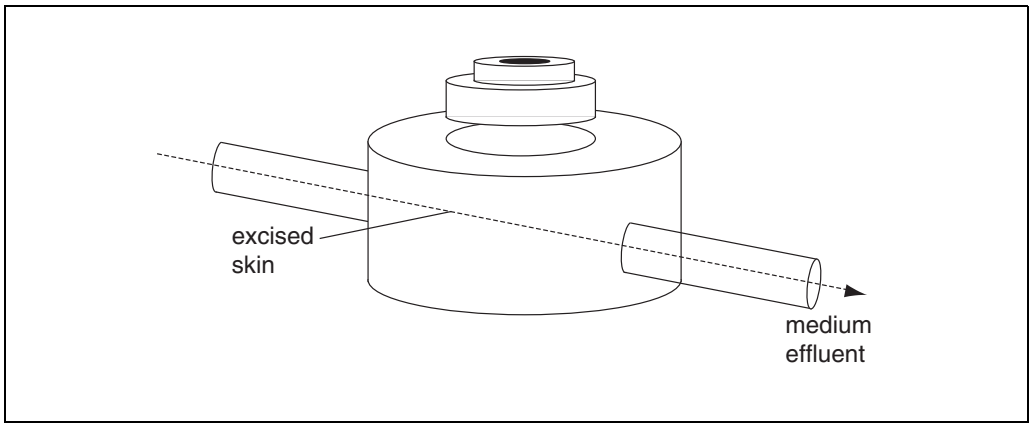

Figure 5.5.3 Illustration of the Teflon flow-through diffusion cell; also indicated are the inlet and outlet arms of the cell through which the medium perfuses.

5. Place dermatomed skin, dermis side down, on gauze presoaked with physiological saline and use within 1 to 2 hr to ensure viability. Examine both sides of dermatomed skin for lesions and use a micrometer to ensure that skin sections 200- to 300-μm thick are selected.

6. Use a 16-mm biopsy punch to provide skin disks that will be loaded into a two-compartment Teflon flow-through diffusion cell (Fig. 5.5.3).

   Depending on the diameter of the diffusion cell selected, dosing area will vary from 0.32 to 0.64 cm^2.

COMMENTARY

Background Information

Improvements in in vitro technology within the last 20 years have allowed for accurate measurements of dermal absorption and metabolism of topically applied drugs and pesticides. Static cell diffusion systems with two-chamber cells were initially used to quantitate percutaneous absorption of drugs and toxicants. The two-chambered cell can be used when steady state kinetics is required to study mechanisms of absorption and for comparing permeation through skin to Fickian diffusion (Bronaugh and Collier, 1993). However, skin is excessively hydrated with this two-chamber system and the donor chamber does not mimic environmental conditions. The flow-through diffusion cell systems (a one-chamber system) as first described by Bronaugh and Stewart (1985) have contributed significantly to quantitating the rate and extent of dermal absorption of drugs and pesticides in humans, rodents, and pigs. In many instances, permeation of lipophilic and hydrophilic drugs in these in vitro systems were comparable to permeation in vivo.

The major benefit of the flow-through diffusion system over the static diffusion system is that the skin is more likely to be viable and the penetrating drug or pesticide molecule is continually removed from the skin, which is analogous to the continual perfusion of blood in vivo (Bronaugh and Stewart, 1985; Grummer and Maibach, 1991). The receptor volume of the diffusion cell is usually small (<0.5 ml) so that it can be completely flushed out during sample collection intervals. Flow rates are usually set at 5 to 10 times the receptor volume (e.g., 2.5 to 5 ml/hr) to allow for adequate removal of the absorbed drug molecules. For these reasons, average flow rates described in this protocol are within this range, 4.0 ml/hr. Other studies have also demonstrated that changes in perfusion rate (Crutcher and Maibach, 1969; Chang and Riviere, 1991), receptor fluid constituents (Bronaugh and Stewart, 1984), environmental conditions (Chang and Riviere, 1991), and skin section thickness (Scott et al., 1991) will dramatically alter penetration of the marker chemical. Review of current literature suggests that the latter variable is often overlooked in the design of in vitro percutaneous studies.

For lipophilic chemicals such as carbaryl and permethrin, penetrating molecules are thought to enter the systemic circulation in vivo at the dermis/epidermis interface and do not

necessarily traverse the full thickness of the dermis. In in vitro experiments, the aqueous dermis can act as a significant, additional artificial barrier for penetrating lipophilic chemicals such as DDT (Reifenrath et al., 1991). Several studies have difficulty demonstrating good agreement between in vitro and in vivo absorption with lipophilic chemicals because of the presence of excess dermis in final skin preparations (Bronaugh and Stewart, 1984; Bronaugh and Collier, 1993). Whereas for more hydrophilic chemicals, good agreement between in vitro and in vivo absorption data is more often achieved. Several other studies have demonstrated that use of skin sections containing mostly epidermis and minimal dermis results in good agreement with in vivo data. For example, cypermethrin did not penetrate in vitro through rat whole skin, but penetrated epidermal membranes and predicted the in vivo absorption in rats (Scott and Ramsey, 1987). Having considered these findings, the flow-through diffusion cell experiments described in this protocol utilizes excised skin sections (200 to 300 μm) with minimal dermis. Furthermore, bovine serum albumin is used as the receptor fluid because it mimics blood and it facilitates partitioning of toxicologically important chemicals, which are often lipophilic, from the skin sections into the receptor fluid.

Critical Parameters and Troubleshooting

Skin sections should be removed at least 48 hr after clipping to ensure adequate time for recovery of the stratum corneum. Recall that the stratum corneum layer is the rate-limiting layer, and its integrity must be maintained if valid comparisons are going to be made.

Dermatoming requires some skill and practice, but the operator can quickly learn to consistently prepare skin at the desired thickness. Dermatoming of skin from anatomical regions of the pig other than the dorsum or skin from other species will require securing dissected skin on firm foam blocks prior to dermatoming. This exercise requires more practice and can result in uneven skin samples. Poor dermatoming and very thin sections can produce highly variable results as the path lengths for molecular diffusion can vary, resulting in considerable variability in absorption of the test chemical.

These are usually mass balance studies, and it is important to account for the dose delivered to the skin surface. It is also important to accurately know the dose that was delivered to the skin surface because this is the frame of reference from which the flux, permeability, and extent of absorption will be determined. The applied dose, usually expressed as $\mu g/cm^2$, can be obtained from the average predose and postdose samples in the original dose vial. This is especially important for very volatile test chemicals. Recall that very small volumes (10 to 20 μl) are usually applied to the skin surface.

Anticipated Results

This section gives examples of the kind of data that can be generated from perfusion of skin in flow-through diffusion cell systems and how diffusion parameters can be calculated from a given data set.

In this first example, porcine skin sections were exposed to 40 $\mu g/cm^2$ of ^{14}C-carbaryl for 8 hr to assess absorption in different vehicles, acetone and DMSO. The plot in Figure 5.5.4 depicts the flux of carbaryl dosed in acetone or DMSO as it diffuses through the skin. At least 4 to 5 replicates are conducted per test chemical for flow-through diffusion cell experiments. Absorption is defined as the total amount of radioactivity detected in the perfusate for the entire 8-hr perfusion period. Penetration is defined as the sum of total absorption and total radioactivity in the skin. Penetration into the stratum corneum layer at 8 hr is based on levels detected in the tape strips. The radioactivity remaining on the skin surface was defined as the amount of radioactivity detected in the skin swab samples. The following ratios can also be calculated to assess the relative disposition in skin such as: (1) relative systemic absorption (absorption/penetration); (2) relative skin surface penetration (penetration/skin surface); (3) stratum corneum/dosed skin; and (4) stratum corneum/skin surface.

Theoretically, Fick's law of diffusion describes the rate of percutaneous absorption through the intercellular pathway in skin. That is, rate of diffusion or flux = $[D \times A \times K \times \Delta C]/H$, where D is the diffusion coefficient or diffusivity, A is the surface area, K is the partition coefficient for stratum corneum/vehicle or octanol/water, ΔC is drug concentration difference across the membrane, H is membrane thickness, and permeability can be obtained from $[D/H] \times K$. The determinants (D, A, K, and ΔC) of diffusion rates for a given skin section may be altered experimentally through manipulation of drug or pesticide formulations. This system can therefore be used to quickly compare absorption of drug or chemical formulations.

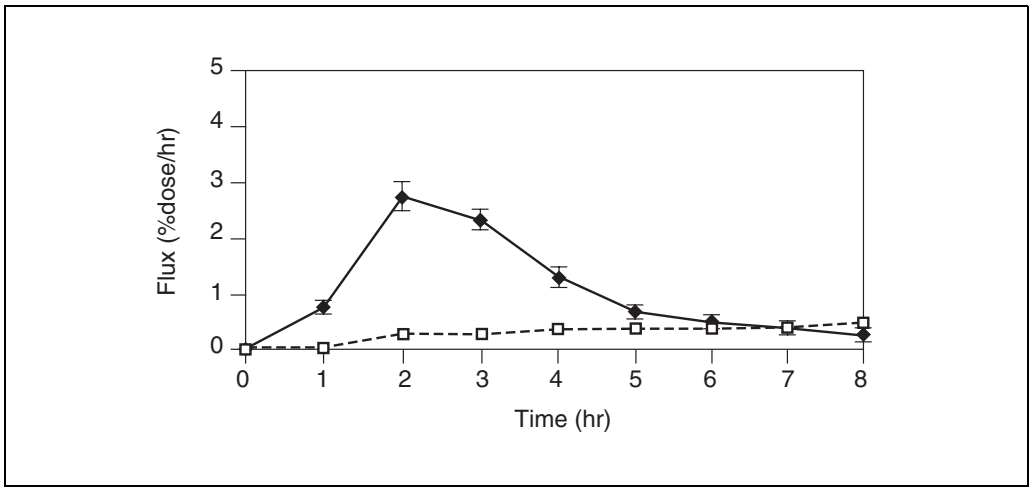

Figure 5.5.4 Flux (%dose/hr) versus time profiles for carbaryl in acetone (circles) or DMSO (squares) vehicles in a flow-through diffusion cell system.

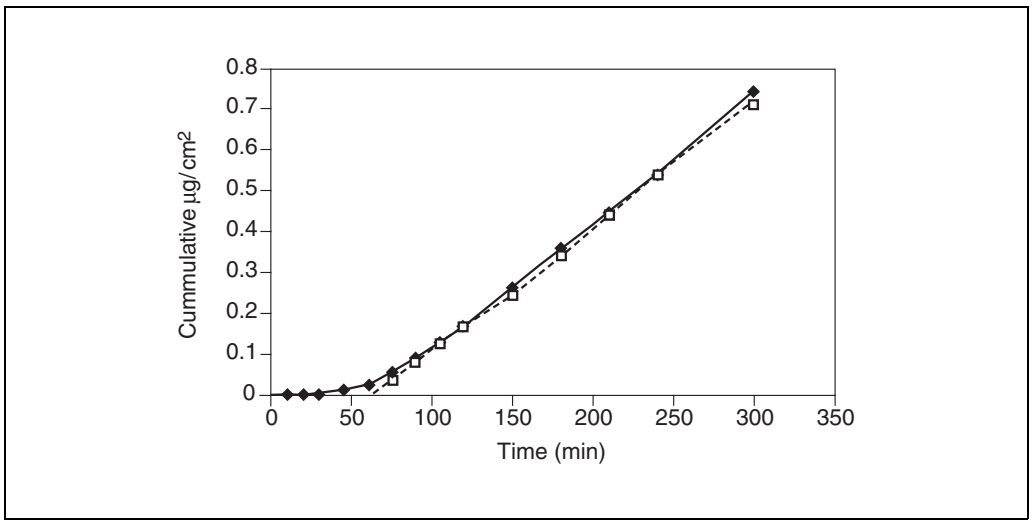

Figure 5.5.5 Cumulative absorption (µg/cm^2) versus time profile for ^{14}C-naphthalene diffusion in JP-8 jet fuel in porcine skin sections.

In the second example, porcine skin sections were exposed to ^{14}C-naphthalene (µg/cm^2) for 5 hr to assess naphthalene absorption in JP-8 fuel. The plot in Figure 5.5.5 depicts the cumulative absorption of naphthalene in porcine skin and how graphically flux, permeability, and lag time can be obtained from this experiment. Flux (µg/cm^2/hr) can be determined at steady state from the slope of the cumulative mass per unit area versus time (hr) curve. Permeability (cm/hr) can be determined from the ratio of individual fluxes to the concentration (µg/cm^3) of initial topical dose. Diffusivity (cm^2/hr) can be determined by obtaining the lag time before steady-state flux is reached. This lag time (τ) is obtained by extrapolating the steady state portion of the curve back to the time- or *x*-axis and is related to diffusivity (D) and membrane thickness (L) by the following equation: $D = L^2/6\tau$, where $L = 250$ µm or selected membrane thickness.

Time Considerations

Bovine serum albumin medium is usually prepared 24 to 48 hr in advance, and it can take up to 1 hr to dissolve the BSA. Surgical preparation requires ~20 min to first anesthetize and euthanize the pig humanely and ~10 to 15 min to dermatome the skin from the dorsum.

Loading the skin in the 14 diffusion cells can take as long as 15 min to ensure that air bubbles are removed from the medium immediately below the skin. Dosing and sample collection can vary depending on the duration of the perfusion experiment. Sometimes, 8-hr experiments are performed to mimic occupational

exposure scenarios for the average worker in the agriculture or chemical industry.

Toxicant Transport by P-Glycoprotein

P-glycoprotein (P-gp) is an ~170-kDa membrane-bound glycoprotein that has been shown to efflux a wide variety of drugs, including chemotherapeutic agents, as well as toxicants. In mammals, P-gp is located on the apical side of organs of elimination, such as the brush border of the proximal tubules in the kidney, the enterocytes of intestinal cells, and the canalicular membrane of hepatocytes. This localization indicates that P-gp plays an important role in eliminating toxicants from the organism or acts to prevent their uptake in the gastrointestinal tract. P-gp is also present in capillary endothelial cells and is important in maintaining the integrity of the blood-brain barrier and the testicular-blood barrier.

P-glycoprotein transport activity can be measured from tissues, from whole cultured cells, or membrane preparations from cultured cells or tissues. The activity is measured in amount of toxicant transported per unit time or amount transported per unit time per milligram of protein. Typically, transport is measured using either a radiolabeled substrate or unlabeled substrate that can readily be detected by high-performance liquid chromatography (HPLC) or gas chromatography (GC) and measuring its uptake and/or elimination into cultured cells or tissue pieces (see Basic Protocol 1). The procedure described in this unit will only cover steps for using a radiolabeled substrate, although the initial steps before detection are very similar to the procedure using unlabeled substrate. A variation of this procedure examines uptake of a radiolabeled substrate into cellular membrane vesicles (see Basic Protocol 2 and Support Protocol for vesicular preparation). Another method for examining P-gp-mediated transport uses polarized epithelial cells, such as Caco-2 cells, cultured in two-chambered vertical diffusion chambers (Transwells), examining the movement of a radiolabeled toxicant from the basolateral to apical side of the culture dishes (see Basic Protocol 3). The last protocol describes an indirect method of examining transport activity, determining whether a compound can compete or inhibit the transport of a known P-glycoprotein substrate doxorubicin (see Basic Protocol 4). This procedure is a quick screening method, avoiding the expense of radiolabeled compounds and the time involved when preparing membrane vesicles. However, this method cannot distinguish whether a toxicant is actually a substrate or an inhibitor of P-glycoprotein.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CELLULAR EFFLUX OF RADIOLABELED TOXICANTS

BASIC PROTOCOL 1

This protocol describes methods for loading cells with a toxicant of interest and then assessing its rate of efflux by liquid scintillation counting of the cells and of the cell culture medium. This procedure can be completed in 1 day and only requires access to standard cell culture items and a radiolabeled toxicant. This procedure can also be modified to examine the efflux of non-radiolabeled compounds by either GC or HPLC.

Materials

Transfected cultured cells expressing P-gp after transfection with a vector containing P-gp cDNA along with a mock-transfected control or tissue, e.g., liver or intestine

Appropriate cell culture medium (e.g., RPMI 1640 supplemented with 10% fetal bovine serum)

Contributed by Lisa J. Bain

Current Protocols in Toxicology (2003) 5.6.1-5.6.13

[^{14}C] or [^{3}H]-labeled toxicant, diluted sufficiently with unlabeled toxicant to provide a 1 to 20 µM solution having 100,000 to 300,000 dpm per 5 µl
5 mM verapamil stock (see recipe)
PBS (*APPENDIX 2A*), ice cold
30% scintillation cocktail (e.g., Scintisafe or equivalent)

12-well culture plates
20-ml scintillation vials
Scintillation counter

Additional reagents and equipment for counting cells (*APPENDIX 3B*)

1. If using cultured cells, harvest cells and dilute to 1×10^6 cells/ml after counting with a hemacytometer (*APPENDIX 3B*). Place 1 ml of cell suspension into a 12-well culture plate along with an additional 1 ml cell culture medium. Plate out enough cells so that each time point can be performed in triplicate.

   For a typical seven-time point efflux assay using both P-glycoprotein-expressing and mock-transfected cells, and with time points at 0, 2, 5, 7, 10, 15, and 30 min, plate 21 wells for each cell line.

2. Incubate cells overnight in a 37°C, 5% CO_2 humidified incubator to allow cells to attach. If using tissues, prepare a crude primary cell suspension as described in Support Protocol, step 1b, count cells (*APPENDIX 3B*), and place 1×10^6 cells into 2 ml cell culture medium in a 12-well culture plate.

   The assays with tissues should be conducted in triplicate using medium with or without the addition of verapamil. For a typical seven-time point efflux assay, use 42 wells.

3. For cultured cell lines with both a transfectant and a mock control, after an overnight attachment period, remove cell culture medium and replace with 2 ml medium containing 5 µl of the radiolabeled toxicant of interest. For primary cells, add 5 µl of the radiolabeled toxicant directly to the culture medium, and add 5 µl of 5 mM verapamil to half of the wells (10 µM verapamil final concentration). Incubate cells or tissues for 4 hr in a 37°C, 5% CO_2 humidified incubator.

4. After 4 hr, aspirate the medium from the wells, and wash the cells two times with 1 ml ice-cold PBS, being careful to handle and dispose of the radiolabeled material properly. Add 1 ml of 37°C prewarmed cell culture medium to each well.

5. At the appropriate time points, remove the cell culture medium and place into labeled 1.5-ml microcentrifuge tubes. Wash the cells or tissue with 1 ml ice-cold PBS two times, aspirating off the washes. Then, add 0.5 ml PBS and scrape cells from the plate. Add 100 µl of the cell culture medium or 0.5 ml of the cell suspension to a 20-ml scintillation vial containing 15 ml of 30% Scintisafe scintillation cocktail and determine the amount of radioactivity transported into the medium or accumulated in the cells by counting on a scintillation counter.

   These same procedures can be used to examine the cellular efflux of unlabeled toxicants that can be measured by gas chromatography (GC) or high-pressure liquid chromatography (HPLC). The investigator would need to work out the time course of accumulation of the toxicant, as well as additional cleanup steps and the appropriate detection methods.

ACCUMULATION OF TOXICANTS INTO CELLULAR MEMBRANE VESICLES

This procedure describes methods of measuring toxicant uptake into plasma membrane vesicles. Although the procedure is relatively quick, preparing the vesicles is a 12 to 15 hr procedure. However, this procedure negates the effects of toxicant uptake and metabolism that may be problematic in the other procedures.

Materials

Membrane vesicles (see Support Protocol)
ATP and AMP solutions (see recipe)
1000 U/ml creatine kinase in Tris-sucrose buffer (store 150-µl aliquots in 0.5-ml microcentrifuge tubes for up to 1 month at −20°C)
Tris-sucrose buffer (see recipe), ice cold
0.5 µCi of 418.2 nM [^{3}H]vincristine (see recipe)
[^{14}C] or [^{3}H]-labeled toxicant, diluted sufficiently with unlabeled toxicant to provide a 10 nm to 10 µM solution having 0.5 µCi per 350 µl Tris-sucrose buffer
22 µM verapamil in Tris-sucrose buffer (see recipe)
50% scintillation cocktail (Scintisafe Plus or equivalent)

0.22-µm membrane filters, 25-mm diameter (e.g., Millipore)
Sampling vacuum manifold for 25-mm filters (e.g., Millipore)
Vacuum pump
Flat-tipped forceps
7-ml scintillation vials
Scintillation counter

IMPORTANT NOTE: Ensure that everything is set up before beginning the experiment as there is a very short period between each sampling time point.

Prepare reagents

1. Heat water bath to 37°C. For each vesicular preparation to be tested, thaw on ice 400 µg membrane vesicles, one tube each of ATP, AMP, and 1000 U/ml creatine kinase for each compound to be tested, plus vincristine as a positive control. Label twenty-four 0.5-ml microcentrifuge tubes with an "a" and twenty-four 0.5-ml microcentrifuge tubes with a "b," and place on ice.

   The tubes will be used in batches of three to perform assays in triplicate for each vesicular preparation, for each compound (vincristine or the toxicant), using either AMP or ATP.

2. Place twenty-four 1.5-ml microcentrifuge tubes on ice and add 1 ml ice-cold Tris-sucrose buffer to each one.

Prepare tubes and filter apparatus

3. To each of three "b" tubes add 6.5 µl Tris-sucrose buffer, 27.5 µl [^{3}H]vincristine solution, 10 µl ATP solution, and 11 µl creatine kinase solution. Keep on ice. To each of three "a" tubes, add 30 µg vesicle preparation and enough Tris-sucrose buffer to make a final volume of 60 µl. Keep on ice.

4. Place twelve 0.22-µm filters on each port of the sampling manifold and hook it up to the vacuum pump. To wet the filters before beginning the assay, pipet 1 ml of ice-cold Tris-sucrose buffer onto each filter and turn on vacuum. Keep the vacuum pump running for the entire set of three tubes.

Start assay

5. Place one of the "b" tubes in the 37°C water bath and preincubate for 1 min. To start the assay, add 50 µl from the warm "b" tube into an "a" tube, place in the 37°C water bath, and start the stop watch (final concentrations: 1 mM ATP, 10 mM $MgCl_2$, 10 mM phosphocreatine, 10 U creatine kinase, and 100 nM [^{3}H]vincristine). Discard the remainder of "b" as radioactive waste.

6. Remove a 20-µl aliquot from the tube at 30 sec, put into one of the 1.5-ml microcentrifuge tubes containing 1 ml Tris-sucrose buffer to immediately stop the reaction. Pipet the entire 1.02 ml onto one of the prewetted 0.22-µm membrane filters and vacuum filter. Then, add 3 ml Tris-sucrose buffer and allow liquid to filter into waste container and repeat two more times with an additional 3 ml of Tris-sucrose buffer. Remove additional aliquots from the tube at 1 min, 2 min, and 3 min and repeat the stop step, filter onto a different 0.22-µm membrane filter, and repeat the washing step.

   At the end of this assay, samples will be filtered onto four membranes and one of the triplicate samples is completed.

7. Repeat steps 5 and 6 for the second and third replicate.

8. After all twelve filters have been used, turn off the vacuum and remove the filters with flat tipped forceps. Place each filter into a prelabeled individual 7-ml scintillation vial. Add 5 ml scintillation cocktail and determine the amount of radioactivity associated with each filter by scintillation counting.

Assess specificity

9. To ensure that the radioactivity associated with the filters is not just nonspecific binding, repeat the assay and substitute AMP for ATP. To three additional 0.5-ml microcentrifuge tubes labeled "b," add to each tube 6.5 µl Tris-sucrose buffer, 27.5 µl [^{3}H]vincristine solution, 10 µl AMP solution, and 11 µl creatine kinase solution. Keep on ice. To three "a" tubes, add to each tube 30 µg vesicle preparation and enough Tris-sucrose buffer to make a final volume of 60 µl. Keep on ice.

10. Repeat steps 4 to 8 for AMP-containing samples.

11. If the vesicular preparation was from transfected cells, repeat steps 3 to 10 with the mock-transfected cells. If the vesicular preparation was from other cultured cells or tissues, repeat steps 3 to 10 while using verapamil as a specific inhibitor of P-glycoprotein-mediated transport. Modify step 3 such that to each tube "b," add 4.5 µl Tris-sucrose buffer and 2 µl verapamil solution, rather than 6.5 µl Tris-sucrose buffer.

Measure nonspecific binding

12. Perform a nonspecific-binding assay to determine how much [^{3}H]vincristine or radiolabeled-toxicant is binding to the filters. To each of two 0.5-ml microcentrifuge tubes, add 66.5 µl Tris-sucrose buffer, 27.5 µl radiolabeled compound, 10 µl ATP solution, and 11 µl creatine kinase solution. Filter through the sampling manifold as described above and determine the amount of radioactivity associated with each membrane, which will be the blank.

13. Subtract the average DPM of the blank samples from that of the other samples to determine the amount of radioactivity associated with the vesicles. Calculate an average for each time point and compound, convert the DPM into pmol transported/mg protein, and plot as a graph with time on the *x*-axis and pmol/mg transported on the *y*-axis.

   For a toxicant to be a substrate of P-gp, the rate of uptake must be greater in the ATP-utilizing samples compared to the AMP-utilizing samples, but it must also be greater

in either the transfected P-gp expressing cells than the mock-transfected cells, or greater in the toxicant vesicles without verapamil than those vesicles incubated with the toxicant plus verapamil.

APICAL TRANSPORT OF TOXICANTS IN CACO-2 CELLS CULTURED ON TRANSWELL INSERTS

BASIC PROTOCOL 3

This protocol describes methods for assessing basolateral to apical transport of toxicants in Caco-2 cells cultured on Transwell inserts. Once the cells on the inserts form the appropriate tight junctions, this is a relatively quick and robust method for examining transport. The limitations are the cost of the Transwells and the time required for the cells to become ready to use.

Materials

Caco-2 cells
Cell culture medium, such as DMEM with high glucose (4.5 g/liter) supplemented with 10% fetal bovine serum
Hank's balanced salt solution (*APPENDIX 2A*) containing 25 mM HEPES, pH 7.4 (HBSS/HEPES)
[^{3}H]- or [^{14}C]-labeled toxicant of interest diluted with unlabeled toxicant to provide a final solution of 1 to 100 µM containing 0.5 µCi/2.5 ml transport medium
5 mM verapamil (see recipe)
50% scintillation cocktail (e.g., Scintisafe Plus or equivalent)

6-well transwell plate (Costar) with 0.45-µm polyester inserts
37°C, 5% CO_2 humidified incubator
7-ml scintillation vials
Scintillation counter

1. Seed 5×10^5 Caco-2 cells/insert on a 6-well transwell plate with 0.45-µm polyester inserts and add 1.6 ml cell culture medium to the apical side and 2.5 ml to the basolateral side. Plate cells such that experiments can be run in triplicate for each compound, for each side of the transwell, and with and without verapamil. For every toxicant tested, set up at least twelve plates. Incubate for 21 days in a 37°C, 5% CO_2 humidified incubator, which is when the tight junction has formed and P-gp expression is near maximum.
2. Before the transport experiments, remove the cell culture medium and replace with an equal volume of warm (37°C) HBSS/HEPES, and incubate 30 min in the 37°C, 5% CO_2 humidified incubator.
3. To start the transport experiments, replace the medium on the apical side with fresh HBSS/HEPES and the basolateral side with HBSS/HEPES containing 0.5 µCi [^{3}H]- or [^{14}C]-radiolabeled toxicant. In transport inhibition assays when verapamil is to be added, add 5 µl verapamil/ml HBSS/HEPES to both sides of the transwell (final concentration is 10 µM verapamil). Incubate for 4 hr in a 37°C, 5% CO_2 humidified incubator and remove a 50-µl aliquot from each compartment at 0-, 0.5-, 1-, 2-, 3-, and 4-hr timepoints.
4. Place each aliquot into a 7-ml scintillation vial containing 5 ml of 50% scintillation cocktail and determine the amount of radioactivity contained in each aliquot by scintillation counting.
5. To determine the rate of transport, convert the DPM from the scintillation counter into nanomoles or picomoles transported per cm^2 of insert surface (the 6-well insert is 4.7 cm^2). Plot on a graph versus time in hours.

For a toxicant to be actively transported by P-gp, the transport from the basolateral side to the apical side should be significantly greater than the transport from the apical to basolateral side. Also, the addition of P-gp inhibitor verapamil should decrease the rate of basolateral-to-apical transport significantly.

6. Determine the apparent permeability coefficient, P_{app} (cm/sec). This is calculated as:

$$P_{app} = dQ/dt \times 1/60 \times 1/c_o \times 1/A$$

where dQ/dt is the increase in toxicant in the receiving chamber (µg/min), c_o is the initial toxicant concentration in the donor chamber (µg/ml), and A is the area of the culture insert in cm^2 (in this case, it is 4.7 cm^2). Use the P_{app} values to determine statistical differences between treatments.

BASIC PROTOCOL 4

INHIBITION OF DOXORUBICIN UPTAKE BY TOXICANTS

This procedure describes toxicant inhibition of doxorubicin accumulation in cultured cells. It is a relatively fast procedure that can be completed in 1 day. The only requirement is to have access to a fluorescence spectrophotometer. However, this assay is not a true assay for transport, as it can only determine whether a toxicant is either a substrate or an inhibitor of P-gp-mediated transport.

Materials

P-glycoprotein expressing cultured cells, such as Caco-2 cells, or transfected cells expressing P-gp after transfection with a vector containing P-gp cDNA and a mock-transfected control
10 mM doxorubicin-HCl stock (see recipe)
Toxicant of interest dissolved in PBS, saline, ethanol, or acetone at a 200-fold concentrate of the final concentration for the assay
5 mM verapamil stock (see recipe)
PBS (*APPENDIX 2A*), ice cold
Extraction solution (see recipe)

1.5-ml microcentrifuge tubes
96-well plates
96-well fluorescence spectrophotometer (e.g., SpectraMax Gemini or equivalent; or a single-cuvette fluorimeter)

Additional reagents and equipment for counting cells (*APPENDIX 3B*)

NOTE: Doxorubicin is a suspected carcinogen. Use appropriate precautions when handling.

1. Harvest P-glycoprotein expressing cultured cells and dilute to 1×10^6 cells/ml after counting on a hemacytometer (*APPENDIX 3B*). Place 1 ml cell suspension in autoclaved 1.5-ml microcentrifuge tubes, using enough cells so that all assays can be performed in triplicate.

2. Add 5 µl of 10 mM doxorubicin-HCl (final concentration 50 µM) along with 5 µl of the toxicant of interest (final concentration 1:200 of stock). Perform controls using only doxorubicin and a positive control containing doxorubicin and 2 µl of 5 mM verapamil (final concentration of 10 µM). Incubate tubes for 4 hr in a 37°C incubator.

3. Centrifuge cells 2 min at 200 × *g*, 4°C. Pour off the culture medium into an appropriate waste container, and resuspend cells in 1 ml ice-cold PBS to wash. Centrifuge 2 min at 200 × *g*, 4°C, and repeat the washing step one additional time. Remove all PBS with a pipet after final wash.

4. Add 1 ml extraction solution to each tube, vortex for 30 sec, and incubate 1 hr at room temperature. Vortex again and pellet cellular debris by centrifuging 2 min at 1000 × *g*, 4°C.

5. Remove 200 µl of solution from each tube, put into a 96-well plate, and measure the amount of doxorubicin extracted from each cell pellet on a 96-well fluorescence spectrophotometer at 470 nm excitation and 585 emission in relative fluorescent units.

   If using a fluorescence spectrophotometer with a single cuvette, use all of the extraction solution for the measurements.

6. Set the fluorescence of the tubes containing only doxorubicin as 0% and the positive control tubes containing both doxorubicin and verapamil as 100%. Using linear regression, calculate the percentage of doxorubicin in the toxicant-containing pellet. If the percentage is >75%, consider the toxicant to interact with P-glycoprotein.

   To determine whether the compound is actually a transport substrate, one must perform one of the additional protocols described here.

PREPARATION OF MEMBRANE VESICLES

SUPPORT PROTOCOL

This procedure details the preparation of cellular membrane vesicles from either cultured cells or from tissues. This is an extremely long procedure, typically requiring ~12 to 15 hr to complete. Although it is recommended that the procedure be completed in 1 day, there is a stopping point at the end of step 7. It is suggested that the remainder of the protocol be completed the following day.

Materials

P-glycoprotein expressing cultured cells in 100-cm^2 culture dishes, such as Caco-2 cells, or transfected cells expressing P-gp after transfection with a vector containing P-gp cDNA and a mock-transfected control or tissue such as liver or intestine
PBS (*APPENDIX 2A*), ice cold
0.05% collagenase (Sigma type I) in PBS
Hypotonic lysis buffer containing protease inhibitors (see recipe)
0.4% trypan blue (Sigma or equivalent)
Tris-sucrose buffer (see recipe)
38% (w/v) sucrose (see recipe)
Bio-Rad protein assay kit

40-µm mesh nylon screen
Hemacytometer
Confocal microscope
Motor-driven Potter-Elvehjem homogenizer (e.g., Dyna-Mix Stirrer, Fisher, or equivalent)
Dounce homogenizer
12-ml polycarbonate round-bottom tubes
Centrifuge with a Beckman SW-40 rotor or equivalent
1-ml pipets
27-G needle and 1-ml syringe
1.5-ml cryovials

NOTE: After step 1, perform all procedures at 4°C.

Lyse cells

1a. *Preparation from cultured cells:* Harvest cells from twenty to thirty 100-cm^2 culture dishes and wash two times with ice-cold PBS. Centrifuge cell suspension 5 min at 200 × *g*, 4°C.

1b. *Preparation from tissue:* Cut 5 g of fresh frozen tissue into small pieces, incubate with 0.05% collagenase in PBS while mixing for 10 min, and press through 40-µm mesh nylon screen. Centrifuge tissue suspension 5 min at 200 × *g*, 4°C.

2. Resuspend cells in 75 ml hypotonic lysis buffer containing protease inhibitors and incubate 2 hr on ice on a rotating shaker (150 rpm) to gently break open the cells. Examine the effectiveness of this procedure by removing 0.1 ml of suspension and mixing with 0.1 ml of 0.4% trypan blue. Incubate 1 min at room temperature, place a drop of dye suspension onto a hemacytometer, and examine under a confocal microscope.

   Intact cells will not take up the dye while cells with compromised cellular membranes will take up the dye, and thus appear blue. At least 90% of the suspension should stain blue.

Collect membranes

3. Centrifuge the cell suspension 45 min at 100,000 × *g*, 4°C, to pellet the membrane fraction. Discard the supernatant.

4. Resuspend the pellet in 30 ml hypotonic lysis buffer and gently homogenize using a motor-driven Potter-Elvehjem homogenizer set at 500 rpm. Keep the suspension on ice at all times and use 30 strokes of the homogenizer such that each stroke (up and down) takes ~20 sec. Take a 1-min break after every ten strokes.

5. Centrifuge the homogenate 10 min at 10,000 × *g*, 4°C. Remove the supernatant and set aside. Resuspend the pellet in 10 ml of Tris-sucrose buffer and homogenize with a Potter-Elvehjem homogenizer for 20 strokes, again taking a 1-min break after every ten strokes. Centrifuge this suspension 10 min at 10,000 × *g*, 4°C.

6. Combine the supernatant with the supernatant from the first centrifugation, and centrifuge 45 min at 100,000 × *g*, 4°C. Decant supernatant.

7. Homogenize the pellet in 15 ml Tris-sucrose buffer with 30 strokes with a tight-fitting Dounce homogenizer.

   If needed, one can stop the procedure at this point by snap-freezing the homogenate in liquid nitrogen and storing at −80°C overnight. On the following morning, thaw the homogenate on ice before continuing the protocol.

Isolate plasma membrane

8. Pipet 7 ml of 38% sucrose into 12-ml polycarbonate round-bottom tubes. Slowly and carefully layer the membrane homogenate on top of the denser sucrose layer, maintaining separate layers. Top off the tubes with additional Tris-sucrose buffer to balance all tubes properly, place into the centrifuge, and screw lids on tightly. Centrifuge the membrane suspension in a swinging bucket rotor 2 hr at 205,000 × *g* (SW-40 rotor 40,000 rpm), 4°C.

   This step separates the plasma membranes (found at the interface of the two layers) from endoplasmic reticulum and Golgi membranes (found at the bottom of the tubes).

9. Use a 1-ml pipet to remove 1 to 2 ml of the Tris-sucrose buffer, being careful not to disturb the interface, then use a 1-ml pipetman to "vacuum" off the membranes at the interface. Make the homogenate up to 15 ml with Tris-sucrose buffer and homogenize the preparation 30 strokes with a tight-fitting Dounce homogenizer. Centrifuge the homogenate 45 min at 100,000 × *g*, 4°C. Decant the supernatant.

Prepare vesicles

10. Resuspend the pellet in 0.6 ml Tris-sucrose buffer and pass the suspension through a 27-G needle attached to a 1-ml syringe 30 times to prepare the vesicles. Determine the protein concentration of the vesicular aliquots using the Bio-Rad protein assay kit or an equivalent procedure. Dispense 30-µl aliquots of the vesicular preparations into cryovials, snap freeze in liquid nitrogen, and store frozen in liquid nitrogen or at −80°C.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ATP and AMP solutions

Dissolve 312.8 mg phosphocreatine di(tris) salt (Sigma), 140.3 mg magnesium chloride hexahydrate, and 65 mg potassium carbonate in 6 ml of Tris-sucrose buffer (see recipe). Divide in half (3 ml each), and add 20.1 mg ATP (dipotassium salt dihydrate, Sigma) to 3 ml and 12 mg AMP to the other 3 ml. Dispense and store in 100-µl aliquots in 0.5-ml microcentrifuge tubes for up to 1 month at −20°C.

Doxorubicin-HCl, 10 mM

Dissolve 5.44 mg doxorubicin-HCl in 1 ml sterile saline (final 10 mM). Store for a maximum of 3 weeks at 4°C.

Extraction buffer

Add 5 ml of 12 N HCl to 45 ml water, then add 50 ml absolute ethanol for a final volume of 100 ml (final 0.6 N HCl in 50% ethanol/water). Store for up to 1 month at room temperature.

Hypotonic lysis buffer

Add 0.416 g EDTA to 90 ml water, pH to 8.0 with 1 N NaOH, and make up to 100 ml (final 10 mM EDTA). Store at room temperature for up to a month. In a separate bottle, add 69.98 mg sodium phosphate monobasic and make up to 990 ml with water. Add 10 ml of 10 mM EDTA (Final: 0.5 mM sodium phosphate monobasic, 0.1 mM EDTA). In an additional bottle, add 70.98 mg dibasic sodium phosphate and make up to 990 ml with water. Add 10 ml of 10 mM EDTA (final 0.5 mM dibasic sodium phosphate, 0.1 mM EDTA). Mix the monobasic and dibasic solutions until pH is at 7.0. Store for up to 1 month at 4°C. Add protease inhibitors (see recipe) immediately before use.

Protease inhibitors

100 mM phenylmethylsulfonyl fluoride (PMSF): Add 174.2 mg PMSF to 10 ml DMSO to make up a solution with a final concentration of 100 mM. Add 10 µl of 100 mM PMSF/ml of hypotonic lysis buffer (see recipe) immediately before use. Store up to 1 month at room temperature.

*154 µ*M aprotinin: Add 1 mg aprotinin to 1 ml water. Add 2.2 µl of 154 µM aprotinin/ml of hypotonic lysis buffer (see recipe) immediately before use. Store up to 2 months at −20°C.

2.1 mM leupeptin: Add 1 mg leupeptin to 1 ml water. Add 0.5 µl of 2.1 mM leupeptin/ml of hypotonic lysis buffer (see recipe) immediately before use. Store up to 2 months at −20°C.

Sucrose, 38% (w/v)

Add 0.596 g HEPES to 90 ml water and pH to 7.4. Make up to 100 ml and then add 38 g sucrose. Store up to 1 month at 4°C.

Tris-sucrose buffer

Add 4.844 g Tris and 341.5 g sucrose, make up to 3.8 liters with water, and pH to 7.4. Bring to 4 liters with water (final 10 mM Tris, 250 mM sucrose). Store up to 1 month at 4°C.

Verapamil, 5 mM

Dissolve 2.45 mg verapamil in 1 ml DMSO. Make fresh daily.

For 22 μM: Dilute 2 μl of 5 mM verapamil into 452 μl Tris-sucrose buffer (see recipe). Make fresh daily.

[^{3}H]vincristine

Add 2 μl [^{3}H]vincristine (10 Ci/mmol; Amersham) to 329.9 μl Tris-sucrose buffer (see recipe). Make up a 10 mM solution of unlabeled vincristine by dissolving 9.23 mg in 1 ml water. Make up a 10 μM solution by diluting 1 μl of 10 mM vincristine into 999 μl Tris-sucrose buffer (see recipe). Add 14.64 μl of 10 μM vincristine solution to the radiolabeled Tris-sucrose solution (final: 0.5 μCi of 418.2 nM vincristine solution).

COMMENTARY

Background Information

P-glycoprotein (P-gp) is a 170-kDa glycoprotein that transports a wide variety of drugs (for a current review, see van Tellingen, 2001), as well as toxicants (Schinkel et al., 1994; Bain and LeBlanc, 1996; Bain et al., 1997). In mammals, P-gp is located on the apical side of organs of elimination, including the proximal tubules in the kidney, the enterocytes of intestinal cells, and the canalicular membrane of hepatocytes (Thiebaut et al., 1987). This localization suggests that P-gp plays an important role in effluxing toxicants from the organism. P-gp is also present in capillary endothelial cells and is important in maintaining the integrity of the blood-brain barrier and the testicular-blood barrier (Cordon-Cardo et al., 1989; Thiebaut et al., 1989).

P-glycoprotein transport activity can be measured from tissues, from whole cultured cells, or membrane preparations from cultured cells or tissues. Historically, the easiest way to study transport of toxicants was using cells in culture and determining the amount of substrate accumulated within the cells. Using this type of procedure was how P-gp was originally discovered (Juliano and Ling, 1976), and when it was discovered that verapamil could specifically inhibit the efflux of vincristine (Tsuruo et al., 1981), using this method and inhibiting the efflux of compounds became the technique of choice (Gottesman and Pastan, 1993). It was quickly realized that other proteins besides P-gp contributed to the phenomenon of altering cellular accumulation and efflux of drugs, and different methods were needed to determine the relative contributions of P-gp to the efflux. Transfected cell lines were made to ensure overexpression of P-gp and minimize the contribution of other transport proteins in altering the apparent uptake and elimination (Ueda et al., 1987). To circumvent alterations in metabolism as well as the potential for the apparent accumulation to be due to nonspecific binding, the use of cellular membrane vesicles was employed (Horio et al., 1988; Leier et al., 1994; Wheeler et al., 2000). Caco-2 cells have more recently been used to examine transport, and also have been used to determine whether metabolites of the toxicant may be potential P-gp substrates (Artursson et al., 1996; Walle, 1996).

The doxorubicin inhibition assay (see Basic Protocol 4) was originally described by Egorin et al. (1974) and then modified by Bain and LeBlanc (1996) as a way to screen a large number of toxicants relatively quickly and easily. However, this method can only discern whether a toxicant interacts with P-gp and cannot distinguish between a P-gp substrate and a P-gp inhibitor. It is a good initial assay to perform before the other, more time-consuming assays mentioned in this unit. The toxicant efflux method (see Basic Protocol 1) was published by Fojo et al. (1985), although modifications have been made by a great number of investigators. This is the most extensively used method to measure P-gp-mediated cellular efflux of toxicants. In performing this procedure, one has the choice of using unlabeled toxicants and measuring their efflux by either GC or HPLC (Bain and LeBlanc, 1996).

The vesicular uptake method (see Basic Protocol 2) was described by Horio (1988) and modified by Ishikawa (1989), then slightly modified to the procedure described in this unit. Using this protocol negates the effects of metabolism on P-gp-mediated transport. Once all materials are in place, it is a relatively rapid procedure, although it does require a time-consuming step of preparing the vesicles (Ishikawa et al., 1990). It can also distinguish between active and passive transport by using both ATP and AMP. It typically provides the largest differences in rates of transport versus any other procedure.

The transport of toxicant by Caco-2 cells (see Basic Protocol 3) was described by Hilgers et al. (1990) and is most recently reviewed by Krishna et al. (2001). In this assay, Caco-2 cells are cultured on transwell plates typically for 20 to 30 days, as P-glycoprotein reaches maximum expression in Caco-2 cells in ~21 days (Anderle et al., 1998). This assay can also be used to determine whether metabolites of the parent toxicant are transport substrates of P-gp. All of the assays described in this unit (except Basic Protocol 4) can effectively measure P-glycoprotein-mediated transport; differences lie as to whether metabolism of a toxicant is important for the questions being asked by the investigator.

Critical Parameters and Troubleshooting

For all assays described in this unit, one of the most critical parameters to consider is the actual concentration of toxicant used in the procedures. The ranges given in the protocols are simply suggested starting points, and the actual concentration needed should be determined by the experimenter. The rate of uptake or efflux must be in the linear range to properly perform the experiment, and there must be enough of the toxicant to discern a difference between two different cell lines, between the addition or deletion of verapamil, or between apical-to-basolateral versus basolateral-to-apical flux. The other important parameter to determine in the protocols is the time points employed for measuring transport in the assays. Again, the times given in the unit are starting points in terms of what has worked in the past. However, depending on the toxicant, more or less time may be required to ensure that the rate of accumulation or efflux is linear and that it can be detected by the appropriate method, such as scintillation counting.

For the vesicular transport described in Basic Protocol 2, one must determine whether there is actual transport across the membrane vesicles rather than just nonspecific binding to the membrane. This can be determined by several methods: ensuring that a time course is performed with appropriate time points, that both AMP and ATP are used to distinguish active transport, and that there is an osmotic dependence on accumulation. The procedure described here is simply a starting point; the actual time needed to observe measurable accumulation may be longer. To determine osmotic dependence, one usually performs the assay while altering the concentration of sucrose in the assay medium, from 250 mM to 1000 mM (Wheeler et al., 2000). The amount of radioactivity associated with the vesicular preparation should be proportional to the amount of sucrose contained in the medium.

The final consideration relates to Basic Protocol 3 and the necessity to ensure that the cells have produced tight junctions. This can be accomplished foremost by culturing the cells on the Transwells for 20 to 30 days. One can also measure the transepithelial resistance using an ohm meter; the resistance should be >160 Ωcm^2 (Krishna et al., 2001). One can also include [^{3}H]- or [^{14}C]-mannitol on either side of the inserts. If the transport of mannitol is <0.5%, one can reasonably assume that the tight junctions are intact and functioning properly.

Anticipated Results

The results typical for the cellular accumulation described in Basic Protocol 1 are up to a ten-fold difference in accumulation, depending on the toxicant used, which translates into picomoles transported per minute. This procedure has the added advantage of not necessarily requiring a radiolabeled compound to perform the assay. Basic Protocol 2 details the transport by membrane vesicles in which one may see a 100-fold difference in uptake, typically measured in terms of pmol transported/min/mg protein. With Basic Protocol 2, one can exclusively measure active transport when these assays are repeated in the presence of AMP rather than ATP. This procedure tends to be more sensitive than Basic Protocol 1 because potential problems associated with metabolism and passive transport of the toxicant that may effect results may be circumvented. However, Basic Protocol 2 must be performed with radioisotopes, which may not readily be available for many toxicants

of interest, and it requires a lengthy isolation procedure to make the membrane vesicles. In Basic Protocol 3, one can measure P_{app} values of up to 40 with actual amounts transported as nmol/cm^2. Differences between basolateral-to-apical transport, for a substrate of P-glycoprotein, versus apical-to-basolateral transport may be two- to 30-fold different, depending on the substrate used. Typically, Basic Protocol 4 can detect differences of up to five fold in the inhibition of transport of doxorubicin in transfected cell lines. The differences are smaller (usually two to three fold) when using primary or non-transfected cells. The advantages to this protocol are the lack of use of a radiolabeled toxicant, and that it is a relatively quick assay. The disadvantage is that one cannot distinguish between a P-gp substrate and a P-gp inhibitor, as the assay will only discern whether or not the toxicant interacts with P-glycoprotein.

Time Considerations

Basic Protocols 1 (cellular efflux of toxicants) and 4 (inhibition of doxorubicin uptake) can be completed easily in 1 day. Basic Protocol 2 (transport into membrane vesicles) is a faster assay, typically requiring 3 hr to complete, however, vesicles must first be prepared (see Support Protocol), which can take 12 to 15 hr to complete. Basic Protocol 3 (transport in Caco-2 cells cultured in transwells) requires ~5 hr to complete, but the cells must be seeded ~3 weeks prior to performing the assay. Basic Protocol 4 (transport of doxorubicin) requires ~6 hr to complete.

Collection of Bile and Urine Samples for Determining the Urinary and Hepatobiliary Disposition of Xenobiotics in Mice

Living organisms are constantly in contact with numerous xenobiotics (foreign compounds) such as environmental pollutants, food additives, pesticides, and drugs. These chemicals are excreted from the body either directly or, in many cases, in the form of metabolites that are often more hydrophilic than the parent compound. This excretion process is essential to life since in its absence, waste and poisonous substances can accumulate to exert deleterious effects.

Many xenobiotics and their metabolites are mostly cleared from the body by elimination in urine, bile, or both. The detection of metabolites present in urine or bile can greatly facilitate the elucidation of metabolic pathways of a test compound. Moreover, many researchers agree that quantitative and qualitative changes in metabolic pathways for a compound can be assessed in vivo by measuring the amount of the original dose excreted in the urine and bile and by determining whether there is a shift in the profile of metabolites.

The mouse is one of the most commonly used rodent species in toxicology and pharmacology research. Its use is becoming more appealing with the availability of transgenic and knockout models. For instance, the development of a number of transgenic mice expressing human biotransformation enzymes and knockout models of either biotransformation enzymes or membrane-associated transporters, as well as transcription factors controlling these processes, allows researchers to use humanized mouse models as more appropriate surrogates for human tissues in xenobiotic metabolism and disposition studies, and to address the in vivo role of biotransformation enzymes and transporters in the metabolism and excretion of xenobiotics. In these types of studies, as well as the classical in vivo studies mentioned earlier, it is often necessary to obtain urine and/or bile samples.

This unit describes procedures for collecting bile and urine samples from a mouse by cannulating the common bile duct (see Basic Protocol). A protocol for collecting bile from gall bladder–cannulated mice is also provided (see Alternate Protocol). Both protocols can be used in non-survival studies to determine the biliary and urinary dispostion for xenobiotics.

COLLECTION OF BILE AND URINE SAMPLES FROM A BILE DUCT–CANNULATED MOUSE

BASIC PROTOCOL

Excretion of xenobiotics in urine and bile is the cumulative result of metabolism and transport processes mainly present in the kidney and liver. Therefore, urine and bile can be used for metabolite profiling and identification. The contribution of specific transporters in the transmembrane movement of xenobiotics and their metabolites from the liver can also be assessed by determining the urinary and biliary disposition of test compounds in a mouse model lacking the transporter of interest. This protocol details procedures for collecting urine and bile from a bile duct–cannulated mouse following a bolus dose of a test compound.

Materials

0.9% saline (NaCl), sterile
Mice (3 to 4 months old or body weight >25 g)

Contributed by José E. Manautou and Chuan Chen
Current Protocols in Toxicology (2004) 5.7.1-5.7.7

Paraffin oil
Ketamine and xylazine mixture or other appropriate anesthetics
Test compound dissolved in appropriate sterile vehicle

Electric clippers
Scalpel blades
Cotton-tipped applicators
Surgical microscope or appropriate magnifier
3-0 silk sutures
Microdissecting forceps
Hemostatic forceps
1.2-French polyurethane tubing (Access Technologies)
Gauze pads
Temperature-control system composed of the following:
  Rectal thermistor probe for rodents
  Heating lamp
  Homeothermic control unit
1.5-ml microcentrifuge tubes
1-ml polypropylene disposable syringe
30- and 25-G needles
Analytical balance

Prepare animal and perform surgery

1. Administer ~20 ml/kg of 0.9% saline to a mouse by either gastric gavage or intraperitoneal injection (i.p.) to ensure the production of sufficient urine during the experiment if the disposition of a test compound via both urinary and hepatobiliary routes is to be assessed.

2. Anesthetize the animal with a combination of 100 mg ketamine/kg and 10 mg xylazine/kg i.p.

   The disappearance of the pedal reflex is a good indication that the surgical plane of anesthesia has been attained.

3. Clip the hair of the abdominal area with electric clippers. Place the animal in a ventral recumbent position. Make a midline ventral skin incision with a scalpel, extending from the xiphoid process at the cranial terminus to the genital area at the caudal terminus if collecting both bile and urine samples.

   A 1.5-in. incision with its cranial terminus just below the xiphoid process should be sufficient for collecting bile samples.

4. Carefully make an abdominal muscle wall and a peritoneum incision as long as the skin incision, along the linea alba.

5. With a saline-moisturized cotton-tipped applicator, gently retract the liver lobes cranially and toward the stomach side to reveal the bile duct.

   Placing a rolled-up gauze pad beneath the animal to arch its back usually makes it easier to retract the liver lobes and allows better access to the bile duct system.

6. Under a surgical microscope or magnification glass, observe the entire bile duct system including the gall bladder, cystic duct, hepatic ducts, and the common bile duct, via which bile received from the hepatic and cystic ducts is drained into the duodenum (see Fig. 5.7.1).

Insert cannula

7. Carefully place two 3-0 silk ligatures beneath the common bile duct: one adjacent to the duodenum and one near the bifurcation of the hepatic ducts, without fully

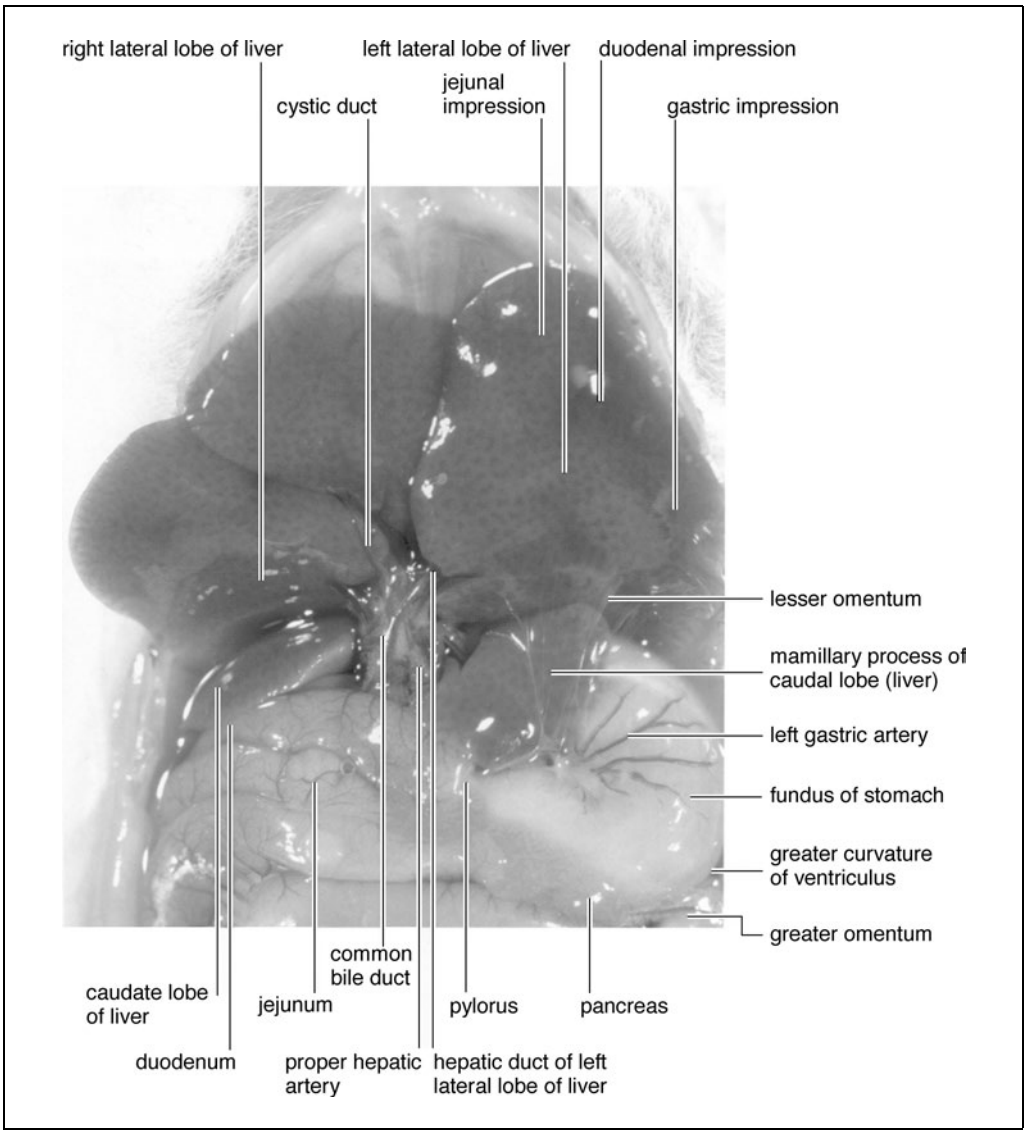

Figure 5.7.1 Diagram of the bile duct system in mice. Figure reproduced from Iwaki et al., (2001) with permission of Braintree Scientific, Inc.

isolating the bile duct between the ligatures. Tie off the first ligature and apply gentle tension to the bile duct by attaching hemostats to the threads of the ligature.

8. With the tip of a scalpel blade (size 11), make a longitudinal nick into the lumen of the bile duct between the two ligatures in a one-directional motion.

   A yellowish liquid can be observed around the nick if the blade cuts open the duct.

9. Take an ~4-in. length of 1.2-French polyurethane tubing and cut both ends at a 30° to 40° angle. Hold one end of the tubing with the bevel up, locate the opening on the bile duct, and push the tubing in until it cannot be further advanced or until its tip travels to the bifurcating point of the hepatic ducts.

10. Make sure the tip of the tubing is located within the lumen of the bile duct, then tie off the second ligature.

    Usually, bile should flow automatically into the cannula. If bile flow is not seen, adjust the position of the cannula to get rid of any kinks and attach a 1-ml syringe to the free end of the cannula and initiate the bile flow by gently withdrawing the plunger.

11. Cover the operation area with a gauze pad moistened with saline. Transfer the bile duct–cannulated mouse to an area dedicated to sample collection. Place a heat lamp ~2 feet right above the animal. Lubricate the tip of a thermistor probe with paraffin oil and gently insert into the rectum of the animal. Begin monitoring body temperature and maintain the core body temperature between 35° and 36°C.

    An alternative approach to attain appropriate body temperature is to place the animal on a thermostatted heating pad rather than under a heat lamp.

Administer test compound and collect urine

12. Collect bile into a pre-weighed microcentrifuge tube for ~10 to 15 min to establish a steady bile flow before the administration of test compound. Make sure that the free end of the cannula is in contact with the walls of the microcentrifuge tube at all times.

    This helps maintain a better and constant bile flow.

13. Externalize the urinary bladder through the midline incision. Empty its content with a 1-ml syringe attached to a 30-G needle.

14. Administer the test compound in a bolus dose via either the tail or the saphenous vein using a 25-G needle.

    If desired, the test compound can also be given i.v. at a constant rate with the use of an infusion pump.

15. Collect bile samples at time intervals between 5 and 30 min into pre-weighed microcentrifuge tubes.

    Depending on the compound being analyzed, investigators should take proper precautions to prevent alterations (e.g., oxidation, degradation) of the compound or metabolites of interest during sample collection by collecting bile into microcentrifuge tubes on ice or tubes containing an appropriate neutralizing/stabilizing reagent.

16. Monitor the anesthesia status of the animal by periodic observation of respiration, color of mucous membranes, and pedal reflex. Administer 1/5 of the initial dose of the anaesthetic i.m. to maintain anesthesia if necessary.

17. Add ~0.3 to 0.6 ml of 0.9% saline every 30 min in the abdominal cavity through the incision to prevent the animal from dehydrating.

18. At the end of the experiment, right before euthanizing the animal, withdraw urine from the urinary bladder with a syringe attached to a 30-G needle. Excise and cut open the bladder to collect any remaining urine.

19. Determine the volume of bile and urine sample by weighing on an analytical balance assuming a specific gravity of 1. Store samples at −80°C until further analysis.

ALTERNATE PROTOCOL

COLLECTION OF BILE SAMPLES FROM GALL BLADDER–CANNULATED MOUSE

Some investigators prefer to collect bile from mice by cannulating the gall bladder instead of the common bile duct. Bile samples collected this way are thought to be composed mostly of freshly excreted bile since stored bile in the gall bladder is drained before sample collection, whereas bile collected from a bile duct–cannulated mouse, especially at the beginning of sample collection, is a mixture of freshly excreted bile and stored bile. If maintaining the integrity of the gall bladder is not an important consideration in the experimental design, this method is a less complicated alternative to bile duct cannulation. Furthermore, in mice of smaller sizes (<25 g), it may be easier to collect bile samples by cannulating the gall bladder.

For materials, see Basic Protocol.

1. Follow Basic Protocol, steps 1 to 4, to anesthetize and dissect the mouse.
2. Carefully lay one 3-0 silk ligature underneath the portion of the common bile duct near the place that the cystic duct from the gall bladder merges into the common bile duct. Tie off the ligature. Place another ligature around the gall bladder and keep it open.
3. Lift the gall bladder by its tip using hemostats and make a small incision using microdissecting scissors.

   Bile will flow out as the gall bladder collapses.

4. Continue holding the tip of the collapsed gall bladder with the hemostats and insert the cannula (see Basic Protocol, step 8). Tie the ligature with a double knot.

   Bile should flow automatically into the cannula. If bile flow is not seen, follow the procedure described in Basic Protocol, step 9, annotation.

5. Follow Basic Protocol, steps 10 to 19, to monitor the animal and collect bile and urine.

COMMENTARY

Background Information

During the nineteenth century, scientists such as Oswald Schmiedeberg and Eugen Baumann discovered all of the major biotransformation pathways including oxidation, reduction, and conjugation reactions using the same type of basic methodology to obtain information on the biochemical fate of chemicals. Xenobiotics were administered to an animal or volunteer, and the urine was qualitatively analyzed for unchanged compounds or their metabolites. Using a similar approach, M.J.B. Orfila found that many metallic poisons taken up by the liver are either retained by that organ or excreted into the bile, while Abel and Rowntree reported in 1909 that a number of phthalein dyes undergo extensive biliary excretion.

Bile flow rate is usually expressed as microliter per minute per 100 g body weight. The amount of the parent compound or metabolite found in bile samples can be expressed as either concentration or mass. The mass of a compound in bile or urine is equal to the product of its concentration and the volume of excreta. When the mass of a compound is further divided by the mass of the administered dose, this represents the percentage of the administered dose excreted in the form of that compound. Additionally, one can determine the cumulative biliary excretion of a compound over time by adding the amount of the compound excreted at a given time point to the total combined amount excreted during earlier time points.

The procedure described in this unit involves bile and urine collection only. (For short-term bile collection from a rat, see *UNIT 14.5*.) Other compartments, such as blood, can also be sampled to gain a better understanding of the kinetic disposition of a xenobiotic. However, collecting multiple fluids simultaneously from a mouse can lead to excessive body fluid loss, which in turn can result in lower survival time. Because of this constraint, some investigators prefer to conduct separate studies, one addressing the hepatobiliary disposition and another investigating the plasma clearance and appearance of metabolites. In cases where the xenobiotic of interest persists in the organism beyond the study period, pharmacokinetic modeling can be used to predict the kinetic behavior of a chemical and its metabolites beyond the usual time frame for disposition studies in mice.

As stated previously, the protocol described in this unit is intended for short-term (1 to 3 hr) disposition studies. Depending on the experimental design and sampling length, investigators may want to consider collecting bile from a fully alert, unrestrained animal. This type of study is commonly done in rats, where animals are allowed to recover from anesthesia after undergoing bile duct cannulation. This procedure is described in detail in the work of Kanz and co-workers (1992). The cannulation methods used allows the bile to be returned to the gastrointestinal tract since the cannula is in the form of a biliary fistula between the bile duct and the small intestine, which can be opened for bile duct collection during the actual disposition studies. Disposition studies are initiated after several days of acclimation and recovery

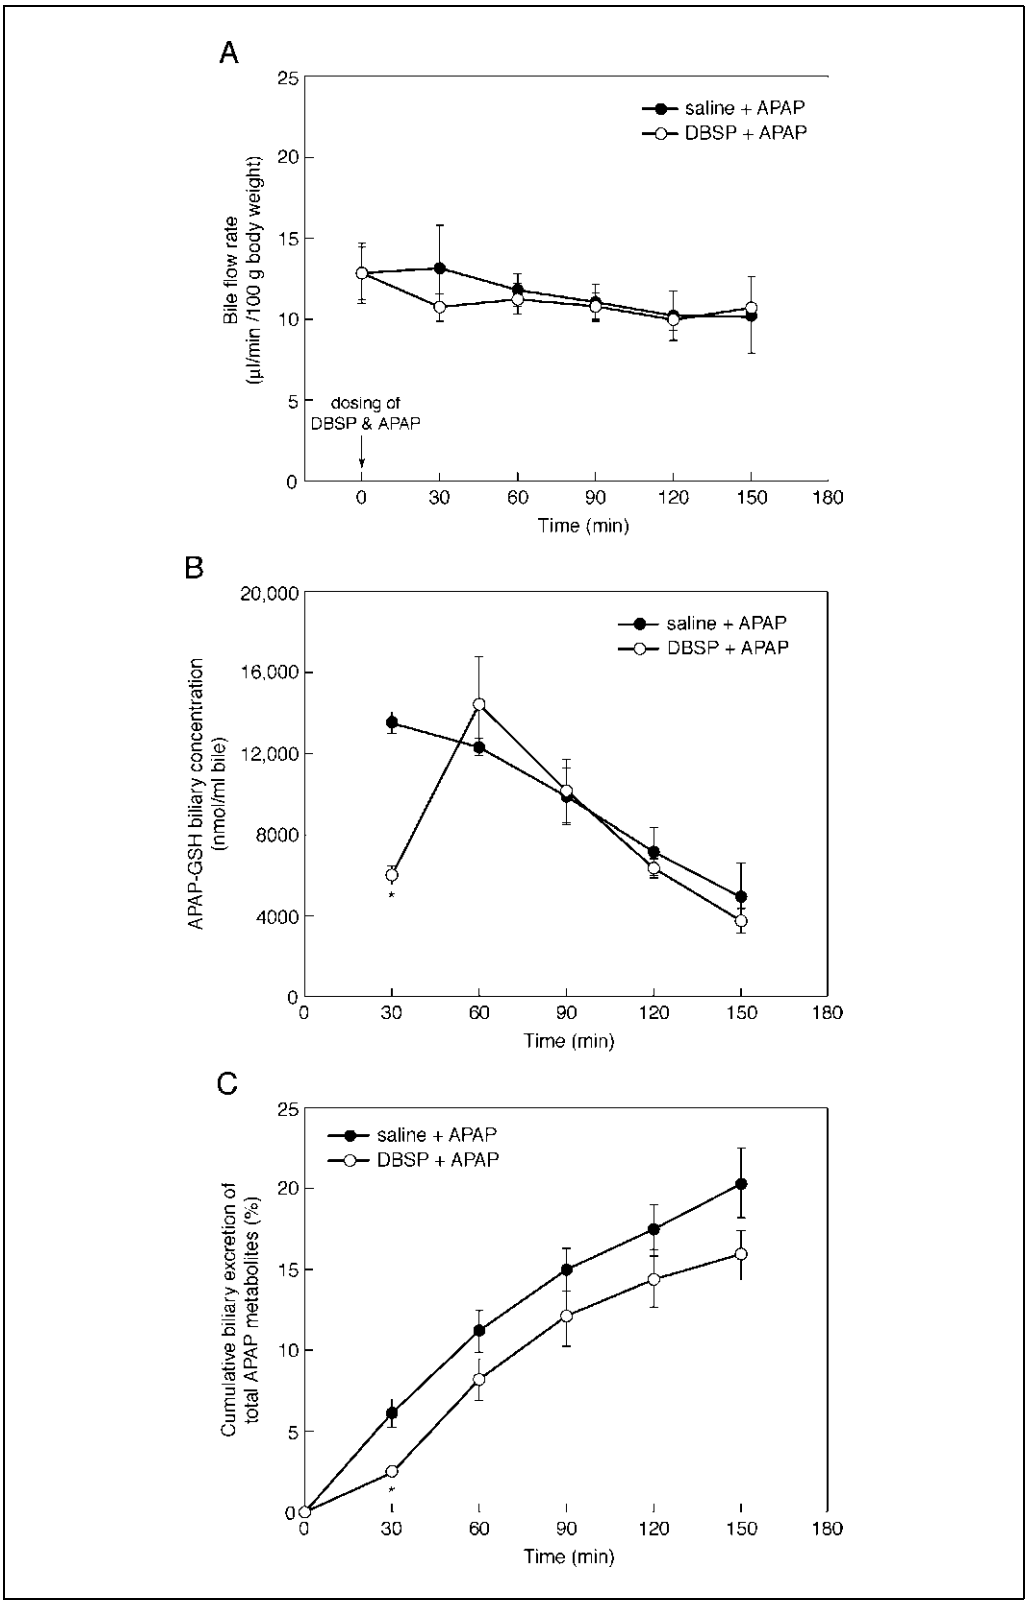

Figure 5.7.2 Effect of the non-metabolizable organic anion dibromosulphothphalein (DBSP) on bile flow rate (**A**); biliary concentration of acetaminophen-glutathione conjugate (APAP-GSH) (**B**); and the cumulative excretion of APAP and its metabolites (**C**). Following overnigt (18 hr) fasting, adult male CD-1 mice were anesthetized and the common bile duct was cannulated. Bile was collected for 15 min before mice received 120 µmol DBSP/kg immediately prior to APAP (1 mmol/kg, i.v.). Controls received saline vehicle before APAP. After APAP dosing, bile was collected for 150 min at 30-min intervals. Results are expressed as means ±SEM for 4 to 5 animals per group. *Significantly different from controls ($p < 0.05$).

from surgery. With this procedure, bile components needed for the processing and absorption of nutrients are not excluded from the small intestine during the recovery period. Proper measures are taken and certain devices are used to prevent rats from chewing on and removeing the bile duct cannula or any other implanted cannulas for collecting fluids delivering drugs. This method claims to minimize some factors that may affect the biliary disposition of xenobiotics and endogenous compounds, including anesthesia and depletion of bile acids. This method also allows for bile sampling over a longer period of time. However, there are some drawbacks associated with this approach. For example, the surgical procedure is far more complex than the non-survival methed used in mice, making it not suitable for investigators with limited surgical expertise. Moreover, it takes much longer to generate hepatobiliary disposition data using this procedure and only a few animals can be done at a time. This approach is less practical in mouse studies due to their more aggressive behavior and the lower likelihood of having a mouse retain an implanted cannula. To the authors' knowledge, biliary disposition studies using freely moving mice have not been documented. Investigators interested in using a freely moving mouse model for hepatobiliary disposition studies may want to contact companies offering surgically modified rodents. Taconic sells mice that are bile duct–cannulated.

Critical Parameters and Troubleshooting

To ensure a steady bile flow, the core body temperature of the mouse should be maintained constant since it is one of the major factors that can affect bile flow. Less bleeding and tissue damage during the operation always lead to longer survival times and fewer complications. Thus, it is recommended to avoid excessive handling of the liver, duodenum, and pancreatic tissue situated around the biliary system while cannulating the bile duct. The level of anesthesia should be closely monitored during the course of this experiment.

Unlike other larger species, rodents do not regurgitate. Therefore, it is not necessary to withhold food prior to surgery to avoid the possibility of aspiring gastric contents into the respiratory system during anesthesia. Some researchers argue that fasting may offer the benefit of limiting individual variability in biotransformation pathways resulting from differences in nutritional status among the experimental animals, while others think that it may promote better absorption of anaesthetics administered intraperitoneally.

These protocols are intended for use in non-survival studies. Thus, it is not necessary to follow aseptic procedures when performing the operation. However, it is appropriate to choose a clean, uncluttered surface in the laboratory as a surgery area.

Anticipated Results

Normally, the range of bile flow rate in bile duct–cannulated mice is between 7 and 14 μl/min/100 g body weight. Bile flow is higher at the beginning of sample collection, decreasing gradually as time progresses (Fig. 5.7.2). This drop in bile flow results from the net loss of biliary constituents via the cannula (e.g., bile salts). Bile salt secretion is a major driving force of bile flow. Some investigators prefer to maintain a more constant bile flow rate throughout the experiment by infusing a bile salt such as tauroursodeoxycholic acid (4 mM in physiological saline at a flow rate of 3 ml/hr). The survival rate for bile duct–cannulated mice generally decreases as the duration of experiment increases. Bile duct–cannulated mice are generally viable for 2 to 3 hr under anesthesia if surgery is done properly.

Time Considerations

In general, the time needed for performing the protocols described greatly depends on the skills of individual investigators and duration/intervals for sample collection. To anesthetize a mouse, it requires ~5 min. It takes ~10 to 15 min for a skilled researcher to cannulate the bile duct of a mouse. Dosing via tail vein injection requires <1 min. The procedure for emptying and withdrawing the content of the urinary bladder requires <5 min.

CHAPTER 6
The Glutathione Pathway

INTRODUCTION

The tripeptide glutathione (GSH) is nearly ubiquitous in cells and has been shown to participate in a multitude of cellular functions (Kosower and Kosower, 1978; Reed and Fariss, 1984; Reed, 1990; Anderson, 1998). Although many of these functions are associated with protection against reactive intermediates, including free radicals and electrophiles, maintenance of a suitable thiol redox balance with low-molecular-weight and protein thiols is also crucial for cellular homeostasis. GSH functions include the glutathione redox cycle involving glutathione peroxidase (*UNIT 7.1*) and reductase (*UNIT 7.2*); electrophile conjugation reactions via the enzymatic activities of many glutathione transferases (*UNIT 6.4*); and a role in protein synthesis, folding, activation, and inhibition. GSH synthesis (*UNIT 6.5*), transport (*UNIT 6.3*), breakdown, and turnover are vital events in cellular existence. Many methods have been developed and many studies conducted to examine the effects of GSH depletion, inhibition of GSH synthesis, and overall GSH metabolism. Recent reports have renewed interest in the role of mitochondria in many cellular processes, including apoptosis. Thus, measurement of mitochondrial GSH (*UNIT 6.2*) and events associated with mitochondrial GSH metabolism are of current interest. These features of GSH are discussed in *UNIT 6.1*, which provides an overview of GSH function and metabolism.

Measurement of GSH and glutathione disulfide (GSSG) is described in *UNIT 6.2*. The focus is on four major methods that permit precise, sensitive measurement of these to species in both cytoplasm and mitochondria. In one approach, treatment of samples with iodoacetic acid to derivatize the thiols present is followed by a second derivatization of amino groups with Sanger's reagent (1-fluoro-2,4-dinitrobenzene) and separation of the products by HPLC. The derivatives can then be detected based on their UV absorption. This procedures measures GSH, cysteine, and several disulfides and mixed disulfides, including glutathione-cysteine mixed disulfide, with subnanomole sensitivity. If picomole sensitivity is required, it can be achieved through substitution of dansyl chloride for Sanger's reagent followed by separation of the products under almost identical HPLC conditions and then fluorescence detection (the tradeoff is that successful performance of this procedure is more difficult than when Sanger's reagent is used). Alternatively, HPLC combined with electrochemical detection can be used for rapid measurement of GSH and GSSG, also with picomole level of sensitivity. Also described is an enzymatic method for measuring GSH and GSSG that involves spectrophotometric detection and provides subnanomole sensitivity.

Transport of GSH is essential to its cellular functions. Since mitochondria are unable to synthesize GSH, its high concentration within the organelles must result from transport processes that favor higher levels of mitochondrial than cytosolic GSH. Techniques for measuring GSH uptake by various cell types and by mitochondria are described in *UNIT 6.3*. Also included are methods for measuring intracellular and mitochondrial matrix volumes, a prerequisite for accurate interpretation of results.

Conjugation of glutathione with a wide variety of electrophiles is catalyzed by glutathione transferases (Hayes and Pulford, 1995). In *UNIT 6.4*, nomenclature describing the transferases is defined, along with the experimental conditions for utilizing a host of electrophile substrates that aid in characterizing the glutathione transferases being measured.

Contributed by Donald J. Reed
Current Protocols in Toxicology (2002) 6.0.1-6.0.3

Also detailed are a continuous spectrophotometric assay for glutathione transferase activity and a noncontinuous colorimetric assay in which activity is assessed at a series of separate time points.

Biosynthesis of glutathione occurs in the cytosol of virtually all cells and involves a two-step process, both steps of which are ATP dependent. In *UNIT 6.5*, HPLC-based fluorescence assays for the two enzymes of glutathione biosynthesis are described; detection in each case is by fluorescence detection of thiol products (previously derivatized with monobromobimane). The first enzyme, glutamate cysteine ligase, requires a substrate, cysteine, that is easily air-oxidized in the presence of transition metals. Thus, the assay is highly dependent upon strict adherence to the described protocol. γ-glutamyl cysteine, a substrate for the second enzyme, glutathione synthase, is even more prone to air oxidation. Successful measurement of these enzymes requires good laboratory techniques in handling substrates that are easily oxidized to products that do not serve as substrates and, if oxidized, will hamper the measurements. GSH, the final product, is also easily oxidized, to GSSG, and if this happens will not be measured, because GSSG is not detectable by the monobromobimane/HPLC procedure.

In mammals, glutathione is maintained at a high intracellular concentration (0.5 to 6 mM) and a very low extracellular concentration (0.25 to 50 μM), with a half-life in blood of 1 to 2 min. Although intracellular enzymes that catalyze the oxidation and conjugation of glutathione exist, there is a lack of any significant level of intracellular enzyme activity to degrade glutathione. A single enzyme, γ-glutamyl transpeptidase (EC 2.3.2.2) is known to initiate extracellular degradation of glutathione; the activity is located mainly in the brush border of the kidney with lesser activity in other organs and tissues. Production of glutathione by the liver, secretion mainly into the blood, and extracellular degradation are the basis for considering glutathione a physiological reservoir for cysteine. Cysteine provided in this manner is then available for uptake by various cells in the body for glutathione synthesis. Measurement of γ-glutamyl transpeptidase activity (*UNIT 6.6*) is described for a spectrophotometric assay that utilizes the transferase activity of this enzyme with γ-glutamyl-*p*-nitroanilide as the substrate and glycylglycine as the donor and acceptor substrate, respectively. The Alternate Protocol describes an assay using γ-glutamyl-3-carboxy-4-nitroanilide, which has a greater solubility than γ-glutamyl-*p*-nitroanilide.

Protocols are presented that demonstrate induction of a glutathione biosynthetic enzyme, γ-glutamylcysteine synthetase (γ-glutamate cysteine ligase, GCS, EC 6.3.2.2), a glutathione degrading enzyme, and gamma-glutamyl transpeptidase (GGT, EC 2.3.3.3) in response to oxidants (*UNIT 6.7*). Methods are described that detail the methods that can provide evidence for increased mRNA and protein content. Transcriptional (nuclear run-on analysis) and/or postranscriptional (i.e., stability of mRNA) regulation can be determined. There is also an assay for measuring GGT activity. The techniques described in *UNIT 6.7* can be used in other studies that involve induction of gene expression.

An important component in elucidating the biological significance of specific reactive products of xenobiotic bioactivation is the identification and quantitation of glutathione conjugates. *UNIT 6.8* describes, in careful detail, the measurement of glutathione conjugates. The Basic Protocol covers the use of HPLC in the measurement of glutathione conjugates, with Alternate Protocols on the radiometric assay of glutathione conjugate formation and a spectrophotometric assay for glutathione *S*-transferases. Four Support Protocols in *UNIT 6.8* provide reagents and methodology for microsomal incubations, preparation of microsomal and cytosolic fractions, purification for glutathione *S* transferases and preparative separation and isolation of glutathione conjugates for characterization by mass spectrometry and proton NMR spectroscopy.

The measurement of oxidative stress events, including changes in cellular thiol redox status, continue to demonstrate the many roles of mitochondria. Because a majority of cellular coenzyme A is found in mitochondria, the authors of *UNIT 6.9* have utilized the redox status of coenzyme A and glutathione to measure mitochondrial oxidative stress. Procedures detailed in *UNIT 6.9* provide a protocol for coenzyme A and coenzyme A-glutathione mixed disulfide determination by HPLC. To limit oxidation, reduction and thiol-disulfide exchange reactions, tissues that have been frozen in liquid nitrogen are treated with the thiol derivatizing agent, N-ethylmaleimide (NEM) as the frozen tissues are homogenized and acidified. The mixed disulfide of coenzyme A and glutathione (CoASSG) and the NEM adduct of coenzyme A (CoAS-NEM) are quantified by their 254 nm absorption during HPLC.

Overview of Glutathione Function and Metabolism

From the time of its discovery in 1888 by De-Rey-Pailhade (De-Rey-Pailhade, 1888a,b), glutathione (GSH) has remained of major interest for researchers in the fields of toxicology, biochemistry, molecular cell biology, and immunology. Although pathways of synthesis and breakdown have been established, transport, uptake, and some metabolic functions remain uncertain. GSH has been shown to be a major key player in reduction processes by maintaining thiol groups of intracellular proteins; by providing reducing power for cysteine, dihydrolipoate, coenzyme A, ascorbate, and vitamin E; and as a factor in the reduction of NTPs into dNTPs. GSH is involved in detoxification of endogenous and exogenous compounds, participates in synthesis of leukotrienes and prostaglandins, serves as a cofactor of various enzymes, stores and transports cysteine, and may even be involved in cell cycle regulation and thermotolerance.

Although GSH was seen for many years as a preventive molecule against results from biotransformations of xenobiotics and normal oxidative products of cellular metabolism, it is now also known to play a role in bioactivation of certain molecules, particularly several halogenated compounds.

GSH is a tripeptide with the sequence γ-Glu-Cys-Gly (Fig. 6.1.1). The disulfide derived from two GSH molecules, by oxidation of the thiol groups of each cysteine moiety, is denoted glutathione disulfide (GSSG). GSH has one peptide bond, one amide bond that is resistant to proteases, two carboxyl groups, one amino group, and one thiol group. The high number of hydrophilic groups and low molecular weight make GSH and GSSG water soluble. GSH shows two quite distinct features: it is protected from hydrolytic cleavage by regular proteases through its γ-glutamyl amide bond, and it has a high reduction potential (E^{01} = –0.33 V) due to the abundance of cysteine. Thiols are very reactive towards free radicals, donating hydrogen atoms to most carbon-, oxygen-, and nitrogen-centered radicals.

GSH is typically present at millimolar concentrations in the cell (0.5 to 10 mM) and is the most abundant low-molecular-weight peptide. Concentrations in mammalian liver are 4 to 8 mM, with nearly all glutathione present as reduced GSH, and <5% present as GSSG. Minor fractions include mixed disulfides of GSH and other cellular thiols, and minor amounts of thioethers from endogenous conjugation reactions. In most cells GSH accounts for >90% of the total nonprotein thiols. Intracellular GSH levels are tightly regulated by a complex mechanism involving control of synthesis, transport, and utilization. GSH must be regarded as an essential cellular component, as prolonged failure to maintain adequate intracellular supply is detrimental to the cell.

This overview focuses on the function, synthesis, turnover, transport, and breakdown of GSH. It also provides the reader with information on manipulation of GSH content and the importance of mitochondrial GSH. Each section emphasizes main events while providing the reader with additional references for further in-depth information.

GLUTATHIONE FUNCTION

It is widely accepted that the two major functions of GSH are (1) as a substrate for GSH peroxidase–mediated reduction of oxygen free

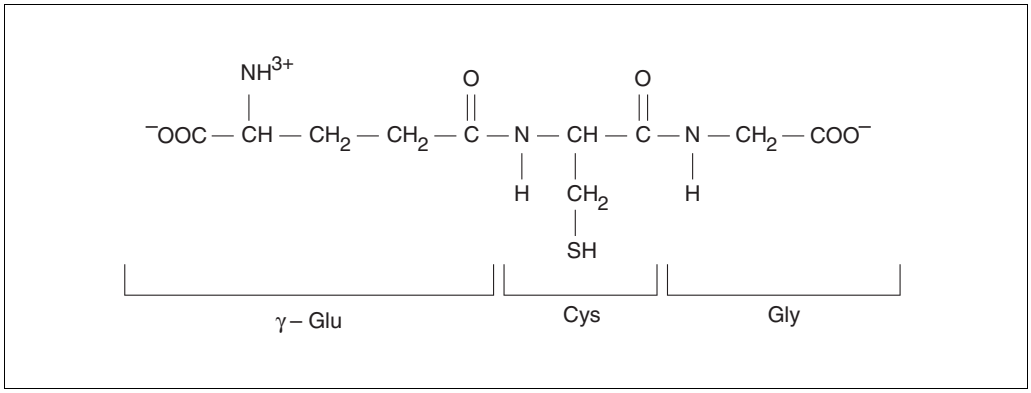

Figure 6.1.1 Structure of reduced glutathione (GSH).

Contributed by Yvonne Will
Current Protocols in Toxicology (1999) 6.1.1-6.1.18

radicals, formed naturally (as the consequence of aerobic metabolism) or through metabolism of foreign compounds that are known to cycle through oxidized/reduced states; and (2) for biotransformation of exogenous compounds catalyzed by glutathione-*S*-transferases (GSTs). Oxidative stress is defined as the imbalance between the production and detoxification of oxygen free radicals, and can be of exogenous or endogenous origin. Exogenous stress can be caused by pollutants, pesticides, drugs, and ionizing radiation. Endogenous oxidative stress results primarily from mitochondrial electron transport, but also from stimulated phagocytic cells undergoing oxidative burst, ischemia-reperfusion, inhibition of antioxidant enzymes, or induction of prooxidant enzymes. Oxidative stress can cause oxidation of cellular constituents, such as GSH protein thiols, and peroxidation of lipids. If oxygen is incompletely reduced, superoxide ($O_2^{\cdot -}$), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2^-$), and hydroxyl radicals (HO^-) are produced. Superoxide radicals can undergo disproportionation to hydrogen peroxide and oxygen either enzymatically (with superoxide dismutase) or nonenzymatically. If hydrogen peroxide is not detoxified it will form hydroxyl radicals by the iron-catalized Haber Weiss reaction

$$Fe^{3+} + O_2^{\cdot -} + H_2O_2 \rightarrow O_2 + HO^- + HO^{\bullet} + Fe^{2+}$$

or the Fenton reaction

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\bullet} + OH^-$$

Hydroxyl radicals are highly reactive and can initiate lipid peroxidation of biological membranes. Several enzymes are involved in protecting the cell and its constituents against oxidative damage including GSH reductase, GSH peroxidase, and GSH transferases.

Glutathione Redox Cycle

The major protective system against naturally occurring reactive oxygen species is the glutathione redox cycle, which consists of GSH peroxidase, GSH reductase, and a source of NADPH. The cycle uses NADPH and indirectly NADH reducing equivalents in the mitochondrial matrix as well as in the cytoplasm to provide a recycling supply for GSH by the GSH reductase–catalyzed reduction of GSSG. In the liver, NADPH reducing equivalents are provided mainly by isocitrate dehydrogenase and to lesser degree by glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, and malic enzyme.

GSH peroxidase, a selenium-dependent enzyme that is extemely specific for GSH, reduces hydrogen peroxide and hydroperoxides to the corresponding water or alcohol, thereby oxidizing GSH to GSSG (*UNIT 7.1*). GSH reductase plays a central role in the biochemistry of GSH, as it is responsible for keeping GSH in its reduced state, thereby maintaining an adequate GSH/GSSG ratio. The reaction occurs in two steps. The first is the reduction of GSH reductase by NADPH. Electrons are channeled through the enzyme via FAD and subsequently through a redox-active protein disulfide bond to GSSG. GSH reductase is inactivated upon reduction by its own electron donor, NADPH, and is reactivated by GSSG. GSH reductase, of all NADPH-dependent enzymes, can have the highest rate of NADPH consumption in the liver. NADPH is also consumed by fatty acid synthesis and mixed-function oxidases. At times when the glutathione redox cycle is functioning at high capacity, mixed-function oxidase activity (a major regulator of fatty acid synthesis) and other NADPH cytochrome reductase activities can be expected (Reed, 1986).

The GSH redox cycle is also involved in the detoxification of reactive drug intermediates, which are generated by bioreduction and cause oxidative stress by redox cycling. Diquat, a hepatotoxic herbicide, is an excellent example of a redox cycling compound. Using molecular oxygen in a one-electron reduction, it generates large amounts of superoxide anion radical and hydrogen peroxide within the cell. That the protective role of GSH is mediated through the GSH redox cycle was proven through the inhibition of GSH reductase by 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU), which increases the toxicity of redox cycling compounds, including adriamycin (Babson and Reed, 1978).

Glutathione-*S*-Transferases

GSTs are a family of isoenzymes that conjugate GSH with electrophilic compounds. For many years it was believed that these reactions only served in the detoxification of xenobiotics—e.g., drugs, certain environmental pollutants, pesticides, herbicides, and carcinogens. Today we know that GSTs play a role in bioactivation of dihalomethanes and dihaloalkenes and are discussed with respect to drug resistance in cancer therapy. GSTs also have physiological catalytic functions—the isomerization of 3-ketosteroids and biosynthesis of leukotriene A4 and eicosanoids. GSTs that have peroxidase

activity are believed to play a role in preventing oxidative stress. In vitro experiments showed that GSTs can reduce fatty acid and DNA hydroperoxides: they can catalyze a Michael addition to unsaturated ketones resulting from the metabolism of dietary lipid peroxides or decomposition of fatty acid hydroperoxides. Other GST-dependent reactions have been observed in inflammation caused by the respiratory burst of immune cells. Because of their abundance (up to 10% of cytosolic protein in liver) as well as their binding properties, it has been suggested that GSTs are involved in storage and transport of hormones, metabolites, drugs, and other hydrophobic nonsubstrates (Listowsky, 1993).

GSTs are present as soluble and membrane-bound forms. GST activity is present in different subcellular fractions of most tissues and blood cells of the mammalian organism. There are four species-independent classes of cytosolic GSTs—alpha, mu, pi, and theta—and one class of microsomal GSTs. GSTs are expressed to different extents both qualitatively and quantitatively in different tissues, which suggests different susceptibility of tissues to certain xenobiotics.

Cytosolic GSTs are dimeric proteins composed of two identical or nonidentical subunits (Mannervik and Danielsson, 1988). Classes pi and theta contain homodimers, while classes alpha and mu are more complex and display multiplicity of homodimeric and heterodimeric isoenzyme forms. The subunits have a catalytic center with two binding sites: a highly specific GSH binding site (G-site) and a hydrophobic site (H-site) where acceptor substrates can be accommodated. The H-site exhibits low specificity.

Microsomal GSTs can account for as much as 3% of endoplasmic reticulum protein (Morgenstern and DePierre, 1983). It has been suggested that microsomal GSTs are involved in protection against lipid peroxidation because they have been shown to reduce fatty acid hydroperoxides (Haenen and Bast, 1983).

GSTs have not only been found in the cytosol but also in the mitochondrion, nucleus, and nucleolus. In mitochondria, a class theta GST was isolated from the matrix by Harris et al. (1991) and a class alpha by Addya et al. (1994). A transferase similar to the microsomal transferase was identified in the outer mitochondrial membrane (Nishino and Ito, 1990). Tirmenstein and Reed (1988) showed a GSH-dependent peroxidase in rat liver nuclear membranes capable of inhibiting lipid peroxidation. Because the nuclear membrane regulates transport of mRNA into the cytoplasm and aids in the process of nuclear division, protection from oxidative damage is extremely important. It is also known that DNA itself is associated with certain regions of the nuclear membrane (Tirmenstein and Reed, 1988).

In detoxification reactions, GSTs catalyze the initial reaction in the biosynthesis of mercapturic acids. The conjugates need to be transferred to the membrane-bound catabolic enzymes. More than fifteen enzyme systems are known to be involved in the formation and disposition of GSH conjugates (Commandeur et al., 1995). The first step in the catabolism of GSH conjugates is the removal of the γ-glutamyl moiety by hydrolysis or by transfer to an appropriate acceptor. This initial step is catalyzed by γ-glutamyl transpeptidase (GGT) and results in the formation of the corresponding cysteine-*S* conjugate that can subsequently be taken up by the cell for further metabolism.

Enzymes involved in the biotransformation of GSH conjugates are distributed throughout the body. As accumulation of GSH conjugates leads to inhibition of GSTs as well as GSH reductase, disposal is of absolute necessity. Transport is carried out by at least three different systems: (1) an ATP-dependent GS-X pump with broad substrate specificity that has been shown to exist in different organs and cell types; (2) a Na^+-dependent system demonstrated in basolateral membranes in the kidney and intestine; and (3) a Na^+-independent system that is probably membrane potential dependent. This latter system has been demonstrated in brush border membranes of intestinal cells and canalicular and sinosoidal membranes of liver cells. Catabolites of GSH conjugates are believed to be transported by carriers that transport amino acids and dipeptides (McGivan and Pastor-Anglada, 1994).

As the liver is the main organ for biosynthesis and disposition, hepatic transport is described in more depth. In order for GSH conjugates to be degraded by GGT (which is located in the bile canalicular membrane of the hepatocyte, the luminal membrane of the biliary epithelium, and the small intestine epithelium), conjugates have to be extruded from the hepatocyte. Extrahepatically formed conjugates can reach the liver via the blood and can be taken up by liver cells. Excretion can occur either across the canalicular or the sinusoidal membrane. GSH conjugates are preferentially excreted into the bile by the ATP-dependent GS-X pump. This transport system is inhibited competitively by GSSG and

other conjugates, but not by GSH. Transport across the sinusoidal membrane is ATP independent but membrane potential driven, suggesting that this system is the sinusoidal GSH transporter. This transport is inhibited at physiological concentrations of GSH and seems only to be of importance at high GSH conjugate concentrations, when biliary transport is saturated.

Once GSH conjugates are transported into the bile they are exposed to GGT and dipeptidases. After hydrolysis, the cysteine-*S* conjugate may be reabsorbed and acetylated within the hepatocyte to form mercapturic acids (Hinchman et al., 1991). The activity of GGT and dipeptidases, as well as the activity of reuptake transporters, determine the extent to which conjugates will be excreted. Mercapturic acids can be excreted into the bile or into the blood, depending on their molecular weight and physicochemical properties. Conjugates excreted into the blood are delivered to the kidney, while conjugates excreted into the bile must first be reabsorbed from the small intestine. For details on intestinal transport mechanisms, see Hagen and Jones (1987). In the kidney, conjugates enter the renal cells via the brush border membrane. For details on transport mechanisms, see Lash and Jones (1984).

GSTs participate in bioactivation of xenobiotics by (1) forming direct-acting GSH conjugates, (2) functioning as a transporter molecule that releases reversibly bound electrophiles at target tissues, (3) forming GSH conjugates that are bioactivated by subsequent metabolism of the GSH moiety, and (4) performing reductive bioactivation mechanisms (Commandeur et al., 1995).

An example for direct-acting GSH conjugates is the bioactivation of haloalkanes and haloalkenes. GSH conjugates form as the initial step, but are unstable and give rise to toxic metabolites. With dihalomethanes (e.g., dichloromethane), formaldehyde is formed. Dihalomethane has been shown to be tumorigenic in mice. There is evidence for DNA damage in mouse hepatocytes. Vicinal dihaloalkenes (e.g., 1,2-dichloroethane, 1,2-dibromoethane) have been shown to be mutagenic and tumorigenic. Their bioactivation leads to the formation of half-sulfur mustards that can undergo an intramolecular cyclization to give a highly reactive episulfonium ion, which may react with cellular nucleophiles.

Examples for GSH as a transporter of reversibly bound electrophiles are conjugation of isocyanates, isothiocyanates, alpha- and beta-unsaturated aldehydes, and aldehydes. These compounds form labile GSH conjugates that may again dissociate to the parent electrophile and GSH. The electrophile can then react with endogenous nucleophiles to form more thermodynamically favored adducts.

Glutathione in Protein Synthesis, Folding, Activation, and Inhibition

The activity of a variety of enzymes is known to be influenced by the GSH/GSSG ratio. Although much attention has been paid to the effect of decreased intracellular concentrations of GSH, little attention has been given to GSSG and how alterations in GSSG levels may alter cellular functions. The following discussion focuses on how GSSG is involved in synthesis, folding, and activation/inactivation of important cellular proteins.

Concentrations of GSSG reported for a variety of tissues range between 4 and 50 μM (Tietze, 1969). Kosower and Kosower (1974) reported that slight increases in GSSG concentration, even in the presence of large amounts of GSH, had effects of potential physiological relevance. These authors showed that 75 μM GSSG in the presence of 1 mM GSH shut off protein synthesis in a lysate of rabbit red blood cells. They hypothesized that GSSG had an effect on an initiation factor that is converted into a GSSG-reactive form when bound to a protein-synthesizing system.

Ruoppolo et al. (1996) studied refolding of RNase by oxidation and disulfide isomerization. The rate-limiting step for folding of disulfide-containing proteins in the endoplasmic reticulum is the formation of native disulfide bonds. The major thiol redox system in the endoplasmic reticulum is provided by GSH. The authors conclude from their studies that refolding occurs in two steps: the formation of a mixed disulfide with GSH, and the internal attack of a free SH group to form an intramolecular disulfide bond. The authors strongly believe that GSS-proteins are important folding intermediates, as shown in refolding studies of RNase A (Torella et al., 1994) and bovine pancreatic trypsin inhibitor (Weissman and Kim, 1995).

GSSG was also shown to have a direct effect on protein function by forming mixed disulfides in the active center of the enzymes, thereby either activating or inactivating the protein. Hexokinase (Eldjarn and Bremer, 1962), pyruvate kinase (Van Berkel et al., 1973), glycogen synthetase D (Ernest and Kim, 1973, 1974), adenylate cyclase (Baba et al., 1978), ribonucleotide reductase (Holmgren, 1978, 1979),

phosphorylase phosphatase (Shimazu et al., 1978; Usami et al., 1980), collagenase (Tscheche and McCartney, 1981), and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGR; Cappel and Gilbert, 1993) have all been shown to be inactivated by GSSG, while δ-aminolevulinate synthetase (Tuboi and Hayasaka, 1972) and SoxR (Ding and Demple, 1996) have been shown to be activated by GSSG.

Van Berkel et al. (1973) studied pyruvate kinase and found two forms that have different kinetic properties and can be interconverted by oxidation/reduction of a sulfhydryl group. GSH was shown to reduce pyruvate kinase, but the kinetics were different when 2-mercaptoethanol was used. The in vitro process was very slow (6 hr for oxidation, 1 hr for reduction). The author therefore can only speculate about the in vivo existence of such a mechanism.

Ernest and Kim (1973, 1974) performed work on glycogen synthetase D. Inactivation of the enzyme was associated with the formation of a mixed disulfide between sulfhydryl groups in the enzyme by the action of GSSG. The authors found that eight sulfhydryl groups exist per subunit. Reaction of GSSG with any four lead to inactivation and dissociation of the enzyme into its subunits.

Baba et al. (1978) performed in vitro studies that showed that adenylate cyclase activity was strongly inhibited by GSSG and was reactivated upon incubation with sulfhydryl compounds including GSH. The inactivation was believed to occur through oxidation of sulfhydryl groups in the enzyme. This hypothesis was supported by the authors' finding of an increased amount of GSS-protein when adenylate cyclase was incubated with GSSG. However, questions remain about the physiological significance of this mechanism. The authors speculate by referring to Isaacs and Binkley (1977), who proposed that formation of Pro-SSG may be a mechanism for maintenance of a disulfide/sulfhydryl ratio to maintain the integrity of membranes in times of oxidative or reductive stress.

Phosphorylase phosphatase was studied by Shimazu et al. (1978) and Usami et al. (1980). GSSG was shown to inactivate the enzyme by forming a mixed disulfide with one of the two sulfhydryl groups contained in the catalytic subunit.

Tscheche and McCartney (1981) found that human polymorphonuclear collagenase could be activated by disulfide thiol exchange brought about by cysteine, GSSG, insulin, and various proteins containing accessible peripheral disulfide bonds. The activation of collagenase involves the release of an inhibitor by an oxidative process that will reform an intramolecular disulfide bond.

Cappel and Gilbert (1993) performed studies that investigated the effect of GSH/GSSG redox status on inactivation and subunit cross-linking of HMGR. The authors report that different dithiol pairs are responsible for inactivation and cross-linking. The fact that Ness et al. (1985) found cross-linked HMGR in microsome preparations when dithiothreitol was excluded in the isolation procedure gave support for the hypothesis that HMGR activity may be regulated by diurnal variations in the GSH/GSSG redox state. In vitro loss of activity showed an oxidation rate constant (K_{ox}) of 0.67 ± 0.07, while disulfide cross-linking required a K_{ox} of 0.19 ± 0.02. What does this mean? Assuming a GSH/GSSG ratio of 300 and a GSH concentration of 10 mM (which is the diurnal high for liver), 10% of HMGR would be expected to be cross-linked and 20% to be inactivated. At a diurnal low GSH/GSSG ratio of 100 and a GSH concentration of 6 mM, 25% of the enzyme would be cross-linked and 53% inactivated. The authors conclude that changes in intracellular GSH redox status needs to be added to the list of effectors that regulate the enzyme activity of HMGR.

Tuboi and Hayasaka (1972) performed in vitro studies on δ-aminolevulinate synthetase, which was shown to be activated by GSSG and also even more successfully by cystine. The authors found that a protein was also required for the activation process; this protein remains to be identified.

Ding and Demple (1996) performed work on SoxR, which is a redox-regulated transcription factor involved in defense against oxidative stress by nitric oxide or hydrogen peroxide in *E. coli*. SoxR contains 2Fe-2S clusters that can be effectively disrupted by GSH, leading to the inactivation of SoxR. The authors suggest that GSH-based free radicals are involved in this disassembly process. The same effects were observed with GSH-deficient mutants in vivo.

With the exception of Shimazu et al. (1978), all the experiments described above were carried out in vitro. This leaves the question about in vivo occurrence and relevance unanswered. Shimazu et al. injected GSSG into the portal vein of rabbits and observed a rapid increase in phosphorylase a activity in the liver, which was probably due to inactivation of phosphorylase phosphatase. Sies et al. (1974) observed that increasing GSSG levels, through injection of hydrogen peroxide into perfused liver, caused

extra release of glucose, lactate, and pyruvate. Both groups suggest that the redox state of GSH in the liver may contribute to the regulation of glycogenolysis and glycolysis.

Even though the in vitro work strongly suggests the involvement of the GSH/GSSG ratio in protein function, no further in vivo studies have been documented to date. However, the fact that changes in GSH/GSSG ratio can occur, that GSSG once produced and not immediately reduced is released from the cells at a relatively slow rate, that the amount of Pro-SSG can account for as much as 35% of total glutathione (Modig, 1968), and that the protein SS/SH ratio is not static but capable of circadian variation does not exclude the strong possibility of a regulatory function for GSSG or the GSH/GSSG ratio.

More recent studies have dealt with the effect of GSH and/or the GSH/GSSG ratio on gene expression, where both direct and indirect effects have been described. Liang et al. (1989) report that increasing GSH levels enhance binding, internalization, and degradation of interleukin 2 (IL-2), not by a direct effect on the cysteine residues of IL-2, but probably by an indirect effect on the target cells. Ginn-Pease and Whisler (1996) investigated the effect of GSH on induction of the transcription factor NFκB. NFκB transactivation response to oxidative stress proceeds in two stages. The initial step involves oxidative triggering of early membrane signaling events while the second stage requires the maintenance of a normal reducing state. In other words, optimal induction of NFκB requires a functional GSH system that can respond to oxidative stress and maintain intracellular redox homeostasis.

GLUTATHIONE SYNTHESIS AND TURNOVER

GSH Synthesis

GSH can be synthesized in the cytosol of most mammalian cells through the action of γ-glutamylcysteine synthetase and glutathione synthetase (GS; Fig. 6.1.2). Both reactions are ATP dependent. γ-Glutamylcysteine synthetase is feedback inhibited by GSH. The inhibition is not allosteric but competitive with respect to glutamate. Information on the isolation, properties, and catalytic mechanisms of the two enzymes have been extensively reviewed (Yan and Meister, 1990; Huang et al., 1993).

The rate-limiting step in GSH synthesis is the availability of cysteine (10^{-4} M), because glutamine and glycine are present at higher concentrations (10^{-3} M). Also, high levels of cysteine are known to be toxic to the cell. The liver is the main synthesizer of glutathione and is also unique in that it can synthesize cysteine from the sulfur of methionine and the carbon of serine via the cystathionine pathway (Fig. 6.1.3). This pathway becomes extremely important at times of dietary limitation or when high levels of biosynthesis of glutathione are required (Reed and Orrenius, 1977). Methionine is first converted via *S*-adenosylmethionine by demethylation to homocysteine. Homocysteine condenses with serine in a reaction catalyzed by cystathionine β-synthase to form cystathionine. This thioether does not seem to have any other metabolic function than serving as an intermediate in the cystathionine pathway. Cystathionine is then cleaved to cysteine, ammonia, and α-ketobutyrate by cystathione γ-lyase.

GSH Transport

As mentioned above, most mammalian cells can synthesize GSH. What happens to GSH after synthesis? GSH is not used just for the functions described above, but also has been shown through many studies to be exported. Export of GSH allows the cell to protect its membranes against oxidative or other forms of damage by keeping thiol groups and membrane components (e.g., vitamin E) in their reduced forms. Export of GSH may also provide a way of reducing compounds such as cystine and dehydroascorbate in the immediate environment of the cell membrane, and it may facilitate transport of certain compounds (Meister, 1991). It has been agreed that the export of GSSG

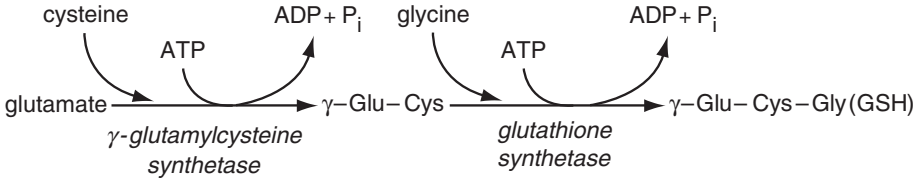

Figure 6.1.2 Synthesis of glutathione.

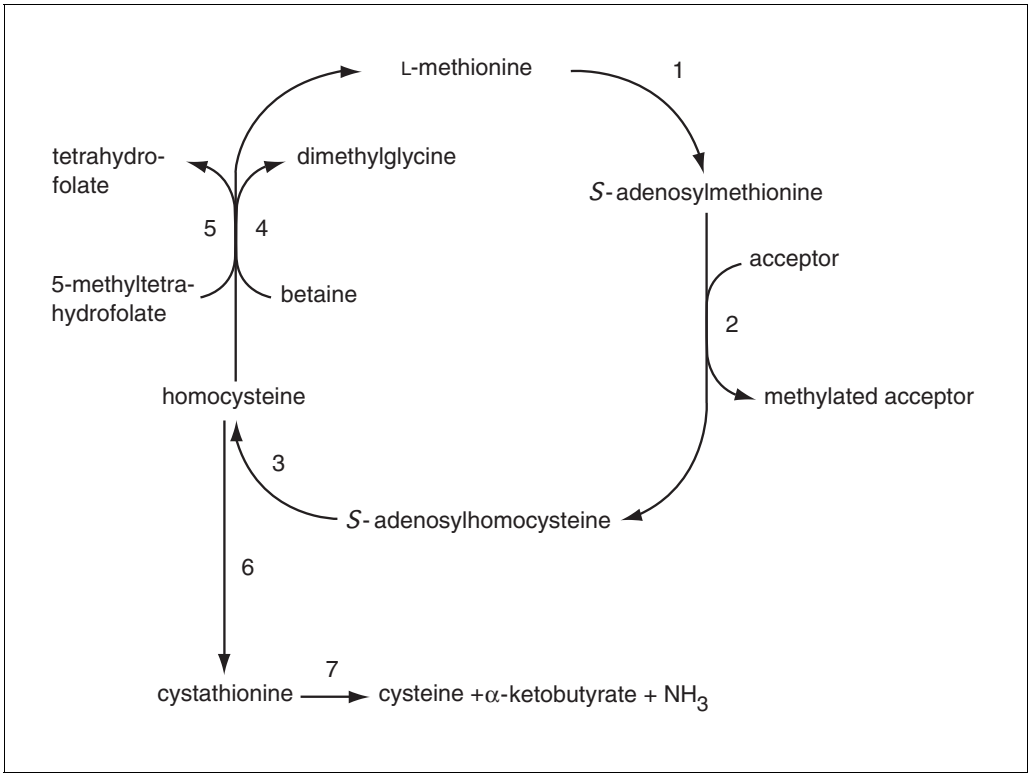

Figure 6.1.3 Cystathione pathway. Enzymes: 1, methionine adenosyltransferase; 2, *S*-adenosylmethionine methyltransferase; 3, adenosylhomocysteinase; 4, betaine-homocysteine *S*-methyltransferase; 5, 5-methyltetrahydrofolate-homocysteine *S*-methyltransferase; 6, cystathionine β-synthase; 7, cystathionine γ-lyase.

serves as a protective mechanism for the cell to eliminate formation of GSH-protein mixed disulfides and assists in the maintenance of thiol redox status or cystine/cysteine status. Export of GSH conjugates is necessary for further disposition.

Export of GSSG and of GSH conjugates seems to require ATP. Little information is available on the mechanism and the specificity of GSH export. There seems to be evidence for a membrane potential–dependent GSH transport by renal brush border membranes, but this process may be different for GSH, GSSG, and GSH conjugates, and the mechanism may also be cell specific. The liver, the main synthesizer of GSH, exports large amounts of GSH into the plasma. GSH is also transported from the liver into the bile, mainly in the form of GSSG.

GSH Breakdown

Plasma GSH derived from the liver can only be utilized by tissues that have considerable amounts of γ-glutamyl transpeptidase (GGT) activity (e.g., kidney, small intestine, and type 2 alveolar cells). Most plasma GSH, however, is transported to the kidney, where it is degraded with a half-life of 1.5 sec. Degradation of GSH begins at the cell surface and requires enzymes located both on the cell surface (GGT) as well as in the cytosol (dipeptidases; Meister and Anderson, 1983). The kidneys take up GSH from the plasma through breakdown of GSH via GGT activity.

GGT is located at the brush border of kidney epithelial cells. GSH, GSSG, and γ-glutamyl GSH react with GGT at the outer surface. The γ-glutamyl moiety is either removed by hydrolysis or transferred to a suitable amino acid acceptor, and both the γ-glutamyl amino acid and the cysteinyl glycine are transported into the cell. Cysteine is necessary in other tissues for GSH synthesis and is also returned to the liver, which closes the GSH cycle. This salvage pathway for glutathione was proven through inhibition of GGT, which raised the plasma glutathione level significantly. GSH accumulated extracellularly and was excreted with the urine. In addition to GSH, cysteine moieties and glutamyl cysteine were excreted with the urine (Reed and Ellis, 1981).

Overall Balance of GSH Turnover

It has been shown in mice that the breakdown of GSH in the kidney accounts for 80% to 90%

of the total GSH turnover (Meister, 1983). GSH efflux occurs even in the absence of GSH synthesis, which has been shown in studies where synthesis of GSH was blocked with buthionine sulfoximine (BSO). The fact that synthesis rate and export rate are very similar strongly suggests that in general there is very little intracellular degradation of GSH in the liver (Meister, 1991). The turnover of glutathione is thus largely accounted for by export of GSH, subsequent degradation by GGT, and return of cysteine moieties to tissues and liver.

GSH Uptake

The question arises if direct uptake of glutathione occurs as well. Studies have been conducted on kidney, liver, brain, and intestine. These experiments are difficult to perform because both synthesis and degradation of GSH must be completely inhibited, but the inhibitor concentrations needed for full inhibition are often toxic to the cell and won't allow kinetic measurements over long periods of time. For these reasons interpretation of results is difficult and has caused controversy about the actual existence of intact GSH uptake. Several studies on different organs and cell types were not able to show uptake of intact GSH at all (Hahn et al., 1978; Dethmers and Meister, 1981; Yoshimura et al., 1982; Tsan et al., 1989). A variety of studies have been conducted on GSH uptake in kidney. It was hypothesized that basolateral transport exists (Ormstadt et al., 1980; McIntyre and Curthoys, 1980); however, detailed studies by Abbott et al. (1984) and Inoue et al. (1986) found that there is little, if any, basolateral uptake.

Hagen and Jones (1989) performed experiments with cell suspensions isolated from kidney, intestine, and lung that showed that cells were protected from *tert*-butylhydroperoxide (TBH), menadione, and paraquat when GSH was added. GSH synthesis and breakdown were inhibited in these studies, but no enzyme activity levels were reported for the time of the experiment to ensure that the enzymes were fully inhibited.

Lash and Torkatz (1990) found that distal renal tubular cells could be protected from oxidative damage by GSH; however, the protection was abolished when BSO and α-amino-3-chloro-4,5-dihydro-5-isoxazoleacetic acid (AT-125 or acivicin) were used to inhibit GSH synthesis and degradation, respectively.

Since 1993, some more convincing studies have been conducted by Kaplowitz and colleagues. In a variety of studies, the authors identified two rat liver GSH transporters and three GSH transport activities in the brain. In the liver, the authors identified a canicular and a sinusoidal transporter, both of which have been cloned (Yi et al., 1994, 1995). Transport was independent of stimulation by ATP, and it was suggested that transport occurs bidirectionally. For more information on the mechanism on these transporters, see Fernandez-Checa et al. (1993) and Lu et al. (1994). Of the three brain GSH transport activities, one corresponded to the Na^+-independent rat canicular GSH transporter, and one was shown to be Na^+-dependent and to exhibit high- and low-affinity GSH transport (Kannan et al., 1996).

Several studies on uptake of intact GSH have been conducted in the intestine. Hunjahn and Evered (1985) and Evered and Wass (1970) used sacs of rat small intestine and reported a Na^+-independent uptake of GSH that was inhibited by triglycine and glycyl-L-leucine. This transport showed properties of carrier-mediated diffusion. Hagen and Jones (1987) showed Na^+-dependent GSH transport with in situ closed-loop vascular perfusion systems. Na^+-independent GSH transport was also shown in brush border membrane vesicles of rabbit small intestine where GGT was inhibited with acivicin (Vincencini et al., 1988).

Studies on the uptake of orally administered GSH have been contradictory. Yoshimura et al. (1982) and Martenson et al. (1990) did not find any uptake of GSH into blood plasma. In contrast, Jones and co-workers (Aw et al., 1991) administered 100 mg/kg GSH to mice and measured plasma GSH levels after 30 min and 1 hr. Plasma GSH levels increased 2.5-fold (from 30 to 75 μM) in the first 30 min and decreased back to 50 μM after 1 hr. This was in agreement with previous studies where increases in plasma GSH were observed in rats and humans after oral administration (Hagen et al., 1988). No increase in tissue GSH was found, with the exception of lung tissue. In the same study (Aw et al., 1991) the authors administered GSH to animals that were depleted in GSH by a 5-day treatment with BSO. In this study a significant increase in tissue GSH was observed in kidney, heart, lung, brain, small intestine, and skin, but not in liver. An interesting observation was the fact that brain and small intestinal GSH levels returned to control levels while the other tissues did not. The lack of an increase in liver tissue GSH level was explained by the fact that liver is the main supplier of plasma GSH and unable to take up exogenous GSH. The differences in uptake rates in the other tissues are not clear, but may be

explained by tissue-specific differences in turnover and uptake. No increase was observed when precursors of GSH (cysteine, glycine, glutamine) were administered, which suggests that uptake of intact GSH may contribute to tissue GSH levels independent of synthesis. The authors discuss four possibilities for actual GSH transport: uptake (1) through the action of transglutaminase, (2) through the action of GGT, (3) through reaction with electrophilic compounds, or (4) as a mixed disulfide with cysteine or plasma proteins like albumin. Despite the question about the uptake mechansims involved, oral administration of GSH may have a beneficial effect under pathological conditions where endogenous GSH levels are significantly decreased (Aw et al., 1991).

Intraperitoneally administered GSH did not show significant increases in the jejunal or colon mucosa. Oral administration of GSH led to an increase of mucosal GSH in colon, jejunum, and stomach (Martenson et al., 1990), but it cannot be excluded that cleavage of GSH or transpeptidation occurred with subsequent resynthesis. Plasma GSH can be increased to millimolar concentrations through intraperitoneal injection of GSH. However, this plasma increase did not significantly increase tissue GSH levels, which shows that plasma GSH is not rapidly taken up by cells.

Although the need for export of GSH is obvious and explainable, the need for uptake of GSH under normal conditions is questionable. It seems that under normal conditions degradation by GGT and subsequent resynthesis are the main route for GSH turnover. The question arises as to whether direct uptake may only exist under pathological conditions where degradation or resynthesis are diminished, or under oxidative stress when cells are not able to fully regenerate GSH from GSSG. Lash and coworkers (Visarius et al., 1996) reinvestigated the question of uptake in renal cells. Renal cellular handling of GSH involves three processes: membrane transport, oxidation, and degradation. Lash showed that renal proximal tubule cells treated with TBH were able to transport GSH across the basolateral plasma membrane, thereby increasing intracellular GSH. However, this uptake was extremely low (<6%) in the absence of acivicin and BSO, and oxidation and degradation were the main route for GSH turnover. When this route was inhibited, uptake of GSH became quite important and accounted for 30% of external GSH loss. Lash concluded that under normal conditions degradation and resynthesis are the major route for GSH turnover. Under pathological conditions (e.g., oxidative stress), cells are not able to fully regenerate GSH from GSSG and have negligible capacity to resynthesize GSH from precursor amino acids. Therefore, uptake of intact GSH may be necessary for the cell in order to maintain its GSH homeostasis (Visarius et al., 1996).

MANIPULATION OF GLUTATHIONE CONTENT

The amount of glutathione can be manipulated by depletion of GSH, through inhibition of key enzymes in the glutathione cycle or through administration of precursors of glutathione. It has been possible to manipulate glutathione levels between 10% and 150% of control levels.

Depletion of Glutathione

One of the most commonly used depleting agents is diethyl maleate (DEM), which was first introduced by Boyland and Chasseaud (1969a,b). DEM is a weak electrophile that reacts with GSH in the presence of GSH transferases. Intraperitoneal injection of DEM (0.6 to 1.0 ml/kg) reduced liver GSH to 6% to 20% of control levels for a period of up to 4 hr. However, the rate of synthesis is increased, which causes an increase in GSH to twice control levels in 24 hr. After that time GSH levels return to control values. Erythrocyte, kidney, lung, and brain GSH amounts are decreased as well, but to a significantly lesser amount than liver GSH. DEM shows a variety of side effects that suggest caution for its use and for interpretation of data. It has been shown to increase bile flow in rats and dogs, to increase hepatic microsomal heme oxygenase in rats in vivo, and to cause lipid peroxidation in isolated hepatocytes.

Another useful GSH-depleting agent is phorone (diisopropylidene acetone), which when given intraperitoneally (250 mg/kg) depletes hepatic GSH to <10% of control levels in rats. In isolated hepatocytes, phorone treatment (0.5 mM) was shown to deplete cytosolic and mitochondrial GSH by 75% and 40%, respectively (Romero et al., 1984). As with DEM administration, the rate of GSH synthesis is also increased, causing a significant increase of GSH levels above control values. Phorone has been shown to increase heme oxygenase and δ-aminolevulinic acid synthetase activity, and to decrease cytochrome P-450 and aminopyrine demethylase activity. However, unlike DEM, phorone does not seem to have an effect on protein synthesis.

Other compounds that have been used, and that deplete GSH by enzyme-catalyzed reactions, include unsaturated compounds (e.g., acrylonitrile and acrylamide) and halogenated hydrocarbons (e.g., iodomethane, chloroacetamide, 2-chloroethanol, and benzylchloride).

Kosower et al. (1969a,b) developed a variety of compounds that oxidize GSH to GSSG. These compounds are derivatives of diazenecarboxylic acid. The most widely used compound has been diazenedicarboxylic acid bis-(*N*,*N*-dimethyl)amide (diamide). GSH levels are lowered to <10% of control levels in a variety of cells; however, side effects have to be kept in mind when interpreting data. Diamide is known to cause slow oxidation of lipoic acid and pyridine nucleotides and fast oxidation of flavin nucleotides. Diamide also causes inhibition of a variety of important enzymes (e.g., protein kinase, tyrosine phosphatase, Na^+/K^+-ATPase, and glucose-6-phosphatase), and is known to cause membrane damage.

GSH can also be depleted (oxidized) using substrates for GSH peroxidase (e.g., hydrogen peroxide and THB). However, the increase in GSSG causes oxidative stress, which can make the in vivo use of hydroperoxides unattractive for certain studies.

Inhibition of GSH Synthesis

Glutathione levels can be effectively decreased by inhibiting the enzymes involved in synthesis: γ-glutamylcysteine synthetase or glutathione synthetase (GS; Fig. 6.1.2). The most useful inhibitor is BSO, which inactivates γ-glutamylcysteine synthetase. BSO is a transition-state inhibitor and mimics the transition intermediate or transition state formed in the reaction between enzyme-bound γ-glutamyl phosphate and the amino group of cysteine. BSO competes with L-glutamate for the active site of the enzyme; however, once bound and phosphorylated, the intermediate is tightly bound. BSO can be administered repeatedly either orally or intraperitoneally. Its success depends on the amount of GSH in individual tissues as well as on the turnover rate of GSH in the cells. BSO itself is not very reactive chemically and appears to be metabolized slowly. BSO therefore allows treatment over several weeks, which creates an artificial chronic GSH deficiency. BSO experiments carried out in vitro or in vivo have shown the importance of GSH in reduction and detoxification processes. It was shown that BSO-induced depletion of GSH sensitized the cells to toxic effects induced by $HgCl_2$, radiation, cyclophosphamide, morphine, and other compounds. BSO treatment also has been shown to have an effect on tumors by increasing the effects of chemotherapy and radiation once GSH is depleted.

Short-term BSO treatment (e.g., single intraperitoneal injection) leads to a rapid decline of GSH in liver, pancreas, kidney, skeletal muscle, and plasma. GSH is depleted to a maximum of 15% to 20% of control levels. The fact that glutathione cannot be further depleted led to the hypothesis that a separate GSH pool existed. This was later associated with the mitochondrial GSH pool (see Mitochondrial Glutathione). Long-term treatment with BSO over several weeks showed a decrease not only in the tissues named above but also in brain, heart, lung, spleen, and intestinal and colon mucosa. BSO therefore can be used to produce "chronic" GSH deficiency. However differences have been observed in treatment of adult versus newborn animals.

Inhibition of GS is not the method of choice to induce glutathione deficiency, because it has been shown that patients with severe inborn GS deficiency show life-threatening acidosis due to overproduction of 5-oxoproline (Meister and Larsson, 1989). When GS is inhibited, γ-glutamylcysteine accumulates; this is converted by γ-glutamylcyclotransferase to cysteine and oxoproline, which is then converted to glutamic acid by 5-oxoprolinase, resulting in severe acidosis.

Glutathione levels can also be decreased by limiting the necessary amino acids, especially cysteine and methionine. However, limitation of synthesis in this way will also have consequences with respect to protein synthesis.

Inhibition of GSH Degradation

GSH content can also be altered by inhibiting GGT. Degradation of GSH by GGT can account for as much as 80% to 90% of GSH turnover. Reed and Ellis (1981) performed in vivo treatment of rats with AT-125 (acivicin), an inhibitor of GGT. AT-125 prevented degradation of plasma GSH, which led to massive urinary excretion of GSH. This treatment lowered the hepatic GSH content, because recycling of cysteine was inhibited.

A GGT-deficient knockout mouse has recently been developed (Lieberman et al., 1996); it shows chronic depletion of GSH in certain organs. Selective depletion is thought to be due to a lack of "recovered" cysteine from the urinary GSH. The most affected organs were the liver and eye, where tissue GSH levels decreased to 20% of control levels. Pancreas, spleen, and thymus were depleted to 50% of control levels,

while brain, heart, and lung showed significant but minor depletion to 80% of control levels. Kidney GSH was not decreased at all (Lieberman et al., 1996; Will and Reed, unpub. observ.). These findings suggest that synthesis, uptake, and turnover of GSH are tissue specific.

Increasing Glutathione Levels

GSH levels can be increased by administration of GSH, GSH esters, or precursors for GS synthesis. The synthesis of GSH may be increased by increasing the amount of substrates for the two synthetases. However, since γ-glutamylcysteine synthetase is feedback inhibited by GSH, this approach may only work under certain conditions (e.g., refeeding after depletion or starvation). Introduction of cysteine is often not the best approach to increase synthesis as it is rapidly metabolized and has been shown to be toxic at high concentrations. *N*-acetyl cysteine (NAc) is a precursor for cysteine that has found therapeutic use in raising GSH levels in HIV patients and patients with respiratory diseases. The compound is transported into cells where it is deacetylated to yield cysteine. Another effective compound is L-2-oxothiazolidine-4-carboxylate (OTC), which is an analog of 5-oxo-L-proline and is a substrate for 5-oxoprolinase.

GSH levels can also be raised by supplying substrate for GS; this is a good approach because this enzyme is not feedback inhibited by GSH. γ-Glutamyl cysteine and γ-glutamyl cystine have been shown to increase the GSH concentration in the kidney. This approach is extremely useful for raising kidney GSH levels because kidney cells have an active transport system for γ-glutamyl amino acids.

The use of GSH itself to raise GSH levels has been subject to controversy. While some authors did not find any increase in plasma or tissue GSH levels after oral administration (Yoshimura et al., 1982; Martenson et al., 1990), Jones and co-workers did show increases in plasma GSH levels (Hagen et al., 1988). However, an increase in tissue GSH levels was observed only when GSH levels were previously depleted through administration of BSO (Aw et al., 1991). Therefore, administration of GSH may have a beneficial effect under pathological conditions where GSH depletion has occurred. In contrast, the administration of monoethyl or monomethyl esters has been shown to increase tissue GSH levels. Anderson et al. (1985) reported rapid uptake of intraperitoneally administered glutathione monoethyl ester into kidney, liver, spleen, pancreas, and lung. Uptake into other tissues occurred at a slower rate. The use of esters is appealing because many cells are equipped with esterases that can catalyze hydrolysis to GSH, but it must be kept in mind that the release of ethanol and methanol can have adverse effects on cellular functions.

MITOCHONDRIAL GLUTATHIONE

The fact that BSO treatment was unable to deplete liver GSH below 10% to 15% of total GSH suggested the existence of more than one pool of GSH in the liver (Edwards and Westerfeld, 1952). In 1973 it was proposed that GSH in the mitochondrial matrix provides a reservoir for reducing equivalents capable of preventing thiol groups from oxidative stress (Vignais and Vignais, 1973).

A complete redox cycle was shown to exist in liver mitochondria, containing reduced GSH, glutathione reductase, glutathione peroxidase, and NADPH (Fig. 6.1.4). This system is capable of reducing a wide range of diazenes and hydroperoxides (Jocelyn, 1978). Since mitochondria contain no catalase, they rely solely on GSH peroxidase to detoxify hydrogen peroxide. Where does the hydrogen peroxide come from? Most is of endogenous origin as a consequence of aerobic metabolism that occurs mostly in the mitochondrion. Reduction of oxygen in the respiratory chain is not absolutely complete and involves the formation of toxic intermediates. About 2% to 5% of mitochondrial oxygen consumption generates hydrogen peroxide. Hydrogen peroxide, if not reduced, leads to the formation of very reactive hydroxyl radicals that can cause lipid peroxidation. Lipid peroxidation damages membranes, nucleic acids, and proteins, thereby altering or inhibiting their function.

Meredith and Reed (1983) made the original observation that the onset of chemically induced cell injury correlated with the depletion of mitochondrial rather than cytosolic GSH. Hepatocytes were treated with ethacrynic acid, which depletes mitochondrial as well as cytosolic GSH. The authors showed that depletion of cytosolic GSH had no observable effect on cell viability, while the depletion of mitochondrial GSH caused cell injury. Cell injury occurred when the total liver GSH was depleted to 10% to 15% of normal levels.

Meredith and Reed (1982) also demonstrated different rates for GSH turnover between cytosol and mitochondria. Their finding indicated a half-life of 2 hr for cytosolic GSH versus 30 hr for mitochondrial GSH. The fact that mitochondrial GSH content (10 mM) is higher

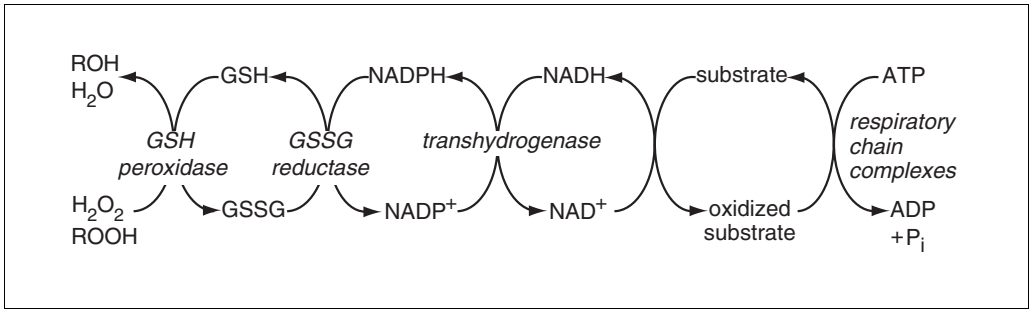

Figure 6.1.4 Mitochondrial GSH redox cycle.

than cytosolic (7 mM) suggests the importance of mitochondrial GSH. The ratio of GSH/GSSG in mitochondria under normal conditions is ~18:1. This ratio can change through oxidative stress of either endogenous or exogenous origin. A change in the GSH/GSSG ratio has adverse effects on mitochondria and subsequently on cells. For example, age-related changes in the mitochondrial GSH/GSSG ratio have been observed by Garcia de la Asuncion et al. (1996). These authors examined mitochondrial GSH/GSSG ratios and oxidative damage to mitochondrial DNA in liver, brain, and kidney in 6-, 18-, and 24-month-old mice and rats. The following results and conclusions were obtained: (1) GSH becomes more oxidized with age. (2) Oxidative damage in mitochondrial DNA increases with age. (3) A correlation (r = 0.95) exists between decreases in the GSH/GSSG ratio and increases in oxidative damage. (4) Changes in mice were much more severe than in rats. Animals with a longer maximum lifespan (rats) had less oxidation than animals with a shorter lifespan (mice). However, within a given species, older animals showed significant oxidation of GSH and mitochondrial DNA when compared to younger animals. Oxidation of GSH through TBH treatment caused release of GSSG from perfused liver (Sies et al., 1974) and isolated hepatocytes (Ekloew et al., 1984). However, TBH treatment of isolated mitochondria caused GSSG formation without subsequent release (Olafsdottir and Reed, 1988).

What would be the consequence of GSSG accumulation in the mitochondria? Accumulation of GSSG will lead to oxidation of thiol groups in mitochondria, which may explain the observation that loss of mitochondrial GSH rather than cytosolic GSH correlates with some types of cell injury (Meredith and Reed, 1983; Olafsdottir and Reed, 1988). Many mitochondrial proteins are highly sensitive to changes in the cellular thiol status, including Ca^{2+}-dependent ATPases, metabolic carriers, and proteins controlling permeability changes in the inner mitochondrial membrane. Ca^{2+}-dependent ATPases serve as membrane-bound Ca^{2+} pumps to maintain cytoplasmic Ca^{2+} at low levels. Interference with Ca^{2+} levels and increase in intracellular Ca^{2+} are known to be involved in cell injury (Bellomo and Orrenius, 1985). Homeostasis of Ca^{2+} and thiols in mitochondria are believed to be closely linked, either directly (Beatrice et al., 1984) or through pyridine nucleotides (Lehninger et al., 1978).

Many metabolic carriers of the inner mitochondrial membrane contain sulfhydryl groups. Oxidation of these groups leads to changes and inhibition of transporting capacities that can result in mitochondrial dysfunction (Le-Quoc and Le-Quoc, 1985). Changes in anion transport as well as transport of monovalent and divalent cations across the inner mitochondrial membrane have been observed when sulfhydryl groups were modified. However, the relationship between thiol modification and membrane properties is often difficult to explain. The question remains whether the effect of the thiol reagent on permeability results from reaction with a protein that specifically controls permeability, or if it is a consequence of a nonspecific perturbation.

This question gets even more complicated when dealing with the question of how the glutathione status may control the proteins that are involved in mitochondrial permeability transition. Many studies have shown that oxidative stress increases permeability in mitochondria. The permeability increase is favored by Ca^{2+} accumulation and causes equilibration of low-molecular-weight solutes (≤1500 Da), depolarization, uncoupling, and release of the previously accumulated Ca^{2+}. This phenomenon is now termed mitochondrial permeability transition (MPT). Studies conducted by Lehninger et al. (1978) linked oxidation of pyridine nucleotides to Ca^{2+} efflux, which could be reversed by reduction of pyridine nucleotides. Changes in permeability were observed, not knowing at this

time that MPT was probably involved. In 1984 the question was revisited by Pfeiffer and coworkers (Beatrice et al., 1984) who were able to independently modulate NADPH/$NADP^+$, NADH/NAD^+, and GSH/GSSG ratios. They came to the conclusion that the latter ratio was the relevant factor for changing permeability. This study was challenged, however, by previously conducted studies by Carbonera and Azzone (1988) and Hoek and Rydstrom (1988). Carbonera and Azzone showed that MPT induced by inorganic hydroperoxides was inhibited by butylhydroxytoluene while GSH remained oxidized. Hoek and Rydstrom showed that oxidation of GSH by 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU), which prevents nucleic acid oxidation, was not followed by Ca^{2+} release.

Although results were not in concert, it was agreed that there seemed to be a strong influence of pyridine nucleotides and GSH on permeability transition, which challenged Bernardi and co-workers to revisit this question. In studies conducted from 1992 to 1996, these authors came to the following conclusions. (1) MPT induction is voltage dependent (Bernardi, 1992). The pore gating potential is shifted towards a more negative membrane potential by thiol oxidation, resulting in a higher probability for pore opening. On the other side, thiol reduction shifts the gating potential toward a less negative membrane potential, resulting in lower probability to pore opening. (2) The MPT gating potential is modified by oxidation/reduction at two different sites that are experimentally distinguishable (Constantini et al., 1996). One site, the P site, is modulated through the oxidation/reduction state of pyridine nucleotides even at times where GSH is fully reduced. The other site, the S site, can be activated even when pyridine nucleotides are fully reduced (Petronilli et al., 1994). In other words, MPT pore opening correlates to both oxidation/reduction of pyridine nucleotides through the P site and presumably GSH through the S site. TBH treatment, by oxidizing both pyridine nucleotides and GSH, could therefore have an effect on both sites. Mitochondrial dysfunction (as a result of MPT) is now considered a key event in a variety of forms of cell death (e.g., ischemia, neurodegeneration, and apoptosis).

Mitochondria cannot synthesize GSH. Griffith and Meister (1985) discovered that mitochondria contain neither γ-glutamylcysteine synthetase nor GS. Therefore an uptake mechanism must exist to shuttle GSH into the mitochondria. Several groups have reported the existence of a mitochondrial anion channel (Selwyn et al., 1979; Garlid and Beavis, 1986; Sorgato et al., 1987). The described channel, which has broad specificity for many anions and is controlled by Mg^{2+} and H^+, would allow a mechanism for loading extramitochondrial components.

Martenson et al. (1990) conducted studies on the kinetics of GSH transport in isolated liver mitochondria. The authors found that the transport system had either a high- or low-affinity component depending on the external GSH concentration. At a GSH concentration <1 mM, a high-affinity component was observed with a K_m of 60 μM and a V_{max} of 0.54 nmol/min/mg protein. At GSH levels of 1 to 8 mM, a low-affinity component was found with a K_m of 5.4 mM and a V_{max} of 5.79 nmol/min/mg protein. Both processes were stimulated by ATP and ADP and inhibited by the uncoupler carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone (FCCP). Efflux of GSH from preloaded mitochondria was shown to be biphasic with an external GSH concentration of 0.15 mM. At external GSH concentrations of 8 mM, 60% of the GSH initially present in the matrix disappeared from the matrix in 15 sec, but was recovered in the matrix after 120 sec. This phenomenon was interpreted by the authors as follows: at high external GSH concentrations there is a rapid flow of external GSH into the intermembranous space, which facilitates reuptake of GSH into the matrix.

A transport system for GSH exists in isolated liver mitochondria (Kurosawa et al., 1990). These data indicated that high external concentrations of GSH and a proton gradient constitute the motive force to bring external GSH into the mitochondria. As cytosolic GSH is present at high concentrations in living cells, the authors assume that this motive force functions under physiological conditions. Isolated liver mitochondria in state 4 (basal respiration on substrate without ADP) incubated with GSSG had increased GSH levels, which suggests that GSSG is taken up and reduced by oxidation of NADPH. The observation of GSSG uptake seems to be unphysiological at first glance. However, GSH reductase and GSH peroxidase have been shown to be located in the intermembrane space and the matrix, which indicates that these enzymes are accessible to substrates from both the extra- and intramitochondrial space (Flohe and Schlegel, 1971; Sandri et al., 1990). Therefore, an uptake mechanism may very well exist in vivo.

Kaplowitz and colleagues (Garcia-Ruiz et al., 1995) were able to successfully express a rat

hepatic mitochondrial GSH carrier in *Xenopus laevis* oocytes and showed that the mitochondrial GSH carrier differed from the previously described sinusoidal and canalicular carriers. The carrier was stimulated by ATP and inhibited by glutamate.

Uptake of GSH by kidney mitochondria has been examined by McKernan et al. (1991) and Schnellmann (1991). In order to understand the mechanism of mitochondrial GSH transport several facts need to be considered. GSH contains two free carboxyl groups and one free amino group and thus has a net charge of −1 at neutral pH. The thiol group contains a dissociable proton with a pK_a of 9.2. This means that at cytosolic pH of 7.4, more or less none (<1%) of the GSH is in the thiolate form, which would mean a net charge of −2. In the mitochondrial matrix at pH 7.8, ~4% of the GSH is in thiolate form. In addition, a membrane potential exists, with the mitochondrial matrix negative relative to the cytosol. The membrane potential, the pH gradient, as well as the net charge of GSH provide a driving force against the uptake of GSH. Therefore, there must be a counteracting driving force in order for GSH uptake to exist. Several anion transporters are known to exist in mitochondria; they are involved in transport of citric acid cycle intermediates against the driving force. One or more of those carriers may be in part responsible for GSH uptake. That neither ΔpH nor the membrane potential are required for transport of GSH into renal mitochondria was shown by McKernan et al. (1991), who observed that the uncoupler 2,4-dinitrophenol and the protonophore carbonyl cyanide *m*-chlorophenyl hydrazone had no negative effect on GSH uptake. However, KCN, ATP, and Ca^{2+} inhibited transport, suggesting an indirect dependence on mitochondrial energetics or adenine nucleotide transport.

Substrate specificity for GSH uptake was examined by measuring the effects of mono- and dicarboxylates (Smith et al., 1996). Monocarboxylates did not have any effect, while malate and succinate did show effects, suggesting that GSH uptake may involve exchange with dicarboxylates. Additionally, glutamate inhibited GSH uptake, suggesting that the glutamyl moiety of GSH may be a recognition site for transport. In summary, GSH uptake into (at least) renal mitochondria is Na^+ independent, and apparently membrane potential independent, involves a net transfer of charge across the membrane, and is inhibited by glutamate and γ-glutamyl compounds, including GSH conjugates (Smith et al., 1996).

Studies by Jocelyn (1975) indicated that the retention and release of mitochondrial GSH is a highly regulated process. Isolated mitochondria retained most of their GSH, indicating that the inner mitochondrial membrane is impermeable to GSH. Only some was lost through outward diffusion, which suggests that the transport mechanism functions to conserve mitochondrial GSH during times of cytosolic depletion (Griffith and Meister, 1985). The addition of phosphate increased the efflux rate. During short-term incubations, no considerable amounts of GSSG were formed unless oxidizing agents were added. GSSG was retained by mitochondria unless phosphate was added to the incubations. Addition of phosphate probably induced MPT, opened the pore, and allowed efflux of mitochondrial components. Studies showing that no GSSG was released from TBH-treated, isolated mitochondria suggested that an efflux pathway for GSSG under non-MPT conditions is absent in mitochondria (Olafsdottir and Reed, 1988).

The question of GSH uptake and release under conditions of MPT was further examined by Savage et al. (1991). MPT was induced with calcium and phosphate (CaP), and nearly 100% GSH was released from the mitochondria in 5 min. Efflux was completely prevented when mitochondria were incubated with cyclosporin A, a known inhibitor of MPT. The authors also showed that GSH could be loaded into mitochondria. Mitochondria were briefly incubated with CaP to induce the transition, and 1 mM GSH was added to the suspensions. Mitochondria took up the GSH at a rate of 0.5 nmol/min/mg protein, which was higher than the uptake rate of mitochondria that were not pretreated with CaP. However, sustained opening of the pore would cause extensive release of mitochondrial components rather than exchange or even uptake; in other words only occasional opening and closing of the pore allows such a mechanism.

Measurement of Glutathione and Glutathione Disulfide

Evaluation of cellular thiol status should include quantification of both reduced (GSH) and oxidized (GSSG) forms of glutathione. This unit describes the methods currently used to quantify both GSH and GSSG, as well as other thiols and disulfides. The main focus is on the use of high-performance liquid chromatography (HPLC) systems to separate cellular thiols with detection by the following methods: (1) ultraviolet (see Basic Protocol 1), (2) fluorescence (see Alternate Protocol 1), and (3) electrochemical (see Alternate Protocol 2). In addition, the use of enzymatic spectrophotometric analysis for glutathione measurement is described (see Basic Protocol 2). HPLC provides a rapid, sensitive, highly versatile, and reproducible means of separating and quantitating sulfur-containing amino acids and related derivatives from a variety of biologic samples. The preparation of samples from a variety of biologic sources is also presented (see Support Protocols 1, 2, and 3).

DERIVATIZATION AND ANALYSIS OF GSH AND GSSG BY HPLC WITH UV DETECTION

BASIC PROTOCOL 1

The HPLC method of Farris and Reed (1987) described here is a modification of an earlier method by Reed et al. (1980). It is based on the initial formation of *S*-carboxymethyl derivatives of free thiols by a reaction with iodoacetic acid. This is followed by addition of Sanger's reagent, 1-fluoro-2,4-dinitrobenzene (FDNB), to convert primary amine groups to their 2,4-dinitrophenyl (DNP) derivatives. Reverse-phase ion-exchange HPLC with a 3-aminopropyl column is used to separate the amino acid DNP derivatives, and the eluted DNP derivatives are measured by ultraviolet (UV) detection at 365 nm. This is a highly versatile method that can be applied to a variety of biological samples to accurately measure several sulfur-containing compounds including GSH, GSSG, and protein-glutathione mixed disulfides (Table 6.2.1). The limits of detection for this method are 50 and 25 pmol/injection onto the column for GSH and GSSG, respectively.

Materials

Perchloric acid (PCA) extract of freshly dissected tissue (see Support Protocol 1), cultured cells (see Support Protocol 2), or hepatocytes (see Support Protocol 3)
0.4 mM γ-glutamyl glutamate (γ-Glu-Glu; see recipe)
100 mM iodoacetic acid (IAA) in 0.2 mM *m*-cresol purple (see recipe)
1% (v/v) 1-fluoro-2,4-dinitrobenzene (FDNB) in 100% HPLC grade ethanol (store at 4°C in a dark container covered with foil)
$KOH/KHCO_3$ solution (see recipe)
0.4 mM GSH (see recipe)
0.4 mM GSSG (see recipe)
Mobile phase A (see recipe)
Mobile phase B (see recipe)

HPLC column: 20-cm × 4.6-mm-i.d. column with 5-μm Exsil silica derivatized with 3-aminopropyltriethoxy silane (CEL Associates; see Reed et al., 1980)
HPLC system:
Pump with gradient capability (Spectra-Physics P200, Spectra-Physics)
UV detector (365 nm; Alltech 200, Alltech)
Recording integrator (Hewlett Packard 3390, Alltech)
Autosampler (optional; Labtronix)

Current Protocols in Toxicology (1999) 6.2.1-6.2.14

Table 6.2.1 Amino Acids and Related Compounds Measured by HPLC[a]

Order of elution	Compound	Retention time (min)
Sulfur-containing compounds		
1	Homocystine	6.68
3	Cystathionine	7.84
4	Cystine (CySS)	8.31
5	Homocysteic acid	12.13
6	Homocysteine	13.18
7	Cysteinylglycine	13.21
8	Penicillamine	13.28
9	γ-Glutamylcysteine	13.49
11	Cysteic acid	15.57
12	Cysteine (CyS)	17.13
13	γ-Glutamyl glutamate (ISTD)	21.95
14	Cysteinyl-glutathione disulfide (CySSG)	22.95
15	Glutathione (GSH)	25.95
16	Glutathione disulfide (GSSG)	30.15
Other compounds		
2	Glutamate (Glu)	7.51
10	Aspartate (Asp)	14.74

[a]Retention times vary with mobile-phase gradient and length and age of column.

Hamilton gas-tight syringe or equivalent (100 µl and 1.0 ml; e.g., Hamilton 1700 series)
Side-arm Erlenmeyer filtration flask (PyrexPlus, 1 or 2 liter)
Millipore filtration apparatus to fit side-arm flask
Millipore polypropylene filters, type HV, pore size 0.45 µm

1. Remove 0.25 ml of the PCA extract, and add to a 2.0-ml microcentrifuge tube containing 50 µl of 0.4 mM γ-Glu-Glu.

   Samples should be derivatized in triplicate.

   The use of γ-glutamyl glutamate as an internal standard for both samples and standards increases the accuracy of the method to >95% as determined for GSH, GSSG, and cysteinyl-glutathione disulfide.

2. Add 50 µl of 100 mM IAA (dissolved in 0.2 mM *m*-cresol purple) to the above tube.

   The solution should turn pink.

   The m-cresol purple included in the IAA solution not only functions as a pH indicator but also acts as a preservative; iodoacetic acid dissolved in m-cresol purple maintains alkylating activity for at least 7 days at 4°C.

3. Add 0.24 ml $KOH/KHCO_3$ solution.

   A precipitate will form and the solution should turn a light purple (pH 8 to 9); add more $KOH/KHCO_3$ solution to bring pH into that range, if necessary.

   The instantaneous pH change, due to the addition of the $KOH/KHCO_3$ solution, in the presence of IAA aids in protecting samples from derivatization-induced thiol oxidation.

4. Incubate 60 min in the dark at room temperature.

   For GSH, the formation of S-carboxymethyl derivatives (following the addition of IAA and $KOH/KHCO_3$ solution) occurs within 5 min (Farris and Reed, 1987).

5. Add 1 ml of 1% FDNB. Cap the mixture, vortex briefly, and store 1 hr at room temperature and then overnight at 4°C.

   Samples should turn yellow. Keep the derivatized samples in the dark by covering tubes with a thick black cloth or aluminum foil.

   The addition of FDNB results in the formation of N-DNP derivatives within 1 hr at room temperature and 4 hr at 4°C. The S-carboxymethyl and N-DNP derivatives are stable for at least 2 weeks at 4°C.

6. Purge HPLC system and begin running mobile phase (80% A/20% B) through the column at a flow of 1.0 ml/min. Maintain this flow rate throughout the gradient that follows.

   The system should be allowed to equilibrate for ~1 hr prior to loading samples.

7. Set up the gradient: from 0 to 8 min, use 80% A/20% B; from 8 to 28 min, use a linear gradient to a final ratio of 1% A/99% B. Hold the mobile phase at 99% B until the final compound, usually GSSG, has eluted.

   The gradient should be adjusted to give the best possible separation of peaks and may need to be lengthened as the column ages.

8. Remove samples from the refrigerator (4°C) and microcentrifuge 1 min at 13,000 × *g*, room temperature.

   Always centrifuge samples just prior to loading into manual or autosampler loops.

9. Rinse the stainless steel loop (total volume = 150 µl) of either a manual injector or an autosampler with 80% methanol using a 1-ml gas-tight syringe. Load 100 µl of the supernatant containing the *N*-DNP derivatives into the loop. Follow this with 20 µl of 80% methanol. Return samples to 4°C.

   Derivatized samples may be stored up to 2 weeks at 4°C.

   Figure 6.2.1 shows a representative HPLC chromatogram of a select mixture of DNP derivatives.

   It is important not to introduce air bubbles into the injector loop(s) and/or column.

10. Prepare a standard curve by running the same derivatization and HPLC gradient with various dilutions of 0.4 mM GSH and GSSG. Quantitate GSH and GSSG as well as other cellular thiols and disulfides in the biological samples by comparison with this standard curve.

    The samples for the standard curve may be prepared and derivatized in triplicate the day prior to the experiment using the reagents prepared for the experiment.

    A range of known quantities of the compounds of interest (GSH and GSSG), along with a constant amount of γ-Glu-Glu (10 to 20 nmol), are derivatized and analyzed by the HPLC/UV technique, and response factors are determined for the compounds. The response factors are then used to quantitate the compounds of interest in each sample.

    The use of internal standards in both samples and standards accurately corrects for alterations in derivatization efficiency and stability, chromatographic conditions (i.e., age of the lamp and/or column), and injection volumes.

DERIVATIZATION AND ANALYSIS OF GSH AND GSSG BY HPLC WITH FLUORESCENCE DETECTION

ALTERNATE PROTOCOL 1

Martin and White (1991) have modified the UV method in Basic Protocol 1 by reacting the *S*-carboxymethyl derivatives, formed following addition of IAA, with dansyl chloride rather than FDNB. The use of dansyl chloride to produce fluorescent derivatives of GSH and GSSG results in increased sensitivity as compared to the UV method, with detection limits for GSH and GSSG reaching 1 pmol and 2 pmol per injection on column, respectively. The drawback to this more sensitive method is that if derivatization with

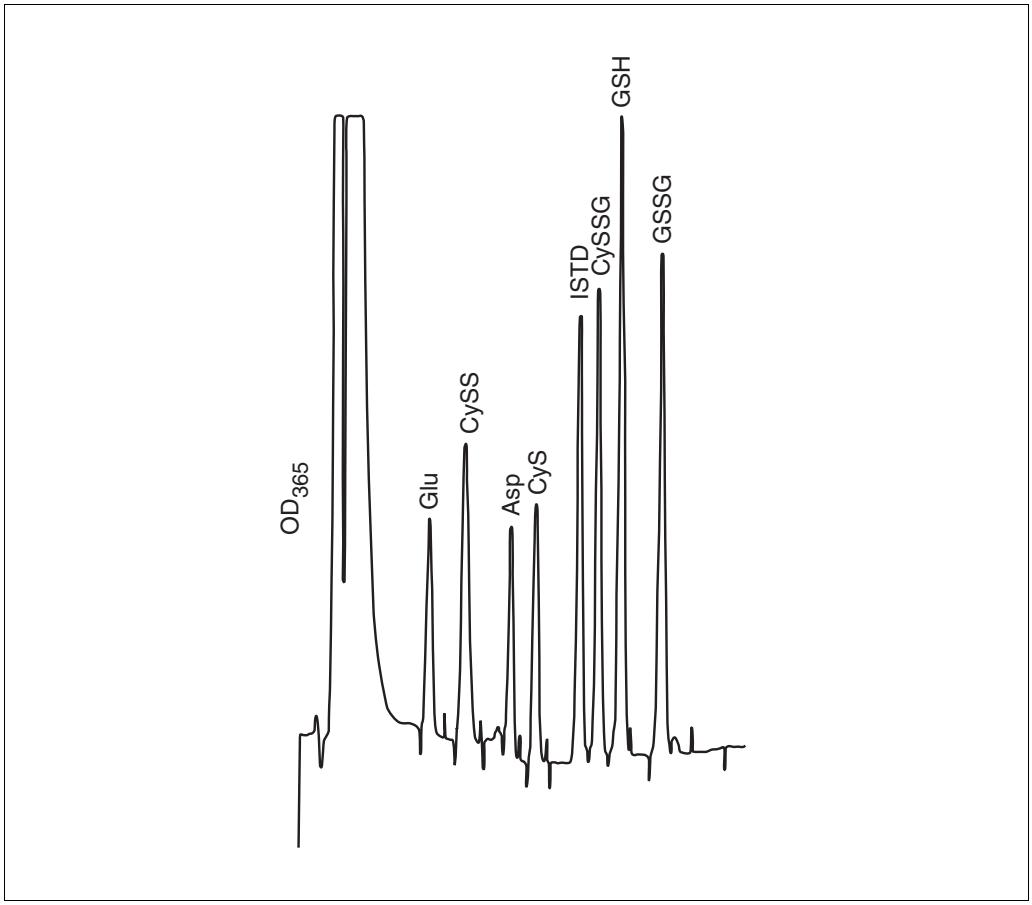

Figure 6.2.1 High-performance liquid chromatograph of a mixture of N-dinitrophenyl-S-carboxymethyl derivatives, including GSH and GSSG. Separation and UV detection were performed under conditions described in Basic Protocol 1. Abbreviations are defined in Table 6.2.1.

dansyl chloride is not complete, a portion of the GSSG is monodansylated and coelutes with the dansylated GSH. Such coelution makes the quantification of GSH and GSSG difficult. Jones et al. (1998) have evaluated the use of dansyl chloride to measure glutathione in human plasma.

Additional Materials *(also see Basic Protocol 1)*

PCA/DEPA indicator solution (see recipe)
1 mg/ml dansyl chloride in acetonitrile
2.0 M LiOH in metal-free water
50 mM IAA in metal-free water (make fresh daily)
0.1 mM γ-Glu-Glu (see recipe)
Fluorescence detector (Hewlett Packard model 1046A; 328 nm excitation and 541 nm emission)

1. Prepare samples (see Support Protocols 1, 2, and 3), replacing PCA/BPDS with PCA/DEPA indicator solution.
2. Remove 200 µl of the acid extract to a microcentrifuge tube.

   Samples should be derivatized in triplicate.
3. Add 5 µl of 0.1 mM γ-Glu-Glu and 20 µl IAA (50 mM).

   Using 0.2 M cresol purple instead of water eliminates the need for hourly preparation of the IAA solution.

4. Add sufficient 2 M LiOH to bring the pH into the range of 8 to 8.5. Vortex briefly and store in the dark for 30 min.

   The approximate amount of 2 M LiOH required may be determined empirically prior to the day of the experiment.

   A precipitate will form and the solution will become mauve in color following addition of LiOH.

   This procedure has been modified to decrease the presence of monodansylated GSSG and its interference with the accurate measurement of derivatized GSH (D. Jones, Emory University, pers. comm; Jones et al., 1998). This is accomplished by substituting 1 M KOH in saturated $K_2B_4O_7$ solution for 2 M LiOH. Sufficient KOH/$K_2B_4O_7$ solution is added to bring the pH of the sample to 9.0 ± 0.2.

5. Add an approximately equal volume of 1 mg/ml dansyl chloride to make a total sample volume of 500 µl. Place samples in the dark and store for 24 hr at room temperature.

   Samples may be stored up to 48 hr at 4°C prior to analysis.

6. Microcentrifuge 1 min at 13,000 × *g*, room temperature.

7. *Optional:* Remove excess dansyl chloride by extracting the derivatized sample with 500 µl of chloroform.

   Sensitivity may be increased by performing this step. (For details, see Martin and White, 1991.)

8. Analyze the supernatant (or the upper aqueous phase from the chloroform extraction, which will contain the dansyl glutathione adducts) on an HPLC system (see Basic Protocol 1, steps 6 to 10), using a fluorescence detector with an excitation wavelength of 328 nm and an emission wavelength of 541 nm.

   A modification of the elution has been reported (Jones et al., pers. comm.) in which the pH of solvent B is reduced to 4.6 (modified solution: 640 ml methanol, 200 ml stock sodium acetate solution, 125 ml glacial acetic acid, and 50 ml metal-free water) so that any monodansylated GSSG that is present will not coelute with the derivatized GSH.

DERIVATIZATION AND ANALYSIS OF GSH AND GSSG BY HPLC WITH ELECTROCHEMICAL DETECTION

ALTERNATE PROTOCOL 2

Electrochemical detection (EC) is the most recent advance for thiol quantification in biological samples. There are two general methods of EC detection, amperemetric and coulometric. Amperemetric methods reach limits of detection of 5 pmol per injection for both GSH and GSSG; however, limits of detection as low as 0.125 pmol GSH and 0.425 pmol GSSG per injection have been reported for coulometric methods using analytical cells with high sensitivity (Krien et al., 1992; Rose and Bode, 1995). EC methods are particularly useful in studies of extrahepatic tissues or cells where limited quantities of material are available. The method described here is based on that of Lakritz et al. (1997), in which the limits of detection have been demonstrated to be 1.63 pmol and 0.8 pmol per injection for GSH and GSSG, respectively.

Additional Materials *(also see Basic Protocol 1)*

Mobile phase: 50 mM NaH_2PO_4/0.05 mM octane sulfonic acid/2% (v/v) acetonitrile adjusted to pH 2.7 with phosphoric acid

200 mM methane sulfonic acid (MSA) containing 5 mM diethylenetriaminepentaacetic acid (DTPA)

Coulometric electrochemical detector with porous graphite electrodes (ESA model 5200, ESA)

Glass Dounce homogenizer

5-µm, 0.4 × 20–cm ODS2 HPLC column

1a. *For freshly dissected tissues:* Remove tissues from animal (see Support Protocol 1, steps 1 to 5) and quickly place fresh (unfrozen) tissue in 200 mM MSA/5 mM DTPA.

The volume of MSA/DTPA used is dependent on the amount of tissue available and the expected concentration of GSH/mg protein.

1b. *For cultured cells:* Scrape cultured cells into 200 mM MSA/5 mM DTPA (see Support Protocol 2, steps 1 to 4, substituting MSA/DTPA for PCA/BPDS).

MSA/DTPA solutions should be kept on ice.

2. Homogenize tissue or cells in 200 mM MSA/5 mM DTPA in a glass Dounce homogenizer.

Samples should be kept on ice during homogenization. The number of strokes depends upon the amount of tissues or cells, as well as whether homogenization is performed by hand or using a drill.

3. Centrifuge for 5 min at 14,000 × *g*, 4°C, and remove supernatant.

Supernatant can be stored at −80°C for subsequent replicate assays; samples are stable for up to 6 weeks.

Protein quantitation (Lowry et al., 1951) should be performed on the acid precipitate to determine the concentration of GSH, GSSG, or other thiol/disulfide of interest, per milligram protein.

4. Dilute supernatant (acid extract) 1:1 with mobile phase. Inject 10 µl onto the preequilibrated column and elute with mobile phase. Monitor elution with a coulometric electrochemical detector using the following settings: guard cell +950 mV, electrode 1 +400 mV, electrode 2 +880 mV.

The column should be equilibrated with mobile phase for 1 hr prior to loading.

Unlike in the two previous HPLC methods, an internal standard is not added to the samples. GSH and GSSG are quantified by use of a standard curve without the inclusion of an internal standard.

BASIC PROTOCOL 2

DERIVATIZATION AND ANALYSIS OF GSH AND GSSG BY ENZYMATIC DETECTION

The enzymatic recycling assay of Griffith (1980) is a modification of an assay developed by Tietze (1969). These assays are sensitive and specific for the quantification of "total glutathione" (GSH and GSSG, measured in GSH equivalents) in a sample; however, the assay must be performed twice on each sample in order to quantitate both GSH and GSSG. The method of Griffith is based on the oxidation of GSH by 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) to form GSSG and 5-thio-2-nitrobenzoic acid (TNB) coupled with reduction of GSSG to GSH by glutathione reductase in the presence of NADPH. The rate of TNB formation is proportional to the sum of GSH and GSSG present in the sample and is monitored at 412 nm. Quantification of GSSG is accomplished by derivatizing the GSH present in the sample with 2-vinylpyridine prior to enzymatic analysis, thus preventing GSH from participating in the reaction. The amount of GSH in the sample is then calculated by subtracting the value determined for GSSG from that determined for the sum of GSH and GSSG in the sample. Sian et al. (1997) demonstrated linearity to 16 pmol GSSG per cuvette using this method.

Materials

1% (w/v) picric acid
Stock buffer: 143 mM sodium phosphate and 6.3 mM sodium EDTA in metal-free water, pH 7.5
0.3 mM NADPH in stock buffer (prepare fresh daily and store at 4°C)

6 mM DTNB in stock buffer (store for 2 weeks at −20°C)
50 U/ml GSH reductase in stock buffer (store for 2 weeks at −20°C)
2-Vinylpyridine (Fluka; store at −20°C and use undiluted; replace if reagent becomes brown or viscous)
Triethanolamine
Spectrophotometer (412 nm; Alltech 200, Alltech)

1. Prepare samples (see Support Protocols 1, 2, and 3, substituting 1% picric acid for the PCA/BPDS protein precipitating reagent).

   CAUTION: *Use care when using picric acid in the laboratory. Picric acid, a component of explosives and matches, explodes when heated rapidly and by percussion. In addition, this reagent will stain skin, clothing, counters, and floors if allowed to come in contact with these surfaces.*

   Griffith (1980) suggests the use of 1% picric acid, rather than 5-sulfosalicylic acid as suggested by Anderson (1985), because it may eliminate the need for addition of triethanolamine (always check the pH of the acid extract).

   If a metal chelator, such as, EDTA or BPDS, is added to the acid of choice in this step, it must be determined that the chelator does not interfere with the enzymatic assay by running a control assay with and without chelator.

   Use aliquots of the supernatant of the picric acid extract for the determination of both total GSH and GSSG and the pellet for protein analysis.

2. For GSSG determination, add 100 µl of the acid extract supernatant to a microcentrifuge tube, followed by 2 µl of 2-vinylpyridine. Cap and vortex.

3. Check the pH of the extract/2-vinylpyridine solution. If it is not >5.5, add a sufficient volume of triethanolamine to bring the pH up to between 6 and 7.

   Do not increase the pH above 7.0.

   Triethanolamine is difficult to pipet because of its viscosity. Griffith suggests using an 8-µl Drummond Microcap to deliver up to 6 µl of this compound. Add the triethanolamine to the inside of the microcentrifuge tube above the level of the sample/standard, cap, and vortex vigorously.

4. Allow the samples to derivatize for 60 min at room temperature.

5. During the above incubation period, add 700 µl of 0.3 mM NADPH, 100 µl of 6 mM DTNB, and an aliquot of picric acid extract to a test tube. Add metal-free water to a total volume of 1 ml.

   For example, if sample volume is 100 µl, add 100 µl of water. These samples will be used for total glutathione determination.

6. Warm test tubes from step 5 in a 30°C water bath for 10 to 15 min.

7. Transfer the mixture from one test tube to a cuvette containing 10 µl of 50 U/ml GSH reductase and monitor A_{412} continuously until it exceeds 2.0 absorbance units. Continue for all samples.

   The rate of TNB formation is usually linear between 1 and 2 absorbance units.

8. Repeat steps 5 to 7 using the GSSG samples from step 4.

   The derivatized samples are used to determine oxidized glutathione (GSSG).

   2-vinylpyridine may separate from the aqueous sample during the derivatization period; however, do not mix the samples prior to removing the aliquot for analysis.

9. Generate a standard curve using known amounts of GSH dissolved in the protein precipitating agent (1% picric acid) and processed as described in steps 5 to 7. Quantify total glutathione by comparing the underivatized samples to this curve.

   All points on the standard curve should be run in triplicate.

10. Generate a second standard curve using GSSG (dissolved in the protein precipitating reagent) treated with both 2-vinylpyridine (60-min derivatization) and triethanolamine (if used in the samples) prior to enzymatic analysis. Quantify GSSG by comparing derivatized samples to this curve.

    All points on the standard curve should be run in triplicate. GSH levels are determined by subtracting the results from step 10 from the results in step 9.

    Recently, Eady et al. (1995) reported that they were unable to determine GSH levels in some of their cell lines by the Tietze enzymatic recycling method due to the presence of an inhibitory agent that was not identified. Therefore, when using enzymatic assays, it is important to determine if inhibitory agents are present in the samples to be assayed. This can be determined by supplementing cell extracts with known quantities of GSH and assaying both the GSH-supplemented and -unsupplemented cell extracts by the Tietze enzymatic method (Eady et al., 1995).

SAMPLE PREPARATION FOR ANALYSIS OF GSH AND GSSG

Support Protocols 1, 2, and 3 describe the preparation of samples from different sources—tissues, monolayer cells, and hepatocytes—for the determination of intracellular GSH and GSSG. While these protocols have been written with Basic Protocol 1 in mind, they may be modified for use with any of the basic or alternate protocols.

NOTE: Consult Basic Protocols 1 and 2 and Alternate Protocols 1 and 2 to determine the appropriate reagents for preparing the acid extract.

SUPPORT PROTOCOL 1

Preparation of Samples from Freshly Dissected Tissues

Tissue is dissected from the animal and frozen in liquid nitrogen. It is then pulverized, refrozen, and extracted with acid. A modification of this procedure has been developed for the measurement of mitochondrial thiols (Reed, 1994).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Animal to be used for tissue studies
1 g/ml sodium pentobarbital
0.9% saline (NaCl; *APPENDIX 2A*) in metal-free water, prewarmed to 37°C
Liquid nitrogen
PCA/BPDS (see recipe)

Peristaltic pump (Barnant 72501-000, VWR)
5-ml cryogenic specimen containers (Nalgene, Fisher)
Mortar and pestle
Ultrasonic cell disrupter (Cole Parmer 4710, Cole Parmer)

1. Anesthetize animal with sodium pentobarbital at a dose of 60 mg/kg body weight (i.p.; dosage determined for rats).
2. Open the abdominal and thoracic cavities and draw blood from either the heart or the inferior vena cava to euthanize the animal.

   Draw blood from the same source for all animals. This blood may be used in assays, if desired.

3. Insert tubing attached to a peristaltic pump into the hepatic portal vein and perfuse the liver with 37°C saline.

4. Remove the liver and, while holding it above a liquid nitrogen–filled cryogenic container, quickly slice the liver into several pieces with scissors, allowing the pieces to fall into the container. Replace the lid on the cryogenic container and store samples in liquid nitrogen or at −70°C for up to 24 hr.

5. Remove additional organs of interest from the anesthetized animal. Rinse each organ with 0.9% NaCl and place it in a cryogenic container filled with liquid nitrogen. Replace lid and store as for liver samples.

   Tissues with high levels of γ-glutamyl transpeptidase, such as kidney and pancreas, should not be frozen and stored in liquid nitrogen, but must be homogenized immediately in PCA/BPDS following removal from the body in order to prevent the loss of both GSH and GSSG (Anderson, 1985; Potter and Tran, 1993). Following homogenization of fresh tissue in PCA, skip to step 9 below.

6. Pour a small amount of liquid nitrogen into a large mortar and pulverize the frozen tissue samples to a fine powder with a pestle. Return the powdered sample to the cryogenic container and store in liquid nitrogen or at −70°C until ready to begin step 7.

   Do not allow the sample to thaw until it has been added to the PCA/BPDS solution.

7. Weigh 50 to 100 mg of the frozen, powdered tissue into a microcentrifuge tube containing 1 ml PCA/BPDS.

   Prompt addition of PCA/BPDS to frozen biological specimens is essential to the rapid termination of metabolic processes and to the prevention of thiol oxidation in tissues, cells, cell organelles, and fluids.

   BPDS has excellent copper- and iron-chelating properties and is used instead of EDTA, because EDTA interferes with the HPLC measurement of GSSG.

8. Sonicate the sample on ice for 30 sec using a power setting of 4.5.

9. Freeze the sonicated, homogenized sample in liquid nitrogen and allow it to thaw on ice.

10. Microcentrifuge the thawed sample 3 min at 15,000 × *g*, room temperature. Remove the supernatant (acid extract) and proceed directly to derivatization for determination of acid-soluble sulfur-containing compounds, i.e., GSH, GSSG, and sulfur-containing amino acids (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2).

    The protein precipitate can be used for the quantification of proteins and protein-mixed disulfides or DNA.

    Work by Roberts and Francetic (1993) suggests that the acid extract can also be stored up to 12 months at −70°C before derivatization.

Preparation of Samples from Cultured Cells

SUPPORT PROTOCOL 2

Cultured adherent cells are being used in an increasing number of studies investigating the role of both GSH and GSSG in normal cell growth, metabolism, and death, as well as the role of GSH in protection from exogenously caused oxidative damage. As with tissues, it is important to stop all metabolic activity in the cell monolayer as quickly as possible. Scraping cell monolayers from dishes directly into PCA/BPDS has been found to give the highest yields and most reproducible results for GSH in cell culture as compared to trypsinization or scraping monolayer cells into PBS (Thioudellet et al., 1995; D.J. Mustacich and D.J. Reed, unpub. observ.).

Materials

Cultured adherent cells
PBS (*APPENDIX 2A*), ice cold
PCA/BPDS (see recipe)

1. Remove medium from tissue culture dish and rinse cell monolayers with 5 ml ice-cold PBS.
2. Remove the PBS and rinse cells a second time with another 5 ml ice-cold PBS.
3. Determine the total amount of PCA/BPDS to be used and immediately add half of this amount to the monolayer.

   The amount of PCA/BPDS is often in the range of 1 to 5 ml but will need to be adjusted depending on the cell number and level of GSH in control cells.
4. Scrape the cells from the dish while covered with PCA/BPDS and transfer suspended cells to a 15-ml (or other appropriately sized) conical centrifuge tube.
5. Repeat steps 3 and 4 with the second half of the PCA/BPDS, and pool both suspensions.
6. Sonicate the cell suspension on ice for 30 sec using a power setting of 4.5 and centrifuge 5 min at 10,000 × *g*, 4°C.
7. Remove the supernatant (acid extract). Proceed immediately to derivatization (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2) or store extract at −70°C until derivatized.

   Since cell counts cannot be performed on cells scraped directly into PCA/BPDS, proteins should be quantitated on the precipitated pellet for determination of GSH and other thiols per milligram protein.

SUPPORT PROTOCOL 3

Preparation of Sample from Hepatocytes

Experiments utilizing isolated hepatocytes (see Farris et al., 1985, for preparation of isolated hepatocytes) to investigate the mechanism(s) of chemical toxicity and cell death require separation of viable cells from nonviable cells to distinguish events that result in cell death from those that result from cell death. Figure 6.2.2 illustrates a technique used to separate viable from nonviable cells and terminate metabolic processes and thiol oxidation in one quick step (Farris et al., 1985).

Materials

PCA/BPDS (see recipe)
Dibutyl phthalate (Sigma)
Isolated hepatocytes

1. Add 0.55 ml PCA/BPDS to a 2.0-ml microcentrifuge tube.
2. Carefully layer 0.45 ml dibutyl phthalate (d = 1.046) over the PCA/BPDS (d = 1.06) and centrifuge 1 min at 13,000 × *g*, room temperature.
3. Carefully layer 0.75 ml of isolated hepatocyte suspension over the dibutyl phthalate layer.
4. Microcentrifuge 1 min at 13,000 × *g*, room temperature.

   This results in viable hepatocytes being forced through the dibutyl phthalate layer into the PCA/BPDS, which lyses the hepatocytes, thereby releasing the intracellular contents of the hepatocytes into the PCA/BPDS layer. The medium and nonviable cells remain above the dibutyl phthalate layer.
5. Remove a portion of the PCA/BPDS layer. Either derivatize immediately (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2) or store at −70°C until derivatized.

   As shown in Figure 6.2.2, intracellular GSH and GSSG, as well as other cellular thiols and disulfides, are located in the PCA/BPDS layer (bottom layer).

   Extracellular constituents, such as GSH and GSSG, may be measured by derivatizing the medium that remains above the dibutyl phthalate layer (Fig. 6.2.2).

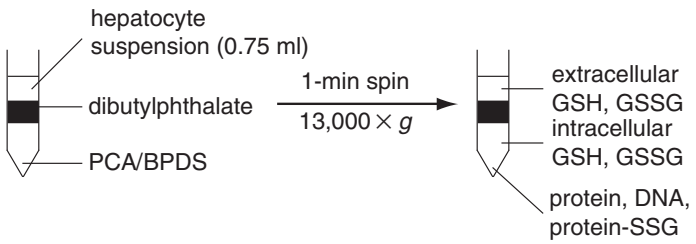

Figure 6.2.2 Analysis of intracellular contents and cell viability by the dibutyl phthalate separation method. PCA, perchloric acid; GSH, glutathione; GSSG, glutathione disulfide; protein-SSG, protein-glutathione mixed disulfide.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

γ-Glutamyl-glutamate (γ-Glu-Glu), 0.1 mM

Prepare a stock solution of 4 mM γ-Glu-Glu in water containing 15 mM bathophenanthrolinedisulfonic acid (BPDS). This can be made in a quantity of 5 ml or more and then divided into aliquots of 25 µl (in microcentrifuge tubes) and stored at −20°C indefinitely. On the day of the experiment, remove one or more tubes and add 975 µl PCA/BPDS (see recipe) to each tube. Vortex and place on ice.

Make fresh working samples immediately prior to use.

γ-Glutamyl-glutamate (γ-Glu-Glu), 0.4 mM

Prepare a stock solution of 4 mM γ-Glu-Glu in water containing 15 mM bathophenanthrolinedisulfonic acid (BPDS). This can be made in a quantity of 5 ml or more and then divided into aliquots of 100 µl (in microcentrifuge tubes) and stored at −20°C indefinitely. On the day of the experiment, remove one or more tubes and add 900 µl PCA/BPDS (see recipe) to each tube. Vortex and place on ice.

Make fresh working samples immediately prior to use.

GSH (reduced glutathione), 0.4 mM

Prepare a stock solution of 4 mM GSH (free acid) in water containing 15 mM bathophenanthrolinedisulfonic acid (BPDS). Dilute 1:10 in PCA/BPDS (see recipe) to obtain working solution.

Make both solutions immediately prior to derivatization of standard curve.

GSSG (oxidized glutathione), 0.4 mM

Prepare a stock solution of 4 mM GSSG (free acid) in water containing 15 mM bathophenanthrolinedisulfonic acid (BPDS). Dilute 1:10 in PCA/BPDS (see recipe) to obtain working solution.

Make both solutions immediately prior to derivatization of standard curve.

Iodoacetic acid (IAA) in 0.2 mM m-cresol purple, 100 mM

Make a 0.2 mM solution of *m*-cresol purple by dissolving 8.1 mg *m*-cresol purple in 10 ml water. Dissolve 20.8 mg iodoacetic acid (sodium salt) in 1 ml of the 0.2 mM *m*-cresol purple to make a 100 mM solution. Store in the dark in a container designed for light-sensitive compounds for up to 1 week at 4°C.

The use of m-cresol purple in the IAA solution not only functions as a pH indicator but also acts as a preservative. Iodoacetic acid dissolved in m-cresol purple maintains alkylating activity for at least 7 days at 4°C.

$KOH/KHCO_3$ solution

Make 10 M KOH by dissolving 56.1 g KOH in 100 ml water. Make 3 M $KHCO_3$ by dissolving 60.1 g $KHCO_3$ in 200 ml water. Combine 40 ml of 10 M KOH with 160 ml of 3 M $KHCO_3$. Store up to 1 week at room temperature.

Mobile phase A

Add 800 ml water to 3.2 liters methanol (HPLC grade).

It is important to always make the mobile phases in the same manner. The solution may be made up to 24 hr in advance and stored at room temperature.

Mobile phase B

Make a 4.0 M sodium acetate stock solution by adding 544 g sodium acetate trihydrate to 224 ml water, then add 756 ml glacial acetic acid. Stir solution over low heat until sodium acetate is in solution. Allow stock solution to cool, then add 800 ml of the stock sodium acetate solution to 3.2 liters of 80% methanol (mobile phase A; see recipe). Mix and filter with a 0.45-μm polypropylene filter.

Store the stock sodium acetate solution at room temperature for up to 1 month. Mobile phase B may be made up to 24 hr in advance and stored at room temperature.

PCA/BPDS

Make a 10% (v/v) solution of perchloric acid (PCA) in water by diluting 70% PCA commercial stock. Dissolve 53.65 mg bathophenanthrolinedisulfonic acid (BPDS) in 100 ml of the 10% PCA to create a 1 mM solution. Store at 4°C. Make fresh weekly.

PCA/DEPA

35.7 ml 70% (v/v) perchloric acid (PCA; 5% final)
0.393 g diethylenetriaminepentaacetic acid (DEPA; 0.2 M final)
6.2 g boric acid (0.2 M final)
2.5 mg cresol red indicator (5 mg/ml final)
H_2O to 500 ml
Store at 4°C. Make fresh weekly.

COMMENTARY

Background Information

Glutathione, the most abundant low-molecular-weight nonprotein thiol found in cells, exists mainly in the reduced state (GSH), with <5% of the total existing as glutathione disulfide (GSSG) under normal physiologic conditions. The GSH/GSSG redox cycle, one of the major endogenous antioxidant systems, protects cells from injurious events resulting from exposure to toxic chemicals, as well as the normal oxidative products of cellular metabolism. The large GSH/GSSG ratio creates a challenge for detection, since very low levels of GSSG need to be accurately determined, and oxidation of GSH to GSSG has to be prevented during sample preparation and derivatization. This is particularly important in studies where alterations in the GSH/GSSG ratio resulting from the presence of endogenous or exogenous compounds are being determined over time. In Basic Protocol 1, thiol oxidation and thiol-disulfide interchange are inhibited during sample preparation and derivatization by (1) the prompt treatment of biologic samples with perchloric acid (PCA) containing a metal chelator (BPDS), (2) the continued presence of BPDS during derivatization, and (3) the instantaneous pH change in the presence of iodoacetic acid (IAA) resulting in the rapid formation of *S*-carboxymethyl derivatives of GSH.

Over the years, analytical methods of glutathione quantification have reflected the demands of current research. Sample preparations with acid extract concentrations of GSH in the micromolar range are easily analyzed with enzymatic or HPLC/UV detection techniques. However, there has been increasing emphasis on measuring the GSH/GSSG ratio within subcellular organelles and extrahepatic tissues. Some of these samples require more sensitive detection methods due either to the low levels of GSH and/or GSSG present or to small sample size.

Analysis of GSH, GSSG, and other sulfur-containing compounds by HPLC/UV is appropriate for freshly dissected tissues (see Support Protocol 1), cultured cells (see Support Protocol 2), hepatocytes (see Support Protocol 3), mitochondrial preparations, serum, and plasma (see Farris and Reed, 1987). However, this method should not be used for the measurement of GSSG in whole blood. A modification of the Farris and Reed method for measuring GSSG in whole blood has been developed in which *N*-ethylmaleimide (NEM) rather than IAA is used to prevent GSH oxidation (Asensi et al., 1994). However, the NEM method cannot be used for GSSH quantification because the GSH-NEM adduct decomposes, resulting in the formation of three separate HPLC peaks. In order to accurately measure both GSSG and GSH in whole-blood samples, a second method must be used for the measurement of GSH. The glutathione-*S*-transferase assay for GSH, developed by Brigelius et al. (1983), can be used in combination with the NEM method for the determination of both GSH and GSSG in whole blood.

Critical Parameters and Troubleshooting

One of the most important determinants of accurate assessment of the GSH/GSSG ratio is fast and careful sample preparation and derivatization. As discussed in Support Protocol 1, tissue samples with low levels of γ-glutamyl transpeptidase (such as liver, heart, brain, and spleen) may be frozen in liquid nitrogen and stored at −70°C for 24 hr prior to derivatization. However, tissues and cells containing high levels of γ-glutamyl transpeptidase (such as kidney) need to be homogenized immediately, without freezing, in PCA/BPDS in order to avoid enzymatic degradation. In addition, derivatized samples should be maintained in the dark at all times by covering them with a thick black cloth or aluminum foil.

When selecting a method, it is important to verify its ability to quantify the thiol or disulfide of choice in the system being studied. To this end recovery studies should be performed in which known amounts of the thiol of interest are added to samples at levels similar to endogenous levels. The thiol is then quantified in both supplemented and unsupplemented samples and percent recovery of the thiol is determined. For the methods described in this unit, recovery should be at least 90%.

The addition of GSH to a sample during acid precipitation, followed by derivatization and quantification of both GSH and GSSG in supplemented and unsupplemented samples, can be used to determine the extent to which GSH is being oxidized to GSSG during the procedure. Farris and Reed (1987) determined that <0.7% of GSH is converted to GSSG during sample preparation and derivatization with their method, and suggest that GSSG levels be corrected for this oxidative artifact. Furthermore, AT125 (acivicin), an inhibitor of γ-glutamyl transpeptidase, can be used to determine the extent to which GSH may be being enzymatically degraded in the system of choice during preparation (Reed and Ellis, 1982).

Finally, a coefficient of variance should be determined for the selected assay by quantifying the thiol of choice in replicate samples (five or more replicates per sample). The coefficient of variance should be <10% for all of the protocols described here.

Anticipated Results

GSH and GSSG levels will vary depending on the species, cell or tissue type, and/or subcellular organelle chosen for study. Most mammalian cells contain GSH at millimolar concentrations; therefore, the amount of material available may determine which assay is chosen for a particular study. The UV method described here has been used for the analysis of most of the organs in the rat and mouse, as well as mitochondrial preparations from liver, kidney, and lung. The limits of detection for each method are given in the protocol introductions.

Time Considerations

Many of the reagents for these assays can be made in advance. In addition, separate tubes should be labeled for the various steps in the procedure the day before the experiment (cryo containers for tissue samples to be frozen, and microcentrifuge tubes for the acid precipitation and derivatization procedures). Finally, the standard curve samples may be prepared and derivatized the day before the experiment using the reagents prepared for the experiment. Depending on the number of samples to be analyzed, preparation for the experiment may require 4 to 6 hr the first time the assay is performed. This time includes making the reagents and mobile phases and setting up and derivatizing the standard curve. Sample preparation time on the day of the experiment will vary with the choice of biologic material. The removal of organs from an anesthetized animal takes minutes, while preparation of hepatocytes requires 1 to 2 hr. HPLC analysis by the UV method

may take 35 to 45 min per sample depending on the age of the column; therefore, use of an autosampler is recommended, particularly if large numbers of samples will be analyzed.

Measurement of Glutathione Transport

The development of methods for accurately measuring the transport of glutathione (GSH) or any metabolite across cellular membranes requires that compartments be efficiently separated. Although some contamination of the space of interest (e.g., intracellular space) is usually unavoidable, quantification of this contamination is critical so that corrections can be made. With GSH as the transport substrate, the redox status of the molecule must be maintained during transport incubations and sample processing. The thiol group of the GSH cysteinyl residue can be readily oxidized in extracellular compartments, either by oxidases or by auto-oxidative processes, particularly in alkaline compartments. In addition, the g-glutamyl residue can be cleaved by g-glutamyltransferase (GGT; EC 2.3.2.2), which is present in large excess in lumenal membranes of several epithelial tissues, such as the renal proximal tubule and small-intestinal epithelium. This oxidation and degradation must be prevented to accurately quantitate the content of GSH in different compartments.

This unit will describe methods for measuring GSH transport into renal proximal tubular cells (see Basic Protocol 1 and Alternate Protocol 1) and into renal cortical mitochondria (see Basic Protocol 2 and Alternate Protocol 2). While these procedures generally apply to measurement of GSH transport in cells or subcellular fractions from other tissues, properties of the kidneys most clearly illustrate the need for appropriate procedures to measure GSH flux accurately. Methods are described for rapidly stopping transport processes at specified times, isolating proximal tubule cells (Support Protocol 1), separating compartments by filtration or centrifugation procedures (Support Protocol 2), quantification of the volume of transport compartments and contaminating space (Support Protocol 4), and ensuring the integrity of the transported substrate by HPLC (Support Protocol 3; also see *UNIT 6.2*). Other methods for incubation and analysis of GSH transport in renal mitochondria have been previously described (Lash, 1995).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (see *APPENDIX 1A*).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

MEASUREMENT OF GSH UPTAKE IN PROXIMAL TUBULAR CELLS FROM RAT KIDNEY

BASIC PROTOCOL 1

This protocol describes a procedure for quantifying GSH uptake by renal proximal tubular (PT) cells. Two critical points in the accurate determination of flux of GSH across renal plasma membranes are that: (1) GSH be neither significantly oxidized nor degraded during transport incubations or sample processing; and (2) contamination of intracellular space with material from the extracellular space be minimized or accounted for so that corrections can be made. The first point is addressed by pretreating cells with acivicin, which is an irreversible inhibitor of GGT (Reed et al., 1980), and by adding an antioxidant during sample processing to prevent auto-oxidation. The second point is addressed by rapid centrifugation of cells through Percoll and monitored by quantifying extracellular volume using a radiolabeled, impermeable solute (i.e., [^{14}C]sucrose; see Support Protocol 4). The following protocol may be used for measuring GSH uptake at incubating concentrations of 0.5 mM or higher using HPLC analysis. A more sensitive method for measuring GSH uptake using radiolabeled substrate is presented in Alternate Protocol 1, which can be used with GSH concentrations as low as 1 μM.

Contributed by Lawrence H. Lash

Current Protocols in Toxicology (1999) 6.3.1-6.3.14

Materials

10× acivicin stock solution (see recipe)
Freshly isolated renal PT cell suspension in 25-ml polypropylene Erlenmeyer flasks (see Support Protocol 1)
10× GSH stock solution (see recipe)
p-aminohippurate (PAH; Sigma)
p-[glycyl-1-,^{14}C]-aminohippuric acid (40 to 60 mCi/mmol; NEN Life Science)
20% (v/v) Percoll (Sigma) in 0.9% (w/v) NaCl
Normal saline: 0.9% (w/v) NaCl (*APPENDIX 2A*)
70% (v/v) perchloric acid
1.5 mM L-γ-glutamyl-L-glutamate (Sigma; prepare fresh in deionized water)
1.5 mM bathophenanthroline disulfonate (Sigma; prepare fresh in deionized water)

25-ml polypropylene Erlenmeyer flasks (e.g., Nalgene)
Dubnoff shaking metabolic incubator (Precision Scientific)
1.5-ml polyethylene microcentrifuge tubes

Treat cells to inhibit GGT activity

1. Add 1 vol of 10× acivicin stock solution to 9 vol renal PT cells (1–5 × 10^6 cells/ml) in a 25-ml polypropylene Erlenmeyer flask.

   Total volume in Erlenmeyer flasks should not exceed 3.0 ml. The final concentration of acivicin is 0.25 mM. Typically, one rat will yield sufficient cells for three to five incubations.

2. Incubate on a Dubnoff metabolic shaking incubator for 15 min at 60 cycles/min, 37°C.

3. Keep cells on ice until needed for transport experiments.

Perform transport incubations

4. In 25-ml Erlenmeyer flasks, gently mix 9 vol of acivicin-pretreated, renal PT cell suspension with 1 vol 10× GSH stock solution.

   Total volume should not exceed 3.0 ml.

   It is important to include a control for measurement of GSH transport in renal proximal tubular cells to demonstrate that the cells are functioning properly. This is accomplished by measuring the transport of a well-characterized substrate, such as p-aminohippurate (PAH). Substitute 1 mM PAH containing 0.1 μCi of p-[glycyl-1-,^{14}C]-aminohippuric acid for the 10× GSH stock solution and process as with the test samples. After step 8, measure radioactivity as described in Alternate Protocol 1, steps 2 to 4, using the ^{14}C channel.

5. Incubate on a Dubnoff shaking metabolic incubator at 60 cycles/min, 37°C.

6. At specified incubation time points (e.g., 1, 2, 3, 5, 10, 15, 20, and 30 min), remove 0.5-ml aliquots and layer on top of 1.0 ml of 20% Percoll in 1.5-ml microcentrifuge tubes at room temperature.

Measure transport

7. Immediately microcentrifuge each sample for 30 sec at 13,000 × *g*, room temperature.

8. Completely remove supernatant with a Pasteur pipet and drain tube dry.

9. Resuspend cell pellets in 0.5 ml normal saline. Add 0.1 ml of 70% (v/v) perchloric acid, 0.05 ml of 1.5 mM L-γ-glutamyl-L-glutamate, and 0.05 ml of 1.5 mM bathophenanthroline disulfonate. Mix vigorously on a vortex mixer.

10. Place 0.5 ml of the acid extract from step 9 into a new 1.5-ml microcentrifuge tube. Store on ice until ready for HPLC analysis of GSH content (see Support Protocol 3).

MEASUREMENT OF GSH TRANSPORT USING RADIOLABELED GSH

ALTERNATE PROTOCOL 1

A more sensitive method of measuring GSH transport uses radiolabeled GSH. This assay can be used with GSH concentrations as low as 1 μM.

Additional Materials *(also see Basic Protocol 1)*

10× GSH stock solution (see recipe) containing 0.01 μCi/ml L-[^{3}H]glycyl-GSH (20 to 50 Ci/mmol; NEN Life Science)
5-ml polyethylene scintillation vials

1. Pretreat PT cells with acivicin and perform time course of incubation with GSH (see Basic Protocol 1, steps 1 to 8), except use 1 vol 10× GSH stock solution containing 0.01 μCi/ml of L-[^{3}H]glycyl-GSH per vol cell suspension, instead of the solution containing cold GSH alone.

   [^{35}S]GSH may be used instead of the ^{3}H-labeled compound.

2. Resuspend each cell pellet in 0.5 ml normal saline. Add 0.1 ml of 70% (v/v) perchloric acid and 0.1 ml of normal saline, then mix vigorously on a vortex mixer.

3. Place 0.5 ml of the acid extract from step 2 in a 5-ml polyethylene scintillation vial.

4. Add 2 ml of scintillation fluid and determine radioactivity by liquid scintillation counting using the ^{3}H channel.

5. Calculate the amount of GSH transported by the following equation:

$$\frac{\text{cpm}}{\text{counting efficiency}} \times \text{dilution factor (ml}^{-1}) \times \text{specific activity (mol/Ci)} \times \frac{1\ \text{Ci}}{2.22\times10^{12}\ \text{cpm}} \times \frac{1\ \text{ml}}{y\times10^{6}\ \text{cells}} = \text{mol GSH transported}/10^{6}\ \text{cells}$$

   where cpm is the result from scintillation counting (see step 4) and *y* (multiplied by 10^6) is the original number of cells in the assay (see step 1).

   The dilution factor is obtained by considering the dilution of the cells during acivicin pretreatment (10/9), the dilution in the incubation (10/9), and the portion sampled for measurement (1/0.5 = 2). Hence, using the dilutions described above, the overall sample dilution = 2.469 ml $^{-1}$ cells.

ISOLATION OF PT CELLS FROM RAT KIDNEY

SUPPORT PROTOCOL 1

This protocol is used to isolate proximal tubule cells from the rat kidney for GSH transport studies. Perfused kidneys are treated with collagenase to release PT cells, which are collected after Percoll gradient centrifugation (Lash and Tokarz, 1989; Lash, 1996).

Materials

Rats (Sprague-Dawley or Fisher 344, 2- to 4-month-old males or 2.5- to 6-month-old females, 175 or 250 g body weight)
50 mg/ml sodium pentobarbital in saline
0.2% (w/v) heparin
Perfusion buffer: Hanks' balanced salt solution (HBBS; *APPENDIX 2A*) without calcium and with 0.12 mM magnesium and 0.5 mM EGTA
Collagenase solution (see recipe)
1× Krebs-Henseleit buffer (see recipe)
45% (v/v) Percoll (Sigma) in HBSS (*APPENDIX 2A*) without calcium and with 0.12 mM magnesium
HBSS (*APPENDIX 2A*) without calcium and with 0.12 mM magnesium

Surgical instruments
4-O silk ligatures
Peristaltic perfusion pump (e.g., MasterFlex), tubing, and cannulas (MasterFlex size 16 to give 0.2 to 20 ml/min; 19-G, cone-shaped)
50-ml round-bottom polycarbonate centrifuge tubes
Sorvall RC-2B or equivalent centrifuge
25-ml polypropylene Erlenmeyer flasks (e.g., Nalgene)
Rubber serum-bottle stoppers (Fisher or VWR)
95% O_2/5% CO_2 gas cylinder with regulator valve

1. Anesthetize rats with an intraperitoneal injection of sodium pentobarbital (0.1 ml of a 50 mg/ml solution in saline per 100 g body weight). Prevent blood clotting by injecting 0.2 ml of 0.2% (w/v) heparin into the tail vein just before surgery.
2. Open the peritoneal cavity by making a midventral incision and free the aorta from the surrounding connective tissue and the adjacent inferior vena cava. Place a 4-O silk ligature around the aorta approximately 0.5 inches below the renal artery and a second ligature around the aorta as high up in the abdomen as possible. Ligate the celiac and superior mesenteric arteries to prevent diversion of perfusate.
3. Make an oblique incision through approximately 50% of the diameter of the aorta above the lower ligature, then insert a cone-shaped 19-gauge cannula into the aorta. Secure the cannula with a new ligature.
4. Perfuse kidneys in situ with 37°C perfusion buffer for 10 min at 5 ml/min with recirculation. Remove the kidneys and euthanize the animal by bilateral pneumothorax and exsanguination.
5. Transfer kidneys to a beaker containing 50 ml of 37°C collagenase solution and perfuse with recirculation for 15 to 18 min at 8 ml/min.
6. Remove kidneys from collagenase and release cortical cells into 40 ml fresh 1× Krebs-Henseleit buffer by removing the renal capsule and connective tissue with scissors and gently squeezing with forceps.

   Cortical cells, although primarily of proximal tubular origin, also contain cells from other nephron segments, including the distal convoluted tubules, cortical collecting tubules, and cortical collecting duct. To obtain an enriched preparation of proximal tubular cells, further processing is required (see steps 7 to 9).

7. Layer 5 ml of renal cortical cell suspension on top of 35 ml of 45% Percoll solution in a 50-ml round-bottom, polycarbonate centrifuge tube and centrifuge 30 min at 20,500 × *g*, 0° to 4°C.
8. Harvest the top 8 ml of the gradient (containing the cells), free pool cells from all gradients, and dilute pooled suspension 5-fold with calcium-free and low-magnesium HBSS. Centrifuge in a tabletop centrifuge 5 min at 1000 × *g*, room temperature, and decant the supernatant to remove Percoll.
9. Resuspend cell pellet in Krebs-Henseleit buffer to a concentration of 2–5 × 10^6 cells/ml and place 2- to 3-ml aliquots in 25-ml polypropylene Erlenmeyer flasks. Purge the flasks for 1 min with 95% O_2/5% CO_2, and seal with rubber serum-bottle stoppers. Keep on ice until used for experiments.

   Degree of purity or enrichment of the PT cell preparation can be assessed by measurement of marker enzymes or functional responses (Lash and Tokarz, 1989). Marker enzymes for PT cells include γ-glutamyltransferase and alkaline phosphatase, both of which are present on brush-border membranes and are at high activities in PT cells but very low in other nephron cell types. Hexokinase can be measured as a distal tubular cell marker and should be present at very low activity in PT cells. Cellular respiration in PT cells, which can be measured with a Clark-type oxygen electrode, should be stimulated by addition of succinate

or other citric acid cycle intermediates. In contrast, these metabolites do not affect cellular oxygen consumption in other nephron cell types, because they are not transported across the plasma membranes in those cells.

MEASUREMENT OF GSH UPTAKE IN SUSPENSIONS OF MITOCHONDRIA FROM RAT KIDNEY CORTEX

BASIC PROTOCOL 2

The incubation protocol described below is for measurement of uptake of GSH by mitochondria at an incubation concentration of 0.5 mM or higher using HPLC analysis. For measurement of lower concentrations, see Alternate Protocol 2.

Materials

10× acivicin stock solution (see recipe)
Freshly isolated mitochondrial suspension from rat renal cortical homogenates (1 to 3 mg protein/ml; see Support Protocol 2)
50 mM dithiothreitol (DTT) in mitochondrial isolation buffer (prepare fresh)
Mitochondrial isolation buffer (see recipe)
Metabolite (optional; e.g., malate or 2-oxoglutarate)
10× GSH stock solution (see recipe)
Extraction solution (see recipe)

25-ml polypropylene Erlenmeyer flasks (e.g., Nalgene)
1.5-ml polyethylene microcentrifuge tubes
Dubnoff shaking metabolic incubator (Precision Scientific)
Centrifuge capable of delivering 10,000 × *g*

Pretreat mitochondria to inhibit GGT activity

1. Add 1 vol 10× acivicin stock solution and 1 vol 50 mM DTT to 8 vol renal cortical mitochondrial suspension (1 to 3 mg protein/ml) in 25-ml polypropylene Erlenmeyer flasks.

   Total volume in Erlenmeyer flasks should not exceed 3.0 ml. The final concentration of acivicin is 0.25 mM. Typically, one rat will yield sufficient cells for 3 to 5 incubations.

2. Incubate on a Dubnoff metabolic shaking incubator for 15 min at 60 cycles/min, 25°C.
3. Keep mitochondrial suspensions on ice until needed for transport experiments.

Perform transport incubations

4. *To measure exchange of GSH for intramatrix metabolites other than inorganic phosphate (e.g., malate); optional:* Incubate acivicin/DTT-pretreated mitochondria with 10 mM of the metabolite (e.g., malate or 2-oxoglutarate) for 5 min at 25°C, to preload cells with metabolite. Centrifuge the preloaded mitochondrial suspension for 2 min at 10,000 × *g*, room temperature. Remove supernatant and resuspend at the same protein concentration as before in fresh mitochondrial isolation buffer.

   GSH uptake into renal cortical mitochondria is largely accounted for by the activity of two carriers, the oxoglutarate carrier (OGC) and the dicarboxylate carrier (DCC; Chen and Lash, 1998). Preloading mitochondria with either inorganic phosphate or a dicarboxylate substrate (e.g., malate, succinate, malonate) can provide information about the function of one or the other carrier if initial rules are measured. As the DCC exchanges dicarboxylates for inorganic phosphate, it will only be active in the presence of inorganic phosphate. In contrast, the OGC exchanges 2-oxoglutarate for other dicarboxylates and will only be active in the presence of dicarboxylates on both sides of the mitochondrial inner membrane.

5. In 25-ml Erlenmeyer flasks, gently mix 9 vol acivicin- and DTT-treated renal cortical mitochondria (preloaded or not) with 1 vol 10× GSH stock solution. Incubate on a Dubnoff shaking metabolic incubator at 60 cycles/min, 25°C.

   Total volume should not exceed 3.0 ml.

6. At specified incubation time points (e.g., 1, 2, 3, 5, 10, 15, 20, and 30 min), remove 0.5-ml aliquots and place in 1.5-ml polyethylene microcentrifuge tubes.
7. Immediately centrifuge mitochondrial aliquots for 30 sec at 13,000 × *g*, room temperature.
8. Remove supernatant, resuspend pellets in 30 ml ice-cold mitochondrial isolation buffer, and centrifuge again for 30 sec at 13,000 × *g*, room temperature.

Measure transport

9. Resuspend pellets in 0.7 ml extraction solution and mix vigorously on a vortex mixer.
10. Place 0.5 ml of the acid extract from step 9 into a new 1.5-ml microcentrifuge tube. Store on ice until ready for HPLC analysis of GSH content (see Support Protocol 3).

ALTERNATE PROTOCOL 2

MEASUREMENT OF MITOCHONDRIAL TRANSPORT USING RADIOLABELED GSH

Basic Protocol 2 is limited by the sensitivity of the assay method. As with cellular GSH transport (see Basic Protocol 1 and Alternate Protocol 1), a more sensitive measurement of mitochondrial GSH transport can be performed using radiolabeled GSH. The protocol below is applicable to measuring uptake of GSH at any incubating concentration of GSH; it can be used with any incubating concentration of GSH, but is applicable to lower concentrations, down to 1 μM GSH.

Additional Materials *(also see Basic Protocol 2)*

10× GSH stock solution (see recipe) containing 0.01 μCi/ml L-[3H-glycyl] GSH (20 to 50 Ci/mmol; NEN Life Science)
10% (v/v) perchloric acid
5-ml polyethylene scintillation vials

1. Pretreat and (optionally) preload mitochondria, and perform time course of incubation with GSH (see Basic Protocol 2, steps 1 to 8), using 10× GSH stock solution containing 0.01 μCi/ml of L-[^{3}H-glycyl]-GSH instead of the solution containing cold GSH alone.

   [^{35}S]-GSH may be used instead of the ^{3}H-labeled compound.

2. Resuspend pellets in 0.5 ml of 10% (v/v) perchloric acid and mix vigorously on a vortex mixer.
3. Place 0.5 ml of the acid extract into a 5-ml polyethylene scintillation vial. Add 2 ml scintillation fluid and determine radioactivity by scintillation spectroscopy using the ^{3}H-channel.
4. Calculate initial rate of GSH uptake.

   The first-order rate constant of GSH uptake, k, is calculated by performing linear curve-fitting on the plot of $\ln[P_{total}/(P_{total} - P_t)]$ versus time. P_{total} represents the total uptake of GSH at equilibrium, which is estimated by performing an exponential decay curve-fitting on the time course data of GSH uptake. P_t represents the GSH uptake at time t. Thus, the initial rate of GSH uptake is determined from the first-order rate equation $v = k(P_{total})$.

SUPPORT PROTOCOL 2

ISOLATION OF MITOCHONDRIA FROM RAT RENAL CORTEX

The method for preparation of isolated mitochondria from rat renal cortex has been described elsewhere and will not be presented here in detail. Refer to Lash and Sall (1993) for a more thorough description.

Materials

Rats (Sprague-Dawley or Fisher 344, 2- to 4-month-old males or 2.5- to 6-month-old females, 175 to 250 g body weight)
50 mg/ml sodium pentobarbital in saline
0.2% (w/v) heparin
Mitochondrial isolation buffer (see recipe), without EGTA

Hand-held Dounce homogenizer (40-ml capacity)
50-ml round-bottom, polycarbonate centrifuge tubes
Sorvall RC-2B or equivalent centrifuge

1. Anesthetize rats with an intraperitoneal injection of sodium pentobarbital (0.1 ml of a 50 mg/ml solution in saline per 100 g body weight). Prevent blood clotting by injecting 0.2 ml of 0.2% (w/v) heparin into the tail vein just before surgery.
2. Open the peritoneal cavity by making a midventral incision. Euthanize the animal by bilateral pneumothorax and exsanguination, then remove the kidneys and place in 2 to 3 ml of ice-cold mitochondrial isolation buffer in a petri dish.
3. Decapsulate kidneys by making a small incision with scissors on one end and peeling the capsule around the kidney. Slice cortices into small pieces, transfer to homogenizer, add 30 ml of ice-cold mitochondrial isolation buffer, then homogenize with 10 to 15 strokes of the hand-held Dounce homogenizer.
4. Isolate mitochondria by differential centrifugation in the following three steps.
   a. Centrifuge homogenate 10 min at 650 × *g*, 0° to 4°C. Transfer supernatant into another tube.
   b. Centrifuge supernatant 5 min at 15,000 × *g*, 0° to 4°C.
   c. Remove supernatant and resuspend pellet in 30 ml isolation buffer. Centrifuge again for 5 min at 15,000 × *g*.
5. Remove supernatant and resuspend pellet in mitochondrial isolation buffer (without EGTA) at a protein concentration of 1 to 5 mg protein/ml. Keep mitochondria on ice until used in transport experiments.

   Protein concentration in suspensions of isolated mitochondria are determined with the Coommassie Blue G dye from Bio-Rad. The Lowry method cannot be used, as the sucrose in the isolation buffer interferes with the assay.

HPLC ANALYSIS OF GSH AND RELATED COMPOUNDS

SUPPORT PROTOCOL 3

This HPLC method is based on that described by Fariss and Reed (1987) and involves derivatization of thiols (e.g., GSH) with iodoacetic acid and of amino groups with 1-fluoro-2,4-dinitrobenzene. Separation of derivatives is achieved by reversed-phase, ion-exchange chromatography. Methanol is used in the mobile phase to rapidly elute the excess 2,4-dinitrophenol and the dinitrophenyl derivatives of basic and neutral amino acids. The low pH of the acetate in the mobile phase (pH = 2.5) maintains the bonded-phase amino groups in the protonated form. Selective elution of the acidic dinitrophenyl derivatives is accomplished by increasing the sodium acetate concentration of the mobile phase, and the eluted derivatives are measured by their absorbance at 365 nm. An internal standard (L-γ-glutamyl-L-glutamate) corrects for errors in dilution and alterations in derivatization efficiency, derivatization stability, and chromatographic conditions.

Materials

Acid extract of PT cells (see Basic Protocol 1, step 10) or mitochondria (see Basic Protocol 2, step 10)

100 mM iodoacetic acid (free acid; made fresh in deionized water)
Neutralization solution (see recipe)
1% (v/v) 1-fluoro-2,4-dinitrobenzene in ethanol (made fresh)
HPLC mobile phases (see recipe)

Tabletop centrifuge (e.g., Clay Adams Dynac)
HPLC column: μBondapak amine 10 μm cartridge (8 mm × 10 cm; Waters)

Derivatize sample

1. Add 50 μl of 100 mM iodoacetic acid to 0.5 ml of acid extract.

   The acid extract contains the internal standard (L-γ-glutamyl-L-glutamate) and antioxidant (bathophenanthroline disulfonate).

2. Bring the acidic solution to pH 8 to 9 by adding 0.48 ml of neutralization solution and incubate for 10 min in the dark at room temperature.

3. Add 1 ml of 1% (v/v) 1-fluoro-2,4-dinitrobenzene. Cap the reaction mixture and mix with a vortex mixer. Store overnight at 4°C.

4. Centrifuge the *S*-carboxymethyl-*N*-dinitrophenyl derivatives for 15 min at 1000 × *g* in a tabletop clinical centrifuge to remove insoluble material. Store supernatant at 4°C in the dark until analysis.

   Samples are stable for up to 2 weeks.

Separate by HPLC

5. Perform HPLC analysis by monitoring absorbance at 365 nm using the following elution conditions.

   Maintain mobile phase at 75% A/25% B for 5 min at a flow rate of 1.5 ml/min;
   Run 30-min linear gradient to 1% A/99% B;
   Hold mobile phase at 1% A/99% B until last compound (usually GSSG) has eluted (10 to 15 min);
   Run 1 min linear gradient to 80% A/20% B;
   Hold at 80% A/20% B for 5 min to reequilibrate to initial conditions.
   These separation conditions will vary depending on the efficiency of the column, which decreases with the age of the column. As resolution decreases, the acetate concentration may need to be lowered and/or the gradient made more shallow.

SUPPORT PROTOCOL 4

MEASUREMENT OF INTRACELLULAR OR MITOCHONDRIAL MATRIX VOLUME

The contamination of intracellular (intramitochondrial) space with extracellular (extramitochondrial) material must be accounted for when measuring GSH uptake so that corrections can be made. This can be accomplished by quantifying the extracellular volume using a radiolabeled, impermeable solute and comparing this with total volume determined using radiolabled water.

Materials

Isolated cells (see Support Protocol 1) or mitochondria (see Support Protocol 2)
Substrate of interest (e.g., GSH or malate)
[U-^{14}C]Sucrose (1.7 mCi/mg; Amersham)
[^{3}H]$_2$O (1 mCi/ml; Amersham)

Additional materials and equipment for GSH transport determination and sample processing (see Basic Protocol 1 or Basic Protocol 2).

1. Incubate isolated cells or mitochondria with the substrate of interest in the appropriate buffer containing 0.1 μCi/ml of [U-^{14}C]sucrose and 1 μCi/ml of [^{3}H]$_2$O.
2. At various time points, remove 0.5-ml aliquots of the isolated cell or mitochondrial suspensions and process by centrifugation as in Basic Protocol 1 or Basic Protocol 2, steps 6 and 7.
3. Determine the radioactivity of pellet and supernatant fractions separately using the ^{14}C and ^{3}H channels.
4. Calculate intracellular or mitochondrial matrix volume according to the following equation:

$$V_{cell} \text{ or } V_{matrix} = V_{H_2O} - V_{sucrose}$$
$$= ([\text{Net (H)}_{pellet}/A^{3}H] - [\text{Net (C)}_{pellet}/A^{14}C]) \times 1/\text{mg protein}$$

where V_{cell} or V_{matrix} are the volume of ^{3}[H]$_2$O in the pellet (V_{H_2O}) minus the volume of [U-^{14}C]sucrose in the pellet (Vsucrose), V_{H_2O} is the total pellet volume calculated from net ^{3}H counts divided by specific ^{3}H counts ($A^{3}H$), and $V_{sucrose}$ is the extracellular or extramitochondrial medium calculated from the net ^{14}C counts divided by specific ^{14}C counts ($A^{14}C$); $A^{3}H$ and $A^{14}C$ are determined by standard samples containing only a known amount of either [^{3}H]$_2$O or [U-^{14}C]-sucrose.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acivicin stock solution, 10×

Prepare a 2.5 mM (10×) stock solution of L-(αS,5S)-α-amino-3-chloro-4,5-dihydro-5-isoxazoleacetic acid (acivicin; Sigma) in Krebs-Henseleit buffer (see recipe). Store at –20°C for up to 1 month.

Collagenase solution

Prepare a 0.15% (w/v) solution of collagenase, type I (Sigma) in Hanks' buffered salt solution (HBSS; *APPENDIX 2A*) with 1.2 mM magnesium and 2 mM calcium chloride. Prepare fresh daily.

Extraction solution

Stock solutions:
70% (v/v) perchloric acid
1.5 mM L-glutamyl-L-glutamate (Sigma)
1.5 mM bathophenanthroline disulfonate (BPDS; Sigma)
0.9% (w/v) NaCl (normal saline; *APPENDIX 2A*)

Add 1 vol 1.5 mM L-γ-glutamyl-L-glutamate, 1 vol BPDS, and 2 vol 70% perchloric acid to 10 vol 0.9% NaCl. Prepare fresh.

GSH stock solution, 10×

Prepare a 1 to 100 mM (choose concentration as needed) solution of reduced glutathione (GSH) in Krebs-Henseleit buffer (see recipe) for isolated cells or mitochondrial isolation buffer (see recipe) for isolated mitrochondria. Prepare fresh daily and keep on ice.

HPLC mobile phases

Mobile phase A: Prepare a solution of 80% (v/v) HPLC-grade methanol in water.

Mobile phase B: Prepare 2.6 M sodium acetate stock solution by adding 272 g sodium acetate and 122 ml of water to 378 ml of glacial acetic acid. Stir with low heat until sodium acetate is in solution. Cool and filter with a 4.0- to 5.5-µm polypropylene filter. Add 200 ml of the sodium acetate stock solution to 800 ml of 80% (v/v) methanol to yield 0.5 M sodium acetate in 64% (v/v) methanol.

Krebs-Henseleit buffer

Stock solution: Prepare a 10× stock solution as follows:

1.18 M NaCl
48 mM KCl
12 mM $MgSO_4 \cdot 7H_2O$
9.6 mM KH_2PO_4
250 mM $NaHCO_3$
25 mM $CaCl_2 \cdot 2H_2O$
250 mM HEPES

Prepare the 10× stock solution in advance and store in a 1-liter polycarbonate bottle at 0° to 4°C for up to 1 month. Add all of the ingredients except $CaCl_2$ and allow to dissolve with stirring. Purge the 10× stock with 95% O_2/5% CO_2 for 30 min, then slowly add the $CaCl_2$ in small aliquots with slow stirring to prevent precipitation of calcium phosphate.

CAUTION: *If the $CaCl_2$ is added too quickly, a cloudy precipitate will form and the solution must be discarded and prepared again.*

Working solution: Prepare the working Krebs-Henseleit buffer (1×) just prior to use by mixing 1 vol 10× stock with 9 vol deionized water. After bubbling with 95% O_2/5% CO_2 for 30 min, adjust the pH of the buffer to 7.4 with 1 M HCl or 1 M NaOH as needed.

Mitochondrial isolation buffer

20 mM triethanolamine·HCl, pH 7.4
225 mM sucrose
3 mM potassium phosphate, pH 7.4
5 mM $MgCl_2$
20 mM KCl
0.1 mM phenylmethylsulfonyl fluoride (PMSF, 99% purity; Sigma)
2 mM EGTA (added only in preparatory steps except final resuspension and incubation of mitochondria)
Adjust pH to 7.4 with 1 M HCl or 1 M KOH as needed
Prepare buffer in advance and store in a 1-liter polycarbonate bottle at 0° to 4°C for up to 1 month

Phenylmethylsulfonyl fluoride is added to inhibit proteolysis.

Neutralization solution

Make a working solution by adding 1 vol of 10 M KOH to 4 vol of 3 M $KHCO_3$, for a final concentration of 2 M KOH/2.4 M $KHCO_3$. Store up to 2 months at 0° to 4°C.

COMMENTARY

Background Information

Until the late 1970s the dogma was that many tissues, in particular the liver, had transport systems for efflux of GSH into the extracellular space but that GSH was not transported into cells as the intact tripeptide. Observations with isolated, perfused kidneys in the late 1970s through the mid 1980s (Fonteles et al., 1976; Griffith and Meister, 1979; Häberle et al., 1979; Anderson et al., 1980; Ormstad et al., 1982; Rankin and

Curthoys, 1982; Rankin et al., 1985) provided evidence that either endogenous or administered GSH was extracted from plasma by both a basolateral and a lumenal mechanism. While the latter was ascribed to glomerular filtration, degradation by brush-border enzymes (i.e., GGT and dipeptidase), and uptake of the constituent amino acids by renal PT cells (Griffith and Meister, 1979; Lash et al., 1988), there was controversy over whether a basolateral transport mechanism for the intact tripeptide of GSH actually existed or if the apparent basolateral extraction of plasma GSH was due to degradation by extralumenal GGT followed by renal cellular uptake of the constituent amino acids and intracellular resynthesis of GSH (Anderson et al., 1980; Abbott et al., 1984; Inoue et al., 1986).

This controversy was resolved by the biochemical description of a Na^+-dependent transport process for uptake of GSH in basolateral membrane vesicles (Lash and Jones, 1983, 1984) and isolated kidney cells (Hagen et al., 1988) and the further demonstration that this system also mediated the uptake of GSH *S*-conjugates (Lash and Jones, 1985). Basolateral uptake of GSH was subsequently shown to be a general property of many epithelial cells, including those found in the small-intestinal jejunum (Lash et al., 1986; Hagen and Jones, 1987), type II pulmonary alveolar cells (Hagen et al., 1986; Bai et al., 1994), and retinal pigment epithelial cells (Davidson et al., 1994; Zlokovic et al., 1994; Kannan et al., 1995; Lu et al., 1995; Mackic et al., 1996).

Within renal PT cells, as well as isolated hepatocytes, GSH is known to be compartmentalized into distinct cytosolic and mitochondrial pools. There are two possible sources of mitochondrial GSH—de novo synthesis from precursor amino acids and transport of GSH from the cytosol. As the enzymes for synthesis of GSH are localized predominantly, if not exclusively, in the cytosol (Griffith and Meister, 1985), transport must supply the mitochondria with their pool of GSH. Because the GSH molecule has a net charge at physiological pH and there exists a pH gradient and membrane potential across the mitochondrial inner membrane, GSH transport into mitochondria cannot occur passively but must occur by a specific, carrier-mediated process. Several investigators subsequently demonstrated the presence of specific, carrier-mediated uptake of GSH in hepatic (Kurosawa et al., 1990; Martensson et al., 1990; Garcia-Ruiz et al., 1995) and renal (McKernan et al., 1991; Schnellmann, 1991) mitochondria. GSH is taken up into renal cortical mitochondria in electroneutral exchange for dicarboxylates such as malate and succinate (McKernan et al., 1991; Chen and Lash, 1997), suggesting that transport is mediated, at least in part, by the dicarboxylate and oxoglutarate carriers that are present in the mitochondrial inner membrane of mitochondria in kidney and several other tissues, including the liver (Klingenberg, 1979; Palmieri et al., 1996).

Critical Parameters

Measurement of transport

This unit examines GSH uptake by isolated renal PT cells and renal cortical mitochondria. Although the kidney has several unique properties with regard to the disposition and metabolism of GSH, the principles should apply to analysis of GSH uptake in isolated cells or mitochondria from most mammalian tissues.

Methods for accurate measurement of GSH transport must take into account not only concerns that exist with measurement of transport of any substrate, but concerns that are specific to the study of GSH transport. General concerns about the accuracy of transport measurements include efficient separation of compartments, prevention of changes in compartment volume during transport measurements and sample processing, and loss of transported substrate during sample processing. Compartment volumes can be readily quantified by use of radiolabeled water, which gives total space, and a radiolabeled impermeant molecule, such as sucrose (see Support Protocol 4). This is a critical parameter to monitor in many cases. With isolated mitochondria, matrix volume can often change due to metabolic state. Antimycin A (2 μM) can be added to incubations to inhibit substrate metabolism and thus substrate-induced changes in matrix volume. Loss of transported substrate during sample processing can be eliminated by addition of a specific, irreversible inhibitor of transport in the incubation stop solution, if one is available. Alternatively, efflux of transported substrate can be measured under the same conditions of sample processing (usually 0° to 4°C, <5 min) and can be shown to be negligible (Chen and Lash, 1998).

Concerns specific to the study of GSH transport include prevention of GSH oxidation and degradation. Oxidation of GSH during sample processing is usually prevented by stopping transport under acidic conditions and including an antioxidant, such as bathophenanthroline disulfonate (BPDS). BPDS is used in preference to EDTA, because the latter contains free amino groups and interferes with detection of GSH by the HPLC method described in Support Protocol

3. Degradation of GSH is not a major concern in tissues such as skeletal muscle or the liver, which have negligible amounts of GGT activity. In the kidney, however, extremely high activity of GGT is present on the brush-border membrane (Lash et al., 1988). Consequently, the presence of even a small amount of contaminating brush-border membranes in a preparation of basolateral membranes (Lash and Jones, 1984) or isolated mitochondria (McKernan et al., 1991) can result in a significant amount of degradation of GSH. This concern is minimized by pretreatment of the preparation with an irreversible inhibitor of GGT, such as acivicin. One must be cautious not to use too high a concentration of acivicin. Although acivicin is a specific glutamine antagonist at relatively low concentrations (usually <1 mM), it becomes a nonspecific alkylating agent at higher concentrations and can inhibit GSH transport (Lash and Jones, 1984). In suspensions of isolated renal cells, which possess both brush-border and basolateral membranes, it is essential to inhibit GGT activity. Buthionine sulfoximine (BSO) can also be added to inhibit GSH synthesis, thereby excluding the possibility that detection of intact GSH arose due to extracellular degradation of GSH, uptake of the constituent amino acids, and intracellular resynthesis of GSH.

In this unit, two methods are described for analysis of transported GSH: analysis by HPLC and use of radiolabeled GSH. The HPLC method has the advantage of demonstrating recovery of intact tripeptide. With the radiolabel method, which must be used when incubating concentrations of GSH are lower than the HPLC limit of detection (<0.5 mM), samples can be spiked with unlabeled GSH and fractions from the HPLC eluate can be collected to demonstrate that the radiolabeled molecule coincides with the derivative of intact GSH.

Sensitivity of method

Sensitivity of the HPLC method is based, in part, on the number of stationary amine groups available with which the chromophore can interact, as well as the sensitivity of the detector. With variable wavelength detectors, disulfides are measured at concentrations as low as 0.5 nmol/ml or 25 pmol/injection, and thiols are measured at concentrations as low as 1.0 nmol/ml or 50 pmol/injection. Approximately 5- to 10-fold greater sensitivities can be achieved with some fixed-wavelength, filter-type detectors. In addition to GSH and GSSG, other relevant compounds that are measurable by this method include glutamate, cystine, cysteine, aspartate, γ-glutamyl-L-cysteine, and the mixed disulfide of GSH and cysteine (also see *UNIT 6.2*).

As the time period during which both isolated renal cells and isolated mitochondria are viable is somewhat limited (2 to 3 hr for isolated cells and 30 min for isolated mitochondria after removal from storage on ice), it is critical that experiments be conducted as soon as possible after preparation of the cell or mitochondrial suspension.

Troubleshooting

Potential problems with measurement of GSH uptake can arise from three areas: (1) quality of the biological preparation, (2) alterations in GSH status during incubation or sample processing, or (3) artifacts during sample processing. There are numerous methods to assess the quality of the biological preparation being used, and these have been detailed elsewhere (e.g., Lash, 1989, 1993, 1996; Lash and Sall, 1993). Problems with the viability of isolated cells or mitochondria will often lead to changes in membrane permeability and hence, changes in apparent transport. If analysis of intracellular or intramitochondrial contents after incubation with GSH reveals significant oxidation or degradation of GSH, incubation conditions should be carefully checked to see if the pH is correct and if acivicin pretreatment is effective. If the incubating pH is too alkaline, auto-oxidation of GSH is more likely to occur. Although previous studies have shown than a 15-min preincubation of renal tissue with 0.25 mM acivicin inhibits ≥98% of GGT activity, this should be assessed if degradation is a problem. As mentioned above, concentrations of acivicin of >1 mM can lead to nonspecific alkylation of proteins. Potential artifacts during sample processing can be assessed by measurement of compartment volumes and determination of sample recovery.

Methods for the accurate measurement of GSH uptake by renal cortical mitochondria from the rat may be compromised by the following factors.

1. The presence of even small amounts of contaminating brush-border membranes, which contain GGT, can lead to significant degradation of GSH, thus either causing underestimation of uptake or making measurement of uptake impossible.

2. Efflux of transported GSH can occur during sample processing, which can lead to underestimation of uptake.

3. Contamination of the mitochondrial pellet with extramitochondrial medium can take place, thus leading to overestimation of uptake.

4. Changes in mitochondrial matrix volume during transport measurements with or without other added substrates can lead to altered transport kinetics.

5. Induction of the membrane permeability transition during transport measurements with or without other added substrates can markedly alter membrane permeability to GSH.

Anticipated Results

The choice of either the HPLC or radiolabel method for quantifying GSH uptake in either cells or mitochondria is wholly dependent on the incubating concentration of GSH and the sensitivity of the HPLC detector. Typically, a limit of detection of 25 to 50 pmol GSH is seen with the HPLC method. This is usually adequate with incubating concentrations of ≥0.5 mM. Using radiolabeled GSH and scintillation counting, incubating concentrations of GSH as low as 1 μM have been successfully used. This lower range is critical because physiological concentrations of GSH in renal plasma are 5 to 20 μM, depending on species. In contrast, renal mitochondria are typically exposed to 1 to 5 mM GSH in the cytosol.

Using two kidneys from 175- to 250-g male rats as starting material, the typical yield of isolated renal PT cells is 30×10^6 cells and that of isolated renal cortical mitochondria is 15 to 25 mg of mitochondrial protein. In both cases, this is usually enough material for 10 to 15 individual samples.

Time Considerations

The amount of time required to measure GSH uptake in isolated renal cells or mitochondria can be divided into three phases: (1) biological preparation, (2) transport incubations and sample preparation, and (3) analysis of GSH. The first and third phases require significantly more time than the second phase. The isolated cell preparation method requires ~3.5 hr to complete. If GSH transport is assessed in cells from other tissues, this time will of course vary depending on the method used to prepare the cells. The mitochondrial isolation method typically requires 45 min to 1 hr to complete. The HPLC method requires ~1 hr per sample while the radiolabel method requires ~5 to 10 min per sample, depending on the number of counts per sample. Longer counting times should be used at low incubating concentrations of GSH to decrease counting error. In contrast to the times required for the first and third phases, the actual transport incubations are done in real time and typically take at most 60 min for experiments with isolated cells and at most 30 min for experiments with isolated mitochondria. In both cases, sample preparation then requires 2 to 5 min per sample.

Measurement of Glutathione Transferases

Glutathione transferases (GSTs) occur in multiple forms with different substrate specificity profiles. In the mammalian species investigated, including man, mouse, and rat, evidence for at least 20 distinct genes is available. The corresponding GST proteins are differentially expressed such that organs differ both qualitatively and quantitatively in their GST contents. Based on similarities in amino acid sequences, the GSTs have been grouped into classes of which the most well characterized are Alpha (A), Mu (M), Pi (P), and Theta (T). Members of these classes are found in the cytosol fraction of cells. There are also membrane-bound GSTs (MGSTs) that have been identified in the microsome fraction (for additional information about GST nomenclature, see Background Information).

The common functional denominator of the GSTs is their ability to catalyze the reaction of the thiol group of glutathione with electrophilic chemical groups. However, with respect to the electrophilic substrate, there is no known chemical substance that is suitable for measuring the catalytic activity of all known GSTs. 1-Chloro-2,4-dinitrobenzene (CDNB) is the substrate most commonly used. The advantages of using CDNB are that the assay is simple to perform, sensitive, and applicable to a wide range of isoenzymes. However, some GSTs do not display any detectable activity with CDNB, and additional compounds are necessary in order to monitor their activities. Alternative substrates are useful in the discrimination among different isoenzymes with overlapping specificities. Therefore, depending on the scope of the investigation, several substrates have to be used to measure GST activity in a given biological sample. Table 6.4.1 gives a list of alternative substrates and details of the assay conditions.

The majority of the recommended assays are based on spectrophotometry because of its convenience. Table 6.4.2 serves as a guide for selecting substrates suitable for distinguishing the forms of GST under consideration. The Basic Protocol provides a convenient method for continuously monitoring changes in absorbance resulting from the consumption of substrate or the formation of product. Most reactions can be monitored directly; however, when using cumene hydroperoxide as a substrate, the formation of the product glutathione disulfide is measured indirectly by coupling the reaction to glutathione reductase–catalyzed oxidation of NADPH. In addition, continuous monitoring is not always possible. When using dichloromethane as a substrate for measuring GST T1-1, an endpoint analysis must be performed. To this end, the Alternate Protocol describes a procedure in which aliquots of the reaction mixture are quenched at various time points, and the product is colorimetrically detected.

Table 6.4.3 presents specific activities of different human GSTs with selected substrates. These substrates can also be used to detect and characterize GSTs from other biological species.

CONTINUOUS SPECTROPHOTOMETRIC ASSAYS FOR GLUTATHIONE TRANSFERASE ACTIVITY

BASIC PROTOCOL

This protocol describes a simple spectrophotometric assay for measuring GST activity in cell lysates and purified enzyme preparations. A number of substrates may be used with this assay, the choice of which depends on the isoform being studied. See Table 6.4.1 for specific assay conditions for each substrate; see Table 6.4.2 for the relative utility of the different substrates in the study of the different GST isoforms.

NOTE: To be able to compare results, reactions must be performed at constant temperature. Tabulated specific activities for GSTs are usually measured at 30°C.

Current Protocols in Toxicology (1999) 6.4.1-6.4.10

Materials

Assay buffer (see recipe and Table 6.4.1)
Glutathione (GSH) stock solution (see recipe and Table 6.4.1; make 20 times the desired final concentration indicated in the table)
Additional reagents for measurements with cumene hydroperoxide (prepare fresh):
Cumene hydroperoxide stock solution (see Table 6.4.1)
6 U/ml glutathione reductase in assay buffer
2 mM NADPH in 10 mM Tris·Cl, pH 7.0
Cell lysate or purified enzyme solution (amount depends on the activity of the sample)

Table 6.4.1 Conditions for Spectrophotometric Assays of Glutathione Transferase Activity[a]

Substrate	Substrate stock solution	Substrate concentration in cuvette (mM)	GSH concentration in cuvette (mM)	Assay buffer	Wavelength (nm)	Extinction coefficient ($mM^{-1}cm^{-1}$)
Δ^5-Androstene-3,17-dione	6.8 mM in methanol	0.068	0.1	25 mM Tris·Cl/sodium phosphate, pH 8.3	248	16.3
1-Chloro-2,4-dinitrobenzene	20 mM in 95% ethanol	1.0	1.0	0.1 M sodium phosphate, pH 6.5	340	9.6
Cumene hydroperoxide[b]	30 mM in 95% ethanol	1.5	1.0	0.1 M sodium phosphate, pH 7.0	340	−6.2[c]
2-Cyano-1,3-dimethyl-1-nitrosoguanidine	20 mM in DMSO	1.0	1.0	0.1 M sodium phosphate, pH 7.5	295	−2.0[c]
Dichloro-methane[d]	3.2% (v/v) (~0.5 M) in 95% ethanol	5.0	10	0.1 M Tris·Cl, pH 8.5	412	8.0
1,2-Dichloro-4-nitrobenzene	20 mM in 95% ethanol	1.0	5.0	0.1 M sodium phosphate, pH 8.0	344	10
Ethacrynic acid	1.0 mM in 95% ethanol	0.05	1.0	0.1 M sodium phosphate, pH 6.5	270	5
1,2-Epoxy-3-(4-nitrophenoxy) propane	10 mM in 95% ethanol	0.5	5.0	0.1 M sodium phosphate, pH 6.5	360	0.5
4-Hydroxynon-2-enal	2 mM in acetonitrile	0.1	0.5	0.1 M sodium phosphate, pH 6.5	224	−13.75
1-Menaphthyl sulfate	10 mM in assay buffer	0.5	5.0	0.1 M sodium phosphate, pH 7.5	298	2.5
4-Nitrobenzyl chloride	5.0 mM in 95% ethanol	0.25	5.0	0.1 M sodium phosphate, pH 6.5	310	1.9

[a]See Mannervik and Widersten (1995) and Sherratt et al. (1997; dichloromethane) for original references.
[b]See Basic Protocol for additional details on cumene hydroperoxide.
[c]A negative extinction coefficient means that the absorbance decreases in the assay.
[d]See Alternate Protocol for additional details on dichloromethane. The extinction coefficient is for the adduct diacetyldihydrobutidine formed in the assay.

Electrophilic substrate (see Table 6.4.1; also see recipe for stock solution)

Spectrophotometer, thermostatically controlled
30°C water bath

1. Prepare a thermostatically controlled spectrophotometer for kinetic measurements, and select the appropriate wavelength for the chosen substrate (Table 6.4.1). Maintain assay buffer at 30°C using, e.g., a temperature-controlled water bath.

   For wavelengths shorter than 340 nm, use a quartz cuvette.

[a]Data is from the review articles by Mannervik and Widersten (1995) and Hayes and Pulford (1995), except for the value for A1-1 with 4-hydroxynon-2-enal (Hubatsch et al., 1998), and the data for A4-4 (Hubatsch et al., 1998), T1-1 (Sherratt et al., 1997), and T2-2 (Tan and Board, 1996; Hayes and Pulford, 1995).

[b]Assay conditions are essentially as described in Table 6.4.1 but for details, see the above references.

[c]—, does not serve as substrate; NA, information not available.

If using a multisample spectrophotometer, an enzyme blank, in which the volume of enzyme is replaced with assay buffer, may be read concurrently with the assay sample.

2a. *If using substrate other than cumene hydroperoxide:* Referring to Table 6.4.1, add assay buffer to the cuvette, followed by GSH and enzyme solution, adjusting the volume of buffer on the basis of the volumes of enzyme and substrate to be added so that the volume in the cuvette is 1.00 ml.

The suitable amount (mg protein per ml) in the cuvette can be estimated from the reciprocal value of (specific activity) × ε × 20 (see Table 6.4.3).

2b. *If using cumene hydroperoxide as the substrate:* In addition to the reagents in step 2a, also add 50 µl of 6 U/ml glutathione reductase and 50 µl of 2 mM NADPH (0.1 mM final). Mix by inversion and incubate 1 min in the spectrophotometer chamber.

To mix the contents of the cuvette, place a piece of Parafilm over the cuvette opening and hold tightly while inverting. Do not shake.

3. Swiftly add the electrophilic substrate and mix by inverting the cuvette 3 to 4 times. Immediately insert the cuvette into the spectrophotometer and start the measurement (change in absorbance versus time). Record the absorbance for each sample continuously or at 5- to 15-sec intervals for 2 to 5 min.

CAUTION: *Some of the substrates may be allergenic (e.g., 1-chloro-2,4-dinitrobenzene) or toxic. Use gloves and follow the precautions listed with the chemicals.*

Optimize activity measurement conditions with respect to assay time and amount of enzyme added (see Critical Parameters and Troubleshooting).

4. Perform steps 2 and 3 on each sample, rinsing the cuvette with deionized water from a squirt bottle and wiping off the outside of the cuvette using a lint-free tissue (e.g., Kimwipe) between measurements.

5. Perform calculations according to example below (in which 1-chloro-2,4-dinitrobenzene is used as the substrate).

The following were added to a cuvette for a final volume of 1.0 ml: 890 µl sodium phosphate pH 6.5; 10 µl enzyme solution (protein concentration in cuvette, 0.050 mg/ml); 50 µl of 20 mM GSH solution (concentration in cuvette, 1 mM); and 50 µl of 20 mM 1-chloro-2,4-dinitrobenzene (concentration in cuvette, 1 mM). An increase of 0.202 absorbance units/min was observed. In a blank, performed without addition of enzyme (900 µl sodium phosphate, pH 6.5, 50 µl of 20 mM GSH solution, and 50 µl of 20 mM 1-chloro-2,4-dinitrobenzene), the increase in absorbance was found to be 0.010/min (nonenzymatic reaction rate).

Enzymatic activity = (0.202 − 0.010)/(9.6 × 1) = 0.020 mM/min = 0.020 mmol/min/liter = 0.020 µmol/min/ml. By relating the activity to the protein concentration, the specific activity is obtained:

Specific activity = 0.020/0.050 µmol/min/mg protein = 0.40 µmol/min/mg protein.

The spectrophotometer gives the activity in ΔA/time unit, where ΔA is the change in absorbance at the chosen wavelength. The time is usually measured in min. The change in absorbance is proportional to the change in substrate concentration as given by the Lambert-Beer law ($A = \varepsilon lc$; where ε is the molar extinction coefficient of the substrate, l is the pathlength of the cuvette and c is the concentration of the substrate). Thus, the activity = Δc per time unit = ΔA per time unit divided by εl. In the example above $\varepsilon = 9.6$ $mM^{-1}cm^{-1}$ and $l = 1$ cm.

IMPORTANT NOTE: *It is crucial that the slopes be obtained from straight lines representing the initial rates of the reactions (see Critical Parameters).*

MEASUREMENT OF GLUTATHIONE TRANSFERASE T1-1 ACTIVITY WITH DICHLOROMETHANE AS THE SUBSTRATE

ALTERNATE PROTOCOL

The only known mammalian GSTs displaying significant activity with dichloromethane as substrate are GST T1-1 orthologs from different species. Thus, the assay below can be used to discriminate GST T1-1 from other GSTs. The activity with dichloromethane and related haloalkanes has attracted some interest, since these compounds are common pollutants. The product of the enzyme-catalyzed reaction between dichloromethane and GSH, *S*-chloromethylglutathione, reacts further nonenzymatically to yield formaldehyde, a carcinogen. A large fraction of the human population lacks GST T1-1, complicating the toxicology of dichloromethane (Hayes and Pulford, 1995; Sherratt et al., 1997). In contrast to the continuous spectrophotometric assay (see Basic Protocol) this assay employs quenching of the reaction followed by colorimetric detection of the reaction product. An advantage with this assay is the low nonenzymatic reaction rate, which can be neglected in the calculations. However, if whole-cell lysates from certain bacteria are used, the possible presence of halogenases should be taken into account.

Additional Materials *(also see Basic Protocol 1)*

Assay buffer: 0.1 M Tris·Cl, pH 8.5 (*APPENDIX 2A*)
0.5 M (3.2% v/v) dichloromethane in 95% ethanol
25% (w/v) trichloroacetic acid (TCA)
Nash reagent (see recipe)

5-ml vials, sealable
Water bath, 42°C

1. Prepare a spectrophotometer for absorbance measurements, with the wavelength set to 412 nm.
2. To a sealable 5-ml vial, add buffer, enzyme, and 250 µl of 20 mM GSH solution (5 ml total volume after addition of dichloromethane) and preincubate in a water bath at the desired temperature (usually 30°or 37°C).
3. Add 50 µl of 0.5 M dichloromethane solution, mix by inversion (do not shake), and begin incubation at the desired temperature.

   The nonenzymatic reaction is slow and can be ignored. Therefore, a blank is unnecessary.
4. Withdraw 0.5-ml aliquots at various time points and dispense into a microcentrifuge tube. Add 100 µl 25% TCA to precipitate enzyme and quench the reaction. Remove any visible precipitate by centrifugation.

   CAUTION: *TCA is corrosive. Use gloves and follow the precautions on the label.*

   The choice of time points depends on amount of enzyme added. For 25 µg/ml purified human GST T1-1, under the assay conditions depicted in Table 6.4.1, suitable time points would be 0, 5, 10, 15, and 20 min.
5. Immediately add an equal volume (0.5 ml) of Nash reagent to the TCA-treated sample and incubate 30 min at 42°C.
6. Transfer samples to cuvettes and measure the absorbance at 412 nm. Plot the absorbance versus time (min) and calculate the slope of the curve using linear regression analysis.

   The data points should be on a straight line. Omit data point(s) that deviate in a systematic fashion, e.g., if the last point is lower than would be expected with regard to previous points. This is most probably due to depletion of substrate.

7. Perform calculations as described in the Basic Protocol, step 5, using an extinction coefficient of 8.0 $mM^{-1}cm^{-1}$. Use the calculated slope as the reaction rate (ΔA/min) and ignore the nonenzymatic reaction rate.

The calculated rate μmol/min/ml) should be multiplied by 2.2 to allow for the dilution of the aliquots.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer

Prepare buffer solutions according to Table 6.4.1. For sodium phosphate buffers, dissolve NaH_2PO_4 to four-fifths of the desired volume, adjust the pH value with NaOH, and add water to desired volume. Make Tris buffers in the same way, except adjust the pH value with HCl. Store up to 2 weeks at 4°C.

GSH stock solution

Make GSH stock solution in water according to Table 6.4.1. It is convenient to add 50 μl GSH solution to the cuvette in the continuous assays, hence make the stock solution 20× as concentrated as the desired concentration in the cuvette (Table 6.4.1). GSH is unstable; make fresh solution every day.

Nash reagent

Prepare in H_2O:
2 M ammonium acetate
50 mM acetic acid
20 mM acetylacetone
Store up to 2 weeks at 4°C

The Nash reagent is mixed 1:1 with aliquots from the dichloromethane assay. Acetylacetone reacts with formaldehyde, formed nonenzymatically from S-chloromethylglutathione, to give a product that absorbs at 412 nm.

Substrate stock solutions

Prepare stock solutions according to Table 6.4.1. The stock solutions are usually stable for several days at 4°C, but for accurate measurements, fresh solutions should be made. Store Δ^5-androstene-3,17-dione solution (Table 6.4.1) at −20°C.

CAUTION: *Some of the substrates may be allergenic (e.g., 1-chloro-2,4-dinitrobenzene) or toxic. Use gloves and follow the precautions on the label.*

COMMENTARY

Background Information

From a toxicological point of view, the multiple forms of GST form an ensemble that collectively effects the detoxication of a wide range of toxic electrophilic chemical compounds. It would appear that natural substrates include genotoxic electrophiles, such as alkenes, epoxides, quinones, and organic hydroperoxides, which are formed by oxidative processes in organisms under normal and pathophysiological conditions. Xenobiotics, including drugs, environmental pollutants, and diverse man-made compounds, may be activated by cytochrome P-450-catalyzed reactions (so-called phase I detoxication reactions), promoting glutathione conjugations catalyzed by GSTs (phase II reactions). Some compounds are sufficiently electrophilic to react with the sulfhydryl group of glutathione directly, but in most cases a phase I reaction is required for activation.

The overlapping substrate specificities of GSTs create difficulties in determining the presence of individual GSTs in biological samples. Accurate identification and quantification may require separation of the different GSTs by high-resolution techniques such as isoelectric focusing or chromatofocusing (Ålin et al., 1985). In

addition, analytical procedures have been developed based on reverse-phase HPLC, in which individual GST subunits are quantified. The procedure is normally based on the chromatography of a pool of GSTs that has been enriched by affinity chromatography (Ostlund Farrants et al., 1987) and requires supplementation with other procedures for the several GSTs not bound to the affinity matrix. Determination of individual subunits rather than the various possible binary combinations found in the native GSTs simplifies the analysis, but has the drawback that the possible significance of heterodimeric GSTs can be overlooked. All in all, no single chromatographic or electrophoretic procedure allows the simultaneous determination of all known GSTs in a given biological sample.

In determinations of the activity of membrane-bound GSTs, the enzyme is solubilized and assayed in the presence of detergent (Morgenstern et al., 1982). The data given for MGST1 in Table 6.4.3 have been measured with enzyme activated by pretreatment with *N*-ethylmaleimide.

A radiometric assay involving labeled *trans*-stilbene oxide as substrate has been found useful for phenotyping in lymphocytes from blood samples with respect to the expression of the polymorphic human GST M1-1 (Seidegård et al., 1985).

Antibodies, polyclonal as well as monoclonal, may be used for quantitative analysis. It appears possible to distinguish closely related isoenzymes from the same GST class (Hao et al., 1994). However, such analysis requires the availability of specific antibodies for each and every GST, and presence of heterodimeric GSTs remains an analytical problem.

The current nomenclature for human GSTs is based on recognized classes of GSTs and their subunit composition. The "soluble" GSTs are dimeric proteins composed of identical or nonidentical subunits from the same class. Thus, the homodimeric enzyme composed of two subunits 1 of the Alpha class is GST A1-1, and the heterodimer composed of subunits 1 and 2 from the same class is designated GST A1-2. This nomenclature is well established for the human enzymes (Mannervik et al., 1992), and the same designations are being developed for mouse and rat GSTs (Hayes and Pulford, 1995). For earlier nomenclatures see Mannervik and Danielson (1988) and Hayes and Pulford (1995). Heterodimers composed of subunits from different GST classes are not known to occur.

Critical Parameters

In order to get reproducible results, care should be taken when pipetting buffer, enzyme solution, GSH solution, and, perhaps most importantly, the electrophilic substrate solution, into the cuvette. The electrophilic substrate is usually dissolved in ethanol (Table 6.4.1) and is therefore more difficult to pipet than the other solutions.

Some of the electrophilic substrates in Table 6.4.1 are difficult to dissolve in buffer, and this could affect the activity measurement. Each time a new substrate is used, the enzymatic activity should be compared to substrate and buffer alone as a control. If the absorbance is not constant before the initiation of the reaction, it is most probably due to incompletely dissolved substrate. In most cases preincubation of substrate with buffer (5 to 10 min in the cuvette prior to addition of enzyme and GSH) will eliminate this problem. Also, each time enzyme activity measurements are performed, the nonenzymatic reaction rate (substrate, GSH, and buffer) should be assayed as well. Even if it has been established that the uncatalyzed reaction is negligible, it is recommended that the nonenzymatic reaction rate be routinely measured and used as an extra control of the assay conditions. If the same substrate concentrations, pH value of buffer, and assay temperature are used, the rate should equal those obtained in previous experiments. To be able to compare activity measurements with or without addition of GST, it is crucial that the experiments be performed at the same temperature and pH values, since GSTs have pH optima with most substrates.

For some substrates there is a substantial nonenzymatic reaction rate. In these cases it is desirable that the amount of enzyme added be optimized such that the reaction rate measured in the presence of enzyme is at least twice that obtained in the absence of enzyme. The nonenzymatic reaction rate increases with pH due to the ionization of the sulfhydryl group of GSH ($pK_a \approx 9$), and it is recommended that all assays be performed at neutral or slightly acidic pH values according to Table 6.4.1.

In general, the activities of GSTs are not affected by altered ionic strength or addition of detergents. However, most of the electrophilic substrates in Table 6.4.1 are hydrophobic, and addition of salts or detergents may affect their solubilities. Appropriate controls for such effects should be made when assay conditions differ significantly from those given in Table 6.4.1.

Small intestine	0.1	Tahir et al., 1988
Testis	1.5	Guthenberg et al., 1985b

[a]Numerous reports of cytosolic specific activities have been published. The values given are primarily from the authors' laboratory, based on the assay protocol recommended in this unit.

Pure or partly purified enzyme or whole-cell lysates can be used as samples for assaying GST activity. However, when crude cell lysates are used as samples, the absorbance of the assay solutions at wavelengths shorter than 340 nm may be high and affect the assay (spectrophotometers work best at absorbances <1). In cases where large amounts of lysate are necessary to detect activity, resulting in high absorbance at the assay wavelength, partial purification of the GST(s) should be considered. Also, the crude lysate may contain GSH, GST inhibitors, or other small compounds that influence the measured reaction rate. These can be removed by running the sample through a gel-filtration column (e.g., a PD-10 column; Amersham Pharmacia Biotech) if the sample volume is small.

GSH is unstable, primarily owing to the oxidation of its thiol group, and the stability decreases with pH. The thiol concentration can be measured using, 5,5′-dithiobis(2-nitrobenzoate) (DTNB, 20 mM in 95% ethanol). To do this, add 50 μl DTNB stock solution to neutral phosphate buffer. Measure the absorbance at 412 nm (using a 1-cm cuvette) before and after addition of 50 μl of a GSH stock solution that has been diluted by a factor of 100 (see Table 6.4.1 and Reagents and Solutions for GSH stock solutions). The final volume should be 1.00 ml. The increase in absorbance is proportional to the amount of GSH added, with an extinction coefficient of 13.6 $mM^{-1}cm^{-1}$. The GSH concentration (c) in the stock solution (mM) equals the change in absorbance times 2000 divided by 13.6 (c = dilution × $\Delta A/\varepsilon$).

Troubleshooting

The result of a GST activity measurement of the kind described in the Basic Protocol, either from a continuous assay or a quenched assay, should be a straight line showing the change in absorbance with time. This is essential in order to get reliable and reproducible results. If a smoothly bent curve is obtained, this is most probably due to addition of too much GST. In this case, repeat the measurement with addition of smaller amounts of enzyme solution until a straight line is obtained. An irregular curve is often due to poor mixing of the reactants; repeat the measurement and mix thoroughly.

Inability to reproduce experiments performed previously could also be related to the points listed in the Critical Parameters section. Check substrates, assay buffer, and temperature. Make sure that the correct wavelength is used and that the pipettors work properly.

Anticipated Results

As pointed out in the Troubleshooting section, the result of a GST activity measurement should be a straight line. The more GST added, the steeper the slope of the line should be. The activity (corrected for the nonenzymatic reaction) should be proportional to the enzyme concentration. Again, to be able to compare results

from different measurements, not only do the the assay conditions need to be identical, but the activity curves on which calculations are based need to be straight lines.

Table 6.4.2 is a quick guide to substrates for different GSTs. Certain substrate/GST combinations have been given preferred status based on two criteria: (1) low nonenzymatic activity compared to enzymatic activity and (2) high enzymatic activity compared to other GSTs; these are represented by double plus marks. Table 6.4.3 lists specific activities for purified GSTs with different substrates. However, caution should be exercised when comparing obtained specific activities with values in Table 6.4.3. The tabulated values might have been obtained under slightly different conditions than those outlined in Table 6.4.1. Note that the data in Tables 6.4.2 and 6.4.3 apply to human GST isoenzymes.

Other mammalian species have GSTs corresponding to the human isoenzymes. Although these orthologs have different specific activities, their activity profiles are often roughly similar, and substrates used to characterize human GSTs are also suitable for studies of GSTs in other mammalian species. Table 6.4.4 gives cytosolic specific activities with CDNB as electrophilic substrate for different human, rat, and mouse tissues. Several of the electrophiles in Table 6.4.1 function as substrates for nonmammalian GSTs as well (e.g., CDNB).

Time Considerations

Several measurements can be performed in one day. Preparing buffer and substrate solutions requires ~1 hr. One continuous assay normally takes 0.5 to 10 min. Adding buffer, substrates, and enzyme solution to the cuvette takes 0.5 to 1 min. The dichloromethane assay takes 10 min to 1 hr, incubation of samples takes 30 min, and absorbance measurements take ~10 min.

HPLC-Based Assays for Enzymes of Glutathione Biosynthesis

The two protocols described in this unit describe assays for the enzymes involved in glutathione (GSH) biosynthesis: glutamate cysteine ligase (GLCL, EC 3.4.4.2; also known as γ-glutamylcysteine synthetase) and glutathione synthetase (GS, EC 6.3.2.3). These enzymes carry out the two-step synthesis of GSH. The first and often rate-limiting step, catalyzed by GLCL, involves the formation of the dipeptide γ-glutamylcysteine (γ-GC) from cysteine and glutamic acid via an unusual γ-carbon peptide bond. The second step involves the addition of glycine by GS to form γ-glutamylcysteinylglycine (GSH).

The protocols detailed here were adapted from the original work by Fahey et al. (1981) and represent modifications of HPLC assays published by Hamel et al. (1992). The fluorescent thiol reactive compound monobromobimane (MBB) is used to derivatize the reaction products, which are then separated by high-performance liquid chromatography (HPLC) and quantified with fluorescence detection.

NOTE: Monobromobimane (MBB) and bimane-derivatized thiols are photolabile. Reactions should be conducted under conditions that protect them from direct light exposure (e.g., in a darkened room or in brown glass reaction tubes).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

ANALYSIS OF GLUTAMATE CYSTEINE LIGASE (GLCL) ACTIVITY IN TISSUES

BASIC PROTOCOL 1

GLCL reactions are set up using cytoplasmic preparations from tissue homogenates as the source for GLCL activity. Samples and standards are derivatized with monobromobimane, and the amount of γ-GC produced is measured by HPLC. The activity of GLCL is determined by comparison with standards.

Materials

Tissue of interest
TES/SB homogenization buffer (see recipe), ice cold
GLCL reaction cocktail (see recipe), ice cold
200 mM 5-sulfosalicylic acid (SSA; Sigma), ice cold
5 mM L-cysteine (Sigma), prepared fresh
γ-Glutamylcysteine (γ-GC; Sigma)
Glutathione (GSH; Sigma)
0.2 M *N*-ethylmorpholine (NEM; Sigma)/0.02 M KOH
25 mM monobromobimane (MBB; Thiolyte reagent, Calbiochem) in acetonitrile

15-ml Corex tubes
Polytron tissue homogenizer (Kinematic AG)

Additional reagents and equipment for HPLC (see Support Protocol)

NOTE: Cysteine, γ-GC, and GSH solutions must be made immediately prior to use, or stored on ice if made in advance. Solutions should not be made more than one hour prior to use in this assay. Cysteine should be at room temperature when it is added to the incubation tubes.

Current Protocols in Toxicology (1999) 6.5.1-6.5.14

Prepare tissue samples

1. Place 1 to 2 g tissue in 4 vol ice-cold TES/SB homogenization buffer in a 15-ml Corex tube. Homogenize on ice with a Polytron tissue homogenizer.

   Homogenization should be carried out on ice to prevent loss of enzyme activity due to overheating of the sample. Homogenize the tissue thoroughly, but avoid excessive homogenization as this can overheat the sample and denature proteins.

   Quantitation of activity in terms of grams of tissue requires accurate weighing and recording of tissue samples prior to analysis.

2. Centrifuge at 10,000 × *g*, 4°C, for 15 min in a floor-model centrifuge. Place sample on ice.

   Only the supernatant (cytoplasmic protein) is used in the assay.

3. Prepare triplicate baseline samples (to determine background γ-GC levels) by adding the following to three microcentrifuge tubes:

   80 µl ice-cold GLCL reaction cocktail
   50 µl water
   50 µl 200 mM ice-cold SSA
   20 µl supernatant sample.

   Place on ice ≥15 min.

   Baseline samples are ready for derivatization (step 12).

Incubate samples for enzymatic activity

4. Prepare triplicate microcentrifuge tubes containing 80 µl ice-cold GLCL reaction cocktail.

   Reaction tubes should be prepared immediately prior to assay or stored on ice to prevent degradation of the ATP.

5. At 15- to 30-sec time intervals, with the sample on ice, add 20 µl sample to each reaction tube and place in a 37°C water bath. Preincubate reaction tubes for 5 min at 37°C.

   Ten samples can be processed during each 5-min incubation if a 30-sec interval is used.

6. At the appropriate time, initiate each reaction by adding 50 µl of 5 mM L-cysteine (final reaction volume 150 µl). Vortex briefly and incubate for 5 min at 37°C.

   It is essential that any modifications to this GLCL activity assay result in a final volume of 150 µl at this step. Otherwise, modifications of the neutralization and derivatization steps will also be required.

7. Stop each reaction at the appropriate time by adding 50 µl ice-cold 200 mM SSA and vortex. Place tubes on ice ≥15 min.

Prepare standards

8. Prepare a 10 mM γ-GC standard solution in TES/SB homogenization buffer. Dilute to desired concentrations (typically 0.1, 0.25, 0.5, 0.75, and 1.0 mM) in TES/SB homogenization buffer.

   Alternatively, diluted GSH solutions can be used to construct a standard curve, because detector response factors (area units/nmol) are identical for bimane-derivatized γ-GC and GSH, and because γ-GC is relatively expensive. A γ-GC standard should be run to characterize the retention time of the γ-GC-bimane derivatization product.

9. Prepare a 10 mM GSH standard solution in TES/SB homogenization buffer. Dilute to desired concentrations (typically 0.1, 0.25, 0.5, 0.75, and 1.0 mM) in TES/SB homogenization buffer.

10. Prepare triplicate standard tubes for each standard dilution by adding the following to microcentrifuge tubes:

    80 µl GLCL reaction cocktail
    50 µl 200 mM SSA
    50 µl water
    20 µl γ-GC or GSH standard solution.

11. Prepare one blank tube as in step 10, but with 20 µl TES/SB homogenization buffer instead of standard.

Derivatize samples and standards

12. Vortex samples and standards. Centrifuge at top speed in a benchtop microcentrifuge for 2 min.

13. Add 200 µl of 0.2 M NEM/0.02 M KOH.

    The pH must be between 7.5 and 8.5 following NEM/KOH addition for efficient derivatization by MBB. It is recommended that this solution be tested on a blank prior to addition to samples, and that pH paper (e.g., colorPhast pH 2 to 9, EM Science) be used to verify pH.

14. Add 20 µl of 25 mM MBB and vortex. Incubate at room temperature in the dark for 30 min.

15. Add 200 µl of 200 mM SSA and vortex. Microcentrifuge at top speed for 2 min.

Determine enzyme activity

16. Analyze samples and standards using HPLC (see Support Protocol).

17. Average triplicates. Prepare standard curves from standards and calculate the amount of GSH and γ-GC in each sample (baseline and incubated).

18. To calculate γ-GC formation, subtract the GSH level in the baseline sample from that in the incubated sample, and then add this difference to the γ-GC level in the incubated sample.

    γ-GC is usually not detected in baseline samples.

19. Express GLCL activity in µmol γ-GC formed/min/g tissue or in nmol/min/mg protein.

    To express activity per mg protein, use the Bradford method for protein determination (see APPENDIX 3). The assay of protein in sample supernatants should be performed immediately after the GLCL assay is completed.

ANALYSIS OF GLCL ACTIVITY IN CULTURED CELLS

ALTERNATE PROTOCOL 1

In order to detect GLCL activity in cultured cells, Basic Protocol 1 can be performed with the following modifications. For convenience, one may substitute phosphate-buffered saline containing serine/borate (PBS/SB) for TES/SB. There is no difference in enzyme activities or baseline GSH levels when employing PBS/SB or TES/SB with cultured cells.

Additional Materials *(also see Basic Protocol 1)*

Cell cultures of interest
PBS/SB: PBS (*APPENDIX 2A*) containing 20 mM boric acid and 1 mM serine, pH 7.4
Probe sonicator

1. Centrifuge cell suspensions in 15- or 50-ml conical polypropylene tubes at 150 to 200 × *g*, 4°C, for 10 min. Place tubes with pelleted cells on ice, remove supernatants, and resuspend cells in ice-cold PBS/SB.

   For best results, pellet cells in medium or PBS containing 5% (v/v) serum to prevent premature rupture and leakage of cytoplasmic contents.

   If activity is to be expressed per million cells (see step 6), the cells should be counted prior to pelleting.

   Cells from suspension or adherent cultures can be used. Adherent cells should be trypsinized and pelleted prior to this step. Note that GLCL activity changes with confluency, so it is essential to test cells at the same level of confluency for consistent results.

2. Using a probe sonicator, disrupt 10 to 15 million cells in 500 µl ice-cold PBS/SB, keeping tube on ice during and after sonication. Use multiple short blasts to minimize local heating of the sample and do not oversonicate as this can affect enzyme activity.

3. Centrifuge cell sample at 14,000 rpm (maximum speed) in a microcentrifuge for 10 min at 4°C. Place on ice.

4. Prepare samples (including baseline sample) as described (see Basic Protocol 1, steps 3 to 7), but reduce the stock concentration of cysteine in step 6 to between 0.5 and 5 mM. Increase incubation time to 10 min for samples with low GLCL activity.

5. Prepare γ-GC and GSH standards (see Basic Protocol 1, steps 8 through 11) at 5, 10, 25, 50, 75, and 100 µM in PBS/SB.

6. Derivatize standards and samples (see Basic Protocol 1, steps 12 to 15) but reduce MBB in step 14 to 12.5 mM. Analyze by HPLC (see Support Protocol) using the high-sensitivity setting on the HPLC fluorescence detector. Increase the injection volume for samples with low GLCL activity. Determine GLCL activity (see Basic Protocol 1, steps 17 to 19), expressing activity as nmol/mg protein/min or as nmol/10^6 cells/min.

BASIC PROTOCOL 2

ANALYSIS OF GLUTATHIONE SYNTHETASE (GS) ACTIVITY IN TISSUES

Cytoplasmic preparations from tissue homogenates are dialyzed to remove endogenous GSH and are then analyzed for GS activity.

Materials

Tissue of interest
TES/SB homogenization buffer (see recipe), ice cold
GS reaction cocktail (see recipe), ice cold
200 mM 5-sulfosalicylic acid (SSA; Sigma), ice cold
5 mM γ-glutamylcysteine (γ-GC; Sigma), prepared fresh
Glutathione (GSH; Sigma)
0.2 M *N*-ethylmorpholine (NEM: Sigma)/0.02 M KOH
25 mM monobromobimane (MBB; Thiolyte reagent, Calbiochem) in acetonitrile

15-ml Corex tubes
Polytron tissue homogenizer (Kinematic AG)
Flow Microdialysis System (Life Technologies)

Additional reagents and equipment for HPLC (see Support Protocol)

NOTE: γ-GC and GSH solutions must be made immediately prior to use, or stored on ice if made in advance. Solutions should not be made more than one hour prior to use in this assay. γ-GC should be at room temperature when it is added to the incubation tubes.

Prepare tissue samples

1. Place 1 to 2 g tissue in 4 vol ice-cold TES/SB homogenization buffer in a 15-ml Corex tube. Homogenize on ice in a Polytron tissue homogenizer.

   Homogenization should be carried out on ice to prevent loss of enzyme activity due to overheating of the sample. Homogenize the tissue thoroughly, but avoid excessive homogenization as this can overheat the sample and denature proteins.

   Quantitation of activity in terms of grams of tissue requires accurate weighing and recording of tissue samples prior to analysis.

2. Centrifuge at 10,000 × *g*, 4°C, for 15 min in a floor-model centrifuge. Place sample on ice.

   Only the supernatant (cytoplasmic protein) is used in the assay.

3. Dialyze the entire supernatant at 4°C for 3 hr by continuous-flow dialysis (e.g., with a Flow Microdialysis system, according to manufacturer's instructions) against 2 liters of TES/SB homogenization buffer. Return to ice.

   This removes ~85% of the endogenous GSH and does not affect enzyme activity.

4. Prepare triplicate baseline samples (to determine background GSH levels) by adding the following to three microcentrifuge tubes:

   80 µl ice-cold GS reaction cocktail
   50 µl water
   50 µl 200 mM ice-cold SSA
   20 µl dialyzed sample.

   Place on ice ≥15 min.

   Baseline samples are ready for derivatization (step 12).

Incubate samples for enzymatic activity

5. Prepare triplicate microcentrifuge tubes containing 80 µl ice-cold GS reaction cocktail.

   Reaction tubes should be prepared immediately prior to assay or stored on ice to prevent degradation of the ATP.

6. At 15- to 30-sec time intervals, with the sample on ice, add 20 µl sample to each reaction tube and place in a 37°C water bath. Preincubate reaction tubes for 5 min at 37°C.

   Ten samples can be processed during each 5-min incubation if a 30-sec interval is used.

7. At the appropriate time, initiate each reaction by adding 50 µl of 5 mM γ-GC. Vortex briefly and incubate for 5 min at 37°C.

   It is essential that any modifications to this GS activity assay result in a final volume of 150 µl at this step. Otherwise, modifications of the neutralization and derivatization steps will also be required.

8. Stop each reaction at the appropriate time by adding 50 µl ice-cold 200 mM SSA and vortex. Place tubes on ice ≥15 min.

Prepare standards

9. Prepare a 10 mM GSH standard solution in TES/SB homogenization buffer. Dilute to desired concentrations (typically 0.1, 0.25, 0.5, 0.75, and 1.0 mM) in TES/SB homogenization buffer.

10. Prepare triplicate standard tubes for each standard dilution by adding the following to microcentrifuge tubes:

    80 µl GS reaction cocktail
    50 µl 200 mM SSA
    50 µl water
    20 µl GSH standard solution.

11. Prepare one blank tube as in step 10, but with 20 µl TES/SB homogenization buffer instead of standard.

Derivatize samples and standards

12. Vortex samples and standards. Centrifuge at maximum speed in a benchtop microcentrifuge for 2 min.

13. Add 200 µl of 0.2 M NEM/0.02 M KOH.

    The pH must be between 7.5 and 8.5 following NEM/KOH addition for efficient derivatization by MBB. It is recommended that this solution be tested on a blank prior to addition to samples, and that pH paper (e.g., colorPhast pH 2 to 9, EM Science) be used to verify pH.

14. Add 20 µl of 25 mM MBB and vortex. Incubate at room temperature in the dark for 30 min.

15. Add 200 µl of 200 mM SSA and vortex. Microcentrifuge at maximum speed for 2 min.

Determine enzyme activity

16. Analyze samples and standards using HPLC (see Support Protocol).

17. Average triplicates. Prepare standard curves from standards and calculate the amount of GSH in each sample (baseline and incubated).

18. To calculate GSH formation, subtract the GSH level in the baseline sample from that in the incubated sample.

19. Express GS activity in µmol GSH formed/min/g tissue or in nmol/min/mg protein.

    To express activity per mg protein rather than per mg tissue, use the Bradford method for protein determination (see APPENDIX 3). The assay of protein in sample supernatants should be performed immediately after the GS assay is completed.

ALTERNATE PROTOCOL 2

ANALYSIS OF GS ACTIVITY IN CULTURED CELLS

In order to detect GS activity in cultured cells, Basic Protocol 2 can be performed with the following modifications. For convenience, one may substitute phosphate-buffered saline containing serine/borate (PBS/SB) for TES/SB. There is no difference in enzyme activities or baseline GSH levels when employing PBS/SB or TES/SB with cultured cells.

Additional Materials *(also see Basic Protocol 2)*

Cell cultures of interest
PBS/SB: PBS (*APPENDIX 2A*) containing 20 mM boric acid and 1 mM serine, pH 7.4
Probe sonicator

1. Centrifuge cell suspensions in 15- or 50-ml conical polypropylene tubes at 150 to 200 × *g*, 4°C, for 10 min. Place tubes with pelleted cells on ice, remove supernatants, and resuspend cells in ice-cold PBS/SB.

For best results, pellet cells in medium or PBS containing 5% (v/v) serum to prevent premature rupture and leakage of cytoplasmic contents.

If activity is to be expressed per million cells (see step 6), the cells should be counted prior to pelleting.

Cells from suspension or adherent cultures can be used. Adherent cells should be trypsinized and pelleted prior to this step. Note that GS activity changes with confluency, so it is essential to test cells at the same level of confluency for consistent results.

2. Using a probe sonicator, disrupt 10 to 15 million cells in 500 µl ice-cold PBS/SB, keeping tube on ice during and after sonication. Use multiple short blasts to minimize local heating of the sample and do not oversonicate as this can affect enzyme activity.
3. Centrifuge cell sample at 14,000 rpm (maximum speed) in a microcentrifuge for 10 min at 4°C. Place on ice.
4. Perform dialysis (against PBS/SB) and prepare samples (including baseline sample) as described (see Basic Protocol 2, steps 3 to 8), but reduce the stock concentration of γ-GC in step 7 to between 0.5 and 5 mM. Increase incubation time to 10 min for samples with low GS activity.
5. Prepare GSH standards (see Basic Protocol 2, steps 9 to 11) at 5, 10, 25, 50, 75, and 100 µM GSH in PBS/SB.
6. Derivatize standards and samples (see Basic Protocol 2, steps 12 to 15) but reduce MBB in step 14 to 12.5 mM. Analyze by HPLC (see Support Protocol) using the high-sensitivity setting on the HPLC fluorescence detector. Increase the injection volume for samples with low GS activity. Determine GS activity (see Basic Protocol 2, steps 17 to 19), expressing activity as nmol/mg protein/min or as nmol/10^6 cells/min.

MEASUREMENT OF γ-GC AND GSH BY HPLC

SUPPORT PROTOCOL

HPLC analysis is used to quantify the activity of GLCL or GS in the synthesis of GSH.

Materials

Derivatized samples and standards for analysis (see Basic Protocols 1 and 2 and Alternate Protocols 1 and 2)
1 mM tetrabutylammonium phosphate (TBAP; Regis), pH adjusted to 3.0 with 10% (v/v) phosphoric acid
HPLC-grade methanol

Shimadzu SIL-6B HPLC system with autosampler, CR5A integrator, and RF-535 fluorescence detector (or equivalent)
Pellicular C18 guard column (Alltech)
150-mm reversed-phase C18 HPLC column (Alltech)

1. Set up an HPLC system with a Pellicular C18 guard column, a 150-mm reversed-phase C18 HPLC column, and fluorescence detection (excitation at 375 nm and emission at 475 nm).

If a fluorescence detector is not available, it is possible to use a UV/visible detector (380 nm). In the authors' experience, however, fluorescence detection provides at least one to two orders of magnitude more sensitivity than that obtained with UV/visible detection.

The conditions described here are optimized for the Shimadzu SIL-6B HPLC with a CR5A integrator and an RF-535 fluorescence detector. Optimal conditions for other systems will have to be determined by the investigator.

Table 6.5.1 Gradient Program for HPLC Analysis

Time (min)	% aqueous phase	% organic phase
0	95	5
1	80	20
10	70	30
12	40	60
14	40	60
16	95	5
21	95	5

Table 6.5.2 Integrator Settings for HPLC Analysis

Feature[a]	Low sensitivity	High sensitivity
Width	5	5
Drift	0	0
T DBL	0	0
Attenuation	7	9
Method	0421	0421
SPL WT	100	100
Slope	15,000	15,000
Minimum area	2,000	50,000
Stop time	16	16
Speed	5	5
Format	0	0
IS WT	1	1

[a]Abbreviations: IS WT, internal standard weight; SPL WT, sample weight; T DBL, slope and width doubling.

2. Prepare mobile phases. Use 1 mM TBAP (an ion-pairing agent), pH 3.0, as the aqueous phase, and HPLC-grade methanol as the organic phase.
3. Program the gradient as indicated in Table 6.5.1 and set the integrator as indicated in Table 6.5.2.
4. Run the column using an autosampler injection volume of 25 to 50 µl and a flow rate of 1.5 ml/min.

Because the level of activity varies with different tissue or cell line sources, the conditions must be optimized for each source to keep the level within the linear range for the assay. This may be accomplished by adjusting the sensitivity, the injection volume, and/or the attenuation settings. The final derivatized samples contain enough volume to run a couple of test injections and to adjust injection and sensitivity settings prior to running the whole set of samples. This is strongly recommended.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

GLCL reaction cocktail

Add to 100 ml of water:
1.2 g ATP (20 mM; Sigma)
1.7 g L-glutamic acid (100 mM; Sigma)

continued

37 mg EDTA (1.0 mM)
406 mg $MgCl_2$ (20 mM)
2.42 g Tris (200 mM)
Adjust pH to 7.4
Store up to 6 months at –20°C

GS reaction cocktail

Add to 100 ml of water:
1.2 g ATP (20 mM; Sigma)
751 mg L-glycine (100 mM; Sigma)
37 mg EDTA (1.0 mM)
406 mg $MgCl_2$ (20 mM)
2.42 g Tris (200 mM)
Adjust pH to 7.4
Store up to 6 months at –20°C

TES/SB homogenization buffer

Add to 1 liter of water:
85.58 g sucrose (0.25 M)
2.42 g Tris (20 mM)
370 mg EDTA (1 mM)
1.24 g boric acid (20 mM)
105 mg L-serine (1 mM)
Adjust pH to 7.4 with 1 N HCl
Store up to 6 months at 4°C

NOTE: *The inclusion of serine and borate in the homogenization buffer is necessary to inhibit any residual γ-glutamyl transpeptidase (GGT) activity. Otherwise, GGT will consume GSH and thus affect the calculation of baseline and sample GSH concentrations.*

COMMENTARY

Background Information

Glutathione (GSH) is important in free radical scavenging, xenobiotic conjugation, and maintenance of thiol redox status; for reviews see Meister (1995) and *UNIT 6.1*. Given adequate cysteine supply, the rate-limiting enzyme in GSH synthesis is GLCL. However, under some circumstances (e.g., cirrhosis of the liver), GS has been shown to be limiting for GSH synthesis (Loguercio et al., 1992).

GLCL is a heterodimeric enzyme consisting of a 70-kDa catalytic subunit (GLCLC) and a 29-kDa subunit (GLCLR) that appears to regulate the catalytic activity of the holoenzyme (Huang et al., 1993a,b). The cDNAs for both subunits have been cloned from rat, human, and mouse cells (Yan and Meister, 1990; Gipp et al., 1992, 1995; Huang et al., 1993a; Kang et al., 1997; Reid et al., 1997a,b). The expression of the mRNAs for both GLCLC and GLCLR has been reported for various tissues in humans (Gipp et al., 1995). Regional expression of GLCLC mRNA has been localized by in situ hybridization in mouse brain (Kang et al., 1997), rat kidney (Li et al., 1996a), and rat brain (Li et al., 1996b). Moreover, both subunit genes have been mapped on human and mouse chromosomes (Tsuchiya et al., 1995; Walsh et al., 1996).

GLCLC is catalytically active as a monomer; however, the K_m for glutamate is high compared to physiological levels, suggesting that in the absence of GLCLR the enzyme would not be active in situ. GLCL activity is negatively regulated by GSH, which competes for the glutamate binding site on the enzyme and inhibits γ-GC synthesis with a K_i of ~8 mM. The holoenzyme has a lower K_m for glutamate and higher K_i for GSH than GLCLC alone (Huang et al., 1993a,b). A model for redox activation of GLCL has been proposed in which a disulfide bridge between the two subunits changes the active site conformation to favor glutamate over GSH. Through this proposed mechanism the enzyme would be activated by oxidizing conditions within the cell. Indeed, in purified enzyme preparations from rat kidney, ~70% of GLCL was disulfide-linked and had an apparent molecular weight of ~100 kDa under nonreducing conditions (Huang et al.,

1993b). These results suggest that in addition to feedback inhibition by GSH there may be a "redox switch" on GLCL that determines enzyme activity. The GLCL assay as detailed in Basic Protocol 1 is not designed to assess the effects of the GLCL regulatory subunit, as glutamate levels are not limiting in the reaction cocktail.

GLCL has been shown to be under transcriptional control, and is induced by many treatments, especially agents that cause oxidative stress (Borroz et al., 1994; O'Dwyer et al., 1996; Cai et al., 1997; Galloway et al., 1997; Sekhar et al., 1997; Tian et al., 1997; Wild et al., 1998). Recently, it was reported that GLCL activity in cells is rapidly increased by H_2O_2, suggesting that post-translational regulation of the enzyme also exists (Ochi, 1995, 1996). The mechanisms of transcriptional and post-translational activation of GLCL are unknown, although recent evidence indicates the presence of antioxidant regulatory elements in the 5′ region of the genes encoding this enzyme (Mulcahy et al., 1997). The combined effect of transcriptional and post-translational upregulation of GLCL activity may explain the rapid and sustained increase in intracellular GSH that is often seen following oxidative stress and GSH depletion. While there is evidence of tissue-specific differences in GS expression (see below), it is commonly believed that control of cellular GSH content is achieved by regulation of GLCL.

Compared to GLCL, much less effort has been spent in studies of GS. Bacterial GS has been extensively studied, but this monomeric enzyme differs substantially from the GS isolated from eukaryotic organisms. The GS gene has been cloned from frogs, rats, mice, and humans (Habenicht et al., 1993; Gali and Board, 1995; Huang et al., 1995; Shi et al., 1996a). Mammalian GS is a 118-kDa enzyme composed of two identical subunits. Humans lacking functional GS demonstrate GSH deficiency, hemolytic anemia, 5-oxoprolinurea, and in severe cases, neurological disorders (Wellner et al., 1974; Larsson and Mattsson, 1976). While only one GS gene has been mapped in humans, the differences in severity of symptoms observed in patients with GS deficiency may be due to several mutations resulting in differential impairment of GS function (Shi et al., 1996b; Dahl et al., 1997). GS is expressed at the highest levels in the kidney, which has approximately three-fold higher GS activity than liver and six- to ten-fold higher activity than brain, lung, or spleen. Lower levels of expression are seen in smooth and cardiac muscle (Shi et al., 1996a).

Although GS is not considered to be the rate-limiting step in GSH formation, there is some evidence to indicate that GS activity is influenced by oxidative stress (Sun, 1997). Recently the GS gene has been shown to have six alternative transcripts, derived as mRNA splice variants from a single gene. There is some indication of organ-specific expression, but little information is available as to the tissue distribution of the various transcripts. While the functional differences of these transcripts are unknown, the prediction that they code for proteins of three different lengths suggests that regulation of GS may occur at multiple levels (Shi et al., 1996a).

Other, non-HPLC-based assays have been used to assess the kinetics of GLCL in purified enzyme preparations from mammalian and bacterially expressed sources (Seelig and Meister, 1985) and in liver cytosol (Sun et al., 1996). The most commonly used kinetic assay is a coupled reaction between GLCL, pyruvate kinase, and lactate dehydrogenase. GLCL uses ATP in the synthesis of γ-GC; the ADP formed is phosphorylated by pyruvate kinase, which converts phosphoenol-pyruvate to pyruvate; the free pyruvate is then reduced to lactate. The rate of reaction is followed by the decrease in the absorbance of NADH, which serves as electron donor for the final reaction. A modification of this method involves the use of L-α-aminobutyrate instead of L-cysteine to reduce complications due to thiol oxidation (Seelig and Meister, 1985). A different approach has been taken by Sun et al. (1996). A fluorogenic glutathione-*S*-transferase (GST) substrate, monochlorobimane, is used to follow the production of GSH in dialyzed liver cytosols. The rate of production of the fluorescent GSH-bimane adduct is compared to GSH-bimane production in samples preincubated with buthionine sulfoximine, a specific inhibitor of GLCL. The increase in bimane fluorescence is taken as a direct measure of GLCL activity since GS and the GSTs are not thought to be rate limiting in liver.

GS activity has been measured by incorporation of radiolabeled glycine into GSH over a reaction period, or by quantification of ADP or P_i production during the reaction. Both γ-GC and L-γ-glutamyl-L-α-aminobutyrate, a non-thiol analog of γ-GC, have been used as reaction substrates for the GS activity assays. [^{14}C]GSH or [^{14}C]L-γ-glutamyl-L-α-aminobutyrylglycine is quantified by scintillation counting after sepa-

ration from unincorporated [^{14}C]Gly. ADP is measured using the pyruvate kinase/lactate dehydrogenase system described above, whereas P_i may be measured by a colorimetric reaction with molybdate (Meister, 1985).

Critical Parameters and Troubleshooting

It is necessary to prepare standards and dilutions of the samples such that the enzyme activities and the response of the HPLC detector are within linear range. To do this one must anticipate relative activities from the tissues to be tested. In general, GLCL activities are highest in kidney and liver, with lower amounts in other tissues. Brain, lung, heart, ovary, and stomach show reasonable expression of GLCL, whereas thymus, uterus, adrenal gland, and eye have little GLCL per milligram total protein.

The protocols described above are appropriate for determination of GLCL and GS activity from strongly expressing tissues such as kidney or liver. The GLCL and GS activity in other tissues or cell types must be determined empirically, as modifications of the basic assay may be required for useful assessment of enzyme activity. For example, lymphocytes, which contain very little GLCL activity per milligram protein, may be assayed at low cysteine concentrations (0.125 to 1.25 mM), which permits HPLC detection at high sensitivity without peak interference from excess cysteine. In contrast, kidney GLCL activity is so high that substrate depletion is a concern at very low cysteine concentrations. Tissues with lower activity may also be assayed with a 10-min incubation time to enhance the sensitivity of the test. In some cases it is simpler to increase or decrease the injection volume of the derivatized products than to alter the assay protocol.

The addition of serine and borate to the homogenization buffers is essential for performing these assays, especially for tissues or cells that contain significant amounts of GGT activity. A protease inhibitor mix, (which may include aprotinin, leupeptin, phenylmethylsulfonyl fluoride, Pefabloc, N^{α}-tosyl-Lys-chloromethyl ketone, and/or N^{α}-tosyl-Phe-chloromethyl ketone) may also be added routinely to homogenization and sonication buffers. This is especially important if numerous samples are to be prepared on the same day, as GLCL is subject to degradation over time even when homogenates are kept on ice.

The stability of GSH, cysteine, and γ-glutamylcysteine at normal pH is very poor. Therefore, it is important to prepare baseline samples and standards immediately before use; the low pH of the SSA solution stabilizes the GSH. In addition, while freezing cell or tissue samples at −80°C prior to homogenization preserves the enzyme activity, it will not prevent loss of GSH. Therefore the GSH "baseline" levels from this assay cannot be used as true measures of reduced GSH in the tissues or cells tested.

Following treatment with SSA, the samples must be kept on ice for at least 15 min to ensure efficient precipitation of cellular proteins. Decreased incubation times can interfere with subsequent derivatization by MBB.

The pH of the sample is critical for efficient MBB derivatization of thiols. A blank should be tested with pH paper after addition of NEM/KOH to ensure that the pH of the sample is between 7.5 and 8.5 prior to addition of MBB. If for some reason the pH is off, it may be necessary to adjust the concentration of the NEM/KOH to attain the desired pH in the sample.

GSH-MBB and γ-GC-MBB adducts are labile and must be stored carefully. The acidic pH of the assay solution following derivatization helps to stabilize the products. However the samples must be protected from light prior to HPLC analysis. If there are too many samples for one day's run, derivatized samples should be stored at −80°C until they can be processed. Storage for longer than 24 hr is not recommended.

If the final GLCL and GS activity values are to be reported per milligram protein, it is important to exercise care with the protein assay. Protein levels in homogenates should be determined on the same day as the enzyme assay is performed, since freeze-thaw cycles can alter soluble protein concentrations. In addition, it is recommended that the Bradford method be used to assay protein levels as it does not rely upon sulfhydryl binding for determination of protein concentrations.

Anticipated Results

A typical HPLC chromatogram obtained using these methods is shown in Figure 6.5.1. Peaks for cysteine, γ-glutamylcysteine, and GSH are indicated. It is convenient to analyze the results of such experiments using a spreadsheet software program (e.g., Excel).

The GSH readings from baseline samples are subtracted from the GSH readings from incubated samples. In the case of the GLCL assay, this difference is then added to the γ-GC levels obtained in incubated samples (γ-GC is usually not detected in baseline samples). The

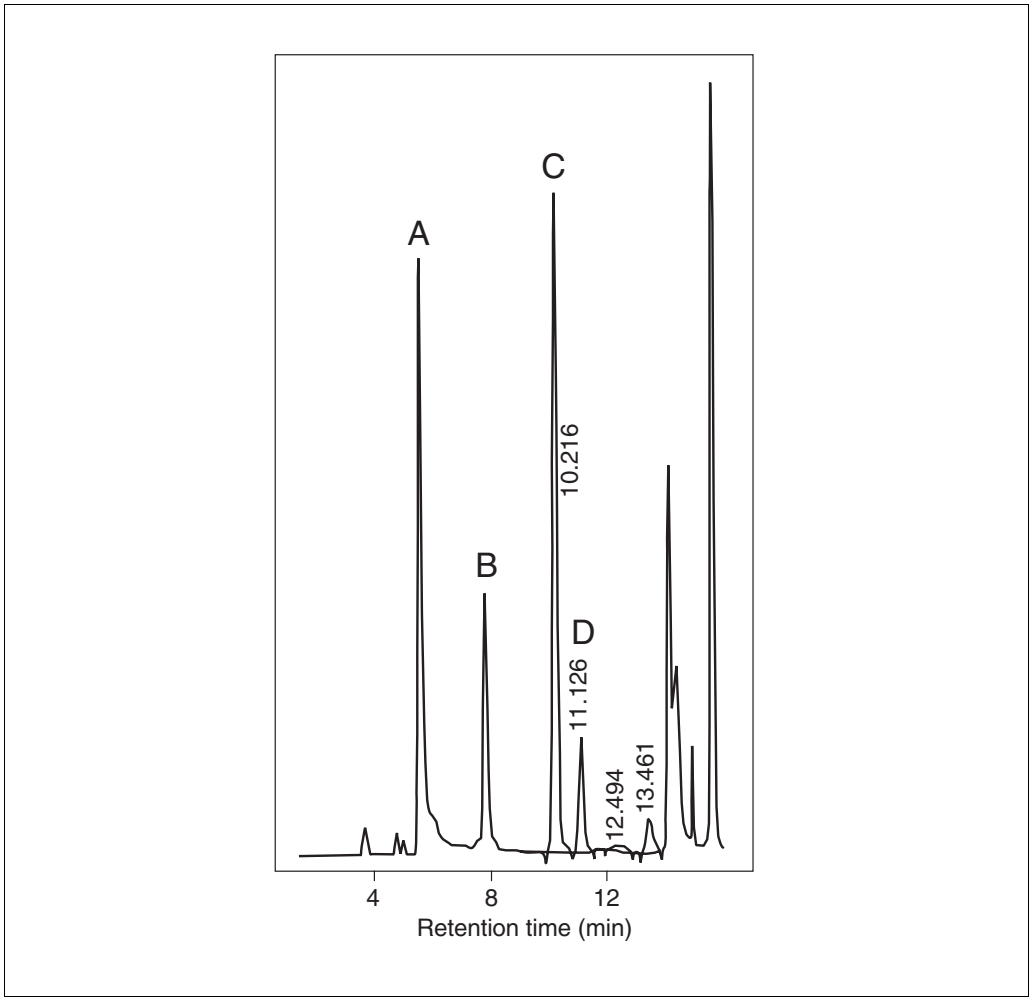

Figure 6.5.1 Typical chromatogram achieved using the GLCL protocol. Peaks corresponding to cysteine (A), free bimane (B), GSH (C), and γ-GC (D) are indicated.

total represents γ-GC formation over the course of the incubation period. In the case of the GS assay, the GSH levels in the baseline samples are simply subtracted from the GSH levels in the incubated samples to give a total of GSH formed during the incubation.

The activity can be expressed as μmol γ-GC or GSH formed/minute/gram tissue (which necessitates the accurate weighing and recording of tissues samples prior to analysis), or nmol γ-GC or GSH formed/min/mg protein. The Bradford method is recommended for protein determination. Methods that rely on bicinchoninic acid (BCA) are not advised as they may be influenced by the thiol redox status of the sample.

Time Considerations

Incubation and derivatization of samples for a typical experiment (25 to 50 reaction tubes plus standards) requires ~2 hr. Homogenization of tissues and determination of protein levels in homogenates will require additional time. HPLC analysis of samples in the autosampler described (see Support Protocol) requires ~30 min per sample. Since the derivatized samples should not be stored more than 24 hr (see Critical Parameters and Troubleshooting), the total number of standards and samples should be limited accordingly. The total number of derivatized samples to be run may be reduced in the following ways. (1) Characterize the HPLC column for retention time of γ-GC and GSH in a separate experiment. (2) Characterize the column for response factors associated with the GSH-bimane or γ-GC-bimane standards, so that a full standard curve does not need to be run with each set of samples. By thoroughly characterizing the chromatography, the investigator minimizes the number of standards that must be run alongside any given set of samples. (3) When handling error ceases to be a problem and triplicate replication is consistently good, reduce the number of GSH baseline samples in

the GLCL assay from three to two. Care should be taken to ensure that the samples are protected from light, that there is adequate paper supply in the integrator, and that there is adequate TBAP and HPLC-grade methanol for processing all of the samples and standards.

γ-Glutamyl Transpeptidase Activity Assay

γ-Glutamyl transpeptidase (EC 2. 3. 2. 2) catalyzes the transfer of a γ-glutamyl group from glutathione or other γ-glutamyl compounds to amino acids or dipeptides. It also catalyzes hydrolysis of the γ-glutamyl bond (Fig. 6.6.1). When a γ-glutamyl donor acts as an acceptor, the reaction catalyzed by the enzyme leads to the formation of a γ-(γ-glutamyl)-glutamyl compound, in which case the reaction is referred to as autotranspeptidation. This enzyme is also known as γ-glutamyltransferase and is frequently abbreviated as GGT, γ-GTP, or γ-GT. It plays an important role in glutathione metabolism because the reaction catalyzed by the enzyme constitutes the first step in the degradation of glutathione. In addition, the removal of a γ-glutamyl moiety from glutathione-*S*-conjugates with xenobiotics by GGT is a step that is involved in the pathway for the formation of mercapturic acids which are excreted into urine.

For assay of GGT activity, the most common substrates are γ-glutamyl derivatives of *p*-nitroaniline or related compounds because they are convenient, give sensitive results, and are sufficiently specific for the enzyme. Since the release of *p*-nitroaniline from γ-glutamyl-*p*-nitroanilide is facilitated by the addition of an appropriate acceptor dipeptide, glycylglycine is usually used as an acceptor substrate in the assay. Although the enzyme can produce *p*-nitroaniline via hydrolysis and/or autotranspeptidation even in the absence of the acceptor, the rate of *p*-nitroaniline release is quite slow. Cleavage of the γ-glutamyl bond of the donor by the enzyme leads to the stoichiometric release of *p*-nitroaniline, which can easily be detected via spectrophotometry.

This unit describes one of the most convenient methods for the assay of GGT activity (see Basic Protocol), in which γ-glutamyl-*p*-nitroanilide and glycylglycine are used as a donor and an acceptor substrate, respectively (Fig. 6.6.2). The use of another *p*-nitroaniline derivative (L-γ-glutamyl-3-carboxy-4-nitroanilide) as the donor is also described (see Alternate Protocol).

SPECTROPHOTOMETRIC ASSAY USING γ-GLUTAMYL-*p*-NITROANILIDE FOR GGT ACTIVITY

BASIC PROTOCOL

An assay method using γ-glutamyl-*p*-nitroanilide and glycylglycine as a donor and an acceptor substrate, respectively, is most commonly used and is suitable for most samples—e.g., tissues, cultured cells, and body fluids. Although a variety of protocols involving these substrates have been reported, they are, in principle, the same as the protocol described here. γ-Glutamyl-*p*-nitroanilide is relatively insoluble in water, and its solubility is quite low at certain pH values. Activity is measured under the following conditions: 0.1 M Tris·Cl buffer, 1 mM γ-glutamyl-*p*-nitroanilide, 20 mM glycylglycine, pH 8.0.

Materials

L-γ-Glutamyl-*p*-nitroanilide (free base or HCl salt; Sigma)
0.2 N HCl
Glycylglycine free base
0.5 M Tris·Cl, pH 9.0 to 9.5 (*APPENDIX 2A*)
Sample (e.g., tissue or cell homogenate, membrane preparation, microsome suspension)
Homogenate buffer (see recipe)

Potter-Elvehjem homogenizer or Dounce homogenizer
Spectrophotometer with temperature-controlled cuvette holder
Semimicro cell (light path = 1 cm)

Current Protocols in Toxicology (2000) 6.6.1-6.6.8

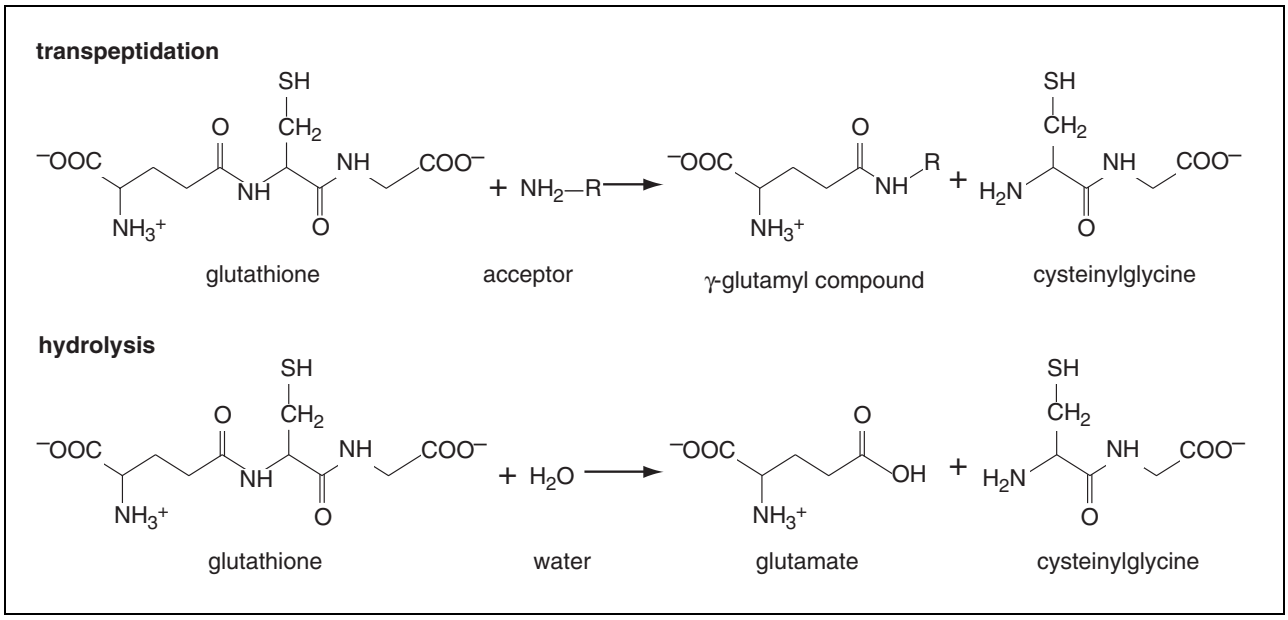

Figure 6.6.1 Reactions catalyzed by γ-glutamyl transpeptidase.

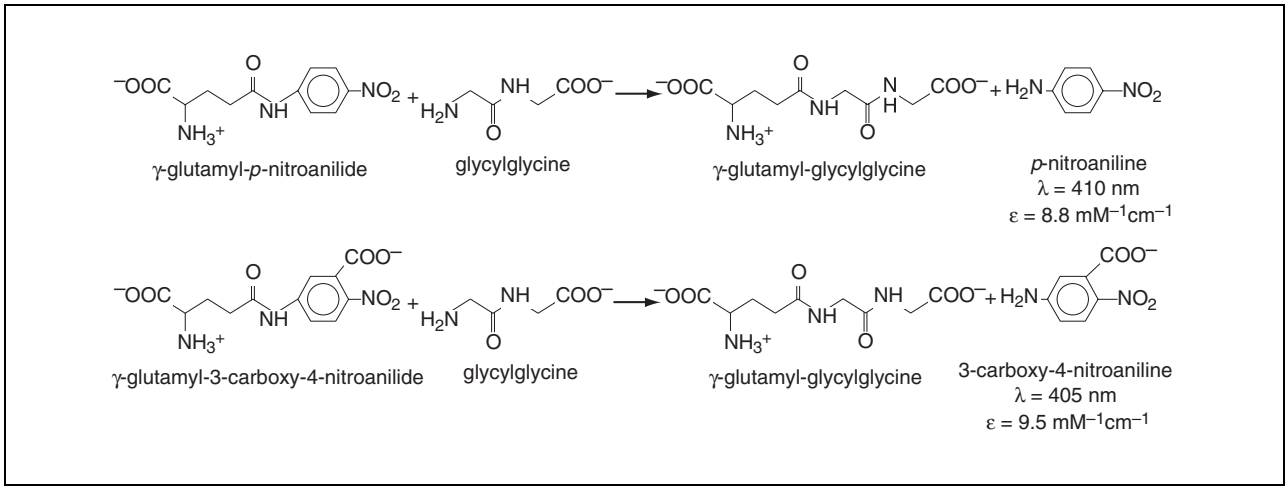

Figure 6.6.2 Reactions which occur in the γ-glutamyl transpeptidase activity assay.

Prepare assay mixture

1. Completely dissolve L-γ-glutamyl-*p*-nitroanilide (0.134 g for free base form or 0.152 g for HCl salt) in 10 ml of 0.2 N HCl.

   An acidic pH is necessary because it is difficult to dissolve the compound in water or in a buffer at pH ~6. In addition, a strong alkaline solution may cause hydrolysis of the γ-glutamyl bond of the substrate.

2. Add 350 ml water to the solution from step 1, and then completely dissolve 1.32 g of glycylglycine (free base) in the resulting mixture.
3. Add 100 ml of 0.5 M Tris·Cl, pH 9.0 to 9.5.
4. Adjust the pH to 8.0 with HCl and bring the volume up to 500 ml with water.

   This assay mixture can be stored at –20°C for up to 1 month and at 4°C for 24 hr.

Prepare sample

5. Suspend cultured cells or diced tissues in the homogenate buffer.

   The homogenate buffer may be replaced by 20 to 100 mM Tris·Cl, pH 8.0, for cells. Most of the commonly used buffers, such as phosphate buffer and HEPES buffer, can also be used as long as the pH is maintained at 7.0 to 8.0. The enzyme appears to be relatively unstable at acidic pH. In addition, borate buffer should be avoided because it can inhibit the enzyme in the presence of L-serine. Approximately 10^7 cells are resuspended in ~400 µl of the buffer.

6. Homogenize the cells or tissues using a Potter-Elvehjem or Dounce homogenizer (~10 strokes).

   In the case of cultured cells, sonication may also be applicable.

7. Centrifuge 10 min at 900 × *g*, 4°C. Retain the supernatant and discard the pellet, which contains debris.

   If the sample is sufficiently homogeneous, this step may be omitted.

Measure γ-glutamyl transpeptidase activity

8. Place 1 ml of the assay mixture (from step 4) into a cuvette (semimicro cell, light path = 1 cm), then place the cuvette into the temperature-controlled cuvette holder of the spectrophotometer and prewarm to 37°C .

9. Add 5 to 20 µl of the homogenized sample (from step 7) to the assay mixture in the cuvette, immediately seal the cuvette with Parafilm, and invert gently but quickly two or three times to mix the contents. Place cuvette in holder and start recording.

10. Record the increase in absorbance at 410 nm continuously on chart paper.

11. Read the absorbance increase per min ($\Delta A_{410}/\Delta t$) in the linear portion of the curve (initial velocity) on a chart (Fig. 6.6.3).

    If a linear response is not obtained in the recording because of excessively high activity, it will be necessary to suitably dilute the homogenate (and hence the enzyme) with a buffer, e.g., 100 mM Tris·Cl, pH 8.0.

12. Calculate the enzyme activity (U/ml of the original homogenate) as follows:

    Activity (U/ml) = $[(\Delta A_{410}/\Delta t)/\varepsilon] \times 1000/$[volume of sample (µl) added to the assay mixture]

    where the amount of the enzyme required to release 1 µmol of *p*-nitroaniline per min is defined as one unit (U).

    In the case of a diluted sample, multiplication by a dilution factor will be necessary to calculate the activity of the original homogenate.

    The molar extinction coefficient (ε) for p-nitroaniline is 8.8 $mM^{-1}cm^{-1}$. Although addition of the enzyme solution to the assay mixture changes the volume and the concentrations of substrates by a few percent, these changes are negligible in terms of the calculation of enzyme activity.

    For samples with a low activity, evaluate a change in absorbance ($\Delta A_{410}/\Delta t$) after subtracting contribution of nonenzymatic hydrolysis of the substrate, which is determined by recording in the absence of enzyme.

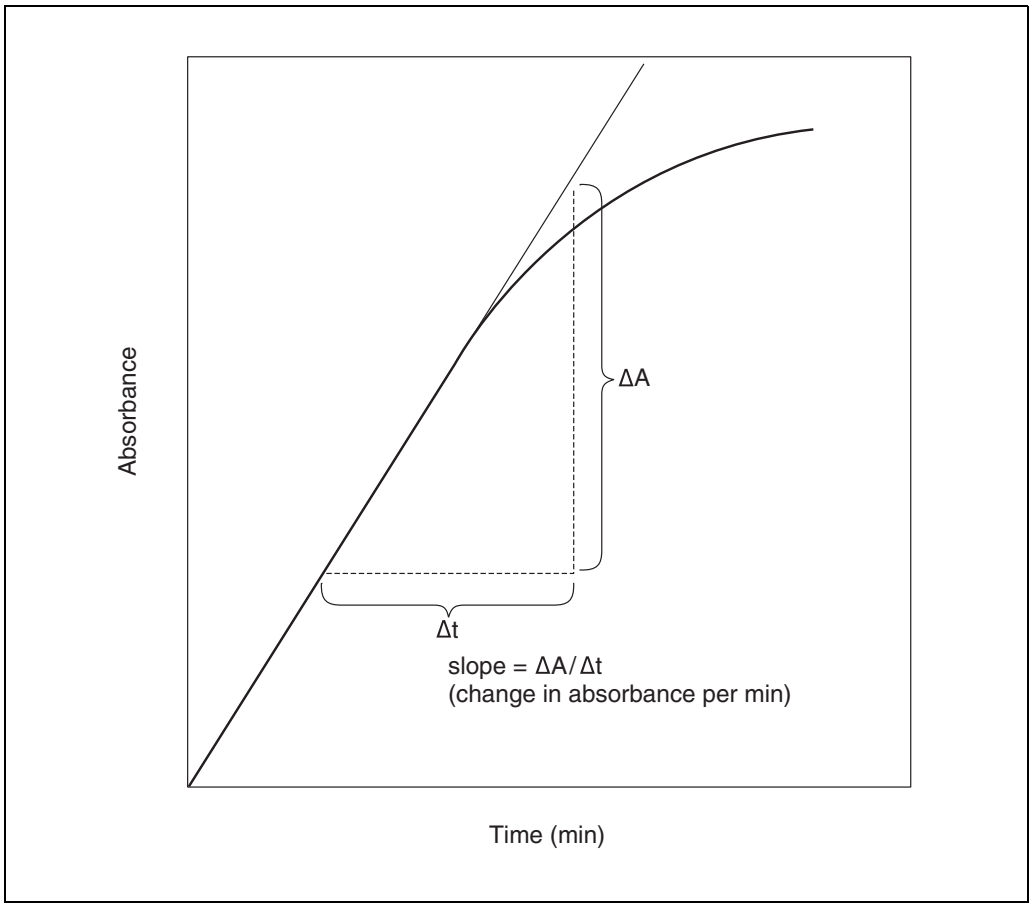

Figure 6.6.3 Estimation of the rate of the release of *p*-nitroaniline.

ALTERNATE PROTOCOL

USE OF L-γ-GLUTAMYL-3-CARBOXY-4-NITROANILIDE AS THE DONOR SUBSTRATE TO MEASURE GGT ACTIVITY

L-γ-Glutamyl-*p*-nitroanilide is the most common substrate for the GGT activity assay, but its solubility is very low at pH values of ~6. In addition, this substrate may be insoluble under certain conditions. When a specialized substrate mixture is necessary, for example, because activity must be assayed at a different pH from that used in the Basic Protocol and at which solubility becomes an issue, L-γ-glutamyl-3-carboxy-4-nitroanilide can be substituted for L-γ-glutamyl-*p*-nitroanilide. L-γ-glutamyl-3-carboxy-4-nitroanilide is more convenient for its higher solubility, but it is more expensive and relatively unstable. The ε value for carboxynitroaniline, a product of the reaction, is 9.5 $mM^{-1}cm^{-1}$.

Additional Materials *(also see Basic Protocol)*

L-γ-glutamyl-3-carboxy-4-nitroanilide (ammonium salt; Sigma)

1. Dissolve L-γ-glutamyl-3-carboxy-4-nitroanilide (ammonium salt) directly to the desired concentration in the buffer, which also contains the acceptor substrate, e.g., 20 mM glycylglycine, and other compounds that may be required for individual purposes.

   This substrate is relatively unstable and is hydrolyzed more easily than the noncarboxylated substrate. Therefore, pH value of the assay mixture should not exceed 8.0. An assay mixture which contains L-γ-glutamyl-3-carboxy-4-nitroanilide can be stored at −20°C up to ~1 week. Do not store at 4°C.

Tris buffer (pH 8.0) and several other types of buffers in which pH is 6.0 to 8.0 can be used. If necessary, the concentration of L-γ-glutamyl-3-carboxy-4-nitroanilide in the assay can be increased over 10 mM because of its high solubility.

2. Prepare cell or tissue homogenate (see Basic Protocol, steps 5 to 7).
3. Determine enzyme activity with this assay mixture (see Basic Protocol, steps 8 to 12) measuring absorbance at 405 nm (A_{405}) and using an extinction coefficient, ε, equal to 9.5 mM^{-1} cm^{-1}.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Homogenate buffer

Mix 8.6 g of sucrose with 2 ml of 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*), and 0.04 ml of 500 mM EDTA, pH 8.0 (*APPENDIX 2A*), and then dilute this with water to ~95 ml. Adjust the pH to 7.4 with HCl, and add water to a final volume of 100 ml. Store up to 1 month at 4°C.

COMMENTARY

Background Information

γ-Glutamyl transpeptidase plays a key role in glutathione metabolism because it catalyzes the first step of the degradation of glutathione (Lieberman et al., 1996) and is a member of the γ-glutamyl cycle, which involves the degradation and biosynthesis of glutathione (Meister and Anderson, 1983; Meister and Larsson, 1995).

GGT activity is most abundant in the kidney and is predominantly localized in the apical surface of the proximal microtubules. The enzyme is a membrane-bound glycoprotein and is anchored to the extracellular surface of the plasma membrane via its N-terminal transmembrane domain; as a result, glutathione is degraded by this enzyme outside the cells. The resulting cysteinylglycine is imported into the cells, and is utilized as a source of cysteine for the biosynthesis of glutathione (Meister et al., 1981; Tate and Meister, 1985). It is generally believed that the enzyme plays an important role in the maintenance of intracellular glutathione levels and appears to be involved in the protection of cells against oxidative damage. On the other hand, in the case of *S*-conjugates of chemical compounds, drugs, and xenobiotics with glutathione, their γ-glutamyl groups are removed by GGT, followed by cleavage of the glycine moiety and *N*-acetylation. These successive conversions lead to the formation of the corresponding mercapturic acids and, as a result, facilitate the excretion of those chemical compounds into urine (Meister and Anderson, 1983; Meister and Larsson, 1995). This action of GGT is directed not only towards glutathione-*S*-conjugates of foreign chemical compounds but also towards conjugates of endogenous substances, such as leukotriene C4, which is converted into leukotriene D4 by this enzyme as the result of removal of the γ-glutamyl moiety (Anderson et al., 1982). There seems to be no isozyme of GGT (Lieberman et al., 1996; Carter et al., 1997), but heterogeneities exist due to glycosylation, as shown by isoelectric focusing and electrophoresis. A related enzyme, referred to as the GGT-related enzyme or γ-glutamyl leukotrienase, is known to hydrolyze the γ-glutamyl bond of glutathione but not particular synthetic substrates (Heisterkamp et al., 1991; Carter et al., 1998).

GGT is a heterodimeric glycoprotein which consists of a large and small subunit. This enzyme is biosynthesized as a single-chain precursor and is then proteolytically cleaved into two subunits (Meister et al., 1981). It is thought that the small subunit is a catalytic one and that the substrate binding site is constituted by both the subunits, as suggested by chemical modification studies and site-directed mutagenesis (Taniguchi and Ikeda, 1998). Kinetic studies have shown that this enzyme follows a ping-pong mechanism and thus forms the γ-glutamyl enzyme intermediate in which a γ-glutamyl group from the donor substrate appears to be covalently bound to the enzyme (Tate and Meister, 1985). The functional group involved in the formation of the intermediate is believed

to be a hydroxyl group (or groups), located in the small subunit (Ikeda et al., 1995; Taniguchi and Ikeda, 1998). Substrate specificities for the donor and acceptor substrates have been the subject of extensive investigation.

GGT transfers the γ-glutamyl group of glutathione, its *S*-substituted derivatives, and γ-glutamyl compounds to a variety of amino acids and dipeptides. GGT displays a relatively broad specificity toward the leaving group, corresponding to the cysteinylglycine moiety of glutathione (Tate and Meister, 1985), as revealed by the capability of the action on *S*-substituted glutathione and synthetic γ-glutamyl donors such as γ-glutamyl-*p*-nitroanilide. This may allow GGT to react with a variety of glutathione S-conjugates and would, therefore, enable the enzyme to play a role in the metabolism of drugs and xenobiotics. On the other hand, in terms of the substrate specificity toward acceptor substrates, neutral amino acids such as cystine, methionine, glutamine, alanine, and serine are preferred as the first amino acid residue in the case of dipeptides or an amino acid acceptor. However, amino acids with a branched side chain are poor acceptors, and L-proline and α-substituted amino acids are inactive. D-isomers of those amino acids are inactive, although both L- and D-isomers of the γ-glutamyl moiety in the donor are equally active as the substrate. When L-γ-glutamyl compounds are used as the substrate in the absence of appropriate acceptor, the γ-glutamyl compound can also act as the acceptor, leading to autotranspeptidation reactions as well as hydrolysis. In the case of a D-isomer of the γ-glutamyl compound, however, the enzyme catalyzes only the hydrolysis of the γ-glutamyl bond (Thompson and Meister, 1976; Meister et al., 1981).

Kinetic analysis of GGT showed that the K_m values for L-γ-glutamyl-*p*-nitroanilide as a donor and for glycylglycine as an acceptor are 1.4 mM and 10 mM, respectively (Ikeda et al., 1996). If one wishes to determine the hydrolytic activity using L-γ-glutamyl-*p*-nitroanilide, separately from the autotranspeptidation, the concentration of the donor substrate must be sufficiently low, e.g., 10 μM or lower. Otherwise, the contribution of the autotranspeptidation to the release of *p*-nitroaniline becomes significant. Alternatively, its D-isomer should be used as the substrate because this isomer cannot act as an acceptor. However, D-γ-glutamyl-*p*-nitroanilide is not commercially available. In the hydrolysis reaction, the K_m for L-γ-glutamyl-*p*-nitroanilide is 5 to 8 μM (Thompson and Meister, 1976; Ikeda et al., 1996).

Many other methods are available for the assay of GGT activity, and the use of a fluorogenic substrate; e.g., 7-(γ-glutamyl)-4-methylcoumarylamide (γ-glutamyl-AMC) provides a more sensitive assay. The assay procedure using γ-glutamyl-AMC is described in Smith et al. (1979) and Tate and Meister (1985). Although procedures for a rate assay with a spectrophotometer are described in this unit, an end-point assay using a 96-well plate would be sufficient to roughly compare the activities of a large number of samples, for example, to determine the elution peak for the enzyme during chromatography. For this qualitative assay, 5 to 10 μl of each sample are placed into wells of the 96-well plate and 100 to 200 μl of the assay mixture is added. The plate is incubated at room temperature until a light yellow color appears, and the optical density at a wavelength ~410 nm is measured using a microtiterplate reader.

It is well known that expression of GGT is increased during chemically induced hepatocarcinogenesis in rodents, and that levels of this enzyme are also high in fetal liver, whereas its expression is quite low, nearly undetectable in normal adult liver. Therefore, this enzyme is often regarded as one of the oncofetal proteins, and it is used as a marker for hyperplastic or neoplastic nodules in chemically induced hepatocarcinogenesis in the rat (Suzuki et al., 1987).

For the measurement of GGT activity, the most common substrate is the γ-glutamyl derivative of *p*-nitroaniline or a related compound; this type of substrate is very convenient to use and sensitive. The assay involving the substrate is also sufficiently specific to the enzyme. The release of *p*-nitroaniline and 3-carboxy-4-nitroaniline from the respective γ-glutamyl derivatives is facilitated by the addition of an appropriate acceptor dipeptide, as shown in Figure 6.6.4 (Ikeda et al., 1993). Glycylglycine is known to be one of the most active acceptors and is usually contained in the assay mixture.

Critical Parameters and Troubleshooting

Although γ-glutamyl transpeptidase is capable of catalyzing both transfer and hydrolysis reactions, the transfer reaction is much faster. In the activity assay for the enzyme, therefore, the transfer reaction using glycylglycine as an acceptor for the γ-glutamyl group is usually used. The transfer reaction proceeds efficiently

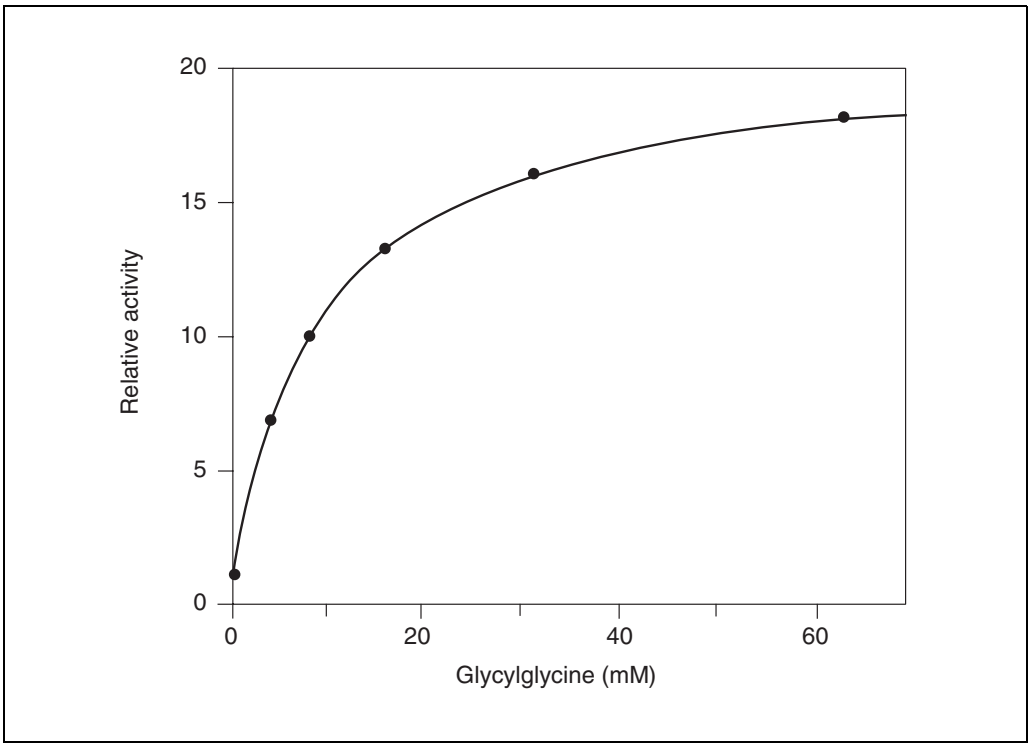

Figure 6.6.4 The effect of a dipeptide acceptor, glycylglycine.

at a relatively high pH, and thus the pH value in the assay mixture should be in excess of 8.0. However, γ-glutamyl-*p*-nitroanilide and γ-glutamyl-3-carboxy-4-nitroanilide are significantly hydrolyzed in a nonenzymatic manner at an extremely high pH.

If one wants to prepare the assay mixture at pH values around 6, for particular experimental reasons, it may be impossible to completely dissolve the γ-glutamyl-*p*-nitroanilide at the desired concentration, since the solubility of the substrate is often poor in this pH range. To avoid this solubility problem, it is desireable to use γ-glutamyl-3-carboxy-4-nitroanilide, rather than γ-glutamyl-*p*-nitroanilide. The carboxylated substrate is easily dissolved in commonly used buffers at various pH values.

When the activity for the enzyme is assayed in tissues, such as liver, in which the expression of this enzyme is quite low, it may be necessary to extract the enzyme with 0.5% to 1.0% (v/v) nonionic detergents such as Triton X-100 and Nonidet P-40. The release of the chromophore, *p*-nitroaniline is very slow because of low activity, and under such conditions, the turbidity of the sample can significantly interfere with the detection of the increase in absorbance at 410 nm. Extraction of the enzyme with detergents results in clarification of the samples, thus circumventing turbidity problems. The enzyme is easily extracted by stirring the homogenized tissues, microsomal fraction, or membrane fraction, in the buffer containing aforementioned detergents for 30 to 60 min at 4°C, followed by ultracentrifugation.

Table 6.6.1 γ-Glutamyl Transpeptidase Activities in Kidney, Liver, and Various Cultured Cells

Source	Activity (U/mg protein)
A549 cells	0.056
COS1 cells	0.0007
GGT cDNA-transfected COS1 cells	3.6
HepG2 cells	0.061
Rat kidney homogenate	1.0
Rat liver homogenate	0.0037

Anticipated Results

The specific activities of γ-glutamyl transpeptidase in various organs and cells, determined under the conditions described in the Basic Protocol, are given in Table 6.6.1.

Time Considerations

The assay, in which the release of *p*-nitroaniline is continuously monitored, requires only a few minutes for a sample with a sufficiently high activity. A much longer time (e.g., ≥30 min) may be required for samples whose activities are very low.

Oxidant-Induced Regulation of Glutathione Synthesis

Protocols in this unit describe experimental methods for demonstrating induction of two glutathione biosynthetic enzymes, γ-glutamylcysteine synthetase (glutamate cysteine ligase, GCS, EC 6.3.2.2) and γ-glutamyltranspeptidase (GGT, EC 2.3.2.2), in response to oxidants. GCS is a heterodimer composed of a catalytic or heavy subunit (GCS-HS) and a regulatory or light subunit (GCS-LS). It catalyzes the first and limiting step in the de novo synthesis of reduced glutathione (GSH), forming γ-glutamylcysteine from L-cysteine and L-glutamate. GGT, on the other hand, degrades extracellular GSH to supply cells with necessary amino acids for intracellular synthesis of GSH, GCS, and GGT gene expression have been shown to be up-regulated upon treating cells with various oxidants and heavy metals. Such induction results in transient elevation of the intracellular GSH concentration that protects cells from subsequent oxidative assault. Nonetheless, to definitively show that a compound can increase the transcription rate of the GCS or GGT genes, it is necessary to perform nuclear run-on analysis (see Basic Protocol 2), which directly measures the transcription rate of the gene being studied.

The following protocols detail the methods by which one can show increased mRNA and protein content (Basic Protocols 1 to 3) of both subunits of GCS as well as GGT, and further allow the determination of the mechanism by which mRNA content is altered in response to oxidants—whether this involves transcriptional (Basic Protocol 2) and/or posttranscriptional (i.e., stability of mRNA; Basic Protocol 1) regulation. Therefore, the protocols can be applied to other studies involving induction of gene expression. Changes in the GSH content and GCS activity can be readily demonstrated using protocols reported elsewhere (*UNITS 6.5 & 6.6*). Support Protocol 3 describes an assay for measuring GGT activity. Increasing evidence suggests that glutathione synthetase (GS, EC6.3.2.3.), which produces GSH from γ-glutamylcysteine, may also be increased by oxidative stress, such as with *tert*-butylhydroperoxide (Sun, 1997; Luo et al., 1998). GS activity can be measured with a simple modification of the procedure for measuring GCS activity (*UNIT 6.5*).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings (*APPENDIX 1A*). Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer.

NORTHERN ANALYSIS OF γ-GLUTAMYLCYSTEINE SYNTHETASE AND γ-GLUTAMYL TRANSPEPTIDASE mRNA CONTENT

BASIC PROTOCOL 1

GCS and GGT mRNA content can be quantitated by standard northern analysis with radiolabeled probes (Brown and Mackey, 1997; *APPENDIX 3E*). After treating cells for various time periods with various oxidants added to the cell culture medium, total RNA is isolated from the cells. cDNA probes (see Support Protocol 1) are used for mRNA analysis of GCS subunits, and a cRNA probe (see Support Protocol 2) is used for GGT.

Materials

Cells to be analyzed
Oxidant, e.g. 5 to 20 μM 2,3-dimethoxyl, 4-naphthoquinone (DMUQ)
Actinomycin D
Agarose
DEPC-treated H_2O, water treated with 0.1% DEPC

Contributed by Rui-Ming Liu, Jinah Choi, and Henry J. Forman
Current Protocols in Toxicology (2001) 6.7.1-6.7.21

1× and 10× MOPS running buffer (see recipe)
37% (w/v) formaldehyde
RNA loading mixture (see recipe)
RNA molecular weight markers
2× SSC (*UNIT 3.5*)
Hybridization solution (e.g., QuikHyb, Stratagene)
Salmon sperm DNA
Radiolabeled γ-glutamylcysteine synthetase light or heavy subunit (GCS-LS or GCS-HS) cDNA probe (see Support Protocol 1) or radiolabeled γ-glutamyl transpeptidase (GGT) cRNA probe (see Support Protocol 2)
2× SSC/0.1% (w/v) SDS
0.1× SSC/0.1% (w/v) SDS, 50°C, and 70° to 75°C

65°C and boiling water baths
Nylon membrane
Capillary blot transfer system
UV cross-linker (e.g., Stratalinker 1800, Stratagene)
Hybridization oven (e.g., Hybaid), 60°C (optional)
X-ray film (e.g., Kodak X-Omat film, Eastman Kodak) or InstantImager (Packard Instrument)

Additional reagents and equipment for isolating total RNA (use commercially available reagents and protocols or see *APPENDIX 3E*), agarose gel electrophoresis (*APPENDIX 3A*), and capillary transfer and probing of RNA (see northern blotting, *APPENDIX 3E*)

CAUTION: Ethidium bromide (in RNA loading mixture) is a mutagen and must be handled carefully.

Isolate RNA

1. Set up ten plates of the cells and then treat with an oxidant. When studying the effect of an oxidant on the stability of GCS or GGT mRNA, treat cells with an oxidant in the presence and absence of actinomycin D (0.05 μg/ml for GCS) for 1, 2, 4, 6, and 8 hr in a 37°C, 5% CO_2 incubator.

   Actinomycin D is used to block the synthesis of mRNA.

2. At the appropriate time point, collect cells and isolate total RNA using commercial protocols and reagents (or refer to *APPENDIX 3A*).

   Approximately 20 μg total RNA is required per sample. RNA isolated from tissues may also be used

   This series of samples is to measure the effect of an oxidant on the stability of GCS or GGT mRNAs.

Resolve and transfer RNA

3. Melt 1.0 g agarose in 85 ml DEPC-treated water in a microwave oven. When the temperature drops to ~65°C, add 10 ml of 10× MOPS running buffer and 5 ml of 37% formaldehyde, and swirl to mix.

   CAUTION: *Work should be carried out in a chemical hood to avoid inhalation of formaldehyde.*

4. Pour ~0.5-cm thick gel into a horizontal gel electrophoresis apparatus (*APPENDIX 3A*). Allow gel to solidify for ≥30 min.

5. Attach electrophoresis unit to a power supply and pre-run the gel, submerged in 1× MOPS running buffer, at 3 to 4 V/cm for 30 min.

6. Dry 20 µg total RNA for each sample in a Speedvac evaporator. Add 15 µl RNA loading mixture to each sample as well as to RNA molecular weight markers and mix by pipetting.

   If the RNA samples are too dry, they will not go back into solution easily.

7. Incubate RNA samples 15 min in a water bath at 65°C, and then chill in an ice-water bath. Centrifuge briefly to recover sample.

8. Load samples into wells of the gel. Designate one lane for running RNA molecular weight markers. Run gel in 1× MOPS running buffer at 3 to 4 V/cm for 3 to 4 hr.

9. Wash gel briefly with DEPC-treated water and then with 2× SSC for 30 min at room temperature, shaking gently.

10. Use a capillary blot transfer system to transfer RNA from the gel to a nylon membrane in 2× SSC buffer overnight at room temperature (*APPENDIX 3E*).

11. Cross-link RNA to membrane using a UV cross-linker.

Hybridize RNA

12. Prehybridize nylon membrane with 10 ml hybridization solution in a hybridization oven at 60°C for 30 min according to manufacturer's instructions. Avoid bubbles.

    Alternatively, see APPENDIX 3A for hybridization technique without a hybridization oven.

13. Add 1 mg salmon sperm DNA to ≥5 × 10^6 cpm radiolabeled GCS-LS or GCS-HS cDNA probe or a radiolabeled GGT cRNA probe and denature probe in a boiling water bath for 5 min. Centrifuge briefly and chill probe on ice.

    Blots should be hybridized with control probes to analyze RNA loading. When measuring GCS mRNA content, the RNA should be hybridized to the GCS probe first and then the control(s), such as GAPDH cDNA or 18S rRNA probes. The GGT cRNA probe is difficult to strip off the membrane (even harder than the 18S rRNA cDNA probe). Therefore, GGT hybridization should be performed last.

    When analyzing GGT mRNA content, avoid using 18S rRNA as a loading control because its molecular weight lies close to that of GGT and because its cDNA probe is difficult to strip off the membrane.

14. Add denatured probe to the prehybridization buffer and hybridize in the hybridization oven 2 hr at 60°C.

15. Pour out the hybridization solution into an appropriate receptacle. Wash membrane twice (10 to 15 min) with 2× SSC/0.1% SDS at room temperature and then once (10 min) with 0.1× SSC/0.1% SDS at 50°C (see Critical Parameters and Troubleshooting).

    The exact time for washing will vary depending on the probe being used and the relative abundance of mRNA in the samples.

16. Wrap membrane in plastic wrap and store inside an X-ray film cassette. Expose X-ray film at −80°C or scan membrane using a InstantImager.

17. To reuse membrane, strip probe by washing membrane in 0.1 × SSC/0.1% SDS at 70° to 75°C. Store membrane tightly sealed with plastic wrap at −80°C until next hybridization.

RADIOLABELING γ-GLUTAMYLCYSTEINE SYNTHETASE LIGHT AND HEAVY SUBUNIT cDNA PROBES

To detect GCS light subunit (GCS-LS) and heavy subunit (GCS-HS) RNA, cDNA probes for each are radiolabeled with [^{32}P]dCTP. The probes are synthesized by PCR extension of cDNA fragments generated by reverse transcription of total RNA from rat epithelial L2 cells (*APPENDIX 3A*). The cDNA fragments are prepared using primers based on rat kidney GCS-LS and GCS-HS cDNA sequences. These probes hybridize with rat, mouse, and human GCS mRNA.

NOTE: This protocol is written specifically for the Rad-Prime DNA labeling system (Life Technologies) and the NucTrap push column (Stratagene). Other labeling kits, reagents, and purification methods can be used; however, the protocol will need to be modified by following the manufacturer's instructions.

Materials

5×10^6 rat epithelial L2 cells
Primers: 12.5 pmol for 50-µl reactions
  GCS-LS 5′ sense: 5′-AGACCGGGAACCTGCTCAAC-3′
  GCS-LS 3′ antisense: 5′-CATCACCCTGATGCCTAAGC-3′
  GCS-HS 5′ sense: 5′-AGACACGGCATCCTCCAGTT-3′
  GCS-HS 3′ antisense: 5′-CTGACACGTAGCTCGGTAA-3′
Rad-Prime DNA labeling system (Life Technologies), or equivalent, containing:
  1:1:1 (v/v/v) dATP/dGTP/dTTP
  2.5× reaction buffer
  Klenow fragment of *E. coli* DNA polymerase I
  Stop buffer
10 µCi/µl [α-^{32}P]dCTP (800 Ci/mmol; e.g., ICN Biomedicals)
1× STE buffer (see recipe)
Scintillation fluid (e.g., Scintisafe Econo 1 cocktail; Fisher)

37°C and boiling water baths
NucTrap push column (Stratagene)

Additional reagents and equipment for reverse transcription (*APPENDIX 3A*) and PCR (*APPENDIX 3C*)

1. Reverse transcribe total RNA from 5×10^6 rat epithelial L2 cells (*APPENDIX 3A*).
2. Use the primers for GCS-LS or GCS-HS to synthesize cDNA fragments from reverse-transcribed RNA by PCR (*APPENDIX 3C*) and purify.

   The primers for GCS-LS (sense strand of 5′ sequence at positions 122 to 141 and antisense strand of 3′ sequence at positions 1104 to 1123) span 1001 nucleotides of the GCS-LS mRNA; those for GCS-HS (sense strand of 5′ sequence at positions 105 to 124 and antisense strand of 3′ sequence at positions 890 to 909) span 804 nucleotides of GCS-HS mRNA.

3. In a microcentrifuge tube, dissolve ~25 to 50 ng of a purified cDNA fragment for GCS-LS or GCS-HS in a total volume of 21 µl using sterile water. Denature in a boiling water bath for 5 min. Immediately chill on ice.
4. Add the following components (50 µl total) and incubate 15 min at 37°C.

   3 µl 1:1:1 dATP/dGTP/dTTP
   20 µl 2.5× reaction buffer
   5 µl 10 µCi/µl [γ-^{32}P]dCTP
   1 µl Klenow fragment.

5. Add 5 µl stop buffer to the reaction mixture and place on ice.
6. Wet a NucTrap push column with 70 µl of 1× STE buffer by pushing solution through the column using a syringe.
7. Place a clean microcentrifuge tube under column. Add reaction mixture on top of the column and then push it through using the syringe. Rinse column with another 70 µl of 1× STE, collecting the solution in the same tube.
8. Take out 1 µl purified ^{32}P-labeled probe and add to 5 ml scintillation fluid in a scintillation vial. Quantify ^{32}P with a scintillation counter.

   About 0.5 to 1 million cpm/µl is expected.
9. Store purified probe up to 1 week at −80°C.

RADIOLABELING OF γ-GLUTAMYL TRANSPEPTIDASE cRNA PROBE

SUPPORT PROTOCOL 2

Because the GGT mRNA level is very low in rat lung epithelia L2 cells, a cRNA probe, not a cDNA probe, is used to detect GGT mRNA.

NOTE: This protocol is written specifically for the Riboprobe in vitro transcription system (Promega). Other labeling kits and reagents can be used; however, the protocol will need to be modified by following the manufacturer's instructions.

Materials

pBluescript γ-glutamyl transpeptidase (GGT) plasmid
*Not*I restriction enzyme and appropriate buffer
1% (w/v) agarose gel
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (with TE-saturated phenol, *UNIT 2.2*)
Riboprobe in vitro transcription system (Promega), or equivalent, containing:
  5× transcription-optimized buffer
  100 mM dithiothreitol (DTT; also see *APPENDIX 2A*)
  40 U/µl ribonuclease inhibitor (RNasin)
  Aqueous ATP/GTP/UTP (2.5 mM each nucleotide)
  15 to 20 U/µl T7 RNA polymerase
  RQ1 RNase-free DNase
10 µCi/µl [α-^{32}P]CTP (800 Ci/mmol; ICN Biomedicals)
DEPC-treated H_2O: water treated with 0.1% DEPC
0.1 M EDTA, pH 8.0 (*APPENDIX 2A*)
10 mg/ml tRNA (Life Technologies)
7.5 M ammonium acetate (*APPENDIX 2A*)
100% ethanol, ice cold
Scintillation fluid and counter

Additional reagents and equipment for restriction enzyme digestion, agarose gel electrophoresis, and spectrophotometric quantification of DNA (*APPENDIX 3A*)

Prepare DNA template

1. Linearize pBluescript-GGT plasmid with *Not*I restriction enzyme. Use ~1 U enzyme per 1 µg plasmid DNA and digest 2 hr at 37°C in an appropriate buffer (*APPENDIX 3A*).
2. Take 1 µl digestion solution and run on a 1% agarose gel, using 1× TBE buffer as the running buffer, at 80 V for 1 hr to confirm that digestion is complete. If digestion is not complete, add more enzyme and digest for an additional hour and check again.

3. Extract completely digested DNA using 25:24:1 phenol/chloroform/isoamyl alcohol and precipitate with ethanol (*APPENDIX 3A*). Resuspend DNA in distilled water, quantify DNA (*APPENDIX 3A*), and adjust concentration to 0.2 to 1.0 mg/ml with distilled water.

Prepare labeled cRNA

4. Use a Riboprobe in vitro transcription system and follow the protocol provided by the manufacturer to make a ^{32}P-labeled GGT cRNA probe. Briefly, add the following components to a microcentrifuge tube at room temperature in the order listed (20 µl final volume):

   4 µl 5× transcription-optimized buffer
   2 µl 100 mM DTT
   1 µl 40 U/µl RNasin
   4 µl aqueous ATP/GTP/UTP (10 nmol each)
   1 µl linearized pBluescript-GGT DNA
   5 µl 10 µCi/µl [α-^{32}P]CTP
   1 µl 15 to 20 U/µl T7 RNA polymerase
   2 µl DEPC-treated water.

   Vortex tube and centrifuge briefly. Incubate reaction mixture 60 min in a water bath at 37°C.

5. To remove DNA template, add 1 µl RQ1 RNase-free DNase and incubate 30 min at 37°C.
6. Stop the reaction by adding 5 µl of 0.1 M EDTA.

Extract and precipitate RNA

7. Add 100 µl of 25:24:1 phenol/chloroform/isoamyl alcohol to the completely digested DNA. Vortex 1 min and then centrifuge 5 min at 12,000 × *g*, 4°C. Transfer upper phase to a new tube without disturbing the interphase.
8. Add the following and chill 20 min at −80°C:

   1 µl 10 mg/ml tRNA
   50 µl 7.5 M ammonium acetate
   450 µl ice-cold 100% ethanol.

9. Centrifuge 30 min at 12,000 × *g*, 4°C.
10. Remove supernatant and air dry pellet 10 min.
11. Resuspend RNA pellet in 50 µl DEPC-treated water.
12. Add 1 µl ^{32}P-labeled RNA to 5 ml scintillation fluid in a scintillation vial. Quantify ^{32}P with a scintillation counter.

    Approximately 1 × 10^6 cpm/µl is expected.

13. Store ^{32}P-labeled RNA no more than 1 day at −80°C.

BASIC PROTOCOL 2

NUCLEAR RUN-ON ANALYSIS OF γ-GLUTAMYLCYSTEINE SYNTHETASE AND γ-GLUTAMYL TRANSPEPTIDASE GENE TRANSCRIPTION RATES

To study the effect of an oxidant on the transcription rate of the GCS or GGT genes, a transcriptional inhibitor such as actinomycin D is used to block gene transcription. A comparison of the changes in the steady-state GCS or GGT mRNA content over time between samples treated with the compound of interest plus or minus actinomycin D is made by standard northern blot analysis (see Basic Protocol 1). If actinomycin D blocks

the increase in the amount of GCS or GGT mRNA induced by an oxidant, an increased transcription rate of that gene is suggested. Nonetheless, to definitively show that a compound can increase the transcription rate of the GCS or GGT genes, it is necessary to perform nuclear run-on analysis, which directly measures the transcription rate of the gene being studied.

Generally, cells are treated with an oxidant such as 5 to 10 µg DMNQ for 1 to 3 hr, and then the nuclei are isolated. In vitro transcription is conducted with each nuclear preparation. Next, the newly synthesized mRNAs, which have been labeled with ^{32}P, are isolated and hybridized to a membrane that has been previously blotted with the cDNAs of the gene of interest and control genes.

NOTE: This protocol is written specifically for the Rapid RNA Isolation Kit (Amresco). Other kits and reagents can be used; however, the protocol will need to be modified by following the manufacturer's instructions.

Materials

Cells to be analyzed, at ~80% confluence ($\geq 20 \times 10^6$)
Oxidant (e.g., *tert*-butylhydroquinone) in cell culture medium
PBS (*APPENDIX 2A*), ice cold
NP-40 lysis buffer (see recipe)
Glycerol storage buffer (see recipe)
Target plasmid DNA, e.g., γ-glutamylcysteine synthetase light subunit (GCS-LS; Liu et al., 1998a), heavy subunit (GCS-HS; Liu et al., 1998a), or γ-glutamyl transpeptidase (GGT; Liu et al., 1998b)
Restriction enzymes (to linearize plasmid DNA) and appropriate buffers
10 N NaOH
6× and 12× SSC (*UNIT 3.5*)
2.5 M $(NH_4)_2SO_4$, autoclave and store at 4°C
1.0 M $MgCl_2$, autoclave and store at 4°C
5.0 M NaCl, autoclave and store at 4°C
0.25 M EDTA, pH 8.0 (*APPENDIX 2A*)
1.0 M $MnCl_2$, autoclave and store at 4°C
2.0 M Tris·Cl, pH 7.9 (*APPENDIX 2A*)
57 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol (store at −20°C)
0.1 M dithiothreitol (DTT; *APPENDIX 2A*)
100 mM riboGTP, ATP, and CTP
40 U/µl ribonuclease inhibitor (RNasin)
DEPC-treated H_2O: water treated with 0.1% DEPC
100 mM phosphocreatine (ICN Biomedicals)
10 mCi/ml [α-^{32}P]UTP (650 Ci/mmol; e.g., ICN Biomedicals)
Glycerol
50 µg/µl yeast tRNA
10 U/µl RNase-free DNase I
DNase I buffer
2× proteinase K buffer (see recipe)
20 mg/ml proteinase K
Rapid RNA Isolation Kit (Amresco), or equivalent
70% (v/v) ethanol
Scintillation fluid
Hybridization buffer (e.g., QuikHyb, Stratagene)
2× SSC/0.1% (v/v) SDS
0.1× SSC/0.1% (v/v) SDS, 50°C

Biodyne nylon membrane (Life Technologies)
Filtration manifold system (e.g., Life Technologies) connected to vacuum pump
UV cross-linker (e.g., Stratalinker 1800, Stratagene)
Blotting paper
5-ml sterile polypropylene centrifuge tube
30°C and 42°C water baths
Spin column (e.g., Pharmacia)
20-ml glass scintillation vials and scintillation counter
Hybridization oven (e.g., Hybaid), 60°C
X-ray film (e.g., Kodak X-Omat film, Eastman Kodak) or InstantImager (Packard Instruments)

Additional reagents and equipment for restriction enzyme digestion (*APPENDIX 3A*)

Treat cells and isolate nuclei

1. Treat cells to be analyzed at ~80% confluence (total cell number should not be <20 $\times 10^6$) with an oxidant such as *tert*-butylhydroquinone (5 to 100 μM for L2 cells) in cell culture medium.

   A time course of treatments (usually from 1 to 6 hr) is generally carried out and results from these time points are compared. This protocol should be scaled up as needed.

2. Remove cell culture medium and wash cells twice with 5 ml ice-cold PBS.
3. Add 5 ml PBS and gently dislodge cells from the plastic surface by scraping with a disposable cell scraper. Transfer cells to a 15-ml centrifuge tube.
4. Centrifuge cells 5 min at 500 × *g*, 4°C. Remove as much PBS as possible. Vortex 5 sec to loosen cell pellet.
5. Add 8 ml NP-40 lysis buffer. Continue vortexing as the buffer is added and then vortex for another 10 sec.
6. Incubate lysed cells 5 min on ice, centrifuge 5 min at 500 × *g*, 4°C, and discard supernatant.
7. Repeat steps 5 and 6.
8. Resuspend pellet in 200 μl glycerol storage buffer by pipetting up and down. Quantify DNA spectrophotometrically (*APPENDIX 3A*). Store nuclei in liquid nitrogen until ready to proceed with in vitro transcription.

Bind plasmid DNA to nylon filter

9. Linearize 5 μg of each target plasmid DNA for one treatment by digesting with a restriction enzyme in its appropriate buffer (*APPENDIX 3A*). Adjust volume to a DNA concentration of 0.1 μg/μl using water.

   The plasmid DNA does not need to be purified after digestion.

   In addition to GCS DNA or GGT DNA, β-actin, glyceraldehyde phosphate dehydrogenase (GAPDH), or 18S rRNA DNA should be used as a control.

   The amount of DNA prepared should be scaled up accordingly. One slot of each target DNA is required per treatment, and 5 μg plasmid DNA is needed for each slot on the manifold. If there are six different treatment groups, 30 μg plasmid DNA is needed for each target.

10. Denature the linearized DNA by adding 0.01 vol of 10 N NaOH (0.1 N NaOH final) and incubate 30 min at room temperature.
11. Add 1 vol of 12× SSC and place DNA on ice.

12. Wet a Biodyne nylon membrane with water and then with 6× SSC. Put membrane on a filtration manifold system connected to a vacuum pump. Turn on pump and leave the release switch at the on position.

13. Pipet 100 µl linearized plasmid DNA solution (i.e., 5 µg plasmid DNA) into a slot on the manifold. Turn on the vacuum. Check that the pressure is ~12 in. Hg (305 mmHg).

14. Wash manifold slot twice with 200 µl of 6× SSC. Turn off the release switch and leave the vacuum on.

15. Carefully remove the membrane and mark the target DNA position with a pencil.

16. Cross-link DNA to the membrane using a UV cross-linker. Place membrane between sheets of blotting paper and store up to 3 months at room temperature.

Perform in vitro transcription

17. Thaw 1–5 × 10^7 nuclei (step 8) that contain ~250 µg DNA. Pipet nuclei into a 5-ml sterile polypropylene centrifuge tube and centrifuge 1 min at 10,000 × *g*, 4°C to pellet nuclei. Carefully remove storage buffer from the nuclear pellet and loosen nuclei by vortexing briefly.

    A separate reaction tube is required to analyze each treatment. These steps should be scaled up accordingly.

18. Combine the following reaction salt mixture components and add to each tube (~40 µl) of nuclei (20 µl per reaction).

    8.5 µl 2.5 M $(NH_4)_2SO_4$ (final 0.3 M)
    0.4 µl 1.0 M $MgCl_2$ (final 4.0 mM)
    4.0 µl 5.0 M NaCl (final 0.2 M)
    0.16 µl 0.25 M EDTA (final 0.4 mM)
    0.4 µl 1.0 M $MnCl_2$ (final 4.0 mM)
    5.0 µl 2.0 M Tris·Cl (final 0.1 M)
    0.2 µl 57 mM PMSF (final 0.1 mM)
    1.2 µl 0.1 M DTT (final 1.2 mM).

    To prepare enough salt mixture for all of the samples, the quantities above should be multiplied by n + 1, where n is the number of samples. This allows for minor pipetting errors.

19. Add the following to each reaction and mix gently after each addition.

    1 µl each of 100 mM riboGTP, ATP, and CTP
    8.75 µl 40 U/µl RNasin (3.5 U/µl final)
    5.25 µl DEPC-treated water
    10 µl 100 mM phosphocreatine (10 mM final)
    15 µl 10 mCi/ml [α-^{32}P]UTP.

20. Add 2 drops glycerol to tube. Incubate 30 min in a water bath at 30°C.

21. Add 4 µl of 50 µg/µl yeast tRNA and 10 µl of 10 U/µl RNase-free DNase I (75 to 100 U). Incubate 20 min at 30°C.

22. Check viscosity of the solution. Add more DNase I if the digestion is not complete (i.e., the solution is still viscous) and incubate an additional 10 min.

23. When solution is no longer viscous, add an equal volume of 2× proteinase K buffer and 5 µl of 20 mg/ml proteinase K. Incubate overnight in a 42°C water bath.

Extract RNA

24. Using a Rapid RNA Isolation Kit, add 1 ml reagent 1, vortex, and centrifuge 2 min at 10,000 × *g*, at room temperature.

25. Carefully transfer supernatant into a fresh tube. Add 1 ml reagent 2, vortex 2 min, and centrifuge 10 min at 10,000 × *g*, at room temperature.

26. Carefully transfer top layer to a fresh tube.

    The white interphase should not be disturbed.

27. Add 200 µl reagent 3 and 600 µl reagent 4. Mix by vortexing briefly after each addition. Centrifuge 5 min at 10,000 × *g*, at room temperature.

28. Transfer supernatant to a fresh tube and add 1.2 ml RNA precipitation reagent. Invert tube several times and centrifuge 10 min at 10,000 × *g*, at room temperature.

29. Remove as much of the supernatant as possible. Rinse pellet with 70% ethanol and centrifuge 5 min at 10,000 × *g*, at room temperature. Remove supernatant.

30. Resuspend pellet in 100 µl sterile nuclease-free water. Purify labeled RNA from free [α-^{32}P]UTP using a spin column.

31. Take a 1-µl aliquot of purified RNA and add to 5 ml scintillation fluid in a scintillation vial. Quantitate ^{32}P with a scintillation counter. Use immediately.

    Approximately 10^5 to 10^6 cpm/µl is expected. When comparing different RNA preparations, the same amount of radiolabeled RNA (in cpm) should be used for each hybridization.

Hybridize labeled RNA to membrane

32. Roll and place a target DNA–bound nylon membrane (step 16) inside a 20-ml glass scintillation vial.

    One membrane strip with target DNAs and control DNA is required for each treatment.

33. Add 3 ml hybridization buffer and rotate vial slowly to spread the membrane and avoid trapping any air bubbles between the membrane and the glass wall.

34. Prehybridize membrane 30 min in a hybridization oven at 60°C, and then add the radiolabeled RNA preparation into tube.

35. Hybridize 2 hr at 60°C.

36. Wash membrane twice with 2× SSC/0.1% SDS for 15 min at room temperature, and then twice with 0.1× SSC/0.1% SDS for 10 to 15 min at 50°C.

37. Wrap membrane in plastic wrap and store membrane inside X-ray film cassette. Expose an X-ray film at −80°C or scan the membrane using a InstantImager.

BASIC PROTOCOL 3

IMMUNOBLOT ANALYSIS OF γ-GLUTAMYLCYSTEINE SYNTHETASE PROTEIN CONTENT

GCS-HS and GCS-LS protein content can be determined using a standard immunoblot analysis protocol with slight modifications (also *UNIT 2.3*). After treating cells with various oxidants, cytosolic proteins are obtained and separated on a denaturing gel. Subsequently, proteins are transferred onto a PVDF membrane and probed with the appropriate antibodies.

Materials

Cells to be analyzed
PBS (*APPENDIX 2A*), ice cold
Cell extraction buffer (see recipe)
4× immunoblot sample loading buffer (see recipe)
10% Tris/glycine gel (e.g., Pre-cast Tris-glycine mini gel, Novex/Invitrogen)
SDS electrophoresis buffer (e.g., Tris-glycine SDS gel running buffer, Novex/Invitrogen or *APPENDIX 2A*)
Protein molecular weight markers
Immunoblot transfer buffer (see recipe)
Methanol
Blocking solution (see recipe)
Anti-γ-glutamylcysteine-synthetase-heavy-subunit (anti-GCS-HS) or -light-subunit (anti-GCS-LS) polyclonal antibodies
T-TBS: 0.05% (v/v) Tween 20 in TBS (see recipe)
Alkaline phosphatase (AP)–conjugated goat anti–rabbit IgG (e.g., Kirkegaard & Perry Laboratories)
Enzymatic chemiluminescence detection kit (e.g., ECL Plus, Amersham Pharmacia Biotech)

Sonicator
95°C water bath
Vertical gel electrophoresis apparatus (e.g., Novex/Invitrogen)
Polyvinylidene difluoride (PVDF) membrane (0.45-μm; e.g., Immobilon-P PVDF membrane, Millipore)
Capillary transfer apparatus (e.g., Mini Trans-Blot Cell, Bio-Rad)
X-ray film (e.g., Hyperfilm ECL, Amersham Pharmacia Biotech)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3A*)

Prepare sample

1. Wash cells to be analyzed once with ice-cold PBS, collect cells, and transfer to a microcentrifuge tube.
2. Add 0.3 to 0.5 ml extraction buffer and sonicate briefly on ice. Centrifuge 20 min at 10,000 × *g*, 4°C, to pellet cell debris.
3. Transfer supernatant to a clean tube and centrifuge 1 hr at 105,000 × *g*, 4°C. Collect supernatant and determine protein concentration.

   A kit (e.g., BCA, Pierce Chemical) can be used for protein quantitation. Also see APPENDIX 3A.

4. Mix 40 μg cellular proteins 3:1 (v/v) with 4× immunoblot sample loading buffer (1× final) and heat 5 min in a water bath at 95°C to denature the GCS holoenzyme. Centrifuge briefly to recover all of the sample.

   Samples can be concentrated by centrifuging the supernatant in a concentrator (e.g., Microcon-10, Millipore).

   The quantity of cytosolic proteins used will depend on the relative abundance of GCS proteins in the sample.

Separate and transfer proteins

5. Place a 10% Tris/glycine gel in a vertical gel electrophoresis apparatus and fill apparatus with SDS electrophoresis buffer. Attach a power supply to the apparatus.

   Detailed protocols for mini-gel SDS-PAGE and immunoblotting are described in UNITS 2.2 & 2.3, respectively.

6. Load denatured sample along with appropriate molecular weight markers onto gel and run at 120 V for 1.5 to 2 hr (for mini-gel system).

   The same volume of 1× immunoblot sample loading solution should be loaded into all empty lanes.

7. Disassemble gel apparatus and open gel plates on a firm surface. Mark orientation of the gel by cutting off one corner with a knife.

8. Shake protein gel gently in transfer buffer for 15 min at room temperature to equilibrate gel.

9. Soak a PVDF membrane 30 sec in methanol, rinse 3 min in water, and then equilibrate 15 min in transfer buffer before setting up the transfer.

   The PVDF membrane must not be allowed to dry out after it is wet.

10. Transfer separated proteins to PVDF membrane using a capillary transfer apparatus per manufacturer's instructions for 2 hr at 75 V (for mini-gel system).

    The transfer system must be kept cold (4°C) during the transfer.

    CAUTION: *The transfer buffer should be disposed of in an organic-waste disposal container.*

Perform immunoblot

11. Disassemble transfer sandwich. Block membrane with blocking solution for 30 min to 1 hr at room temperature on a shaker.

12. Incubate membrane overnight at 4°C with anti-GCS-HS or anti-GCS-LS polyclonal antibodies in fresh blocking solution, shaking gently.

    Antibodies are raised against a 19–amino acid GCS-HS peptide (amino acids 295-313, NH_2-CRWGVISASVDDRTREERG-COOH) conjugated to carrier keyhole limpet hemocyanin. Light subunit antibodies can be raised against a holoenzyme purified from rat hepatocytes (Sun et al., 1996). Due to the high homology of GCS sequences among species (~95% sequence identity), human and mouse GCS equivalents are also recognized by these antibodies against the rat enzyme. GCS-LS antibodies are purified from the GCS-LS serum, according to Meyer et al. (1982, 1990). Appropriate dilutions should be determined for each antibody preparation.

13. Wash membrane with T-TBS and then incubate it with a 1:20,000 dilution of AP-conjugated goat anti–rabbit IgG in blotting solution for 1 to 2 hr at room temperature with shaking.

14. Wash with T-TBS and use enzymatic chemiluminescence detection kit (follow manufacturer's instructions) and X-ray film to detect GCS proteins.

15. Determine molecular weights of the proteins of interest by comparison with the molecular weight markers.

    The GCS-LS is ~30 kDa and the GCS-HS is 73 kDa.

SUPPORT PROTOCOL 3

γ-GLUTAMYL TRANSPEPTIDASE ACTIVITY ASSAY

The specificity of GGT toward γ-glutamyl compounds is quite broad and has allowed the development of several different activity assays (*UNIT 6.6*). The most common assay uses L-γ-glutamyl-*p*-nitroanilide, with the product detected by absorbance spectrophotometry. Another assay for the measurement of GGT activity depends upon the conversion of radiolabeled leukotriene L_4 (LTC_4) to leukotriene D_4 (LTD_4) and separation by high-per-

formance liquid chromatography. Such a method was particularly useful in assaying the activity of a γ-glutamyl-cleaving enzyme related to GGT, which does not recognize the synthetic substrates L-γ-glutamyl-7-amino-4-methyl-coumarin (γ-glutamyl-AMC) and γ-glutamyl-*p*-nitroanilide. A more sensitive assay, which is described here, was developed by using the fluorescent substrate γ-glutamyl-AMC (Smith et al., 1979). Because other enzymatic or non-enzymatic reactions may cleave γ-glutamyl compounds, the inhibitor acivicin (AT-125; L-(α*S*,5*S*)-α-amino-3-chloro-4,5-dihydro-5-isoxazoleacetic acid) is used to assess specificity of the enzymatic reaction. This is done by adding acivicin to one of the duplicate samples. The GGT activity is calculated by subtracting the fluorescence of the acivicin-containing tube from that of the acivicin-free tube.

Materials

Cells to be analyzed
Oxidant
PBS (*APPENDIX 2A*)
Acivicin (Sigma-Aldrich)
0.2 M 2-amino-2-methyl-1-3-propandiol (ammediol)/HCl buffer, pH 8.6
0.2 M glycylglycine
10 mM L-γ-glutamyl-7-amino-4-methyl-coumarin (γ-glutamyl-AMC) in methoxyethanol (e.g., Sigma-Aldrich)
Triton X-100
0.05 M glycine, cold
10 mM AMC in methoxyethanol (e.g., Sigma-Aldrich)

Sonicator
Fluorescence spectrophotometer (excitation 370 nm, emission 440 nm)

Prepare cell extract

1. Treat cells to be analyzed with an oxidant.

   A time course of treatments (usually from 6 to 24 hr) is generally carried out and results from these time points are compared. This protocol should be scaled up as needed.

2. Collect cells in 5 ml PBS in a 15-ml tube and sonicate briefly in a sonicator.
3. Centrifuge 5 min at low speed (4000 × *g*) to remove any unbroken cells, and collect supernatant (cell extract).

Set up enzymatic assay

4. Add 0.1 ml cell extract to duplicate tubes. Add 10 µM acivicin to one tube.

   The specific activity is confirmed by using 10 µM acivicin to inhibit the enzymatic reaction.

5. Dilute 10 mM AMC as needed in methoxyethanol and set up standard tubes containing 0.01 ml diluted AMC to cover a concentration range of 20 to 900 pmol/tube.
6. For each sample and standards, make up a reaction mixture containing:

   125 µl 0.2 M ammediol/HCl buffer (final 0.1 M)
   25 µl 0.2 M glycylglycine (final 20 mM)
   5 µl 10 mM γ-glutamyl-AMC in methoxyethanol (final 200 µM)
   0.25 µl Triton X-100 (final 0.1%)
   94.75 µl water.

7. Add 0.25 ml reaction mixture (cell extract) to each sample.
8. Incubate reactions 30 min in a water bath at 37°C and terminate by adding 1.5 ml cold 0.05 M glycine to each tube.

Analyze fluorescence

9. Use a fluorescence spectrophotometer to measure fluorescence of the samples and standards at 440 nm with an excitation wavelength of 370 nm.

10. Use AMC standards to generate a standard curve. Calculate product formation in the cell extract by comparison with the standard curve. To confirm the specificity of the enzyme activity, add 10 µM acivicin to one of the duplicate sample tubes to inhibit the enzyme activity in that tube.

    The advantage of this assay is that multiple samples can be assayed simultaneously. This is important when activity is low, requiring a prolonged incubation to produce a significant amount of product. Fortunately, under such conditions product formation can be linear for hours.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution

5% (w/v) nonfat dry milk in TBS (see recipe)
Make fresh on day of experiment and keep at 4°C

Cell extraction buffer

20 mM Tris·Cl (*APPENDIX 2A*)
150 mM NaCl
1 mM $MgCl_2$
2 mM $CaCl_2$
2.5 mM EDTA, pH 8.0 (*APPENDIX 2A*)
2.5 mM EGTA
Adjust pH to 7.8 with HCl
Store up to 6 months at 4°C
Just before use add:
1 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol
10 µg/ml aprotinin
10 µg/ml leupeptin

Glycerol storage buffer

50 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
40% (v/v) glycerol
5 mM $MgC1_2$
0.1 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Autoclave and store up to 6 months at 4°C

Immunoblot sample loading buffer, 4×

1 ml 1 M Tris base, pH 6.5 (0.25 M final)
1.6 ml glycerol (40% final)
0.32 g SDS (8% final)
0.4 ml 0.05% (w/v) Pyronin Y (0.005% final)
123.2 mg dithiothreitol (DTT; 0.2 M final)
H_2O to 4 ml
Store up to 6 months at −20°C

Immunoblot transfer buffer

12.2 g Tris base
57.6 g glycine
H_2O to 3.2 liters
Store up to 6 months at 4°C
On the day of experiment, add 200 ml methanol/800 ml solution and keep at 4°C until use

3-(N-Morpholino)propanesulfonic acid (MOPS) running buffer, 10×

41.8 g MOPS (200 mM final)
800 ml DEPC-treated H_2O: water treated with 1% DEPC
Adjust to pH 7 with NaOH or acetic acid
16.6 ml 3 M DEPC-treated sodium acetate, pH 5.2 (50 mM final; *APPENDIX 2A*)
20.0 ml 0.5 M DEPC-treated EDTA, pH 8.0 (10 mM final; *APPENDIX 2A*)
Add DEPC-treated H_2O to 1 liter
Filter sterilize
Store protected from light up to 3 months at room temperature
Dilute as needed with DEPC-treated H_2O

Nonidet P-40 (NP-40) lysis buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
10 mM NaCl
3 mM $MgCl_2$
0.5% NP-40
Autoclave and store up to 6 months at 4°C

Northern gel loading buffer

5 % (v/v) glycerol
1 mM EDTA, pH 8.0 (*APPENDIX 2A*)
0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol FF
Store up to 2 years at −80°C

Proteinase K buffer, 2×

0.04 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
2% (w/v) SDS (*APPENDIX 2A*)
20 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Autoclave and store up to 6 months at −20°C

RNA loading mixture

28 µl northern gel loading buffer (see recipe; 10% final)
140 µl formamide (50% final)
14 µl 1 mg/ml ethidium bromide (0.05 µg final)
70 µl DEPC-treated H_2O: water treated with 0.1% DEPC
28 µl 10× MOPS running buffer (see recipe; 1× final)
Mix well and store protected from light up to 1 year at −20°C

CAUTION: *Ethidium bromide is a mutagen and must be handled carefully.*

STE buffer, 1×

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM NaCl
1 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Store up to 1 year at room temperature

Tris-buffered saline (TBS)

4.84 g Tris base (10 mM final)
35.06 g NaCl (0.9% final)
H_2O to 4 liters
Adjust pH to 7.6 with HCl
Store up to 6 months at 4°C (stable ≥6 months)

COMMENTARY

Background Information

Among the principal functions of reduced glutathione (GSH) is its participation in reduction of hydroperoxides and in conjugation to physiologic and xenobiotic compounds. Using depletion of GSH through conjugation reactions, inhibition of its synthesis, or inhibition of reduction of glutathione that becomes oxidized during reduction of hydroperoxides, a great number of studies have shown that low GSH content increases susceptibility to oxidative stress and xenobiotic toxicity. In contrast, it is also well established that increasing the GSH steady-state content and/or the rate of GSH synthesis provides protection against oxidative stress. Although a few types of cells can directly take up GSH from the surrounding fluid, most cells depend on de novo GSH synthesis to maintain their intracellular GSH content. Thus, it is not surprising that an increase in de novo GSH synthesis is a well-established component of adaptation to stress from oxidants and xenobiotics. This increase in GSH synthesis is due, in part, to an elevation of the protein content and enzymatic activities of both γ-glutamylcysteine synthetase (GCS) and γ-glutamyl transpeptidase (GGT), which are involved in the synthesis of GSH and the metabolism of extracellular GSH, respectively.

This unit is complementary to *UNIT 6.5*, which describes assays for enzymatic activity of GSH biosynthesis, and to *UNIT 6.6*, which describes assays for GGT. Here, the principal focus is on methods for studying the regulation of enzymes of glutathione biosynthesis at the transcriptional and translational levels with a particular focus on changes in response to oxidative or xenobiotic stress. The methods described in this unit are used to document these changes and can be used to examine the effects of other agents with the potential for regulating GSH synthesis as well.

GCS catalyzes the first step in de novo GSH synthesis. The reaction, production of γ-glutamylcysteine from glutamate and cysteine driven by ATP hydrolysis, is normally the rate-limiting step in GSH production. Under physiological conditions, GCS is substantially feedback inhibited by GSH (Richman and Meister, 1975). Therefore, when an agent causes an initial depletion of GSH, release of the GSH bound to GCS can result in a temporary enhancement of the rate of GSH synthesis (Wallig et al., 1992; Ochi, 1993). In contrast, a sustained increase in synthesis of the enzyme itself can provide a mechanism for a sustained increase in GSH. GCS is composed of two subunits: a catalytic or heavy subunit (GCS-HS; 73 kDa) and a regulatory or light subunit (GCS-LS; ~30 kDa). In the recent past, stress-induced expression of both GCS subunits has been shown to occur. Based upon experiments with recombinant proteins, GCS-LS, although not essential for catalysis, lowered the K_m for glutamate and decreased the affinity for GSH, which inhibits enzymatic activity by competing for the glutamate binding site (Richman and Meister, 1975). It was also suggested that formation of a disulfide bridge between the subunits augments the effects upon enzyme kinetics (Huang et al., 1993), although the reducing environment in the cell, in which >95% of glutathione is found in the reduced state except under major oxidative stress, would normally inhibit disulfide formation between subunits. Mulcahy et al. (1995) found that cotransfection of COS cells with both GCS-HS cDNA and GCS-LS cDNA led to a greater increase in intracellular GSH content than transfection with either subunit alone when the total amount of cDNA used was equal between cotransfection and individual transfection experiments. These data clearly suggest an important role of the light subunit for GCS activity under physiological conditions.

The regulation of GCS-HS gene expression has been extensively studied. It has been found that various agents and conditions, such as heat shock, heavy metals, substances that deplete GSH through conjugation or by inhibiting its synthesis, hormones, oxidants and antioxidants, and tumor necrosis factor, induce the expression of GCS-HS. An increased GCS-HS expression and GSH content have also been

found in drug-resistant tumor cells, implicating a potential role of this enzyme in such resistance. The regulation of the GCS-LS, on the other hand, has been less intensively studied until recently. Several compounds that induce the expression of GCS-HS have been found to induce the expression of GCS-LS as well (Galloway et al., 1997; Sekhar et al., 1997a; Tian et al., 1997). However, some hormones, such as insulin and glucocorticoid (Cai et al., 1997) or the anticancer drug cisplatin (Yao et al., 1995), have been found to induce GCS-HS but not GCS-LS, indicating dissociated regulation of the two GCS subunits. Differences in the ratio of the two GCS subunit mRNAs among various tissues further indicate that the expression of two GCS subunit genes is controlled by different mechanisms (Gipp et al., 1995). Exposure to 4-hydroxynonenal (4HNE), a reactive product of lipid peroxidation that is always present in cells, at a slightly higher-than-normal physiological concentration increased both GCS subunit proteins (Liu et al., 1998a). Nonetheless, experiments employing the protein synthesis inhibitor emetine indicated that the induction of GCS-LS by 4HNE, but not GCS-HS, required new protein synthesis. Thus, the increased transcription of GCS-LS mRNA is an indirect response to 4HNE while increased transcription of GCS-HS is a direct response to 4HNE. Previous investigations have shown that the induction of GCS-HS by other oxidants is a direct response (Shi et al., 1994; Rahman et al., 1996a,b). While the increase in transcription of both subunit mRNAs has also been shown with a variety of xenobiotic agents, 4HNE also caused an increase in the stability of both GCS-HS and GCS-LS mRNAs. Thus, an increase in the mRNAs of either of the two GCS subunits does not necessarily imply increased transcription.

Yet, increased transcription of GCS subunits does occur in response to a variety of agents. Several recent studies have suggested that transcription of the catalytic subunit of GCS (GCS-HS) can be under control of the *cis* elements κB (Urata et al., 1996; Iwanaga et al., 1998), two different AP-1 binding sites (Yao et al., 1995; Rahman et al., 1996a,b; Morales et al., 1997; Sekhar et al., 1997b; Tomonari et al., 1997a,b), and the most distal antioxidant response element (ARE; Mulcahy et al., 1997). These studies, which have relied upon reporter-gene constructs have used a variety of agents and cell types. Fewer studies have been made of the control of the regulatory subunit of GCS (GCS-LS); however, an AP-1 binding site has been suggested to control its transcription as well (Moinova and Mulcahy, 1998). Nonetheless, as described above, transcription of GCS-HS and GCS-LS are not always coordinated.

The K_m value for cysteine for GCS (0.35 mM) is close to its intracellular concentration. Therefore, the availability of cysteine may also limit the rate of GSH synthesis (Richman and Meister, 1975). For most cells, cysteine can be obtained by degradation of circulating GSH through the action of GGT, a membrane-bound enzyme (Suzuki et al., 1993; Meister, 1994). GGT transfers the γ-glutamyl moiety of GSH to an amino acid, forming a γ-glutamyl–amino acid and cysteinylglycine. Cysteinylglycine is degraded by dipeptidases on the surface of cells and the amino acids are transported into the cell (Deneke and Fanburg, 1989). The γ-glutamyl–amino acids are also transported into the cell and metabolized to release the amino acid and 5-oxoproline, which is converted to glutamate. When the acceptor amino acid for GGT activity is cystine, the resulting product, γ-glutamylcystine, can be taken up by cells and then reduced to cysteine and γ-glutamylcysteine, both of which can be used in GSH synthesis in the so-called scavenger pathway. GSH depletion or oxidative stress increases the activities of the amino acid transport systems. Another source of cysteine is its synthesis in the cystathionine pathway present in some tissues, particularly liver. The cystathionine pathway is also active in the lung and increases during hyperoxic exposure (Rusakow et al., 1993). Thus, a variety of mechanisms exist for providing cysteine for GSH synthesis.

In pulmonary epithelial cells during oxidative stress, GGT increases in coordination with GCS and provides a major source of cysteine (Liu et al., 1996). GGT has been shown to increase in response to quinones, hyperoxia, and nitrogen dioxide (Kugelman et al., 1994; Joyce-Brady et al., 1996; Takahashi et al., 1997). For the quinones, this increase has been shown to result from an increase in transcription or mRNA stability, depending upon whether the quinone redox cycles or conjugates with GSH (Liu et al., 1998b).

GGT gene regulation is complex. In humans, there are several GGT genes and a closely related protein. In rats and mice, there is only one GGT gene, but at least seven different mRNAs are made due to multiple transcription start sites and alternative splicing. Fortunately, in terms of understanding GGT, the coding region of all the GGT mRNAs is the same. It appears that only one mRNA of GGT (type III)

is normally present in lung cells after birth. In hyperoxia, the evidence suggests that this form alone increases. Following NO_2 exposure, it appears that a second fetal type reappears along with an increase in type III. GGT is a TATA-less gene, but the promoter-enhancer region of type III contains a putative ARE sequence, which has been suggested to be responsible for the increase during oxidative stress (Joyce-Brady et al., 1996).

Clearly, understanding the regulation of the expression of the two GCS genes and the GGT gene has much further to go. The methods described here can be used for determining whether alterations in mRNAs involve transcription or RNA stability and whether those are coordinated with changes in enzymatic activity (GGT) and protein content (GCS). These are important first steps in this investigation.

Critical Parameters and Troubleshooting

Northern analysis

RNA degradation must be avoided. RNase contamination, which will lead to the degradation of RNA, is the most serious and common problem during RNA isolation and analysis. Therefore, it is strongly suggested that all tubes, tips, and glassware used for RNA isolation be autoclaved and all solutions be made with fresh DEPC-treated water. If RNA is isolated from tissues, this should be performed as soon as possible once the animals are sacrificed to minimize RNA degradation.

When transferring RNA from a gel to a membrane, care should be taken to ensure that bubbles are not trapped between the gel and the membrane or the blotting paper to avoid uneven transfer.

The hybridization of the GCS cDNA probe to GCS RNA is not very strong, and therefore, extreme care should be taken while washing the membrane. Generally, membranes can be washed twice with 2× SSC/0.1% SDS at room temperature for ~10 to 15 min for GCS-HS and GCS-LS hybridizations. Then, the temperature is raised to 50°C and the membrane is washed with 0.1× SSC/0.1% SDS for another 10 min. The radioactivity on the membrane should be checked with a Geiger counter every 3 to 5 min after the first 10-min high-temperature wash. However, the exact time should be determined for each experiment. The wash solutions should be brought to the desired temperature before use.

On the other hand, the binding of the GGT cRNA probe to GGT RNA is very strong and it is very difficult to strip the probe off the membrane after hybridization. Therefore, it is suggested that the hybridization with the GGT cRNA probe be performed after the membrane has been hybridized with other probes of interest.

Nuclear run-on experiment

When isolating nuclei, it is important to make sure that the cells are lysed completely in order to get a high yield of nuclei. The optimal lysis condition varies with the cell type and therefore should be predetermined. After cells are treated with the lysis buffer for various time periods, check the cells under a microscope. The shortest time it takes to break the plasma membrane without compromising the integrity of the nucleus will be the optimum lysis time for those cells.

RNA degradation must be avoided. As in northern analysis, RNase contamination should be avoided during the isolation and handling of RNA after in vitro transcription. Autoclaved tubes, tips, and RNase-free solutions should be used.

The amount of RNA may be too small to be seen after centrifugation, and therefore RNA may be lost during isolation. It is strongly suggested that some carrier DNA, usually yeast DNA, be used when isolating RNA after in vitro transcription to increase the visibility of the RNA.

It is critical to linearize the plasmid completely as supercoiled plasmids tend to show reduced hybridization potential. A 1% agarose gel should be run after the restriction enzyme digest to make sure that the digestion is complete. It is also strongly suggested that one mark the position of the target DNA on the membrane with a pencil after removing the membrane from the filtration manifold. As in northern analysis, extreme care should be taken when washing the membrane after hybridization.

A troubleshooting guide to GCS and GGT regulation and expression is provided in Table 6.7.1.

Anticipated Results

Rat GCS-HS mRNA is ~3.7 kb in length and the protein is ~73 kDa. Typical northern analysis yields two rat GCS-LS mRNA species of 5.2 kb and 1.8 kb in length. Immunoblot analysis, on the other hand, shows one rat GCS-LS protein band, of ~30 kDa in size. It is generally considered that kidney expresses the highest levels of GCS-HS and GCS-LS as well as GGT at both the protein and mRNA levels. The

Table 6.7.1 Troubleshooting Guide to GCS and GGT Regulation and Expression

Problem	Potential reason	Solution
No RNA signal	Degraded RNA	Use autoclaved tubes and tips and DEPC-treated water for solutions.
	Membrane washed too thoroughly	Wash carefully at 50°C. Check radioactivity every 2-5 min after first 10-min wash.
No gene induction	Cells post-confluence	Treat cells at ~80% confluence.
Low signal in nuclear run-on	Incomplete cell lysis	Make sure cells are lysed completely.
	Incomplete DNA digestion	Extend digestion time.
	RNase contamination	Use RNase-free solutions and sterile tubes and tips.
Multiple bands on immunoblot	GCS holoenzyme not completely denatured	Make sure GCS holoenzyme is completely denatured. Use a 2× immunoblot sample loading solution that contains 12 M urea and 600 mM DTT. Use purified protein to identify the band.
	Antibodies not pure	Purify antibodies.

expression of GCS and GGT has been reported in numerous tissues and cells. GGT activity is very high in kidney and relatively low in adult liver.

Time Considerations

Typical northern analysis takes 1 to 2 weeks for completion. From RNA isolation through transfer of RNA to the membrane usually takes <3 days, while the actual hybridization with multiple probes takes ~1 to 1.5 weeks, including film exposure time. The actual time frame, however, will depend on the availability of the probes for hybridization and the intensity of the signal. For immunoblot analysis, sample preparation usually takes one whole day, and the rest of the procedure can be completed in 2 additional days.

Nuclear run-on analysis tends to be time-consuming. Plasmid preparation itself, which should take place before the protocol, takes ~1 to 2 weeks, but once the plasmids are isolated, they can be used several times (30 µg of each plasmid for each experiment, for an average of six different treatments per experiment). Growing and treating cells and isolating nuclei from them requires ~1 week to complete. Linearizing plasmids and binding cDNA probes to the membrane requires an additional 2 days. In vitro transcription, isolation of RNA, and hybridization requires another 2 to 3 days. Therefore, one experiment typically requires ~1 week if all plasmid cDNAs are available and the cells are ready to be treated.

Measurement of Glutathione Conjugates

Although conjugation with the nucleophile glutathione can result in products with increased toxicological activity, the vast majority of reactions that generate glutathione conjugates result in products with decreased biologic activity and increased chemical stability. Since the metabolic precursors to glutathione conjugates are generally chemically unstable, systems that efficiently trap such metabolites to form chemically stable glutathione adducts have been utilized to obtain additional structural information on reactive metabolites. There are many instances when a compound is metabolized by the cytochrome P450 monooxygenase system to multiple reactive metabolites. Differences in the cytotoxic and carcinogenic activities of these have been described extensively in the literature (Thakker et al., 1985). Thus, trapping reactive metabolites with glutathione offers a means of separately measuring each of the different precursor metabolites. In practice, these procedures work well when in vitro experimental approaches are used to address questions. When the experimental paradigm involves work conducted in vivo, measurement of mercapturic acids can often be assessed in excreta as a measure of the quantity of glutathione conjugate precursor generated.

The high polarity of glutathione conjugates and their lack of volatility have dictated the use of HPLC-based methods as a primary means of following the formation of such metabolites. Assays that are based on an initial chromatographic step (see Basic Protocol) offer obvious advantages in terms of specificity over either radiometric (see Alternate Protocol 1) or spectrophotometric (see Alternate Protocol 2) assays, but they are more time consuming. Radiometric assays, in which labeled (^{14}C, ^{3}H, or ^{35}S) parent compound is utilized in microsomal incubations (with appropriate glutathione trapping followed by extraction of unreacted parent substrate and analysis of water-soluble glutathione conjugates), offer a rapid and relatively high-throughput approach for measuring the overall rates of conjugate formation. Spectrophotometric assays in which substrates, such as 1-chloro-2,4-dinitrobenzene, that generate a product with an absorbance maximum significantly different from the parent substrate can be used to measure glutathione *S*-transferase activities with simple time-based increases in absorbance. Generally, those substrates utilized in spectrophotometric assays are not particularly reactive and, although these approaches are effective in surveys of enzyme activity, they are not as useful in assays designed for efficient trapping of reactive metabolites generated from cytochrome P450–dependent metabolic activation. Thus, a method based on continuous monitoring of conjugate formation spectrophotometrically is presented here for the purpose of providing a more complete survey of methods available for measuring glutathione conjugates, with the caveat that these approaches are used principally for the assessment of glutathione *S*-transferase activities. Since these protocols are less specific, the primary protocol presented here is based on separation of conjugates from other metabolites by HPLC followed by post-column detection and analysis. Support protocols are provided for reaction conditions (see Support Protocol 1), preparation of cytosolic and microsomal fractions (see Support Protocol 2), preparation of glutathione *S*-transferase (see Support Protocol 3), and preparation of samples for mass spectrometric or NMR analysis (see Support Protocol 4).

MEASUREMENT OF GLUTATHIONE CONJUGATES BY HPLC

BASIC PROTOCOL

Separation and quantitative measurement of glutathione conjugates can be accomplished by using an HPLC system coupled to an appropriate detection system. With the high efficiency columns currently available and with appropriate mobile phases, multiple glutathione conjugates, including those arising as diastereomers, can be measured to assess both regio- and stereoselective formation of aromatic hydrocarbon epoxides.

Contributed by Michael A. Shultz, Dexter Morin, Katherine Watt Chan, and Alan R. Buckpitt
Current Protocols in Toxicology (2002) 6.8.1-6.8.24

HPLC using a reversed-phase column with ion pairing has been used with numerous aromatic/aliphatic hydrocarbon epoxide–derived glutathione conjugates (Hernandez et al., 1980; Armstrong et al., 1981; Steele et al., 1981; Plakunov et al., 1987). Ion-exchange columns have proven effective in the isolation of conjugates derived from dichloroethylene (Dowsley et al., 1995), 4-ipomeanol (Buckpitt and Boyd, 1980), or benzo(a)pyrene (Jernstrom et al., 1982).

The method presented here has been used for the separation of 1-nitronaphthalene glutathione conjugates (Watt et al., 1999) and is similar to the method for naphthalene conjugates (Buckpitt et al., 1987). This method also has been successfully used for separation and analysis of glutathione conjugates derived from epoxides of 2-methylnaphthalene, anthracene, and benzo(a)pyrene (Shultz et al., 2001). The method utilizes reversed-phase HPLC on a Spherisorb C18 ODS 2 column with ion-pairing/ion suppression of the conjugates with triethylamine adjusted to pH 3.1 using phosphoric acid. The method is capable of separating numerous glutathione conjugates derived from attack of glutathione at the C-5, C-6, C-7, or C-8 positions (Fig. 6.8.1). Other end-capped C18 ODS-2 columns are likely to work well with slight modifications of acetonitrile concentrations in the mobile phase. Conjugates can be separated successfully using methods involving simple addition of 1% acetic acid to act as an ion suppressing/ion pairing agent. However, in practice, peak shape is not as symmetrical as with separations utilizing triethylamine/phosphoric acid. The method described here is capable of separating regio- and stereoisomers generated via formation of both the 5,6- and 7,8-epoxides of 1-nitronaphthalene. The use of [^{3}H]glutathione is included for radiochemical detection, and the generation of appropriate quantitative standards. Samples are quantitatively measured by UV detection at 256 nm. The protocol begins with the assumption that metabolites have been generated using microsomal incubations supplemented with glutathione *S*-transferase and glutathione. Refer to Support Protocol 1 for microsomal incubation conditions. Similar approaches can be adapted for incubations using isolated cells, perfused tissues, or recombinant cytochrome P450 monooxygenases.

As mentioned, the above method was developed for detecting 1-nitronaphthalene epoxides through their respective glutathione conjugates. The following is a good starting point for establishing a new protocol for detecting glutathione conjugates from other substrates of interest. The acetonitrile gradient should be optimized to yield appropriate separation of metabolites. Glutathione conjugates that are more and less polar than those generated from 1-nitronaphthalene will require lower and higher concentrations of acetonitrile, respectively, for elution. For example, glutathione conjugates from 1-nitronaphthalene are separated on a 5% to 16% acetonitrile gradient, those from anthracene required a 15% to 22% gradient, and those from benzo(a)pyrene used a 24% to 29% gradient (Watt et al., 1999; Shultz et al., 2001). While the final pH of the mobile phase has an effect on the elution of glutathione conjugates, a pH of 3.1 has been found to be optimal for many of the metabolites isolated in this laboratory. For method development, the authors recommend the use of [^{3}H]glutathione (such as presented here) or radiolabeled substrate (if available) for ease of detection and quantification of the metabolites. If standards are available, UV detection is all that is necessary for quantification of metabolite peaks. Larger quantities of glutathione adducts can be obtained by simple scale-up of the procedures outlined here (see Support Protocol 4) for analysis by mass spectrometry with electrospray ionization (to confirm suspected glutathione conjugates) and proton nuclear magnetic resonance spectroscopy (to identify sites of nucleophilic attack on an aromatic nucleus).

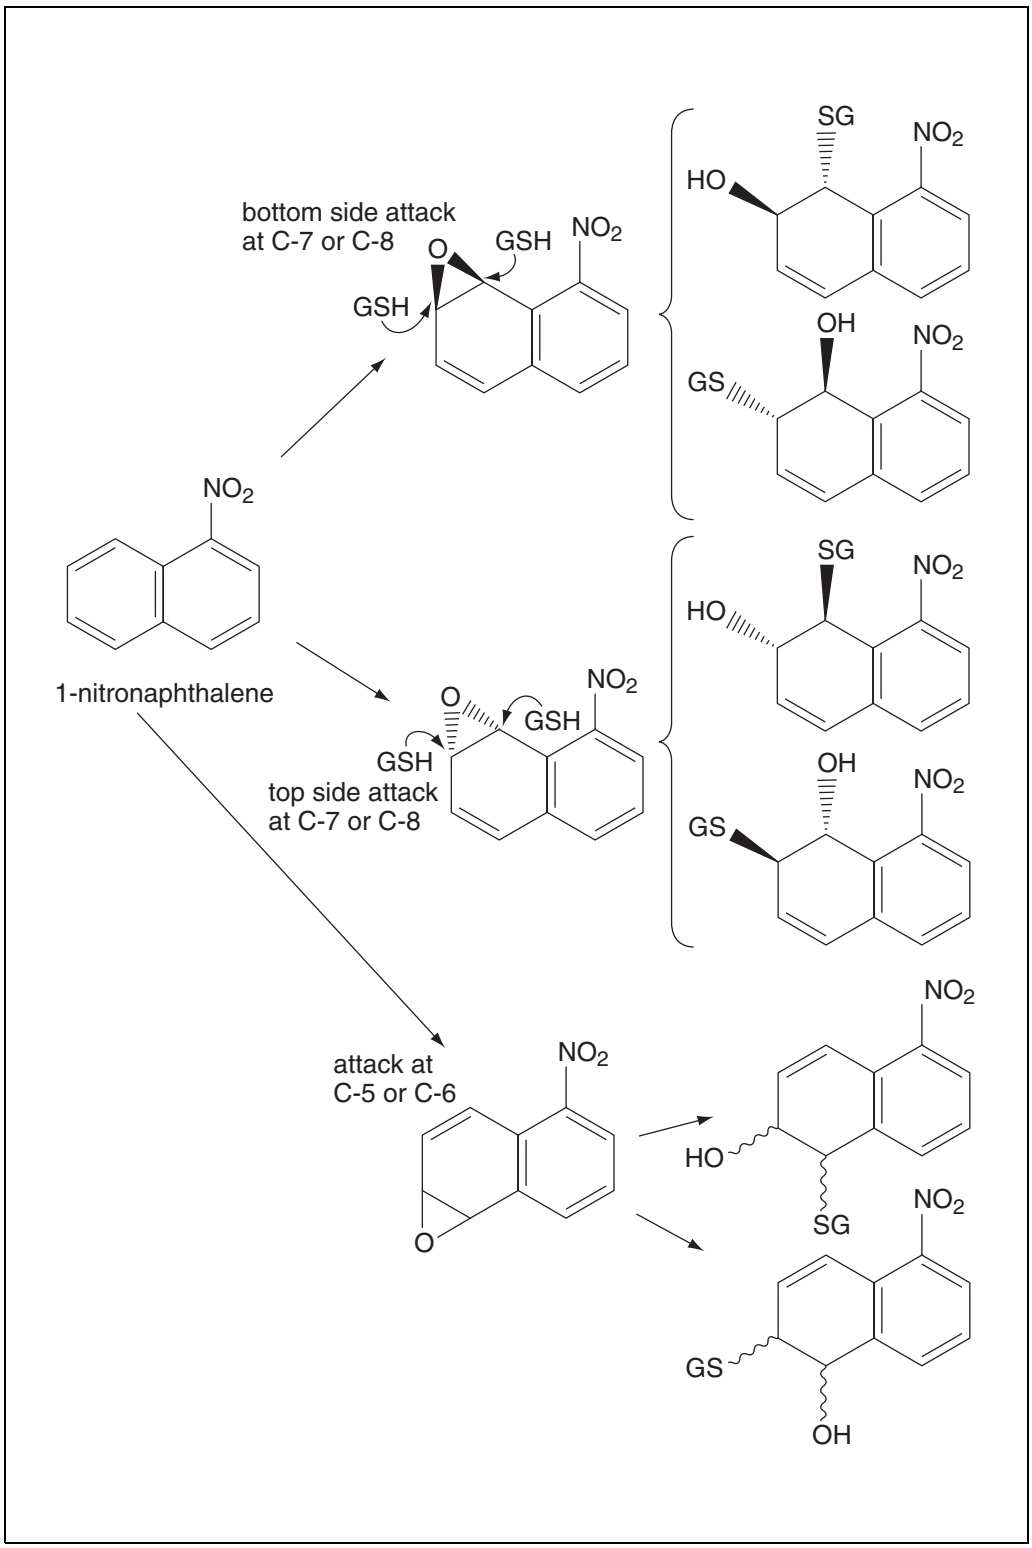

Figure 6.8.1 Diagram showing the metabolic pathways for conversion of 1-nitronaphthalene to glutathione conjugates. Note that stereochemistry is not shown for the bottom pair of products.

Materials

Sample derived from microsomal incubation (see Support Protocol 1)
100% HPLC-grade acetonitrile
Solvent A: 0.06% triethylamine, pH 3.1 (see recipe)
Solvent B: 60% acetonitrile in 0.06% triethylamine (see recipe)
Scintillation cocktail appropriate for aqueous samples

Gradient HPLC:
- 0.46 × 20–cm C18 ODS-2 Spherisorb HPLC column with 5-µm packing material and matching precolumn (Waters) or equivalent
- Injector
- Gradient pump
- UV (variable wavelength or photodiode array preferred)
- Fraction collector (e.g., Gilson model 202)
- Waste collector
- Data collection and storage device (e.g., Millennium integration and control software; Waters)

Scintillation vials

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CAUTION: The electrophilic metabolites generated for glutathione trapping are generally more toxic than the parent compounds and appropriate precautions should be taken to ensure the safety of investigators. Many of these electrophilic metabolites are potent mutagens/carcinogens and/or cytotoxicants. Appropriate protective clothing, gloves, and bench paper should be used while handling all samples.

Prepare incubated samples for HPLC

1. Vortex vials containing samples derived from microsomal incubation briefly.

   The vial contents may appear cloudy (from the precipitated protein) and may contain crystals (from precipitated buffer).

2. Transfer entire vial contents to microcentrifuge tubes using a Pasteur pipet. Microcentrifuge tubes 30 min at 14,000 rpm, 4°C, to pellet insoluble material.

3. Using a Pasteur pipet, transfer supernatant to a fresh microcentrifuge tube. Be certain to avoid transferring any of the particulate material at the bottom of the microcentrifuge tube.

4. Evaporate the supernatants to dryness in a vacuum evaporator (e.g., SpeedVac).

   CAUTION: *In cases where a volatile radiolabeled or toxic substrate is used, the use of a nitrogen evaporator (as opposed to a vacuum centrifuge) in a chemical hood is advisable. Preextraction of the incubations with a water-immiscible solvent may be advisable to remove volatile substrate and to prevent contamination.*

5. Resuspend each sample in 100 µl water and vortex well for 5 min.

6. Microcentrifuge samples briefly (~10 sec) to consolidate the entire volume.

   At this point, the samples are ready for HPLC injection. Most glutathione conjugates are quite stable. In the authors' hands, glutathione conjugates generated from aromatic hydrocarbon epoxides can be stored in 66:34 methanol/H_2O for months at −20°C without detectable loss.

Set up and equilibrate the HPLC system

7. Set up the HPLC system utilizing a 0.46 × 20–cm C18 ODS-2 Spherisorb HPLC column with 5-µm packing material and matching precolumn, an injector, gradient pump, UV detector, fraction collector, waste collector, and data collection and storage device.

   The authors' laboratory utilizes equipment from Waters/Hewlett Packard with Waters Millennium integration and control software. The fraction collector is a Gilson Model 202. For substrates that are highly fluorescent, detection with a fluorescence detector might offer optimal sensitivity. However, unless the fluorescence characteristics ($\lambda_{ex}/\lambda_{em}$) of the conjugates are known, it would be advisable to establish the HPLC methods with a UV detector. Once methods are established, the fluorescence characteristics of the conjugate(s) can be determined separately.

   In some cases isocratic separations are adequate, but for method development, a solvent delivery system capable of generating solvent gradients saves time and, with some substrates, may be necessary for complete separation of metabolites.

8. Set UV detector to monitor at 256 nm.

9. Rinse the column well with 100% HPLC-grade acetonitrile at a slow flow rate (i.e., 0.5 to 1.0 ml/min) for 15 to 30 min or until the baseline stabilizes.

10. Equilibrate the system in 95% solvent A/5% solvent B until the baseline is stable. Set up the gradient program given in Table 6.8.1.

    Note that all gradient steps assume a linear conversion between steps.

11. Set fraction collector to collect 1-min fractions of the HPLC eluent over the course of the entire gradient. Place the appropriate number of scintillation vials in the racks.

    Once the retention times of the metabolites have been established, collect only over the time at which conjugates elute. Collecting fractions for a shorter time (15 to 30 sec) can be useful for better resolution of peaks.

Inject samples, collect fractions, and count to determine regions of interest

12. Set aside a small aliquot of the sample (1% to 5% injection volume). Inject samples and begin gradient program at 1 ml/min and fraction collection. Allow the gradient program to complete.

13. Count the separate sample aliquot to determine total radioactivity injected onto the column.

    This will be used to calculate recoveries from the chromatographic step.

14. Add 5 ml scintillation cocktail to each scintillation vial. Cap, mix, and place tubes in a scintillation counter. Include a blank (i.e., 1 ml mobile phase in 5 ml cocktail) to measure background levels.

Table 6.8.1 Gradient Program for HPLC

Time (min)	Solvent A (%)	Solvent B (%)
0	95	5
60	84	16
65	0	100
85	0	100
90	95	5
110	95	5

15. Count samples using the appropriate channel for ^{3}H or $^{14}C/^{35}S$ as appropriate for the substrate being used.
16. Plot dpm/fraction versus time to generate a chromatographic profile of the metabolites.
17. Determine recovery of radioactivity.

    All (i.e., 100%) of the radioactivity injected onto the HPLC column should be recovered, although this often varies from 85% to 110% due to errors in counting and in determining an accurate background subtraction. Low recovery is an indication that the gradient is incapable of eluting all the metabolites, and the percentage of organic modifier (acetonitrile) should be increased. Be certain to dispose of all waste as radioactive waste.

Interpret data, prepare standards, and validate quantitative methods

18. Optimize the separation of any ^{3}H-labeled glutathione conjugate metabolites eluting from extracts of incubation no. 1 (see Table 6.8.2), but which are absent from control incubations (nos. 2 or 4) by adjusting acetonitrile concentrations (see Support Protocol 1 for list of incubation conditions).

    If the presumed glutathione conjugates are likely to absorb in the UV region, compare the UV trace of sample no. 1 with that of sample no. 3 (without glutathione). This comparison will be helpful in determining whether there is an "underlying" peak which elutes along with the putative glutathione conjugate.

    The first step in the further development of this methodology is to obtain additional characterization of the conjugate(s). If a photodiode array detector is used, UV_{max} for the conjugates can be determined "on-line." Otherwise, conjugate peaks can be collected for analysis in a scanning spectrophotometer.

    It is best to collect just the center two-thirds of the peak to obtain the most concentrated portion of the sample. Many spectrophotometers are capable of reading small sample volumes (i.e., 50 to 100 μl) and better spectra can be obtained by collecting the most concentrated portions of the eluting peak. These data can be utilized to optimize the wavelength of the HPLC detector. Depending upon the needs of the study, further analysis by mass spectrometry and/or NMR spectroscopy may be desirable (see Support Protocol 4).

    If the putative glutathione conjugates elute in a region where there are no obvious interfering UV peaks, then the time and expense of using radiolabeled substrate, and of collecting and counting fractions to do quantitative determinations of conjugate formation, can be eliminated. This approach requires that the investigator demonstrate that there are no interfering peaks which elute with conjugates. The blank sample (no. 3) can be used to determine this. Basing the quantitative determinations of conjugate formation on areas of peaks detected by UV absorbance will either require synthesis of sufficient quantities of conjugates so that they can be purified and weighed, or the accurate determination of extinction coefficients from UV spectra and scintillation counts of conjugates generated in incubations with known specific activities of radiolabeled substrate (either parent compound or with glutathione). In practice, measuring the UV area under the conjugate peak and the amount of radioactivity in this peak yields UV area/nmol conjugate. If radioactive standards are to be used as a basis for standardization, several standards should be analyzed with each batch of samples.

19. Sum the amount of radioactivity eluting with each conjugate peak minus background. Calculate nanomoles conjugate generated in the incubation:

$$\text{conjugate} = \frac{\text{peak} - \text{background}}{\text{substrate specific activity}}$$

    where radioactivity is expressed in dpm and specific activity is expressed as dpm per nanomole.

    These quantitative measurements assume all samples in a series of incubations include [^{3}H]glutathione.

RADIOMETRIC ASSAY OF GLUTATHIONE CONJUGATE FORMATION

ALTERNATE PROTOCOL 1

This assay depends upon substantial differences in polarity between glutathione conjugates, the parent substrate, and other metabolites. They potentially provide much higher throughput than those described above (see Basic Protocol) and are ideal for substrates generating a single glutathione conjugate or when separate analysis of multiple conjugates is unnecessary. This method is based on a thorough study published by Gill et al. (1983), which describes relatively easy methods for synthesizing radiolabeled *cis*- and *trans*-stilbene oxides. Diols and remaining epoxide can be efficiently extracted into 1-hexanol, while radiolabeled glutathione conjugates remaining in the aqueous phase can be counted. The efficiency of the extraction is very high, resulting in a reproducible assay. This method depends on the purchase or preparation of synthetic radiolabeled substrate as well as good partitioning of parent compound and metabolites other than the glutathione conjugates into 1-hexanol.

Materials

1-Hexanol
Glass culture tube with Teflon-lined screw cap (for volatile substrates)
Scintillation fluid
Scintillation vials

Additional reagents and equipment for microsomal or cytosolic incubations (see Support Protocol 1)

CAUTION: Radiolabeled probes are hazardous; see *APPENDIX 1A* for guidelines on handling, storage, and disposal.

1. Conduct microsomal or cytosolic incubations directly in extraction tubes (see Support Protocol 1). Use glass culture tubes with Teflon-lined screw caps if the substrate is volatile.

   The amount of radiolabeled substrate used depends on its turnover to glutathione conjugate. If the efficiency of extraction is high, the generation of 500 dpm glutathione conjugate should be sufficient for accurate quantitation using reasonable counting times (10 to 20 min).

   Be certain to include control incubations, which contain all reagents except glutathione. This validates that the extraction procedure removes all residual radioactivity from the incubations except glutathione conjugates. The amounts of radioactivity in these control incubations should be >100 dpm.

2. Following the appropriate time of incubation, add 500 µl of 1-hexanol.

   All volumes in the protocol assume that the volume of the incubation was 250 µl.

   The time of incubation depends upon the stability of the intermediate substrate and the rates of substrate metabolism. Optimal times will need to be established experimentally. For many studies, linearity with time and protein content will need to be determined prior to the use of the assay method for quantitative determinations.

3. Vortex tubes vigorously for 2 min. Centrifuge samples 3 min at 200 × *g*, room temperature, to separate the layers. Discard the top (hexanol) layer as radioactive waste.

4. Add another 500-µl aliquot of hexanol. Repeat step 3.

5. Discard the hexanol layer. Determine radioactivity of the aqueous layer by transferring 150 to 200 µl to a scintillation vial containing 5 ml scintillation fluid and counting in a liquid scintillation counter.

   Remove the aliquot of aqueous phase carefully since inclusion of any precipitate in the counted sample could lead to artifactually high values associated with radiolabel bound covalently to protein.

6. The nanomoles of glutathione conjugate generated during the incubation can be calculated by:

$$\text{conjugate} = \frac{\text{peak} - \text{background}}{\text{substrate specific activity}} \times \frac{\text{incubation vol.}}{\text{vol. counted}}$$

where radioactivity is expressed in dpm, substrate specific activity is expressed as dpm per nanomole, and volumes are expressed in microliters.

ALTERNATE PROTOCOL 2

SPECTROPHOTOMETRIC ASSAY FOR GLUTATHIONE *S*-TRANSERASES

One of the earliest reported and still one of the most useful assays for glutathione *S*-transferase activity depends upon monitoring the formation of glutathione conjugates of 1-chloro-2,4-dinitrobenzene (CDNB) spectrophotometrically at 340 nm. This is a popular assay for glutathione *S*-transferase activity because CDNB is a reasonably good substrate for most of the glutathione *S*-transferase isoforms. In addition to CDNB, there are other substrates that, after conjugation with glutathione, generate products with absorption spectra significantly different from that of the parent compound. Continuous monitoring of product formation in the UV or visible region provides the basis for measurement of glutathione conjugate formation. These assays can be conducted with moderate throughput on standard spectrophotometers with kinetics assemblies. The assays are readily adapted for use with microtiter plate readers with a corresponding increase in throughput. These assays are likely to be less useful in monitoring the formation of electrophilic metabolites generated during cytochrome P450–dependent metabolic activation. The protocol presented here is based on the original publication by Habig et al. (1974). In theory, these approaches could be applied to any substrate where the glutathione conjugate has a wavelength maximum which differs from that of the parent substrate. Conjugate standards are necessary for the calculation of extinction coefficients.

Materials

0.1 M sodium phosphate buffer, pH 6.5 (*APPENDIX 2A*)
3.3 mM glutathione (see recipe)
33 mM CDNB (see recipe)
Enzyme preparation (e.g., cytosol; see Support Protocol 2)
VIS spectrophotometer (e.g., Beckman DU-70) with thermostatting device

1. Turn on the spectrophotometer and allow to stabilize 15 min prior to use. Set wavelength to 340 nm in kinetics mode (if kinetics assembly is used) and thermostatting device (i.e., cuvette temperature) at 25°C.

   The specifics of this assay depend upon the type of equipment used. In the authors' laboratory, a single-beam spectrophotometer (Beckman DU-70) with a kinetics assembly is used.

Prepare blanks

2. Add 940 µl of 0.1 M phosphate buffer, pH 6.5, to a 1-ml cuvette.
3. Add 30 µl of 3.3 mM glutathione and mix contents well.
4. Add 30 µl of 33 mM CDNB, mix contents well, place cuvette in holder, rezero the instrument and record baseline for 3 min. Run a fresh blank with each set of 4 to 6 samples.

   This is the rate of nonenzymatic reaction and must be subtracted from the rate of enzymatic reaction.

Prepare and analyze samples

5. Prepare a total of four cuvettes each containing 930 to 935 µl phosphate buffer, 30 µl glutathione, and 30 µl CDNB.

   The total volume in each cuvette should be 1 ml after addition of enzyme preparation.

6. Add 5 µl buffer to the first cuvette (blank) and 5 to 10 µl enzyme preparation (e.g., cytosol) to cuvettes 2 to 4 and record increase in absorbance for 2 to 3 min.

   The change in absorbance should not exceed 0.1 AU/min. If it does, repeat the assay using less of the enzyme preparation. Significant dilution will result in lower than expected values. Work at the highest concentrations possible which still allow accurate sample pipetting.

Analyze data

7. Calculate the net increase in absorbance (i.e., enzyme − blank) per minute.

$$\frac{\left(\dfrac{\text{change in absorbance/min (sample)} - \text{change in absorbance/min (blank)}}{\text{volume of protein assayed}}\right)}{\left(\dfrac{9.6}{\text{total volume in cuvette}}\right)}$$

   where all volumes are expressed in milliliters.

   The extinction coefficient of the glutathione conjugate of 1-chloro-2,4-dinitrobenzene is 9600 $M^{-1}cm^{-1}$. One CDNB unit is defined as 1 µmol product formed per min.

MICROSOMAL INCUBATIONS

SUPPORT PROTOCOL 1

This protocol generates glutathione conjugates from substrates of interest which are metabolized to electrophilic derivatives capable of forming glutathione conjugates. The incubations are relatively straightforward and, in many cases, are capable of generating sufficiently large amounts of glutathione conjugate to be easily measured quantitatively. In addition, the extracts obtained from microsomal incubations tend to be less complex than materials obtained from perfused tissue experiments or from matrices such as urine or bile, making the separation and analysis easier.

Materials

Microsomes from tissue of interest (0.5 to 5 mg microsomal protein/ml; see Support Protocol 2) or recombinant cytochrome P450/P450 reductase
0.5 mM 5000 dpm/nmole [^{3}H]glutathione (see recipe)
50 to 100 CDNB U/ml glutathione *S*-transferases (see Support Protocol 3)
1 M $MgCl_2$
12.5 mM NADPH or NADPH regeneration system (see recipes)
0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
50 mM 1-nitronapthalene (see recipe)
Methanol, ice cold
1-ml glass vials with caps
37°C shaking water bath

Table 6.8.2 Basic Components of Incubations to Isolate Glutathione Conjugates[a,b]

Incubation no.	Label	5 mg/ml microsomes	0.5 mM [^{3}H]glutathione	50 U/ml glutathione *S*-transferase	NADPH regenerating system	1 M $MgCl_2$	50 mM 1-nitronaphthalene	0.1 M phosphate buffer, pH 7.4	Total volume
1	Complete	100	50	50	20	2.5	2.5	25	250
2	No nitronaphthalene	100	50	50	20	2.5	0	27.5	250
3	No glutathione	100	0	50	20	2.5	2.5	75	250
4	No NADPH regenerating system	100	50	50	0	2.5	2.5	45	250

[a] All volumes are given in microliters.

[b] All concentrations in the table refer to concentrations of the substance to be added. The final concentrations of various incubation components are specified earlier.

Perform incubations

1. Add the following components given in Table 6.8.2 to appropriate 1-ml glass vials:

   1 to 2 mg/ml microsomes (final)
   0.5 mM 5000 dpm/nmole [^{3}H]glutathione (0.1 mM final)
   50 to 100 CDNB U/ml glutathione *S*-transferase (10 U/ml final)
   1 M $MgCl_2$ (10 mM final)
   12.5 mM NADPH (1 mM final) or NADPH regeneration system (5.7 mM glucose-6-phosphate, 0.21 mM NADP, and 0.3 U/ml glucose-6-phosphate dehydrogenase final)

   Bring final volume to 250 µl with 0.1 M sodium phosphate buffer, pH 7.4.

   The final concentration of microsomes should not exceed 2 mg/ml.

   It is recommended that a "guide sheet" (e.g., Table 6.8.2) be used, outlining the addition of specific volumes of the necessary components. In studies where numerous incubations contain the same concentrations of glutathione, glutathione S-transferase, and other reagents, the use of master mixes containing all of the components is recommended to simplify and normalize the procedure. This approach is especially useful when conducting kinetic studies.

   All incubation components must be kept on ice at all times. It is advisable to precool the incubation vials on ice before adding any incubation components.

2. Gently swirl each vial to thoroughly mix the components and place on ice.

3. On ice, add 2.5 µl of 50 mM 1-nitronaphthalene (0.5 mM final). Cap each tube immediately, keeping them on ice until all tubes are capped.

   CAUTION: *Perform this step in a chemical hood to avoid any exposure to 1-nitronaphthalene, which is somewhat volatile. Keeping everything on ice minimizes the loss of substrate through volatilization. Organic solvents used to dissolve substrates should constitute no more than 1% of the total incubation volume.*

4. Place tubes in a rack, transfer to a 37°C shaking water bath, and incubate 5 to 30 min.

   For kinetic studies (determination of Michaelis constants), linearity with time and protein concentration must be established and all incubations must be conducted within the linear portions of the time and protein curves.

5. Transfer vials (in the same rack) to a slurry of ice-water at the end of the incubation.

   Keep all vials in the rack together to minimize differences in incubation time. Cool vials for 1 min to allow any volatilized 1-nitronaphthalene to condense into the aqueous phase. Uncap vials in a chemical fume hood to avoid exposure to any volatilized 1-nitronaphthalene.

6. Add twice the incubation volume (500 µl) of ice-cold methanol to each vial to completely quench the reaction.

7. Recap and place vials at –20°C overnight (minimum ≥1 hr) to precipitate the protein before continuing with sample analysis.

PREPARATION OF MICROSOMAL AND CYTOSOLIC FRACTIONS

SUPPORT PROTOCOL 2

This protocol provides the enzymes necessary to conduct the incubations to generate glutathione conjugates. There are many variations in the preparation of microsomal and cytosolic fractions and each procedure generates fractions which are capable of working well to generate glutathione conjugates from appropriate substrates.

Materials

Mouse livers
Homogenization buffer (see recipe)
0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)

Motor-driven Potter-Elvehjem Teflon-glass homogenizers
Refrigerated ultracentrifuge (capable of 100,000 × *g*) and appropriate tubes
Cotton-tipped applicator
Hand-held glass-glass homogenizer

Additional reagents and equipment for Bradford assay of protein concentration (*APPENDIX 3G*)

CAUTION: Glass homogenizers should be placed in an ice bucket and held at the top of the vessel only. The high rotating force created during the homogenization processes can occasionally cause the homogenization vessels to shatter, resulting in a significant hazard to the operator. The use of puncture resistant gloves is strongly recommended.

CAUTION: Samples for the ultracentrifuge must be balanced within 100 mg. All rotor gaskets and the speed disk should be checked prior to use of the ultracentrifuge.

NOTE: The following procedures should be conducted at 0° to 4°C.

1. To mouse livers, add four volumes homogenization buffer per gram wet weight and homogenize using a motor-driven Potter-Elvehjem Teflon-glass homogenizer.

   The authors use 5 to 6 complete passes of the homogenizer.

2. Centrifuge homogenate 30 min at 9,000 × *g*, 2°C. Transfer the supernatant containing the cytosolic and microsomal fractions to ultracentrifuge tubes, avoiding the fat layer at the top of the tube and the fluffy layer near the interface of the cytosol with the pellet. Balance the sample tubes to within 100 mg.
3. Ultracentrifuge the supernatant 60 min at 100,000 × *g*, 2°C. Remove the supernatant, avoiding any remaining fat layer.

   The supernatant fraction can be used to partially purify glutathione S-transferases (see Support Protocol 3) or can be used directly as a source of cytosol for measurement of cytosolic glutathione transferase activities.

4. Wipe the sides of the tube with a cotton-tipped applicator to remove any remaining fat. Resuspend the pellet in homogenization buffer to approximately half the original volume. Homogenize using hand-held glass-glass homogenizer by hand, avoiding any aeration of the sample. Centrifuge the resuspended samples 60 min at 100,000 × *g*, 2°C.
5. Discard the supernatant and resuspend the pellet in 0.1 M phosphate buffer, pH 7.4, at a volume likely to provide protein concentrations ≥5 mg/ml.

   This can be calculated based on the expected yield of microsomal protein (e.g., 10 to 15 mg microsomal protein/g liver, 2 to 3 mg microsomal protein/g lung).

6. Determine protein content using the Bradford Coomassie Blue dye binding procedure (*APPENDIX 3G*).

SUPPORT PROTOCOL 3

PURIFICATION OF GLUTATHIONE *S*-TRANSFERASES

The procedures described in this support protocol are intended to provide an extract which is highly enriched in glutathione S-transferases, and are based on the method of Simmons and Vander Jagt (1977). Essentially this is a two step procedure (removal of glutathione, followed by affinity chromatography of glutathione-free cytosol), which is designed to

recover a fraction highly enriched in glutathione S-transferases. This preparation provides transferases at relatively high specific activity for use in incubations to generate glutathione conjugates.

Materials

175- to 520-µm coarse Sephadex G-25 resin
Resuspension buffer (see recipe) with and without 0.5 M NaCl
Sample (100,000 × *g* supernatant; see Support Protocol 2, step 3)
Glutathione affinity resin—i.e., glutathione-agarose (Sigma) or equivalent
Glutathione elution buffer (see recipe)
0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)

Glass columns
Buffer resevoir
Column monitor (e.g., ISCO UA5; optional)
Amicon PM-10 membrane ultraconcentrator (10,000 MWCO) or equivalent
12,000- to 14,000-MWCO dialysis membrane

Perform Sephadex G-25 chromatography

1. Preswell 175- to 520-µm coarse Sephadex G-25 resin in resuspension buffer according to the manufacturer's instructions. Pour a bed volume at least three times the sample volume into a glass column, taking care to pour all of the resin at one time and excluding bubbles.

   The authors use a 2.5 × 70–cm column. This column has a 350-ml bed volume, which allows 100 ml cytosol to be applied.

   When not in use, store the column at 4°C in buffer with 0.05% (w/v) sodium azide to prevent bacterial contamination.

2. Equilibrate the column with 5 vol fresh resuspension buffer.

3. Apply sample to the column being careful not to disrupt the top of the resin bed. As the last of the sample enters the resin bed, add fresh resuspension buffer, again being careful not to disturb the resin bed. Then attach a buffer reservoir to the column.

   For the size stated, flow rates are 10 to 15 ml/min. Do not allow the column to go dry.

4a. *For column monitor:* Elute with resuspension buffer. Collect all of the initial peak until the absorbance at 280 nm begins to show a second peak (i.e., void volume).

   The column monitor can be run at its lowest sensitivity.

4b. *For manual isolation:* Elute with resuspension buffer. Collect all of the red-colored fractions (i.e., void volume).

   The void volume is marked by intensely red-colored proteins.

   Glutathione is retained at least two void volumes behind the initial proteins.

   This step is intended to remove glutathione from the supernatant which is isolated by ultracentrifugation of homogenized mouse liver (see Support Protocol 2).

Perform glutathione-affinity chromatography

5. Pour a chromatography column using glutathione-affinity resin and an appropriate glass column.

   The affinity resin is a glutathione agarose matrix where glutathione is attached through the sulfur. The column should contain a minimum of 1 ml resin for every 200 U glutathione S-transferase (based on CDNB activity) to be bound.

6. Equilibrate this column with 5 bed volumes resuspension buffer with freshly added DTT.
7. For a 50-ml bed volume (2.5-cm diameter column), apply eluent from the Sephadex column (step 4a or b) at a flow rate of ~1 ml/min.

   Gravity feed is recommended because the resin is soft and is easily compacted if pressurized.
8. After applying all of the supernatant, wash the column with at least five column volumes of resuspension buffer followed by five column volumes of resuspension buffer containing 0.5 M NaCl.

   If a column monitor is used, wash the column until absorbance at 280 nm returns to baseline.
9. Elute the glutathione *S*-transferases from the affinity column with glutathione elution buffer.

   Elution using two column volumes is optimal. Using less results in lower yields of transferase, while more will result in dilute enzyme which must be concentrated further on an Amicon concentrator. Thus, for a 50-ml column use 100 ml elution buffer.

10a. *For column monitor:* Collect from first baseline change to one column volume. Collect a second column volume separately.

   75% of the total glutathione S-transferase protein will come off in the first column volume and 25% will be in the second volume.

   For maximal concentration of eluted glutathione S-transferase use a column monitor.

10b. *For manual isolation:* If no column monitor is used, simply collect the first and second column volumes separately.

Concentrate and dialyze

11. Once the semipurified preparation of glutathione *S*-transferases has been collected from the column, concentrate if necessary using an Amicon PM10 membrane ultraconcentrator (10,000-MWCO) according to manufacturer's instructions. Dialyze concentrate at 4°C in 12,000- to 14,000-MWCO dialysis membrane against two changes of at least 20 vol of 0.1 M sodium phosphate buffer, pH 7.4, as soon as possible.

    Do not allow enzyme to remain at pH 9.0 overnight as significant losses of enzymatic activity will result. Do not allow the sample to concentrate to dryness as significant losses of glutathione S-transferases will result.
12. Measure glutathione *S*-transferase activity in the samples after dialysis and concentration (see Alternate Protocol 2).

    Aliquots of this preparation can be stored at −80°C for up to six months in phosphate buffer. Check enzymatic activities prior to use.

    Do not repeatedly freeze/thaw aliquots. An activity loss of ~50% will occur after a second freeze/thaw cycle.

SUPPORT PROTOCOL 4

PREPARATIVE SEPARATION AND ISOLATION OF GLUTATHIONE CONJUGATES FOR CHARACTERIZATION BY MASS SPECTROMETRY AND PROTON NMR SPECTROSCOPY

One of the advantages of establishing methodology capable of measuring individual glutathione conjugates by HPLC is that these methods can be used to isolate sufficient quantities of conjugate for further characterization by mass spectrometry and proton NMR spectroscopy. The availability of semipreparative HPLC columns coupled with enhancements in instrument sensitivity available for both mass spectrometry and proton NMR

spectroscopy has considerably decreased the amount of effort required to assign structures to the metabolites isolated. In some cases, metabolites are derived from enantiomeric epoxides and the precise structural assignments (R versus S carbon configuration) depends upon the synthesis of epoxide enantiomers. However, the regiochemistry of glutathione conjugates can be determined by appropriate NMR techniques.

There are two options for generating sufficient quantities of reactive metabolites to prepare glutathione conjugates for spectral characterization and for standards. Many reactive metabolites such as those from acetaminophen (*N*-acetyl-*p*-benzoquionone imine; Dahlin and Nelson, 1982), aflatoxin B_1 (the 8,9-epoxide; Raney et al., 1992), and naphthalene (the 1,2-epoxide; van Bladeren et al., 1984) can be synthesized. For those which are difficult to synthesize, sufficient quantities of glutathione conjugates can be obtained for spectral characterization and to serve as standards from large microsomal incubations (1 to 2 liters) by scaling up the procedures described (see Support Protocols 1 and 2).

Materials

Substrate
Methanol, ice cold
SM-16 resin (macroporous polystyrene divinyl benzene; BioRad) or equivalent
Methanol, HPLC grade
1% acetic acid or equivalent (e.g., 0.5% formic acid, 0.05% trifluoroacetic acid)
50% glacial acetic acid or equivalent (e.g., 50% concentrated formic acid, trifluoroacetic acid)
75% acetonitrile
12.4 M pyridine (99%)

Rotary evaporator and flask or large-volume centrifugal evaporator
Disposable low-pressure column
Teflon or silanized-glass containers (optional)
HPLC system:
- Semipreparative 8- to 30-mm-diameter column packed with material identical to that used in the analytical separation (see Basic Protocol)
- Gradient HPLC pump capable of delivering flow rates that vary from 5 to 40 ml/min

Lyophilizer

Additional reagents and equipment for sample preparation (see Support Protocol 1, steps 1 to 5)

Incubation and initial sample preparation

1. Incubate substrate with microsomes, glutathione *S*-transferases, and glutathione using proportionally larger quantities of starting material as described (see Support Protocol 1, steps 1 to 5).

   Once the analytical conditions have been established, the use of [^{3}H]glutathione is unnecessary; many core spectroscopy facilities will not allow radioisotopes in their facilities.

2. Stop the reaction with 2 vol ice-cold methanol and allow mixture to stand overnight at −20°C.

3. Centrifuge the reaction mixture 30 min at 5,000 × *g*, room temperature, to remove precipitated protein and salts.

4. Transfer the supernatant to a rotary evaporator flask and evaporate solvent under reduced pressure. Alternatively, use a large-volume centrifugal evaporator.

Partial purification of large samples

5. Prepare a disposable low-pressure solid-phase extraction column filled with either a C18 or a styrene-divinylbenzene-based resin (i.e., SM-16).

   The bed volume will depend upon the amount of material being bound and the binding characteristics of the resin used. If an estimate of column volume is necessary, overestimate, as the resin is reusable.

6. Rinse the solid-phase extraction column with ten column volumes of HPLC-grade methanol followed by ten column volumes of 1% acetic acid (0.5% formic or 0.05% trifluoroacetic acid).

7. Redissolve the evaporated residue from step 4 in 2% acetic acid and check the pH. Use a solution of 50% glacial acid to adjust the pH to 2.5 to 3.5.

   Note that 1% formic or 0.5% trifluoroacetic acid can be used to dissolve the evaporated sample. The pH would then be adjusted with 50% concentrated formic or trifluoroacetic acid, respectively.

8. Apply sample to the column, allowing the entire sample to wash onto the bed. Rinse with ten column volumes of 1% acetic acid (0.5% formic or trifluoroacetic acid). Discard the initial charge solution and washes.

9. Elute column with 75% acetonitrile and collect the eluate containing the glutathione conjugate(s) of interest.

   From this step on, the use of Teflon or silanized glass containers is highly recommended. If glass containers are used, they must be silanized with chlorotrimethylsilane prior to use. Significant losses will occur with standard glass surfaces. Most plasticware contains plasticizers (phthalate) which interfere with mass spectral and NMR analysis.

10. *Optional:* If the conjugate is acid labile, adjust the pH of the column eluate to neutrality with 12.4 M pyridine. Lyophilize the water/acetonitrile (pyridine) extract to dryness and reconstitute the sample in water.

    Pyridine acetate is volatile and can therefore be removed by lyophilization.

Perform final purification of samples

11. Purify conjugates by HPLC using a semipreparative 8- to 30-mm-diameter HPLC column packed with material identical to that used in the analytical separation.

    The retention times should be similar to the Basic Protocol if proportional column flows are used. The pattern of peak elution should stay the same. If possible, add a small amount of extract prepared with radioactive conjugates (prepared in Support Protocol 1) to the unlabeled sample and run these together to verify peak retention times and patterns. This only needs to be done once to determine the exact elution profile.

    Flow rate depends on the internal diameter of the column. As the internal diameter of a column doubles, the flow rate should be increased 3- to 4-fold.

    Unless the conjugates are known to be stable indefinitely at room temperature, it is best to collect samples on ice and keep them cold throughout the preparation.

    Volumes of column eluate collected will be much greater during preparative chromatography. For example, a 1-min fraction on the analytical system will have a volume of 1 ml; on the 22.5-mm diameter semipreparative system each 1-min fraction is 11.5 ml. Radioactivity can be quantitated by counting a portion of each fraction (i.e., 1 ml). This requires that more radioactivity be injected into the column or, alternatively, that shorter time intervals be used to collect fractions (such as 0.1 min). Supplies can be conserved by collecting only during those times when conjugates are eluting from the column.

12. To prepare the samples for spectroscopic analysis, lyophilize the samples to dryness and repeat steps 5 to 10.

    a. In step 8, be certain to rinse the solid-phase extraction column with 20 column volumes of equilibration solution (e.g., 1% acetic, 0.5% formic, or 0.05% trifluoracetic acid) to wash all of the triethylamine phosphate through the column.

       Each sample (peak) collected from the HPLC has triethylamine phosphate buffer in it which is incompatible with mass spectrometry and NMR spectroscopy.

    b. Elute and neutralize the sample as described in step 10.

       If very small amounts of conjugates are being purified, a C18 analytical column washed and prepared as described in step 6 can be used in place of the solid-phase extraction column. Monitoring the column eluate with a UV absorbance detector makes it easier to determine when to collect the eluate.

    c. Lyophilize samples extensively as described in step 10 to remove all volatile salts and water, being careful to exclude water vapor when venting the lyophilizer if NMR identification is required.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acetonitrile, 60% in 0.06% triethylamine

Combine 600 ml 0.06% triethylamine, pH 3.1 (see recipe) with 400 ml HPLC-grade acetonitrile containing 0.06% triethylamine. Store unfiltered solution up to 5 days at 4°C. Filter through a 0.45-um filter just before use.

CDNB, 33 mM

Dissolve 6.75 mg recrystallized 1-chloro-2,4-dinitrobenzene (CDNB) in 1 ml of 100% ethanol. Store up to 1 month at −20°C in an airtight container in the dark.

This reagent is used at a final concentration of 1 mM for spectrophotometric measurement of glutathione conjugate formation.

[^{3}H]Glutathione, 0.5 mM

After receipt of a batch of 20- to 50-Ci/mmole [^{3}H]glutathione (New England Nuclear Life Science Products; Perkin Elmer), place 5- to 20-µCi aliquots in separate tubes under argon at −80°C to avoid repetitive freeze/thaw cycles.

Just prior to use, dissolve 7.6 mg glutathione in 5 ml of 0.1 M sodium phosphate buffer, pH 8.5 (*APPENDIX 2A*). Add 50 µl of this stock glutathione solution to a clean vial. Add 3 µl freshly thawed [^{3}H]glutathione to the vial and bring the solution to 500 µl with 0.1 M sodium phosphate buffer, pH 7.4. Count at least two separate 2- to 5-µl aliquots to determine the exact specific activity. The remainder should be sufficient for eight microsomal incubations at 0.1 mM, assuming an addition of 50 µl and a total reaction volume of 250 µl.

Since these steps form the basis for creating standards for the assays, they must be performed carefully.

Glutathione is readily oxidized, especially at basic pH, and the ^{3}H-labeled material is unstable.

Calculations here assume a starting specific activity of 20 Ci/mmole.

Glutathione, 3.3 mM

Dissolve 101.1 mg glutathione in 10 ml sodium phosphate buffer, pH 8.5 (*APPENDIX 2A*). Prepare just prior to use and keep cold (i.e., 4°C).

Glutathione elution buffer

Just prior to use (i.e., 1 hr or less), dissolve 0.24 g Tris base and 2.92 g NaCl in 90 ml water. Cool the solution to 4°C and add 0.76 g glutathione (50 mM final). After glutathione is dissolved, adjust the pH of the solution to 9.0 with 1 N NaOH and bring the total volume to 100 ml. Keep cold (i.e., 4°C) until use since glutathione is easily oxidized at basic pH.

Sparging the solution with He or N_2 will minimize dissolved oxygen levels and consequent disulfide formation.

Homogenization buffer

Dissolve 2.4 g Tris base and 11.5 g KCl in 800 ml water. Add 336 mg disodium EDTA. Cool to 4°C and adjust the pH to 7.4 with 6 M HCl. Adjust volume to 1 liter. Store up to 1 month at 4°C. Just prior to use add 154 mg DTT.

Final concentrations are 20 mM Tris, 1.15% KCl, 1 mM DTT, and 1 mM EDTA.

Note that the pH of Tris buffers differs substantially with temperature (dpH/dt = –0.028/1°C; also see APPENDIX 2A)

NADPH, 12.5 mM

Prepare a solution of 10.4 mg tetrasodium NADPH in 1 ml of 0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*). Prepare fresh just prior to use.

Addition of 20 μl of this solution to an incubation with a total volume of 250 μl provides a concentration of 1 mM NADPH in the incubation.

NADPH regeneration system

Dissolve 20 mg NADP and 50 mg glucose 6-phosphate in 1.0 ml of 0.1 M sodium phosphate buffer, pH 8.5 (*APPENDIX 2A*). Add 12.5 U glucose-6-phosphate dehydrogenase. Maintain protected from light at 4°C until use.

Regeneration system is only stable for ~1 hr after the addition of the dehydrogenase.

1-Nitronaphthalene, 50 mM

Dissolve 8.6 mg 1-nitronaphthalene in 1 ml methanol. Store 1 month at –20°C.

Use 2.5 μl per 250 μl incubation. The final concentration in the incubation is 0.5 mM.

Resuspension buffer

Dissolve 6.07 grams Tris base in 800 ml water. Add 372 mg disodium EDTA and cool the solution to 4°C. Adjust the pH to 7.0 using 6 N HCl and the volume to 1 liter with water. Store this solution up to 1 month at 4°C. Just prior to use add 154 mg DTT.

Triethylamine, 0.06%, pH 3.1

Add 0.6 ml HPLC-grade triethylamine to 800 ml water. Adjust the pH to 3.1 using HPLC-grade phosphoric acid. Bring volume to 1 liter with water. Store up to 1 week at 4°C. Filter through a 0.45-μm filter before use.

In some HPLC systems, which use low pressure mixing, it will be essential to sparge the mobile phase with helium prior to and during use.

COMMENTARY

Background Information

Although conjugation with glutathione occasionally results in derivatives with greater toxicologic activity (van Bladeren, 2000), the vast majority of reactions involving conjugation with glutathione result in detoxification of a wide variety of electrophilic chemicals, many of which are derived from cytochrome P450–mediated metabolism. Numerous studies have demonstrated that the balance between activation and glutathione-dependent detoxification reactions is a critical determinant in the sub-

sequent pathologic outcome of exposure to these toxicants. Accordingly, the advent of techniques for monitoring the formation of glutathione conjugates has provided important insights regarding: (1) the chemical nature of reactive metabolites generated, (2) the roles of various cytochrome P450s involved in the metabolic activation of the parent substrate, (3) the importance of various glutathione *S*-transferase isoforms in regio- and enantioselective metabolism of epoxides, and (4) the influence of other modifying factors on the overall balance between activation and detoxification reactions. In addition, the ability to monitor glutathione conjugation reactions with high sensitivity has given rise to assays capable of functionally analyzing those enzymes responsible for the activation and detoxification of drugs/environmental toxicants in well-defined subcompartments and in cells of heterogeneous tissues such as the nose, lung, kidney, and GI tract.

Three different approaches have been presented here that are capable of measuring the rates of glutathione conjugate formation. Separation and quantitative measurement of conjugates by HPLC constitutes one of the most widely used techniques for assessing the rates of reactive metabolite formation. This approach has several advantages. The sensitivity of the method depends upon the extinction coefficient of the conjugate or the specific activity of the starting substrate if radiolabeled material is utilized in the incubations. Regardless, many of these methods are sufficiently sensitive to permit the measurement of conjugates formed in microgram to low milligram tissue samples or microgram amounts of microsomal protein. This allows comparisons of glutathione conjugate formation to be conducted with target and nontarget cells in heterogeneous tissues. Moreover, these assays allow for distinction of the glutathione derived versus other metabolites. Although this is not an issue in microsomal incubations with substrates like acetaminophen that forms a single glutathione adduct (Hinson et al., 1982), this can be an important consideration if the rates of acetaminophen metabolism are being assessed in tissue slices, isolated cells, or perfused tissues because of the generation of sulfate and glucuronides in addition to the thioether metabolites. Another example is work conducted on the pulmonary metabolism of dichloroethylene where three primary metabolites are generated during microsomal incubations with dichloroethylene. Two glutathione conjugates are derived from dichloroethylene epoxide and one from an acetal which arises via metabolism of the parent compound to the dichloroacetaldehyde (Dowsley et al., 1995, 1996, 1999). Since the epoxide is the metabolite presumed to mediate the toxicity of dichloroethylene, only methods capable of distinguishing the epoxide-derived versus aldehyde-derived metabolites are useful in studies of cross-species comparisons of metabolic activity. In cases where multiple reactive metabolites are generated, glutathione conjugates derived from these metabolites, in many cases, can be separated providing the ability to examine species, cell, and tissue differences in the rates of formation of the conjugates. For example, studies on the microsomal metabolism of 1-nitronaphthalene demonstrated that pulmonary P450 monooxygenases metabolize 1-nitronaphthalene primarily to the glutathione conjugates derived from the 7,8-epoxide in both the rat and mouse, whereas the 5,6-epoxide is the predominant metabolite generated in hepatic microsomal incubations (Watt et al., 1999; Watt and Buckpitt, 2000). Similarly, the ability to separate diastereomeric glutathione conjugates has been critical to the assessments of the enantioselectivity of the glutathione *S*-transferases. An elegant example where the ability to monitor conjugation at both benzylic and allylic sites of a number of *syn*- and *anti*-diol epoxides of polycyclic aromatic hydrocarbons has been presented by Sundberg and colleagues (1997). The results show that conjugation of the R-configured benzylic carbon is strongly favored with all of the anti-diol epoxides, a result that is highly consistent with models of the A site of the glutathione *S*-transferase isoforms used in these studies.

When the study is designed to survey the activities of conjugate-generating enzymes in a particular species, cell, or tissue rather than to understand the precise chemical nature of reactive metabolites generated or the regio/stereoselectivity of conjugation, the latter two protocols (radiometric partitioning and spectrophotometric assays) can potentially provide much higher throughput at a lower cost. As long as radiolabeled parent substrate is available, the partition assays should be relatively inexpensive; highly sensitive assays will depend upon the availability of substrate with high specific activity. These assays should be readily adaptable to a wide variety of electrophilic substrates. Likewise, if the study is designed to examine the distribution of glutathione *S*-transferase activities with a specific

substrate, a spectrophotometric assay, such as that described for CDNB (see Alternate Protocol 2), can be used. Although the sensitivity of the assay could be lower than that of the HPLC or radiochemical partition assays, high sensitivity may not be necessary to answer the question being posed. The key requirement of these assays is that the product generated has a UV_{max} different from that of the parent substrate. As indicated earlier, these assays are unlikely to be of much benefit in cases where initial cytochrome P450-dependent metabolic activation of the parent substrate is required for reactive metabolite generation.

Critical Parameters and Troubleshooting

Establishing a new assay for measuring the formation of glutathione conjugate(s) with a xenobiotic in the absence of standards can be a daunting task. However, several steps can be taken to make the process easier. The first issue is to determine whether there is any indication that the compound in question conjugates with glutathione. Evidence for this can be obtained by examining depletion of glutathione in vivo. Likewise, depletion of glutathione from isolated cells or tissue subcompartments can provide presumptive evidence for the formation of glutathione conjugates. There are several well-established procedures for the measurement of this reduced tripeptide in tissues (see *UNIT 6.2*). Once this is established, the use of [^{3}H]glutathione provides a mechanism for isolating putative glutathione conjugates as long as a full series of controls is run simultaneously. It can be helpful if [^{14}C]labeled parent substrate is available, because this makes dual-label experiments possible.

If the experiment is designed to use glutathione as a trapping method for reactive metabolites generated by a cytochrome P450–dependent process, it is important to account for the overall disposition of the parent compound. For example, naphthalene is metabolized to an intermediate epoxide which can rearrange spontaneously to 1-naphthol, undergo epoxide hydrolase–mediated hydration to a dihydrodiol, and/or bind covalently to proteins. If the experiments are designed to trap all of the naphthalene epoxide formed, care must be taken to optimize glutathione and glutathione *S*-transferase concentrations. Although the use of 0.5 mM glutathione and 10 CDNB units glutathione *S*-transferases/ml was nearly optimal for trapping reactive naphthalene metabolites, these conditions could be substrate dependent and should be optimized for each substrate tested. Even under conditions where all of the substrates and cofactor have been optimized, small quantities of the epoxide are diverted to other pathways (Buckpitt et al., 1992). The ability to account for the loss of substrate and the formation of each of the products generated during the cytochrome P450–dependent metabolism almost necessitates the use of radiolabeled substrates. For those compounds that cannot be purchased or easily synthesized, the tasks of developing the methodology and validating trapping efficiencies are considerably more difficult.

There are a number of experimental steps that can be an impediment to a successful study. If there is evidence that the compound of interest is metabolized to a glutathione conjugate, but chromatographic evidence is lacking, the compound in question may deplete tissue/cellular glutathione stores by mechanisms other than conjugation (e.g., oxidation of reduced glutathione to glutathione disulfide). Another possible explanation is that the glutathione conjugate is unstable or is lost during sample preparation. If conjugates are generated in hepatocytes, they may be further metabolized to cysteinylglycine, cysteine, and/or *N*-acetylcysteine derivatives (Buonarati et al., 1989). Finally, microsomal enzyme systems used to generate reactive metabolites that are subsequently metabolized to glutathione conjugates is a multicomponent system. Lack of function at any one of these steps could lead to a negative experimental result. Individual segments of the reaction should be tested for satisfactory function. The best approach may be to utilize a positive control; either styrene or naphthalene would serve this purpose as the metabolism and conjugation of these two substrates has been described in detail previously (Steele et al., 1981; Buckpitt et al., 1987). The advantage of styrene is that the epoxide is commercially available, and the glutathione conjugates can be prepared without microsomal activation.

As mentioned earlier, if radiolabeled glutathione or parent substrate is used as the basis for assay quantitation, the specific activity of the starting material must be known precisely. In preparing substrate for use in these assays, it is worthwhile taking several samples of substrate to determine specific activity. In cases where the substrate is radiolabeled and absorbs in the UV region, it is often possible to deter-

mine specific activity precisely by UV scanning and counting samples of the actual substrate used in the reaction mixture. Knowledge of the extinction coefficient then allows precise measurements of the concentrations in the cuvette.

Anticipated Results

Analyzing HPLC chromatograms

Comparison of HPLC UV/radiochromatograms of complete incubations (microsomes, substrate, [^{3}H]glutathione, NADPH, glutathione *S*-transferase) versus those containing all components except NADPH or substrate can provide a good indication that a suspected peak is a glutathione conjugate. Figure 6.8.2 shows an example of the separation of 1-nitronaphthalene glutathione conjugates. The radiochromatogram (Fig. 6.8.2A) is from an incubation containing 1-nitronaphthalene, microsomes, NADPH-generating system, [^{3}H]glutathione, and glutathione *S*-transferases. The radiochromatogram in Figure 6.8.2C is identical except that the NADPH generating system was omitted from the incubation. Based on these profiles, peaks 1 to 7 were tentatively identified as glutathione conjugates. Later structural analysis by mass spectrometry and proton NMR spectroscopy confirmed this finding and established the regiochemistry of nucleophilic attack. In some situations, substrate-to-product turnover can be quite slow, making metabolite identification more difficult. Extending the incubation time can occasionally result in increased quantities of metabolite. The amount of metabolite per peak can be calculated using a pre-established specific activity (example: 5000 dpm/nmole) of the radiolabeled substrate. Turnover is reported as nanomoles conjugate per milligram microsomal protein (or per nanomole cytochrome P450 or milligram cytosolic protein) per minute.

As indicated earlier, the advantage of the radiometric assay over that provided in the Basic Protocol, is speed. Fifty or more samples can be processed easily in a day's time. The sensitivity of this assay will be dependent upon the specific activity of the starting substrate and on the rates of nonenzymatic reaction of the substrate with glutathione in the absence of transferase.

Spectrophotometric assays capable of monitoring glutathione conjugate formation are particularly useful for monitoring glutathione transferase activities. The use of multicell cuvette holders means that a moderate number of samples can be assessed in a single day.

Time Considerations

Measurement of glutathione conjugates by HPLC

Although the protocol for measuring glutathione conjugates by HPLC can be completed successfully in one day, it is wise to divide the steps into two to three days. The first day consists of preparing for and conducting the incubations. Depending on whether microsomes are made fresh or are from frozen specimens, this portion of the protocol can vary from 2 hr to a full day of work. Once the incubations have been quenched with methanol, they may be stored at −20°C overnight, which is a good stopping point.

On the second day, samples are prepared for HPLC, and the column is equilibrated. Long centrifugation times allow for multi-tasking. Removal of protein by centrifugation takes 30 min, and the vacuum centrifugation usually takes 3 to 4 hr. While the samples are evaporating, mobile phase should be prepared, and the column should be equilibrated.

In cases where radiolabeled substrates were used, a third day will likely be necessary. Depending upon the complexity of the samples and the corresponding length of the chromatographic runs, as few as three to four samples can be injected and counted in one day. Flow-through β detectors could simplify and speed this process, but specific activities of the starting substrate must be high as a result of generally lower sensitivity of these detectors and shorter count times. Packard Instruments offers multichannel β counters where samples are collected directly into 96-well plates containing a solid scintillant.

Radiometric assay of glutathione conjugate formation

The assay described in this protocol can be conducted in 4 to 8 hr, depending upon the number of samples. The samples can be counted overnight with results of the assay available the following morning.

Spectrophotometric assay for glutathione S-transferase

Once the enzyme preparation is available and substrates are prepared, this assay takes

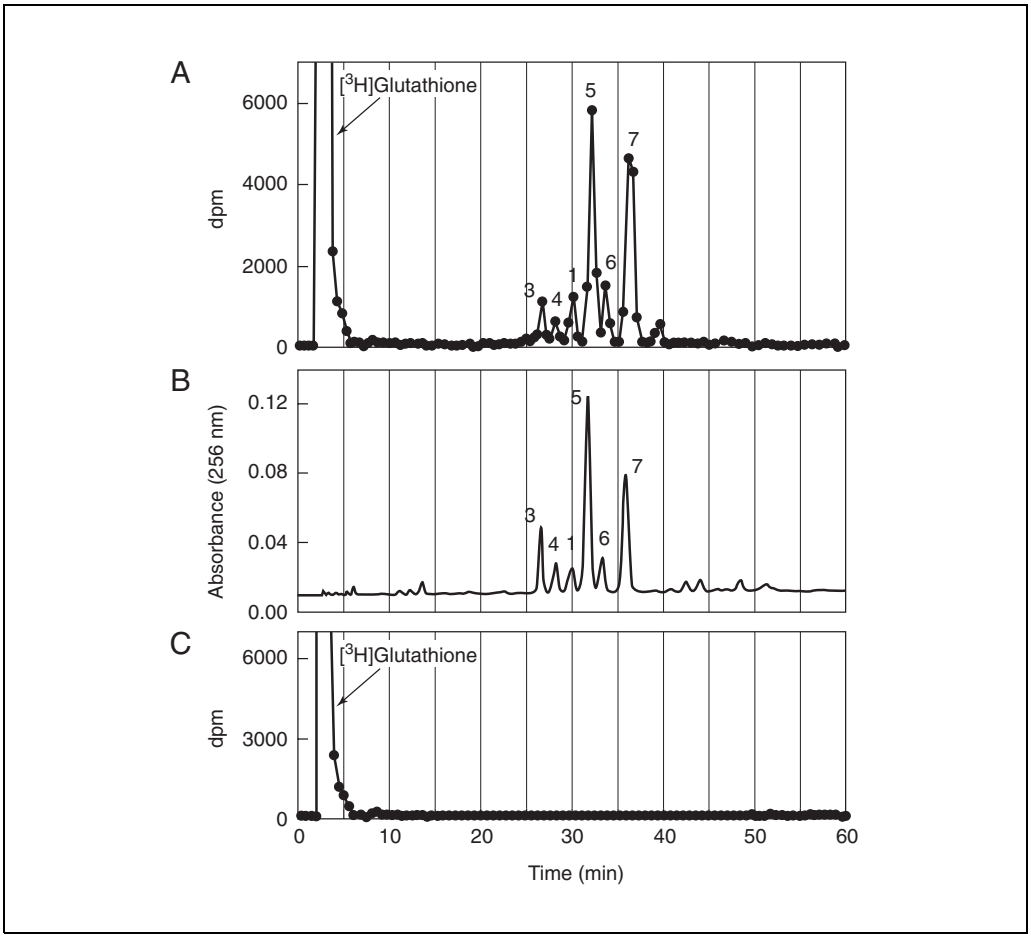

Figure 6.8.2 HPLC chromatograms showing the elution of glutathione conjugates derived from 1-nitronaphthalene. (**A**) Radiochromatogram from incubations containing [^{3}H]glutathione, 1-nitronaphthalene, microsomes, and all cofactors (Table 6.8.2). (**C**) Identical to conditions in panel A, except that the NADPH generating system was omitted from the incubations. (**B**) UV trace of conjugate elution.

<10 min for three samples and a blank. Accordingly, numerous samples can be processed in a single 4-hr period.

Microsomal incubations

Once microsomal preparations are available and all other reagents are prepared, the actual incubations to generate product can be completed in 1 to 2 hr depending upon the number of samples to be processed. Because there are multiple reagents that must be added to each vial, the authors have found that it is more time efficient to mix most of the reagents together (i.e., glutathione, transferase, NADPH regenerating solution, and buffer) and to add the variable components, such as varying concentrations of substrate or microsomes from different tissues, to the incubation separately.

Preparation of microsomal and cytosolic fractions

Preparation of microsomal and cytosolic fractions requires 4 to 6 hr from the time tissues are removed from the animal. With some degree of organization, an investigator can prepare microsomal fractions and conduct incubations during the same work day. Once the microsomal incubation is complete, samples can generally be stored at −20°C or colder for days to weeks as long as the glutathione adducts are stable in 66:34 methanol/water.

Purification of glutathione S-transferases

Cytosolic fractions prepared during the isolation of microsomal membranes can be stored at −80°C without substantial loss of enzyme activity. Gel filtration (Sephadex G-25) and glutathione affinity columns should be poured prior to the day in which the transferases are to

be affinity purified. They can be rinsed and equilibrated while the cytosolic fractions are being thawed. The two chromatographic steps (gel filtration and affinity chromatography) can be accomplished in a little more than 4 hr. Depending upon the volume of enzyme solution and the degree of concentration required, pressure dialysis requires a further 3 to 5 hrs. The preparation can be assayed and frozen in smaller aliquots for future use.

Preparative separation and isolation of glutathione conjugates for characterization by mass spectrometry and proton NMR spectroscopy

Once large incubations are completed, concentration of samples on a rotary evaporator or centrifugal concentrator can require several hours to overnight. It is advisable, unless there is information to suggest otherwise, to evaporate excess solvent (i.e., methanol/water) at room temperature. Although this adds to the time required to conduct this step, it decreases the chances that the conjugates will decompose. Column chromatography of the conjugates on SM-16 or equivalent resins requires 2 to 4 hr with further time needed for evaporation of excess solvent. Optimizing and validating the HPLC conditions for preparative chromatography can require from a few hours to several days depending upon the complexity of the separation. The time required for separation and purification of sufficient quantities of material for NMR analysis depends upon the rates at which these metabolites are generated in the incubation, whether several metabolites must be isolated, and the size of the HPLC column used. Generally, the greater the column diameter, the higher the loading capacity of the column. Further steps including neutralization of the column eluent containing the conjugates, lyophylization and repurification can take an additional several days to a few weeks.

Coenzyme A and Coenzyme A-Glutathione Mixed Disulfide Measurements by HPLC

Oxidant stresses occurring in an organism may exhibit differential expression in subcellular compartments. In many studies published to date, measurement of thiols and disulfides, most commonly glutathione (GSH) and glutathione disulfide (GSSG), have been used as biomarkers of oxidant stress status in biological models (Reed and Savage, 1995). However, assessments of oxidative status of subcellular compartments based on measurements of GSH and GSSG following isolation of subcellular fractions are problematic because of oxidation, reduction, and thiol-disulfide exchange reactions that can occur during tissue processing and isolation of subcellular fractions. Most of the current methods for sample preparation attenuate thiol redox reactions but have limitations as to either their feasibility or effectiveness in analyses of subcellular components. As one approach to circumventing these fundamental barriers, the authors of this unit have measured coenzyme A (CoASH) and coenzyme A–glutathione mixed disulfide (CoASSG) in tissue homogenates derived from tissues frozen in liquid nitrogen that have been treated with the derivatizing agent *N*-ethylmaleimide (NEM) at the time of homogenization and subsequently acidified.

The redox couple CoASH and CoASSG was chosen for analysis because CoASH is found primarily within the mitochondria (Robishaw and Neely, 1985; Tahiliani and Neely, 1987) and possesses a critical thiol group that undergoes thiol/disufilde exchange with GSH and GSSG (Gilbert, 1982). Measurements of CoASH and CoASSG levels may provide a method for assessing changes in the oxidative state within mitochondria of intact tissues. However, the important roles played by CoASH in normal cell physiology and the recent description of the potent vasoconstrictor effects of CoASSG further extend the potential implications of any changes observed in these molecular species (Schluter et al., 1995; van der Giet et al., 2001).

The following protocol describes in detail the procedures required for accurate measurement of both CoASH and CoASSG by HPLC. The method requires attention to detail, as well as the ability to adjust chromatographic conditions to optimize separation of the desired analytes from other substances encountered in specific samples.

Materials

Test animal
Liquid N_2
0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*), 4°C
1 M NEM (see recipe), 4°C
4% perchloric acid ($HClO_4$): dilute 5.1 ml concentrated (68% to 70%) $HClO_4$ to 100 ml with H_2O; prechill to 4°C at time of use
Mobile phases A, B, and C for either tertiary/quaternary or binary HPLC solvent program (see recipe)
CoAS-NEM and CoASSG standards (see recipes)

Freeze clamps: 2 × 2 × 0.5–in. aluminum blocks and stainless steel towel clamps altered to hold them (see recipe)
Mortar and pestle designed for grinding under liquid nitrogen (Fisher Scientific)
2-ml dounce homogenizer with loose and tight pestles (Wheaton; VWR)
Refrigerated centrifuge
HPLC system with UV detector (capable of measurement at 254 nm)
Precolumn filter (0.062 × 0.250-µm, 4 µm pore size; Western Analytical Inc.)
C_{18} guard column (4.6 × 125 mm, Zorbax SB; Mac-Mod Analytical, Inc.)
C_{18} analytical HPLC column (4.6 × 150 mm, Zorbax SB; Mac-Mod Analytical, Inc.)

Prepare samples

1. Remove tissue(s) from animal and "freeze-clamp" the tissue(s) as rapidly as possible, using the following technique:

   a. Cool 2 × 2 × 0.5–in. aluminum blocks by immersing in liquid N_2 until the rapid bubbling of the liquid has stopped, indicting that the blocks have reached a temperature close to that of the liquid N_2.

   b. Immediately upon removal from the animal, place the tissue on the horizontal surface within the open precooled aluminum blocks and flatten it with pressure while closing the clamp and submerge the tissue and the blocks once again into liquid N_2.

   c. After the bubbling subsides, remove the tissue from the liquid N_2 and the aluminum blocks.

   d. Break the flattened piece of frozen tissue into smaller pieces by striking it sharply with the handle of a pair of scissors or similar object.

   e. Wrap the broken tissue pieces in prelabeled aluminum foil and store at −80°C indefinitely until analysis.

2. Precool the mortar and pestle by pouring liquid N_2 into the mortar and placing the pestle in the liquid. Prepare the Dounce homogenizer by placing 0.78 ml of 0.1 M sodium phosphate buffer, pH 7.4, and 20 µl of 1 M NEM into the mortar of the homogenizer and placing the entire unit in ice.

3. At time of analysis, remove the tissue samples from the freezer and maintain them in liquid N_2 or on dry ice.

4. Accurately and quickly, weigh ~0.2 g of tissue and place in the liquid N_2–cooled mortar. Grind the tissue to a powder using the cooled pestle.

   IMPORTANT NOTE: *This must be done quickly, without allowing the tissue to thaw. Be sure to maintain enough liquid N_2 in the mortar to prevent the tissue from thawing.*

5. Carefully transfer the powdered tissue to the Dounce homogenizer and homogenize using 8 strokes with the loose pestle and 8 strokes with the tight pestle.

6. Transfer the homogenate to a centrifuge tube and add either 20 µl of concentrated $HClO_4$ or 1 ml of cold 4% $HClO_4$. Mix, then centrifuge 20 min at 12,000 × *g*, 4°C.

   To minimize sample dilution, one can add 20 µl of concentrated (~70%) $HClO_4$, but 1 ml of 4% $HClO_4$ is sufficient for protein precipitation; the additional dilution in some cases generates a chromatogram with less baseline noise. Samples can be maintained on ice after addition of $HClO_4$, and all prepared samples can be centrifuged at the same time.

7. Transfer the supernatant to a new tube and maintain at 4°C prior to analysis by HPLC.

Perform HPLC analysis

8. Place mobile phases A, B, and C (if tertiary or quaternary HPLC system is to be used) or mobile phases A and B (if binary HPLC system is to be used) in the appropriate containers on the HPLC.

9. Install an in-line precolumn filter, a C_{18} guard column, and a C_{18} analytical column in sequence on the HPLC.

   The precolumn filter removes particles that can plug a guard column or analytical column, and is much less expensive to replace. The use of a precolumn filter is especially important for analysis of tissue homogenates.

10. Program the HPLC mobile phase gradient as follows.

    a. For a tertiary or quaternary system:

6 min	equilibration inject	90% A, 0% B, 10% C
2 min	hold	90% A, 0% B, 10% C
20 min	linear gradient to:	5% A, 85% B, 10% C
10 min	clean-out	90% B, 10% C

    b. For a binary system:

6 min	equilibration inject	100% A
40 min	parabolic gradient to:	40% A, 60% B
5 min	linear gradient to:	100% B
10 min	clean-out	100% B

11. Inject CoAS-NEM and CoASSG standard into the HPLC in appropriate amount to generate a standard curve ranging from 0 to 500 pmol of CoAS-NEM and 0 to 50 pmol of CoASSG on column.

12. Inject the homogenized tissue samples (from step 7) and determine the concentrations of CoASH and CoASSG by comparing the respective peak areas of unknowns with peak areas obtained with injections of standards of known concentrations (Fig. 6.9.1).

    Use the equation $y = mx + b$ where y is the peak area, x is nmol of CoA species on the column, m is the slope of the standards curve, and b is the y intercept calculated from the standards curve.

    For example, for a peak area of 344357 mvolts:

$$y = (721431)x + (-7753.96)$$

$$x = \frac{344357 - (-7753.96)}{721431}$$

$$= 0.488 \text{ nmol CoASH on the column}$$

    Normalized to the grams of tissue injected (0.0028 g liver), this value becomes

$$\frac{0.488 \text{ nmol CoASH}}{0.0028} = 174.28 \text{ nmol/gram liver}$$

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all reagents and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CoAS-NEM standard

10 mM CoAS-NEM stock:
7.9 mg CoASH, sodium salt (Sigma-Aldrich)
980 µl 0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
20 µl 1 M NEM (see recipe)
Store in aliquots up to 1 year at −20°C

0.01 mM CoAS-NEM working standard: At time of use, dilute in 0.1 M sodium phosphate, pH 3.0 (see recipe), to yield a concentration of 0.01 mM CoAS-NEM.

Standards are more stable at pH 3.0, but the initial reaction of CoASH with NEM requires a neutral pH.

CoASSG standard

Prepare a solution of 100 nmol CoASH and 100 nmol GSH on 0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*). Add 100 nmol diamide in the same buffer, to a final volume of 1 ml. Incubate 10 min and add 1000 nmol NEM. Incubate 10 min. Add 10 µl H_3PO_4. Analyze the mixture by HPLC. Store up to 1 year at −20°C.

In the systems studied by the author, CoASSG peak precedes CoASH-NEM by 1 to 3 min. The new peak prepared by diamide oxidation coelutes with CoASSG purchased from Sigma-Aldrich. Peak areas of CoASSG are 1.1 time the eak areas observed with eqimolar amounts of CoASH-NEM, and this response factor ratio is used to CoASSG concentrations from experimentally derived standard curves for CoASH-NEM contents.

N-ethylmaleimide (NEM), 1 M

Dissolve 125.1 mg *N*-ethylmaleimide in 1 ml acetonitrile. Store in sealed container indefinitely at −20°C to prevent evaporation.

Freeze clamps

Cut two 2 × 2–in square blocks from 0.5-in sheet aluminum. Drill an 0.25-in screw hole into the center of one of the flat sides of each block. Bend towel clamps (purchased from any surgical supply company) to fit around the two blocks with the blocks resting flat against each other with the "eyes" of the towel clamps aligned with the screw hole. Place a screw through the towel clamp into the screw hole of the block to secure the clamp to the block.

HPLC mobile phases

For tertiary or quaternary HPLC solvent programming:

Mobile phase A: 25% (v/v) methanol (HPLC grade)/75% (v/v) water

Mobile phase B: 65% (v/v) methanol (HPLC grade)/35% (v/v) water

Mobile phase C: 100 mM tetrabutylammonium hydrogen sulfate (TBAS; Sigma-Aldrich)

Dissolve 34 g TBAS in 1 liter of water and adjust to pH 5.0 with NH_4OH. Filter through 4-µm filter before use.

For binary HPLC solvent programming:

Mobile phase A (10% methanol/10 mM tetrabutylammonium hydrogen sulfate): Dissolve 3.4 g of TBAS (Sigma-Aldrich) in 850 ml of water, adjust pH to 5.0 with NH_4OH, adjust volume to 900 ml with water, filter, then add 100 ml of HPLC-grade methanol.

Mobile phase B (85% methanol/10 mM tetrabutylammonium hydrogen sulfate): Dissolve 3.4 g of TBAS in 100 ml of water, adjust pH to 5.0 with NH_4OH, adjust volume to 150 ml with water, filter, then add 850 ml of HPLC-grade methanol.

Store mobile phases up to 1 month at room temperature.

If the HPLC system does not have an in-line degasser, degas the mobile phase solutions.

0.1 M sodium phosphate buffer, pH 3.0

Dissolve 1.37 g monobasic sodium phosphate in 90 ml water. Adjust the pH to 3.0 by dropwise addition of phosphoric acid.

COMMENTARY

Background Information

Assessments of oxidative stress responses within subcellular compartments of an organism have been particularly challenging. Even isolation techniques that are "really fast" require several minutes of conditions that will not prevent artifactual effects on oxidative biomarkers. Three methods commonly employed to minimize thiol redox chemistry are freezing to liquid nitrogen temperatures, alkylation of free thiol groups with electrophilic derivatizing agents, and acidification. How-

ever, important details in the use of each may be overlooked. For example, rapid freezing or "freeze-clamping" of tissues with liquid nitrogen-cooled metal blocks is superior to simply placing a piece of tissue in a plastic tube or other container and dropping the sample into liquid nitrogen. Although the same temperature is attained by both methods, the rates of cooling are substantially different. The authors have found that samples frozen initially at liquid nitrogen temperatures (−196°C) can be stored at −80°C without measurable alterations. For alkylation of thiols, *N*-ethylmaleimide (NEM) reacts significantly more rapidly than do other commonly employed reagents, such as iodoacetic acid and monobromobimane. As with freezing, the final products of derivatization are comparably effective in avoiding redox artifacts, once formed. However, greater concentrations of GSSG are observed in tissues derivatized with iodoacetic acid or monobromobimane than in tissues treated with NEM, reflecting the effects of the slower thiol alkylations by the former reagents. Although thiols and disulfides are reasonably stable under acid conditions, the authors found that processing frozen tissue samples by homogenization in acid gave significantly higher measured concentrations of CoASSG and GSSG than that observed in the same tissues derivatized with NEM prior to acidification (Table 6.9.1). In these examples of freeze-clamped tissues powdered under liquid nitrogen, the effects of acidification should be quite rapid. The results implicate reaction of oxidizing species present in tissues whose effects on GSH and CoASH, and presumably other thiols, are stimulated by acidification but can be minimized by derivatization of thiols prior to acidification.

Unfortunately, freeze-clamping of tissues is not compatible with subsequent isolation of subcellular fractions, thus presenting something of a problem for assessments of compartmental redox status in relevant biological models in vivo. To circumvent this problem, a redox-active molecule was identified in the authors' laboratory that is found primarily in the mitochondria of mammalian tissues, 75% and 95% in rat liver and heart respectively (Robishaw and Neely, 1985; Tahiliani and Neely, 1987). CoASH equilibrates with GSH and GSSG in vitro, forming and reducing, respectively, the mixed disulfide CoASSG (Gilbert, 1982). In these studies, CoASH and CoASSG levels, obtained using tissue homogenates from liquid N_2 freeze-clamped tissues derivatized with NEM and subsequently acidified as potential biomarkers of oxidative stress within the mitochondrial compartment, were investigated.

Earlier methods for measurement of CoASH described homogenizing tissues directly into 4% $HClO_4$, centrifuging the homogenates, and analyzing the supernatants. The CoASH levels in samples precipitated with $HClO_4$ alone deteriorated rapidly, and thus required homogenization of each sample just prior to analysis. The authors of this unit also measured higher concentrations of GSSG in tissue homogenate supernatants prepared with $HClO_4$ than were observed with other methods. Ansensi et al. (1994) have reported greater oxidation ex vivo with $HClO_4$ treatment than with other acids used for sample preparation.

Table 6.9.1 Effects of Sample Processing on Levels of CoASH, CoASSG, GSH, and GSSG Measured in Mouse Liver[a]

	CoASH (nmol/g liver)	CoASSG[b,c] (nmol/g liver)	GSH (μmol/g liver)	GSSG[b,c] (nmol/g)
TCA (0.6 M)	115.5 ± 10.9	7.7 ± 2.3^{I}	6.1 ± 0.8	112.4 ± 10.7^{IV}
H_3PO_4 (4%)	112.9 ± 21.0	$4.1 \pm 1.2^{I,II}$	8.8 ± 1.9	103.3 ± 9.7^{V}
NEM (pH 7.4)	125.7 ± 4.5	$1.3 \pm 0.2^{I,II,III}$	Not determined	$33.1 \pm 6.7^{IV,V,VI}$
$HClO_4$ (4%)	97.6 ± 6.6	$8.9 \pm 0.4^{II,III}$	7.3 ± 1.0	$326.4 \pm 21.1^{IV,V,VI}$

[a]Mouse livers were freeze-clamped and powdered under liquid nitrogen. The powdered liver samples were homogenized in 0.6 M trichloroacetic acid (TCA), 4% H_3PO_4 or 4% $HClO_4$; samples homogenized in 20 mM NEM were acidified by addition of 20 μl of 70% $HClO_4$. Concentrations of CoASH and CoASSG in the supernatants were measured by HPLC as described in the Basic Protocol, and GSH and GSSG were measured by the enzyme recycling method described previously by the authors of this unit (Rogers et al., 2000). Results are expressed as means ± SEM (n = 5-12 animals). Data were analyzed by one-way ANOVA with LSD post hoc.

[b]Different by one-way ANOVA, $p<0.005$.

[c]Common superscripted roman numerals indicate groups that are different by LSD.

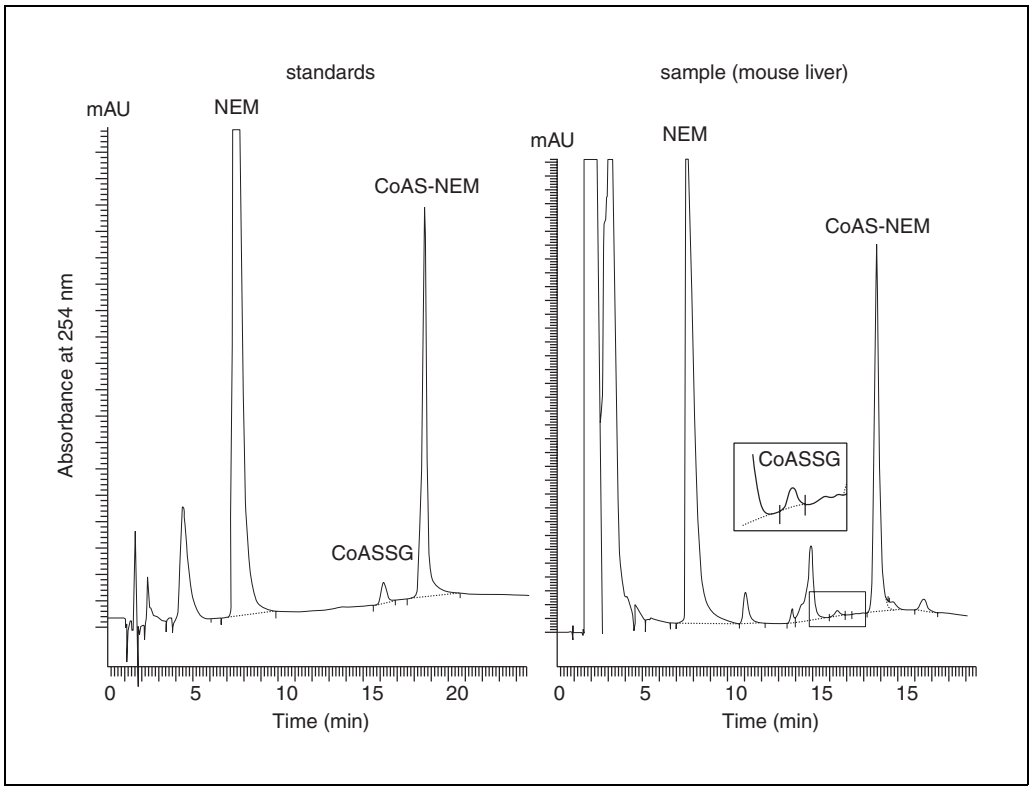

Figure 6.9.1 HPLC separation of CoASH and CoASSG. The standards injected on the column were CoAS-NEM, 1 nmol, and CoASSG, 0.1 nmol. Mouse liver tissue obtained from an animal that had been fasted 24 hr prior to sacrifice was prepared as described in the Basic Protocol, and 80 µl of the resulting supernatant were injected. The analysis was preformed on a quaternary system with UV detection at 254 nm. Analysis of the tissue sample indicated a CoASH level of 163.1 nmol/g tissue and a level of CoASSG of 0.53 nmol/g tissue.

Several acids commonly used for sample preparation and measurements of GSH, GSSG, CoASH, and CoASSG (Table 6.9.1) were therefore compared. The authors included in the analysis samples treated with the thiol derivatizing agent *N*-ethylmaleimide (NEM) and subsequently acidified with $HClO_4$. The higher levels of GSSG and CoASSG measured in acid-treated samples as compared with NEM-treated samples indicate that GSSG and CoASSG can be formed with acid treatment of samples as a product of oxidation occurring during sample preparation. NEM treatment with subsequent acidification was more effective than were any of the methods investigated that employed acidification alone for minimizing artifactual oxidation.

Methods previously developed for HPLC separation of CoASH and CoASSG have involved high-salt mobile phases that were difficult to prepare (King and Reiss, 1985), required daily preparation, and were damaging to analytical columns and the HPLC pumps. The authors chose to use a variation of the ion-pairing method described by Baker and Schooley (1981) because, using that method, it was possible to obtain good resolution of the CoAS-NEM adduct, the mobile phases were more stable, and the mobile phases were not as damaging to the to the components of the HPLC system. The HPLC analysis of the CoAS-NEM adducts also provides increased absorbance at 254 nm, due to the presence of NEM, and a sharper peak shape than that obtained for CoASH (Fig. 6.9.1). Limits of detection for CoAS-NEM of 2 pmol on column at a signal-to-noise ratio of 3:1 were observed, while the limit of detection for CoASSG was 6 pmol on column. The day-to-day coefficients of variation observed by the authors were 4.3% for CoAS-NEM and 11.2% for CoASSG.

NEM is unstable in alkaline solutions. Sacchetta et al. (1986) reported essentially complete hydrolysis of NEM in 5 min at pH 11 but <5 % hydrolysis at pH 7. The authors have not studied the effect of pH, but in the protocol described NEM is added from an anhydrous acetonitrile solution and the derivation is conducted at the physiological pH of 7.4 at which reactions of NEM with thiols is very rapid. The

samples are then acidified to precipitate proteins from the biological samples, and this helps stabilize the CoAS-NEM adduct. The CoAS-NEM adduct is sufficiently stable to allow preparation of samples and standards and injection in overnight runs, but the long-term stability has not been studied.

Critical Parameters and Troubleshooting

As noted previously, great care must be taken to minimize artifactual redox reactions during sample processing. Sample acquisition must be efficient and rapid, and sample storage must be at temperatures below −70°C. In sample preparation, the tissue must remain frozen until it is added to the NEM-containing buffer. Efficient transfer of the powdered tissue from the mortar to the buffer also requires careful attention.

The HPLC method described in the Basic Protocol is reasonably robust, requiring minimal maintenance to the equipment and relatively simple mobile phases. Problems with the HPLC separations usually lie in two areas. One is a noisy baseline. The baseline can be quieted by helium sparging the mobile phases and maintaining a back pressure on the bottles (see manufacturer for suggested pressures) and by regular changing of the precolumn filter. Changing the precolumn filter also minimizes increases in system pressure arising from multiple injections of tissue samples. The second problem with separation is interfering peaks that may obscure quantitation of the desired peak. The authors have observed differences in chromatograms arising from species, tissue, diet, or drug treatments of animals, but have found that minor adjustments in mobile-phase gradient profile usually provide the separation needed. Increasing the time course of the gradient in the portion of the solvent program that encompasses the peak of interest is usually sufficient to resolve the interfering peaks. Changing the shape of the gradient from concave to more linear or vice versa can also be employed if time sequence expansion proves not to be sufficient.

Anticipated Results

The authors have observed absolute levels of CoASH and CoASSG within a given tissue to be variable between different species or even within different strains of animals within a species. They have previously reported CoASH and CoASSG levels in the livers of ICR mice to be within the range of 101 to 130 and 0.8 to1.1 nmol/g tissue, respectively, for fed animals, and 112 to 142 and 0.9 to 1.3 nmol/g tissue, respectively, for fasted animals. Hepatic CoASH levels in these mice were decreased with acetaminophen treatment, but CoASSG levels were unchanged. In contrast, furosemide treatment caused no changes in hepatic CoASH levels, but increases were observed in CoASSG levels after 2 hr (Rogers et al., 2000). Higher levels of CoASH and CoASSG were found in control liver tissue of C57Bl/6 mice, 228 and 6.7 nmol/g tissue, respectively, and increases in concentrations of CoASSG were observed in response to 48 and 72 hours of hyperoxia exposure (Wong et al., 2001). Lung tissues were also analyzed in these animals, resulting in CoASH levels of 20.7 nmol/g tissue and CoASSG levels of 1.1 nmol/g tissue in control lungs, with levels of both analytes decreasing with time in hyperoxia. These results indicate that physiological stresses within a whole animal can cause changes in both CoASH and CoASSG levels.

Time Considerations

The HPLC analysis of CoASH and CoASSG described here is not simple, and requires a working knowledge of HPLC analyses. The amount of time required to establish or adapt this assay will depend upon the experience of the chromatographer and the particular tissues to be analyzed.

Once the system is running and optimized for the particular sample type to be analyzed, sample preparation requires only about 5 min per sample and a 30 to 45 min analysis time. Several samples can be prepared at a given time and stored at room temperature overnight, as in an unrefrigerated autoinjector, or at 4°C for up to 48 hr prior to analysis.

CHAPTER 7
Assessment of the Activity of Antioxidant Enzymes

INTRODUCTION

The use of molecular oxygen to sustain life has as a metabolic byproduct the formation of superoxide and hydrogen peroxide. Glutathione (GSH)–dependent metabolism of hydrogen peroxide via GSH-dependent peroxidases is a vital process to prevent oxidative stress. These antioxidant enzymes in conjunction with glutathione reductase comprise the glutathione redox cycle (Reed, 1985, 1986). In conjunction with the superoxide dismutases, this cycle serves an essential role in limiting the production of hydroxyl radical and other reactive oxygen species that can cause indiscriminate damage to cellular constituents. As a substrate of several isoenzymes of glutathione peroxidases (*UNIT 7.1*), GSH is also used to limit the same oxidative events induced by organic hydroperoxides, including fatty acid hydroperoxides.

Methods for analyzing a variety of GSH-related enzymes are presented in *UNIT 7.1*. Glutathione peroxidase activity is measured using one of several hydroperoxide substrates, including the commercially available cumene hydroperoxide. Procedures are also given for the synthesis of phosphatidylcholine hydroperoxide to allow the measurement of GPX4 (PHGPX). Since some glutathione peroxidase activity is accompanied by glutathione transferase activity, dual assays are also included, as are chromatographic separation and immunoprecipitation techniques and assays of different isoenzymes.

Glutathione reductase is very specific for the reduction of GSSG to GSH through the use of NADPH reducing equivalents (Carlberg and Mannervik, 1975). This feature of the enzyme allows the continuous spectrophotometric assay of glutathione reductase activity (*UNIT 7.2).*

Two molecules of superoxide, the one-electron reduction product of molecular oxygen, will undergo spontaneous dismutation to yield hydrogen peroxide. This reaction is slow, however, compared to the same reaction catalyzed by superoxide dismutase (SOD) activity (Fridovich, 1995). Superoxide dismutases containing Cu and Zn (Cu,Zn-SODs) are found in both the cytoplasm and in extracellular fluids, whereas Mn-SOD is found in the mitochondrial matrix. Reduction of cytochrome *c* by superoxide produced by xanthine/xanthine oxidase forms the basis for the assay of total SOD activity presented in *UNIT 7.3*. Methods for determining the relative contributions of Cu,Zn-SOD and Mn-SOD to the total SOD activity in cell extracts are also described.

UNIT 7.5 contains protocols that permit the measurement of activity of SOD enzymes; in this case using a number of indirect competitive inhibition assays. The activities of the copper/zinc containing enzymes can be distinguished from the MnSOD activity in mammalian tissue homogenates using the differential sensitivity of these enzymes to inhibition by cyanide. In addition, a modified protocol is described in which the metal chelator, bathocuproinedisulfonic acid (BCS) is used to inhibit electron transport chain-associated interference in the assay. These assays (*UNIT 7.5*) utilize a xanthine oxidase system to generate superoxide and spectrophotomeric detection based on the reduction of nitroblue tetrazolium (NBT) which competes with SOD activity for superoxide.

Current Protocols in Toxicology (2002) 7.0.1-7.0.2

Cellular thiol and redox status is important for the structure and function of hundreds of thiol-containing enzymes. In addition, reducing equivalents are necessary for biosynthetic pathways, regulation of oxidative stress, and protection against oxidative damage. The ubiquitous thioredoxin system, thioredoxin (Trx) and thioredoxin reductase (TrxR), has a major role in these processes in bacterial, plant, and mammalian organisms. A hallmark of Trx, a redox-active protein, is the capacity to reduce protein disulfides. *UNIT 7.4* describes a method to measure purified Trx or TrxR by a spectrophotometric insulin-reduction assay. An alternative for biological samples is an end-point insulin-reduction assay. Mammalian-type Trx can be measured with NADPH as a direct reductant in the absence of TrxR. This assay is a coupled assay in that reduced Trx drives the reduction of Ellman's reagent, DTNB [5,5′-dithio-bis(2-nitrobenzoic acid)] to TNB (5-thio-2-nitrobenzoic acid), which is measured spectrophotometrically at 412 nm. A third protocol uses the reducing power of DTT to drive the reduction of Trx in the absence of TrxR; this reaction is ~1000-fold faster than the reduction of insulin by DTT. The reduction of insulin by Trx is another 100-fold faster than DTT reduction of insulin. Therefore, it is possible to measure the reducing capacity of Trx by a Trx-catalyzed reduction with DTT providing the reducing equivalents to Trx but not at a significant rate to insulin.

Ascorbic acid is a major water-soluble antioxidant in the cell cytoplasm and has an important role in the maintenance of redox homeostasis. Due to the power of ascorbic acid to be a reducing agent, the ease of its oxidation is always of concern during the preparation, handling, and assay of biological samples for accurate measurement of ascorbic acid and dehydroascorbic acid. *UNIT 7.6* focuses on the measurement of ascorbic acid, dehydroascorbic acid, isoascorbic acid, dehydroisoascorbic acid, and uric acid in biological samples. In addition, this unit describes the utilization of HPLC with electrochemical detection along with potential pitfalls in the analysis of these labile compounds. Protocols for the preparation of plasma, isolated-cell, and tissue samples are given in detail. A passivation procedure for the HPLC system (Support Protocol 4) is described to assist in lowering the detector background. Support Protocol 4 provides the procedures for the use of endogenous and internal standards in data analysis.

Analysis of Glutathione-Related Enzymes

This unit describes a basic spectrophotometric glutathione peroxidase (GPX) activity assay applicable to nearly any type of sample (see Basic Protocol). Variations of the Basic Protocol provide means to detect members of three gene family products with glutathione peroxidase activity, either as a collective activity or as subsets. Alternate protocols are described that can be used in conjunction with basic assay protocols to further distinguish among the six to seven major glutathione peroxidase isoenzymes (see Alternate Protocols 1 to 7). Support protocols for the preparation of substrates used in the basic variations are supplied (see Support Protocols 1 and 2) along with a support protocol for calculating specific activity (see Support Protocol 3). Short-cut methods are provided where multiple types of glutathione peroxidase activities are to be assayed. Novel reagents are discussed that can be used as an adjunct to the alternate protocols in difficult projects, and an alternate protocol is briefly described that permits the exploration of different reducing substrates (see Alternate Protocol 8). Critical issues of cell culture nutrition, sample preparation, and sample storage that need to be considered in advance of projects are discussed in the Commentary, which also provides an overview of HPLC and thin-layer chromatography systems that could be used to assay glutathione peroxidases.

STRATEGIC PLANNING

Glutathione peroxidase (GPX) is the name given to activities that catalyze the following reaction:

$$ROOH + 2GSH \rightarrow ROH + GSSG + H_2O$$

R can be hydrogen, a free fatty acyl group, cholesterol, a steroid, an ester of one of these groups, or free bases of DNA or RNA. GSH is the thiol tripeptide γ-glutamyl cysteinyl glycine, known as (reduced) glutathione and GSSG is the oxidized form of glutathione. Protein products of two unrelated gene families have glutathione peroxidase activity—the seleno-(Se)GPXs and the glutathione transferases (GSTs). A recently described non-GST, Se-independent GPX (antioxidant protein 2 or Aop2; Phelan et al., 1998), found in the ciliary body of the eye, in the olfactory epithelium, and in the skin, heart, liver, and kidney, may really be a thioredoxin peroxidase (see Background Information). However, conclusive evidence that this protein does not have glutathione peroxidase activity has not been provided. Expression of the genes for these proteins is quite variable among animal species, tissues, and derived cell lines. In the literature, glutathione peroxidase activity can refer either to the activity of a single protein (GPX1 in solid tissues or GPX3 in plasma) or to different collections of activities (GPX1, GPX2, GSTs, and GPX4) depending on the species of animal, the tissues or derived cell lines sampled, the assay conditions, and the inclination of authors. The use of different assay conditions can be fairly exclusive or inclusive as to the type of activities detected. Selective assay conditions used with unfractionated samples, or, combined with the use of sizing columns or other one-step separation methods, can be used to effectively report on individual components in many of the combinations of glutathione peroxidase proteins that are produced in tissues. The main strategic questions are as follows.

1. What should be assayed?
2. Is use of the Basic Protocol or Alternate Protocols 1 to 3 adequate to assay the glutathione peroxidase of interest, or will Alternate Protocols 4 to 7 need to be used?
3. Are there any special nutritional requirements for cultured cells to be sure that the activities will be produced?

Contributed by R.S. Esworthy, F.-F. Chu, and J.H. Doroshow

Current Protocols in Toxicology (1999) 7.1.1-7.1.32

4. Are there any special requirements for sample processing?

The successful detection of glutathione peroxidase activities in many cell lines depends on conditions established long before cell line harvesting, and, for both cell line and tissue samples, success can be dependent on the application of particular care during processing. If the study of glutathione peroxidases is new for the investigator or if the tissues or cell lines are novel and not well characterized, see Commentary for a discussion of these points.

A Basic Protocol is presented that is fairly exclusive for the assay of the major SeGPX in most solid tissues, GPX1. GPX1 is the major cytosolic and mitochondrial GPX activity. Exclusiveness of the assay is based on the use of hydrogen peroxide as substrate and on the broad distribution of GPX1 as opposed to the more limited distribution of other hydrogen peroxide–reducing isoenzymes. For cases where GPX2, GPX3, or Aop2 will be detected, see Background Information. Seven alternatives to the Basic Protocol are presented. Alternate Protocols 1 and 3 are more inclusive glutathione peroxidase assays that will detect GSTs with glutathione peroxidase activity, as well as GPX1-3. Alternate Protocol 2 is fairly exclusive for the assay of GPX4, also called phospholipid hydroperoxide GPX (PHGPX). Under some circumstances, this latter assay method can be used to detect microsomal GST with glutathione peroxidase activity, as well as a novel protein from the retina.

Protocols are presented that are useful in advance of the assays to enrich for particular glutathione peroxidase activities so that even inclusive assays (Alternate Protocols 1 and 3) can be used to determine levels of selected components. This type of strategy may be used when it is not clear which type of glutathione peroxidase activity is central to the question being asked. Animal and cell line resources that can be used to simplify the detection of subsets of the glutathione peroxidase families or used to confirm novel observations are also briefly discussed in Background Information.

Identification of the pertinent GPX activities in a toxicological study may require more thorough characterization of the sample(s) than is possible with the Basic Protocol and Alternate Protocols 1 to 3. Too often, studies of minor tissues and the GI tract are based on the false premise that the only GPX activities are from GPX1 or GSTs—or indiscriminately lump GPX1 and GST activities together. Investigations on less well characterized materials and animal species should begin with methods that could identify other isoenzymes (e.g., Alternate Protocols 4 to 7), before the decision is made that the Basic Protocol or Alternate Protocols 1 to 3 are sufficient for the purpose of the study.

Neither the Basic Protocol nor the first seven Alternate Protocols will permit the testing of alternative reducing substrates. An assay method is discussed (see Alternate Protocol 8) that can be used to examine different reducing substrates in purified samples.

BASIC PROTOCOL

MEASUREMENT OF GLUTATHIONE PEROXIDASE ACTIVITY

This protocol can be used to assay for SeGPXs 1 to 3 and Aop2. The isoenzyme subsets detected in crude samples will depend on the tissues or cell lines assayed (see appropriate Support Protocols and see Background Information). The protocol below is the method of Paglia and Valentine (1967) as modified by Lawrence and Burk (1976).

For the assay, a small volume of a clarified sample is mixed with assay buffer, as well as solutions containing GSH, NADPH, and glutathione reductase, in a cuvette rated for near-UV use. The mixture is allowed to equilibrate for 5 to 10 min. Hydrogen peroxide is then added to the mixture to begin the assay. The decline in the absorbance at 340 nm monitors the consumption of NADPH in the following reaction, which is catalyzed by glutathione reductase:

$$H^+ + GSSG + NADPH \rightarrow 2GSH + NADP^+$$

This reaction is driven by the formation of GSSG, coupling the glutathione peroxidase reaction to the change in absorbance monitored in the assay.

The coupled assay is quite adaptable. Many hydroperoxide substrates and detergents, as well as a range of pHs, different buffers, and ionic strengths can be used with this type of assay. This allows the study of the many proteins with glutathione peroxidase activity, some of which require hydroperoxide substrates other than hydrogen peroxide and conditions different from those in the Basic Protocol assay. Alternate Protocols 1 to 3 will substantially expand the repertoire of any laboratory studying glutathione peroxidases. However, there may be projects in which recourse to Alternate Protocols 4 to 8 will be needed.

Materials

Samples for analysis of glutathione peroxidase (GPX) activity
GPX-positive control (for first-time investigations; see recipe)
10 mM GSH (freshly prepared; see recipe)
2 mM β-NADPH (freshly prepared; see recipe)
5 mM H_2O_2 (see recipe)
100 U/ml glutathione reductase (see recipe)
Assay buffer: 50 mM sodium phosphate, pH 7.0 (*APPENDIX 2A*)
1.125 M sodium azide (see recipe)

Recording spectrophotometer with lamp and filters for 340-nm operation
1-ml near-uv-rated plastic cuvettes with 1-cm path (the assay can be easily scaled to smaller or larger volumes, if desired)

1. Warm up the spectrophotometer lamp.
2. Begin defrosting samples, GPX standards, if frozen, and GPX-positive controls (for first-time investigations), keeping all of these materials on ice. Assemble pipets, pipet tips, and samples at the assay site.

   Positive controls are required only for the total novice and only for the first few times that assays are performed or for troubleshooting purposes. After a few experiences with the assay, the positive control can be dispensed with unless the assay conditions are substantially altered for some purpose.

   The positive control should be prepared as a series of four or or five 1:1 serial dilutions. Do all dilutions in homogenization buffer. If the study samples are novel for the investigator, then this time can also be used to prepare dilutions. Three 1:5 serial dilutions of samples are a good starting point.

3. Prepare the 10 mM GSH, 2 mM NADPH, 5 mM H_2O_2, and 100 U/ml glutathione reductase according to their recipes (see Reagents and Solutions).

   If the GSH and NADPH have been properly handled to this point, they may be combined into a single solution for use.

4. For a 1-ml assay, add the following to a 1-ml cuvette in the order indicated:

   0.63 ml assay buffer (50 mM sodium phosphate, pH 7.0)
   0.1 ml 10 mM GSH
   0.1 ml 2 mM NADPH
   0.01 ml 1.125 M sodium azide
   0.01 ml 100 U/ml glutathione reductase.

   Add the sample in ≤0.1 ml. Add balance (to 0.1 ml) of the homogenization buffer used to process the sample (see Critical Parameters, Sample Isolation and Processing), if the sample volume is less than 0.1 ml. Mix the contents of the cuvette well and allow to equilibrate 5 to 10 min.

Blank assays should be performed first, followed by GPX positive controls, if used. To save time, up to four samples can be equilibrated at once. It is practical to perform four assays at one time on a multisampler-equipped spectrophotometer. Delays between adding substrate and recording results make it a bad practice to set up more than four assays at a time. Sample equilibration can be done in the spectrophotometer.

The assay set should begin with a blank assay containing homogenization buffer (0.1 ml) or in the case of blood plasma, phosphate buffered saline, in place of the sample in the above reaction mix. The blank is essential since hydrogen peroxide and GSH react spontaneously at a slow rate. The blank assay data will be used in the calculation of specific activity (see Support Protocol 1) at 340 nm. All assays including the blanks should be performed in duplicate. Triplicate assays are generally required only if the occasional discrepency shows up between duplicate assays.

5. Set up the spectrophotometer to give a full-scale span of 0.5 absorbance units (or other setting as determined by optimization) at 340 nm.

   The setting will depend on the actual amount of NADPH in the assay, the noise level in the recording, the types of samples, and the type of spectrophotometer. Experience will be needed to optimize the settings. Be sure to make a note of the settings so that calculations can be performed later. The assays will be run for 1 to 5 min to get data for rate determinations. Adjust the speed setting on a chart or the maximum interval for a program, accordingly. The blank(s) should run for 5 min, since it will be the slowest sample.

6. Make sure the blank is registering on the chart (if a chart recorder is used) at the higher end of the absorbance range.

   The assay follows the consumption of the absorbing species, so that the absorbance will decline as the assay proceeds. After mixing, the blank (minus H_2O_2) absorbance should be stable. If it is not, this may mean that the mixing was incomplete or that the temperature of the mixture is still equilibrating.

7. Start the chart, then add 50 µl of 5 mM H_2O_2 to the blank sample (total volume in cuvette 1 ml). Mix the sample quickly and thoroughly. Start recording the change in absorbance.

   At a setting of 0.5 absorbance full scale the blank will proceed at a rate of ~$^5/_{100}$ divisions per min (0.025 A_{340}/min). Concern is warranted only if this rate is zero or >$^{15}/_{100}$ divisions per min (0.07 A_{340}/min). However, consistency in the blank rate is expected from day to day. If this is not happening then something is wrong with the reagents or techniques.

8. Using the same procedure as for the blank (step 7), assay a dilution series of the positive control, processing the reactions one at a time.

   The purpose of the dilution series of the positive control is to test the assay mix and to establish the upper limit for the linear response of the assay. This assay will handle ~0 to 25 mU of activity (1 U = 1 µmol/min of NADPH consumed). This would correspond approximately to a rate of $^{35}/_{100}$ division/min (0.17 A_{340}/min). The dilution series of the positive control will establish that all of the reagents are good and will indicate the maximum acceptable rate that falls in the linear range (i.e., two-fold increase in sample amount produces a two-fold increase in rate after adjustment for the blank rate). After the positive control has been tested a few times, it can be dispensed with. The study samples should be well characterized by this point and they can be used for this purpose.

9. Pause at this point to determine the blank rate and maximum acceptable rate.

   During the study assays, be alert for samples whose rates approach or exceed the allowed maximum rate or are close to the blank rate. Data derived from such assays may be of limited value. Such assays may be terminated early and redone with appropriate sample amounts.

10. Using the reaction volumes described in steps 4 and 7, proceed to the assay of the study samples.

    If this is the first assay of samples, monitor the assay during equilibration to see if there is a spontaneous downward drift. If the activity of the samples is low, this small drift may have to be subtracted from the assay rate, in addition to the blank rate, to obtain accurate activity calculations. This practice may have to be continued if it is expected that activities will be low for the balance of the project(s).

    If a break is required, make sure that all of the samples and the diluted glutathione reductase are maintained at ice temperatures. After a prolonged break, the blank should be performed again. If the current blank rate is less than the initial blank rate, it may be necessary to prepare new GSH and NADPH. The blank rate is determined again with the fresh reagents.

11. Calculate the activity of the samples (see Support Protocol 3).

ASSAY OF GSTs WITH GPX ACTIVITY AND SeGPX WITH CUMENE HYDROPEROXIDE

ALTERNATE PROTOCOL 1

GPX1 and GSTs with glutathione peroxidase activity are collectively assayed using the conditions originally established by Lawrence and Burk (1976). Results collected with this assay are of little value by themselves, since too many activities are detected. It is best to combine this assay with results from the Basic Protocol (see "short-cut" method, Alternate Protocol 4) or to use this assay in conjunction with methods that can resolve SeGPX and GST activities (Alternate Protocol 6). GPX4 will not contribute significantly to the total activity measured in this protocol. It is impractical to use this variation for GPX4 and far from optimal to use it for Aop2, even with fractionation of the samples. Alternate Protocol 3 is better suited for detection of these activities.

Additional Materials *(also see Basic Protocol)*

30 mM cumene hydroperoxide (see recipe)

1. Set up spectrophotometer and reaction mixes (see Basic Protocol, step 1 to 4).

   A new blank rate must be established for this assay. Positive controls described for the Basic Protocol (see Reagents and Solutions) will work for this alternate protocol.

2. At step 7, add 50 µl of 30 mM cumene hydroperoxide, for a final 1.5-mM concentration, instead of hydrogen peroxide.

3. Peform the assays and calculate the activities (see Basic Protocol, steps 7 to 11).

ASSAY OF GPX4 (PHGPX) WITH PHOSPHATIDYL CHOLINE HYDROPEROXIDE

ALTERNATE PROTOCOL 2

GPX4 can be specifically assayed with several minor reagent modifications and a major change in the type of hydroperoxide substrate (Zhang et al., 1989; Maiorino et al., 1990). If one has a working familiarity with the Basic Protocol, the GPX4 assay will not be difficult to run. Triton X-100 (peroxide-free; Sigma, Aldrich, Boehringer Mannheim) is added from a separate stock so that the final concentration in the assay is 0.1% to 0.2% (v/v). It is essential that Triton X-100 be in the assay when GPX4 activity measurements are made. Cholate-based detergents cannot be used in the tissue preparation or in the assay, since they will denature GPX4. The pH of the assay buffer should be 7.3 to 7.6 to obtain the sensitivity needed for the assay. This will require a different buffer. A standard version of the GPX4 assay method uses a buffer of very high concentration, so that smaller volumes can be used in the assay (0.4 M Tris·Cl). Much more sample can then be used without upsetting the assay pH. This may be required for some samples (even as 20% homogenates), due to the paucity of GPX4 activity in many animal tissues and cell lines.

Tissue levels of GPX4 tend to be 0.2% to 20% of GPX1 levels (Zhang et al., 1989). Testis is an exception where the level of GPX4 exceeds that of GPX1 (Roveri et al., 1992). Dilution of samples should not be performed until an initial survey of the GPX4 levels, performed on the undiluted samples, shows that this can be done.

The most widely used differential substrate is the hydroperoxide species (PLOOH) obtained from the action of soybean lipoxygenase on phosphatidyl choline in the presence of deoxycholate (see Support Protocol 1). PLOOH can be synthesized and enriched to usable form by most laboratories. This substrate is used at 20 to 30 μM concentrations in the assay (see Support Protocol 1, step 8). This assay was developed by Zhang et al. (1989) and modified by Maorino et al. (1990).

The equipment used is the same as that used in the Basic Protocol, except that 3- to 4-ml cuvettes are used to accommodate the 2.5-ml assay volume. This is flexible, as the assay can be scaled down to 1 ml. Mixing requirements may preclude the use of <1-ml volumes.

Materials

Assay mix for GPX4 (see recipe)
100 U/μl glutathione reductase (see recipe) in ice-cold 0.4 M Tris·Cl, pH 7.4
10% (v/v) peroxide-free Triton X-100 (Sigma, Aldrich, Boehringer Mannheim) in H_2O (keep on ice)
Phosphatidyl hydroperoxide (PLOOH) substrate in methanol (see Support Protocol 1; concentration such that the substrate can be added to a final concentration of 20 to 30 μM in the assay mix by adding a 20- to 25-μl aliquot of the methanol solution)
GPX4 positive control (see recipe)
Negative control: GPX1 standard free of GPX4 (optional, but advisable for the novice; see recipe)
3- to 4-ml near-UV-rated plastic cuvettes with 1-cm path for spectrophotometer

1. Add the following to a 3- to 4-ml cuvette:

   0.5 ml assay mix for GPX4
   10 μl 100 U/μl glutathione reductase
   30 to 60 μl 10% peroxide-free Triton X-100 (final concentration 0.1% to 0.2% v/v)

   then add water to adjust the volume to 2.48 ml, less the sample volume.

   Sample volumes up to 0.5 ml are routine in this assay. The constraining factors are the possible alteration in pH and GSH concentration with the addition of sample.

   Buffer should be prepared in advance. Sodium azide can be included at a concentration of 10 mM; in that case the buffer can be used in the Basic Protocol—i.e., GPX1 can be assayed in this buffer as well.

2. Add up to 0.5 ml of the sample, positive control, or negative control, mix thoroughly, and allow an extended (e.g., 15-min) equilibration period.

   The blank for this should be homogenization buffer used for the samples (see Critical Parameters, Sample Isolation and Processing).

   Most samples probably will not require dilution. A positive control sample of rodent testis may be diluted 1:1 or 1:5 in homogenization buffer before use.

3. Carry out the assay (see Basic Protocol, steps 5 to 11), with the following variations.

   a. Set the full-scale span of the spectrophotometer at 0.2 A_{340} for chart recorders.

b. Monitor the assay equilibration phase after the sample is added since there is often a small, continuous downward drift that may be slow to cease.

This may have to be tolerated for the sake of throughput with a sample set of any size and factored into the calculations as a second rate, subtracted after the blank rate.

c. Measure the A_{340} of blanks and samples for several minutes (up to tens of minutes in some cases) to obtain good rate data because the signal-to-noise ratio is less than what is seen in the Basic Protocol.

The recommended positive control will be deceiving in this regard; it will have activity much greater than most other samples. Therefore, it is very important not to adjust the recommended parameters for the assay of samples based on the performance of a rodent testes control sample. A 1.5 to 2 A_{340} full-scale setting is used only with the positive control to determine the substrate concentration (see Support Protocol 1). However, this is the only occasion for a compressed full-scale setting.

4. Start the assay by adding 20 to 25 µl of phosphatidyl choline hydroperoxide (for a 20 to 30 µM concentration in the cuvette) and quickly but completely mixing the cuvette contents.

The PLOOH can be made while the reagents are equilibrating to room temperature or made in advance (see Support Protocol 2). An aliquot sufficient to assay the samples can be kept on ice while the balance is returned to −70°C storage.

The substrate could be hydrogen peroxide or a free fatty acid hydroperoxide (Alternate Protocol 3) rather than PLOOH. Triton X-100 would be omitted in these cases. The range of glutathione peroxidase activities detected is thereby altered, and the assay is no longer specific for GPX4. For strip-chart recorder setup, the absorbance setting and chart speeds would have to be adjusted to those used for Basic Protocol or Alternate Protocol 1.

Specific activities obtained for major organ samples with this assay will be in the range of 5 to 20 mU/mg protein. By comparison, GPX1 major organ specific activities with these conditions (with hydrogen peroxide as the substrate) are in the range of hundreds to thousands of mU/mg (Zhang et al., 1989). For the testis control, the GPX4 specific activity will be 40 to 100 mU/mg, depending on species, buffers used for extraction, and the vigor of the tissue disruption method (Esworthy et al., 1997; Roveri et al., 1992).

Interference from microsomal GST seems to be negligible (Mosialou and Morgenstern, 1989). This may be due to the requirement of microsomal GST for activation with potent thiols, the small quantities present in most sources, the microsomal localization, or the lability of this enzyme. In some eye tissues, an activity other than GPX4 or microsomal GST is detected (Lam et al., 1993). The origin of this activity is a protein with physical properties unlike any known glutathione peroxidase.

SYNTHESIS OF PHOSPHATIDYL CHOLINE HYDROPEROXIDE (PLOOH) FOR THE ASSAY OF PHGPX

SUPPORT PROTOCOL 1

The substrate derived from this method can be used to assay very specifically for GPX4, with minor exceptions (Lam et al., 1993; also see Alternate Protocol 2). GPX1-3 and most GSTs have only marginal activity with the PLOOH substrate (Maiorino et al., 1990). The substrate is used at a concentration of 20 to 30 µM. A simple and fast method (1 hr) for making the substrate was published in by Maiorino et al. (1990). The yield of substrate from the published method is sufficient for up to 50 assays.

Materials

Phosphatidyl choline (PL; Avanti Polar Lipids, Sigma, or Aldrich)
Source of nitrogen gas
0.2 M sodium borate, pH 9 (or other buffer for pH 9 to 10 range)
0.05 M sodium deoxycholate

Soybean lipoxygenase (Sigma Type IV or equivalent)
Absolute methanol
GPX4 positive control sample (see recipe)
1-ml Sep-Pak C18 cartridge column, or equivalent

Additional reagents and equipment for assaying GPX4 (see Alternate Protocol 2)

1. Dry a solution of phosphatidyl choline (PL) under nitrogen in a 50-ml beaker.

   The amount of PL stock used should yield a 0.3 mM solution in 18 to 19 ml (see step 2).

2. Resuspend the dry PL, with stirring in 18 to 19 ml 0.2 M sodium borate, pH 9, for a final concentration of 0.3 mM.

3. Add 0.05 M sodium deoxycholate stock to a final concentration of 5 mM in a volume of 20 ml. Sonicate or vigorously stir to properly dissolve the PL and to aerate the mix.

4. Add 100,000 U soybean lipoxygenase. Stir mixture 20 min to allow oxidation of the PL to PLOOH.

5. During this time, prepare a 1-ml C18 column by washing with 20 to 30 ml water, 20 to 30 ml absolute methanol, and again with 20 to 30 ml water.

6. Taking care to observe the column manufacturer's precautions about maximum flow rates, rapidly pass the oxidized PL over the column. Wash the column with 30 ml water.

   The goal of this step is to remove the sodium deoxycholate. If not removed, the detergent will interfere with the assay.

7. Slowly elute the PLOOH from the column with ~3 ml absolute methanol.

   The substrate may be ready to use at this point. However after an initial titration of the substrate (step 8), it may be found that it should be concentrated. This can be performed under a stream of nitrogen. The final eluate will probably have some water. This will limit the stability of the substrate even with careful storage (−70°C, under nitrogen). Two weeks is the longest time that the authors have been able to store a preparation.

8. Estimate the yield of the substrate by permitting a reaction with a GPX4 control sample to exhaust the hydroperoxide substrate (see Alternate Protocol 2).

   It may be necessary to run the assay reaction with GPX1 and hydrogen peroxide, or other GPX1 substrate, to determine the total OD units of NADPH that are in the assay mixture. Then, the GPX4 substrate is added to a series of positive control assays at lower and lower amounts until it is possible to see the assay running to completion well before the NADPH supply is used up. Using the millimolar extinction coefficient of 6.22 for NADPH, it is possible to calculate the amount of substrate in the reaction.

   In this case, the total OD change from the time of the addition of substrate until the substrate is consumed is divided by 6.22×10^3 OD units/mol. This value is again divided by 1000 to yield the moles of substrate in the aliquot used in the titration. Also see Support Protocol 3, step 4.

   The substrate should not drive an assay that has GPX1 and no GPX4. See Reagents and Solutions for preparation of GPX4-positive controls and GPX1 standard.

ALTERNATE PROTOCOL 3

INCLUSIVE GPX ASSAY WITH UNIVERSAL SUBSTRATES

A more inclusive version of the assay method than that described in Alternate Protocol 1 is possible with hydroperoxides of linoleic acid or arachidonic acid (Maiorino et al., 1990; Hong et al., 1989). Results collected from this alternate protocol will have little interpretative value on crude samples. It is best applied in projects where glutathione peroxidases

are resolved by some means. At a concentration of 50 μM fatty acid hydroperoxide, almost any glutathione peroxidase activity can be detected. Expense, skill at synthesis and purification, and lability of the substrates are the main barriers to the routine use of these substrates at high concentrations. The hydroperoxides are commercially available or they can be synthesized. HPLC is very useful for substrate purification following synthesis. However, it is not essential with linoleic acid hydroperoxides (see Support Protocol 2).

The assay with these substrates is best performed using the conditions described in Alternate Protocol 2, where the increased GSH concentration and higher pH of the assay buffer increase the sensitivity enough to detect GPX4 activity. However, Triton X-100 is left out of the assay when free fatty acid hydroperoxides are the substrates. Even in this variation, GPX4 may contribute little to the total activity. The assay will register activity in fractions where GPX4 has been resolved from GPX1 and GSTs. Ultimately, the quantitation of GPX4 is dependent on fractionation of the sample and/or the use of Alternate Protocol 2.

Perform Alternate Protocol 2 as described, except omit Triton X-100 from the assay and substitute linoleic acid hydroperoxide (50 μM) for phosphotidylcholine hydroperoxide in step 4 of that protocol. See Support Protocol 2 for synthesis of linoleic acid hydroperoxide. Perform a blank reaction with the linoleic acid hydroperoxide and use a sample with GPX activity as a positive control.

SYNTHESIS AND ISOLATION OF LINOLEIC ACID HYDROPEROXIDE FOR THE ASSAY OF GPX

SUPPORT PROTOCOL 2

Linoleic and arachidonic acid hydroperoxides can be purchased from Cayman Chemical. Both can be synthesized using the free fatty acids and lipoxygenases or by oxidation in air (Forman and Kim, 1989). Purification of linoleic acid hydroperoxides can be performed with or without HPLC. The authors have used the non-HPLC method of Forman and Kim (1989), described below, with good results. However, verification of the purity of the substrates is best done with HPLC or thin-layer chromatography methods. For the isolation method described here, a large fume hood is required for the many solvent extractions. A rotary evaporation device is useful, but may be replaced with a nitrogen or argon gas flow. A full H-type gas cylinder may be needed if a rotary evaporation device is not available.

Additional Materials *(also see Support Protocol 1)*

Linoleic acid (Cayman Chemical)
0.5 M sodium borate, pH 9
Petroleum ether
Ethyl acetate
70:40:1 acetonitrile/H_2O/acetic acid

Rotary evaporator or full H-type nitrogen or argon cylinder
Compressed air or oxygen tank to facilitate oxygenation of substrate
3-ml and 1-ml Sep-Pak C18 cartridge columns, or equivalent
Separatory funnels or other glassware for extractions

1. Remove solvent from the linoleic acid, if any is present, by blowing a stream of nitrogen or argon over the sample.

   Good yield is achieved by starting with 0.2 to 0.4 ml linoleic acid.

2. Resuspend linoleic acid in 50 ml of 0.5 M sodium borate, pH 9.0, using a magnetic stirrer. Aerate solution with air or pure oxygen.

3. Peroxidize the linoleic acid by adding eight aliquots of soybean lipoxygenase containing 125,000 U each, from a stock of 1,000,000 U, over a 2-hr period.
4. During this time, prepare three 3-ml C18 columns by washing with 20 ml water, 20 ml absolute ethanol, and again with 20 ml water.
5. Load one-third of the sample onto each C18 column.
6. Elute the lipid using ~8 ml methanol per column. Pool the eluate and bring to dryness under a stream of nitrogen.
7. Resuspend the lipid in 20 to 40 ml petroleum ether.
8. Extract the suspension in an equal volume of 3:1 methanol:water, then repeat with the extracted petroleum ether phase.
9. Concentrate the methanol:water extracts to 4 ml with rotary evaporation or a stream of nitrogen/argon.
10. Extract the sample twice, each time with an equal volume of ethyl acetate. Evaporate the ethyl acetate extracts to dryness under nitrogen/argon.
11. Dissolve the concentrated sample in 70:40:1 acetonitrile:water:acetic acid. Load 1-ml aliquots of the solution on 1-ml C18 columns and elute with 2 ml of 70:40:1 acetonitrile: water:acetic acid.
12. Combine fractions and concentrate as in step 9. Extract the concentrated material twice with ethyl acetate and bring to dryness as in step 10. Resuspend in 3 ml absolute ethanol.

    The yield should be at least 20 µmol, i.e., 3 ml of a 7 mM solution.

13. Store sample at –70°C in a light-proof, stoppered container that has been flushed with nitrogen.

    If properly done, the method will supply a good yield of hydroperoxides (i.e., 9 and 13 hydroperoxide isomers), with >90% purity, in one day. Other types of lipoxygenase can be used to yield other combinations of isomers (Forman and Kim, 1989).

ALTERNATE PROTOCOL 4

ASSAY OF SeGPX AND GST IN MIXTURES (DUAL ASSAYS)

There is really little value in reporting only the "total" glutathione peroxidase activities (i.e., cumene hydroperoxide, linoleic acid hydroperoxide) or attempting to draw firm conclusions about glutathione peroxidase responses to experimental conditions based on such results (see Commentary). Under the conditions described in the Basic Protocol and for Alternate Protocol 1, both substrates will come very close to saturating GPX1. The V_{max} of GPX1 for all hydroperoxides is theoretically the same. The sample activity with hydrogen peroxide will be approximately the activity of GPX1 with cumene hydroperoxide; and the difference in the activity measured with cumene hydroperoxide and hydrogen peroxide is an estimate of the fraction of activity from GSTs relative to the total cumene hydroperoxide activity. The estimate is suitable for preliminary work. More definitive means to verify the estimate are found in Alternate Protocol 6. Use of dual assays is strongly urged if these glutathione peroxidase activities will not be resolved or distinguished by other means. This will require the use of two blank reactions and two separate assays, one for each substrate. For the following steps, see Basic Protocol, Alternate Protocol 1, and Support Protocol 3 for reagents and equipment.

1. Assay one aliquot of the sample (and blank) with hydrogen peroxide (see Basic Protocol).

2. Assay a second aliquot of the sample (and blank) with cumene hydroperoxide (see Alternate Protocol 1).
3. Calculate the GPX specific activity of the sample from each assay (see Support Protocol 3).

GPX1-specific activity is obtained with H_2O_2 as the substrate (see Basic Protocol and Support Protocol 3). The GST peroxidase activity is the difference between the specific activity calculated from Alternate Protocol 1 and the specific activity calculated from Basic Protocol. Both activities can be presented as a fraction of the activity obtained with cumene hydroperoxide as substrate.

ASSAY OF GPX1 AND GPX4

ALTERNATE PROTOCOL 5

If both GPX1 and GPX4 assays are required for a project, the buffers and conditions used in Alternate Protocol 2 can be used for both isoenzymes. Triton X-100 will not interfere with the assay of GPX1 when hydrogen peroxide is the substrate, but it could be omitted when GPX1 is assayed. For accurate rates, quite different amounts of sample may have to be used to assay each activity. The spectrophotometer/recorder settings (full-scale chart settings, assay duration settings, or chart speeds) will have to be reset between assays of the isoenzymes.

Set up the sample assays and blanks in the same way as for Alternate Protocol 2, except omit Triton X-100 when GPX1 is to be assayed with hydrogen peroxide as substrate in step 4. Start the GPX1 assay with the addition of 10 µl of 5 mM hydrogen peroxide stock.

Some workers actually perform both GPX1 and GPX4 assays on a single sample aliquot by first using the GPX4 substrate, then hydrogen peroxide (sequential assay). A supply of extra concentrated NADPH stock may be required to replenish the assay between each part of the sequential assay. The spectrophotometer/recorder setting may also have to be redialed each time. For the sequential assay a 10 mM stock of β-NADPH can be prepared in the event that the GPX1 assays terminate too soon for a rate estimate due to depletion in the PHGPX assay.

For materials and equipment, see Basic Protocol and Alternate Protocol 2.

1. Proceed with the assay of PHGPX as described in Alternate Protocol 2.
2. After the PHGPX assay has run sufficiently so that a rate can be established, make a judgment about which of two procedures should be followed before proceeding to the assay of GPX1.
   a. If the PHGPX activity is very low there may be no need to let the reaction deplete the PLOOH stock before proceeding to the assay of GPX1.
   b. If the PHGPX activity is substantial, the reaction should be allowed time to deplete the PLOOH substrate before proceeding. The more PHGPX activity in the sample, the less the waiting time.
   c. An aliquot of the concentrated β-NADPH stock would be added at this point, if it appears to be needed.
3. Assay the GPX1 in the sample by adding 10 µl hydrogen peroxide.
4. Be sure to run a blank through the sequential assay.

The GPX1 activity values may be underestimated in the sequential assay because of interferences (minor) and because the maximum capacity of the assay will frequently be exceeded. The sequential assay is useful for identifying samples from columns or subcellular fractions with GPX1 or GPX4 activities where qualitative results will suffice and economy of sample is a consideration. GPX1 fractions recovered from Sephadex G-50 to

200 will not have GPX4, activity if the fractionation was competently performed. A blank rate for the PLOOH will be found in these fractions after several minutes. Human GPX1 and GPX3 samples sometimes have a rate above the blank rate for a minute or so, possibly due to PLOOH substrate deterioration. However, this spurious reaction can be distinguished from the real reaction since it is not linear. The real PLOOH blank rate is negligible in comparison to GPX1 activity rates and can be ignored when proceeding to the second part of the sequential assay. In subcellular fractions, both activities may be present. In this case, the GPX4 assay is run until the substrate is exhausted, then the GPX1 assay is performed. GPX4 contribution to activity with hydrogen peroxide is generally negligible.

ALTERNATE PROTOCOL 6

CHROMATOGRAPHIC SEPARATION AND ASSAY OF GPX ISOENZYMES

The question of whether to measure one, some, or all of the glutathione peroxidase activities in a sample requires some consideration. If it cannot be determined, a priori, which glutathione peroxidase activity is central to a question, a common substrate such as cumene hydroperoxide (Alternate Protocol 1) or better yet, linoleic acid hydroperoxide (Alternate Protocol 3), can be applied to a sample in which the isoenzymes have been resolved on a sizing column or by some other suitable methods. Then, information can be obtained for the activity of major components.

Far more methods have been described for the resolution of glutathione peroxidases than can be discussed here. Partial to complete resolution of GPX1, GSTs, and GPX4 is possible with gel-filtration columns. GPX1-3 migrate on columns of Sephadex G-100 to 200 with apparent masses of 80,000 to 100,000 Da; GSTs migrate with apparent masses of 40,000 to 55,000 Da; GPX4 has an apparent mass of 15,000 to 22,000 Da (Lawrence and Burk, 1976; Maiorino et al., 1991). Aop2 appears to have different native sizes in different tissues. In the ciliary body of the eye, the apparent mass was 110,000 Da, while in nasal epithelium the mass was estimated at 55,000 Da (Singh and Shichi, 1998; Peshenko et al., 1998). The subunit mass is 28,000 Da in the many tissues where it has been detected. However, the nature of the multimer is not known for most tissues. Thus, gel filtration methods can be used to distinguish among the more common combinations of activities found in tissues, but there will be cases where this method may not be suitable.

Materials

Column buffer with reducing agent (see recipe)
Column standards: any set of proteins with native sizes of 15,000 to 100,000 Da
Sample to be fractionated

Columns: 50 cm length × 1.5 cm diameter to 100 cm length × 2 cm diameter (see Hagel, 1998)
Tubing to connect the column and fraction collector
Sephadex G-150 to 200 (see Hagel, 1998)
Fraction collector with a capacity for up to 100 tubes (5- to 10-ml volume)

Additional reagents and equipment for assays of GPX activities (see Basic Protocol, Alternate Protocol 1, and Alternate Protocol 3)

NOTE: Perform all steps at 4°C to 10°C using a cold room or other suitable means.

Perform gel-filtration chromatography

1. Set up and standardize the column.

   This should be done a day or two in advance of fractionating the sample.The details of column setup, operation, and standardization are beyond the scope of this chapter. A good reference for gel-filtration chromatography in general is Hagel (1998).

2. Assay the unfractionated sample for GPX activity to establish that the starting activity is sufficient to be used for this purpose (see Basic Protocol).

   The sample will be diluted several-fold by the action of the gel filtration and the components will be resolved into separate fractions. If the activity is difficult to detect at this stage, it may be impossible to detect after fractionation. A larger quantity of material (5× to 10×) can be concentrated down to the 4 to 5 ml that can be loaded onto the column, or a more sensitive assay can be used.

3. A few hours prior to the fractionation of the sample, fill the column reservoir with buffer containing a fresh supply of reducing agent and flush the column with the fresh buffer.

4. Apply the sample and begin collecting fractions at a flow rate of ~0.2 to 0.5 ml/min.

   Columns with the dimensions mentioned above will handle up to 5 ml of sample.

   Collection of individual fractions can be delayed up to the point of the void volume of the column, if determined (see Hagel, 1998). However, a portion of the void sample should be kept for use in the blank assay (see step 5, below). Collect fractions so that the total amount of buffer run over the column is at least 5 column volumes.

   Fraction volumes of 2 to 6 ml should be adequate for most purposes. The run time will be several hours. It is most convenient to run the column overnight and perform the assay of the fractions first thing the next day.

5. Collect eluate just after sample is applied (i.e., from the void volume) for use as a blank.

6. Assay the fractions (Alternate Protocol 1 or 3) taking note of the volume of the unfractionated sample that was needed to detect activity and the fact that the activities will be resolved and diluted by the fractionation.

   As a time-saving measure, alternate tubes can be skipped during the initial survey of activities.

Identify the major activities

7. Plot the total activity per fraction (assuming equal volumes) as a function of fraction number.

8. Compare the locations of the activity peaks to the fractions in which the standards eluted (assuming that fraction volumes are equal) for a size estimate of the component GPX activities.

   Refer to the introduction to this protocol for the native sizes of the respective activities. In this way, the identity of the major activities can be surmised and/or some candidates eliminated. Confirmation of component identities can be made by assaying with specific substrates.

   The column can be reused many times. Flow rates and fraction volumes will have to be examined as the column is reused. By standardizing samples for total protein load, semiquantitative and quantitative comparisons can be made of individual components.

ASSAY OF GPX1 AND GPX2 AFTER SELECTIVE IMMUNOPRECIPITATION

ALTERNATE PROTOCOL 7

GPX1 and GPX2 are coproduced in the GI tract mucosal epithelium (Esworthy et al., 1998). Indirect methods suggest that GPX2 is also produced in breast tissues (epithelium) and human liver (Chu et al., 1993). Several cell lines produce GPX2; a few of these barely produce GPX1 (Esworthy et al., 1995). GPX1 and GPX2 cannot be resolved by simple one-step column methods. Several combinations of multistep column chromatography

methods that the authors have tried have produced only partial resolution (Esworthy, et al., 1998). None were adequate for quantifying the separate isoenzyme activities.

Antibodies against GPX1 generally cross-react only slightly with GPX2 and vice versa. Antibodies can be used to remove the bulk of one isoenzyme from a mixture so that the balance of the activity can be assayed (Esworthy et al., 1998). GPX1 antibodies seem to be better at this than GPX2 antibodies, and GPX2 antibodies are not available for general use. However, GPX1 antibody is commercially available and many laboratories share GPX1 antibodies. If antibody methods are used in conjunction with activity assays, immune Ig preparations depleted of plasma GPX3 will be required. This can be accomplished with many methods that are used to enrich the Ig fraction of plasma or sera (Esworthy et al., 1998). Difficult cases may also be approached using animals that underproduce GPX1, or using other reagents (see Background Information).

Materials

GPX-depleted immune (IgG) fraction of rabbit plasma (Esworthy et al., 1998): preimmune and anti-GPX1
Immunoprecipitation buffer (see recipe)
10% (w/v) suspension of washed *Staphylococcus aureus* protein A (see recipe)

Additional reagents and equipment for assay of GPX4 (see Alternate Protocol 2)

1. Incubate the plasma GPX-depleted immune fraction (IgG) with the sample (10 to 25 mU GPX activity) in immunoprecipitation buffer at 4° to 8°C in a final volume of 200 µl, for a minimum of 5 hr (up to but not exceeding 18 hr) at 4°C. Prepare blank reactions containing the same components as the sample or control reactions except substitute the sample buffer for the sample or control activity.

   Triton X-100 and GSH may have to added from separate concentrated stocks if the sample volume alone is near 200 µl.

   The optimal amount of Ig to add to the samples will have to be determined empirically. The proper amount of protein A added to the reaction (see step 2) may be affected by alterations in the amount of Ig added.

   The controls for this assay involve the use of preimmune Ig and semipurified GPX1 activity (see Alternate Protocol 6). The controls are used to demonstrate that the Ig preparation was immunoreactive with GPX and that the reactions are specific under these conditions. The depletion of plasma GPX activity from the Ig preps may not be complete. Therefore, a separate blank rate must be determined for each Ig preparation based on the volumes used in the test samples. A GPX2 control can be obtained from the GI tract of Gpx1 gene knockout mice (see Background Information).

2. Add 50 to 75 µl of a 10% suspension of washed protein A or some other Ig-binding/precipitating agent to the mixture and incubate 1 hr at 4°C.

3. Remove immune complexes by centrifuging 10 min at 10,000 × *g*, room temperature.

   This centrifugation must be done at room temperature so that the temperature of the supernatant does not interfere with the assay performed in the next step.

4. Recover the entire supernatant and assay according to Alternate Protocol 2, using hydrogen peroxide as the substrate in step 4 of that protocol.

   Alternate Protocol 2 is used because that assay system can accommodate the large sample volume and tolerate all of the sample additives.

THE FERRICYANATE METHOD OF HYDROPEROXIDE DETERMINATION TO ASSAY GLUTATHIONE PEROXIDASE

One shortcoming of the coupled method (using the Basic Protocol and Alternate Protocols 1 to 4) is that potentially interesting reducing substrates cannot be freely substituted for GSH. Glutathione reductase from most sources does not reduce a broad range of oxidized thiols. Some mixed disulfides of the type GSSX can be reduced. Thioredoxin reductase can be used as a coupling enzyme to study thioredoxin as a reducing substrate (Bjornstedt et al., 1994). Thioredoxin reductase, itself, has been found to be a reducing substrate for extracellular GPX (GPX3). There is a family of thioredoxin peroxidases with no relationship to any of the families of proteins with glutathione peroxidase activity (Chae et al., 1994). Before using thioredoxin and/or the reductase as alternative substrates, the glutathione peroxidase activities of a tissue may have to be partially or completely purified.

Alternative reducing substrates can be examined using methods that monitor hydroperoxide concentrations. Most hydroperoxide concentration assays are easy to use, very sensitive, and adaptable to glutathione peroxidase assays. The ferricyanate method of Thurman et al. (1972) can be used to assay glutathione peroxidase activity via the consumption of hydroperoxides, as a simple alternative to HPLC or thin-layer chromatography methods. The authors have used hydrogen peroxide, cumene hydroperoxide, and *t*-butyl hydroperoxide with this method. The strengths of the method are that particulates in the sample (even intact cells) can be tolerated, that it uses few costly reagents, that alternative reducing substrates can be freely explored in purified samples of glutathione peroxidases, and that the equipment requirements are less than with the coupled method. There are some weaknesses in this method, however. In crude homogenates or partially purified GPX preparations, consumption of hydroperoxides may be occurring via non-GSH-dependent means. This will be reflected in the assay results. Proper controls and/or precautions that were used in the coupled assay can determine or prevent the non-GSH dependent consumption. Neither hydroperoxide nor GSH concentrations are constant in this method, so rates will deviate from linear. A lot of sample may be required since multiple aliquots are needed to construct a hydroperoxide consumption curve. Many tubes must be labeled and set out in an orderly fashion. Manipulation of a caustic reagent (TCA) is required. Distractions cannot be tolerated once an assay has been started. It is difficult to perform more than two assays at one time. Establishing proper aliquot sampling times, size, and other parameters can be labor-intensive and time-consuming.

Additional Materials *(see Basic Protocol and Alternate Protocols)*

50% or 100% trichloroacetic acid (TCA)
10 mM ferrous ammonium sulfate
2.5 M potassium thiocyanate
Spectrophotometer

NOTE: The first step is either to carefully plan the assay so that some quantitative data can be obtained right away or to perform the assay on a trial basis using GSH as the reducing substrate so that real planning is possible. The time course of the reaction for a given sample activity can be roughly estimated from the parameters of the Basic Protocol or Alternate Protocols 1, 3, or 4. GSH is usually the best substrate for GPX, so that reactions with alternative reducing substrates should run more slowly.

1. Label a set of 1.5- to 1.7-ml plastic microcentrifuge tubes.

   These tubes will hold the TCA that will stop the enzyme reaction when an aliquot of sample is added and mixed. The labels will reflect the sample (if multiple samples are to be tested) and a time point or time point code reflecting the time lapse from the start of the reaction. Five to ten tubes may be needed per reaction.

2. Add 0.2 ml of 50% TCA or 0.1 ml of 100% TCA to each tube.

3. Prepare the reaction mixture (buffer and sample).

   The buffers can be the same as those used in the Basic Protocol or the Alternate Protocols if an enzyme preparation is to be tested. The buffers used in Alternate Protocol 3 will probably provide the best sensitivity. The volume of test enzyme will be based on a preliminary test with GSH as the reducing substrate in one of the protocols in this unit; the authors recommend using Alternate Protocol 3 conditions. The buffer could also be some type of buffered saline solution if intact cells are tested. The assay mixture will contain GSH (or test reducing source) and sample as in Alternate Protocol 3, but NADPH and glutathione reductase are not used.

4. Set up an assay reaction of sufficient volume that multiple (five to ten) sample aliquots of 0.8 to 0.9 ml can be removed.

   The reaction tube must allow mixing of contents and rapid removal of aliquots. A 15-ml screw-cap plastic centrifuge tube works well.

   A series of hydroperoxide standards is used to make a standard curve to convert the OD reading to hydroperoxide concentrations or amounts. The useful range of hydroperoxide concentrations is ~1 to 150 μM. Each type of hydroperoxide will have to have its own standard curve. A blank is prepared with sample, leaving out the substrate.

5. Set a timer and be prepared to start timing as soon as possible following addition of the substrate.

6. Start each assay with the addition of hydroperoxide, with complete mixing, and starting the timer immediately following this.

   Since the goal is to evaluate alternative reducing substrates, the hydroperoxide can be any that reacts well with ferricyanate reagent (hydrogen peroxide, cumene hydroperoxide, and t-butyl hydroperoxide will definitely work) and can be efficiently reduced by the sample enzyme when GSH is the reducing substrate. For example, if the GPX activity was a GST, t-butyl hydroperoxide should be avoided, since it is generally poor substrate for GSTs. Cumene hydroperoxide would be the best choice in that case.

7. Stop the reaction in sample aliquots, according to a predetermined schedule, by mixing aliquots with the aliquots of TCA prepared in step 2.

   Any combination of TCA and sample giving a final 10% TCA concentration can be used. This has the effect of stopping the reaction cold while the glutathione peroxidase is quickly denatured.

   A T_0 sample is made by mixing a sample aliquot with TCA, then adding a substrate volume scaled to the aliquot size.

8. When all of the sample aliquots have been taken, determine the hydroperoxide content of each aliquot by mixing the contents of each tube (1 ml vol) with 0.2 ml of 10 mM ferrous ammonium sulfate and 0.1 ml of 2.5 M potassium thiocyanate so that a color reaction (OD at 480 nm) occurs dependent on the amount of hydroperoxide remaining in the tubes.

9. Centrifuge the tubes 5 min at 14,000 × *g*, room temperature, to pellet the precipitate formed in the presence of the TCA.

10. Read the OD at 480 nm of the sample supernatant.

    The blank value (sample but no substrate) will be subtracted from the assay value before the substrate concentrations are determined from the standard curve.

CALCULATIONS OF SPECIFIC ACTIVITY

For the basic sample activity calculation, results from protein assays, DNA assays, cell counts, or other sample-quantifying methods will generally have to be available to put the data into the most useful format for analysis—i.e., specific activity. Exceptions to this may be cases where samples were fractionated on columns or where plasma, milk, or aqueous humor activity have been assayed. In such cases, enzyme activity units per fraction (volume) or unit volume may suffice for analysis or presentation. During assays, it is more convenient to record sample volumes used in each assay (with notations of any dilutions prior to assay) rather than to try and calculate sample-aliquot protein or DNA content on the spot. There is some merit to knowing the actual sample content of an assay aliquot. Specific activities can be calculated during assays, particularly with the slower GPX4 assays (Alternate Protocol 2).

Calculations will be illustrated for conversion of data to milliUnits enzyme activity per milligram protein. The use of protein content as the sample measurement is the most widely used convention; it is the only practical form for projects where purification or subcellular fractionation is performed. The enzyme activity unit is based on the international convention of 1 μmol substrate consumed or product formed per min. This convention is generally valid for coupled assays, since the GSH concentration is constant during the assay and hydroperoxide substrate concentrations up to 10 times the K_m ensure linear rates in the assay.

If a strip chart recorder was used, the settings used on the machine/chart recorder have to be recorded with each assay to translate the data. The sample calculation that follows will assume the setting of 0.5 OD/full scale, a 1-ml assay volume, and a 1-cm path length. Most spectrophotometers now come with microprocessors that compute the results to OD/min or can be programmed to perform all the calculations to the point of enzyme activity in the sample (after the blank rate has been determined and input).

1. First, read the blank assay trace as chart units per min or convert to OD/min (no other calculation need be done).

   This value will be subtracted from every assay (in like units), and the net value used as the basis to calculate specific activities.

   The spontaneous rates for each day's assays will be the same, if all the reagents have been properly measured out and were prepared from good stocks. The blank provides a quality check for the reagents. The blank should contain the same homogenization buffer(s) used for the samples added, in volumes similar to those anticipated for the sample(s). This is critical when GSH has been added to the samples for stabilization of activity. Examination of homogenates of cell lines lacking GPX activity and the tissues of selenium-deficient animals and GPX1 gene-knockout animals reveals that there is a small background above the spontaneous rate in all of these samples (0.5% to 5% wild-type levels; for exceptions, see Background Information). For many applications, accounting for the spontaneous rate with the blank is all that is required for accurate specific activity determinations.

2. Put the raw data from the assay in the form of net OD units per min to start the calculations (where net OD refers to the rate after subtraction of the blank rate).

   The spontaneous rate has to be subtracted from the sample rates for valid calculations of enzyme specific activity.

   OD/min can be determined by finding the chart interval corresponding to 1 min on the time axis and measuring the number of chart units along the OD axis that the assay trace runs through. For the blank and for samples with low activity, it will probably be necessary to base rate determinations on time intervals of 2 to 5 min. The selection of the region for the rate estimation must correspond to a part of the assay trace where a linear result occurred that is representative of the whole reaction trace (see Fig. 7.1.1).

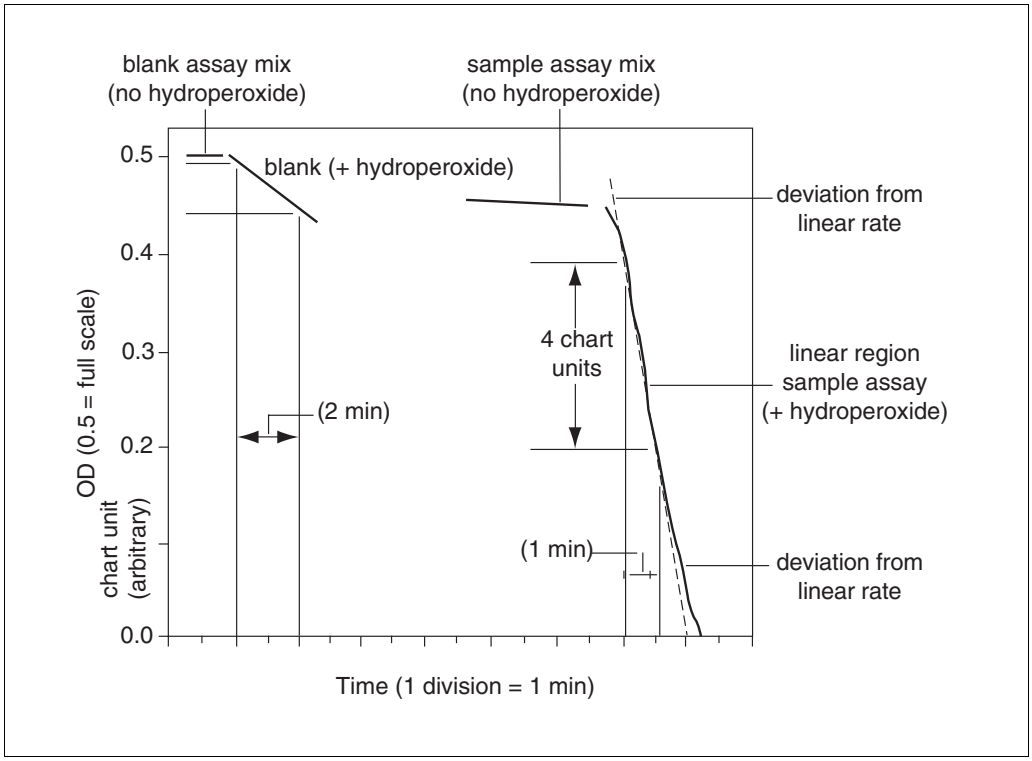

Figure 7.1.1 Schematic representation of typical spectrophotometric output during glutathione peroxidase assay under standard conditions.

3. Divide the number of OD chart subdivisions per min by the total chart subdivisions, multiplied by 0.5 OD and divided by 1 min, or the number of minutes needed to get a good estimate.

   From Figure 7.1.1, the blank trace traversed one chart subdivision (chart unit) out of 10 chart units (full scale) in 2 min. The rate is 0.5 chart units/min. The net sample rate is 4 chart units/min (total rate) – 0.5 chart units/ min (blank rate) = 3.5 chart units/min. This is converted to OD min as follows: 3.5 chart units/min ÷ 10 chart units (full scale) × 0.5 OD (full scale) = 0.175 OD/min. This is the net sample activity in OD/min.

   Accurate results cannot be expected in cases where the trace passes through more than 35% of the chart span/min or 0.17 OD/min. The reason is that the reaction rate may have exceeded the linear range. The investigator will, however, have performed a positive control series to aid in this judgment. Also, some samples will have a spontaneous rate prior to addition of hydroperoxide. It may be critical to account for this, to have accurate calculations, by subtracting this rate as for the blank rate. This is likely to be the case in GPX4 assays for most samples, and where sample activities of other GPXs are low. Cell lines grown without selenium supplementation, selenium-deficient animals, and GPX1 assays of guinea pigs are cases where this may be true.

4. Convert the OD/min results to enzyme units.

   One enzyme unit = 1 μmole substrate consumed or product formed/min. For glutathione peroxidase activity, in the coupled assay, the NADPH consumption rate is used in place of these values to calculate activity. The calculation is:

   [Net OD/min ÷ 6.22×10^3 OD/M] ÷ 1000 = mol NADPH consumed/min.

   The value 6.22×10^3 is the OD of a 1 M solution of NADPH in a path length of 1 cm. The divisor of 1000 corrects the NADPH consumption from per liter to the actual assay volume of 1 ml.

   For the example in Figure 7.1.1, this becomes [0.175 OD/min ÷ 6.22×10^5 mol/liter/OD] ÷ 1000 = 2.8×10^{-8} mol NADPH consumed/min. This converts to 0.028 U or 28 mU.

5. At this point, divide the enzyme activity units value by the amount of protein in the assayed sample aliquot, expressed in mg, to yield the sample specific activity.

The enzyme activity in this example in Figure 7.1.1 is roughly that expected for 0.08 mg of rat liver cytosol protein. The specific activity would then be calculated as 28 mU ÷ 0.08 mg = 350 mU/mg protein.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay mix for GPX4 (see Alternate Protocol 2)

0.4 M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
15 mM GSH (reduced glutathione)
1.25 mM NADPH (β–nicotine adenine dinucleotide phosphate, reduced form)
Prepare immediately before the assay

Allow the dry GSH and NADPH to equilibrate to room temperature 30 min prior to assay. The authors prepare the GSH and NADPH directly in the assay buffer (0.4 M Tris·Cl), but they can also be prepared separately in water.

Column buffer

0.1 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)
5 mM EDTA

Prepare 2 to 4 liters of buffer without reducing agent. Store indefinitely at 4°C. Just prior to use with gel-filtration column, add 1 to 5 mM GSH, 1 to 3 mM 2-mercaptoethanol, or 0.1 to 1 mM dithiothreitol (DTT) as reducing agent.

Cumene hydroperoxide, 30 mM

Prepare a working (20×) stock of cumene hydroperoxide in water (the reagent is commercially available as a 7 to 8 M stock from Sigma and Aldrich). Use ethanol to prepare a 5× (0.15 M) stock that can be diluted 5-fold for a (30 mM) working stock.

CAUTION: *The odor of cumene hydroperoxide is quite pungent, and the chemical is hazardous. The commercial stock should be handled in a fume hood. Gloves should be worn at all times when handling this reagent.*

Drabkin's reagent

0.0016 M KCN
0.0012 M $K_3Fe(CN)_6$

This is indefinitely stable.

Glutathione reductase, 100 U/ml

Dilute the ammonium sulfate suspension of glutathione reductase to 100 U per ml in a small aliquot of ice-cold assay buffer.

The diluted glutathione reductase will be stable for two or three days at 4°C.

GPX positive control (see Basic Protocol)

This should be available for first-time investigations (see Basic Protocol). Prepare as a series of four or five 1:2 serial dilutions. Sources for the positive control could be one of the following:

1. *Murine red blood cells:* Prepare 10% (v/v) cells in 0.1× PBS (*APPENDIX 2A*), lyse by sonication, and mix 1:1 (v/v) with 2× Drabkin's reagent (see recipe). Centrifuge 10 min at 15,000 × *g*, 4° to 8°C. Store supernatant indefinitely at −70°C.

continued

2. *Rat plasma:* Dilute 1:10 in PBS (*APPENDIX 2A*). Store indefinitely at −20°C.

3. *Rat or mouse liver or kidney:* Prepare the same way as the study samples, then dilute 1/10 in homogenization buffer (see Critical Parameters). Store indefinitely at −20°C.

4. *Human or bovine GPX1:* Purchase enzyme from Sigma and prepare stocks at 200 mU/ml in homogenization buffer (see Critical Parameters) containing albumin at 0.1 mg/ml to help stabilize the stock. Divide into aliquots and store indefinitely at −20°C.

GPX1 positive control, free of GPX4 (see Support Protocol 1)

Obtain GPX1-enriched material by collecting 75,000- to 120,000-Da fractions from columns (see Alternate Protocol 6).

The starting material for this control can be erythrocytes, liver, or kidney.

GPX4 positive control (see Alternate Protocol 2 and Support Protocol 1)

Prepare a positive control GPX4 enzyme sample by making a 10% homogenate of rat or mouse testes in a buffered solution (pH 7.2) with 5 mM EDTA, 1 mM PMSF, 0.1 M NaCl, 0.2% Triton X-100, and 3 mM GSH (other reducing agents can be used).

The 10,000 × g supernatant will be very rich in GPX4 activity. GPX1 can be removed by fractionating the sample over Sephadex G-50-200 and collecting the 15,000- to 22,000-Da fractions (see Alternate Protocol 6).

GSH, 10 mM

Prepare fresh solution on each day the assay is to be performed. 30 min prior to the assay, allow the dry GSH (reduced glutathione; mol. wt. 307.3) to equilibrate to room temperature (for new batches, this will be an opportunity to subdivide the material into aliquots for storage, where each aliquot would be the amount of material consumed in a week to a month of assays). Weigh out 3.1 g per liter (scaled down to the volume required for the assay of the study samples or for 50 to 100 assays, maximum) and dissolve in room temperature assay buffer (50 mM sodium phosphate, pH 7.0; *APPENDIX 2A*).

The dry GSH should be divided into aliquots so that it is subjected to the open air at room temperature only a few times.

The GSH and NADPH will oxidize. While each working stock may last longer than the time required for 100 assays, it is best to test this gradually and then plan from experience. The working stocks of GSH and NADPH may or may not survive overnight storage in the refrigerator or freezer. The authors have had variable success using day-old assay stocks of GSH and NADPH. Because the assay is so easy and so few solutions are required, it is better to make fresh solutions each day.

Hydrogen peroxide (H_2O_2), 5 mM

Dilute ~5 to 6 µl of 30% (8 to 9 M) hydrogen peroxide into 10 ml water.

The actual concentration of hydrogen peroxide in the commercial 30% solution can be determined by using the value 0.071 as the millimolar extinction coefficient at 230 nm.

The diluted hydrogen peroxide is stable at 4°C for a few days if stored in an iron-free container. The spontaneous activity of the blank can be used to determine whether the diluted hydrogen peroxide is spent (see below).

Immunoprecipitation buffer

0.1 M NaCl
0.2% (v/v) Triton X-100
0.1 mg/ml bovine serum albumin (BSA)
3 mM GSH (reduced glutathione)
0.15 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)
5 mM EGTA
Store up to 1 week at 4°C

Triton X-100 and GSH may have to added from separate concentrated stocks if the sample volume alone is near 200 μl.

NADPH, 2 mM

Prepare fresh solution on each day the assay is to be performed. 30 min prior to assay, allow the dry β-NADPH (β–nicotine adenine dinucleotide phosphate, reduced form) to equilibrate to room temperature (for new batches, this will be an opportunity to subdivide the material into aliquots for storage, where each aliquot would be the amount of material consumed in a week to a month of assays). Weigh out 1.5 g/liter (scaled down to the volume required for the assay of the study samples or for 50 to 100 assays, maximum) and dissolve in room temperature assay buffer (50 mM sodium phosphate, pH 7.0; *APPENDIX 2A*).

The dry NADPH should be divided into aliquots at the first opportunity.

The GSH and NADPH will oxidize. While each working stock may last longer than the time required for 100 assays, it is best to test this gradually and then plan from experience. The working stocks of GSH and NADPH may or may not survive overnight storage in the refrigerator or freezer. The authors have had variable success using day-old assay stocks of GSH and NADPH. Because the assay is so easy and so few solutions are required, it is better to make fresh solutions each day.

Protein A, washed, 10% suspension

Suspend protein A (from *Staphylococcus aureus* Cowan I strain, fixed cells; ICN Biochemicals) in 10 vol (w/v) Dulbecco's phosphate-buffered saline (DPBS, without calcium; Life Technologies). Centrifuge 5 min at 3000 × *g*. Pour off the supernatant and resuspend the pellet in DPBS containing 0.2% (v/v) Triton X-100. Centrifuge 5 min at 3000 × *g*, pour off the supernatant, then wash three times (to remove excess Triton X-100 and protein A fines), each time by resuspending in 10 vol DPBS, centrifuging 5 min at 3000 × *g*, and pouring off the supernatant. Resuspend the final pellet in 10 vol DPBS, and store indefinitely in 1- to 2-ml aliquots at ×20°C.

Washing the Protein A removes fine particles that will interfere with the immunoprecipitation.

Sodium azide, 1.125 M

Prepare the working stock (1.125 M) by measuring 73.12 g NaN_3 per liter into water (indefinitely stable).

Sodium azide can also be prepared in the assay buffer stock at 1.1 mM. This has the advantage that it will not be forgotten, and it prevents contamination when the buffer is stored at room temperature. Note that if azide is a component of the buffer, the buffer cannot be used for catalase assays.

COMMENTARY

Background Information

The glutathione peroxidase reaction seems to be the principal activity of SeGPX. For some SeGPX isoenzymes, glutathione may be substituted by GSNO (GPX1), 2-mercaptoethanol (GPX4), other small thiols such as cysteine and dihydrolipoic acid (GPX4), and thioredoxin (GPX3)—also see Maiorino (1994), Bjornstedt et al. (1994), and Freedman et al. (1995). Proteins with vincinal thiol groups or exposed free thiols have also been reported to serve as reducing substrates. Evidence has been presented for the utilization and possible physiological significance of GSNO and thioredoxin as substrates of SeGPX isoenzymes (Esworthy et al., 1993; Bjornstedt et al., 1994; Freedman et al., 1996). Within solid tissues, GSH is so abundant that it will be the major reducing substrate of glutathione peroxidases, regardless of the presence of other thiols. In plasma, it is not clear which reducing substrates are important.

In the major organs of most animals, the glutathione peroxidase activity detected with hydrogen peroxide as substrate will be GPX1 (Table 7.1.1). GSTs cannot use hydrogen peroxide as a substrate. Exceptions to the rule of GPX1 as the major activity are the blood plasma, where GPX3 is the sole GPX, and the mucosal epithelium of the GI tract, where GPX2 accounts for up to 50% of the activity. GPX2 may also be a major activity in human liver and in human and rodent breast tissues. GPX3 is also associated with kidney, intestine, and placenta. The GPX3 contribution to total activity in these tissues seems to be negligible based on results obtained from *Gpx1* gene knockout mice. A GPX activity is observed in the hearts of *Gpx1* gene knockout mice that is between 15% to 30% of wild-type mouse levels. The source of the activity is not known although GPX3 and Aop2 mRNAs are detectable in this organ.

In some minor organs, other putative GPX species are produced at very high levels. In the ciliary body of the eye and the nasal epithelium, Aop2 has been proposed to compete with GPX1 as the major activity detected with hydrogen peroxide (Peshenko et al., 1998;Singh and Shichi, 1998). Aop2 protein is detected in the major organs. However, it seems fairly clear that it does not contribute in a major way to the GPX activity under normal conditions. In *Gpx1* gene knockout mice, there is a small background GPX activity (0.5% to 5% of the activity of wild-type mice; 15% to 30% in heart) in the major organs (Cheng et al., 1997). This could

[a]Specific activity in mU/mg protein

[b]Lawrence and Burk (1978)

[c]Zhang et al. (1989)

[d]Roveri et al. (1992)

[e]Himeno et al. (1993)

[f]The values reported in Himeno et al (1993) may be higher than those found in other reports. The activity in mouse kidney and other organs relative to mouse liver seems appropriate. However, 3-fold discrepancies between various reports are common in assays of mice (using Alternate Protocol 3, rat liver has an activity of 2500 to 2900 mU/mg, while mouse liver activity is ~4200 mU/mg).

[g]Weitzel et al. (1990)

[h]Cheng et al. (1997)

[i]Esworthy et al. (1997)

arise from activities like that of Aop2 and, in some cases, GPX3. Aop2 mRNA is highly induced in skin keratinocytes as part of the early wound healing response (Munz et al., 1997). This protein may be very relevant to toxicology regardless of its final classification. However, the true nature of this protein is in dispute. Sequence homology criteria would place it among the C1-type thioredoxin peroxidases. C1-type thioredoxin peroxidases can have thiol peroxidase activity (Chae et al., 1994). Definitive evidence that GSH can serve as the donor thiol has not been provided. A strong case for GSH as a donor has recently been made specifically with Aop2, and at the same time the whole idea that the protein has any GPX activity has been strongly challenged.

Glutathione peroxidase activity can best be described as a genuine side reaction of a subset of a third protein family, i.e., GSTs. The kinetic parameters that describe the glutathione peroxidase activity of GSTs show that these enzymes may be relatively inefficient in comparison with SeGPXs (Hong et al., 1989). The K_m for GSH is low enough for the enzymes to be saturated in most cell types. However, the V_{max} with hydroperoxides tends to be very low and the K_m for many hydroperoxides is very high relative to SeGPX. Aop2 also has a very low V_{max}. However, the K_m with hydroperoxides is in the range of GPX1. Since tissue hydroperoxide levels may seldom exceed 1 μM, not all of the glutathione peroxidase activities detected with cumene hydroperoxide at 1.5 mM or linoleic acid hydroperoxide at 50 μM will have bearing on physiological roles or possibly even toxicological roles. This is the picture emerging from studies of paraquat toxicity on *Gpx1* gene knockout mice.

In some tissues, GSTs are very abundant and, in some animals and tissues, SeGPX isoenzymes are not prevalent (Lawrence and Burk, 1978). Under these conditions GSTs could contribute significantly to lipid hydroperoxide metabolism. Some GST isoenzymes have good activity with what may be regarded as physiological substrates. In the data of Hong et al. (1989), it can be seen that 15-HPETE has a K_m with GSTs that is similar to GPX1. The data of Hiratsuka et al. (1997) show that cholesterol 7-hydroperoxides are superior substrates for alpha-class GST over GPX1. However, the valid comparison would be with GPX4, which has excellent activity with cholesterol hydroperoxide substrates (Esworthy et al., 1993). If a particular physiological substrate is the object of research and is practical to use, it is best to use that substrate rather than a "model" substrate to determine whether GSTs could be effective peroxidases.

One other link between GSTs and GPX1 is the "compensatory" increase in GST activity observed when rodents were subjected to extreme selenium deprivation. This was held up as evidence for a role of GSTs as glutathione peroxidases. However, careful work with the selenium-deprived rodent model (Reiter and Wendel, 1983) and recent studies with *Gpx1* gene knockout mice (Cheng et al., 1997) show that there is no compensatory increase of GSTs with GPX1 decline. Rather, it is very low selenium levels that trigger this response, irrespective of GPX1 status.

Many studies report only results for the collective glutathione peroxidase activity with cumene hydroperoxide. In most cases, the rationale provided is doubtful at best. It is difficult to interpret what such values mean under different study conditions in the absence of supporting data on the abundance of each enzyme. The regulation of GSTs and SeGPX isoenzymes appear to be completely different. An assay that lumps GSTs with SeGPXs risks losing the signal of one in the background of the other, and therefore, losing much of the meaning.

Any assay of GPX isoenzymes (SeGPX) has inherent limitations and peculiarities due to the unusual reaction mechanism (Paglia and Valentine, 1967). Under practical assay conditions, it is not possible to saturate SeGPX isoenzymes with GSH. In fact, GPX rates are almost directly proportional to GSH concentration (0 to 5 mM) when hydroperoxide concentrations in the assay are 25 μM or greater, which is standard. This property makes the coupled assay so useful. In that assay, GSH levels are held constant, enabling linear rates to be obtained.

In the cell, where hydroperoxide levels probably do not exceed 1×10^{-6} M and GSH levels are in the millimolar range, the selenium-dependent enzymes would be nearly saturated with respect to GSH (Flohe, 1982). Under these conditions, the reaction rate (V) can be approximated as:

$$V \cong [\mathrm{ROOH}]/\Phi_{\mathrm{ROOH}} \times [\mathrm{E}_0]$$

where Φ is the Dalziel coefficients, $\Phi = 1/K$, where K is the rate constant for the respective step of the enzyme reaction, and E_0 is the enzyme concentration. K values for some commonly used hydroperoxide substrates of GPX1, GPX3, and GPX4 and the K values for GSH are found in Table 7.1.2.

Table 7.1.2 SeGPX rate constants K_1 (ROOH) and K_2 (GSH)[a]

SeGPX enzyme	Substrate[b,c]				
	K_1 (H_2O_2)	K_1 (LinOOH)	K_1 (CumeneOOH)	K_1 (PLOOH)	K_2 (GSH)
Hamster GPX1	2.9×10^6	2.3×10^6	1×10^6	ND	4.8×10^4
Human GPX1	5.2×10^6	2.7×10^6	—[d]	ND	1.5×10^4
Human GPX2	—[d]	—[d]	—[d]	—[d]	—[d]
Human GPX3	2.0×10^6	5.9×10^6	—[d]	ND	4×10^3
Porcine GPX4	1.9×10^5	1.8×10^6	1.3×10^5	7.0×10^5	5×10^3

[a]Sources: Chaudiere and Tappel (1983); Esworthy et al. (1993); Ursini et al. (1985).
[b]K_1 and K_2 have units of mM^{-1} min^{-1}. Assays conducted in Tris·Cl, pH 7.6.
[c]Abbreviations: CumeneOOH, cumene hydroperoxide; GSH, reduced glutathione; LinOOH, linoleic acid hydroperoxide; ND, no activity detected; PLOOH, phosphadidyl choline hydroperoxide.
[d]No data.

It is possible to saturate the enzyme with many hydroperoxide substrates when GSH is in the millimolar range, which is a standard assay condition. V_{max} for any hydroperoxide substrate is determined by the following equation:

$$V_{max} = [GSH]/\Phi_{GSH} \times [E_0]$$

All of the terms in this equation relate to enzyme or GSH. In other words, the theoretical V_{max} for all hydroperoxide substrates is the same. Specific activity estimations are usually derived for SeGPX isoenzymes under near-saturating conditions, so that differences among SeGPXs will largely reflect differences in the interaction of enzymes with GSH. Specific activity estimations based on maximum velocities are at variance with the parameters that describe enzyme velocities in vivo. The enzyme activity assay can be used to determine relative enzyme levels. But, for reasons mentioned above—the presence of competing reactions and limitations of substrate—in vivo, activity assays cannot be related to physiological function without elaborate modeling.

The apparent K_m for individual hydroperoxide substrates is quite different (Hong et al., 1989). This property of the reaction produces some of the variation reported for GPX activities when different substrates are used. The K_m is a variable, contingent on GSH concentration:

$$K_{m\,ROOH} = [GSH] \times \Phi_{ROOH}/\Phi_{GSH}$$

GPX isoenzyme activity rates are highly pH dependent (Paglia and Valentine, 1967). The pH dependence follows partially from the dissociation reaction, $GSH \leftrightarrow GS^- (pK_{SH}, \cong 9.) + H^+$. Other factors also affect the pH dependence of the reaction. The maximum rate occurs around pH 8.8. The spontaneous reaction is so fast at this pH that it is not practical to perform the assay under this condition. On the other hand, GPX4 activity in most tissues is barely detectable at pH 7.0. A good compromise between noise and signal is found between pH 7.3 to 7.6.

A problem with literature reports of GPX activities derives, in part, from the lack of simple optimal conditions that has led to endless variations in assay conditions, as well as the use of many substrates. This is additionally complicated in studies of cell lines, since most sera and media supply selenium in a form suboptimal for full expression of SeGPX activities (Germain and Arnson, 1977; Maiorino et al., 1991). Any report of glutathione peroxidase activity must provide the pH, GSH concentration, hydroperoxide substrates, and concentrations. Also, the report should provide information on the selenium status of the organism or cell line. It is best if this information is stated in the body of the publication even if a reference is provided for the assay method.

Alternative tissue reagents for glutathione peroxidase studies

Recently, *Gpx1* gene knockout mouse lines have been introduced (Ho et al., 1997; de Haan et al, 1998). These lines are already widely distributed, and the results of many studies using the homozygous knockout gene lines have already been published. These lines are particularly useful in studying glutathione peroxidase activities in tissues where GPX1 is (or was, in the case of the knockout line) present and obscures other activities (Esworthy et al.,

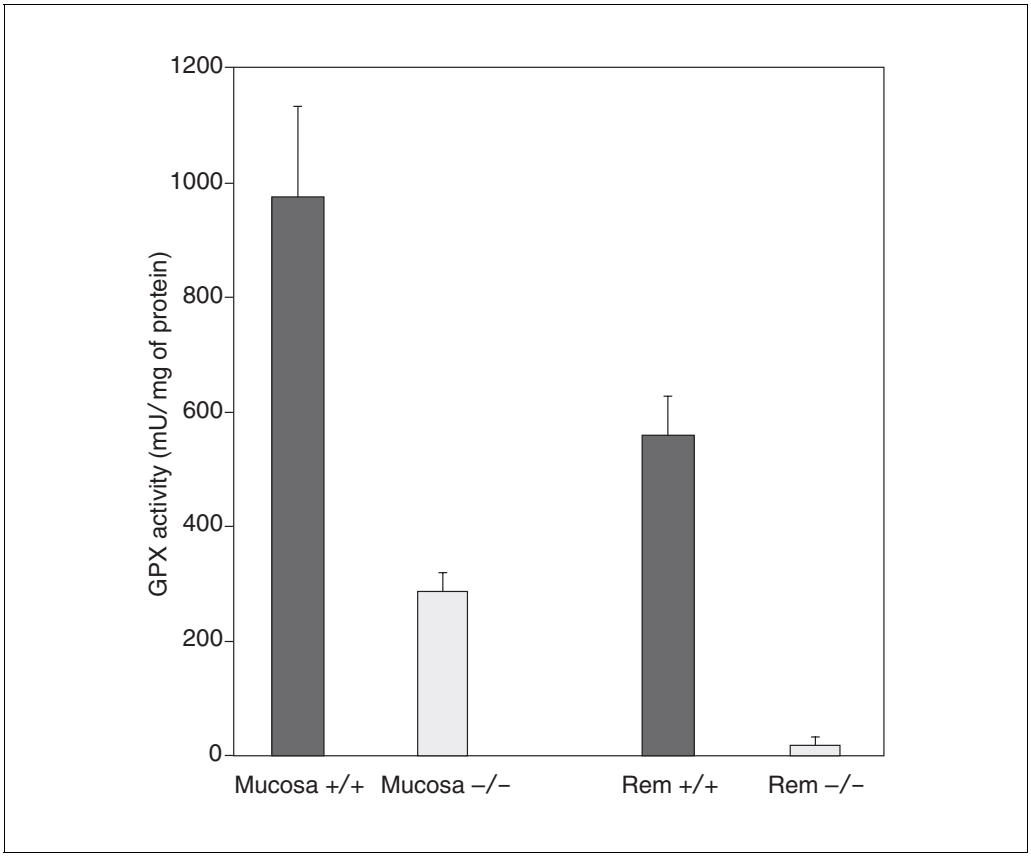

Figure 7.1.2 Glutathione peroxidase activity measured in the mucosa and muscular remnant (Rem) of mouse small intestine. The black bars show activity obtained from control mice, which have normal *Gpx1* genotype (+/+); the gray bars represent Gpx1-knockout mice with *Gpx1* (–/–) genotype. The error bars represent standard deviations obtained from four male mice. The activity was measured with H_2O_2 as the substrate.

1997, 1998). No up-regulation of other SeGPX isoenzymes, GSTs, or other antioxidant activities has been detected in these mouse lines (Cheng et al., 1997; Ho et al., 1997).

As an example of the application of the *Gpx1* gene knockout line, GPX2 is coproduced with GPX1 in the mucosal epithelium of the GI tract. It is possible to use antibodies to assay for the activity of GPX2 in the presence of GPX1. But GPX2 activity is easily detected in the *Gpx1* gene knockout line by comparison of residual GPX activity in the mucosal and the non-mucosal tissues of the GI tract toward hydrogen peroxide (see Fig. 7.1.2). Alternative mitochondrial activities could also be studied in this mouse line (Esworthy et al., 1997). The detection of Aop2 and other novel activities may be facilitated by the use of these mice.

Cell lines are reported in which SeGPXs (GPX1 and GPX4) and GST activities are altered via transgenic means (Chu et al., 1990; Mirault et al., 1991; Lavole et al., 1992; Yagi et al., 1996). Many transgenic cell lines are very useful, since the parental cell lines were picked for their lack of SeGPX isoenzyme or GST production. Nonproduction of GPX1 is very common, and nonproduction of GPX4 occurs as well (Esworthy et al., 1995). Use of paired lines can eliminate some of the interpretation problems inherent in selenium manipulation. A classic example of complications with selenium manipulation is the 100-fold amplification of the catalase gene (with up-regulation of the activity) that occurs in a few cell lines when they are selenium-depleted (Lin et al., 1995). However, selenium manipulation of SeGPX status in cell lines is an easy and often useful means for studying these enzymes (Chu et al., 1990). For both the cell lines and animals, much toxicological data is already available for altered selenium status, GSH status, and from the genetically altered lines.

Comparisons with other methods

Almost any method capable of measuring hydroperoxides or GSH can be applied to the assay of glutathione peroxidase activities. There are a wide variety of such assay methods

available, suitable to nearly any laboratory situation. Commercial kits are available for activity assays of glutathione peroxidases (Sigma), and an ELISA kit is available for determination of the levels of the SeGPX isoenzyme of the plasma (Oxis International). These methods offer huge throughput and provide most of the reagents and standards required. These kits are also expensive and may lack the range of the methods described in this unit. If a kit is adaptable to a particular study sample, it can be an attractive alternative to assembling reagents and testing assay conditions for the protocols described above. Variations of the coupled assay of Paglia and Valentine (see Basic Protocol and Alternate Protocols 1 to 7) are still the most widely used methods. With a multisampler-equipped recording spectrophotometer, tens to hundreds of samples can be assayed in a day using, e.g., variable hydroperoxides, pH, and GSH concentrations. When set up with a programmable data collection/processing system, this method is still competitive with multiwell micromethods for speed.

The glutathione reductase couple in this type of assay replaces cumbersome GSH measurements used in many older assay methods. The coupled method has the advantage that the GSH concentration in the assay does not change until the indicator NADPH runs out. This is important, since it is not practical to assay SeGPXs or Aop2 activities under conditions where GSH concentrations come anywhere near those needed to saturate the enzymes. It is possible to use many hydroperoxide substrates at up to ten times the apparent K_m of the enzymes, providing nearly linear rates for tens of seconds to minutes. This simplifies specific activity estimations and permits the reporting of activities in a conventional format. With noncoupled methods, the rates obtained are not linear. This is not a real problem. An acceptable enzyme activity unit used under these conditions, as well as calculation of the activity in these units from raw data, is described by Flohe and Gunzler (1984). The unit is a counterpart of the k unit used in catalase assays. The paper also provides conversion units that can be used to move from the k unit system to μmol NADPH consumed/min for certain assay conditions.

Many HPLC methods provide a means for following hydroperoxide consumption, alcohol product formation (sometimes both simultaneously), or GSH oxidation (Terao et al., 1988; Pascual et al., 1992; Bao et al., 1995). The published range of hydroperoxide substrates and/or alcohol products that can be completely resolved from reaction mixtures and quantified with HPLC systems is more than sufficient to study any glutathione peroxidase activity. Some workers strongly advocate this type of assay system, since both substrate and product can be monitored and there is no dependence on a coupling system that has some limitations (Pascual et al., 1992). Also, increased sensitivity in the assay of GPX4 is achieved in HPLC systems (Bao et al., 1995). If the questions of a study go beyond simple issues of glutathione peroxidase activity levels—e.g., by asking via what routes can hydroperoxides be metabolized in plasma or tissues—then systems (such as HPLC and thin layer chromatography) that can quantitate alcohol product formation and detect alternative products are essential (Terao et al., 1988). The question of whether hydroperoxides are being consumed at substantial rates in a sample in the absence of added reduced glutathione can be determined with or without HPLC systems (e.g., by the ferrithiocyanate method, Alternate Protocol 8). The throughput of HPLC methods can be substantially less than that of other methods, and multiple columns and HPLC reagents are required to study a range of hydroperoxide substrates. Thin-layer chromatography systems are also used in glutathione peroxidase assays (Esworthy et al., 1993).

Critical Parameters

Selenium status

This is an issue for cells in tissue culture. Most animal diets supply selenium at optimal levels, and Western diets ensure adequate selenium in humans. Serum for tissue culture, used at standard concentrations (5% to 20%), does not routinely supply selenium to cells in a form that is optimal for SeGPX production (Maiorino et al., 1991). Optimum production can yield cell line specific activities comparable to tissue of origin levels (Esworthy et al., 1995). However, the full details for the nutritional requirements of optimal SeGPX production in cell lines remains to be investigated.

In many studies, suboptimal SeGPX production is not a problem. SeGPX activities will be 10% to 40% of maximal values in most cases, and occasionally up to 80%. This is often adequate for detection of GPX1. In many human cell lines and some rodent cell lines, this may not be adequate for production of GPX4 or GPX2 (in those rare cases where GPX2 is the sole SeGPX produced) at detectable levels (Maiorino et al., 1991; Esworthy et al., 1995).

Tissue culture media can be supplemented with selenium in many forms (sodium selenite, selenates, selenious acid, or organoselenium compounds) to optimize SeGPX production. The serum in the medium will mask some of the supplemented selenium (Chu et al., 1990), so that the more serum in the medium, the higher the concentration of selenium needed for optimal production (30 to 300 nM). Full equilibration of cell line SeGPX to a new level with selenium modulation averages 4 to 10 days duration (Chu et al., 1990). Growth rates of the cell lines may affect this parameter. Each cell line will have to be individually examined for the minimum equilibration interval.

Sample isolation and processing

Intact tissues or cell line material can be quickly frozen for later processing. A storage temperature of at least −20°C is essential, and −70°C is recommended. With tissues or cell lines containing GPX2, −20°C storage should be confined to <1 week.

For homogenization and sample fractionation, tissues should be prepared as 10% to 20% homogenates (tissue weight/volume of buffer) in ice-cold buffer that is compatible with both good glutathione peroxidase activity recovery and the assay. If GPX2 is in the tissue, a 20% homogenate is advisable. The pH of the homogenization buffer should be between 6.5 and 7.5. The molarity of the buffering species should be low enough so that if the pH of the homogenization buffer is not the same as that of the assay buffer, the pH of the final assay mixture is not perturbed. A pH <6.5 will promote denaturation of SeGPX. With most standard tissue homogenization protocols there will be no problems. The usual precautions of keeping the samples chilled and preventing excessive foaming during disruption apply. The special requirements for recovery of particular glutathione peroxidase activities in some tissues are addressed below.

Particulates will cause problems in some assays (certainly in coupled assays) so that some means of clarifying the homogenates prior to assaying may be necessary. SeGPX1-3 and most GSTs behave as soluble proteins, although GPX1 is found in the mitochondrial inner space (up to 25% of the total activity) and may be present in the nucleus (Esworthy et al., 1997). Some SeGPX activity can be recovered from the microsomal fractions. This latter activity tends to be a very small portion of the total activity. GPX4 is generally recovered in the soluble fraction (Maiorino et al., 1990). However, a little GPX4 is found in mitochondria associated with pores in all tissues. In the testes, most of the GPX4 is bound to the outer membrane of the mitochondria (Roveri, et al., 1992). Bound GPX4 can be solubilized with the combination of high salt concentrations (at least 0.1 M) and the use of 0.2% Triton X-100. Mitochondria are also lysed under these conditions, with sonication.

Most glutathione peroxidase activity measurements are made on post-nuclear fractions. There is very little difference in the specific activities obtained for most tissues between the post-mitochondrial fraction and the 100,000 × *g* soluble fraction. However, the use of the post-nuclear fractions from tissues or clarified, detergent extracted tissues can produce significantly lower specific activities.

Reaction mixture

An equal volume of 2× Drabkin's reagent should be included when washed erythrocytes are to be assayed. Drabkin's reagent will convert the hemoglobin to cyanomethemoglobin, which will not react with hydroperoxide. Drabkin's reagent is not necessary with solid tissue preparations or the blood plasma fraction (Paglia and Valentine, 1967).

Sodium azide is included in the assay buffer to eliminate catalase activity with hydrogen peroxide. Azide can be included in the homogenization buffers, provided that catalase activity measurements are not to be performed on the samples. Azide is not needed if hydrogen peroxide will not be used as a substrate. The authors have found it most convenient to avoid using azide in homogenization buffers and to use it in the assay buffers.

The use of detergents should be carefully considered. Detergents can be used in homogenization buffers and may be required to obtain complete recovery of GPX4 and microsomal GST in the soluble fraction of homogenates. If the hydroperoxide substrate is lipid-soluble, most detergents will partially shield lipid-soluble substrates from GPX1-3 and GSTs (Maiorino et al., 1986). Hydroperoxide concentrations may have to be adjusted upward to compensate for this effect and thus maintain linear rates over the time span of an assay. Triton X-100 (<0.2%) is tolerable with assays of most glutathione peroxidase activities, except for the effect on lipid hydroperoxide partitioning. Deoxycholate definitely should not be used on human samples, unless it is to be removed before assay, as it has adverse effects on human SeGPXs (Maiorino et al., 1986; Es-

Table 7.1.3 Troubleshooting Guide to GPX Activity Measurements

Problem	Possible cause	Solution
No activity in blank	A reagent was forgotten	Use a check list until a ritual is established
	A reagent is bad	Keep the working stocks of each reagent separate before and during assays so that reagents can be easily identified.
	GSH gets oxidized in storage or in solution sufficiently to deplete the NADPH before the assay begins	Determine that this is a problem by monitoring the blank as it equilibrates immediately following the addition of all components (all components must be at room temperature and mixed for this to be valid). If the OD drops continuously, the GSH is probably bad. Adding more NADPH can sometimes remedy this problem as a short-term measure, since only a small percentage of the GSH is actually oxidized.
	The NADPH is bad	Store this as the dry powder in aliquots at −20° to −70°C. Be sure that it is the β isomer.
	pH is too low	Some buffers allow drift with aging. Measure pH of buffer, readjust to 7.0, check pH for stability.
	Inhibition of the glutathione reductase (unlikely, but possible)	Diluted glutathione reductase can go bad. The ammonium sulfate suspension of the enzyme is very stable. It is unlikely that the problem is in the commercial preparation, unless it was exposed to heat or left at room temperature for days. The remedy is generally to prepare a new dilution from the commercial stock.
Activity in blank but very little in sample	Sample was not added	Use a check list until a ritual is established
	Sample was diluted too much	Try lower dilution if possible
	Improper sample preparation or handling: e.g., homogenization was too vigorous (heating or foaming occurred); thiol in sample, if present, was oxidized and depleted the NADPH; sample needed thiol for storage but this was omitted (some GPX activities do not preserve well); or buffers in sample have lower pH and greater ionic strength than the assay buffer, resulting in wrong reaction conditions.	Repeat with fresh sample

continued

worthy et al., 1993). For GPX4, the effect is a direct inhibition of activity from all sources (including nonhuman). With human GPX1 and 3, the authors have observed an alteration of substrate range and a significant loss of activity with hydrogen peroxide if the detergent concentration is >0.5 mM. When detergents are used during tissue disruption, GPX1 is exposed to more proteases. Generally, this seems to be limited to the cleavage of the amino terminus without loss of activity. Including EDTA (1 mM) in the buffers will prevent most proteolysis of GPX1 when there are no detergents. The use of EDTA and PMSF (and/or mixtures of other protease inhibitors) will prevent proteolysis when detergents are used.

Stabilizing agents other than protease inhibitors used in protein purification, such as glycerol and some detergents, can be used to stabilize glutathione peroxidase activities and

Table 7.1.3 Troubleshooting Guide to GPX Activity Measurements, continued

Problem	Possible cause	Solution
Activity detected but rate erratic	Poor mixing of assay mix; temperature differences between components	Improper temperature equilibration or poor mixing will cause the rate to be variable. The sample and the diluted GSSG reductase should be kept at ice temperatures. The rest of the components can be kept at room temperature. This will lessen problems
	Particulate present in sample	Recentrifuge the sample or attempt to solubilize the particulate, depending on the goals of the project
	Lamp is bad or other spectrophotometer problems	Service spectrophotometer
Activity detected but reaction terminates very early	Too little NADPH; bad NADPH	Add more fresh NADPH; if this doesn't help open a fresh stock container and prepare new solution
	GSH is oxidized either in assay stock or in samples and has depleted the NADPH	Prepare a new solution from a fresh dry stock
	Too little hydroperoxide added or azide was omitted, allowing catalase to metabolize H_2O_2	Verify H_2O_2 content of commercial stock by OD_{230}. Prepare new buffer and double-check addition of azide.

prevent unwanted aggregates from forming. In dilute solutions, proteins can be added to stabilize SeGPX. However, as with detergents, serum albumin will complex with lipid hydroperoxides and slow down the rate of reduction of these hydroperoxides. Concentrations of serum albumin should be maintained so that in the assay the concentration is <1 mg/ml when lipid hydroperoxide will be used. Reducing agents are often used to stabilize SeGPX activities and thus avoid permanent activity loss that can accompany processing and storage in an open-air environment. Inactivation via this route is fairly slow at ice temperatures immediately after homogenization. Addition of reducing agents can generally be held off until after centrifugation of homogenates is accomplished. If the assays are to be performed immediately, there is often no need to consider the use of reducing agents in the homogenates. Reversible loss of GPX1 activity that is sometimes observed under these circumstances can be eliminated by preincubation of the samples in the assay buffer for 10 min. However, there are some cases where the use of reducing agents in the homogenates or other solutions is necessary. If the sample is to be dialyzed, chromatographed, or, in certain cases, simply stored before assaying (e.g., on ice for a long break or overnight at subzero temperatures), a reducing agent in the buffers or homogenates should be considered. Reducing agents interfere with many protein assays. Therefore, some provision is generally made for protein assays. This could be the use of the TCA-insoluble fraction of the homogenate. Since SeGPX will withstand some period of time in the absence of reducing reagents, samples can be split into portions for protein assays and activity assays after recovery of the soluble fraction from centrifugation.

The use of a reducing agent is recommended when GPX2 is anticipated to be a sizable portion of the activity, even when the immediate assay of the samples is planned. GPX2 is known or is indicated to be present in GI tract tissues, breast tissues, human liver, and many human cancer-derived cell lines of lung, breast, liver, and GI tract origin. Even in this instance, the addition of the reducing agent can be postponed until after a clarification step. The authors have sometimes observed reversible loss of >50% of GPX activity at ice temperatures within a few hours of recovery of post-mitochondrial supernatants of GI tract samples. As opposed to the reactivation of GPX1 by incubation in the assay buffer for 10 min, GPX2 sometimes required >½ hr of exposure to potent reducing agents such as DTT (0.1 mM) before full activity was restored. DTT (0.1 to 1 mM) is effective for

subzero storage of GPX2 activities, provided only one or two freeze-thaw cycles are anticipated, or if dialysis or other steps are confined to <24 hr before fresh DTT is supplied. At 4° to 8°C, oxidation of DTT can promote the inactivation of GPX2. This is largely reversible with addition of more DTT or dialysis against a fresh solution within a 24-hr time interval. Thereafter, the fraction of irreversible inactivation will steadily progress to completion by 48 hr. GSH, at 3 to 5 mM, is the best reducing agent for frozen storage and steps performed at 4°C.

Troubleshooting

Table 7.1.3 provices a guide to troubleshooting the measurement of GPX activity.

Anticipated Results

The variability in the production of glutathione peroxidases, the requirement for selenium in SeGPX production, and the substrate options preclude a definitive statement on anticipated results. Most murine, bovine, ovine, and primate tissue samples will have one to two types of glutathione peroxidase activity in the detectable range. Exotic animal species, uncharacterized minor tissues, and minor cell types within tissues and cell lines, in particular, may defy any preconceptions about the pivotal role of glutathione peroxidase that have been formulated from antioxidant theory. Table 7.1.1 shows values that will be obtained with some recommended control samples as well as the cautionary example of the guinea pig.

Time Considerations

In many cases, samples can be prepared and assayed within one day. If the sample size is very large, it is convenient to process the samples and do sample-content assays on one day, followed by the activity assays on the second day. The need for sample fractionation may increase the time for sample processing up to three days.

Measurement of Glutathione Reductase Activity

Glutathione reductase catalyzes the reduction of glutathione disulfide (GSSG) by NADPH. The product, reduced glutathione (GSH), is essential to the survival of cells of most aerobic organisms. GSH, a thiol, is a major intracellular antioxidant (normally present in cells at a concentration of 1 to 10 mM) that provides protection against hydroperoxides as well as free radicals. GSH is also involved in the inactivation of many toxic and carcinogenic electrophiles of both endogenous and xenobiotic origins through reactions catalyzed by the numerous glutathione transferases (see Chapter 6). As a substrate for glutaredoxin, GSH serves as a reductant in the ribonucleotide reductase–catalyzed biosynthesis of the DNA precursors deoxyribonucleotides. Many other cellular functions are also dependent on the presence of reduced glutathione (Mannervik et al., 1989), and the important biochemical role of glutathione reductase is obvious (Josephy et al., 1997).

Glutathione reductase occurs in all cell types. The spectrophotometric assay (see Basic Protocol) is suitable for measurement of its activity in the cytosol fraction or other particle-free samples, crude or purified.

CONTINUOUS SPECTROPHOTOMETRIC ASSAY OF GLUTATHIONE REDUCTASE

BASIC PROTOCOL

The protocol described below is based on monitoring NADPH oxidation linked to GSSG reduction. NADPH absorbs at 340 nm, and its oxidation is reflected by a decrease in absorbance at this wavelength.

NOTE: To be able to compare results, it is important to perform the reactions at constant temperature. Specific activities given are measured at 30°C.

Materials

Assay buffer: 0.2 M potassium phosphate, pH 7.0/2 mM EDTA (see *APPENDIX 2A* for preparation of potassium phosphate and EDTA stocks)
20 mM GSSG (Boehringer or Sigma) in water, prepared fresh each day
2 mM NADPH (Boehringer or Sigma) in 10 mM Tris·Cl, pH 7.0, prepared fresh each day and kept on ice
Sample to be tested for glutathione reductase activity (see Critical Parameters)

Spectrophotometer (preferably a recording instrument) with thermostat
Spectrophotometer cuvette (transparent at 340 nm, quartz or disposable) with 1-cm pathlength
Water bath (or other temperature-controlling device)

1. Prepare a spectrophotometer with thermostat for kinetic measurements. Set the measurement wavelength to 340 nm. Equilibrate assay buffer to 30°C (e.g., using a water bath).
2. Add the following to a cuvette at 30°C:

   500 µl assay buffer
   50 µl 20 mM GSSG solution
   50 µl 2 mM NADPH solution
   H_2O to give a final volume of 1.00 ml *after* sample is added in step 3.

   The amount of sample that should be added will depend on the range of concentrations and the specific activity of glutathione reductase expected in the sample. For crude cytosolic fractions, try 10 µl.

Contributed by Bengt Mannervik
Current Protocols in Toxicology (1999) 7.2.1-7.2.4

3. Add the enzyme-containing sample to the cuvette to initiate the reaction. Place a piece of Parafilm over cuvette opening, cover Parafilm with finger, and invert cuvette three or four times to mix (do not shake). Immediately place cuvette in spectrophotometer and begin recording. Moniter the reaction for 1 min, or until a 10% decrease in absorbance ($\Delta A = 0.06$) at 340 nm has occurred. Test samples in duplicate or triplicate.

   Optimize activity measurement conditions with respect to assay time and amount of enzyme added (see Critical Parameters and Troubleshooting). The time between addition of sample to start of monitoring the reaction should not exceed 10 sec. Dilute the enzyme sample if the reaction trace is not linear.

4. Between measurements, rinse cuvette with deionized water from a squirt bottle and wipe off outside of cuvette using paper tissue (Kimwipes or equivalent). Alternatively, use a new (disposable) cuvette each time.

5. As controls, also prepare one tube containing all the components listed above except GSSG, and one tube (blank) containing all the components listed except sample (i.e., adjust to correct volume with extra water). Monitor the absorbance at 340 nm of each control.

   The blank is expected to show negligible reduction; the reaction without GSSG may show low levels of reduction involving other physiologically occurring disulfides in the sample (see Background Information).

6. Adjust the values obtained for the samples by subtracting any enzymatic oxidation of NADPH observed in the absence of GSSG from the rates obtained for the samples.

7. Calculate glutathione reductase activity, with a unit of glutathione reductase activity defined as the amount of enzyme that catalyzes the reduction of 1 μmol of GSSG per minute (equivalent to oxidation of 1 μmol of NADPH per minute).

   The enzyme activity is measured in ΔA/time units, where ΔA is the change in absorbance at the chosen wavelength. The time is measured in minutes. The change in absorbance is proportional to the change in NADPH concentration as given by the Lambert-Beer law ($A = \varepsilon lc$; where ε is the molar extinction coefficient of NADPH, l is the pathlength of the cuvette, and c is the concentration of NADPH). Thus, the activity = Δc per time unit = ΔA per time unit divided by εl. In the present case, $\varepsilon = 6.2\ mM^{-1}cm^{-1}$ and $l = 1$ cm.

   IMPORTANT NOTE: *It is crucial that the slopes be obtained from straight lines representing the initial rates of the reactions.*

COMMENTARY

Background Information

Glutathione reductase plays a pivotal role in the biochemistry of the tripeptide glutathione by catalyzing the regeneration of the reduced (thiol) form from its oxidized (disulfide) state (Mannervik et al., 1989). Glutathione disulfide (GSSG) is formed by enzymatic redox reactions in which reduced glutathione (GSH) is used as a reductant—for example, in glutathione peroxidase reactions involving the reduction of organic hydroperoxides (ROOH) as well as hydrogen peroxide (R=H):

$$2\ GSH + ROOH \rightarrow GSSG + ROH + H_2O$$

Other reactions in which GSH is used as a reductant are represented by the reduction of disulfides (RSSR) catalyzed by thioltransferase:

$$2\ GSH + RSSR \rightarrow GSSG + 2\ RSH$$

The available evidence indicates that in most normal cells the major portion of the total glutathione concentration is present in the reduced form (≥95%). Maintenance of this redox state is dependent on the following glutathione reductase–catalyzed reaction and the availability of the reductant NADPH:

$$GSSG + NADPH + H^+ \rightarrow 2\ GSH + NADP^+$$

Glutathione reductase is a dimeric protein composed of identical subunits (Williams, 1991). It contains flavin adenine dinucleotide

as a redox-active prosthetic group that mediates transfer of reducing equivalents from NADPH to a disulfide group of the protein, which then reduces the substrate GSSG. Glutathione reductase from mammalian sources is highly specific for NADPH as the reductant; the activity with NADH is <1% of that with NADPH at physiological pH and ionic strength. Similarly, the specificity for the disulfide substrate is high. Of all the physiologically occurring disulfides tested as substrates, only the mixed disulfide of coenzyme A and GSH gives an activity above a few percent of that obtained with GSSG (Carlberg and Mannervik, 1975). Claims that mixed disulfides of glutathione and hemoglobin or other thiol-containing proteins serve as substrates have not been corroborated (Mannervik and Axelsson, 1975). On the other hand, as with many flavoproteins, glutathione reductase may use artificial electron acceptors as substitutes for the physiological substrate GSSG (Carlberg and Mannervik, 1986). Such "diaphorase activity" involving, for example, aromatic nitro compounds or quinones may interfere with determinations of the normal glutathione reductase activity.

Critical Parameters

Crude cytosol fractions or purified samples of biological tissues can be assayed with the spectrophotometric procedure described, as long as they are optically clear solutions without interfering turbidity. Strong color, such as is found in hemolysates, may interfere with the measurements because of high background absorbance. In general, the assay is robust and not sensitive to the presence of moderate concentrations of salt, detergents, or other additives that may be employed in the preparation of samples for analysis.

Buffer and stock solutions should be prepared in Milli-Q-purified water or equivalent. GSSG stock solution is usually stable for several days at 4°C, but for accurate measurements fresh solutions should be made daily. The NADPH solution should be made fresh daily and kept cold (preferably in an ice bucket). NADPH should be prepared in Tris·Cl buffer, as described, because it is not stable when dissolved in unbuffered water.

In order to obtain reproducible results, care should be taken when pipetting buffer, substrate, and enzyme solutions into the cuvette. Most importantly, the activity is proportional to enzyme concentration in the cuvette, and any error in the volume of enzyme sample added gives a proportional error in activity.

Even if it has been established that the uncatalyzed reaction level is negligible (see Basic Protocol), it is recommended to routinely measure the nonenzymatic reaction rate and use it as an extra check of the assay conditions. If no reaction occurs, the enzyme sample could be added. Any measurable nonenzymatic rate should be subtracted.

NADPH is somewhat unstable, and its stability decreases with pH. The initial absorbance at 340 nm in the assay system should be ~0.6 at 0.1 mM NADPH.

Troubleshooting

The progress curve of the glutathione reductase reaction should be a straight line. This is essential in order to get reliable and reproducible results. If a smoothly bent curve is obtained it is most probably due to addition of too much enzyme-containing sample. Repeat the measurement using smaller amounts of sample until a straight line is obtained. The activity (slope) should be proportional to enzyme concentration in the assay system. A curve that is not linear or smoothly bent may be due to poor mixing of the reactants. Mix thoroughly and repeat the measurement. In general, it is sufficient to follow the reaction for < 10% oxidation of NADPH ($\Delta A < 0.06$).

Inability to reproduce experiments performed previously could also be related to the points listed in the Critical Parameters section. Check substrates, assay buffer, and temperature. Make sure that the correct wavelength is used and that the pipettor works properly.

Table 7.2.1 Cytosolic Specific Activities of Glutathione Reductase

Tissue	Specific activity (μmol/min per mg protein)	Reference
Rat liver	0.10	Carlberg et al., 1981
Calf liver	0.12	Carlberg and Mannervik, 1985
Human erythrocytes	0.004	Worthington and Rosemeyer, 1974
Pig erythrocytes	0.002	Boggaram et al., 1979

Anticipated Results

As pointed out in the Troubleshooting section and Basic Protocol, the progress curve of the glutathione reductase reaction should be a straight line with a negative slope. The more enzyme is added, the steeper the slope of the line should be. Table 7.2.1 gives cytosolic specific activities of glutathione reductase for some representative tissues.

Time Considerations

Many measurements can be performed in 1 day. Preparing buffer and substrate solutions requires ~1 hr. Adding buffer, substrates, and enzyme solution to the cuvette takes 0.5 to 1 min. One measurement normally takes 0.5 to 10 min.

Analysis of Superoxide Dismutase Activity

The superoxide dismutase (SOD) enzymes present unusual challenges to those who wish to quantify their activities. Their substrate, the superoxide radical ($O_2^{\cdot -}$), is quite unstable in the physiological pH range. It reacts rapidly with itself, or dismutates, with a second-order rate constant of ~10^5 $M^{-1}sec^{-1}$:

$$O_2^{\cdot -} + O_2^{\cdot -} + 2H^+ \rightarrow O_2 + H_2O_2$$

Superoxide reacts with SOD, however, with a second-order rate constant of ~2×10^9 M^{-1} sec^{-1}, about 20,000 times faster than it reacts with itself. This rate approaches diffusion limitation, the theoretical maximally efficient rate where every molecular collision leads to fruitful reaction. SOD thus has an enzymatic turnover of ~10^6 reactions per second, one of the highest known. Coupled with the fact that the cytosolic concentration of SOD is greater than the steady-state concentration of its substrate, the overall effect of the enzyme is to lower the steady-state concentration of superoxide in the cell—by a factor of ~50,000 in liver cells, for example. It should be noted that the rate of superoxide dismutation, in either the presence or the absence of the enzyme, must equal the rate of superoxide generation, as dictated by the steady-state assumption. This also means that once steady state is reached, the presence of SOD has no effect on the rate of H_2O_2 accumulation or the amount produced (which are governed by the rate of superoxide generation)—a concept that eludes many, and has led to the introduction of a certain amount of confusion in the literature by those who erroneously believe that more SOD should, somehow, lead to the production of more H_2O_2.

The standard international unit (IU) definition—1 μmol/min of product at a saturating concentration of substrate—cannot be applied to SOD. In addition to the problem of substrate instability due to nonenzymatic dismutation described above, the K_M for superoxide has been estimated to be 3.5 mM, a concentration that cannot even be approached at physiological pH. Thus, most practical assays of SOD are indirect, based on competition for superoxide between SOD and some indicator molecule that reacts avidly with the radical to produce a measurable change in absorbance. The two most widely used indicators are cytochrome *c* and nitroblue tetrazolium. Because of the arbitrary nature of SOD assays, they have cross-laboratory meaning only when compared to an accepted standard. When superoxide dismutase was first described, a set of standard assay conditions was also described, and a standard unit of activity was defined under these conditions (McCord and Fridovich, 1969; see Critical Parameters for further discussion). This standard assay is presented below (see Basic Protocol 1). Since mammals produce three distinct SODs—a cytosolic Cu,Zn-SOD, a mitochondrial Mn-SOD, and a secreted extracellular Cu,Zn-SOD—variations on the assay have been developed that are useful in distinguishing these various forms of SOD; these procedures are also included (see Alternate Protocol and see Basic Protocol 2).

ASSAY OF TOTAL SOD ACTIVITY BY THE XANTHINE OXIDASE/XANTHINE/ CYTOCHROME *c* METHOD

BASIC PROTOCOL 1

This procedure describes a spectrophotometric (visible-light) assay procedure for quantifying the activity of any solution or cell extract containing SOD, or the total activity due to any mixture of SODs. The results will be in standard, or McCord-Fridovich, units.

Materials

SOD assay cocktail (see recipe)
SOD-containing sample
Xanthine oxidase solution (see recipe)

Contributed by Joe M. McCord
Current Protocols in Toxicology (1999) 7.3.1-7.3.9

Recording, visible-wavelength spectrophotometer with thermostat set at 25°C
3-ml cuvettes

1. Place 3 ml SOD assay cocktail in a cuvette. Set the spectrophotometer reading at 550 nm to zero.
2. Add ~10 µl xanthine oxidase solution (~3 mIU) and record the rate of increase in absorbance (*A*) at 550 nm. The rate should be ~0.02 *A*/min, but it need not be exactly this value. Add more or less xanthine oxidase, if necessary, to obtain a rate in the range of 0.015 to 0.025 *A*/min. This is the control rate.

   Xanthine oxidase catalyzes the reaction of xanthine and oxygen, generating superoxide at ~1 µM/min. It will efficiently react with ferricytochrome c, reducing it to ferrocytochrome c and causing an increase in absorbance at 550 nm with a molar extinction coefficient increase of 20,000 cm^{-1} (from 9,000 to 29,000 cm^{-1}).

3. Dilute an aliquot of enzyme sample (preferably 10 to 50 µl) containing ~1 standard unit of SOD in SOD assay cocktail to 3 ml, then repeat the assay, using the amount of xanthine oxidase determined in step 2.

   This time the rate of increase in absorbance at 550 nm will be lower—under these assay conditions, the amount of SOD producing 50% inhibition of reduction of ferricytochrome c equals 1 standard unit of activity. Percent inhibition is calculated as follows:

   % inhibition = [(control rate - sample rate)/control rate] × 100.

   If the amount of inhibition produced is more than ~60% or less than ~40%, the assay should be repeated with an adjusted volume of sample until inhibition is achieved in the 40% to 60% range, where the slope of the inhibition curve (see Fig. 7.3.2A) is neither too steep nor too flat. This will produce more accurate calculations.

   This time the rate of cytochrome c reduction is lower because SOD competes with 10 µM ferricytochrome c for available superoxide. If the level of inhibition is exactly 50%, the amount of SOD is defined as a standard unit and is ~0.3 µg of mammalian Cu,Zn-SOD under these assay conditions.

4. Calculate the number of units of SOD in the sample assay using the formula:

   units = % inhibition/(100 − % inhibition).

ALTERNATE PROTOCOL

ASSESSMENT OF RELATIVE CONTRIBUTIONS OF Cu,Zn-SOD AND Mn-SOD TO TOTAL SOD ACTIVITY IN CELL EXTRACTS

Mammalian organisms have three genes that encode SODs. In most tissues, the predominant SOD is the cytosolic Cu,Zn-SOD. Mitochondria contain a Mn-SOD that is quite inducible and may also be found in the cytosol in certain species and under certain circumstances. Some tissues and extracellular fluids may contain a third SOD—extracellular SOD, or EC-SOD. EC-SOD is also a Cu,Zn-SOD and is encoded by a gene that is clearly related to the cytosolic Cu,Zn-SOD. The assay described in Basic Protocol 1 works equally well for any SOD and will simply reflect total SOD activity if a mixture of enzymes is assayed. (All SODs have roughly the same specific activity of 3000 to 5000 standard units per milligram protein.) Often, however, it may be desirable to assay the SODs separately. The Cu,Zn-SODs may be inhibited by a variety of agents including cyanide, H_2O_2, or diethyldithiocarbamate. Most methods therefore rely on assaying total activity in a sample, then reassaying under conditions where the Cu,Zn-SOD will be inhibited and only the Mn-SOD activity remains. The addition of 3 mM sodium cyanide to the assay is one simple approach that has been widely used, but this method is far from ideal. The cyanide does not cause 100% inhibition, and interferes somewhat with the xanthine oxidase/cytochrome *c* reaction. The following protocol will give more reliable analysis of Mn-SOD, and more complete inactivation of Cu,Zn-SOD.

Additional Materials (also see Basic Protocol 1)

SOD-containing sample with known total activity (see Basic Protocol 1)
25 mM sodium diethyldithiocarbamate
25 mM H_2O_2

1. To an aliquot of sample of known total SOD activity, add 1 vol of 25 mM diethyldithiocarbamate per 24 vol of sample (bringing the final concentration of diethyldithiocarbamate in the sample to 1 mM). Incubate 1 hr at 37°C.

   Diethyldithiocarbamate causes a rapid and reversible inhibition of Cu,Zn-SODs, followed by a slower, irreversible inactivation. Mn-SODs are not affected.

2. Add 1 vol of 25 mM H_2O_2 to the 25 vol of mixture, and continue to incubate for an additional 15 min at 37°C.

   Diethyldithiocarbamate can interfere with the xanthine oxidase/cytochrome c assay, so excess reagent is neutralized by reaction with equimolar H_2O_2 prior to the assay.

3. Assay the sample for SOD activity (see Basic Protocol 1, steps 2 to 4); the SOD activity observed is due to Mn-SOD.

4. Multiply the units observed by 1.08 to correct for the dilution of sample by the reagents added above, then calculate Cu,Zn-SOD activity by subtracting Mn-SOD activity from total activity.

QUANTITATIVE ASSAY OF SODs BY ACTIVITY STAINING OF ELECTROPHORETIC GELS

BASIC PROTOCOL 2

An alternative and very useful technique for the differential assay of Cu,Zn- and Mn-SODs makes use of an activity stain applicable to thin-film agarose or native polyacrylamide electrophoretic gels. Qualitative results are easily obtained, and with a little more care and effort surprisingly good quantitative results may be achieved. The method relies on the photochemical generation of superoxide radical throughout the gel, and its reaction with a soluble, pale-yellow indicator molecule, nitroblue tetrazolium chloride (NBT). As NBT reacts with superoxide, an insoluble, intensely purple precipitate called formazan is formed. This compound stains the gel uniformly purple, except at bands of SOD activity, which remain colorless due to scavenging of the radical.

Materials

SOD-containing sample with known total activity (see Basic Protocol 1)
Gel staining solutions A and B (see recipes)

Thin-film agarose gels (Universal Gel/8, Ciba-Corning Diagnostics) *or* native polyacrylamide slab gels (*APPENDIX 3*), 1-mm thick
Small rectangular dish for soaking the gel in a minimal volume of staining solution
Fluorescent desk lamp for illuminating and developing the gel
Camera, densitometer, or other device(s) for recording band intensity

Additional reagents and equipment for native PAGE (*APPENDIX 3*)

1. Prepare a thin-film agarose gel (according to manufacturer's instructions) or a native polyacrylamide slab gel (see *APPENDIX 3*). Load aliquots of sample, each containing 0.2 to 1.0 standard units SOD, into individual wells of the gel. If the gel is to be analyzed quantitatively, load at least four calibration standards containing known and varying amounts of a purified SOD, from 0.2 to 0.5 standard units, into individual wells of the gel.

The calibration standards will be used in the preparation of a standard calibration curve for each gel run. Because of the variation in staining from one gel to the next, standards must generally be included on each gel if quantification is to be expected.

2. Perform gel electrophoresis under native conditions using standard procedures (follow manufacturer's instructions for thin-film agarose gels and *APPENDIX 3* for native polyacrylamide gels).
3. When the electrophoresis is completed, mix together in subdued light 40 ml gel staining solution A and 2 ml gel staining solution B. Place this with the gel in the staining dish, and incubate in the dark for 3 to 5 min.

   Once the staining solutions are mixed together, do not expose to bright light. The solution may be reused to soak subsequent gels during the course of several days but should be discarded when it begins to turn purple.
4. Remove the gel from the staining solution, draining excess solution from its surface, and place the gel under a fluorescent desk lamp, ~6 in. (15 cm) from the tubes, so that the gel receives even illumination. Expose until the gel is uniformly purple, and the bands of SOD activity are clearly visible. This may take 10 to 15 min.

   The thin-film agarose gels have a convenient plastic backing, which makes handling easy. Polyacrylamide slab gels may be placed on a glass plate and covered with plastic film, if desired, to prevent drying during exposure.
5. When the desired color development has been achieved, remove gel from the light source and soak in water for 10 or 15 min to remove unreacted staining reagents as well as buffer salts. Photograph and/or scan the gel, wet or dried, as desired.

   Rough quantification may be achieved by visually comparing the intensity of bands of unknown samples to the known standards on the same gel. For more precise analysis, the lanes can be scanned and the areas under the curves integrated using a densitometer or a digital imaging program such as NIH Image or Matrix (QuantiVison Canada; Fig. 7.3.1). The Cu,Zn- and Mn-SODs are readily separated by electrophoresis and may be quantified

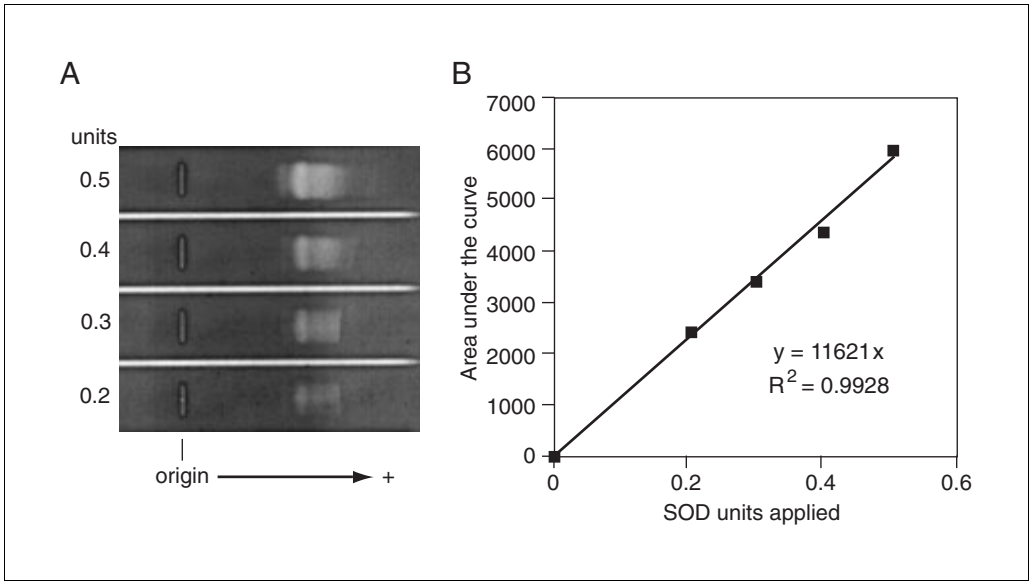

Figure 7.3.1 (**A**) A thin-film agarose gel (Universal Gel/8, Ciba-Corning Diagnostics) loaded with samples containing from 0.2 to 0.5 standard units of recombinant human Cu,Zn-SOD. The gel was electrophoresed in 0.02 M Tris/glycine buffer, pH 8.45, for 30 min at 200 V. The family of closely spaced bands reflects charge isomers, and is characteristic of the Cu,Zn-SODs. The gel was stained as described in Basic Protocol 2 and the dried gel digitally scanned (not shown) and analyzed using Matrix software (QuantiVison Canada). (**B**) The integrated area under the curve from each lane is plotted versus the amount of SOD applied.

individually by this technique. Often, the Mn-SOD is induced while the Cu,Zn-SOD level remains constant. When this is the case, the Cu,Zn-SOD may be used as an internal standard. Changes in Mn-SOD may then be reported relative to Cu,Zn-SOD, eliminating the need for external standards.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytochrome c stock solution, 1 mM

Prepare 1 mM ferricytochrome *c* (Sigma; from horse heart, minimum 95%) in 0.05 M potassium phosphate buffer, pH 7.8 (*APPENDIX 2A*). Store frozen at −20°C (stable indefinitely).

Gel staining solutions

Gel staining solution A:
0.05 M potassium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
1 mM EDTA
0.25 mM NBT (nitroblue tetrazolium chloride)
Gel staining solution B:
0.5 mM riboflavin in water

Stock solutions of NBT and riboflavin may be used. The gel staining solutions can be stored for days in the dark at room temperature.

SOD assay cocktail

To 141 ml of 0.05 potassium phosphate buffer, pH 7.8 (*APPENDIX 2A*)/0.1 mM EDTA, add 7.5 ml of 1 mM xanthine stock solution (see recipe). Add 1.5 ml of 1 mM cytochrome *c* solution (see recipe). Check the cytochrome *c* concentration by placing an aliquot in a 1-cm cuvette and measuring the absorbance at 550 nm. Add a few crystals of solid sodium dithionite (a strong reducing agent), mix, and re-measure the absorbance. It should increase by exactly 0.20 A. If it does not, correct the cytochrome *c* concentration by adding more stock solution or diluting with sodium phosphate/xanthine mixture, as necessary. Store up to several days at 4°C or indefinitely frozen at −20°C.

Prepare an amount of cocktail appropriate for the anticipated number of assays; 150 ml is sufficient for 50 assays. Final concentrations are 0.05 M xanthine and 10 μM ferricytochrome c.

IMPORTANT NOTE: *It is critical that the cocktail contain exactly 10 μM ferricytochrome c, as this is what SOD competes against for superoxide. Any variation in this concentration will change the amount of inhibition produced by a given quantity of SOD, rendering the assay nonstandard.*

Xanthine oxidase solution

Dissolve purified bovine buttermilk xanthine oxidase (Sigma, grade III, or equivalent), at ~0.3 IU/ml in 0.05 M potassium phosphate buffer, pH 7.8 (*APPENDIX 2A*)/0.1 mM EDTA. Store frozen at −20°C.

This solution will lose some activity with repeated freezing and thawing, but the amount of xanthine oxidase added per assay is not critical, as long as it is constant between samples and their controls.

Xanthine stock solution

Prepare 1 mM xanthine (sodium salt) in 0.05 M potassium phosphate buffer, pH 7.8 (*APPENDIX 2A*). Heat to near boiling to assure complete dissolution (this concentration is near the solubility limit of xanthine). If desired, store frozen at −20°C in aliquots for future use; reheat after thawing to redissolve the xanthine prior to use.

COMMENTARY

Background Information

The metabolism of molecular oxygen is handled largely by cytochrome oxidase, the terminal oxidase in mitochondrial electron transport, which produces only H_2O as its product. From 2% to 5% of the oxygen animals inspire, however, is reduced by other pathways by one or two electrons, producing $O_2^{\cdot -}$ and H_2O_2. These cytotoxic, partially reduced forms of oxygen are produced not only by normal metabolism (resting myocardium makes superoxide at ~0.1 mM/min) but also in large amounts under pathological circumstances: by the NADPH oxidase of inflammatory cells and by injured mitochondria in post-ischemic tissues.

Because these partially reduced forms of oxygen are cytotoxic, protective antioxidant enzymes exist to convert them to water, including superoxide dismutases (SODs), catalase, and glutathione peroxidases. SOD catalyzes the reaction:

$$O_2^{\cdot -} + O_2^{\cdot -} + 2H^+ \rightarrow H_2O_2 + O_2$$

Catalase catalyzes an analogous reaction:

$$H_2O_2 + H_2O_2 \rightarrow O_2 + 2H_2O$$

Using reduced glutathione as the reducing agent, glutathione peroxidases also convert H_2O_2 to water.

Superoxide dismutases were discovered by McCord and Fridovich in 1969. The first SOD described was a cuprozinc enzyme from bovine red cells, but other members of this ubiquitous family of enzymes were quickly identified. A manganese-containing enzyme (Keele et al., 1970) and later an iron-containing enzyme (Yost and Fridovich, 1973) were isolated from *Escherichia coli*. The manganese enzyme was then found in mitochondria (Weisiger and Fridovich, 1973). Mammals possess a second cuprozinc SOD, extracellular SOD, that is secreted into extracellular fluids where it binds to cell surfaces and to components of the extracellular matrix (Marklund, 1982) and can be assayed like any other SOD. It may be separated from other SODs on the basis of its ability to bind to a column containing heparin-agarose (McCord et al., 1994).

Critical Parameters

The unique features of the reaction catalyzed by SOD dictate a very unconventional assay. Rather than being able to supply the enzyme with a saturating amount of substrate, it is necessary to continuously generate this unstable substrate in the reaction mixture where it accumulates only to levels that are perhaps as much as five orders of magnitude below its K_M value. The basis for measuring SOD activity then depends upon its ability to compete equally with a known "standard" reaction, in which this superoxide reacts with an indicator molecule, ferricytochrome *c*, under specified conditions of pH, ionic strength, temperature, and cytochrome *c* concentration. When the "control rate" is determined, essentially 100% of the superoxide is scavenged by the cytochrome *c* present. Reaction with cytochrome *c* is greatly favored over spontaneous dismutation, which would occur in the absence of an efficient scavenger molecule. The rate of disappearance of superoxide via reaction with cytochrome *c* ($R_{\text{cyt } c}$) is represented by the equation:

$$R_{\text{cyt } c} = k_{\text{cyt } c} [O_2^{\cdot -}] [\text{cytochrome } c],$$

where $k_{\text{cyt } c}$ is the rate constant for the reaction of cytochrome *c* with $O_2^{\cdot -}$. The value of this rate constant is ~6×10^5 $M^{-1}sec^{-1}$ at pH 7.8, 25°C (Simic et al., 1975). When 1 unit of SOD is present in the assay, the rate of disappearance of superoxide via catalyzed dismutation (R_{SOD}) is represented by the equation:

$$R_{SOD} = k_{SOD} [O_2^{\cdot -}] [SOD],$$

where k_{SOD} is the rate constant for the reaction of SOD with $O_2^{\cdot -}$. The value of this rate constant is ~2×10^9 $M^{-1}sec^{-1}$ at pH 7.8, 25°C for the cytosolic cuprozinc enzymes (Klug et al., 1972). When the rate of the indicator reaction is reduced by 50% (i.e., when 1 standard unit of SOD is present), the two rates by which superoxide disappears are equal:

$$k_{SOD} [O_2^{\cdot -}] [SOD] = k_{\text{cyt } c} [O_2^{\cdot -}] [\text{Cyt } c]$$

and

$$[SOD] = k_{\text{cyt } c} [\text{cytochrome } c]/k_{SOD} = 3 \times 10^{-9} \text{ M}$$

Note that the standard unit of SOD is a *concentration*, not an amount of enzyme. When the volume of the standard assay is defined as 3 ml, then the amount of a standard unit becomes 0.3 µg (using the molecular weight of 32,000 for bovine Cu,Zn-SOD). Hence, it is critical to take into account the volume of the assay reaction. If the assay were conducted with 1 ml of cocktail, 50% inhibition would be achieved at the same concentration of SOD, but the amount of enzyme added to the cuvette would be only 0.1 µg. This nonstandard unit may be converted to standard unit by simply

dividing the result by 3. Note also that the concentration of superoxide does not appear in the final equation, meaning that the unit observed depends only on the concentration of cytochrome *c*, and not on the steady-state concentration of $O_2^{\cdot -}$. Hence, for accurate analysis it is important to verify precisely the ferricytochrome *c* concentration, but the amount of xanthine oxidase added is not critical.

Similarly, the sensitivity of the standard assay changes if the pH is varied from 7.8. At pH 10, the rate constant for the reaction of $O_2^{\cdot -}$ with cytochrome *c* decreases by about an order of magnitude. The rate constant for the reaction of $O_2^{\cdot -}$ with bovine Cu,Zn-SOD, however, hardly changes at all. (The rate constant for the reaction of $O_2^{\cdot -}$ with human Mn-SOD decreases by a factor of five at pH 10.) Accordingly, if the assay is performed in a 3-ml reaction volume at pH 10, a unit of bovine Cu,Zn-SOD activity appears to be about one-tenth the "standard unit," or ~0.03 µg. Because different SODs show different effects of pH on their activities, assaying at two different pHs has been used to determine their relative contributions in a mixture (Crapo et al., 1978).

Another alteration that can be made in the assay is to substitute a different reactive indicator (against which SOD competes for superoxide) for cytochrome *c*. For example, NBT, which is used here for the gel activity stain, may also be used in solution.

IMPORTANT NOTE: An investigator may find it useful to change some of the above parameters to create modified assay conditions appropriate for specific applications. It is *crucial*, however, that any such nonstandard assay be compared to the standard assay to determine a conversion factor, and that results be published in equivalent standard units. There are numerous reports in the literature that report SOD activity only in arbitrary nonstandard units and that therefore cannot, unfortunately, be compared to studies performed in other laboratories.

A calibration curve prepared by plotting percent inhibition versus standard units of SOD will be a rectangular hyperbola, as shown in Figure 7.3.2A. Rectangular hyperbolae are linearized in double-reciprocal plots, as shown in Figure 7.3.2B. Here it may be seen that the *y* intercept equals 0.01. That is, as SOD concentration approaches infinity, the inhibition will approach 100%. The mathematical formula for a rectangular hyperbola may be conveniently rearranged as shown to allow easy calculation of units from percent inhibition when the amount of inhibition observed is not exactly 50%.

The application of a modified version of the SOD assay to agarose or acrylamide gels is a widely used technique that can give surprisingly quantitative results. Figure 7.3.1A shows a thin-film agarose gel that was stained using

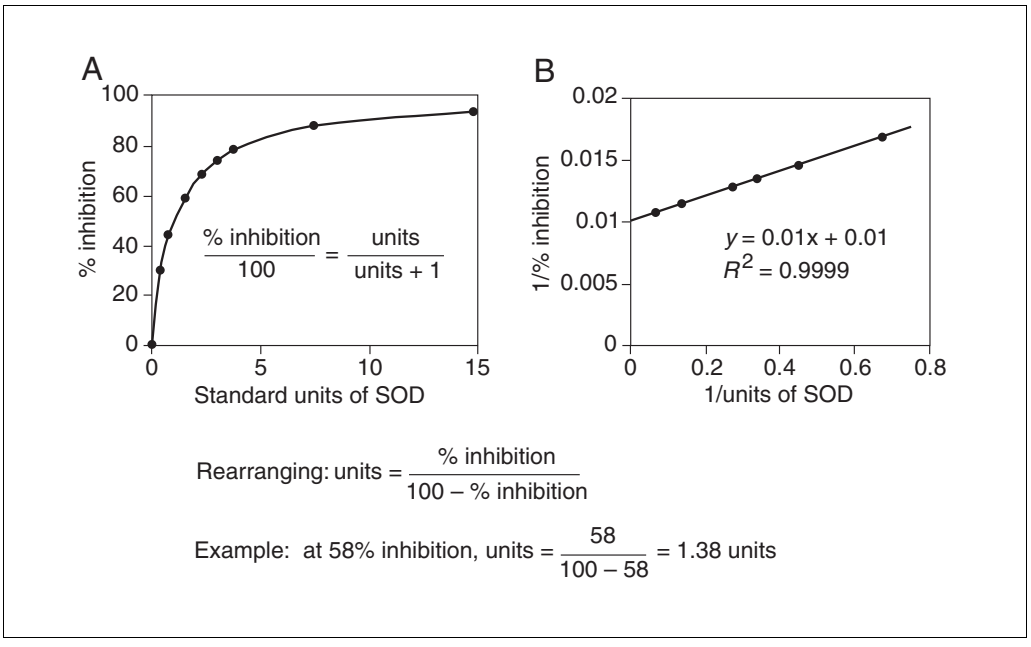

Figure 7.3.2 Calibration curves showing the relationship between units of SOD and percent inhibition of the standard assay. Purified bovine Cu,Zn-SOD was assayed under standard assay conditions to obtain the data shown. (**A**) A rectangular hyperbolic calibrating curve. (**B**) A linear double-reciprocal calibrating curve.

the technique described in Basic Protocol 2. SOD samples varied from 0.2 to 0.5 standard units per lane (60 to 150 ng of purified SOD). In this range, the values of integrated areas (Fig. 7.3.1B) under the scanned curves proved to be remarkably linear when plotted against the amount of SOD applied, even though there are theoretical reasons that the relationship should not be a linear one. In any event, the technique can provide quite quantitative results, provided that standards are run on the same gel as the unknowns and that the unknowns fall within the range of the standards' values. Because the Cu,Zn- and Mn-SODs are readily separated with this system, it is also useful and accurate for determining their relative contributions in tissue extracts that contain both types of enzymes.

Troubleshooting

All SOD assays must be interpreted cautiously, and care must be taken to include all necessary controls, because the assays are subject to the effects of a number of interfering substances. The ability to reduce ferricytochrome *c* is certainly not unique to superoxide; hence, the presence of other reducing agents in biological fluids and tissue extracts is always a concern. In Basic Protocol 1, step 3, it is often necessary, after adding the sample to the cocktail, to record a rate of absorbance change at 550 nm *before* adding xanthine oxidase. If low-molecular-weight substances are present that are capable of reducing cytochrome *c* (enzymatically or nonenzymatically), such a rate will be seen. If this rate is slow relative to the control rate (in the presence of xanthine oxidase but the absence of SOD), and if it continues linearly for several minutes, it may be noted and subtracted from all subsequent rates containing that amount of sample. Occasionally the rate will be rapid but short-lived. Here the sample may be incubated with cocktail until this background rate subsides. If ≤10% of the cytochrome *c* is reduced, one may then proceed normally. If the level of cytochrome *c* reduction is greater, the reducing agents present in the samples must be removed by dialysis or gel filtration before the samples may be accurately assayed.

Another common interference is the reoxidation of ferrocytochrome *c* by enzymes such as cytochrome oxidase, cytochrome *c* peroxidase, or lactoperoxidase. The mitochondrial cytochrome oxidase may appear to be SOD activity—instead of preventing the reduction of the cytochrome, cytochrome oxidase promptly reoxidizes cytochrome *c* using molecular oxygen as its other substrate. Fortunately, cytochrome oxidase is very sensitive to inhibition by cyanide. The addition of 10 μM sodium cyanide to the reaction mixture will eliminate interference by cytochrome oxidase without appreciably inhibiting the Cu,Zn-SODs (which requires ~3 mM; see Alternate Protocol). (Solutions of sodium cyanide should be prepared with appropriate caution, and should be freshly prepared.) Impure xanthine oxidase preparations sometimes contain an enzyme called lactoperoxidase, which can catalyze the oxidation of ferrocytochrome *c* by H_2O_2. Because there is no H_2O_2 in the assay initially, lactoperoxidase has no effect on initial rates. As the xanthine oxidase reaction progresses, however, H_2O_2 accumulates, and the reoxidation of cytochrome *c* becomes faster and faster, eventually overcoming the rate of reduction. The often surprising effect is that the change in absorbance slows, stops, and reverses, picking up speed in the negative direction until all the cytochrome is again oxidized! Purifying one's own xanthine oxidase from raw cream, using the method of Waud and Rajagopalan (Waud et al., 1975), is the best solution to this problem. Alternatively, one can try adding catalase to the assay mixture (~200 IU; Sigma, from bovine liver, crystalline suspension in water). This may effectively eliminate H_2O_2 as it is produced by xanthine oxidase, preventing its use by contaminating peroxidases.

Literally scores of SOD assay methods have been published. Many are variations on the themes described here, specially modified for particular applications, for automation, or for increased sensitivity. Others are quite novel and different. In principal, virtually any process that is superoxide dependent may be configured to serve as an assay for SOD.

Anticipated Results

Accuracy and reproducibility using Basic Protocol 1 should be well within ±5%. Because of additional steps involved in Alternate Protocol and Basic Protocol 2, variability may be somewhat higher with those assays. Likewise, variability will increase if interference with the assay, such as the presence of low-molecular-weight reductants which require correction or removal, is encountered.

Time Considerations

Once all required solutions are in hand, an unknown sample of SOD can be assayed by Basic Protocol 1, in duplicate, with duplicate

control rates, in 30 to 40 min. The Alternate Protocol, because of the incubation times, will require 1.5 to 2 hr. A thin-film agarose gel can be loaded, run, and stained according to Basic Protocol 2 in little more than 1 hr.

Measurement of Thioredoxin and Thioredoxin Reductase

The thioredoxin system—i.e., thioredoxin (Trx), thioredoxin reductase (TrxR), and NADPH—is ubiquitous, providing reducing equivalents to essential biosynthetic enzymes like ribonucleotide reductase, and it is critical for cellular redox regulation, control of oxidative stress, and protection against oxidative damage. In recent years, particularly, the mammalian thioredoxin system has been the subject of rapidly increasing interest due to discoveries of novel functions of Trx in mammalian organisms, the disclosure that TrxR contains a catalytically-active selenocysteine residue, and identification of several isoenzymes of both Trx and TrxR (see Background Information).

Two functional properties characterize the thioredoxin family of proteins: (1) reduced thioredoxin with a an active site dithiol [Trx-$(SH)_2$] catalyzes protein disulfide reductions, and (2) oxidized thioredoxin with an active site disulfide (Trx-S_2) is reduced by thioredoxin reductase, which acquires electrons from NADPH. This is illustrated in the following reactions:

$$\mathrm{Trx-(SH)_2 + protein-S_2 \rightleftharpoons Trx-S_2 + protein-(SH)_2}$$

$$\mathrm{NADPH + H^+ + Trx-S_2 \overset{TrxR}{\rightleftharpoons} NADP^+ + Trx-(SH)_2}$$

TrxR isoenzymes from higher organisms are larger and fundamentally different from TrxR found in bacteria, yeast, or plant cells (see Commentary for further discussion). Of importance for the protocols in this unit is that the smaller TrxR enzymes of lower organisms are species-specific and usually accept only the homologous Trx as substrate, whereas the mammalian type of enzyme reduces Trx from many different organisms and also a range of other substrates. The protocols provided are used for measurement of Trx and TrxR—either measurement of total enzyme activity in biological samples or that of purified Trx or TrxR. Basic Protocols 1 and 2 and the Alternate Protocol describe specific assays based upon the reduction of Trx by TrxR, coupled with reduction of insulin disulfides by Trx. In the first assay (see Basic Protocol 1) the user continuously follows the reaction spectrophotometrically; this is preferable for use with purified enzymes, whereas the second (see Alternate Protocol) describes a more sensitive end-point assay that can be used with small amounts of enzyme or with complex samples, such as biological extracts. Another protocol describes direct measurement of DTNB reduction by TrxR (see Basic Protocol 2), a standard assay for TrxR upon which the enzyme unit is defined. The final protocol describes a method to directly analyze Trx-catalyzed protein disulfide reduction by dithiothreitol (DTT), without coupling to TrxR (see Basic Protocol 3).

SPECTROPHOTOMETRIC INSULIN ASSAY FOR MEASUREMENT OF ENZYMATIC ACTIVITY OF PURIFIED THIOREDOXINS OR THIOREDOXIN REDUCTASES

BASIC PROTOCOL 1

The thioredoxin reactions are coupled in the following protocol, using insulin as the protein substrate, since thioredoxin is rapidly oxidized by the disulfides of insulin. This assay can be used as a basic method for determining the activity of either thioredoxin or thioredoxin reductase by using a relative excess of one of the proteins.

Contributed by Elias S.J. Arnér and Arne Holmgren

Current Protocols in Toxicology (2000) 7.4.1-7.4.14

The assay is performed at room temperature (20°C ± 2°C) using the following conditions: 50 mM Tris·Cl/2 mM EDTA, pH 7.5 (TE buffer), 160 µM (1 mg/ml) insulin, and 150 µM NADPH.

NOTE: Inclusion of EDTA is necessary due to inhibition of TrxR and Trx by heavy metal ions. Insulin, however, should be hexameric zinc-containing insulin and is therefore prepared in a buffer without EDTA, as described below.

Materials

1.6 mM insulin (see recipe) in Tris·Cl, pH 7.5
50 mM NADPH (see recipe)
TE buffer, pH 7.5: 50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*) containing 2 mM EDTA
Pure control thioredoxin reductase (TrxR; IMCO)
Pure control thioredoxin (Trx; IMCO)
Protein sample to be assayed for Trx or TrxR activity
Double-beam spectrophotometer with semimicro quartz cuvettes

NOTE: Wild-type human Trx has a pronounced tendency to loose activity and aggregate due to oxidation of structural cysteine residues upon storage and freezing-thawing in air-containing buffers. This affects the assay and can be overcome by reducing the Trx sample with DTT. The *E. coli* and mutant human C62S/C73S Trx are however preferred for the assay since these thioredoxins do not have the tendency to aggregate due to oxidation and are stable upon storage.

1. Make a master mixture as follows (enough for 15 samples):

   825 µl 1.6 mM insulin (160 µM final)
   25 µl 50 mM NADPH (150 µM final)
   4650 µl TE buffer, pH 7.5
   Total volume, 5500 µl.

2a. *For measurement of Trx activity in a purified protein of interest:* Mix the following components:

   333 µl master mixture (from step 1)
   (157 – *x*) µl TE buffer, pH 7.5 (where *x* is volume of protein or Trx standard added)
   10 µl 3.75 µM pure control TrxR (~75 nM final)
   x µl purified protein or Trx standard (usually to give 0 to 5 µM Trx final)
   Total volume, 500 µl.

   Immediately after addition of the protein to be assayed for Trx activity, or the Trx standard, mix the contents of the cuvette and follow consumption of NADPH as decrease of absorbance at 340 nm, using a sample without addition of Trx as reference cuvette. Prepare a standard curve using pure control Trx (0 to 5 µM; added as ~100 µM working dilution in TE buffer, pH 7.5) for comparison of activity.

   The pure control Trx should preferably be from the homologous organism; alternatively E coli Trx or the mutant human C62S/C73S Trx may be used.

2b. *For measurement of TrxR activity in a purified protein of interest:* Mix the following components:

   333 µl master mixture (from step 1)
   (67 – *x*) µl TE buffer, pH 7.5 (where *x* is the volume of sample added)
   100 µl pure control Trx (~20 µM final)

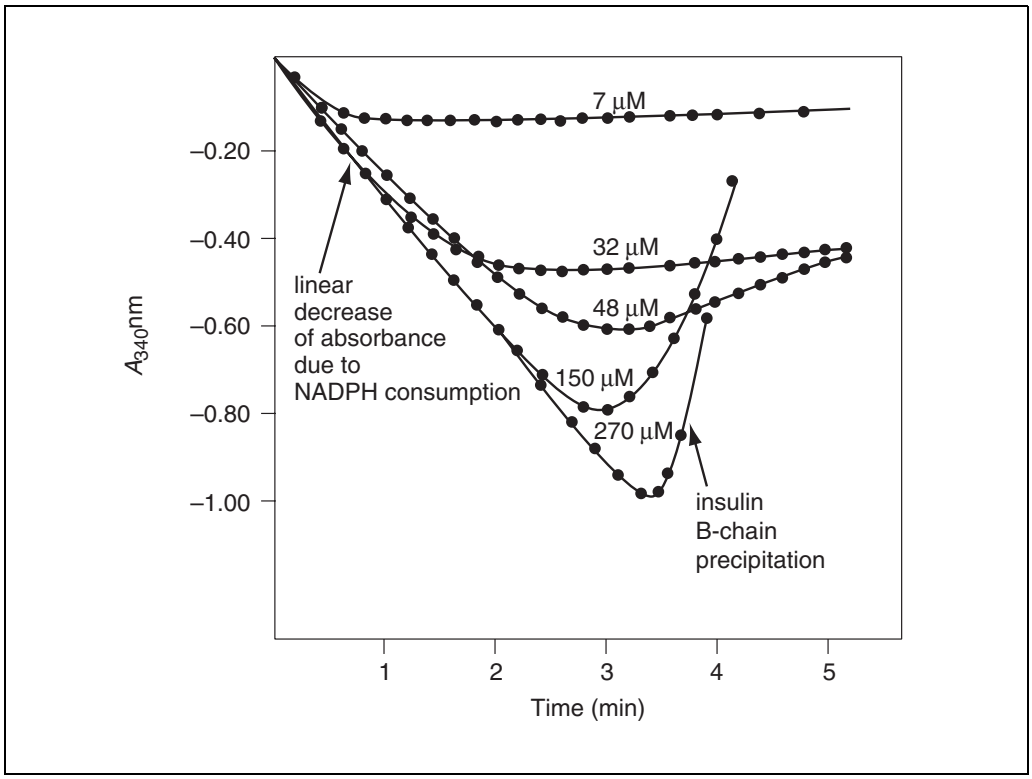

Figure 7.4.1 The spectrophotometric insulin assay. NADPH consumption is determined from the decrease of absorbance at 340 nm, during the initial linear phase. Subsequently, the absorbance increases, which is due to precipitation of reduced insulin B chains. The effects of varying insulin concentration is also shown in the figure (insulin included at 7 μM, 32 μM, 48 μM, 150 μM, and 270 μM, as shown) in an assay with 4.0 μM *E. coli* Trx, 400 μM NADPH, and 100 nM *E. coli* TrxR at pH 7.0. Adapted from Holmgren (1979a).

x μl purified protein or TrxR standard (usually to give TrxR activity equivalent to 0 to 10 nM pure TrxR)
Total volume, 500 μl.

Immediately after addition of the protein to be assayed for TrxR activity, or the TrxR standard, mix the contents of the cuvettes and then follow consumption of NADPH as decrease of absorbance at 340 nm, using a sample without addition of TrxR as reference cuvette. Prepare a standard curve using pure control TrxR [0 to 10 nM; added from 1 U/ml working dilution (250 nM for the mammalian enzyme), freshly prepared in TE buffer, pH 7.5] for comparison of activity.

The pure control TrxR should preferably be from the homologous organism; alternatively, mammalian TrxR may be used at a dilution of ~1 U/ml (~250 nM for the mammalian enzyme). For definition of units, see Basic Protocol 2.

3. Calculate the activity using the extinction coefficient of NADPH at 340 nm, i.e., 6200 $M^{-1}cm^{-1}$:

$$\text{turnover } (\text{min}^{-1}) = \frac{\text{linear initial rate of decrease at 340 nm}}{6200 \times (\text{enzyme concentration [M] in cuvette})}$$

Illustrative curves from assays similar to those described in steps 2a or 2b are shown in Figure 7.4.1, also illustrating the influence of increasing insulin concentrations. With the lower insulin concentrations, the reaction stops after the disulfides of insulin have been reduced (this may also be used to record the number of disulfides reduced in any protein,

by calculation of the amount of NADPH consumed, see below). The increase in absorbance after some time is due to turbidity caused by precipitation of reduced insulin B-chains and can be detected at all wavelengths (also see Basic Protocol 3). It is only the initial linear part of the curve, with decrease of absorbance at 340 nm, that should be used for determination of enzymatic activity; the decrease is directly proportional to the consumption of NADPH.

Note that in most cases the inclusion of a standard curve in the assay is the best way of calculating activity for a given sample protein. Also see Critical Parameters and Troubleshooting.

ALTERNATE PROTOCOL

END-POINT INSULIN ASSAY FOR MEASUREMENT OF THIOREDOXIN OR THIOREDOXIN REDUCTASE ENZYMATIC ACTIVITY IN BIOLOGICAL SAMPLES

The spectrophotometric insulin assay described in Basic Protocol 1 is not always applicable to complex biological samples, such as cell or tissue extracts, usually due to small amounts of Trx or TrxR, and more importantly due to interfering NADPH-metabolizing enzymes present in the samples, giving rise to a high background and making results difficult to interpret. This protocol is a modified procedure, whereby the number of thiols formed in the reduced insulin are determined with DTNB after the reaction has been stopped by guanidine hydrochloride, which, when using adequate control samples, will result in a correct measurement of the Trx or TrxR activities in complex protein samples.

Additional Materials *(also see Basic Protocol 1)*

200 mM HEPES buffer, pH 7.6
0.2 M EDTA (*APPENDIX 2A*)
Protein sample to be analyzed, e.g., from cell or tissue extracts
DTNB/guanidine solution (see recipe)

1. Make a master mixture as follows (enough for 30 samples):

   1295 µl 200 mM HEPES buffer (85 mM final)
   625 µl 1.6 mM insulin (0.3 mM final)
   40 µl 50 mM NADPH (660 µM final)
   40 µl 0.2 M EDTA (3 mM final)
   Total volume, 2000 µl.

2a. *For measurement of Trx activity in a complex protein sample:* Prepare two reaction mixes (A and B) per sample in the bottoms of separate semimicro cuvettes as follows:

   Reaction mix A (with TrxR)
   33 µl master mixture (from step 1)
   (7 – *x*) µl 200 mM HEPES buffer (where *x* is the volume of sample added)
   10 µl 250 nM pure control TrxR (~50 nM final)
   x µl protein sample (usually 10 to 20 µg total protein)
   Total volume, 50 µl

   Reaction mix B (without TrxR)
   33 µl master mixture (from step 1)
   (17 – *x*) µl 200 mM HEPES buffer (where *x* is the volume of sample added)
   x µl protein sample
   Total volume, 50 µl.

2b. *For measurement of TrxR activity in a complex protein sample:* Prepare two reaction mixes (A and B) per sample in the bottoms of separate semimicro cuvettes as follows:

   Reaction mix A (with Trx)
   33 µl master mixture (from step 1)

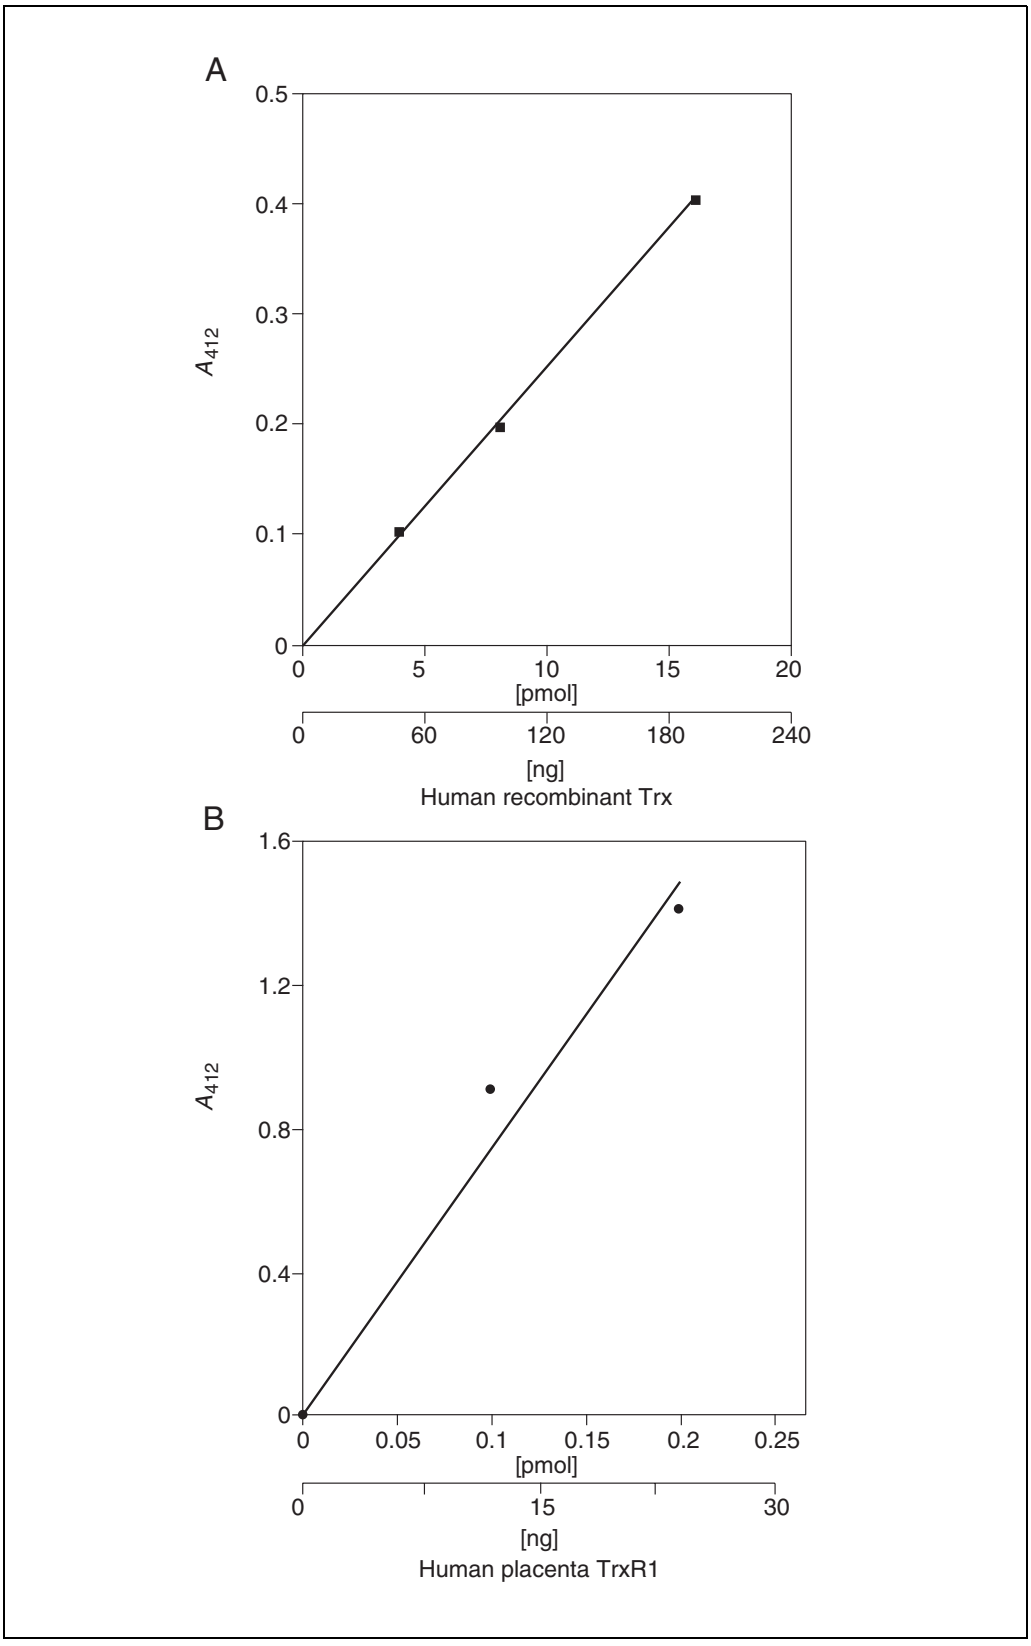

Figure 7.4.2 Standard curves of the end-point insulin assay. In (**A**) a typical standard curve for measurement of Trx is shown. The amount of human Trx (recombinant) added to the assay is shown with the resulting absorbance at 412 nm illustrated by the standard curve. In (**B**) a typical standard curve for measurement of TrxR is shown. However, this particular assay was incubated 1 hr at 37°C in order to increase the sensitivity. The amount of human TrxR (purified from placenta) added to the assay is shown with the resulting absorbance at 412 nm.

(9 – *x*) TE buffer, pH 7.5 (where *x* is the volume of sample added)
8 µl 100 µM (1.2 mg/ml) pure control Trx (15 µM final)
x µl protein sample (usually 10 to 20 µg total protein)
Total volume, 50 µl

Reaction mix B (without Trx)
33 µl master mixture (from step 1)
(17 – *x*) µl TE buffer, pH 7.5 (where *x* is the volume of sample added)
x µl protein sample (usually 10 to 20 µg total protein)
Total volume, 50 µl.

Disposable plastic cuvettes can be used if many samples are to be analyzed at one time, or, alternatively, the assay can be scaled down for use of 96-well microplates if a spectrophotometer for reading of such is available.

The protein sample will depend on the area of interest of the investigator. Be sure to include EDTA in the sample, since TrxR is easily inhibited by metal ions; also keep the pH within physiological range (7.0 to 8.0), and possibly include protease inhibitors.

A useful protein concentration in the sample is 1 to 5 µg/µl.

3. Incubate all samples 20 min at 37°C.
4. Add 500 µl DTNB/guanidine solution.

   This will denature all proteins and determine thiols with DTNB, resulting in high absorbance at 412 nm, with the extinction coefficient for the released TNB being 13,600 $M^{-1}cm^{-1}$.

5. Determine the absorbances at 412 nm of reaction mix A and reaction mix B for each sample.

   The difference (A – B) will correlate with the presence of Trx or TrxR in the protein sample, as determined in step 2a or 2b, respectively. The actual amount can be determined from a standard curve run in parallel, using pure control Trx or TrxR (see Figs. 7.4.2A and B). Preferably, this standard curve should also be performed in the presence of sample protein, to make certain that no inhibitory or stimulatory factor in the sample will affect the determination. As given here, the assay is optimized for 0 to 20 pmol Trx (0 to 200 ng; step 2a) or 0 to 2 pmol TrxR (0 to 250 ng of dimeric mammalian enzyme; step 2b). The sensitivity of the assay can however be further increased by prolonging the incubation time at 37°C.

   Some thioredoxins (e.g., human wild-type Trx) have additional structural cysteines that may oxidize and form aggregates with low or no initial activity. For frozen samples stored for longer periods of time, this becomes a problem. Such protein samples may be preincubated for 15 min at 37°C with 100 µM DTT to activate thioredoxin. However, DTT in the reaction mixture will also react with DTNB, thereby raising the background absorbance, which has to be subtracted.

BASIC PROTOCOL 2

MEASURING MAMMALIAN-TYPE THIOREDOXIN REDUCTASE

The mammalian-type thioredoxin reductase has, in contrast to the enzyme from prokaryotes, plants or yeast, a remarkably broad substrate specificity (see Commentary). One of the substrates directly reduced by mammalian TrxR and NADPH is Ellman's reagent [5,5′-dithio-bis(2-nitrobenzoic acid); DTNB]; which is used in the Alternate Protocol to measure thiols. The reaction and its products in direct reduction by mammalian TrxR are:

$$NADPH + H^+ + DTNB \rightarrow NADP^+ + 2\ TNB$$

The reaction is fast, and since the extinction coefficient of TNB is high (13,600 $M^{-1}cm^{-1}$) this assay is preferred for determination of the catalytic activity of mammalian TrxR and constitutes the basis for calculation of enzyme units.

Materials

62.5 mM (25 mg/ml) DTNB in spectroscopic grade 99% ethanol
50 mM NADPH (see recipe)
PE buffer, pH 7.0: 100 mM potassium phosphate, pH 7.0 (*APPENDIX 2A*) containing 2 mM EDTA
20 mg/ml bovine serum albumin (BSA) in water
Pure control mammalian TrxR
TrxR sample to be analyzed
Double-beam spectrophotometer with semimicro quartz cuvettes

NOTE: Inclusion of albumin in the assay protects TrxR from absorbing to the plastic surface of the vial; the disulfides of albumin are buried internally and are not reduced by the enzyme, and thereby do not interfere with the assay. The standard assay is performed at room temperature (20°C).

1. Make a master mixture as follows (enough for 10 samples):

   660 µl 62.5 mM DTNB (5 mM DTNB, 8% ethanol final)
   50 µl 50 mM NADPH (300 µM final)
   4790 µl PE buffer
   Total volume, 5500.

   IMPORTANT NOTE: *The final concentration of ethanol in the assay due to the DTNB solution should be kept <10% in the reaction mixture, due to the risk of enzyme denaturation.*

2. At time of assay, freshly dilute the pure control mammalian TrxR to 0.05 to 0.25 U/ml (~35 to 105 nM) in PE buffer containing 100 µg/ml of bovine serum albumin (added from 20 mg/ml BSA stock).

   See definition of TrxR units below.

3. Mix the following components:

   333 µl master mixture (from step 1)
   (67 – *x*) µl PE buffer (where *x* is the volume of TrxR sample added)
   x µl TrxR to be analyzed or pure TrxR standard (from step 2; usually ~5 nM final)
   Total volume, 500 µl

   Immediately after addition of TrxR, mix the contents of the cuvettes and then follow reduction of NADPH as increase of absorbance at 412 nm, using a sample without addition of TrxR as the reference cuvette. Prepare a standard curve using purified control TrxR (0 to 5 nM) for comparison of activity.

4. Calculate activity and units as follows, using an extinction coefficient of 13,600 $M^{-1}cm^{-1}$ for TNB based on the fact that two molecules of TNB are formed per DTNB molecules:

$$\text{turnover } (\text{min}^{-1}) = \frac{\text{linear initial rate of increase at 412 nm}}{13{,}600 \times 2 \times (\text{TrxR concentration [M] in cuvette})}$$

The turnover for cytosolic mammalian TrxR (TrxR1) of liver, thymus, or placenta in this standard assay is ~4000 min^{-1}.

One unit (U) of TrxR is defined as the amount catalyzing the oxidation of 1 μmol NADPH, i.e., reduction of 1 μmol DTNB (formation of 2 μmol TNB), per min, which, with a molecular mass of 115 kDa for the dimeric enzyme, amounts to ~35 U/mg.

DTNB is also used in determination of total glutathione via NADPH and glutathione reductase. Therefore, in extracts containing both GSH and glutathione reductase, the activity of TrxR could be overestimated. After removal of GSH, accurate values are obtained. Alternatively, addition of 20 μM gold thioglucose, a specific inhibitor of mammalian TrxR, allows measurement of the TrxR activity even in the presence of GSH and glutathione reductase by determination of the fraction of the activity inhibited by the gold compound (Hill et al., 1997).

BASIC PROTOCOL 3

THIOREDOXIN-CATALYZED INSULIN REDUCTION BY DTT

As stated in the introduction to this unit, the capacity of Trx to reduce protein disulfides is a hallmark of this redox-active protein, usually coupled to regeneration of active Trx by TrxR; this is the basis for Basic Protocol 1 and Alternate Protocol. This protocol describes an alternative way of analyzing the protein disulfide reduction by Trx without the use of TrxR, but instead coupled to DTT. This protocol is useful for characterization of the protein disulfide reduction by novel thioredoxins. Formation of the reduced insulin can easily be monitored by turbidimetric measurements, i.e., by following the appearance of turbidity due to precipitated reduced insulin (also see Fig. 7.4.1). The regeneration of active Trx by DTT is much faster than direct reduction of insulin by DTT (by about three orders of magnitude), and Trx-catalyzed reduction of insulin is exceptionally fast, as already mentioned above (about five orders of magnitude faster than DTT-catalyzed reduction of insulin).

NOTE: This assay, based upon turbidity measurement, is performed at pH 6.5 to increase the sensitivity of the assay due to a lower solubility of reduced insulin at this pH value.

Materials

1.6 mM insulin (see recipe) in 100 mM potassium phosphate buffer, pH 6.5
PE buffer, pH 6.5: 100 mM potassium phosphate, pH 6.5 containing 2 mM EDTA
100 mM dithiothreitol (DTT; *APPENDIX 2A*), freshly made in water
Sample: purified Trx to be analyzed
Double-beam spectrophotometer with semimicro quartz cuvettes

1. Make a master mixture as follows (enough for 10 samples):

   825 μl 1.6 mM insulin (160 μM final)
   4675 μl PE buffer
   Total volume, 5500 μl.

2. Mix the following components:

   333 μl master mixture (from step 1)
   (162 – *x*) μl PE buffer (where *x* is the volume of Trx sample added)
   5 μl 100 mM DTT (1 mM final)
   x μl Trx to be analyzed (usually 0 to 10 μM final)
   Total volume, 500 μl.

3. Measure the absorbance at 650 nm for 40 min, with an identical sample excluding Trx as reference cuvette.

   See Figure 7.4.3 for illustrative curves demonstrating this assay.

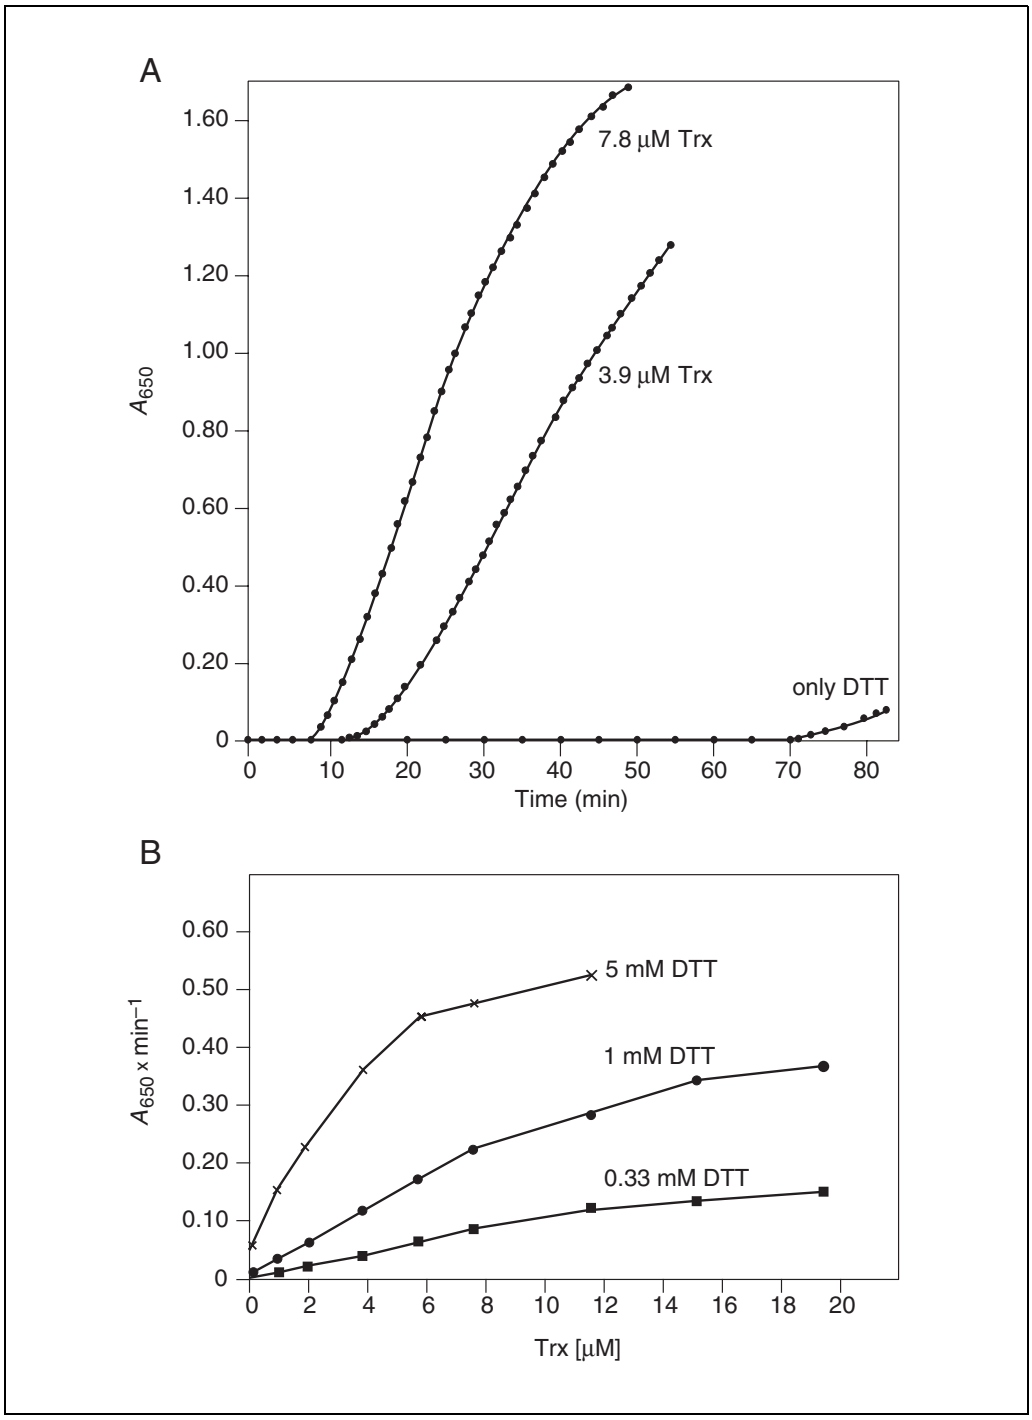

Figure 7.4.3 Reduction of insulin by DTT catalyzed by Trx. In (**A**) typical turbidimetric curves upon addition of *E. coli* Trx (3.9 or 7.8 μM, as indicated) are shown, in comparison to turbidity formed upon addition of only DTT (at pH 7.0 with 130 μM insulin and 330 μM DTT). It can be seen that both the onset of detectable precipitation as well as the slope of the curve are dependent on the Trx activity and thereby both these parameters can be used to quantitate the activity. However, the maximal rate of precipitation, given as the increase per minute of absorbance at 650 nm, is the most useful parameter. In (**B**) the effects of DTT or Trx concentrations on this reaction (at pH 6.5 with 130 μM insulin, e.g., similar to the conditions utilized in the protocol given here) are demonstrated. Note that this assay is a simple way of monitoring the Trx-catalyzed insulin reduction by DTT, but it is limited by nonlinear increase in A_{650} using high DTT levels. As seen, however, $\Delta A_{650} \times \text{min}^{-1}$ with 1 mM DTT at pH 6.5 is linear over the *E. coli* Trx concentration 0 to 10 μM (conditions utilized in Basic Protocol 3). Adapted from Holmgren (1979b).

The appearance of turbidity is not always linearily correlated to the rate of reduction of insulin. With E. coli or mammalian Trx between 0 and 10 μM Trx at pH 6.5 with 1 mM DTT, the precipitation of insulin is linearily dependent on the activity of the Trx. However, for novel thioredoxins the linearity of the assay may be different.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DTNB/guanidine solution

First make 6 M guanidine·HCl by dissolving 28.66 g guanidine·HCl in 50 ml Tris·Cl, pH 8.0 (*APPENDIX 2A*; store at room temperature). Also make 10 mM (4 mg/ml) DTNB [5,5′-dithio-bis(2-nitrobenzoic acid); Ellman's reagent] in spectroscopic grade 99% ethanol (store at −20°C in well sealed glass vials). At the time of assay, add 1 ml of the 10 mM DTNB to 9 ml of the 6 M guanidine hydrochloride, which will be enough for 20 samples; keep on ice.

CAUTION: *Guanidine·HCl is highly corrosive.*

Insulin, 1.6 mM

Make a 1.6 mM (10 mg/ml) stock solution by suspending 50 mg insulin (from bovine pancreas; Sigma) in 2.5 ml of 50 mM Tris·Cl, pH 7.5 for Basic Protocol 1 or Alternate Protocol or in 100 mM potassium phosphate, pH 6.5 for Basic Protocol 3 (see *APPENDIX 2A* for both buffers); adjust pH to 2 to 3 with 1 M HCl to dissolve the protein completely, then titrate back to the original pH of the buffer with 1 M NaOH. Finally adjust the volume with water to 5.0 ml.

This clear stock solution of insulin (10 mg/ml) can be kept at –20°C.

NADPH, 50 mM

Prepare stock vials by keeping 10-mg portions of β-NADPH (dry) in separate small microcentrifuge tubes at −20°C. Dissolve in 250 μl water at time of use (40 mg/ml, 50 mM final concentration). Store the stock solution up to 2 months at −20°C and reuse no more than two times, since the reduced β-NADPH will oxidize (and become yellow) by repeated freezing-thawing, or with time.

COMMENTARY

Background Information

At least one thioredoxin of 12 kDa exists in the cytosol of all living cells; this enzyme has a large number of activities (Holmgren, 1985, 1989, 1995; Yodoi and Tursz, 1991; Williams, 1992; Holmgren and Björnstedt, 1995). Reduced thioredoxin is a powerful protein disulfide reductase required to regenerate an active site dithiol after each catalytic cycle in, e.g., ribonucleotide reductase or methionine sulfoxide reductases. Disulfide reduction by thioredoxin is involved in redox regulation of enzymes and transcription factors. Secreted mammalian thioredoxin has co-cytokine-like activity on certain mammalian cells by an unknown mechanism but probably also involving thiol-disulfide exchange (Holmgren, 1985, 1989, 1995; Yodoi and Tursz, 1991; Holmgren and Björnstedt, 1995; Powis et al., 1995). Thioredoxin, NADPH, and thioredoxin reductase also play an important role in signal transduction and defense against oxidative stress.

Thioredoxin reductase from *Escherichia coli* has been crystallized (Williams, 1992), and a high-resolution X-ray structure shows surprisingly large differences from other members of the pyridine nucleotide-disulfide oxidoreductase family, notably glutathione reductase (Kuriyan et al., 1991; Waksman et al., 1994). *E. coli* TrxR is smaller and has a different domain organization than glutathione reductase, suggesting functionally convergent evolution of the two enzymes (Kuriyan et al., 1991). The structural features of TrxR from *E. coli* and a high specificity for its homologous Trx, are typical also for TrxR from prokaryotes, lower eukaryotes like yeast, or cytosol from plants

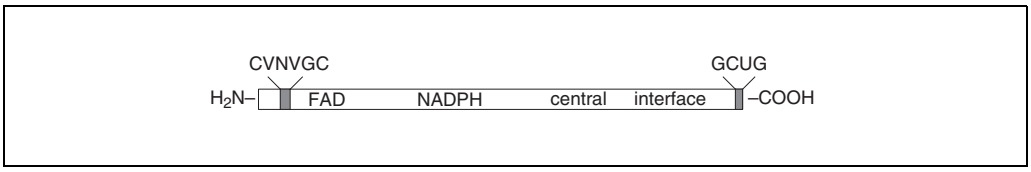

Figure 7.4.4 Schematic drawing of the mammalian cytosolic TrxR. Shown are the FAD, NADPH, central, and interface domains, based upon the high homology to glutathione reductase and other enzymes of the pyridine disulfide oxidoreductase family (Williams, 1992; Zhong et al., 1998). The sequences of the glutathione reductase–like redox active motif in the N-terminal part of the protein and the carboxyterminal motif including selenocysteine are shown by one-letter amino acid codes. Key residues with redox activity are shown in bold. U = selenocysteine.

(Kuriyan et al., 1991; Williams, 1992; Waksman et al., 1994; Dai et al., 1996).

It has long been known that mammalian TrxR has strikingly different properties when compared to the enzyme from *E. coli* and lower organisms (Holmgren, 1985, 1989; Holmgren and Björnstedt, 1995). The enzymes from calf liver and thymus and rat liver were the ones first purified to homogeneity, and they showed subunits with a molecular mass of 58 kDa (Holmgren, 1977; Luthman and Holmgren, 1982).

Recently, the mammalian TrxR was cloned and sequenced; the amino acid sequence revealed a strikingly high homology to glutathione reductase (Gasdaska et al., 1995; Zhong et al., 1998). The conserved features of all the structural components of glutathione reductase were preserved in mammalian TrxR, including a redox-active disulfide motif in the N-terminal FAD domain, the NADPH-binding domain, and the carboxyterminal interface region that governs the association of the two subunits in the homodimeric holoenzyme. Interestingly, the mammalian TrxR was also found to be a selenoprotein, carrying a catalytically active selenocysteine (Sec) residue in the penultimate carboxyterminal end (Gladyshev et al., 1996; Tamura and Stadtman, 1996; Zhong et al., 1998). Together with a neighboring cysteine residue in the conserved sequence -Gly-Cys-Sec-Gly-COOH, the selenocysteine has been suggested to be part of an open active site motif, explaining the wide substrate specificity of the enzyme. The general domain organization is shown in Figure 7.4.4.

Recently two additional mammalian TrxR isoenzymes were discovered—one mitochondrial and one mainly detected in testis—that all carry the same carboxyterminal selenocysteine-containing motif (Miranda-Vizuete et al., 1999; Sun et al., 1999; Watabe et al., 1999). In *C. elegans*, two TrxR isoenzymes were found—one a selenoprotein and one a cysteine-containing homolog (Zhong et al., 1998; Gladyshev et al., 1999). A yeast mitochondrial thioredoxin system was also newly discovered, but these enzymes were also similar to the prokaryotic type (Pedrajas et al., 1999). Several other Trx or TrxR isoenzymes exist with certainty in different organisms—some already discovered and some yet to be discovered. The protocols described in this unit are based upon the hallmarks of Trx and TrxR enzymatic activities and can be used in the initial characterizations of the novel isoenzymes as well as for the determination of their activities in different cells and tissues.

Critical Parameters and Troubleshooting

Kinetic parameters of *E. coli* and mammalian TrxR are given in Table 7.4.1. It should be emphasized that since the Trx-coupled assays given in Basic Protocol 1 and the Alternate Protocol, for practical and economic reasons, make use of limited amounts of Trx (0 to 20 μM), these assays result in nonsaturating conditions for TrxR with respect to Trx. It is therefore necessary to always include a standard curve in each experiment to enable correct extrapolation of Trx or TrxR activities in unknown samples, or, alternatively, to increase the Trx concentration to yield saturating conditions.

The presence of selenocysteine in the mammalian TrxR isoenzymes evokes several difficulties in studying these enzymes. First, the selenocysteine residue is at physiological pH in its selenolate form and is thus easily alkylated. This explains why the enzyme is easily irreversibly inhibited by electrophilic agents (see Nordberg et al., 1998; Arnér et al., 1999a, and references therein). Also, EDTA must be included in assays of the enzyme, since metal ions easily inhibit the activity. Moreover, the selenium may be lost during the purification procedure, resulting in an enzyme with lower specific activity than normal (Arnér et al., 1999a). Most important, however, is the fact

Table 7.4.1 Kinetic Parameters of *E. coli* and Mammalian TrxR[a]

		E. coli TrxR	Mammalian TrxR
E coli Trx	K_m	3.0 μM	35 μM
	k_{cat}	2000 min^{-1}	3000 min^{-1}
Mammalian Trx	K_m	No activity	2.5 μM
	k_{cat}	—	3300 min^{-1}
DTNB	K_m	No activity	0.5 mM
	k_{cat}	—	4000 min^{-1}

[a]Representative figures are taken from the literature. Note that *E. coli* TrxR is specific for its homologous Trx whereas mammalian TrxR is not. Trx and TrxR of different mammalian species are virtually fully interchangable in terms of substrate specificities and activity. The mutant C62S/C73S Trx shows essentially the same kinetic parameters as wild-type mammalian Trx.

that mammalian selenoproteins cannot normally be expressed directly in bacteria as recombinant products, due to the fact that selenocysteine—the 21st amino acid (Böck et al., 1991)—is cotranslationally inserted at the position of a UGA codon, normally conferring translational termination. The alternative decoding as selenocysteine is dependent on secondary structures in the selenoprotein mRNA, so-called selenocysteine insertion sequence (SECIS) elements, that are noncompatible between mammalian and bacterial systems (Low and Berry, 1996; Tormay and Böck, 1997). Recently, however, the authors succeeded in overcoming this species barrier by engineering SECIS elements compatible with the bacterial translation machinery, but still encoding the carboxyterminal end of mammalian TrxR, and resulting in enzymatically active recombinant enzyme (Arnér et al., 1999b). Thereby, larger amounts can now be produced, to be used as control TrxR in the protocols.

If DTT or other low-molecular-mass thiol compounds are included in the DTNB-based assays, either as described or because they were included during purification of the proteins analyzed, care must be taken because of the presence of the additional thiol groups and their reaction with DTNB. Adequate controls must be utilized, i.e., measuring control Trx or TrxR in the same DTT-containing background as that used for the samples analyzed. The NADPH-dependent reaction described in Basic Protocol 1 can be used with 0.1 to 1 mM DTT (final concentration) without affecting the rate at A_{340}. However, the range of the assay is limited by the precipitation of insulin at earlier time points due to reactions determined in Basic Protocol 3.

Some spectrophotometers with lower-intensity lamps cannot measure absorbance at 340 nm when NADPH concentrations are higher than 200 μM.

Anticipated Results

The given protocols describe determinations of Trx- and TrxR-derived enzymatic activities in purified or complex samples. The levels of these enzymes are highly dependent on cells, tissues, organelles, conditions of growth or purification protocols utilized by the investigator. As a rough guide, cytosol of *E. coli*, yeast, or mammalian cells can be considered to normally contain Trx in the range of 5 to 10 μM (~1 to 2 μg/mg protein) and TrxR in the range of ~100 nm (~200 ng/mg protein).

Time Considerations

The actual assays described in the protocols require no more than an hour in total to perform, and the reagents (except for the control enzymes) do not require much time to prepare.

Measurement of MnSOD and CuZnSOD Activity in Mammalian Tissue Homogenates

Three basic forms of mammalian superoxide dismutase (SOD) enzymes exist and are distinguished by their size and localization. CuZnSOD is a homodimer consisting of two ~16 kDa subunits and is primarily found in the cytosolic and nuclear compartments of the cell, while MnSOD is a tetramer consisting of four ~24 kDa subunits and is primarily found in the mitochondria. Extracellular superoxide dismutase (ECSOD) is a copper- and zinc-containing tetrameric glycoprotein consisting of ~30 kDa subunits and is found predominantly in the soluble extracellular compartment but can also be bound to the surface of cells.

SOD enzymatic activity is not easily measured by direct assays, because substrate disappearance is very rapid at physiological pH. The activity of SOD enzymes can be determined by a number of indirect competitive inhibition assays based on the principle that SOD activity will inhibit the rate at which $O_2^{\cdot-}$ will reduce an indicator substrate—e.g., nitroblue tetrazolium (NBT) or cytochrome *c* in a competitive fashion. The SOD-mediated inhibition (percent inhibition) of indicator substrate reduction can then be quantitated and plotted as a function of the quantity of protein added to the reaction to construct an inhibition curve. The amount of cellular protein that causes 50% maximum inhibition can then be calculated and defined as containing one unit SOD activity. The units of SOD activity per milligram protein can then be related to the quantity of pure enzyme needed to reach 50% maximum inhibition under similar reaction conditions. The activities of the copper/zinc containing enzymes can be distinguished from the MnSOD activity in mammalian tissue homogenates using the differential sensitivity of these enzymes to inhibition by sodium cyanide. The major difficulties encountered when using such methods for the measurement of SOD activity arise from the fact that mammalian cell and tissue homogenates contain factors that directly reduce the indicator in a nonSOD inhibitable fashion, and the homogenates themselves can produce superoxide. Tissue-specific interference in the assay can cause the assay to inaccurately detect known amounts of SOD activity spiked into unknown samples. These tissue-specific assay interferences have been discussed in detail in a previous publication (Spitz and Oberley, 1989). A modified protocol for the spectrophotometric measurement of SOD activity, using xanthine oxidase and nitroblue tetrazolium (NBT) in mammalian tissue homogenates, has been developed based on the inclusion of a powerful metal chelator, bathocuproinedisulfonic acid (BCS), that inhibits electron transport chain–associated interference in the assay (Spitz and Oberley, 1989). This unit describes this modified NBT-BCS SOD assay procedure and provides a detailed protocol for use in differentiating between MnSOD and CuZnSOD activities in mammalian tissue homogenates.

NBT-BCS SUPEROXIDE DISMUTASE ACTIVITY ASSAY

BASIC PROTOCOL

The NBT-BCS SOD activity assay scheme is shown in Figure 7.5.1. The catalytic conversion of xanthine to uric acid and $O_2^{\cdot-}$ by xanthine oxidase provides an initial constant flux of superoxide in a phosphate buffered solution at room temperature. The rate of NBT reduction to blue formazan by the $O_2^{\cdot-}$ generated by the xanthine oxidase reaction is monitored spectrophotometrically at 560 nm. When increasing concentrations of pure SOD enzyme or protein homogenate containing SOD activity are added to the reaction, the rate of NBT reduction by xanthine/xanthine oxidase is progressively inhibited until maximum inhibition (typically 95%) is reached for the NBT-BCS assay. Catalase is added to the reaction to remove H_2O_2.

Current Protocols in Toxicology (2001) 7.5.1-7.5.11

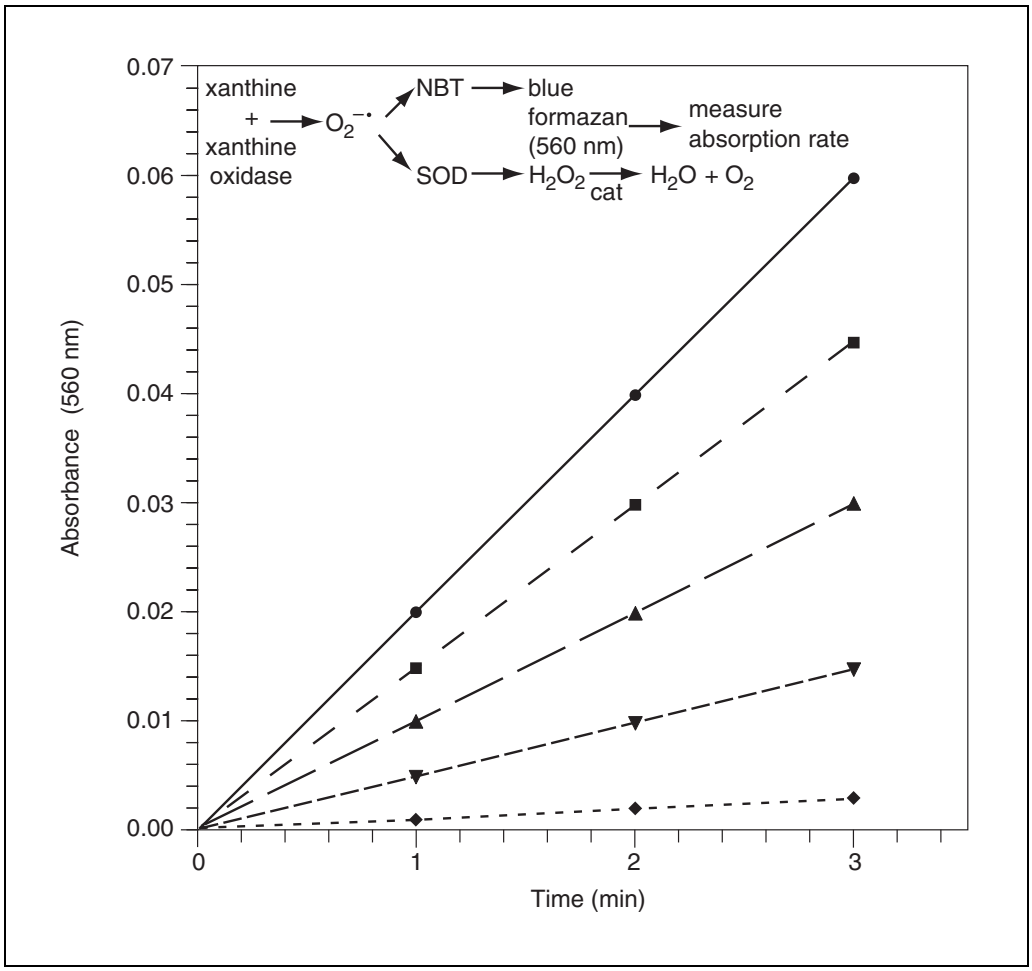

Figure 7.5.1 NBT-BCS competitive inhibition SOD activity assay. Above: an idealized reaction scheme. Below: an idealized data set showing the rates of NBT reduction monitored spectrophotometrically with increasing quantities of pure CuZnSOD standard at 0 (circles), 4 (squares), 8 (triangles), 25 (inverted triangles), and 500 (diamonds) ng. In this idealized circumstance, maximum inhibition is 95%, ½ maximum inhibition is 47.5%, and 1 unit is 8 ng.

Materials

3×10^7 cells or tissue
Phosphate buffered saline (PBS; *APPENDIX 2A*)
1.34 mM DETAPAC buffer (see recipe)
BSA in DETAPAC buffer (see recipe)
40 U/ml catalase (Sigma-Aldrich) in 0.05 M potassium phosphate buffer (see recipe); store up to 1 month at 4°C as a 4000 U/ml solution
2.24 mM nitroblue tetrazolium (NBT; see recipe)
1.18 mM xanthine (see recipe)
0.05 M potassium phosphate buffer, pH 7.8 (see recipe)
0.33 M NaCN (see recipe)
BCS (see recipe)
1 M HCl or 1 M KOH (optional)
5 µg/ml bovine CuZn superoxide dismutase (CuZnSOD; OXIS International): store up to 5 years at −20°C (avoid multiple freeze-thaw cycles)
13.2 U/ml xanthine oxidase (XO; Sigma-Aldrich), on ice

15-ml centrifuge tubes
400-W microtip sonicator (nonfragile cell culture or tissue)

Brinkman homogenizer with microtip (tissue)
10 × 75–mm borosilicate glass test tubes
Beckman 650 spectrophotometer or equivalent reading at 560 nm with 6 position automatic sample changer and enzyme kinetics software package
1-ml polystyrene cuvettes

NOTE: All solutions, unless otherwise specified, are prepared in 0.05 M potassium phosphate buffer, pH 7.8, stored at 4°C, and warmed to room temperature prior to assay. The water is double-distilled or Nanopure 18.3-megaohm purified (Barnstead/Thermolyne).

Prepare homogenate

For cell cultures

1a. Rinse cultures once with 5 ml of 4°C PBS. Scrape harvest 3×10^7 cells into 5 ml of 4°C PBS and transfer to a 15-ml centrifuge tube. Carry out all procedures at 4°C.

2a. Centrifuge 5 min at $400 \times g$, 4°C. Discard the supernatant being careful to remove as much PBS as possible. Freeze cell pellet overnight at −20°C or below to break open the cells.

3a. Thaw cell pellet. Homogenize in 0.5 ml of 1.34 mM DETAPAC buffer by repeated pipetting in a small-bore pipet tip if cells are fragile; otherwise, sonicate on ice with six 5-sec bursts from a 400-W microtip sonicator at 70% output.

This should yield a homogenate with a protein concentration of ~5 mg/ml measured using the method of Lowry et al. (1951; APPENDIX 3A).

For tissue samples

1b. Mince tissue with scissors in a petri dish containing 5 to 10 vol DETAPAC buffer on ice.

2b. Homogenize on ice using a Brinkman homogenizer with a microtip for five 2-sec bursts.

3b. Sonicate with six 5-sec bursts on ice with a 400-W microtip sonicator at 70% output.

In samples that are extremely turbid due to connective tissue in the homogenate, low-speed centrifugation (i.e., 2 min at ~50 × g, 4°C in a tabletop centrifuge) can be used to remove macroscopic clumps.

Prepare assay solutions

4. Combine stock solutions, in order, in two separate 250-ml beakers (one each for assay solution, one with and one without NaCN) as described in Table 7.5.1 to prepare assay solutions. Stir after each stock solution is added.

CAUTION: *NaCN is hazardous. Use with care and dispose of solutions containing it appropriately.*

The assay solutions are yellowish/green in color and slightly hazy after the addition of NBT. The recipe given in Table 7.5.1 is for 20 assay tubes (total volume 16 ml; 800 µl/tube), which is usually sufficient to run a complete inhibition curve (once in the presence and once in the absence of NaCN) on a homogenate containing 5 mg/ml protein as determined by the method of Lowry et al. (1951).

When running multiple samples or standards in a single day (a maximum of 12 samples and 1 standard for one person in one day; see Time Considerations), the desired multiples of these final assay solutions should be prepared and used within 6 hr. It is recommended (when possible) that all the samples from each experimental comparison be assayed within 2 days using the same stock solutions. Every day, a standard percent inhibition curve should

Table 7.5.1 Assay Solution Composition

Stock solutions	Total added volume[a] (ml)	Final concentration[b]
BSA in DETAPAC buffer	12.90	0.05 M potassium phosphate buffer; 1 mM DETAPAC; 0.13 mg/ml BSA
40 U/ml catalase	0.50	1.0 U
2.24 mM nitroblue tetrazolium (NBT)	0.50	5.6×10^{-5} M
1.18 mM xanthine	1.70	10^{-4} M
0.05 M potassium phosphate buffer or 0.33 M NaCN	0.30	0 or 5 mM CN^-
0.01 M BCS	0.10	50.0 µM

[a]The total volume of the final assay solution is 16.0 ml. Multiples of this recipe can be prepared for more than one sample.
[b]Final concentration is for each assay tube after all of the ingredients have been added.

be run using purified CuZnSOD prior to running the samples to verify that the reagents are working properly (see Fig. 7.5.2).

5. (*Optional*) Adjust final assay solutions to pH 7.8 using 1 M HCl or 1 M KOH.

   This will allow for the use of the same XO solution for both NaCN-containing and nonNaCN-containing assay tubes. If the pH is not readjusted, the XO solution may need to be diluted prior to running the NaCN-containing tubes in order to keep the rate of NBT reduction in the desired range.

Prepare blanks, samples, and standards

6. Prepare sample or standard (i.e., 5 µg/ml bovine CuZnSOD) dilutions in 0.05 M potassium phosphate buffer, pH 7.8, such that each 100 µl added to the reaction contains increasing quantities of protein (1 to 500 µg protein for each sample homogenate or 2 to 500 ng protein for the CuZnSOD standard). Adjust dilutions so that most points are taken between 10% to 60% inhibition (usually 2 to 50 µg protein for most homogenates and 2 to 50 ng for most purified CuZnSOD preparations).

   Be sure that maximum inhibition for each unknown sample is reached for both nonNaCN- and NaCN-containing tubes. Maximum inhibition is usually between 80% and 95% inhibition, requiring addition of 500 µg protein for most homogenates (500 ng for purified SOD standards). The assay is usually 10 tubes for a total SOD activity assay and 10 tubes with CN^- for a MnSOD activity assay. A dilution table and assay results for a purified CuZnSOD standard are shown in Figure 7.5.2.

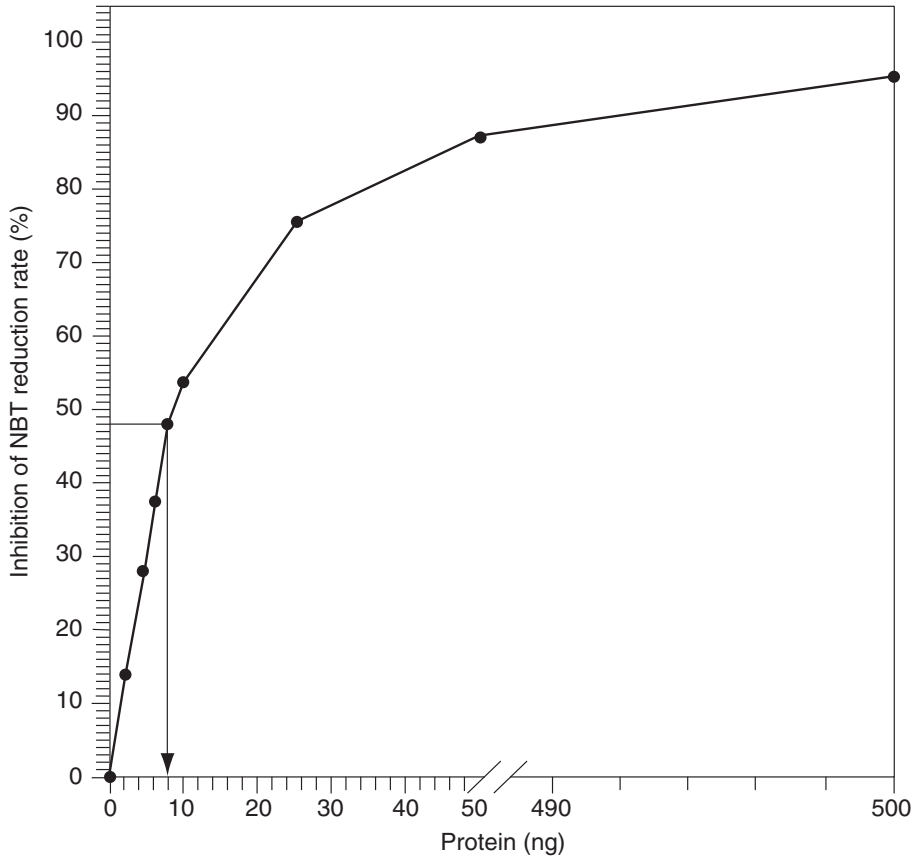
7. Pipet 100 µl sample or standard into duplicate 10 × 75–mm borosilicate glass test tubes (i.e., for NaCN- and nonNaCN-containing reactions).

   Each protein dilution must be pipetted in duplicate and run with both nonNaCN- and NaCN-containing final assay solutions to obtain total SOD activity per milligram protein as well as NaCN-resistant SOD activity.

8. Prepare blanks by pipetting 100 µl of 0.05 M potassium phosphate buffer, pH 7.8, into duplicate 10 × 75–mm borosilicate glass test tubes (i.e., for NaCN- and non-NaCN-containing reactions).

   These tubes will be run with each set of samples or standards to determine the rate of NBT reduction in the absence of SOD activity for the calculation of percent inhibition in both the presence and absence of NaCN.

   One blank is run with each set of 5 samples or standards (the sample changer holds six cuvettes).



SOD (ng)	std. (µl)	buffer (µl)	total (µl)	rate	inhibition (%)
0-blank	0	100	100	0.0227	0
2	2	498	100	0.0195	13.9
4	4	496	100	0.0163	28.0
6	6	494	100	0.0142	37.3
8	8	492	100	0.0122	46.1
10	10	490	100	0.0105	53.6
25	25	475	100	0.0055	75.7
50	50	450	100	0.0029	87.2
500	100 µl undiluted SOD std.			0.0010	95.6
0-blank			100	0.0226	0

Figure 7.5.2 Top: NBT-BCS superoxide dismutase activity assay of purified 5 µg/ml CuZnSOD standard provided by OXIS International. Maximum inhibition is 95.6%, 1/2 maximum inhibition is 47.8%, and 1 unit is 8 ng. Bottom: Dilution table for this assay describing how to mix the standard and buffer to obtain the inhibition curve shown in the top figure. 100 µl of each dilution is added to 800 µl of assay reagent, then 100 µl of XO solution is added to initiate the reaction. The reaction is monitored for 2.5 min to obtain the absorption/min, which is the reported rate.

Begin competitive assay

9. Add 800 µl assay solution to blanks, standards, and samples with and without NaCN.
10. *To inactivate CuZnSOD activity:* Incubate tubes containing NaCN assay solution for each protein dilution for at least 45 min at room temperature to allow for the inhibition of CuZnSOD by CN^-.

    This can be accomplished by running all the nonNaCN-containing tubes from a series first, and then running all the NaCN-containing tubes. The NaCN-containing tubes should not be incubated >2.5 hr.

11. Dilute 10 µl of 13.2 U/ml xanthine oxidase (XO) to 3.5 ml with 1.34 mM DETAPAC buffer. Add to a nonNaCN blank first and adjust concentration as necessary to give an inhibition rate for NBT reduction in the absence of SOD between 0.016 to 0.025 AU/min (0.02 AU/min is ideal) at 560 nm using a Beckman DU-650 (or equivalent) spectrophotometer. Store XO solution on ice during the assay or the activity will diminish.

    If the desired rate is not obtained, add more XO or dilute the XO solution with DETAPAC buffer to give the desired rate.

12. Add 100 µl XO to initiate the reaction. Incubate the reaction 1 min at room temperature to allow the XO reaction to reach V_{max}.

    Xanthine oxidase (XO) is the last component added to each tube to initiate the reaction, and it should be added no more than 1 min before the sample is read.

    The XO reaction is now linear for ~5 min but should be read between 1 and 3 min following addition of XO.

Determine absorbance rate

13. Transfer reaction to a 1-ml polystyrene cuvette. Place a blank (phosphate buffer instead of sample or standard) in cuvette position 1 of the automatic sample changer and put samples or standards in cuvette positions 2 through 6. Monitor absorbance at 560 nm every 15 sec for 2.5 min. Run the standard curve (as shown in Fig. 7.5.2) first to make sure all assay conditions are optimized.
14. Record rate of change in absorbance for at least 2.5 min or until a straight line is obtained. Record rates of AU/min for blank and samples for use in calculating percent inhibition. Dispose of the cuvettes and the glassware appropriately.

    At the end of the assay the solutions should be blue.

15. Run every series (blank and 5 samples) in the same way (steps 12 to 14) until all the non-CN^- tubes are analyzed. Then repeat the same process with CN^- containing tubes.

Analyze data

16. Calculate the percent inhibition for each blank, standard, or sample:

$$\text{percent inhibition} = \frac{\text{blank rate} - \text{sample rate}}{\text{blank rate}} \times 100$$

    Blank rate is the mean of the blanks run at the beginning and the end of each sample or standard.

17. Plot percent inhibition versus protein concentration (see Fig. 7.5.2 and Fig. 7.5.3). Determine the highest maximum inhibition for each group of sample curves to be compared and calculate the amount of protein that inhibits NBT reduction by 50% maximum inhibition.

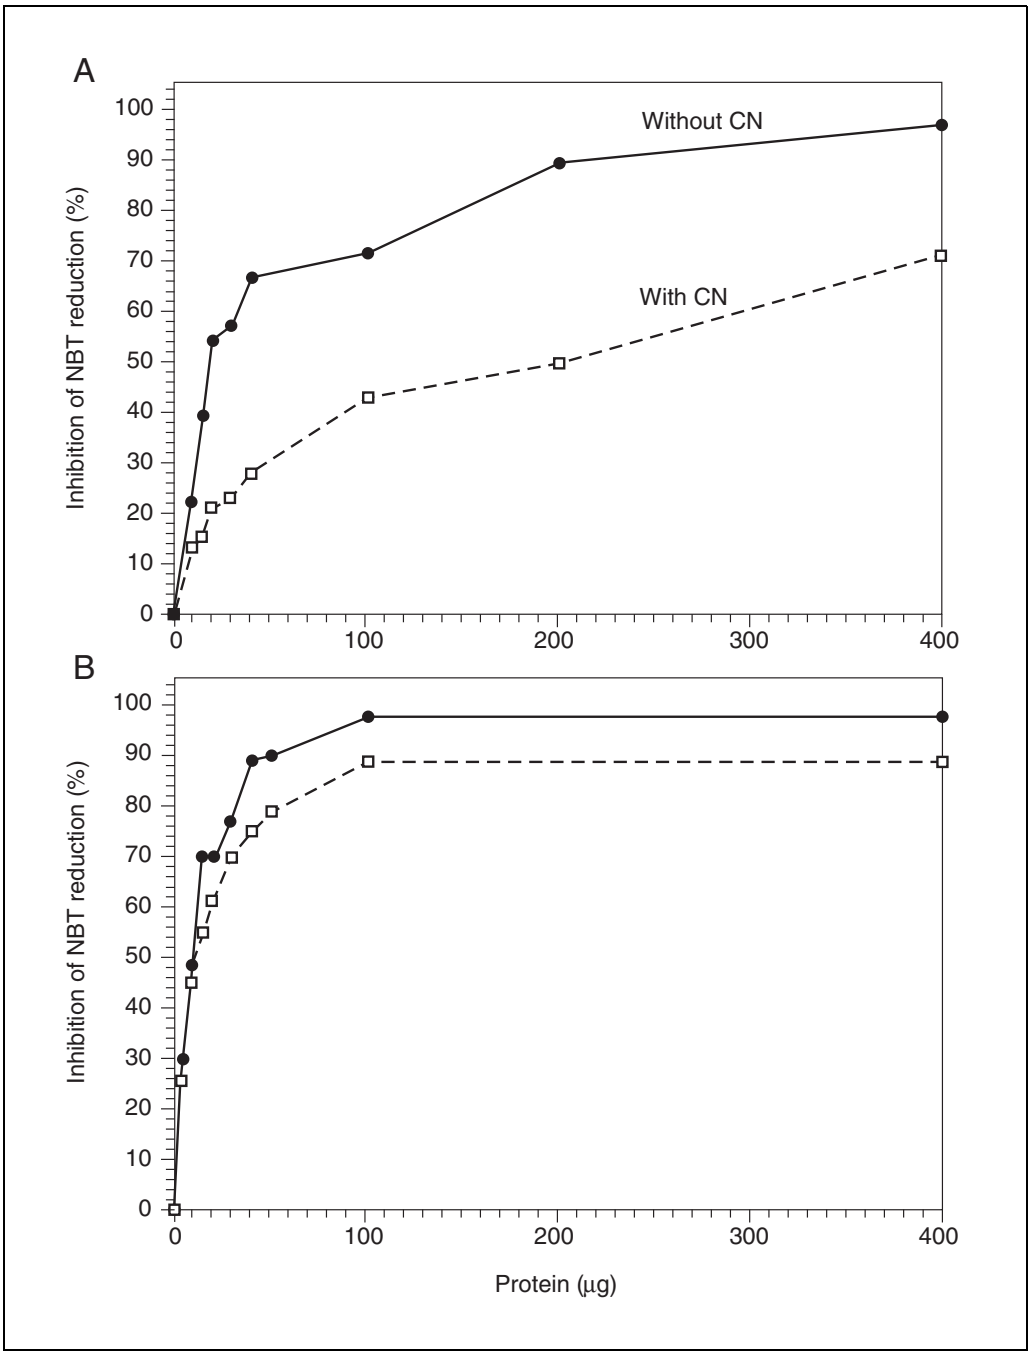


Figure 7.5.3 NBT-BCS SOD activity assay of whole homogenates from A549 human lung adenocarcinoma cells incubated in the absence (**A**) or presence (**B**) of tumor necrosis factor (TNF) and interferon (IFN) for 14 hr. The highest maximum inhibition in the two samples to be compared (A and B) for nonCN$^-$ containing reactions (solid circles) is 98%, and 1/2 maximum inhibition is 49%, while for CN$^-$ containing reactions (open squares) the highest maximum inhibition is 90% and 1/2 maximum inhibition is 45%. (Whenever a group of samples is being compared to each other, it is necessary to use the highest maximum inhibition obtained from the group to get the best relative comparison for the group. This is true for both CN$^-$ containing and nonCN$^-$ containing comparisons.) Therefore, total SOD activity is 46.5 U/mg, MnSOD activity is 8 U/mg, and CuZnSOD activity is 38.5 U/mg in the sample shown in (A). Total SOD activity is 100 U/mg, MnSOD activity is 95.2 U/mg, and CuZnSOD activity is 4.8 U/mg for the sample shown in (B).

The plot of percent inhibition verses protein concentration can be fit with a curve using a computer program (e.g., Enzfitter, version 1.03, Michaelis Menton kinetics, R.J. Leatherbarrow, Sigma Scientific) or simply by hand drawing a best fit curve through the points on engineering graph paper.

One unit of activity is defined as the amount of protein that will inhibit NBT reduction by 50% (e.g., if maximum inhibition = 95%, then 50% of maximum = 47.5%; therefore, 1 unit is defined as the amount of protein which yields 47.5% inhibition). Usually one unit of activity is 6 to 10 ng protein for purified CuZnSOD (OXIS International), 35 to 50 ng of purified MnSOD, or 10 to 20 µg protein for total SOD activity (i.e., in the absence of NaCN) in an average cell sample. Units of total SOD activity/milligram protein in the nonNaCN-containing assay can then be calculated for a given sample by taking 1000/ug protein per unit. Units of CN^- resistant (or MnSOD) activity can be calculated from a similar percent inhibition curve run in the presence of NaCN using the highest maximum inhibition obtained for samples run in the presence of NaCN.

See the examples of a standard curve (Fig. 7.5.2) or sample curves (Fig. 7.5.3) for data sets in which SOD activity was determined using this methodology. Notice in Figure 7.5.3 how the assay differentiates between CuZn- and MnSOD activity under conditions where MnSOD is being induced by exposure to tumor necrosis factor (TNF) and interferon-gamma (IF-γ).

18. Determine MnSOD activity from the CN^- containing tubes. Determine total activity from the nonCN^- tubes.
19. Calculate CuZnSOD activity, which is the total SOD activity minus the MnSOD activity.

REAGENTS AND SOLUTIONS

Use double distilled or Nanopure 18.3-megaohm purified water (Barnstead/Thermolyne) for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BCS

Dissolve 0.00565 g bathocuproinedisulfonic acid (BCS) disodium salt in 1 ml of 0.05 M potassium phosphate buffer (see recipe). Store up to 2 days at 4°C.

BSA in DETAPAC buffer

Dissolve 0.0202 g BSA in 100 ml DETAPAC buffer (see recipe). Store up to 3 days at 4°C.

DETAPAC buffer, 1.34 mM

Dissolve 0.2653 g diethylenetriaminiepentaacetic acid (Sigma-Aldrich) in 500 ml 0.05 M potassium phosphate buffer, pH 7.8 (see recipe) with stirring. Store up to 1 year at 4°C.

NaCN, 0.33 M

Dissolve 0.8093 g NaCN (Fisher Scientific) in 50 ml 0.05 M potassium phosphate buffer, pH 7.8 (see recipe). Store up to 3 days at 4°C.

CAUTION: *NaCN is poisonous and care is advised in handling. It should be used and disposed of according to local health and safety regulations.*

Nitroblue tetrazolium (NBT), 2.24 mM

Dissolve 0.1832 g NBT (Sigma-Aldrich) in 100 ml 0.05 M potassium phosphate buffer, pH 7.8 (see recipe) with stirring. Store in a brown bottle (i.e., protected from light) up to 1 year at 4°C.

Potassium phosphate buffer, pH 7.8

Monobasic solution:

Dilute 10 ml 1 M potassium phosphate monobasic (Fisher Scientific; 136 gm/liter KH_2PO_4) to 200 ml with H_2O

Dibasic solution:

Dilute 50 ml 1 M potassium phosphate dibasic (Fisher Scientific; 174 gm/liter K_2PO_4) to 1 liter with H_2O

Potassium phosphate buffer:

Add monobasic solution to dibasic solution with constant stirring at room temperature until pH reaches 7.8. Store up to 1 year at 4°C.

Xanthine, 1.18 mM

Heat while stirring 0.0045 g xanthine (Sigma-Aldrich) in 25 ml 0.05 M potassium phosphate buffer, pH 7.8 (see recipe). Store up to 7 days at 4°C.

COMMENTARY

Background Information

The discovery that O_2-metabolizing cells contain enzymes that exhibit superoxide dismutase activity (SOD) has lead to an explosion of interest in the field of free radical biology (Fridovich, 1978; Halliwell and Gutteridge, 1999). These enzymes catalyze the conversion of superoxide ($O_2^{-\cdot}$) to H_2O_2 and O_2 according to the following reaction: $2O_2^- + 2H_2 \rightarrow H_2O_2 + O_2$. The SOD enzymes are thought to limit the steady state concentration of superoxide ($O_2^{-\cdot}$) formed as a byproduct of electron transport chain activity as well as mono-oxygenase enzymatic activity. Superoxide is a weak oxidant but an excellent reductant; therefore, if steady state concentrations of $O_2^{-\cdot}$ are not held in check via the action of SOD enzymes, it is believed that $O_2^{-\cdot}$ could reduce redox active metal ions such as Fe^{3+} and Cu^{2+} to potent oxidants such as Fe^{2+} and Cu^{1+}, which could promote excessive damage to critical biomolecules (e.g., lipids, proteins, nucleic acids) as well as leading to the formation of other reactive oxygen species such as hydroxyl radical (·OH), organic hydroperoxides (ROOH), alkoxyl radicals (RO·), and hydroperoxyl radicals (ROO·). In addition, $O_2^{-\cdot}$ can react with another biologically significant free radical, nitric oxide (NO·), to form peroxynitrite ($ONOO^-$), which can act as a potent oxidant capable of causing damage to critical biomolecules. For these reasons the superoxide dismutase enzymes are generally thought to play a protective role in cellular physiology and the regulation of these enzymatic activities is thought to contribute to mammalian cellular responses to a wide variety of biologically significant stresses of toxicological importance.

The NBT-BCS SOD assay was developed in order to provide an accurate and reproducible quantitative assay for CuZnSOD and MnSOD activities in whole mammalian tissue homogenates (Spitz and Oberley, 1989). This was necessary, because whole mammalian tissue homogenates contain substances that interfere with the accurate determination of SOD activity during standard addition experiments (Spitz and Oberley, 1989). The inclusion of metal chelators that also inhibit electron transport through iron-sulfur proteins was found to inhibit the interfering reactions and allow for the accurate determination of SOD activity in whole homogenates (Spitz and Oberley, 1989). Since the original development of the assay, several studies looking at the correlation between the activity measurements obtained with the NBT-BCS assay and quantities of SOD protein as determined by immunoblotting procedures have shown excellent agreement (Oberley et al., 1989; Spitz et al., 1990).

The major strength of the NBT-BCS assay is the rigorous quantitative determination of MnSOD and CuZnSOD activity in whole homogenates of mammalian tissues and cells. Whole homogenates are desirable, because when preparing the sample, one need only homogenize in 50 mM potassium phosphate buffer, pH 7.8, containing 1.34 mM DETAPAC (i.e., DETAPAC buffer). This avoids any tissue processing or extraction procedure that could remove SOD activity from the sample. In addition the NBT-BCS assay is significantly more sensitive than activity assays based on cytochrome c reduction (Spitz and Oberley, 1989). Native gel SOD activity assays (Beauchamp and Fridovich, 1971) will also provide a

Table 7.5.2 Representative Rat Tissue SOD Activity

Tissue	Activity (U/mg protein)		
	Total SOD	MnSOD	CuZnSOD
14-day lactating breast[a]	200	13	187
Breast adenocarcinoma[a]	105	12	93
Rat liver[b]	442	78	364

[a]Spitz and Oberley (1989).
[b]Brown et al. (1998).

semiquantitative determination of MnSOD and CuZnSOD activity when using whole homogenates, but these assays have difficulty discriminating between samples that display ≤2-fold differences in activity. Direct assays of SOD activity based on following the disappearance of superoxide in aqueous solutions (from potassium superoxide) have also been described (Marklund, 1985) but require doing the assay in pH ranges that alter the activity of MnSOD. Direct kinetic assays based on stopped-flow devices have also been used to accurately determine SOD activity (Wiess et al., 1993), but these assays are generally not amenable to use with whole homogenates. For these reasons the authors have found the NBT-BCS to be the most sensitive, accurate, and reproducible method for use with whole mammalian tissue homogenates.

Troubleshooting

The problems that arise during the use of the NBT-BCS assay all derive from very low activity in the sample or interfering substances that are not totally inhibited by the inclusion of DETAPAC and BCS. These include:

1. Turbidity of samples where very large amounts of protein need to be added to reach maximum inhibition. This is the problem in samples with very nonlinear rates. A low-speed ($<50 \times g$) centrifugation step to remove macroscopic pieces of connective tissue will usually solve this problem.

2. Low maximum percent inhibition (the maximum percent inhibition is <90%) due to nonSOD inhibitable NBT reduction. This problem can be solved by always constructing a complete protein versus percent inhibition curve and using the maximum percent inhibition obtained. In a series of samples being compared to one another always use the greatest maximum inhibition value obtained during that particular comparison so that all the samples are being compared using the same value.

3. Spontaneous NBT reduction occurring in the absence of exogenous xanthine oxidase (the solution in the tube will turn light purple or blue before XO solution is added). When this happens, it is always prudent to split the sample into two aliquots and do a standard addition experiment to be sure that the assay is accurately detecting known amounts of SOD activity added to the sample. Standard addition experiments are described in great detail elsewhere (Spitz and Oberley, 1989).

Anticipated Results

Overall, when utilized according to the aforementioned protocol, the NBT-BCS is the most accurate and reproducible method for discriminating between CuZn and Mn SOD activity in mammalian tissue homogenates that the authors' group of SOD researchers have found to date. Typical results from rat tissue whole homogenates are shown in Table 7.5.2.

Time Considerations

The major drawback to the NBT-BCS assay is the cost in time and supplies necessary to construct full percent inhibition versus protein concentration curves for each sample in the presence and absence of NaCN; however, by utilizing an automated spectrophotometer and pipetting the dilutions of the samples to be run beforehand, two workers can easily accomplish 12 samples and a standard curve each work day. Also the added reliability of data obtained from complete percent inhibition versus protein concentration curves justifies the additional cost and effort.

Measurement of Ascorbic Acid and Dehydroascorbic Acid in Biological Samples

Ascorbic acid (AA) and dehydroascorbic acid (DHA) play an important role in the maintenance of redox homeostasis. The concentrations of these biomolecules in such samples as plasma, isolated cells, and tissues are frequently used as markers of oxidative stress levels in a variety of experimental setups ranging from cellular biology to animal models and clinical trials. With an emphasis on HPLC with electrochemical detection (see Basic Protocol), this unit describes measurement of the antioxidant-couple AA-DHA as well as isoascorbic acid (IAA or erythorbic acid), dehydroisoascorbic acid (DHIA or dehydroerythorbic acid), and uric acid (UA) and discusses realistic expectations and potential pitfalls in the analysis of these labile compounds. The importance of sample preparation is discussed, and procedures for the proper preparation and stabilization of samples from a variety of biological origins are provided (see Support Protocols 1, 2, and 3). Furthermore, passivation of HPLC equipment for lowering detector background (see Support Protocol 4) and the use of endogenous and internal standards in data analysis (see Support Protocol 5) are described.

BASIC PROTOCOL

ANALYSIS OF ASCORBIC ACID, DEHYDROASCORBIC ACID, ISOASCORBIC ACID, DEHYDROISOASCORBIC ACID, AND URIC ACID BY HPLC WITH COULOMETRIC DETECTION

The HPLC method (Lykkesfeldt, 2000) described here with some modifications is based on the measurement of ascorbic acid (AA), isoascorbic acid (IAA), and uric acid (UA), and in a separate parallel run, total AA, total IAA, and UA in samples stabilized with *meta*-phosphoric acid (MPA; Fig. 7.6.1). The concentrations of dehydroascorbic acid (DHA) and dehydroisoascorbic acid (DHIA) are subsequently calculated by subtraction of the AA and IAA concentrations from those of total AA and total IAA, respectively. Total AA and IAA concentrations are obtained by reducing a sample aliquot with tris(2-carboxyethyl)phosphine hydrochloride (TCEP) prior to its analysis. Reversed-phase ion-pairing HPLC separates the analytes, and the compounds are quantified by coulometric electrochemical detection. This highly sensitive, specific, and fast method accurately measures AA, DHA, IAA, DHIA, and UA in a wide variety of biological samples.

Materials

Mobile phase (see recipe)
Plasma (see Support Protocol 1), isolated-cell (see Support Protocol 2), or tissue homogenate sample (see Support Protocol 3) stabilized with *meta*-phosphoric acid (MPA)
1 mM Na_2EDTA prepared from 10 mM Na_2EDTA (372 mg/100 ml)
TCEP solution (see recipe)
McIlvaine buffer (see recipe)
Standard mixture (see recipe)
5% MPA/EDTA solution (see recipe)

High-performance liquid chromatography (HPLC) system (for passivation see Support Protocol 3), including:
- Isocratic pump (Agilent 1100 series, or equivalent low-pulsation-type pump)
- Vacuum degasser (e.g., Agilent 1100 series), optional
- Column thermostat (e.g., Agilent 1100 series), 30°C
- Thermostatted autosampler, 10-µl injection volume (e.g., Agilent 1100 series), 5°C

Current Protocols in Toxicology (2002) 7.6.1-7.6.15

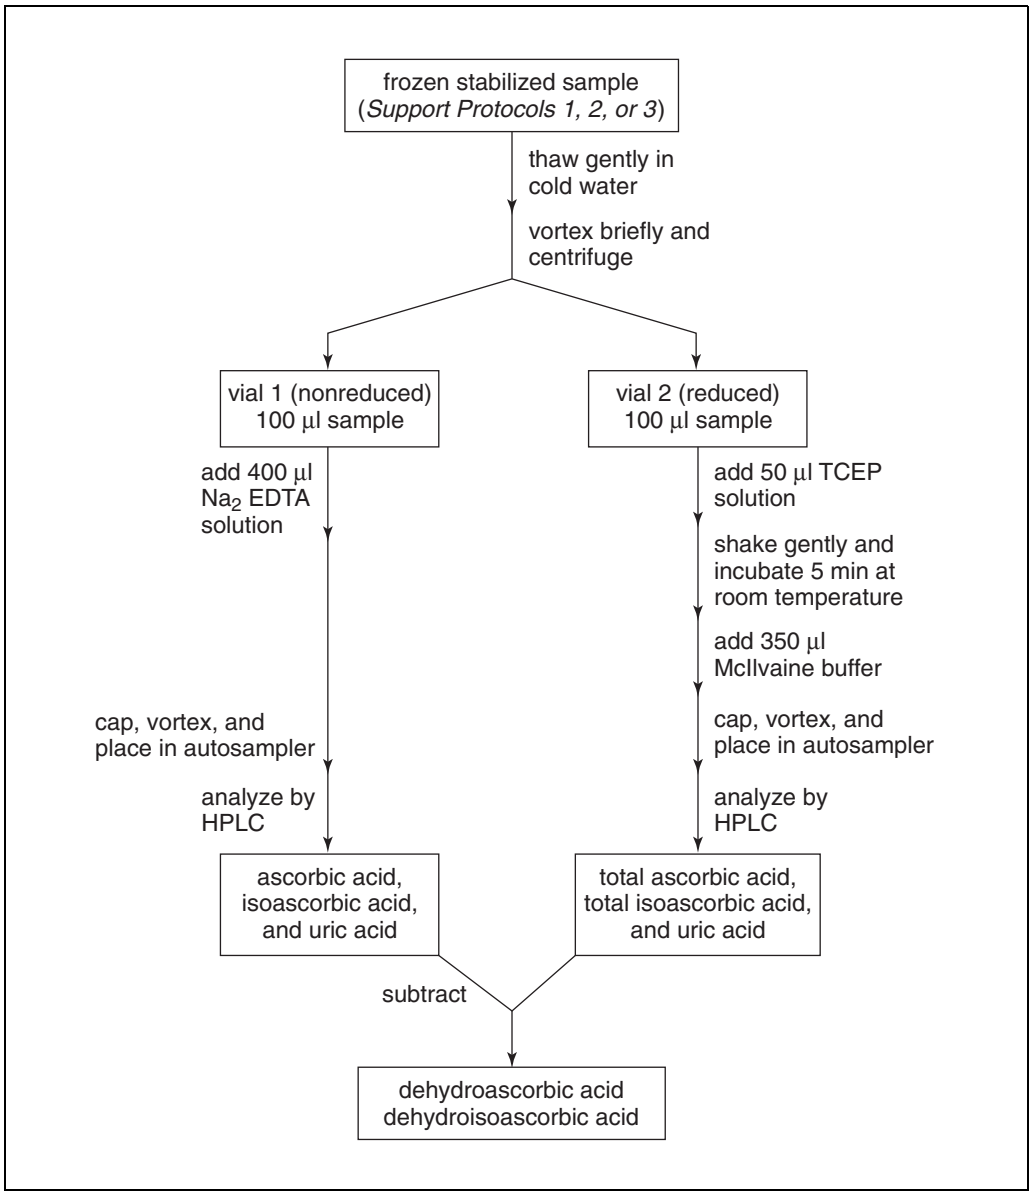

Figure 7.6.1 Sample preparation, analysis, and quantification of ascorbic acid, dehydroascorbic acid, isoascorbic acid, dehydroisoascorbic acid, and uric acid in a biological sample. The individual steps are described in detail in the Basic Protocol.

Uninterruptible power supply (UPS) for HPLC system (e.g., Smart-UPS 3000VA with extended battery pack, part nos. SU3000INET and SU48BP, respectively; American Power Conversion), optional, but highly recommended

Coulometric detector (ESA Coulochem II; ESA) and accessories, including:
- HP 35900E interface module (Agilent)
- Model 5020 guard cell (ESA)
- Model 5010 dual analytical cell (ESA)

HPLC column: 7.5-cm × 4.6-mm (i.d.) Luna C18(2) 3-µm particle size (Phenomenex)

Guard column: 4.0-mm × 3.0-mm (i.d.) SecurityGuard C18 (Phenomenex)

Microcentrifuge (e.g., Eppendorf 5417R or equivalent), 4°C

Amber HPLC vials with caps (e.g., Agilent), inserts may be required for small volumes

Set up HPLC system

1. Set up an HPLC system consisting of an isocratic pump, an optional vacuum degasser, a column thermostat, and a thermostatted autosampler. Set the autosampler to deliver a 10-µl volume. Use a UPS for the system.

   The vacuum degasser provides optimal protection against air from the mobile phase in the pump heads but can be omitted if the mobile phase is thoroughly degassed using a vacuum filtration system (e.g., Alltech Associates) or a sonicator.

   A UPS for the coulometric detector, or ideally for the entire system, provides excellent protection against surges, spikes, and shifts in current that may otherwise turn off the detector. Although optional, the use of a UPS is therefore highly recommended in facilities where a constant supply of power cannot be guaranteed.

2. Set up a coulometric detector connected via an HP 35900E interface module and fitted with a model 5020 guard cell (placed between the pump and the autosampler) operated at +450 mV and a model 5010 dual analytical cell (placed after the column) operated at −200/+400 mV.

   The current range is typically 1 to 10 µA. The precise potentials applied may change from one electrochemical cell to another, and therefore it is always important to generate voltammograms for all analytes whenever the electrochemical cell is changed and every 6 months thereafter for sensitivity control.

3a. *For new columns only:* Start up the HPLC system and flush an HPLC column with mobile phase for 1 week at a flow rate of 1 ml/min.

   Because of the ion-pairing separation principle, no retention of the analytes is observed on a new unequilibrated column. Thus, a new column needs to be thoroughly equilibrated prior to use. Recycling of mobile phase during the equilibration is not advised. The procedure may conveniently be performed on a separate HPLC pump. Gradually, retention is observed, and retention times eventually stabilize at roughly 3.5, 4.5, and 5.5 min for AA, IAA, and UA, respectively. The column can then be stored in the mobile phase ready for use on the main system. Guard columns do not need to be equilibrated and are changed as dictated by increasing back pressure.

3b. *For previously used columns:* Start up the HPLC system and flush a guard column and an HPLC column with mobile phase for ~10 min at a flow rate of 1 ml/min.

   During normal use, the system needs to equilibrate for ~10 min prior to sample loading. The flow rate can be adjusted as necessary as the column ages to maintain a 5- to 7-min run time. A column usually shows excellent performance for several thousand samples.

   Between batches of samples, the flow rate is kept at 0.05 ml/min with the detector on at all times for optimal performance. Only for major maintenance or long-term operation shutdown is the detector turned off. Mobile phase may be recycled after an appropriate rinse-out period.

Analyze sample

4. Gently thaw a plasma, isolated-cell, or tissue homogenate sample in cold water. Vortex sample and microcentrifuge 2 min at 16,000 × *g*, 4°C (Fig. 7.6.1).

   Samples are thawed and prepared in batches of eight to twenty, depending on the experience of the analyst, to limit the sample preparation time for each sample.

   Depending on how quickly samples were originally frozen during preparation (i.e., if samples were placed in a −20°C or −80°C freezer, on dry ice, or in liquid nitrogen), some fractionation of the sample may have occurred leading to very poor results if used directly. Consequently, vortexing the thawed sample, even if it appears homogeneous, can be vital. The subsequent centrifugation can be omitted if samples are consistently free of precipitate.

5. Transfer 100 µl sample to each of two separate amber HPLC vials.

   Smaller volumes down to ~5 to 10 µl of sample can be used without problems with proper adjustment of the amounts in the following steps. With smaller volumes it may be necessary to use vial inserts to ensure proper injection volume if an autosampler is used.

   Sometimes dilution can be necessary, in particular for tissue samples. In this case the 100-µl sample is diluted with 5% MPA/EDTA solution (e.g., 25 µl sample and 75 µl of 5% MPA/EDTA solution) and processed as described below.

6. To the first vial, add 400 µl of 1 mM Na_2EDTA. Cap the vial, vortex briefly, and place the 500-µl sample in the thermostatted autosampler at 5°C and analyze in the shortest time possible.

   Here and in step 8, the autosampler will inject a 10-µl aliquot from the sample onto the HPLC column. Alternatively, the sample may be manually injected onto the column.

   When analyzing multiple samples, steps 6 to 8 may be performed by using a multipipettor for increased speed and reproducibility.

   This sample represents AA, IAA, and UA. Because AA and IAA are prone to oxidation, samples should be analyzed within 12 hr, preferably less.

   Figure 7.6.2 shows representative HPLC chromatograms of various samples.

7. Add 50 µl TCEP solution to the second vial, shake gently, and leave it for 5 min at room temperature.

   Reduction of oxidized AA and IAA occurs in <5 min.

8. Add 350 µl McIlvaine buffer. Cap the vial, vortex briefly, and place the 500-µl sample in the autosampler at 5°C and analyze.

   This sample represents total AA and IAA (AA plus DHA and IAA plus DHIA, respectively) and UA. Standards and samples containing TCEP are stable in the autosampler for ≥4 days even at room temperature. Analyzing the nonreduced (step 6) and reduced (step 8) samples in pairs gives the best results in terms of quantification reproducibility and reduces the risk of error due to voltammogram shifts and changes in detector efficiency.

Prepare standards

9. Prepare a series of 100-µl standard mixture dilutions in amber HPLC vials using 5% MPA/EDTA.

   Standards containing 1 to 100 µl standard mixture diluted to 100 µl (corresponding to 1 to 100 pmol AA and IAA and 5 to 500 pmol UA per 10-µl injected sample) are used depending on the material that is analyzed.

10. Repeat steps 7 and 8 using the 100-µl standard mixture dilutions.

11. Use the HPLC data to generate a standard curve.

Quantify acid levels

12. Quantify AA, IAA, and UA by comparison to the prepared standard curve, perform relevant corrections if applicable (see Support Protocol 5), and calculate DHA and DHIA by subtraction.

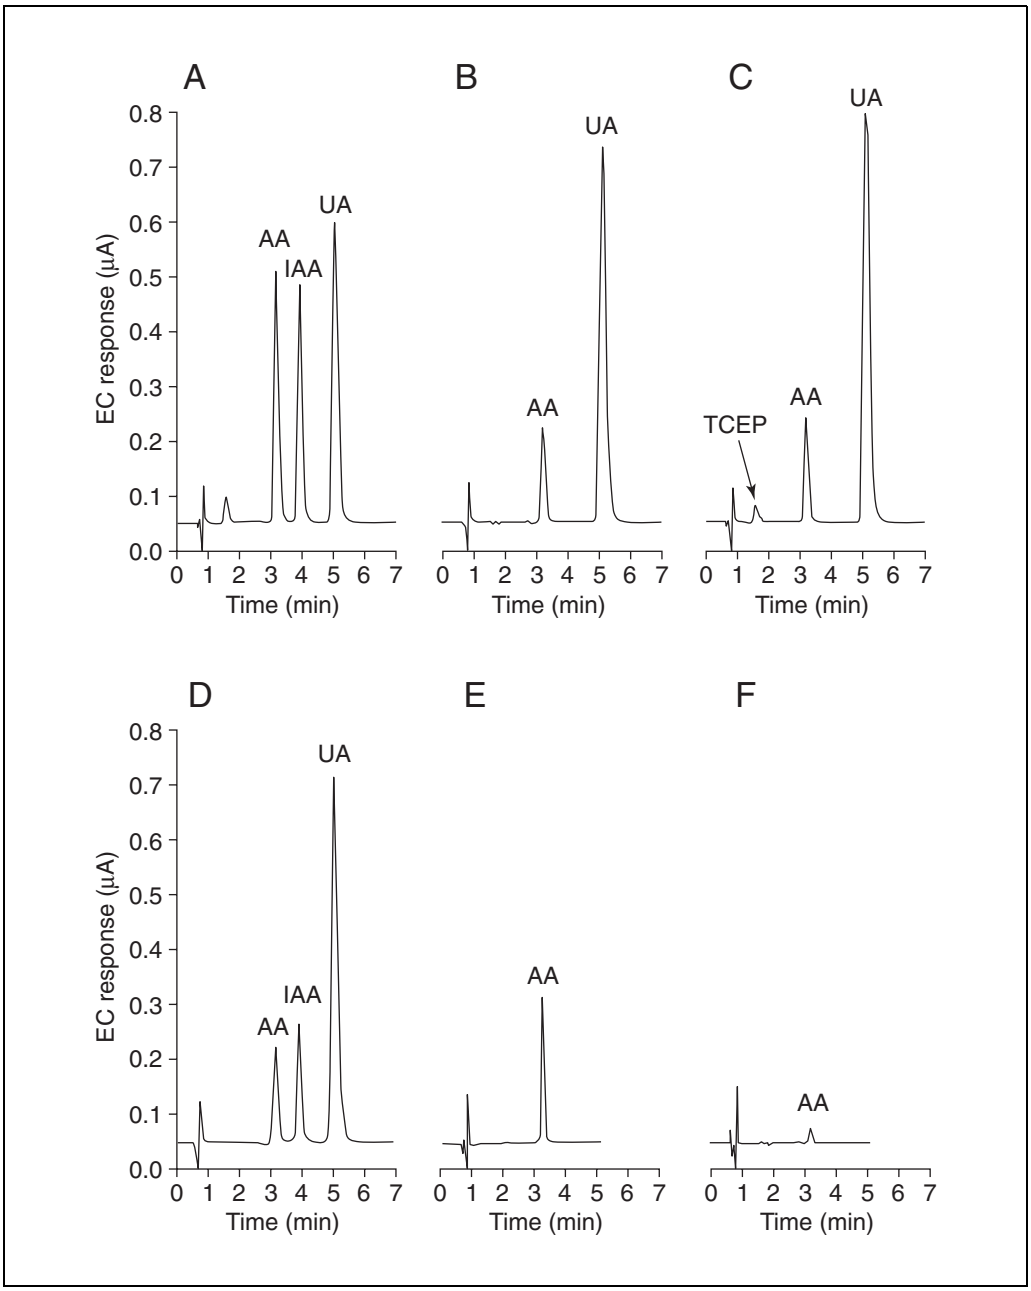

Figure 7.6.2 Separation of ascorbic acid (AA), isoascorbic acid (IAA), and uric acid (UA) by HPLC with coulometric detection. Conditions are as described in the Basic Protocol. (**A**) Standard mixture containing 100, 100, and 250 μM of AA, IAA, and UA, respectively. (**B**) Human plasma sample (male smoker, fasted overnight). AA and UA peaks correspond to 42 and 340 μM, respectively. (**C**) Same human plasma sample run in parallel after reduction with tris(2-carboxyethyl)phosphine hydrochloride (TCEP) as described. After correction for intrasample error using UA (see Support Protocol 5), the dehydroascorbic acid (DHA) concentration was calculated by subtraction to be 0.55 μM, corresponding to 1.2% of the total AA. (**D**) Plasma sample from the same individual taken 2 hr after oral administration of 1 g IAA in water. AA, IAA, and UA peaks correspond to 43, 53, and 331 μM, respectively. (**E**) Lung biopsy from pig (61 mg tissue homogenized and diluted 4-fold). AA peak corresponds to 1.3 nmol/mg tissue. (**F**) Freshly isolated hepatocytes from guinea pig. AA peak corresponds to 2.5 nmol/10^6 cells. EC, electrochemical.

COLLECTION AND STORAGE OF BIOLOGICAL SAMPLES INTENDED FOR ASCORBIC ACID AND DEHYDROASCORBIC ACID ANALYSIS

Due to the lability of the ascorbic acid (AA), dehydroascorbic acid (DHA), isoascorbic acid (IAA), and dehydroisoascorbic acid (DHIA), proper sample collection is vital in order to obtain reproducible results. The oxidation of AA and IAA starts very rapidly following blood drawing, cell lysis, or tissue homogenization, and all steps must therefore be performed as quickly and uniformly as possible. Protocols for the collection, sample stabilization, and storage conditions for plasma (see Support Protocol 1), isolated cells (see Support Protocol 2), and tissue (see Support Protocol 3) are outlined below. In general, the author stores plasma samples and other body fluids at −80°C or less and processes them within 1 to 2 months, whereas tissue and cell samples are stored at −80°C or less and processed within 1 to 2 weeks.

SUPPORT PROTOCOL 1

Preparation of Plasma Samples

This protocol can also be used to prepare samples from other body fluids.

Materials

Anticoagulated blood sample (e.g., collected in an EDTA- or heparin-containing vacutainer)
10% MPA/EDTA solution (see recipe), 4°C
Microcentrifuge (e.g., Eppendorf 5417R or equivalent), 4°C

1. Immediately following the collection of an anticoagulated blood sample, microcentrifuge a 1-ml aliquot 2 min at 16,000 × *g*, 4°C.

   When analyzing fluids other than blood, such as cerebrospinal fluid (CSF) or urine, perform only steps 2 to 4.

   A smaller amount can be used if necessary (e.g., for CSF).

   Care should be taken to avoid hemolysis, because the presence of metal ions in the plasma facilitates AA oxidation. If hemolysis is frequently observed with vacutainers, blood can be drawn more safely (albeit less conveniently) by using a butterfly needle.

2. Transfer 400 µl plasma to a microcentrifuge tube containing an equal volume of cold 10% MPA/EDTA solution and vortex.

   If necessary, the samples can be frozen at −80°C at this stage to save time during sample collection. However, sample stability has not been properly evaluated for this procedure, and it is therefore recommended that samples stored in this way be analyzed within 2 weeks.

3. Microcentrifuge the mixture 1 min at 16,000 × *g*, 4°C.

4. Store the supernatant at −80°C and process within 6 months (see Basic Protocol).

   Sample stability has only been tested up to 6 months after preparation and may be longer. In general, the author stores plasma samples and other body fluids at −80°C or less and processes within 1 to 2 months.

SUPPORT PROTOCOL 2

Preparation of Isolated-Cell Samples

Most intact, viable cells are not prone to oxidation in the same way as plasma and isolated tissues are because any dehydroascorbic acid (DHA) formed is efficiently reduced to ascorbic acid (AA) intracellularly. Once acidified, however, the cells lose this ability and should be treated as other AA-containing samples.

Materials

Isolated cells in suspension (e.g., 2×10^6 hepatocytes/ml)
10% MPA/EDTA solution (see recipe), 4°C
Microcentrifuge (e.g., Eppendorf 5417R or equivalent), 4°C

1. Mix isolated cells in suspension with an equal volume of cold 10% MPA/EDTA solution and shake vigorously for 1 min.

   The intracellular concentrations of the analytes are measured here because the extracellular concentrations are negligible following the cell isolation procedure, which includes several washes (Berry et al., 1991).

2. Microcentrifuge the mixture for 1 min at 16,000 × *g*, 4°C.

   Some researchers use disruption of the cells prior to centrifugation, but in the author's experience this is not necessary. Meta-phosphoric acid (MPA) treatment results in quantitative release of the analytes (Lykkesfeldt and Ames, 1999).

3. Store the supernatant at −80°C and process within 1 month (see Basic Protocol).

   Sample stability has only been tested up to 1 month after preparation and may be longer. In general, the author stores cell samples at −80°C or less and processes them within 1 to 2 weeks.

Preparation of Tissue Samples

SUPPORT PROTOCOL 3

Tissues can be either snap-frozen in liquid nitrogen and stored at −80°C until homogenization or homogenized prior to storage.

Materials

Isolated intact organ
PBS (*APPENDIX 2A*) or 1.15% (w/v) potassium chloride, 4°C
5% MPA/EDTA solution (see recipe), 4°C

2-ml conical Potter-Elvehjem homogenizer, on ice
Stirring motor for homogenization (e.g., IKA Eurostar digital, part no. 2482000; IKA-Werke)
Microcentrifuge (e.g., Eppendorf 5417R or equivalent), 4°C

1. Quickly rinse an isolated intact organ in PBS or 1.15% potassium chloride.

   Alternatively, the organ can be perfused in situ depending on the desired experimental protocol.

2. Dry organ surfaces gently by blotting on a piece of lint-free tissue.

3. Snap-freeze the entire organ or a suitable, freshly cut block of tissue in liquid nitrogen and store ≤1 month at −80°C until sample preparation and analysis.

   The tissue, in particular a block of tissue, should be frozen immediately. Analysis can easily be performed on 10 mg tissue, so the amount of tissue that is saved depends largely on the number of other experiments intended and convenience. This step is omitted if tissues are homogenized immediately.

4. Quickly weigh out 20 to 40 mg frozen tissue and homogenize immediately in a final 50-fold dilution of cold 5% MPA/EDTA solution (e.g., 980 µl/20 mg tissue) using a 2-ml conical Potter Elvehjem homogenizer and stirring motor. Keep the homogenizer in an ice bath.

Mechanical glass-Teflon Potter-Elvehjem homogenizers usually work well for liver and brain tissue (2 to 3 min, 750 rpm), but for lung and muscle tissue the author uses a manual glass-glass homogenizer (without a stirring motor) for better and quicker disruption of the tissue.

The use of sonication or high-speed metal shaft homogenizers for tissue disruption is not recommended because the metal rods appear to facilitate catalyzed autooxidation.

5. Microcentrifuge the mixture 1 min at 16,000 × *g*, 4°C.
6. Process samples immediately (see Basic Protocol).

Alternatively, if using fresh tissue, the sample supernatant can be stored for ≤1 month at −80°C until analyzed. Sample stability has only been tested up to 1 month after preparation and may be longer. In general, the author stores tissue samples at −80°C or less and processes them within 1 to 2 weeks.

SUPPORT PROTOCOL 4

PASSIVATION OF AN HPLC SYSTEM

When using electrochemical detectors, liquid chromatography components made from stainless steel can contribute to baseline noise and high background current due to wash-off of electrochemically active substances from the metal surfaces. In order to maximize detector performance, the chromatographic system should be cleaned (passivated) once or twice a year or when the baseline noise is too high.

Additional Materials *(also see Basic Protocol)*

6 N nitric acid
Glacial acetic acid
Unions appropriate for the high-performance liquid chromatography (HPLC) system

1. Switch off the electrochemical cell and shut down the pump of an HPLC system and coulometric detector (see Basic Protocol).

It may not be necessary to turn off the actual electrochemical detector if the electrochemical cells can be switched off separately, in which case the detector can be left on for a quicker resumption of optimal performance.

2. Remove and cap the guard column, analytical column, and electrochemical cells (guard and detector cells) and replace them with appropriate unions.

By replacing the columns and electrochemical cells with unions, the entire system is passivated while bypassing the acid-incompatible parts.

3. Pump water through the system at 1 ml/min for 1 hr while inspecting for leaks.
4. Change the water to 6 N nitric acid and pump through the system at 1 ml/min for 30 min.
5. Switch the nitric acid over to glacial acetic acid. Pump the glacial acetic acid through the HPLC system at 1 ml/min for 30 min.
6. Change the glacial acetic acid to water and pump it through the system for ≥30 hr and make sure that the pH of the effluent is approximately ≥5.0.
7. Change to the original mobile phase and pump it through the system at 1 ml/min for 30 min. Turn off the pump and replace the unions with the guard column, analytical column, and electrochemical cells. Turn on the pump and subsequently the electrochemical cells and continue equilibration.

After a short equilibration period of the electrochemical detector cell (~2 hr) the system is ready for use, but full sensitivity is usually not restored until the following day.

QUANTIFICATION OF ASCORBIC ACID AND DEHYDROASCORBIC ACID USING SUBTRACTION METHODS WITH ENDOGENOUS AND/OR INTERNAL STANDARDS

With this subtraction method, both ascorbic acid (AA) and, following the reduction of any dehydroascorbic acid (DHA), total AA levels present in the sample are analyzed. The amount of DHA originally present is then calculated by subtraction of AA from total AA. This method is also used to quantify isoascorbic acid (IAA) and dehydroisoascorbic acid (DHIA). A more detailed discussion of the problems associated with this assay principle is given below (see Background Information). Depending on the origin of the biological material and the experimental design, uric acid (UA) and IAA can be used as endogenous and internal standards, respectively.

The Use of an Endogenous Standard to Correct for Intrasample Error of Analysis

Because UA is not affected by the tris(2-carboxyethyl)phosphine hydrochloride (TCEP) reduction step, this compound can conveniently be used to correct for intrasample error of analysis—such as that due to pipetting or the apparatus—between the paired nonreduced and reduced samples. Because >99% of ascorbic acid found in biological samples isolated under nonstressing conditions is in the reduced form, this correction greatly reduces the error in the subsequent DHA (or DHIA) calculation and is therefore highly recommended. If UA is not present in the biological material under investigation, an appropriate amount (~100 μM final concentration) of exogenous UA can be added prior to sample workup. However, because additional sample handling may contribute to oxidation, this should be used primarily for optimizing procedures using test samples.

Use the following formulas for the correction:

$$AA_C = AA \times (UA_T/UA)$$
$$DHA = AA_T - AA_C$$

where AA_C is the AA concentration after correction, UA, AA, UA_T, and AA_T, are the UA and AA concentrations in the nonreduced and reduced samples, respectively. AA can be exchanged with IAA to determine the quantity of DHIA in the sample.

The Use of an Internal Standard to Correct for Artifactual Sample Oxidation

Regardless of any measures taken to avoid artifactual oxidation of AA, oxidation will occur—if not during sample collection and/or sample preparation, then during the analysis itself (i.e., on the HPLC instrument)—resulting in the production of DHA. This is particularly true for the nonreduced sample, but, even for the reduced sample, minute amounts of oxidized metabolite may be formed when AA is separated from the reducing agent on the column. For example, in samples from control material (e.g., healthy nonsmoking humans), the artifactual oxidation will constitute the majority if not all of the measured DHA (typically ~1% to 4% of the measured AA concentration). Addition of IAA to a set of samples at the time of collection or at the time of analysis can help reveal the origin and amount of artifactual oxidation during the different steps of the assay in a particular laboratory. However, due to the autooxidation of IAA itself, it may not be practical to use IAA as a general internal standard if multiple samples are collected over time as in a clinical setting. Also, the biological material should be checked to confirm that IAA is not naturally present before it is used as a standard (see Anticipated Results). When an internal standard is included, the following formula can be used to estimate the artifactual oxidation of AA:

$$DHA_C = AA_T - (AA_C \times IAA_T/IAA_C)$$

where DHA_C represents the corrected concentration of DHA; IAA_T is the total amount of IAA added; and IAA_C is the amount of IAA measured by HPLI after correction for UA as described above. Although AA and IAA have identical redox properties (Iheanacho et al., 1995), this simple equation does not take into account that the AA or IAA oxidation rate is also concentration dependent. In order to limit this error, the amount of IAA used should be in the same range as that of AA in the sample.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

McIlvaine buffer

Dissolve 89 g $Na_2HPO_4 \cdot 2H_2O$ in 500 ml water (1 M final). Dissolve 52.5 g citric acid monohydrate in 500 ml water (0.5 M final). Adjust the pH of the citrate solution to 4.5 by adding the sodium phosphate solution (~415 ml). Filter through a 0.22-µm filter and store up to 1 year, or longer, at room temperature.

Mobile phase

Solution A:

Dissolve 17.8 g sodium dihydrogen phosphate monohydrate (129 mM final), 17.6 g anhydrous sodium acetate (215 mM final), 372 mg Na_2EDTA (1.0 mM final), and 50 mg dodecyltrimethylammonium chloride (189 µM final) in 750 ml water.

Solution B:

Dissolve 20 mg tetraoctylammonium bromide (36.6 µM final) in 250 ml methanol.

To make ~1 liter mobile phase, mix 750 ml solution A with 250 ml solution B and adjust the pH of the mixture to 5.4 with *ortho*-phosphoric acid. Store up to 1 month, or longer, at room temperature. Sonicate the mobile phase 5 min and filter on a vacuum filtration system using 0.2-µm PVDF filter membranes.

The author routinely prepares 10-liter batches.

MPA/EDTA solution, 10%

Dissolve 5.0 g *meta*-phosphoric acid (MPA) in 40 ml water (10% w/v final) and add 10 ml 10 mM Na_2EDTA (372 mg/100 ml; 2.0 mM final). Stir or shake at room temperature until the solution is homogenous (~5 to 10 min) and store at 4°C. Make fresh every 3 weeks.

For 5% MPA/EDTA, dilute 10% solution 1:1 with water.

Standard mixture

For uric acid standard:

Dissolve 8.4 mg uric acid (UA) in 100 ml 10% MPA/EDTA solution (see recipe; 0.5 mM final UA). Heat mixture 15 min at 90°C and leave to cool to facilitate dissolution. Store in 600-µl aliquots up to 6 months, or longer, at −80°C.

For ascorbic and isoascorbic acid standards:

Add 44.0 mg ascorbic acid (AA) to 250 ml water (1 mM final) at room temperature. Simultaneously dissolve 44.0 mg isoascorbic acid (IAA) in 250 ml water at room temperature. Dissolve both by inversion.

For standard mixture:

Immediately mix 50 µl 1 mM AA and 50 µl 1 mM IAA with 500 µl cold 0.5 mM UA and dilute to 1 ml with 400 µl water. Make AA and IAA solutions and the final standard mixture immediately prior to preparation of the standard curve.

When used undiluted, this standard mixture corresponds to plasma concentrations of 100 µM AA, 100 µM IAA, and 500 µM UA.

TCEP solution

Dissolve 0.72 mg tris(2-carboxyethyl)phosphine hydrochloride (TCEP, 2.5 mM final) per 1 ml 800 mM Tris buffer, pH 9.0 (see recipe). Make fresh each day.

Tris buffer, 800 mM, pH 9.0

Dissolve 9.69 g tris(hydroxymethyl)aminomethane (Tris) in 90 ml water, adjust the pH to 9.0 with ortho-phosphoric acid, and dilute to 100 ml with water. Store up to 1 month, or longer, at 4°C.

This buffer is stable for at least a year at −20°C.

COMMENTARY

Background Information

Accurate and reproducible measurements of ascorbic acid (AA) and dehydroascorbic acid (DHA) are necessary prerequisites for their application as biomarkers of oxidative stress as well as for understanding their roles in biology. AA has been referred to as "the most important water-soluble antioxidant in plasma" (Frei et al., 1989). It acts as a major radical scavenger in vivo as well as in regenerating other antioxidants such as vitamin E. AA predominately exists in its reduced state in vivo. Upon oxidation via the semidehydroascorbyl radical, the resulting DHA is transported into erythrocytes, and AA is subsequently regenerated intracellularly by one of several possible mechanisms. If not reduced, DHA is hydrolyzed irreversibly to 2,3-diketoglulonic acid, which has no antiscorbutic or antioxidant activity. The concentrations of AA and DHA in such samples as plasma, isolated cells, and tissues have been used as markers of oxidative stress levels in a variety of experiments ranging from test tube cellular biology to animal models and clinical trials (Lykkesfeldt et al., 1996, 1997, 1998, 2000; Hagen et al., 1998, 1999; Poulsen et al., 1998; Lykkesfeldt and Ames, 1999).

Assessment of AA concentrations in plasma is routinely performed in many laboratories. A wide variety of methods have been presented over the last decades employing spectrophotometry; fluorometry; gas chromatography; enzymatic assays; and capillary electrophoresis HPLC with UV, fluorescence, or electrochemical detection (reviewed by Rumsey and Levine, 2000). In some cases, AA has been measured as DHA following oxidation. Most methods of AA measurement, in particular HPLC-based methods, are capable of producing valid results if the precautions described below (see Critical Parameters and Troubleshooting) are taken. Some postsampling oxidation can even be eliminated by using tris(2-carboxyethyl)phosphine hydrochloride (TCEP) as the reductant as described in the Basic Protocol.

In contrast to AA measurements, quantification of DHA is a substantial challenge for several reasons. First of all, DHA is a highly labile compound with a half-life of only a few minutes at neutral pH (Bode et al., 1990). AA is converted to DHA nonenzymatically, and, practically speaking, it is not possible to completely avoid artifactual DHA formation at a concentration equal to a few percent of the AA in the sample unless the experiment is carried out in an oxygen-free environment. Also, DHA can be irreversibly hydrolyzed as mentioned above and thereby lost from the AA pool. Second, whereas detection of AA by coulometry is both selective and highly sensitive, no direct and sensitive method exists for the detection of DHA. Consequently, each assay principle employed for DHA involves tradeoffs. Precolumn, postcolumn, or in-line derivatization of DHA in combination with HPLC with fluorescence detection is used in the analysis of foodstuffs where the concentration of DHA is considerable (Ali and Phillippo, 1996; Kall and Andersen, 1999). However, the methods are not sensitive enough to quantify the minute amounts found in biological systems. Mass-spectrometry methods have also been employed in DHA analysis (Deutsch and Kolhouse, 1993). Although these methods have the ability to quantify small amounts, sample preparation is tedious and the operation requires very expensive equipment and often highly specialized staff. Moreover, derivatization techniques in general have the drawback of unintentionally shifting the equilibrium between AA and DHA instead of preserving it.

A different methodology of DHA quantification is the so-called subtraction method described in the Basic Protocol. Here AA is measured in one aliquot of a sample followed by

measurement of total AA (i.e., AA and DHA) in a second aliquot of the same sample. Subsequently, the DHA concentration can be indirectly assessed by subtracting the measured AA concentration from the total AA concentration. The major drawback of this assay principle is that AA and total AA concentrations are similar and usually many-fold greater than the concentration of DHA. Consequently, the resulting DHA concentration is encumbered with a relatively large error compared with a directly measured concentration. As discussed below (see Anticipated Results), one must realize that no existing method for the measurement of DHA is ideal and can completely eliminate the artifactual postsampling formation of the compound. However, the more useful and recent methods have incorporated various measures to limit this error.

Another inconvenience of subtraction methods is that the reducing agent used for the total AA measurement often has to be removed prior to HPLC analysis because of chromatographic interference. Dithiothreitol (DTT) is a convenient and powerful reducing agent commonly used in total AA analysis. However, although removal of DTT is usually not necessary before HPLC separation, the pH at which samples are usually stored in the autosampler is too low (typically <3) for DTT to have any ability to keep AA reduced. In the case of both removal and inactivity of the reducing agent, the stability of AA in the reduced samples is compromised, and rapid analysis is necessary to obtain valid results. In contrast, the reducing agent TCEP used in the Basic Protocol appears to be ideal for total AA measurement. It does not interfere with the chromatography and remains active at pH 4.5, the pH at which the samples are stored and remain stable.

The method described in the Basic Protocol is modified from Lykkesfeldt (2000) and offers several important and convenient advantages: (1) it is fast and accurate and based on a sensitive and specific analytical principle; (2) it has successfully been employed in the analysis of a wide variety of biological materials; (3) the reduced samples are stable for days, even at room temperature; (4) tedious removal of the reductant from the reduced samples prior to analysis is neither required nor desired; (5) endogenous and/or internal standards can be used to eliminate the intrasample error resulting from the subtraction methodology and to estimate the artifactual oxidation, respectively; and 6) in addition to AA and DHA, the method offers superior separation and co-analysis of IAA, UA, and, subsequently, calculation of DHIA by subtraction.

Critical Parameters and Troubleshooting

One of the most important determinants of accurate assessment of AA, IAA, and their oxidized metabolites is time. The importance of fast and meticulous sample collection, stabilization, storage, and preparation cannot be emphasized enough, as it is by far the most common reason for unanticipated results (Lykkesfeldt et al., 1995). If only the total amount of AA or IAA is of interest, the time factor is less critical albeit still important. Due to their superior stability, reduced samples prepared with TCEP are highly recommended even when the DHA or DHIA concentration is not desired. In comprehensive clinical trials, it may simply not be feasible to measure DHA if proper sample collection is not possible. Decisions regarding which of the biomarkers will be measured should therefore be made in advance so that methods to ensure proper sample handling can be taken into account in the planning phase.

When samples are collected and prepared as described in this unit, the sample stability is relatively good. However once thawed, the samples start to oxidize, and analysis of samples that have previously been thawed for other purposes or reanalysis of samples will usually not give proper results. In other words, one only has a single chance of getting it right per sample. Consequently, it is highly advisable to store biological samples in separate aliquots whenever possible.

The presence of hemolysis in plasma samples should be avoided because the resulting increase in iron concentration greatly facilitates oxidation of AA and IAA. When analyzing tissue, perfusing the tissue prior to sample collection can limit the contamination of iron from hemolysis. Tissue concentrations of AA are usually ~20- to 50-fold higher than those of plasma, so the AA contribution from the blood is very limited.

No matter how carefully the sample collection and preparation are planned and carried out, other problems such as a power failure can ruin the experiment. A power failure will stop the sample analysis, cooling of the autosampler, and data collection as a whole, whereas a deep momentary sag in voltage may often just turn off the sensitive coulometric detector resulting

in continued sample separations without detection and data collection. As mentioned above, reanalysis of the nonreduced samples is not a valid option in most cases. Besides saving several aliquots whenever possible as assurance against this type of problem, the author has installed an uninterruptible power supply (UPS). This unit supplies the power for two complete HPLC systems with attached detectors and interface units as well as the computer workstation used for controlling the equipment and data collection (the computer monitor has been left out of the UPS circuit to conserve battery power). The system will maintain full operation on both HPLC systems for ~2 hr during a full power failure. Of equal importance is the complete protection the UPS offers from momentary sags in voltage, which could otherwise accidentally turn off the coulometric detector.

Anticipated Results

AA concentrations vary considerably depending on the species, tissue type, or body fluid under investigation. In most mammalian species, tissues have AA concentrations in the low millimolar range, whereas plasma concentrations usually fall between 10 and 100 μM. IAA is not a naturally occurring compound in animals and will therefore normally not be detectable in fasted subjects. However, in plasma samples taken from humans postprandially, the IAA concentration can amount to as much as 30% of that of AA because IAA is commonly used as a food additive (Sauberlich et al., 1991). The limit of detection for this assay, which is well below these levels (<1 pmol per injection), is not an issue for most applications.

Regarding DHA or DHIA measurements, it is important to realize the limitations of not only the method presented in this unit but also any available method for DHA or DHIA measurement. Most researchers in the field agree that in a normal biological sample (e.g., a plasma sample from a healthy nonsmoking individual), the concentration of DHA is very close to zero in vivo. But artifactual oxidation will occur during sample collection, preparation, and analysis. Even if one is successful in limiting these undesirable events, DHA or DHIA concentrations of up to a few percent of the AA and IAA concentrations, respectively, will commonly be found. It is important to understand that this fact is independent of whether a subtraction method like the one present here or a direct assay is used. Consequently, practice and inclusion of proper controls is the only way of making sure that the assay is correctly performed.

Unfortunately, the true difficulties in measuring DHA and the major risk of artifactual oxidation of AA have been ignored until recently and are only starting to be more widely recognized. Consequently, a considerable proportion of the existing literature on DHA and even recently published papers continue to report values that clearly show artifactually elevated concentrations of DHA of up to 30% of the total AA in healthy subjects. A sound rule of thumb is that the AA pool in plasma, cells, and tissues of normal and healthy origin is >99% reduced in vivo. This starting point combined with meticulous practice and optimization of the procedures will help minimize artifactual formation of DHA in future experiments. Postsampling oxidation of IAA results in artifactual formation of DHIA, and thus all concerns about AA oxidation apply to IAA as well.

Time Considerations

Time is a vital parameter in the collection and stabilization of samples intended for ascorbate analysis as well as in sample preparation and analysis.

The actual sample preparation should be performed as close to the time of analysis as possible due to the lability of the analytes. However, most of the reagents for the assay can be made in advance, and the sample preparation is relatively simple. Thus once in operation, this assay is quick and allows the analysis of up to ~100 samples per day (i.e., 50 samples, nonreduced and reduced) prepared in batches of 8 to 20. The number of samples processed in one batch depends on how quickly the various steps can safely and adequately be performed. The time from when the samples are thawed to when they are placed in the autosampler should be ≤10 to 15 min. Preparation of 100 samples will take 1 to 2 hr followed by HPLC analysis for <12 hr. Although more samples could easily be prepared in a day, it is not recommended to extend the time in the autosampler beyond 10 to 12 hr for samples without reductant, and the less time spent in the autosampler the better. For long runs, a standard sample without reductant can be included for every ten samples to monitor stability. Alternatively, because the run time is normally only 5 to 7 min, the samples of the day can be prepared in two or three portions with 2 to 3 hr between each, thereby reducing the autosampler storage time for the

later samples. In contrast to samples without reductant, samples containing TCEP are stable for ≥4 days in the autosampler (Lykkesfeldt, 2000).

Equilibration of a new analytical column takes considerable time, indicating a slow modification of the stationary phase. If a separate HPLC pump is available, a spare column can conveniently be equilibrated in advance and stored in the mobile phase. Do not begin sample preparation of the biological material before making sure that the column is sufficiently equilibrated and operational. Once equilibrated, the column will usually run thousands of samples before it needs to be replaced. The guard column is changed whenever the back pressure becomes markedly increased. The author routinely starts up the HPLC system and runs a few blanks followed by a standard from the previous day (it takes ~30 min, including a 10-min start-up period) to verify that the equipment is working properly, while preparing the day's standards and reagents. This also appears to stabilize the response of the electrochemical cell. This procedure ensures that the system is working as it should before preparation of the biological samples is initiated.

After extended use, when the column starts to fail in performance, it should be replaced, and the new column thoroughly equilibrated and/or tested before continuing sample analysis. The old column may be used for other purposes, but trying to clean it with solvents or otherwise restore its performance for AA separation is not recommended due to the extensive equilibration time needed afterwards combined with the uncertainty of the outcome.

CHAPTER 8
Heme Synthesis Pathway

INTRODUCTION

Heme is essential for the function of all aerobic cells. As the prosthetic group of the heme proteins—a category that includes hemoglobin, myoglobin, mitochondrial and microsomal cytochromes, catalase, peroxidase, tryptophan pyrrolase, and nitric oxide synthase—heme catalyzes reactions involved in oxygen and electron transport, in the oxidative metabolism of various endogenous and exogenous chemicals, in the decomposition of hydrogen peroxide and organic peroxides, in the oxidation of tryptophan, and in the synthesis of nitric oxide. There is approximately 500 to 700 g of hemoglobin (of which 3.8% is heme) in the body of a normal 70-kg adult man. Approximately 85% of heme is synthesized in the erythropoietic bone marrow, and the remainder largely by the liver. Hepatic heme synthesis undergoes a marked induction when cytochrome P-450 synthesis is stimulated.

Inherited deficiencies or acquired defects of enzymes in the heme biosynthetic pathway lead to the disorders of heme biosynthesis, as described in *UNIT 8.1* A number of conditions, such as metal poisoning, environmental chemical exposure, drug induction, inflammation, heat shock and stress reactions, and hypoxia, can also influence the rate of heme biosynthesis and therefore the quantity of heme protein present (Fig. 8.0.1).

Figure 8.0.2 illustrates the steps involved in heme biosynthesis, with the relevant enzymes, as well as inherited enzymatic deficiencies and acquired enzymatic defects relating to this pathway. The nonspecific δ-aminolevulinate synthase (ALAS1) is under negative feedback control by heme, the end-product of the pathway, but may undergo marked induction when hepatic cytochrome P-450 synthesis is stimulated by drug treatment. Because ALAS1 induction and inhibition by chemicals (*UNIT 8.2*) directly influence cytochrome P-450 level and heme concentration (*UNIT 8.3*), this enzyme is critically important in hepatic toxicology. The erythroid-specific ALAS (ALAS2) is essential for erythroid heme syn-

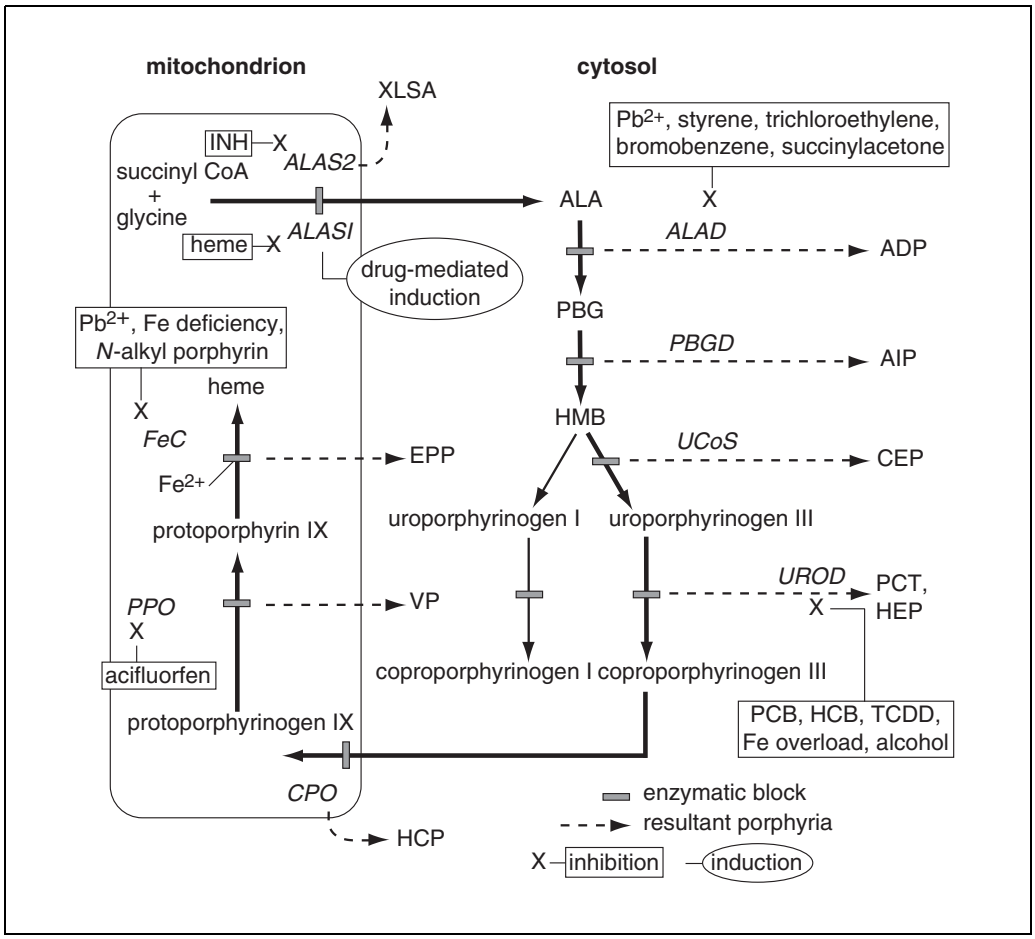

Figure 8.0.2 Heme biosynthetic pathway. Inherited enzymatic deficiencies (in boldface) and acquired enzymatic defects (with the enzyme names in italics) are indicated. Abbreviations: ADP, ALAD deficiency porphyria; AIP, acute intermittent porphyria; ALAD, δ-aminolevulate dehydratase; ALAS, δ-aminolevulinate synthase; CPO, coproporphyrinogen oxidase; EPP, erythropoietic protoporphyria; FeC, ferrochelatase; HCB, hexachlorobenzene; HCP, hereditary coproporphyria; HEP, hepatoerythropoietic porphyria; HMB, hydroxymethylbilane; INH, isonicotinic acid hydrazide; PCT, porphyria cutanea tarda; PBGD, porphobilinogen deaminase; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; UCoS, uroporphyrinogen III cosynthase; UROD, uroporphyrinogen decarboxylase; VP, variegate porphyria; XLSA, X-linked sideroblastic anemia.

thesis, and its inherited deficiency, or inhibition by chemicals such as isoniazid, results in sideroblastic anemia (Fig. 8.0.2).

Four major heme-synthetic enzymes that are the targets of toxic effects by chemicals are ALA dehydratase (ALAD), uroporphyrinogen decarboxylase (UROD), protoporphyrinogen oxidase (PPO), and ferrochelatase (FeC). Inhibition of these enzymes results in conditions that mimic the porphyrias caused by corresponding inherited enzyme deficiencies (Fig. 8.0.2). As discussed in *UNIT 8.6*, ALAD represents one of the most sensitive sites of inhibition of heme biosynthesis by toxicological substances, including lead, styrene oxide, bromobenzene, and trichloroethylene. As described in *UNIT 8.4*, UROD activity can be inhibited by hexachlorobenzene, polychlorinated biphenyls, or dioxins, while as discussed in *UNIT 8.5*, PPO activity is specifically inhibited by acifluorfens, which because of this property are used as herbicides. Like ALAD, FeC is vulnerable to inhibition by heavy metal ions such as lead and mercury; its activity is also additionally decreased by iron deficiency and inhibited by N-alkyl porphyrins, i.e., degradation products of the heme moiety of P-450 (*UNIT 8.7*). Disruption of FeC activity leads to an accumulation of Zn-protoporphyrin in erythrocytes. Measurement of erythrocyte protoporphyrin is used

as an important clinical test for childhood lead poisoning (*UNIT 8.8*). Heme biosynthesis, therefore, is of special interest in environmental toxicology.

Differential response of heme biosynthetic pathway enzymes to drugs and environmental chemicals may result in changes in urinary, blood, tissue, and/or fecal patterns of porphyrin composition. Detecting these changes is a useful diagnostic tool. This analysis requires a relatively rapid and effective procedure for porphyrin separation and measurement. *UNIT 8.9* describes an HPLC method which meets all the stated required criteria.

The Heme Biosynthesis Pathway and Clinical Manifestations of Abnormal Function

The biosynthesis of heme is an essential process in both prokaryotes and eukaryotes. A multienzyme pathway is used in all species to convert simple precursor molecules to the complex tetrapyrrole protoporphyrin IX. Ferrous iron is then complexed with protoporphyrin IX to form heme (Fig. 8.1.1). The chemistry of porphyrins and the fully reduced porphyrinogens is unique. It is not surprising, therefore, that the enzymes comprising the heme biosynthetic pathway are highly homologous in all species. In humans, both inherited and acquired factors (such as exposure to drugs or environmental toxins) affect the activities of heme biosynthetic enzymes, giving rise to a group of diseases known collectively as the porphyrias (Kappas et al., 1995).

Porphyrins are intensely colored (the term porphyrin is derived from the Greek *porphuros*, meaning red-purple) and they display strong light absorption in the Soret band of the spectrum (~400 nm). Porphyrins fluoresce and it is this property that mediates cellular damage in the skin of patients with several types of porphyria. Although the porphyrin precursors δ-aminolevulinic acid (ALA) and porphobilinogen (PBG) do not fluoresce, neurovisceral symptoms occur when they are present in excess. These neurovisceral symptoms are extremely varied and are usually episodic. It is not known if the neurologic abnormalities are mediated by toxic effects of ALA or PBG, or by a deficiency of heme in neural cells.
