Porphyric disorders in which only porphyrins are produced in excess are characterized clinically by photosensitivity restricted to light-exposed areas. Porphyric disorders in which ALA, PBG, or both are produced in excess are characterized by abdominal colic, peripheral neuropathy, paralysis, psychosis, and even coma. When both porphyrins and porphyrin precursors are produced in excess, both photosensitivity and neurovisceral manifestations are found. A practical classification of the porphyrias, based on the predominant clinical manifestations, is presented in Table 8.1.1.

Inherited heme biosynthetic defects are responsible for most forms of porphyria, but these defects are not the only abnormalities of heme biosynthesis that have clinical importance. For example, iron deficiency affects ferrochelatase activity and protoporphyrin accumulates in iron-deficient red cells. Lead, mercury, arsenic, and other metals may affect heme biosynthesis in humans (Daniell et al., 1997). Lead affects the pathway by inhibiting δ-aminolevulinate dehydratase (ALAD) and it probably also affects the function of coproporphyrinogen oxidase (CPO) and ferrochelatase (Dailey, 1997). Both ALA and porphyrins are excreted in excess in patients with lead poisoning, and the clinical syndrome, in particular the characteristic abdominal pain, resembles an acute porphyric attack.

A number of chemicals, particularly halogenated aromatic hydrocarbons, cause inhibition of hepatic uroporphyrinogen decarboxylase (UROD) activity and produce a syndrome biochemically identical to porphyria cutanea tarda (PCT; Wyckoff and Kushner, 1994). Finally, an uncommon X-linked anemia—characterized by microcytic circulating red cells, iron-laden mitochondria in red cell precursors (ringed sideroblasts), and markedly reduced synthesis of porphyrins and heme—results from mutations in the erythroid-specific form of δ-aminolevulinate synthase (ALAS; Wyckoff and Kushner, 1994).

This overview will emphasize the genetics, biochemistry, and clinical description of the porphyrias, but some of the nonporphyric disorders will also be described. Each step in the heme biosynthetic pathway will be reviewed, including the enzyme mechanism if known, molecular characterization of the relevant genes, disease phenotype, and interacting toxic mediators.

ALA SYNTHASE (ALAS)

Most of the ALA formed on earth is synthesized by plants, photosynthetic algae, and a majority of bacteria via a pathway designated the five-carbon pathway. Glutamate supplies the five-carbon backbone and three enzymes are required: glutamyl tRNA synthase, glutamyl tRNA reductase, and glutamyl 1-semialdehyde aminotransferase (Dailey, 1995). In animals and some bacteria, ALA is formed by the condensation of a glycine with succinyl-CoA (Fig. 8.1.1). In eukaryotes, the enzyme catalyzing the formation of ALA is ALA synthase (ALAS). ALAS is synthesized on ribosomes in the cytosol and then translocated to the mitochondrial matrix, the site of succinyl-

Current Protocols in Toxicology (1999) 8.1.1-8.1.10

CoA generation by the tricarboxylic acid cycle. Pyridoxal 5′ phosphate (PLP) is a required cofactor for ALAS, and the first step in the synthesis of ALA is the formation of an enzyme-PLP-glycine Schiff base complex. The α-carbon of glycine is then deprotonated to yield a stabilized carbanion species. Succinyl-CoA then reacts with the complex and CoA is released. Finally, glycine is decarboxylated, stereospecific addition of a proton occurs, and ALA is released (Dailey, 1995).

Mammals and other higher animals express two forms of ALAS, a "housekeeping" form present in all tissues (ALAS1) and an erythroid-specific form (ALAS2; Wyckoff and Kushner, 1994; Kappas et al., 1995). The two forms of ALAS are encoded by two separate genes on different chromosomes (ALAS1 on 3p21 and

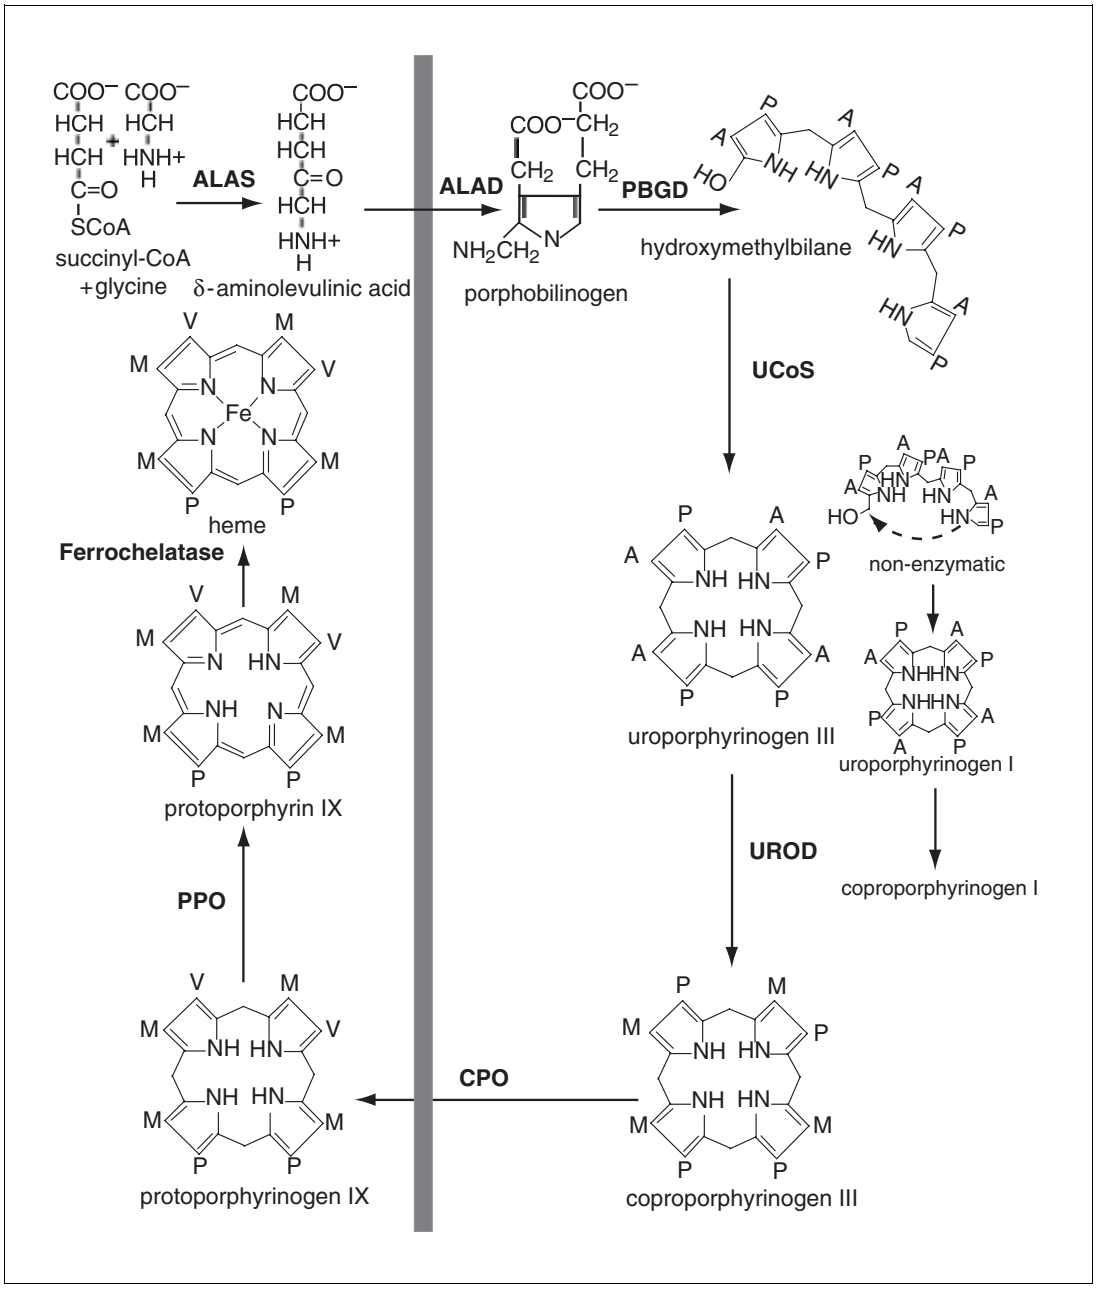

Figure 8.1.1 The heme biosynthetic pathway. Enzymatic reactions to the left of the broad shaded line occur in mitochondria. Reactions to the right of the line occur in the cytosol. Coproporphyrinogen oxidase (CPO) is located in the intermembrane space bordered by the inner and outer mitochondrial membranes. Enzymes that catalyze the reactions are indicated. Abbreviations: ALAS, δ-aminolevulinate synthase; ALAD, δ-aminolevulinate dehydratase; PBGD, porphobilinogen deaminase; UCoS, uroporphyrinogen III cosynthase; UROD, uroporphyrinogen decarboxylase; PPO, protoporphyrinogen oxidase; side chains: A, $-CH_2COO-$; P, $-CH_2CH_2COO-$; V, -CH=CH; M, $-CH_3$.

Table 8.1.1 Classification of the Porphyrias[a]

Classification	Deficient enzyme	Inheritance	Drugs or toxins involved	Laboratory findings		
				Red cells	Urine	Stool
Cutaneous photosensitivity						
Congenital erythropoietic porphyria (CEP)	Uroporphyrinogen III cosynthase	Recessive	No	Uroporphyrin I and coproporphyrin I	Uroporphyrin I	Coproporphyrin I
Porphyria cutanea tarda (PCT)	Uroporphyrinogen decarboxylase	Variable[b,c]	Yes	NA	Uroporphyrin, 7-COOH porphyrin	Isocoproporphyrin
Erythropoietic protoporphyria (EPP)	Ferrochelatase	Dominant[b]	No	Protoporphyrin	NA	Protoporphyrin
Neurovisceral symptoms						
ALAD deficiency porphyria (ADP)	ALA-dehydratase	Recessive	Yes	Zn-protoporphyrin	ALA	NA
Acute intermittent porphyria (AIP)	PBG deaminase	Dominant[b]	Yes	NA	ALA and PBG	NA
Neurovisceral and cutaneous manifestations						
Hereditary coproporphyria (HCP)	Coproporphyrinogen oxidase	Dominant[b]	Yes	NA	ALA, PBG, and coproporphyrin	Coproporphyrin
Variegate porphyria (VP)	Protoporphyrinogen oxidase	Dominant[b]	Yes	NA	ALA, PBG, and coproporphyrin	Coproporphyrin and protoporphyrin

[a]Abbreviations: ALA, δ-aminolevulinic acid; PBG, porphobilinogen; NA, not applicable.

[b]Homozygous or compound heterozygous cases have been described.

[c]PCT is transmitted as an autosomal dominant trait in some families, but in many cases no inherited defect in uroporphyrinogen decarboxylase can be demonstrated. The homozygous or compound heterozygous form of uroporphyrinogen decarboxylase deficiency is known as hepatoerythropoietic porphyria (HEP).

ALAS2 on Xq11.21). ALAS1 is the rate-limiting step in the heme biosynthetic pathway in all nonerythroid cells, and ALAS1 activity is regulated by heme. Heme regulates its own synthesis by affecting transcription of the ALAS1 gene, stability of ALAS1 mRNA, and the transport of ALAS1 protein from cytosol to mitochondria. No mutations affecting ALAS1 have been described.

The erythroid-specific ALAS2 gene is regulated quite differently, as the heme biosynthetic demands of the red cell exceed by far those of any other cell. Transcription of ALAS2 is regulated by erythroid-specific transcription factors interacting with *cis* elements in the 5′ noncoding region of the gene. Translational regulation of ALAS2 is mediated by the interaction of a *cis*-acting iron regulatory element in the 5′-untranslated region of the ALAS2 mRNA with an iron regulatory element–binding protein. When the protein is bound to the iron regulatory element, translation is inhibited. In the presence of iron, the protein dissociates, ALAS2 mRNA binds to the ribosome, and ALAS2 protein is synthesized. In the red cell, therefore, translation of ALAS2 mRNA depends on the availability of iron.

Both inherited and acquired factors affecting ALAS2 genes cause sideroblastic anemia (Wyckoff and Kushner, 1994). X-linked sideroblastic anemia, an uncommon inherited disease, generally produces a microcytic anemia in males, which is recognized in childhood. Rare cases have been noted in females when lyonization has inactivated the wild-type allele. The severity of the anemia is quite variable, but in all cases the production of porphyrins and heme by erythrocytes is subnormal. Iron stains of bone marrow reveal a halo of iron-laden mitochondria surrounding the nucleus of erythroblasts (ringed sideroblasts). X-linked sideroblastic anemia often improves with the administration of large doses of pyridoxine. Several ALAS2 mutations have been detected that affect the pyridoxal phosphate binding site but do not directly change the lysine that mediates the binding of pyridoxal phosphate.

Isonicotinic acid hydrazide (INH), which is widely used in the treatment of tuberculosis, can also cause sideroblastic anemia. INH reacts with pyridoxal to form a hydrazone that inhibits pyridoxal phosphokinase, the enzyme responsible for the synthesis of pyridoxal phosphate. A microcytic anemia occurs frequently with prolonged ingestion of INH but the anemia is usually mild. Ringed sideroblasts are invariably found in the marrow, but this abnormality and the anemia are fully reversible on withdrawal of INH or by the administration of a large, daily dose of pyridoxine.

ALA DEHYDRATASE (ALAD)

ALAD catalyzes the condensation of two molecules of ALA to form the monopyrrole porphobilinogen (Fig. 8.1.1). The enzyme has been purified from many sources, and the ALAD gene has been cloned from bacteria, yeast, plants, and mammals. The crystal structure of yeast ALAD has been solved, and the yeast enzyme, a homooctameric metalloenzyme, is highly homologous to mammalian ALADs (Erskine et al., 1997). Mammalian ALAD is an octamer of eight identical subunits, arranged as a tetramer of dimers. Each of the eight active sites has two substrate binding positions (Dailey, 1997). The ALA molecule contributing the propionate side chain of porphobilinogen and the pyrrole nitrogen binds first, at a position designated the P site. Binding of ALA at the P site is required before a second ALA molecule, which contributes the acetate side chain and the amino-methyl group, binds at the position designated the A site. Eight zinc atoms are present in mammalian ALAD, one atom per subunit. The zinc atoms exist in two different environments. One zinc atom in each dimer is required for catalytic activity. The other is bound to the protein but is not directly involved in catalysis. This noncatalytic metal has been termed a "structural zinc" and probably serves to stabilize the enzyme. The zinc atoms bind in a cysteine-rich region with sequence similarity to a motif found in zinc-finger proteins (Dailey, 1997).

Two alleles of the ALAD gene have been identified in humans. They differ by only a single nucleotide in codon 59, which changes lysine to asparagine. The lysine allele is more common and is found in 80% to 90% of the human population. Most people are homozygous for this allele. The asparagine allele is present in 10% to 20% of humans. There is no difference in ALAD activity among the three possible phenotypes (Lys-Lys, Lys-Asp, Asp-Asp), but the Asp-Asp phenotype may be associated with an altered response to lead exposure (see below; Kappas et al., 1995).

ALAD deficiency is associated with human disease, and the activity of the enzyme can be inhibited in three ways: an ALAD deficiency can be inherited, an inherited defect in tyrosine metabolism can lead to the generation of an inhibitor of ALAD, and ALAD can be inhibited by toxic metals, particularly lead.

Six cases of a clinical syndrome associated with genetically transmitted severe ALAD deficiency have been described (Wyckoff and Kushner, 1994; Kappas et al., 1995). Two were unrelated adolescent German males who developed neurovisceral symptoms, including pain in the abdomen and extremities. One of the two German cases went on to develop a mixed motor/sensory polyneuropathy. Symptoms were made worse in both cases following alcohol intake or decreased food intake. Molecular analysis in one of the German cases revealed that the patient was a compound heterozygote with two different mutant ALAD alleles. Cells from both parents had half the normal amount of ALAD activity. The third case was a two-year-old Swedish boy with retarded development, limb paralysis, respiratory insufficiency, and generalized muscle weakness. The child had repetitive episodes during which symptoms worsened, followed by periods of improvement. This case also proved to represent compound heterozygosity with a different mutation present on each ALAD allele. The Swedish boy underwent liver transplantation at the age of seven years, but basal urinary secretion of ALA did not change and there was little change in the neurovisceral symptoms. The fourth case was quite unusual, as symptoms due to a subacute polyneuropathy did not develop until the seventh decade. The last two cases occurred in Chilean siblings who developed neurovisceral symptoms in the third decade.

In all cases, patients show a marked increase in the urinary excretion of ALA. Further, they show an increase in the urinary excretion of coproporphyrin. This is surprising, because ALAD activity in these patients ranges from 1% to 12% of normal values. It is presumed that the excess of ALA which results from ALAD deficiency is toxic to nerve cells and this is causative for the neurovisceral symptoms. ALA has strong structural homology with γ-aminobutyric acid (GABA) and can activate GABA receptors on neurons. An alternate hypothesis, neither proven nor rejected, is that the neurovisceral symptoms are due to heme deficiency in neural cells.

Succinylacetone, a structural analog of ALA, is an extremely potent inhibitor of ALAD and has been widely used in vitro as an inhibitor of heme biosynthesis in cultured cells. Patients with hereditary tyrosinemia, a disorder caused by an inherited deficiency of fumarylacetoacetate hydrolase, produce large amounts of succinylacetone, and ALAD activity in their erythrocytes and liver is markedly depressed (Kappas et al., 1995). Urinary secretion of ALA is also markedly increased. Some patients with hereditary tyrosinemia develop neurovisceral symptoms similar to those seen in patients with porphyria due to ALAD deficiency and other porphyrias.

Lead is a reversible inhibitor of ALAD and probably acts by displacing zinc from the holoenzyme. Patients with lead poisoning excrete increased amounts of ALA in the urine and display clinical symptoms resembling those seen in ALAD-deficiency porphyria and other porphyric disorders, including abdominal pain, peripheral neuropathy, and other neurovisceral symptoms. Following comparable exposure to lead, individuals with the ALAD Asp-Asp phenotype have higher concentrations of lead in their blood than individuals with the Lys-Lys phenotype (Dailey, 1997). The clinical relevance of this difference is unclear. Two conflicting views have been offered. The Asp-Asp phenotype might be associated with an increased susceptibility to lead poisoning or, in contrast, the Asp-Asp phenotype might protect against lead toxicity by sequestering lead.

Lead also affects the activity of coproporphyrinogen oxidase and ferrochelatase. Urinary excretion of coproporphyrin is increased in lead poisoning but there is little evidence suggesting that excess coproporphyrin mediates any of the clinical findings. Heme synthesis in red cells is clearly affected by lead, especially in children in whom a microcytic anemia is commonly associated with lead poisoning.

PORPHOBILINOGEN DEAMINASE (PBGD)

PBGD catalyzes the polymerization of four molecules of PBG to form the unstable linear tetrapyrrole, hydroxymethyl bilane (Fig. 8.1.1; Dailey, 1995). The enzyme is cytosolic and monomeric. Human PBGD has a molecular weight of ~38 kDa, but the molecular mass varies slightly, depending on how the gene transcript is processed (see below). PBGD from bacteria was the first heme biosynthetic enzyme to be crystallized (Wyckoff and Kushner, 1994; Kappas et al., 1995). A dipyrrole cofactor is required for enzyme activity. The cofactor is assembled by the PBGD apoprotein by the deamination and polymerization of two molecules of PBG. The dipyrrole cofactor is covalently linked to the apoprotein to form the holoenzyme. During the enzymatic reaction, four molecules of PBG are deaminated and added sequentially to the cofactor to assemble a hexapyrrole. Finally, the distal tetrapyrrole is

cleaved from the cofactor and released as hydroxymethyl bilane. The cofactor remains enzyme-bound and is not turned over.

The gene encoding PBGD has been cloned from both prokaryotes and eukaryotes (Wyckoff and Kushner, 1994). The single human PBGD gene produces two different transcripts that differ at their 5′ ends. The "housekeeping" form of PBGD is derived from an mRNA in which exon 1 is spliced to exon 3. The second transcript, produced only in erythroid cells, initiates at exon 2. Translation of the housekeeping mRNA yields a protein with 17 amino acids at the amino terminus (encoded by exon 1) that are not present in erythroid-specific PBGD. Activation of transcription is controlled by two different promoters. The housekeeping promoter is located upstream of exon 1, and the erythroid promoter lies between exon 1 and exon 2.

Mutations in the PBGD gene are responsible for acute intermittent porphyria (AIP; Kappas et al., 1995). The incidence of a defective allele of PBGD in the United States has been estimated at between 5 and 10 per 100,000. AIP is transmitted as an autosomal dominant trait, but most carriers of a mutant allele never develop symptoms. Those who do, predominantly women, manifest an illness characterized by recurrent, acute attacks of abdominal pain associated with autonomic dysfunction. Constipation and even obstipation often accompanies the abdominal pain. Other abnormalities that may be present during an attack include peripheral motor neuropathy, cranial neuropathies, delirium, seizures and, rarely, death. During an attack ALAS1 is induced in hepatocytes and ALA and PBG are produced in excess and secreted in the urine, presumably because of the partial block in heme biosynthesis. As is the case with ALAD deficiency, it is not clear if the acute attacks that characterize AIP are due to neurotoxic effects of ALA (or PBG) or to a heme deficiency in neural cells. Intravenous infusions of hematin or heme-arginate have been widely accepted as appropriate treatment for acute attacks. Hematin or heme-arginate infusions induce a prompt decrease in the urinary excretion of ALA and PBG, mediated by the suppression of ALAS1 in the liver. Despite this clear biochemical effect, a controlled trial with heme-arginate generated only marginal evidence of clinical efficacy.

Acute attacks of AIP often follow the ingestion of a wide variety of drugs. Most of the drugs induce hepatic cytochrome P-450s, thereby increasing the demand for heme synthesis. Barbiturates, anticonvulsants, and sulfonamide antibiotics have been most commonly recognized as precipitating agents (Kappas et al., 1995). It is prudent, however, to recommend avoidance of all drugs whenever possible, especially drugs metabolized by P-450-dependent pathways.

Numerous PBGD mutations have been detected in patients with AIP (Wyckoff and Kushner, 1994; Kappas et al., 1995). Most mutations result in an allele that produces either no protein or an unstable protein. Mutations that affect splice junctions, introduce termination codons, cause frameshifts, or alter protein stability have all been described. Approximately 20% of mutant alleles represent point mutations that affect catalytic activity but not protein stability. Assays of PBGD activity are generally done using red cell lysates as the source of UROD. The activity of PBGD in red cells almost always parallels the activity of the enzyme in liver. In a few pedigrees, however, point mutations in exon 1 cause an enzyme deficiency that is restricted to nonerythroid cells. Rare cases have been described with severe symptoms and very large amounts of PBG in the urine. In one such case, compound heterozygosity for different point mutations affecting the same codon in exon 10 were found.

UROPORPHYRINOGEN III COSYNTHASE (UCoS)

Hydroxymethyl bilane released from PBGD will spontaneously cyclize to form uroporphyrinogen I, but in the presence of UCoS the cyclization occurs with concomitant inversion of the terminal pyrrole ring to form uroporphyrinogen III (Fig. 8.1.1). In all cells, UCoS is present in excess relative to PBGD activity. UCoS also has a high turnover number and enzymatic formation of uroporphyrinogen III is rapid. Collectively, these factors favor the synthesis of uroporphyrinogen III. In mammals, the enzyme is cytosolic. UCoS has been purified to homogeneity from prokaryotes and eukaryotes. Enzymes from these diverse sources are monomers with molecular weights of ~30 kDa, are inactivated by lead, and appear to require reactive thiols for activity. UCoS cDNAs have been cloned from several sources, and human UCoS has been mapped to chromosome 10q. Very little is known about the enzymatic mechanism of UCoS, but it is clear that hydroxymethyl bilane is the substrate and a spiro mechanism is probably involved in rearrangement of the D ring (Wyckoff and Kushner, 1994; Kappas et al., 1995).

UCoS mutations are responsible for a rare but dramatic form of porphyria called congenital erythropoietic porphyria (CEP). CEP is transmitted as a recessive trait and fewer than 300 cases have been reported. Homozygotes or compound heterozygotes generally display <10% of normal UCoS activity. There are no known interactions of UCoS with toxins or with drugs. The disease is usually detected in infancy and is often first recognized by pink or purple staining of the diapers. Staining is due to the urinary excretion of large amounts of uroporphyrin I. Extreme photosensitivity is common and severe photomutilation often occurs. The site of porphyrin overproduction is the developing erythroblast and hemolytic anemia and splenomegaly have been described in most cases. Deposition of porphyrins in the dentin of developing teeth causes both discoloration and fluorescence under UV light. The treatment of CEP is based on avoidance of exposure to sunlight through the use of protective clothing and appropriate sunscreens. Bone marrow transplantation has proven effective in several cases (Thomas et al., 1996).

Eight mutant UCoS alleles have been characterized. Six are point mutations that cause changes in amino acids, one is a deletion, and one is an insertion that produced a frameshift.

UROPORPHYRINOGEN DECARBOXYLASE (UROD)

UROD catalyzes the sequential decarboxylation of the four acetate side chains of uroporphyrinogen to form coproporphyrinogen (Fig. 8.1.1). Either the III or the I isomer of uroporphyrinogen may serve as substrate, but only coproporphyrinogen III is a substrate for the next enzyme in the pathway, coproporphyrinogen oxidase. The mechanism of decarboxylation is not known, but the enzyme does not require cofactors or prosthetic groups for activity. Human UROD is a homodimer with a monomeric molecular weight of ~41 kDa. The crystal structure of human UROD has been determined at 1.60 Å resolution (Whitby et al., 1998). There is one active-site cleft per monomer which is adjacent to that of its neighbor in the dimer. This creates a single extended cleft large enough to accommodate two substrate molecules in close proximity or to allow reaction intermediates to shuttle between monomers. The gene encoding UROD has been cloned from many species. There is no evidence to suggest tissue-specific processing of the transcript.

Subnormal activity of UROD in hepatocytes causes the most common form of porphyria in humans, porphyria cutanea tarda (PCT; Wyckoff and Kushner, 1994; Kappas et al., 1995). PCT is characterized clinically by skin fragility, bullous lesions, and hypertrichosis on sun-exposed areas. Biochemically, the disease is characterized by the accumulation of uroporphyrin in the liver (liver biopsy specimens fluoresce under long-range UV light) and the urinary excretion of these compounds in great excess.

Four variants of PCT have been described, two of which are due to UROD mutations (Wyckoff and Kushner, 1994; Kappas et al., 1995). Familial PCT (F-PCT) is transmitted as an autosomal dominant trait and accounts for about one-third of the cases of PCT. Affected individuals display half the normal amount of UROD activity in all tissues. Many UROD mutations have been identified in patients with F-PCT. The most common is a splice-site mutation leading to deletion of exon 6. Most carriers of mutant UROD alleles do not express a clinical phenotype unless additional factors that lead to further reduction of UROD activity in the liver are present. Important additional factors include alcohol abuse, exposure to the hepatitis C virus, the use of medicinal estrogens, and the development of hepatic siderosis. Depletion of hepatic iron stores through phlebotomy therapy corrects the clinical and biochemical phenotype. A second variant of PCT, designated hepatoerythropoietic porphyria (HEP), is rare and occurs in individuals with two mutant UROD alleles, either homozygotes for a single mutation or compound heterozygotes. The photosensitive dermatosis may be severe and is generally recognized in childhood. Phlebotomy is usually not effective. A third variant of PCT is called sporadic PCT (S-PCT) and accounts for ~50% to 60% of cases. In S-PCT, the UROD defect is restricted to the liver and no mutations have been identified in the UROD gene. The concentration of UROD protein in the liver is normal, even though enzyme activity is reduced, suggesting the presence of an enzyme inhibitor. Alcohol abuse, hepatitis C, and estrogen use all have been identified as risk factors and, as with F-PCT, hepatic siderosis is a nearly uniform finding. Phlebotomy therapy is effective, suggesting that iron is required for generation of the putative UROD inhibitor.

A fourth variant, designated toxic PCT, is associated with exposure to halogenated aromatic hydrocarbons. An epidemic of toxic PCT affecting more than 3000 people occurred in Turkey between 1956 and 1961. Seed wheat

treated with the fungicide hexachlorobenzene was responsible for the epidemic. Although animal models of toxic PCT, have been intensely studied (mainly in rodents), the exact mechanism by which halogenated aromatics cause inhibition of hepatic UROD activity is not known. Iron appears to be required, as does the induction of specific isoforms of cytochrome P-450.

COPROPORPHYRINOGEN OXIDASE (CPO)

CPO converts the propionate groups at positions 2 and 4 of coproporphyrinogen III to vinyls, yielding protoporphyrinogen (Fig. 8.1.1). The oxidative decarboxylation in eukaryotes requires molecular oxygen as the electron acceptor, and two molecules of CO_2 are generated. CPO has been cloned from both prokaryotic and eukaryotic species (Martasek et al., 1994). In mammals, CPO is encoded by a nuclear gene, but the enzyme is located in the mitochondrial intermembrane space, probably associated with the outer face of the inner membrane. In anaerobic prokaryotes, the CPO reaction is oxygen-independent and alternate electron receptors are used. Human CPO is a homodimer with a subunit molecular weight of 37 kDa. The enzyme mechanism has not been clarified, but inhibitor studies indicate that at least one tyrosine is required for enzymatic activity.

Mutations of the CPO gene in humans are responsible for the disease hereditary coproporphyria (HCP; Wyckoff and Kushner, 1994; Kappas et al., 1995). CPO activity is reduced to half the normal amount in all tissues, but coproporphyrin accumulates only in the liver. HCP is transmitted as an autosomal dominant trait, but rare instances of homozygous CPO deficiency have been reported and are associated with a more severe phenotype. Clinical manifestations of HCP generally occur after puberty and include both acute neurovisceral attacks similar to those seen in patients with AIP and bullous lesions on light-exposed areas as seen in patients with PCT. Approximately two-thirds of individuals heterozygous for CPO mutations never become clinically ill. The distinguishing feature in HCP is the excretion of large amounts of coproporphyrin in feces, even in the absence of clinical symptoms. During acute attacks, urinary excretion of ALA, PBG, and coproporphyrin is also increased.

The treatment of acute attacks is identical to the treatment of AIP.

PROTOPORPHYRINOGEN OXIDASE (PPO)

PPO is an integral protein of the inner mitochondrial membrane. PPO has been cloned and characterized from eukaryotic and prokaryotic sources (Dailey and Dailey, 1996). The enzyme is membrane bound in all organisms except *Bacillus subtilis*. The enzyme catalyzes the oxidation of protoporphyrinogen to protoporphyrin (Fig. 8.1.1). The mammalian enzyme requires molecular oxygen as the terminal electron acceptor. Three molecules of molecular oxygen are reduced to H_2O_2 as protoporphyrin is formed. The human enzyme is a homodimer with a subunit molecular weight of 51 kDa and contains a single, noncovalently bound molecule of FAD per dimer. PPO shares significant homologies with many oxidases containing an FAD-binding motif near the amino terminus.

Mutations of the PPO gene are responsible for variegate porphyria (VP; Wyckoff and Kushner, 1994; Kappas et al., 1995). The clinical manifestations of VP are similar to those described in patients with HCP. Both dermal photosensitivity and acute neurovisceral attacks may occur. The biochemical hallmark of VP is excessive fecal excretion of protoporphyrin and coproporphyrin. Porphyrin concentration is higher in the bile than in feces. Elevated fecal porphyrins are found in almost all patients after puberty, even in those who display no clinical phenotype. During acute neurovisceral attacks there is an increase in the urinary excretion of ALA, PBG, and coproporphyrin, but their concentrations in urine are generally normal between attacks.

The incidence of VP in South African Caucasians is ~3 per 1000, and nearly all cases are descendants of a Dutch couple settling in South Africa late in the 17th century. The ancestral PPO mutation in South Africa is R59W. The incidence of VP in other countries is not known and several other mutations of the PPO gene have been characterized.

The diphenyl-ether class of herbicides are potent inhibitors of PPO and are widely used. These herbicides also inhibit PPO from mammalian sources but no toxic effects have been clinically recognized.

FERROCHELATASE

Ferrochelatase, the final enzyme in the heme biosynthetic pathway, catalyzes the insertion of one atom of ferrous iron into the protoporphyrin macrocycle (Fig. 8.1.1). In eukaryotes, the enzyme is encoded by a nuclear gene, synthesized on cytoplasmic ribosomes, and

translocated to the mitochondria where the protein is inserted into the inner mitochondrial membrane. The active site is located on the matrix side. The active site of PPO is located in the outer side of the inner mitochondrial membrane, suggesting that a transport system is required to move protoporphyrin to the matrix side where it serves as a substrate for ferrochelatase (Wyckoff and Kushner, 1994).

Ferrochelatase is a homodimer. The mammalian enzyme contains a labile iron-sulfur cluster near the carboxyl terminus. The cluster is destroyed by nitric oxide, causing the enzyme to lose activity, but it is not known if this process reflects a physiologic regulatory role in vivo. The only crystal structure for ferrochelatase that has been solved is the enzyme from *B. subtilis*, which does not contain an iron-sulfur cluster (Al-Karadaghi et al., 1997).

Ferrochelatase will catalyze the insertion of Fe^{2+}, Co^{2+}, and Zn^{2+} into protoporphyrin and a variety of other IX isomer polymers. Ferrochelatase is inhibited by several divalent heavy metals, including Hg^{2+}, Pb^{2+}, Mn^{2+}, and Cd^{2+}. A naturally occurring inhibitor of ferrochelatase is *N*-methylprotoporphyrin, generated from the heme of cytochrome P-450. A variety of synthetic *N*-alkylporphyrins are also potent inhibitors of ferrochelatase (Dailey, 1997).

Ferrochelatase mutations are responsible for erythropoietic protoporphyria (EPP; Wyckoff and Kushner, 1994; Kappas et al., 1995). Subnormal ferrochelatase activity causes the accumulation of protoporphyrin in red blood cells. Protoporphyrin diffuses into plasma, is cleared by the liver, and secreted in bile. The protoporphyrin content of stool is increased in patients with EPP, but some of the protoporphyrin secreted into the gut is reabsorbed and processed again by the liver.

EPP is transmitted as an autosomal dominant trait. The clinical phenotype is characterized by a distinctive type of cutaneous photosensitivity. Neurovisceral attacks do not occur. Cutaneous symptoms may be limited to a sensation of burning and itching, after even brief periods of sun exposure. In some patients, edema and erythema may follow. Chronic changes include prematurely aged skin, shallow scars on the nose and cheeks, and leathery pseudovesicles over the nose and hands. In contrast to other porphyrias associated with photosensitivity, bullae, fragility, dramatic scarring, and hirsutism rarely occur. The increased content of protoporphyrin in bile leads to the formation of photoporphyrin-containing gallstones in ~10% of patients. Extreme cholestasis can lead to progressive liver disease, cirrhosis, and death, but this is a rare complication of EPP.

The diagnosis of EPP requires recognition of the clinical syndrome, coupled with findings of increased free erythrocyte protoporphyrin in red cells and an increase in fecal protoporphyrin excretion. The fecal content of protoporphyrin may vary widely because of variations in enteric reabsorption.

Treatment with orally administered β-carotene may provide systemic photoprotection but has no effect on protoporphyrin production, clearance, or excretion. Chenodeoxycholic acid may prove to be useful, as this agent diminishes the protoporphyrin content of both red cells and plasma and reduces fecal protoporphyrin excretion. Liver transplantation is the only effective therapy for the rare patients who develop severe liver disease.

A number of ferrochelatase mutants have been identified in patients with EPP, indicating that the disease is heterogeneous at the molecular level (Wyckoff and Kushner, 1994; Kappas et al., 1995; Dailey, 1997). One point mutation resulted in the formation of a catalytically inactive heterodimer composed of one normal and one mutant monomer. Ferrochelatase activity was 25% of normal, the predicted outcome if enzyme activity is restricted to dimers composed of two normal monomers.

INTERPRETATION OF URINARY PORPHYRIN EXCRETION

Nearly all hepatobiliary diseases may be associated with an increase in the urinary excretion of coproporphyrin and occasionally uroporphyrin, but not ALA or PBG. Impaired secretion of porphyrins in bile leads to an increase in urinary excretion, but there are no clinical manifestations resembling those associated with any of the porphyric disorders. Incorrect interpretation of moderate increases in urinary coproporphyrin excretion is a common cause of misdiagnosis of porphyria.

SUMMARY

With the possible exception of some forms of PCT, the porphyrias are inherited disorders. Nevertheless, most dominantly inherited porphyric traits are not associated with a manifest clinical phenotype unless a drug is ingested or exposure to a toxin occurs. The acute neurovisceral attacks of AIP, HCP, and VP are often precipitated by drugs that induce one or more of the cytochrome P-450s. Attacks in women

may occur at specific times in the menstrual cycle, implying a role for hormones in inducing attacks. The most dramatic example of environmental interactions in the pathogenesis of porphyria is PCT. Alcohol, estrogens, polychlorinated biphenyls (and other halogenated aromatic compounds), infection with the hepatitis C virus, and hepatic iron overload (due to mutations at the hemochromatosis locus or to unidentified factors) have all been implicated in precipitation of the clinical phenotype.

With the exception of heavy metals, some herbicides, and *N*-alkylporphyrins, little is known about how environmental factors interact with enzymes of the heme biosynthetic pathway. The molecular characterization of mutant genes from patients with porphyria and from microorganisms is beginning to lead to the identification of key domains required for the activity of heme biosynthetic enzymes. Structure-function relationships derived from crystal structures are beginning to unfold. The complex interactions between environmental and inherited factors affecting porphyrin metabolism are now approachable.

Measurement of ALA Synthase Activity

In most cells, δ-aminolevulinate (ALA) synthase is the rate-limiting enzyme in heme biosynthesis. In the liver, the enzyme is inducible by drugs and toxins and it is regulated through a feedback mechanism by heme, the end-product of the pathway. Measurement of ALA synthase activity is important for determining whether accumulation of porphyrins and heme in the tissue is due to an increased activity of the enzyme. This unit describes two methods for measuring ALA synthase activity: a radiometric assay that uses ^{14}C-labeled succinate as a substrate (see Basic Protocol 1) and a colorimetric procedure that involves conversion of the product ALA to a pyrrole (see Basic Protocol 2). The concentration of the pyrrole is estimated by measuring its absorbance after reaction with Ehrlich's reagent. The radiometric procedure can be used to measure the basal activity of ALA synthase and small increases in that rate in all cells, whereas the colorimetric procedure is best suited for measuring considerable increases in activity above basal levels.

RADIOMETRIC ASSAY FOR ALA SYNTHASE

BASIC PROTOCOL 1

Compared to many enzymes of intermediary metabolism, the concentration of ALA synthase is very low in most cells or tissues. Its activity is expressed in units (U) of nmol/hr, and, in some instances, only a radiometric assay can provide sufficient sensitivity for accurate measurement of ALA synthase activity. In this protocol, tissue or cell extracts are incubated with [^{14}C]succinate and the product, [^{14}C]δ-aminolevulinate, is separated from the residual succinate and other radioactive contaminants by treatment with alkaline SDS and ion-exchange chromatography.

Materials

Control (C) and reaction (R) buffers (see recipes)
Cofactor solution (see recipe)
[2,3-^{14}C]succinate (see recipe)
Cell or tissue sample
Succinyl-CoA synthase (see recipe)
0.5 M NaOH
8.7 M acetic acid
Stop solution: 10% (w/v) SDS containing 10 mM sodium succinate and 1 mM δ-aminolevulinic acid
Dowex 50W-X8 cation exchange resin, 100-200 mesh (see recipe)
0.1 M sodium acetate, pH 3.9
Methanol/0.1 M sodium acetate, pH 3.9 (2:1, v/v)
0.01 M HCl
1.0 M Tris base (aqueous solution with unadjusted pH of ~10.5)
Aquasol II or other liquid scintillation fluid compatible with aqueous samples

2-ml screw-cap tubes (e.g., Sarstedt)
Heating blocks, 37° and 65°C
10-ml chromatography columns (e.g., Bio-Rad)
Stacking cap (e.g., Bio-Rad #731-1555), optional

Incubate extracts to form radioactive ALA

1. Prepare control and reaction cocktails by mixing: 1.0 ml C or R buffer, 0.25 ml cofactor solution, and 0.03 ml [^{14}C]succinate.

2. For each sample to be assayed or variable to be tested, transfer 0.2 ml control cocktail into a 2-ml screw-cap tube and 0.2 ml reaction cocktail into another tube.

Contributed by Peter R. Sinclair, Nadia Gorma, and Neal W. Cornell
Current Protocols in Toxicology (1999) 8.2.1-8.2.11

3. Incubate all tubes 5 min at 37°C. Add 50 µl tissue or cell extract and 10 µl diluted succinyl-CoA synthase to each control or reaction mixture. Make these additions at timed intervals (e.g., 30 to 60 sec) so that the incubations can be stopped at the same intervals.

4. Mix by gentle vortexing and incubate 20 min at 37°C.

Stop reactions with alkaline SDS

5. At the appropriate time intervals, add 1.0 ml of 10% SDS/10 mM succinate/1 mM ALA stop solution to each incubation, followed by 28 µl of 0.5 M NaOH for control samples *or* 55 µl of 0.5 M NaOH for reaction samples. Mix by vortexing immediately after adding NaOH.

   Addition of NaOH will raise the pH of the sample to 8.5 to 8.8.

6. Incubate samples 60 min at 65°C.

7. Adjust the pH to 3.6 to 3.8 by adding 50 µl of 8.7 M acetic acid to control samples and 75 µl to reaction samples.

Purify ALA by cation-exchange chromatography

8. Swirl the washed Dowex 50W-X8 (equilibrated with 0.1 M sodium acetate, pH 3.9) to obtain a uniform suspension. Pipet 3 ml of suspension into each 10-ml column. Drain under gravity flow.

   The packed resin bed volume should be ~1.5 ml.

9. Apply 1.00 ml of control sample or 1.04 ml of reaction sample from step 7 to each column. Allow sample to enter resin bed.

   These volumes are equivalent to 75% of the sample volumes.

10. Wash each column successively with: 20 ml of 0.10 M sodium acetate, pH 3.9; 20 ml of methanol/0.1 M sodium acetate, pH 3.9; and 10 ml of 0.01 M HCl.

    A screw-cap 50-ml plastic tube is convenient for collecting these eluants, which should be discarded in radioactive waste. Column washing is greatly facilitated by using a stacking cap (e.g., Bio-Rad #731-1555) that allows a second column to be "piggy-backed"onto the one containing the resin bed and by elevating the column system so that a 15-cm length of tubing can be attached to the outflow of the lower column to create a larger hydrostatic head. Remove the tubing before the elution of the radioactive product in the next step.

11. Elute [^{14}C]δ-aminolevulinate by adding 3 ml of 1.0 M Tris base directly to resin bed. Collect eluant in a clean tube.

12. Mix Tris eluant by vortexing, and place 1.0 ml into a liquid scintillation vial. Add 4 ml Aquasol II (or equivalent), mix by vortexing, and determine radioactivity as disintegrations/minute (dpm) in a scintillation counter.

13. For one reaction incubation and its respective control, measure the radioactivity in 10 µl of the 25% of the samples remaining after step 8. Mix with 0.99 ml H_2O and add the mixture to 4 ml liquid scintillation fluid as in step 12.

    This step serves to assure the accuracy of the volumes pipetted to constitute the control and reaction samples through step 7. The expected radioactivity is determined by the specific activity of the labeled succinate, and the ratio of control:reaction counts should be 1.00:1.04.

14. Calculate ALA synthase activity as follows: Divide dpm (reaction minus control) by 2200 dpm/nCi and by the specific activity (nCi/nmol) of the succinate in control and reaction cocktails. Multiply by 3 to get total nmol in the Tris eluate and again by 3

(if the incubation time was 20 min) to get nmol/hr (U). Divide by 0.75, the fraction of sample applied to the Dowex resin, to get total U in the assayed sample. Finally, divide by the volume of sample (e.g., 50 µl) put into the incubation to get U/ml of extract.

If the incubation times and assayed sample volumes are the same for all incubations, all of the factors in the calculation can be collected into one constant that can be multiplied by dpm to directly give U/ml of extract.

COLORIMETRIC ASSAY FOR ALA SYNTHASE

BASIC PROTOCOL 2

This protocol describes the assay of ALA synthase in liver or hepatocyte culture homogenates incubated with glycine (one of the enzyme's substrates) and citrate, which the mitochondria metabolize to succinyl-CoA (its other substrate). The reaction products are ALA and carbon dioxide. The assay is performed in the presence of succinyl acetone or levulinate, which inhibit the next enzyme of the heme biosynthetic pathway, ALA dehydratase. Although the dehydratase is present at a higher concentration than ALA synthase in liver, its K_M for ALA is high and it metabolizes only small amounts of ALA during the reaction. After deproteinization of the reaction mix, the ALA is reacted with acetylacetone (2,4-pentadione) to form ALA pyrrole (2-methyl-3-acetyl-4-propionic acid). Under conditions in which considerable aminoacetone is formed during the reaction of glycine with acetyl-CoA, the aminoacetone pyrrole is removed by neutralizing the solution and extracting with dichloromethane. ALA pyrrole left in the aqueous solution is then allowed to react with modified Ehrlich reagent, giving a solution with a pink color with a maximum absorption at 552 nm and a shoulder at 520 nm (see Fig. 8.2.1). The amount of ALA is calculated from the extinction coefficient.

Materials

Cultured hepatocytes or liver
Glycine medium (GM) assay buffer (no glycine; see recipe)
0.25 M glycine solution (see recipe)
15% (v/v) trichloroacetic acid (TCA) prepared from 100% (w/v) TCA
2 M sodium acetate in H_2O
8% acetylacetone (2,4-pentanedione) in 2 M sodium acetate (see recipe)
NaOH-phosphate solution (see recipe)
Dichloromethane
Modified Ehrlich reagent (see recipe)

12 × 75–mm culture tubes
Heating block or water bath, 85° to 95°C
Spectrophotometer

1. Prepare 10% (w/v) liver homogenates in GM assay buffer or scrape cultured liver cells in GM buffer using 1 ml buffer per 15-cm plate (or per two 10-cm plates) for each assay.

   Liver homogenates can also be made in 0.25 M sucrose/20 mM Tris, pH 7.4 and then a portion diluted 1:1 with 2× GM buffer.

2. Place 0.2 ml homogenate in each of three or four tubes on ice. Add 0.05 ml of 0.25 M glycine solution. Add 0.15 ml of 15% TCA to the blank (zero time) tube and mix. Incubate the other tubes 40 min in a 37°C shaking water bath. Return incubated sample tubes to ice, add 0.15 ml of 15% TCA, and mix. Allow samples to stand for 15 min, then centrifuge suspensions 10 min at 2000 × *g*.

   Glycine is added as a separate solution so that the ALA synthase reaction does not begin during preparation of homogenates.

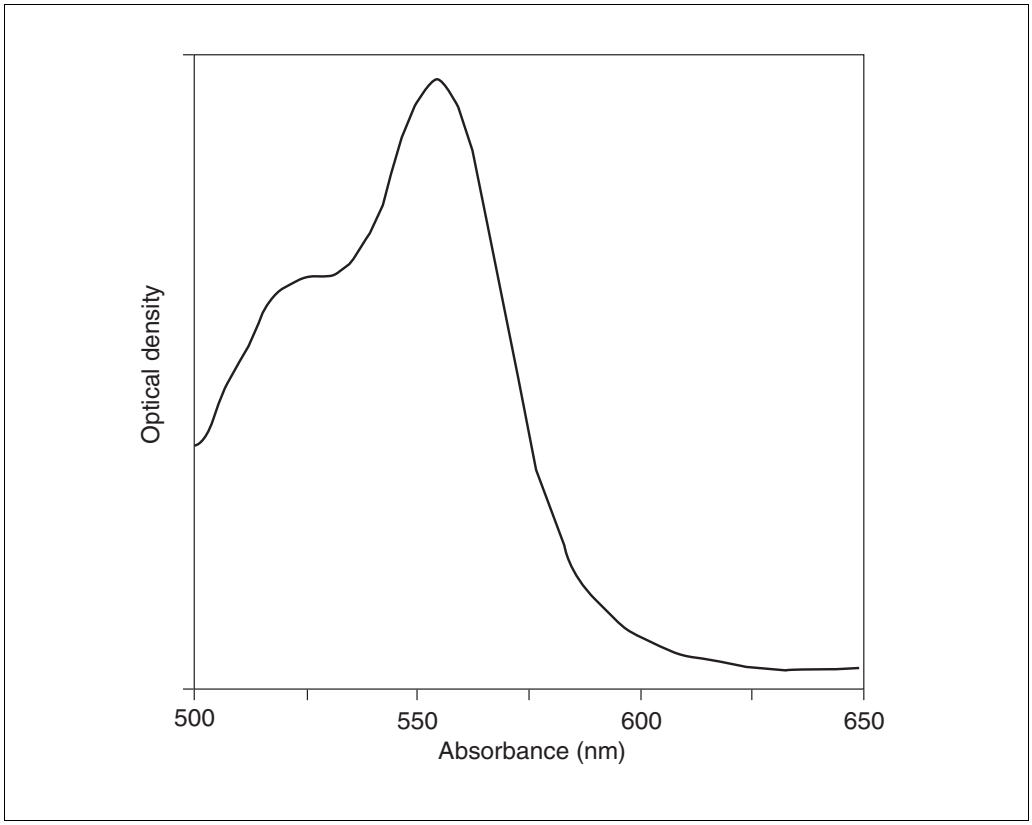

Figure 8.2.1 Absorbance spectrum of ALA-Ehrlich pyrrole.

3. From each reaction tube and blank, carefully remove 0.3 ml supernatant to another set of numbered tubes at room temperature.

   After taking TCA supernatants, samples can be stored overnight at 4°C.

4. Add 0.1 ml of 2 M sodium acetate/ 8% (v/v) acetylacetone. Mix samples and incubate 15 min at 85° to 95°C. Allow to cool.

   It is very important that the pH of the solution after addition of acetate/acetylacetone, before heating to 85°C, is between pH 4 and 5, not 2 to 3 or >5.5. The pH is most readily checked by taking a tiny drop from some tubes and applying to universal pH paper. With narrow tubes and with the lower temperature it is not necessary to cap the tubes during heating.

To measure ALA pyrrole directly

5a. Add 0.4 ml modified Ehrlich reagent and mix vigorously using a Vortex mixer.

6a. After 15 min, but not more than 45 min, scan each incubated sample from 500 to 650 nm against the zero time blank for that sample in a spectrophotometer. Measure the difference in absorbance between 552 and 650 nm. Calculate ALA concentrations using ε_{mM} of 58 for the Ehrlich pyrrole color salt. Calculate rates as nmole ALA per milligram homogenate protein (or gram tissue wet wt) per hour.

   The spectrum of the color salt should have a peak at 552 nm and a shoulder at 525 nm with a ratio of absorbances 525/552 of ~0.7, and the spectrum should be quite flat from 600 to 650 nm (Fig. 8.2.1). Other substances can react with Ehrlich reagent and cause distortion of the pure ALA pyrrole spectrum. Because prolonged incubation with Ehrlich reagent can result in absorbances due to other compounds, the Ehrlich reaction should be planned so that only as many samples are processed as can be scanned within the 45-min limit. It is recommended that an ALA standard be run through the assay to measure recovery and to obtain a typical spectrum for comparison with that obtained from cell homogenates.

To remove aminoacetone before measuring ALA pyrrole

5b. Adjust pH of sample to ~7.0 by adding 0.05 ml of 0.5 M NaOH-phosphate solution. Add an equal volume of dichloromethane and vortex vigorously. If organic and aqueous layers are not cleanly separated, centrifuge 5 min at 2000 × *g*. Remove 0.3 ml aqueous supernatant to a clean tube and add an equal volume of modified Ehrlich reagent.

This method is usually not necessary with avian liver or hepatocyte culture as aminoacetone is not a major product. Others have reported that aminoacetone is a problem in rat liver homogenate incubations. It is important for the pH to be ~7.0 for the separation of the two pyrroles by this method. The pH of the solutions should be checked by placing a small drop from some tubes on universal pH paper.

6b. Read absorbance of samples and calculate ALA concentration as in step 6a.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acetylacetone (2,4-pentanedione), 8%

Add acetylacetone to 2 M sodium acetate to a final concentration of 8 % (v/v). Warm the solution to 45° to 50°C and mix vigorously to make the mixture homogeneous. The solution must be made fresh prior to use.

CAUTION: *Acetylacetone is toxic. Avoid inhalation or contact with skin.*

Control (C) buffer

Per 100 ml

1.83 g of 2-{[*tris*-(hydroxymethyl)-methyl]-amino}-ethanesulfonic acid (TES; 80 mM final)

0.47 g EDTA (16 mM final)

0.65 g $MgCl_2 \cdot 6H_2O$ (32 mM final)

0.1 ml of 0.1 M sodium succinate (non-radioactive; 0.1 mM final)

Add ~90 ml H_2O

Adjust to pH 7.0 to 7.5 by adding KOH pellets, one at a time, with rapid stirring and continuous monitoring (~16 KOH pellets). Cool the solution to room temperature, and add 4 mg of pyridoxal phosphate (final concentration 0.16 mM). Use 1 M to 3 M KOH to adjust the room-temperature pH to a value that will make the pH 7.25 at 37°C; e.g., at 25°C, adjust the pH to 7.6. Bring final volume to 100 ml with H_2O.

Aliquot buffer into working portions that will be thawed only once. Store up to one month at –20°C, protected from light.

Cofactor solution

Prepare 3.3 mM coenzyme A (CoA)/26 mM GTP by dissolving 3.1 mg of the trilithium salt of CoA and either 18.9 mg of disodium GTP or 18.0 mg of trilithium GTP in 1.0 ml H_2O. If disodium GTP is used, adjust to pH ~6.5 by adding 23.5 µl of 1.5 M NaOH. If trilithium GTP is used, add 23.5 µl H_2O instead of NaOH. Prepare just prior to setting up incubations, and keep on ice until used.

The specified weights of CoA and GTP assume that the commercially available preparations contain 85% CoA or 80% GTP.

Dowex 50W-X8

100 to 200–mesh resin (e.g., from Sigma) works well in this procedure. Convert resin to the sodium form by washing with 2 vol of 2 M NaOH at 50°C three times or until the washes are colorless and odorless. Wash eight times with at least 3 vol H_2O, and equilibrate resin with 0.1 M sodium acetate, pH 3.9. Adjust the final volume of sodium acetate buffer to approximately the volume of settled resin so that pipetting 3 ml of resuspended resin will give ~1.5 ml of packed resin in a column.

Glycine medium (GM) assay buffer (no glycine)

Per 100 ml:

0.43 g Tris base (35 mM final)

0.42 g Na_2HPO_4 (30 mM final)

0.25 g Na citrate·$2H_2O$ (8.5 mM final)

0.16 g $MgCl_2·6H_2O$ (8 mM final)

5 mg pyridoxal phosphate (PLP; 0.2 mM final)

0.1 ml of 10 mM (1.6 mg/ml) succinyl acetone or 1 ml of 1 M levulinate (0.01 mM succinyl acetone or 10 mM levulinate final)

1 ml 0.5 M EDTA, adjusted to pH 8 with NaOH (5 mM final)

Adjust GM assay buffer to pH 7.4 with 1 M HCl. Filter sterilize if storing for more than one week at 4°C.

Glycine solution, 0.25 M

19 mg glycine/ml GM assay buffer. Adjust to pH 7.4 if necessary.

Modified Ehrlich reagent

Minus p-dimethylamino benzaldehyde (DMAB): For 100 ml, mix 54 ml glacial acetic acid, 23 ml of 70% (w/v) perchloric acid, and 23 ml of 1.5% (w/v) mercuric chloride dissolved in glacial acetic acid.

This solution is stable at room temperature.

On the day of use, add DMAB to a final concentration of 0.12 M; e.g., 1.8 g DMAB/100 ml Ehrlich reagent. Mix well.

CAUTION: *Ehrlich reagent is highly reactive with skin and contains Hg^{2+}. Wear appropriate gloves when handling solution.*

NaOH-phosphate solution

Mix 3 vol of 2 M NaOH with 1 vol of 0.5 M Na_2HPO_4

Reaction (R) buffer

Per 100 ml:

1.83 g of 2-{[*tris*-(hydroxymethyl)-methyl]-amino}-ethanesulfonic acid (TES; 80 mM final)

0.47 g EDTA (16 mM final)

0.65 g $MgCl_2·6H_2O$ (32 mM final)

0.1 ml of 0.1 M sodium succinate (non-radioactive; 0.1 mM final)

1.20 g glycine (160 mM final)

Add ~90 ml H_2O

Adjust to pH 7.0 to 7.5 by adding KOH pellets, one at a time, with rapid stirring and continuous monitoring (~16 KOH pellets). Cool the solution to room temperature, and add 4 mg of pyridoxal phosphate (final concentration 0.16 mM). Use 1 M to 3 M KOH to adjust the room-temperature pH to a value that will make the pH 7.25 at 37°C; e.g., at 25°C, adjust the pH to 7.6. Bring final volume to 100 ml with H_2O.

Aliquot buffer into working portions that will be thawed only once. Store up to one month at –20°C, protected from light.

[2,3-^{14}C]succinate

Commercially available [2,3-^{14}C]succinate is usually supplied as the free acid with a specific activity of ~50 mCi/mmol and a concentration of succinic acid of ~1.7 mM (e.g., DuPont NEN #NEC-201) in 10% ethanol. Convert succinate to the sodium salt by adding 1.8 mol of NaOH (from a 0.5 M solution) per mol of succinic acid. Then add 0.1 M sodium succinate, pH 7.0, and adjust the volume so the total succinate concentration is 2.22 mM.

NOTE: *In the control or reaction cocktail, 40% of the total succinate comes from the addition of the labeled material and 60% from unlabeled succinate in the C or R buffer. Thus, the specific activity of succinate in the cocktails should be 15 to 20 nCi/nmol. Determine the specific activity precisely by counting 5 to 10 µl of cocktail each time a new batch of labeled succinate is put into use. Ignore the 10% ethanol in some commercial preparations of labeled succinic acid; it causes no problem in this procedure.*

Succinyl-CoA synthase

Succinyl-CoA synthase from pig heart (e.g., Boehringer Mannheim) is available as a suspension in ammonium sulfate at 50 to 80 U/ml. Just before use, dilute a small portion of the enzyme with water to yield 10 U/ml or a total of 0.1 U in the 10 µl added to the control or reaction incubation.

COMMENTARY

Background Information

The radiometric assay described in Basic Protocol 1 can be used for all assays of ALA synthase as it has the sensitivity to measure the enzyme activity in all tissues, including basal levels or enzyme activities induced by drugs and other xenobiotics. The procedure is highly reproducible and has been used for a variety of tissues.

The radiochemical assay was developed to provide the sensitivity needed to determine ALA synthase activity in samples of such small size or low enzyme concentration as to preclude accurate measurement by the colorimetric procedure. The protocol described here is based on work by Ebert et al. (1970) and Scotto et al. (1983), and it permits the measurement of as little as 0.05 U of activity (0.05 nmol ALA formed per hour). Even smaller activities can be determined either by increasing the incubation time (in step 4) or by using a larger fraction of the Tris eluant for scintillation counting (steps 11 and 12). By comparison, the lower limit of the colorimetric assay is >0.5 U (Lien and Beattie, 1982). No systematic effort has been made to determine the upper limit of the radiochemical assay, but, with liver homogenates from rats treated with 2-allyl-2-isopropylacetamide (AIA), good proportionality was observed with 0.1 to 4 U in the assay. Results with this assay agree with those obtained with the colorimetric assay; e.g., samples that had activities of 0.61, 1.42, and 3.74 U in the radioactive assay gave 0.62, 1.35, and 3.94 U, respectively, when assayed colorimetrically. Untreated male Sprague-Dawley rats that had been starved for 24 hr had 113 ± 12 U/g of liver (n = 5), which agrees well with values determined colorimetrically (Lien and Beattie, 1982). Treatment of rats that had been starved for 24 hr with AIA (40 mg/kg body weight) caused a 12 to 15–fold increase in hepatic ALA synthase activity after 4 hr; thereafter, the activity declined gradually but was still ~10-fold greater than that in controls 18 hr after AIA injection. The latter is also in agreement with colorimetric measurements.

Using a sample of ^{14}C-aminolevulinate that had a radiochemical purity of 82%, it was found that there is negligible utilization of ALA in incubations with rat liver homogenates performed as outlined here, and that recovery of ALA added at step 1 of the protocol (but with unlabeled succinate) was 88% to 94%. No correction was made for recovery. As mentioned above, the sensitivity of the radiochemical assay makes it valuable in studies of tissues or cells with low content of ALA synthase. One example of that is a preliminary study of induction of the enzyme by succinyl acetone or polychlorinated biphenyls in isolated fish hepatocytes in which basal activity is only 15 to 20 U/g of wet weight of cells (Cornell et al., 1995).

Following the original description by Ebert et al. (1970) of the isolation of ALA by cation-exchange chromatography, several groups reported the occurrence of radioactive contaminants that co-elute with aminolevulinate, and

various approaches were proposed to eliminate those contaminants. Strand et al. (1972) used three steps of ion-exchange chromatography in which acid-stopped incubation mixtures were applied to an anion-exchange column that was used in tandem with a cation-exchange column. ALA eluted from the latter was then converted to the pyrrole and isolated by another round of anion-exchange chromatography. Bishop and Wood (1977) used a semi-automated amino acid analyzer and counted the radioactivity in the fraction corresponding to authentic ALA. Brooker et al. (1982) performed cation-exchange chromatography as described by Ebert et al. (1970), but converted ALA in the final eluate to the pyrrole, extracted it into ethyl acetate, evaporated the extract to dryness, and counted the radioactivity in the entire dried residue.

Minaga et al. (1978) reported that the major co-eluting contaminant was a breakdown product of succinyl-CoA, succinyl-cysteamine thioester, formed via the action of an amidase or peptidase. The thioester has a free amino group and is stable at a pH of ≤4.0, but at a higher pH (especially pH 8 to 10) it rapidly rearranges to succinyl-*N*-cysteamine and oxidizes to the stable disulfide, which has no free amino group. Thus, in ALA synthase incubations that are stopped with acid and adjusted to pH 3.9 for cation exchange chromatography as outlined by Ebert et al. (1970), the succinyl-cysteamine thioester will remain bound to the resin through the low pH washes, but will co-elute with ALA when an alkaline solution is applied to the column. Wolfson et al. (1980) also found that succinyl-CoA and its generating system can be the source of major contamination of the ALA fraction from cation-exchange chromatography, but they concluded that formation of the contaminant is blocked by inclusion of 10 mM EDTA in the ALA synthase incubation.

Scotto et al. (1983) confirmed and extended the work of Minaga et al. (1978), and they presented evidence that the succinyl-CoA degrading enzyme is located on the outer side of the inner mitochondrial membrane and is an amidase that requires cobalt or manganese as a metal ion cofactor. These researchers substituted alkaline SDS (pH 8.8) as the agent for stopping incubations, replacing the trichloroacetic acid that had been used by Ebert et al. (1970) and most subsequent users of the radiochemical assay of ALA synthase. The alkaline pH causes the rearrangement of the succinyl-cysteamine thioester to the stable disulfide, which does not bind to the cation-exchange resin, and SDS converts proteins in the incubation to polyvalent anions that also pass through the resin. With these changes, Scotto et al. (1983) found that the single column method of Ebert et al. (1970) gives good agreement with multi-column procedures involving conversion of ALA to its pyrrole, even when an exogenous succinyl-CoA generating system is included in the incubation mixture. Those changes are incorporated in the method outlined in Basic Protocol 1.

There are several disadvantages of this radiochemical assay. It is lengthy and labor intensive, and, while it avoids the strong acid and toxic agents needed for the colorimetric assay, it generates radioactive waste, the disposal of which is becoming increasingly difficult. The most serious disadvantage, which is also true for the colorimetric assay, is that it is a fixed-time assay that makes it laborious to determine the time course of the reaction and difficult to accurately establish kinetic parameters for ALA synthase. Recently two continuous, spectrophotometric assays have been described (Hunter and Ferreira, 1995; Shoolingin-Jordan et al., 1997) in which the activity of ALA synthase is coupled to an enzyme system that produces NADH. However, use of either of these assays is limited to somewhat purified, concentrated preparations of ALA synthase; e.g., to obtain an absorbance increase of 0.001/min would require ~10 U of the enzyme or the amount present in 0.1 gram of liver from an uninduced rat. With other tissues, that requirement would be even greater.

The colorimetric procedure has a long history of use and can be used for large numbers of samples of tissues or cultured cells. However its sensitivity is limited and so it is not recommended for studies of variation in activity in the region of 2 to 3–fold above control or at baseline or lower activities. The sensitivity can be increased by using higher concentrations of tissue or cell homogenates per incubation and scaling the procedure down, but the linearity of such assays with respect to time and protein must be checked. As described, the colorimetric assay relies on intact functioning mitochondria in the homogenate so that frozen material is less suitable. However, the authors have found that freezing liver homogenates from chick embryos at −80°C for 11 days did not result in decreased activities (G. Buzzell, N. Gorman, P. Sinclair, unpub. observ.). If activity is lost, then commercially available succinyl-CoA synthase can be added as described (Lien and Beattie, 1982).

When first establishing this assay in the laboratory, it is recommended that liver from animals given treatments known to increase ALA synthase as well as untreated animals be used. Increases in ALA synthase activity similar to those reported in the literature should be obtained before proceeding with tests of chemicals whose ALA synthase–inducing capacities are unknown.

Once increases in enzyme activities have been measured following treatment with test substances, it would be logical to test the appearance of ALA synthase protein using immunoblotting with a commercially available antibody (Agen Biomedicals) and to measure changes in ALA synthase mRNA (Hamilton et al., 1988). It should be noted that erythroid ALA synthase mRNA is transcribed from a different gene than the housekeeping gene found in liver and other tissues so that different probes are required (Riddle et al., 1989). Measurement of mRNA can be performed using Northern blotting (Riddle et al., 1989) or solution hybridization (Hamilton et al., 1988), the latter having the advantage of yielding quantitative data, but requiring DNA-free RNA prepared by CsCl density-gradient centrifugation.

An alternative procedure for measuring ALA synthase activity in cultured hepatocytes, especially in the highly inducible chick hepatocyte cultures, measures the activity in intact cells by adding the assay medium directly to the culture plates following chemical induction of ALA synthase (Sinclair and Granick, 1977). This method has been used by several laboratories and simplifies the procedure allowing more variations to be studied in a single experiment (Sassa and Kappas, 1977).

Critical Parameters and Troubleshooting

For the radiometric procedure, it is essential to control the pH as indicated at every stage of this procedure. With this assay, rat liver ALA synthase activity is maximal at pH 7.25 and decreases by only 10% to 20% at pH 7.1 or 7.4. However, the activity declines sharply at pH values outside that range. The pK of TES, 7.5 at 20°C, has a significant temperature dependence (–0.020/°C) and a small concentration dependence. It was empirically determined that, with 10% homogenates from rat liver, a pH of 7.6 at 25°C for the stock C and R buffers is necessary to obtain a pH of 7.25 at 37°C in the fully constituted incubations (steps 1 to 4 in Basic Protocol 1). For assays of different types of cell or tissue extract, replace the radioactive succinate in step 1 with unlabeled succinate, and measure the pH at step 4. If it differs from 7.25 by more than 0.05 pH units, readjust the pH of the C or R buffer.

For the SDS stop solution (used in step 5), a pH in the range of 8.5 to 8.8 is optimal for eliminating a labeled contaminant (see above) that co-elutes from Dowex 50 with ALA in assays stopped by other means (Scotto et al., 1983). Elimination of that contaminant decreases progressively at stop solutions with a pH <8.0, and the recovery of authentic ALA declines at pH values >9.0. Following the 65°C incubation with alkaline SDS, ascertain that the acetic acid addition in step 7 makes the pH 3.6 to 3.8. Likewise, take care that the Dowex 50 resin suspension and the sodium acetate wash buffer are at pH 3.9. ALA, which is quantitatively retained by the resin at pH values <4.0, begins to elute at pH 4.1. In contrast, radioactive amino acids such as glutamate and aspartate, which could be formed from [^{14}C]succinate during the incubation (step 4), elute from Dowex 50 at a pH ≥3.7. Thus, column washes at pH 3.9 separate those amino acids from ALA, which remains bound to the resin. The methanol/0.1 M sodium acetate, pH 3.9, and 0.01 M HCl washes remove the succinate that remains nonspecifically adsorbed to the resin after the first wash with 0.1 M sodium acetate, pH 3.9 (Ebert et al., 1970).

Following the low pH washes, sharp elution of ALA is effected by applying a concentrated basic solution. For that purpose, Ebert et al., 1970, used 1.0 M NH_4OH, which works well but is undesirable when the procedure is performed on an open bench. A 1.0 M solution of Tris base (e.g., Trizma base from Sigma) has an unadjusted pH of ~10.5, and is a satisfactory substitute for the NH_4OH.

The need for an exogenous succinyl-CoA generating system should be evaluated for each type of tissue and subcellular preparation. There appears to be general agreement that an added system is necessary to obtain full ALA synthase activity in homogenates of chicken (Yoda et al., 1975), mouse, or human liver (Bonkowsky and Pomeroy, 1978). However, data of Bonkowsky and Pomeroy (1978) showed only about a 10% increase in ALA synthase activity on addition of a succinyl-CoA generating system to rat liver homogenates, and they concluded that the addition is unnecessary. Brooker et al. (1982) reported that the addition was required for full expression of synthase activity in rat liver mitochondria, and they recommended also including it in assays of rat liver

homogenates. In contrast, Scotto et al. (1983) reported that an exogenous generating system actually decreased ALA production by intact rat liver mitochondria. The protocol described here has been used primarily with 10% homogenates of rat liver that were prepared with low osmolarity buffers and frozen/thawed once before assaying. Under these conditions, addition of a succinyl-CoA generating system gave a low but variable (10% to 60%) increase in ALA production, and it was decided to routinely make this addition (N.W. Cornell, unpub. observ.).

For the colorimetric procedure, as mentioned above, sufficient activity must be present to give reasonable differences in absorbance at 552 to 650 nm for the Ehrlich-pyrrole compound. Anything <0.03 OD units should be regarded as insufficient, and such low values are likely to lead to poor quality spectra as described in the method presented in Basic Protocol 2. Glycine itself gives some color in the reaction with Ehrlich reagent and minimal concentrations are used that still satisfy the high K_M of the enzyme for this substrate. The most frequent problem is the presence of nonspecific reactions of substance carried over from tissue or generated in the acetylacetone reaction, usually due to use of pH values outside the 4 to 6 region during that reaction.

It is always important to use a zero time incubation blank for each sample. This is particularly important when using tissue or cells from animals or cultures highly induced for ALA synthase as there will already be some ALA carrying over from the intact cells. There may be some porphobilinogen pyrrole (PBG) as well, which reacts directly with Ehrlich reagent, but usually there is much less PBG than the generated ALA. Another problem occurs if Ehrlich reagent is made with perchloric acid at <70% (w/v). The reagent must be mixed thoroughly with samples as the reagent is very dense.

Anticipated Results

For the radiometric assay, the actual data acquired are in counts/minute (cpm) for the 1-ml aliquots of Tris eluate mixed with scintillation fluid. Most counters now correct the counts obtained with each sample for background, quenching, and instrumental efficiency, so the output includes cpm and calculated disintegrations/minute (dpm). Each sample should be counted for sufficient time to reduce the statistical counting error to ≤5%; this requires accumulating at least 1600 total counts for each sample. In this protocol, assay of an extract with 0.05 U in 50 µl would give ~200 dpm in the 1 ml of Tris eluate, which would require ~8 to 10 min of counting.

Basal chick embryo and rat liver ALA synthase activities are in the range of 10 to 100 nmol ALA/hr/g liver. Upon induction, values increase to 2000 to 3000 nmol/g liver for chicken embryo (Hamilton et al., 1988); and for rat liver to 400 to 500 nml/hr/g liver (Scotto et al., 1983). In the cultures, activities of 0.3 to 0.6 nmol ALA/hr/mg homogenate protein are observed in livers from untreated embyros and up to 40 nmol/hr/mg protein in highly induced samples.

Time Considerations

For the radiometric assay, if the C and R buffers are prepared, a person experienced with this protocol can process 16 samples through step 11 in ~4 hr. The column chromatography requires ~2.5 hr, but it is greatly facilitated by having a linear rack with clips for holding the chromatography columns. Once the 1 ml of Tris eluant is mixed with scintillation fluid, counting can be postponed until a convenient time. If desired, the procedure can be broken up by conducting the incubation with alkaline SDS (step 6) overnight at room temperature (Scotto et al., 1983).

For the colorimetric assay, solutions should be prepared the day before the tissues samples are harvested from animals or culture. Incubations and preparation of TCA supernatants can be performed the next day, and reactions with Ehrlich reagents and reading of absorbances can be performed on the third day.

Measurement of Heme Concentration

Heme (iron-protoporphyrin IX) is the prosthetic group of a number of hemoproteins in different tissues including hemoglobin, myoglobin, cytochrome P-450s, mitochondrial cytochromes, catalase, and peroxidases. The measurement of heme is often used as an indirect way to show the changes in liver cytochrome P-450. Heme present in the so-called "free heme" pool, which is used for the synthesis of these hemoproteins, is also the regulator of the first enzyme in the biosynthesis of heme, δ-aminolevulinate synthase. Environmental agents and mutations of the biosynthetic pathway can affect the synthesis and degradation of heme, which is most readily measured using radioactive precursors. In this unit several methods are described for measuring heme concentration in tissue homogenates or cultured cells. The basic method measures heme as the pyridine hemochrome, which has a characteristic spectrum and is readily measured spectrophotometrically (see Basic Protocol). A more sensitive fluorescence method, particularly suitable for cultured cells, is also presented (see Alternate Protocol 1). An HPLC-based method is presented for purifying and quantifying heme itself and other hemes such as heme A (see Alternate Protocol 2). Finally, the use of these basic methods to measure radioactive heme is presented for the determination of rates of heme synthesis (see Alternate Protocol 3).

SPECTROPHOTOMETRIC HEME ASSAY OF PYRIDINE HEMOCHROME

BASIC PROTOCOL

In this assay the nitrogen ligands from protein-bound heme are replaced by pyridine in alkali. The resultant hemochrome is quantitated by the difference spectrum of the reduced and oxidized compound. The sensitivity of the assay is a function of the sensitivity of the spectrophotometer and of the ability to use microcells for minimal volumes.

CAUTION: Due to the toxicity and odor of pyridine, the procedure should be performed in a hood as much as possible and cuvettes should be capped or sealed with Parafilm.

Materials

5% (w/v) tissue sample suspension: tissue homogenate, or a homogenate or sonicate of tissue culture cells (minimally, 2 mg protein)
Reagent-grade pyridine (discard if yellow)
1.0 M NaOH
Sodium dithionite crystals
3 M potassium ferricyanide

12 × 75–mm disposable glass tubes (Fisher)
Sensitive scanning spectrophotometer
Appropriate cuvettes with caps

1. Place 0.84 ml of 5% (w/v) aqueous tissue sample suspension in a 12 × 75–mm disposable glass tube.

   The volumes given throughout the assay can be reduced or increased proportionately.

2. Add 0.2 ml reagent-grade pyridine and mix by vortexing.
3. Add 0.1 ml of 1 M NaOH and mix thoroughly by vortexing.

   In tissue culture assays, NaOH can be replaced by 0.16 M sodium borate, pH 9.0.

4. Split the sample between two cuvettes and obtain a baseline absorbance spectrum from 500 to 600 nm.
5. Using the tip of a fine spatula, add a few crystals of sodium dithionite and 0.01 ml water to one cuvette and mix to reduce hemochrome.

Contributed by Peter R. Sinclair, Nadia Gorman, and Judith M. Jacobs
Current Protocols in Toxicology (1999) 8.3.1-8.3.7

Very little dithionite is needed and the amount depends in part on the volume and other reducible compounds present. The solid should be a free-running powder and should be stored in small vials in a desiccator. Discard if it becomes totally solid and buy a new stock bottle once a year.

6. Add 0.01 ml of 3 M potasium ferricyanide to the other cuvette and mix to oxidize the hemochrome.

   Ferricyanide may not be necessary, but the effect should be tested.

7. Obtain and record a spectrum of reduced versus oxidized heme between 500 and 600 nm.

   To ensure that reduction is complete, a little more dithionite can be added and the spectrum rescanned to see if any increase occurs.

8. Calculate heme concentration based on the millimolar extinction coefficient of 20.7 for the difference in absorption between the peak at 557 nm and the trough at 541 nm.

ALTERNATE PROTOCOL 1

FLUORESCENCE HEME ASSAY

In this method, the iron in heme is removed by heating in a strong oxalic acid solution and the resultant protoporphyrin is measured by fluorescence. This method needs to be optimized for each type of tissue used, but it is very sensitive. One disadvantage is that the method cannot be used when the tissue already contains a large amount of porphyrin or other substances that fluoresce at the assay wavelengths, unless the amount of this fluorescence can be accurately subtracted using a reagent blank.

Materials

Tissue culture cells or tissue (sonicate or homogenate; see Basic Protocol materials)
2 M oxalic acid solution (see recipe)
1 mg/ml heme standard solution (see recipe) or protoporphyrin standard solution (Porphyrin Products)

Heating block at 100°C
6 × 50–mm disposable glass tubes (Fisher)
Spectrofluorometer equipped with cell holder and preferably with red-sensitive phototube (Hamamatsu R928, R446, or R3896, or equivalent)

1. Collect tissue culture cells in 6 × 50–mm disposable glass tubes by centrifugation or place a small volume (up to 50 µl) in the tubes.

   Protein amount should be <10 µg/tube. The assay is linear from 1 nM to 1 µM (or 0.5 pmol to 0.5 nmol) heme per tube.

   The assay is most conveniently performed using a cell holder that holds four 6 × 50–mm tubes. Alternatively, samples can be transferred into disposable plastic cuvettes for fluorescent measurements.

2. Add 0.5 ml of 2 M oxalic acid solution and mix thoroughly.

3. Put sample tubes in a heating block set at 100°C for 30 min. Do not heat blanks.

   Blank and sample tubes contain tissue and oxalic acid, but the blanks are not heated.

4. Read fluorescence of porphyrin using 400 nm excitation and 662 or 608 nm emission, after determining that these represent the actual peaks with the instrument used.

   The 662 nm emission peak has lower fluorescence than the peak at 608 nm, but also has less scatter and other interference.

   Actual peaks vary from instrument to instrument.

5. Subtract blank values (parallel unheated samples in oxalic acid) from samples.

6. Calculate heme content based on a standard heme curve over the range of 0 to 1 nmol heme per tube, or calibrate with 1 mg/ml heme standard solution or a protoporphyrin standard.

ASSAY OF HEME AND BIOSYNTHETIC INTERMEDIATES BY REVERSED-PHASE HPLC

ALTERNATE PROTOCOL 2

This method, though considerably more elaborate than those described above, gives more precise assays for heme and also measures intermediates in the heme pathway. Other modifications permit the detection of heme A (the prosthetic group of cytochrome oxidase) and its biosynthetic intermediate, heme O (Tzagoloff et al., 1993).

CAUTION: Acetone is highly flammable and should not be used near heaters or open flames. Acetone will dissolve tissue culture plastic and should not remain in contact with plastic for >5 min.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

Tissue culture cells or tissue (sonicate or homogenate; see Basic Protocol materials)
Aqueous cell homogenate or tissue culture cells
Acetone/HCl/water (see recipe)
Acetone/HCl (see recipe)
Buffer A (see recipe)
HPLC-grade methanol (buffer B)
Heme/porphyrin standard injection mixture (see recipe)

HPLC system with multisolvent delivery system, absorbance detection for heme (400 nm), and fluorescence detection for porphyrins (excitation 400 nm, emission 600 nm)
C18 HPLC column (e.g., Waters μBondapak; 39 × 300 mm) and C18 precolumn

1a. *For tissue culture cells in culture dishes:* Remove culture medium from tissue culture dishes and add acetone/HCl/water (e.g., 2 ml to a 6-cm dish) directly to the cells. Remove solution and repeat extraction.

The extraction is performed with acetone/HCl/water, because in the absence of water heme is trapped in the dehydrated pellets and is then only slowly extractable using multiple extractions.

1b. *For cell homogenates:* Add an equal volume of acetone/HCl to an aqueous cell homogenate, mix vigorously, and centrifuge 10 min at 2000 × *g* using capped tubes. Transfer the extracts to glass tubes with screw-on caps. Reextract with half the original volume of acetone/HCl/water.

The second extraction is performed with acetone/HCl/water, because in the absence of water heme is trapped in the dehydrated pellets and then requires multiple extractions.

2. Mix acetone extract with an equal volume of buffer A, pH 7 to 8, and test some samples to check that the final pH is 3.5 to 4.0.

The resulting solution can be injected onto the column or stored up to 24 hr in the dark at room temperature.

3. Load 0.25 to 1.0 ml heme/porphyrin standard injection mixture on a C18 HPLC column and run gradient HPLC over 15 min with a linear gradient from 60%/40% (v/v) buffer A/buffer B to 100% buffer B.
4. Maintain at 100% buffer B for another 10 min.
5. Return to original conditions over 5 min, then maintain for 10 min before injecting the first sample.
6. Repeat steps 3 to 5 for samples.

NOTE: *The method must be optimized for each HPLC system and column due to differences in packing material and pump head volumes. The pH of buffer A may have to be optimized between pH 3.0 and 3.5 for maximal separation.*

ALTERNATE PROTOCOL 3

ASSAY OF RADIOACTIVE HEME BY SOLVENT EXTRACTION

This method is for the measurement of newly synthesized heme in tissue culture cells and is based on the specific activity of the added radioactive compound. This method can also be used for measuring total heme if labeling with radioactive δ-aminolevulinic acid (ALA) is continued for sufficient time (≥24 hr) to essentially replace all heme in the cells. The protocol described for measuring labeled heme involves a rapid solvent extraction and purification. Determination of radiolabel in heme biosynthetic intermediates can be determined by HPLC as described above (see Alternate Protocol 2). Suitable radioactive heme precursors include [^{14}C]glycine, [4-^{14}C]ALA, and [^{3}H]ALA. Because glycine will label many cellular compounds, the solvent extraction method is not suitable for preparation of heme when glycine is used as the radioactive precursor.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CAUTION: Ethyl ether is highly flammable and the vapors are dense, tending to run across laboratory benches. The whole extraction and evaporation process should be performed in an explosion-proof hood. Because stored ether can develop peroxides and explode, it is best to use small bottles and to dispose of any remaining liquid by evaporation in a hood. Do not store opened bottles for >1 month.

CAUTION: Acetone is highly flammable and should not be used near heaters or open flames. Acetone will dissolve tissue culture plastic and should not remain in contact with plastic for >5 min.

Materials

Radiolabeled tissue culture cells
2 M HCl
Ethyl ether
Aqueous scintillation fluid
~45°C water bath

Additional reagents and equipment for preparing acetone extracts (see Alternate Protocol 2)

1. Prepare acid acetone extracts (see Alternate Protocol 2, steps 1a and 1b) of tissue culture cells incubated with radioactively labeled glycine or 5-aminolevulinic acid (ALA).

The amount and concentration of radioactive compound must be optimized for different cell types.

2. Place all of the acid-acetone extract in a 20-ml glass scintillation vial.
3. Add 5 ml ethyl ether and 2 ml of 2 M HCl. Screw on plastic ether- and acetone-resistant caps and vortex vigorously. Allow the layers to separate.

   Heme is extracted into the ether upper layer and labeled porphyrins into the aqueous layer.

4. Remove the bottom (aqueous) layer with a Pasteur pipet and discard. Repeat extraction of ether with another 2 ml of 2 M HCl. Repeat once more.
5. Evaporate ether by placing vial in a warm water bath (~45°C).
6. Add aqueous scintillation solution, mix well to dissolve the heme, and determine radioactivity in a suitable counter.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acetone/HCl

97.5 ml acetone
2.5 ml concentrated HCl
Prepare fresh

Acetone/HCl/water

97.5 ml acetone
2.5 ml concentrated HCl
20 ml water
Prepare fresh

Buffer A

For HPLC gradient: Dissolve 19.3 g $NH_4H_2PO_4$ in 1680 ml double-distilled water and filter through a 0.22-µm filter. Add 1320 ml HPLC-grade methanol (final 56 mM $NH_4H_2PO_4$). Adjust pH to 3.15 with concentrated H_3PO_4. Store up to several months at room temperature.

For addition to sample: Add 10 M NaOH (*APPENDIX 2A*) to buffer A to adjust pH to 7 to 8 (requires ~0.015 ml NaOH per milliliter buffer A).

Heme standard solution, 1 mg/ml

Dissolve heme at 1 mg/ml in dimethyl sulfoxide (DMSO). Determine concentration by spectrophotometry of an ~1:300 (v/v) dilution in 40% (v/v) DMSO, using a millimolar extinction coefficient of 180 at 400 nm. Store indefinitely at room temperature.

Heme/porphyrin standard injection mixture

For 0.2 mM heme standard solution: Dissolve 2.6 mg heme in 20 ml dimethyl sulfoxide (DMSO). Check concentration by spectrophotometry of a 1:40 (v/v) dilution in 40% (v/v) DMSO, using a millimolar extinction coefficient of 180 at 400 nm. Store indefinitely at room temperature.

For 0.25 mM protoporphyrin standard solution: Dissolve 2.5 mg protoporphyrin in 20 ml dimethyl sulfoxide (DMSO). Check concentration by spectrophotometry of a 1:80 (v/v) dilution in 2.7 M HCl, using a millimolar extinction coefficient of 262 at 410 nm. Store indefinitely at room temperature.

continued

For standard solution of other porphyrins: Use a commercially available mixture (Porphyrin Products) containing 10 nmol of each porphyrin per tube. Dissolve according to supplier's instructions. Store indefinitely at room temperature.

For standard injection mixture: Use appropriate volumes of diluted standard solutions such that the injected volume contains 50 to 200 pmole heme and 5 to 20 pmole of protoporphyrin and each other porphyrin. Store indefinitely at room temperature.

Porphyrins are light sensitive. Samples containing porphyrins need to be protected from direct light and should be in dark vials when used in an autosampler.

Oxalic acid, 2 M

Prepare a 2 M solution of oxalic acid in water. Because this is close to saturation, heat solution to dissolve. Cool to room temperature and use the saturated supernatant. Store up to several months at room temperature.

COMMENTARY

Background Information

The protocols described here provide methods for determining the amount of heme in tissue samples and cultured cells. The values obtained can be compared with assays of individual hemoproteins. In liver, for example, more than half of the heme may be present in cytochrome P-450s. Following drug treatments that induce cytochrome P-450, two- to threefold increases in heme may be observed. For isolated microsomes, total heme is often compared with total cytochrome P-450, determined spectrophotometrically or immunologically, in order to determine whether the cytochrome is present as the apo or holo forms.

Four different protocols are described to measure heme. The simplest and most often used remains measurement of heme from the reduced-minus-oxidized difference spectrum of the pyridine hemochrome as originally used by Paul et al. (1953) and described in Fuhrhop and Smith (1975). The main disadvantage of this method is the use of pyridine and the requirement for a sensitive scanning spectophotometer. Use of the difference spectrum allows assay of heme in the presence of other colored compounds (such as porphyrins) and turbidity. With instruments that have the ability to determine spectra of turbid samples, this method can be used with samples that contain small amounts of heme and that scatter light. It is advisable to spike such samples with heme to ensure the method is yielding quantitative results. Dual-wavelength spectrophotometry, in which only one cuvette is required, can be used for measurement of the pyridine hemochrome. The baseline spectrum is subtracted from that of the subsequent reduced samples (Berry and Trumpower, 1987).

The fluorescence assay for heme (Sassa, 1976) is more sensitive than the pyridine hemochrome, but needs to be optimized for each tissue, adding heme to samples to determine the linear range of the response. HPLC determinations of heme are probably the most accurate, once the recovery of the extraction has been determined. It also provides a pure product and the concentrations of some other heme synthetic intermediates are also obtained (Bonkovsky et al., 1986; Jacobs et al., 1992). This HPLC method can also be used to determine radioactivity in heme in tissue culture samples, or heme can be extracted and prepared free of other radioactive heme pathway components by the solvent extraction and washing method described (Healey et al., 1981; Jacobs et al., 1998). The advantage of the latter procedure is the removal of radioactive porphyrins in the acid wash. A third wash is recommended to ensure that the heme remaining in the ether is not contaminated with porphyrins, which usually have much higher specific activities than the heme itself. Even heme labeled with ^{59}Fe can be purified in this way, in which the acid washing of the heme in ether effectively removes free ^{59}Fe (Taketani et al., 1998).

One problem with all of these methods is that total protoheme is measured, including that from hemoglobin. Therefore, perfusion should be used to remove as much blood as possible from the tissue in order to obtain useful data. It is possible to independently measure hemoglobin by converting it to methemoglobin and measuring this by the cyanide complex (Waterman, 1978).

Critical Parameters and Troubleshooting

In the pyridine hemochrome method, the condition of the solid dithionite is important, as well as ensuring that neither too little nor too

much of this powerful reductant is used for reducing the hemochrome. It is important that spectra of high quality be produced with two definite peaks at 557 and 526 nm. The spectrum of the hemochrome of pure heme should be determined for comparison. Likewise, the fluorescence spectrum of de-ironed heme (protoporphyrin) should be compared to that of pure protoporphyrin (Sassa, 1976), noting that the ratios of the two fluorescence peaks can vary with different photomultipliers.

In the heme extraction method with acetone/HCl into ether, emulsions may be produced with highly fatty tissues. These can usually be broken by cooling the samples and with centrifugation, if necessary. Although this method will give radioactive pure heme in most cases (plus a small amount of heme A), the authors have found that, using HPLC and in the presence of iron in tissue cultures, the ether fraction contains considerable radioactivity that is not heme. This probably contains heme degradation products.

Anticipated Results

These heme extraction procedures usually give ~75% to 80% recovery of heme added to samples. This number may need to be determined using spiked controls and applied as a correction factor to data obtained by this method. Heme values of 100 to 200 pmol/mg protein can be expected from chick hepatocytes (Sassa and Kappas, 1977).

Time Considerations

The pyridine hemochrome and fluorescence methods are only limited by the time taken to prepare and run the spectrum for each sample. The heme extraction for 20 to 40 samples can be performed in ~2 to 3 hr. HPLC analyses are limited by the 45-min required for each sample. However, 20 samples can be analyzed overnight with an autosampler.

Measurement of Uroporphyrinogen Decarboxylase Activity

Uroporphyrinogen decarboxylase (UROD) catalyzes the decarboxylation of the four acetate side chains of uroporphyrinogen to form coproporphyrinogen. Both naturally occurring isomers of uroporphyrinogen (isomers I and III) are substrates for UROD, but only coproporphyrinogen III can ultimately be converted to heme. Subnormal activity of UROD in hepatocytes is the cause of porphyria cutanea tarda (PCT), the most common form of porphyria in humans. *UNIT 8.1* provides a more detailed description of the enzyme and diseases associated with deficient activity.

UROD activity can be assayed using a variety of substrates. Any of the intermediates in the conversion of uroporphyrinogen to coproporphyrinogen can serve as substrates for the enzyme (i.e., porphyrinogens with seven, six, or five carboxyl groups of either the I or III isomer series). Commercially available porphyrins can be chemically reduced to the corresponding porphyrinogens with either sodium amalgam or potassium borohydride. Uroporphyrinogen I can also be formed enzymatically.

This unit contains protocols for measuring UROD activity using substrate that is enzymatically prepared (see Basic Protocol) or chemically prepared (see Alternate Protocol). Once the substrate has been formed, the UROD assay reaction and analysis of the products in the Basic Protocol and Alternate Protocol are quite similar. There are also protocols for preparation of bacterial porphobilinogen deaminase (PBGD; see Support Protocol 1), which is used to prepare the substrate in the Basic Protocol, and erythrocyte lysates for UROD activity measurements (see Support Protocol 2).

MEASUREMENT OF UROD ACTIVITY USING ENZYMATICALLY REDUCED PORPHYRINS AS SUBSTRATES

BASIC PROTOCOL

Assaying UROD activity can be divided into three steps. The first is to form the porphyrinogen substrate for the assay. In this protocol, the enzymatic preparation of uroporphyrinogen I is described (an alternative procedure involving the chemical reduction of commercially available porphyrins is described in the Alternate Protocol). The second step is the reaction of the substrate with the source of UROD to be assayed. The third step is the separation and quantification of the reaction products. Regardless of how the substrate is generated, the second step must be started immediately, as porphyrinogens are oxidized quickly. Once the second step is completed, the products are quite stable and can be analyzed when convenient. This protocol is partially modified from Straka et al. (1982).

Materials

- 0.1 M dithiothreitol (DTT) in 0.1 M Tris·Cl, pH 7.65 (see *APPENDIX 2A* for Tris·Cl buffer)
- 2.4 mM porphobilinogen (Porphyrin Products) in 0.1 M Tris·Cl, pH 7.65 (see *APPENDIX 2A* for Tris·Cl)
- Porphobilinogen deaminase (PBGD; see Support Protocol 1), diluted in 10 mM KH_2PO_4, pH 7.6 so that 150 µl will produce 30 to 60 µM uroporphyrinogen in 30 min in the reaction mix in step 2
- N_2 source
- 0.15 M KH_2PO_4, pH 4.45 (mix 1 M KH_2PO_4 and 1 M K_2HPO_4 to a pH of 4.5 and dilute to 0.15 M with H_2O)
- UROD source to be assayed (see, e.g., Support Protocol 2)
- 0.1 M DTT in 0.1 M KH_2PO_4, pH 6.8 (see *APPENDIX 2A* for potassium phosphate buffer)

continued

Current Protocols in Toxicology (1999) 8.4.1-8.4.13

3 M HCl
3.5 µM mesoporphyrin IX dihydrochloride (Porphyrin Products)
Methanol (HPLC grade)
Methanol/phosphate (see recipe)
Porphyrin standards, dissolved in 3.0 M HCl (Porphyrin Acids Chromatographic Marker Kit, Porphyrin Products)

12 × 75–mm tube to prepare substrate
Red lamp
Woods lamp (UV, "black light")
HPLC system fitted with a gradient maker and fluorescence detector (excitation 404 nm, emission 618 nm)
C18 column for separation of porphyrins (e.g., Waters µBondapak 3.9 × 300 mm)

Prepare reaction mix

1. Determine the number of samples to be assayed (see steps 4 and 5), including at least one blank. Prelabel assay tubes in duplicate and keep on ice to avoid delays; also calculate the amount of uroporphyrinogen I substrate solution which must be prepared in step 2.

   Each assay tube will require 0.30 ml of the uroporphyrinogen I solution that will be prepared in step 2, making allowances for pipetting errors.

Enzymatically generate uroporphyrinogen I substrate solution

2. For each duplicate sample to be assayed, including the blanks, combine the following in a 12 × 75–mm tube in the dark or under red light:

   50 µl 0.1 M DTT in 0.1 M Tris·Cl, pH 7.65
   50 µl 2.4 mM PBG
   150 µl PBGD solution (appropriately diluted; see Support Protocol 1).

   Thoroughly purge the reaction mix with N_2 gas, and top the tube with N_2 before sealing tightly. Incubate 30 to 40 min at 37°C.

   Tubes can be sealed with Parafilm or 000 stoppers depending on quantity and preference. The key is to reduce O_2 as quickly and completely as possible.

   The reaction described will produce enough uroporphyrinogen I so that there will be ~30 µM substrate in the decarboxylation reaction, a saturating concentration for UROD in most tissue lysates. See Straka et al. (1982) for additional detail.

   The amount of substrate prepared must be scaled appropriately, taking into consideration that samples are usually assayed in duplicate and that allowances must be made for pipetting errors. For instance, if 20 tubes are to be prepared in step 4 the reaction mixture above would be scaled up to 1.00 ml of 0.1 M DTT, 1.00 ml of 2.4 mM PBG, and 3.00 ml of the PBGD solution; the reaction would then be stopped using 1.00 ml of 0.15 M KH_2PO_4, pH 4.45, in step 3.

3. Place on ice and stop the reaction by adding 50 µl of 0.15 M KH_2PO_4, pH 4.45, which will inactivate PBGD by lowering the pH from 7.65 to 6.80.

   This is the optimal pH for the UROD reaction in the subsequent steps.

React assay samples with substrate

4. Working in the dark or under a red lamp to avoid photooxidation of the substrate, add the following to each assay tube, on ice:

   175 µl of UROD source to be assayed
   25 µl 0.1 M DTT in 0.1 M KH_2PO_4, pH 6.8
   300 µl of substrate from step 3.

   Top tubes with N_2, mix gently, and incubate in the dark for 30 min at 37°C.

Table 8.4.1 Solvent Gradient for HPLC Separation of Porphyrins

Time (min)	Flow rate (ml/min)	Methanol/phosphate[a]	Methanol	Slope[b]
0	1.0	100%	0%	—
13	1.0	0%	100%	5
15	1.0	0%	100%	1
15.1	1.0	100%	0%	6
25	1.0	100%	0%	1

[a]See recipe in Reagents and Solutions.
[b]Gradient curve profile as specified by Waters.

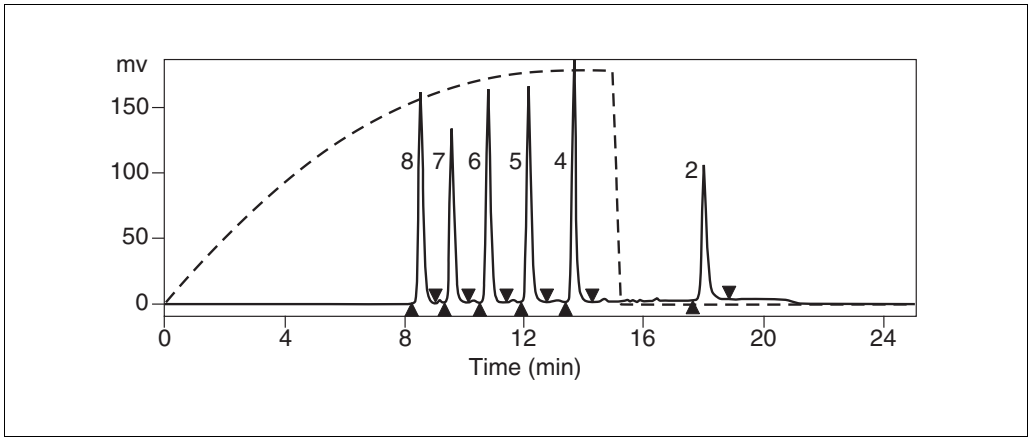

Figure 8.4.1 Chromatogram of porphyrin standards separated by reverse-phase HPLC. A 25-µl aliquot of a standard containing 62.5 pmol of each of the following porphyrins was separated with a Waters HPLC system using a C18 column: uroporphyrin (8), heptacarboxyl porphyrin (7), hexacarboxyl porphyrin (6), pentacarboxyl porphyrin (5), coproporphyrin (4), and mesoporphyrin (2). The aqueous solvent was 50% (v/v) methanol/NaH_2PO_4, pH 4.5; the organic phase was 100% methanol. A flow rate of 1 ml/min was used and the shape of the gradient is shown with the dashed line. The peaks were quantified with the Millennium software provided with the instrument.

When assaying UROD activity from a tissue homogenate or cell lysate (see Support Protocol 2), it is important to include a "no substrate" control reaction to account for any endogenous porphyrins present in the sample. A blank (substrate only, no enzyme) should also be included to verify the concentration of uroporphyrinogen I in the reaction mix.

5. Add 500 µl of 3 M HCl to each tube to stop the reaction. Place samples at room temperature under a Woods lamp for 30 min to oxidize porphyrinogens to porphyrins.

   If a Woods lamp is not available, samples can be oxidized in sunlight for 1.5 to 2 hr.

Separate and quantify reaction products

6. Microcentrifuge samples 5 min at 13,000 × *g*, room temperature, to bring down precipitated proteins.

7. Remove a 100-µl aliquot of the supernatant and mix it with 20 µl of 3.5 µM mesoporphyrin IX dihydrochloride as an internal standard.

   This serves both to be a reference for quantification and to monitor retention time of the porphyrin peaks.

   Retain the remainder of the supernatant in case samples need to be rerun on the HPLC.

8. Set up HPLC system with C18 column to separate porphyrins. Program the solvent delivery system of the HPLC as described in Table 8.4.1. Inject a 25-µl aliquot of each internal-standard-spiked sample from step 7 into the HPLC system.

9. Detect the elution of the porphyrins with a fluorescence detector set at an excitation wavelength of 404 nm and emission wavelength of 618 nm (Ford et al., 1981).

Uroporphyrin elutes first and porphyrins containing fewer carboxyl groups are retained longer.

10. Using the same HPLC technique as for the samples, analyze a standard (from the chromatographic marker kit) that contains 62.5 pmol each of 8-, 7-, 6-, 5-, 4-, and 2-carboxylporphyrins and set up a calibration profile (Fig. 8.4.1).

11. Quantify chromatogram from each sample by comparison to the standard, using software provided with the HPLC system. Express activity as nmol substrate decarboxylated per hr per mg of protein or hemoglobin, or per liter of red cells.

If UROD that has been purified to homogeneity is used, a specific activity can be calculated.

ALTERNATE PROTOCOL

MEASUREMENT OF UROD ACTIVITY USING CHEMICALLY REDUCED PORPHYRINS AS SUBSTRATES

This protocol describes the chemical reduction of porphyrins to generate porphyrinogen substrates for UROD. The porphyrin to be used is solubilized and quantified spectrophotometrically. A quantity sufficient for the assay is reduced by the addition of sodium amalgam. The pH of the porphyrinogen solution is adjusted, and the solution is incubated with the fraction containing the UROD enzyme. The total volume of the reaction is reduced by half when using chemically reduced substrates, as the porphyrins are relatively costly. The buffering capacity of the reaction has also been increased because of the alkaline nature of the chemically reduced substrate. Analysis and quantification of the reaction products is the same as described above for the enzymatically generated substrate (see Basic Protocol).

NOTE: If the pentacarboxyl porphyrinogen I isomer is used as a substrate, the UROD assay should be run at pH 5.4 (Francis and Smith, 1984). Buffers used for the assay should be adjusted to pH 5.4 in this specific case.

Additional Materials *(also see Basic Protocol)*

Porphyrin dihydrochloride (generally uroporphyrin I or III or pentacarboxyl porphyrin I or III; Porphyrin Products)
2 M NH_4OH
1.5 M HCl
1 M and 50 mM KH_2PO_4, pH 6.8 (*APPENDIX 2A*)
5% sodium amalgam (Anachemia, or as prepared in Straka et al., 1982)
1 M DTT
2 M H_3PO_4
pH paper, 5 to 10 range

Desiccator jar large enough for a tube rack and ice, with a 3-way stopcock
Spectrophotometer (able to scan from 350 nm to 550 nm)

Chemically reduce a porphyrin

1. Solubilize 5 to 10 mg of the porphyrin by adding 3 to 4 drops of 2 M NH_4OH.

2. Dilute 2-µl aliquots of the porphyrin 1:1000 and 1:10,000 with 1.5 M HCl. Scan each of these dilutions from 370 nm to 430 nm and record the absorbance at the peak.

3. Calculate the concentration of porphyrin present based on the molar extinction coefficients given in Table 8.4.2.

Table 8.4.2 Wavelength Maxima and Molar Extinction Coefficients for Porphyrins in 1.5 M HCl[a]

Substrate	Wavelength maximum (nm)	ε $(mM/l)^{-1}$ cm^{-1}
Uroporphyrin	406	541
Heptacarboxyl porphyrin	405	528
Hexacarboxyl porphyrin	404	514
Pentacarboxyl porphyrin	402	502
Coproporphyrin	400	489

[a]Values from Straka et al., 1982.

4. Dilute the porphyrin solution to 2 mM in 50 mM KH_2PO_4, pH 6.8. Top tube with nitrogen and keep on ice.

   IMPORTANT NOTE: *All subsequent steps should be performed in nitrogen-purged tubes, on ice, and in the dark or under red light to minimize oxidation.*

5. Add ~75 to 150 mg of 5% sodium amalgam (blot dry before use) per 100 µl of porphyrin solution to be reduced. Top tube with nitrogen, seal, and incubate on ice, vortexing occasionally.

   CAUTION: *Sodium amalgam is a chemical with high reductive potential, so explosions may occur. The reaction using sodium amalgam produces mercury, which must be disposed of properly. Work in a fume hood and take appropriate safety precautions.*

6. Check the reduction of porphyrin to porphyrinogen periodically by briefly examining the tube under the Woods lamp.

   When no fluorescence is visible, the reduction is complete, usually after 5 to 10 min for a 100- to 200-µl sample.

React porphyrinogen with UROD source

7. Before running the actual reactions, set up a mock reaction tube to determine the amount of H_3PO_4 required to achieve a final pH of 6.8, by adding the following to a tube in the order indicated:

   5 µl of the reduced substrate solution from step 6
   20 µl 1 M KH_2PO_4
   2.5 µl 1 M DTT
   5 µl 2 M H_3PO_4
   42.5 µl 50 mM KH_2PO_4.

   Finally, add an additional 175 µl 50 mM KH_2PO_4 (to account for the enzyme fraction to be added). Check the pH by spotting on pH paper; it should be ~6.8. If not, add 1- to 2-µl increments of 2 M H_3PO_4, checking the pH after each addition. Once a pH of 6.8 has been reached, record the amount of 2 M H_3PO_4 added and add this amount of 2 M H_3PO_4 to each of the samples to be assayed (see step 9; however, in step 8 adjust volume of 50 mM KH_2PO_4 to maintain a final total volume of 250 µl if the amount of 2 M H_3PO_4 needed is >5 µl).

8. For each sample to be assayed, add the following in the order indicated to a microcentrifuge tube on ice:

   42.5 µl 50 mM KH_2PO_4 (adjusted for volume of 2 M H_3PO_4 needed; see step 7)
   2.5 µl 1 M DTT
   20 µl 1 M KH_2PO_4
   175 µl sample of the UROD source (~1 µg of purified UROD protein) to be assayed.

   Mix each tube and place in a rack. Place the rack on ice in a desiccator and purge desiccator twice with nitrogen. Let stand for 5 to 10 min to remove oxygen.

9. Remove the tubes from the desiccator and, while blowing nitrogen over the top of the solution, add 5 µl H_3PO_4 (or volume determined in step 7) down one side of the tube, then add 5 µl of substrate (from step 6) down the other side. Cap the tubes, mix gently, and return to ice.

   Have solutions ready before removing tubes; this step should be done quickly minimizing exposure to O_2.

10. When all samples are ready, place them in a 37°C water bath and incubate in the dark for 30 min.

11. Add 250 µl 3 M HCl to stop the reaction.

12. Oxidize for 30 min under the Woods lamp, and then microcentrifuge 5 min at 13,000 × *g*, room temperature, to bring down precipitated proteins.

13. Quantify reaction products by HPLC (Basic Protocol, steps 7 to 11).

SUPPORT PROTOCOL 1

PURIFICATION OF PBGD FROM *RHODOBACTER SPHEROIDES*

The conjugation of four molecules of porphobilinogen into the tetrapyrrole hydroxymethylbilane requires the enzyme porphobilinogen deaminase (PBGD). Hydroxymethylbilane is the substrate for uroporphyrinogen III synthase and is a highly labile compound. In the absence of uroporphyrinogen III synthase there is a nonenzymatic cyclization of the hydroxymethylbilane to form uroporphyrinogen I. The purification of PBGD described (modified from Jordan and Shemin, 1973) takes advantage of the thermal stability of the enzyme. Uroporphyrinogen III synthase, on the other hand, is thermally labile and is rapidly and irreversibly inactivated in the purification procedure. The procedure outlined below provides a good yield of product and can be accomplished in ~3 days.

Materials

R. spheroides (Porphyrin Products)
10 mM KH_2PO_4, pH 7.6 (*APPENDIX 2A*)
100% ethanol, ice cold
$(NH_4)_2SO_4$
3 mM KH_2PO_4, pH 6.8
0 to 0.50 M KCl gradient in 3 mM KH_2PO_4, pH 6.8
0.01 M DTT
0.1 M Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.54 mg/ml porphobilinogen, (PBG; Porphyrin Products) in 0.1 M Tris·Cl, pH 7.6
3 M HCl
0.15 M KH_2PO_4, pH 4.45
50 mM KH_2PO_4, pH 6.8

Probe sonicator
Refrigerated centrifuge accommodating 1-liter buckets and 50-ml centrifuge tubes
Dialysis tubing, 12,000 to 14,000 MWCO
70°C water bath
DE-52 column, 50 ml bed volume, equilibrated with 3 mM KH_2PO_4, pH 6.8 (see recipe)
Concentrator (e.g., Amicon Centriprep 10)
Fraction collector
UV monitor to measure absorbance at 280 nm, or UV spectrophotometer
Woods lamp

Additional reagents and equipment for dialysis (*APPENDIX 3*)

Prepare R. spheroides lysate

1. Freeze-thaw a 100-ml sample of *R. spheroides*, twice.
2. Dilute the thick slurry with 100 ml of 10 mM KH_2PO_4, pH 7.6, and sonicate for 3 min on ice following manufacturers instructions.

   Following freeze-thaw and sonication, cells will be newly 100% lysed.
3. Place the sample in a cold room or refrigerator and gradually add 800 ml of ice-cold 100% ethanol. Stir for 2 hr, to allow protein to precipitate.
4. Centrifuge 30 min at 10,000 × *g*, 4°C. Pour off the supernatant and discard. Resuspend the pellet in 500 ml ice-cold 100% ethanol, to wash off more of the chlorophyll.
5. Centrifuge again for 30 min at 10,000 × *g*, 4°C. Drain the ethanol completely from the pellet, then resuspend the pellet in 250 ml 10 mM KH_2PO_4, pH 7.6.
6. Using a 12,000 to 14,000 MWCO dialysis membrane, dialyze the sample overnight at 4°C against 10 mM KH_2PO_4, pH 7.6.

   Several changes of buffer are required to remove all the ethanol. The authors suggest making one change before leaving at night after 2 to 3 hr of dialysis, and another change in the morning 2 to 3 hr before ending the dialysis.

Heat denature uroporphyrinogen III synthase

7. Divide the sample into 100-ml aliquots in 500-ml Erlenmeyer flasks, each containing a thermometer.
8. Place samples in a 70°C water bath and heat them until they reach 60°C. Hold this temperature for 5 min.

   Place flask briefly on ice if the temperature rises above 60°C.
9. Place the flasks on ice to cool. Transfer contents to 50-ml centrifuge tubes and centrifuge 30 min at 18,000 × *g*, 4°C. Keep the supernatant. Resuspend the pellet in 50 ml 10 mM KH_2PO_4, pH 7.6, mix well, and centrifuge as before. Combine the supernatants and measure the total volume.

Precipitate the enzyme with ammonium sulfate

10. Weigh out enough $(NH_4)_2SO_4$ to bring the $(NH_4)_2SO_4$ concentration to 32% of saturation (i.e., assuming 765 g/liter is 100%). Over 30 min, while stirring in the cold box, slowly add the $(NH_4)_2SO_4$ to the sample. Allow the solution to equilibrate for 1 hr after the last addition.

    Example: (765 g/1000 ml) (0.32) (300 ml) = 73.4 g $(NH_4)_2SO_4$ needed to make the 0% to 32% cut in 300 ml.
11. Centrifuge 30 min at 10,000 × *g*, 4°C. Keep the supernatant. Make a 32% to 55% $(NH_4)_2SO_4$ cut by weighing out more $(NH_4)_2SO_4$ based on the original volume. Add as above and allow to equilibrate for 2 hr to overnight.

    Example: (765 g/1000 ml) (0.55) (300 ml) = 126.2 g − 73.4 g = 52.8 g $(NH_4)_2SO_4$ needed to make the 32% to 55% cut.
12. Centrifuge 45 min at 18,000 × *g*, 4°C. Discard the supernatant and resuspend the pellet in 40 ml of 3 mM KH_2PO_4, pH 6.8.
13. Using a 12,000 to 14,000 MWCO dialysis membrane, dialyze against 2 liters of 3 mM KH_2PO_4, pH 6.8, at 4°C, until the pH is 6.8.

    This usually requires four buffer changes of 2 liters.

14. Centrifuge 15 min at 10,000 × *g*, 4°C, to remove any remaining precipitated protein.

Column purify the enzyme

15. Apply the supernatant to a 50-ml DE-52 column equilibrated with 3 mM KH_2PO_4, pH 6.8. Wash the column with 400 ml of the same buffer.

16. Elute the bound protein with 200 ml of 3 mM KH_2PO_4, pH 6.8, using a 0 to 0.5 M KCl gradient, and collecting 3.0 ml fractions. Monitor the eluate for protein, based on absorbance at 280 nm.

17. Assay PBGD activity in every other fraction across all protein peaks as follows:

    a. Mix 0.1 ml of fraction, 0.1 ml 0.01 M DTT, 0.225 ml 0.1 M Tris·Cl, pH 7.6, and 0.075 ml of 0.54 mg/ml PBG.
    b. Incubate 60 min at 37°C in the dark.
    c. Add of 0.5 ml 3 M HCl to stop the reaction, and oxidize under a Woods lamp for 30 min.
    d. Visually examine the assay from each fraction for fluorescence under the Woods lamp. Rank fluorescence on scale of 0 to 5.
    e. Pool all fractions with fluorescence values of ≥1.5.

    This should be ~60 ml.

18. Using a 12,000 to 14,000 MWCO dialysis membrane, dialyze pooled fractions against 10 mM KH_2PO_4, pH 7.6, then concentrate to 40 to 50 ml using an Amicon Centriprep concentrator or equivalent.

Determine necessary enzyme concentration

19. Set up assays as described in step 17, substep a, using 0.025, 0.050, 0.075, and 0.100 ml of the purified PBGD. Incubate 30 min at 37°C.

20. To each reaction add 0.10 ml 0.15 M KH_2PO_4, pH 4.45, and 0.40 ml 50 mM KH_2PO_4, pH 6.8. Incubate for an additional 30 min.

21. Add 1.0 ml of 3 M HCl to stop each reaction and analyze by HPLC (see Basic Protocol, steps 7 to 11).

22. Quantify the amount of uroporphyrinogen I made in each reaction. Determine the amount of PBGD needed to produce 30 to 40 µM uroporphyrinogen I in 30 min.

23. Adjust the concentration of the protein with 10 mM KH_2PO_4, pH 7.6, so that 150 µl will produce the required concentration of uroporphyrinogen I. Freeze 3- to 5-ml aliquots of PBGD at −70°C.

SUPPORT PROTOCOL 2

PREPARATION OF ERYTHROCYTE LYSATES FOR UROD ASSAYS

Erythrocyte UROD activity is generally reported with reference to the hemoglobin content of the blood sample. Since hemoglobin constitutes over 95% of protein in erythrocytes, simply determining the hemoglobin content of the lysate provides a reliable index of the total erythrocyte protein. Hemoglobin is converted to cyanomethemoglobin and the concentration is determined by measuring the absorption maximum at 540 nm. The concentration of cyanomethemoglobin is calculated by dividing the A_{540} by the extinction coefficient of 0.683 ml mg^{-1}. An alternative is to report UROD activity based on a defined volume of erythrocytes (McManus et al., 1988). If UROD is to be assayed in tissues other than red cells, a more direct measurement of protein may be required such as the method of Lowry et al. (1951), or a dye-binding assay (Bio-Rad).

Materials

Isoton II (Beckman Coulter)
Drabkin's reagent (see recipe)
5 mM and 0.1 M KH_2PO_4, pH 6.8
0.5 M KCl in 5 mM KH_2PO_4, pH 6.8

Heparinized Vacutainers
Tabletop centrifuge
DE-52 column, equilibrated with 5 mM KH_2PO_4, pH 6.8 (see recipe)

Lyse red blood cells

1. Draw 30-ml samples of blood in heparinized Vacutainers and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard the plasma and buffy coat. Wash the red cells with an equal volume of Isoton II and centrifuge at 1000 × *g* for 5 min. Repeat the wash.
3. Osmotically lyse the red cells in a beaker with 4 vol sterile distilled water chilled to 4°C. Stir gently with a flea magnet overnight at 4°C.

   Be careful not to stir too briskly.
4. Centrifuge the lysate 25 min at 18,000 × *g*, 4°C. Carefully remove the clear red supernatant.

   Do not take any of the loose pellet on top of the firm pellet. It is best to hold the tube up to a red light to ensure that only the clear portion is harvested.

   The supernatant may be stored at –70°C pending further processing.

Measure the amount of hemoglobin

5. Dilute 20 µl of red cell lysate to a total volume of 5.0 ml (1:250 dilution) with Drabkin's reagent, and allow to stand for 10 to 60 min.
6. Measure the optical density at 540 nm and calculate the amount of hemoglobin present using the extinction coefficient of 0.683 ml mg^{-1}.

Remove hemoglobin

7. Load the equivalent of 500 mg hemoglobin onto an equilibrated DE-52 column. Wash the column with ~50 ml of 5 mM KH_2PO_4, or until the eluate is colorless.
8. Add 4 ml of 0.5 M KCl, gently resuspend the resin and let stand 1 hr.
9. Collect the 4 ml of buffer, then elute again with 3 ml of 0.5 M KCl. Collect the buffer.
10. Assay UROD activity from 80 µl of the eluate diluted with 95 µl 0.1 M KH_2PO_4 (see Basic Protocol).
11. Store 500-µl aliquots at −70°C until ready to assay. Avoid repeated freeze-thaw cycles.

    Samples of erythrocyte lysate frozen at −70°C are stable for up to one year.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DE-52 columns, equilibrated in 3 or 5 mM KH_2PO_4

Make a slurry of DE-52 resin (Whatman) in water. Let sit 1 hr, remove fines by decantation, and equilibrate by one or two washings with 0.1 M KH_2PO_4, pH 6.8 (*APPENDIX 2A*). Make a slurry of equal volumes of settled resin and 5 mM KH_2PO_4, pH 6.8, and transfer ~6 ml into a disposable 15-ml syringe fitted with a frit at the bottom (disposable columns work equally well). Equilibrate the column with 5 volumes of 5 mM KH_2PO_4, pH 6.8 (the final packed volume of resin should be ~3 ml).

Many columns can be made at one time, sealed and stored at 4°C in 5 mM KH_2PO_4, pH 6.8, containing 0.02% NaN_3. Remove NaN_3 prior to use.

For purification of PBGD prepare the DE-52 as described above. Pack a column to contain a 50-ml bed volume. Equilibrate with 10 column volumes of 3 mM KH_2PO_4, pH 6.8.

Drabkin's reagent

To 1 liter of H_2O, add:
1.0 g $NaHCO_3$ (12 mM final)
0.05 g KCN (0.768 mM final)
0.20 g $K_3Fe(CN)_6$ (0.607 mM, final).
Store up to several months at 4°C.

Methanol/phosphate

Prepare 100 mM $NaH_2PO_4 \cdot H_2O$ (13.8 g/liter). Adjust pH to 3.5 with 2 M H_3PO_4. Mix 500 ml methanol with 500 ml of the phosphate buffer and adjust pH to 4.5 with 2 M H_3PO_4. Store up to 1 week at room temperature.

Final concentration: 50% (v/v) methanol/50 mM phosphate.

COMMENTARY

Background Information

UROD activity in erythrocytes provides the basis for the commonly used classification system for porphyria cutanea tarda (PCT). Individuals with half-normal activity have familial PCT (F-PCT, or type I), a disorder transmitted as an autosomal dominant trait. When UROD activity is normal, the designation of sporadic-PCT (S-PCT, or type II) is assigned. A rare third variant of PCT, type III PCT, occurs when the defect in porphyrin production is transmitted as an autosomal dominant trait but is restricted to the liver (Kappas et al., 1995). This suggests that there are other genetic factors that can affect the expression of UROD and precipitate the PCT phenotype. In rare cases there is homozygosity (or compound heterozygosity) for mutant UROD alleles and UROD activity is extremely low (~10% of normal). These individuals are classified as having hepatoerythropoetic porphyria (HEP).

Hepatic UROD activity in individuals with all types of PCT is markedly decreased, resulting in the accumulation of uroporphyrin and its partially decarboxylated intermediates. Another characteristic feature seen in patients with all forms of PCT is the excretion of isocoproporphyrin III in the feces. This phenomenon is thought to be due to a specific reduction in levels of UROD activity in the presence of normal levels of coproporphyrinogen oxidase activity. The pentacarboxyl porphyrinogen III isomer is normally present at extremely low levels; however, when in excess due to low UROD activity it competes with coproporphyrinogen III as a substrate for coproporphyrinogen oxidase. The incompletely modified isocoproporphyrinogen III cannot be used as a substrate for subsequent steps in the pathway and is oxidized to isocoproporphyrin and excreted in the feces (Elder, 1975).

To fully characterize and correctly classify individuals with PCT it may be necessary to determine the level of UROD protein present in both liver and blood samples by immunoblotting. In cases where half-normal levels of

UROD protein are present, analysis of UROD mRNA levels by northern blotting, ribonuclease protection assays, or quantitative RT-PCR can often be informative. Mutations in the UROD locus that lead to the PCT phenotype can be simple missense mutations that result in an inactive protein or can be mutations that produce a protein with reduced stability. Large genomic deletions and nonsense mutations have been reported, which result in half-normal UROD mRNA and hence half-normal protein.

Both chick liver cell culture and rodent models of PCT have been described, where UROD activity can be inhibited by exposure to iron, polyhalogenated aromatic hydrocarbons (PAH), and combinations of both (Sassa et al., 1986; Smith et al., 1986). These models of S-PCT were developed based on the report by Schmid (1960) who identified hexachlorobenzene as the precipitating agent in ~4000 cases of S-PCT in the late 1950s. Since then this observation has been used by many investigators to identify the relationship between these types of compounds and the inhibition of UROD activity seen in hepatocytes.

Development of a UROD specific inhibitor in mice requires induction of the P-4501A2 isozyme. Mice that are homozygous null mutants for P-4501A2 (*Cyp1a2* -/-) cannot be induced to a porphyric state using the PAHs and iron (Sinclair et al., 1998). A developing hypothesis is that PAHs somehow uncouple the cytochrome P-450 cycle, leading to excessive free radical formation in the presence of excess cellular iron (De Matteis and Marks, 1996). It is unclear if the free radicals then produce the UROD specific inhibitor or if it is only an accumulation of the uroporphyrin and partially decarboxylated porphyrins (not substrates for the enzyme) that act as competitive inhibitors of UROD.

Uroporphyrinogen decarboxylase (UROD) activity has been assayed using protein from many sources. Most studies of enzyme kinetics have been done with purified or partially purified mammalian UROD (de Verneuil et al., 1980, 1983; Elder et al., 1983; Straka and Kushner, 1983). The results indicate that activity is maximal when the ionic strength of the assay buffer is ~100 mM. The optimum pH for the reaction is near 6.8 for all of the substrates with the exception of pentacarboxyl I, which has an optimal pH of ~5.4. Divalent metals have been shown to inhibit UROD activity. This is of particular interest since many patients expressing the PCT phenotype have increased hepatic iron stores and the phenotype can be corrected by depleting hepatic iron stores with phlebotomy therapy. UROD activity can be assayed from any source using the above references as guidelines for additional assay requirements.

Critical Parameters

Analysis of the reaction products can be made much simpler if an isomer of pentacarboxyl porphyrinogen is chemically reduced and used as the substrate for the assay (i.e., if there is only one reaction product). A disadvantage, however, is that some UROD mutations have been shown to alter decarboxylation of uroporphyrinogen but do not alter decarboxylation of the pentacarboxyl substrate (Wyckoff et al., 1996). In such cases UROD activity may inappropriately appear normal. The advantage to the enzymatic generation of the uroporphyrinogen I substrate is the reproducibility of the ionic strength and pH of the system. This method can also be utilized to produce radiolabeled substrate starting with labeled porphobilinogen.

If a gradient maker for the HPLC is not available for the reversed-phase separation described here, an isocratic system can be utilized. The porphyrin products of the reaction are converted to their corresponding methyl esters, separated on a silica column (Waters μPorasil or equivalent), and visualized using a detector set to read absorbance at 405 nm by spectroscopy. The process of esterification and analysis is clearly described by Straka et al. (1982). When using the isocratic method for separation it is necessary to consider losses associated with the extraction and esterification of the porphyrins.

Preparation of sodium amalgam is dangerous and uses both toxic and potentially explosive materials; if the assays are to be done rarely, purchasing the sodium amalgam is recommended (Anachemia). An alternative to sodium amalgam for the reduction of porphyrins is the use of potassium borohydride (Mukerji et al., 1984).

The most problematic aspect of the UROD assay involves the inadvertent use of oxidized substrate. This can occur if chemical reduction of a porphyrin is incomplete or if fully reduced substrate is allowed to partially oxidize. Keeping the samples purged with nitrogen is critical. Porphyrinogens are also very susceptible to photooxidation and solutions and samples should be kept covered and examined only under red light. This is especially important, as oxidized porphyrins may inhibit UROD activ-

Table 8.4.3 URO-D Activity Present in a Variety of Normal and Porphyric Tissues

Species	Tissue	Activity (U)[a]	Reference
Human	Liver (normal)	1.61 (1.27-2.42)	Straka et al., 1982.
Human	Liver (porphyric)	0.73 (0.25-1.09)	Straka et al., 1982
Human	Red cell	0.35 (0.30-0.42)	Straka et al., 1982
Rat, female	Liver (normal)	0.99 ± 0.09	Franklin et al., 1997
Rat, female	Liver (porphyric)	0.23 ± 0.07	Franklin et al., 1997
Mouse	Liver (normal)	1.25 ± 0.13	unpub. observ.

[a]Units (U) are equivalent to nmol/hr/mg hemoglobin. Range in parentheses.

ity (Lambrecht et al., 1990). If a chemically reduced substrate is being used, the pH should be checked carefully since the reaction of sodium amalgam and aqueous buffer produces hydrogen and sodium hydroxide.

Freezing and thawing of UROD, as with many proteins, can affect stability. Purified UROD is relatively stable at 4°C and can be stored for ~1 month in a solution consisting of 10% glycerol, 50 mM Tris·Cl, pH 6.8, and 2 mM 2-mercaptoethanol. When freezing aliquots of UROD, 10% glycerol is added to the buffer to stabilize the protein. When a purified source of UROD is used, bovine serum albumin (0.1 mg/ml) is added to the enzyme sample to prevent losses due to adsorption to plastic and glass. A standard time of 30 min is used in all assays to minimize oxidization of the substrate.

Troubleshooting

The most common problem encountered with enzymatic generation of substrate is the unknown concentration of PBGD being used. An initial experiment, done to determine the exact amount of PBGD to add, usually corrects this problem. Once the amount of enzyme to be added has been determined, appropriately sized aliquots are prepared and stored for later use.

The most common problem in assays using chemically generated substrate is having an alkaline pH in the final enzymatic reaction. Performing the initial test to determine the exact amount of H_3PO_4 to be added in a mock sample will help ensure that the final pH is optimal. The activity of UROD drops steeply as the pH increases above 7.0 (Elder and Wyvill, 1982, Straka and Kushner, 1983).

Anticipated Results

UROD activity is generally expressed in units (U) with 1 U equal to one nmol substrate decarboxylated per hr per mg of protein. The specific activity for both native and recombinant purified human UROD is in the range of $4–10 \times 10^3$ U, using either uroporphyrinogen I or III as substrate (de Verneuil et al., 1983; Wyckoff et al., 1996). These results have been reported for assays in which the substrate concentration is saturating (~30 μM substrate and 1 μg or less UROD protein). When assaying tissue homogenates, cell lysates, or column fractions, the amount of UROD should be in this range (Elder and Wyvill, 1982). Some typical results are given in Table 8.4.3.

Time Considerations

The time required to enzymatically produce uroporphyrinogen I and assay UROD activity in 20 samples is ~3 hr. Set up of the HPLC, preparation of buffers, and calibration of the HPLC can be done in 2 hr. Separation of the reaction products takes ~30 min per sample; therefore 20 samples requires 12 hr of HPLC time. A more rapid method for separation of porphyrins by HPLC has been described by Adjarov and Elder (1988). Data analysis for 20 samples is ~1.5 hr. The chemical reduction of a porphyrin substrate can be done in 15 to 20 min, but initial solubilization and estimation of the porphyrin concentration will take 1 to 2 hr. Time for cleanup and disposal of the sodium amalgam waste should also be considered.

Measurement of Protoporphyrinogen Oxidase Activity

Protoporphyrinogen oxidase catalyzes the penultimate step in the heme biosynthetic pathway, the oxidation of protoporphyrinogen to protoporphyrin. This membrane-bound mitochondrial enzyme is of special interest, since it is the target of photobleaching herbicides and its deficiency in humans leads to one type of porphyria. The assay of protoporphyrinogen oxidase activity involves following the increase in fluorescence as the colorless, nonfluorescent protoporphyrinogen is converted to colored, fluorescent protoporphyrin by oxidation. Protoporphyrinogen, the substrate of the enzyme, is prepared from protoporphyrin by reduction with sodium amalgam.

There are two methods for following the increase in protoporphyrin fluorescence during enzymatic oxidation of protoporphyrinogen. In the indirect assay (see Basic Protocol), aliquots are removed at intervals from the reaction mixture, diluted into a measuring mixture, and the protoporphyrin fluorescence determined. In the direct assay (see Alternate Protocol 1), protoporphyrin fluorescence is monitored directly in a fluorometric cuvette containing the enzyme reaction mixture. Accumulation of protoporphyrinogen in cells actively synthesizing heme or chlorophyll is measured using Alternate Protocol 2. Protocols are included for preparing sodium amalgam (see Support Protocol 1) and *Escherichia coli* membranes (see Support Protocol 2) for detection of accumulated protoporphyrinogen.

CAUTION: All procedures involving mercury must be performed in a chemical safety hood. Proper protective equipment (chemical-resistant gloves, mercury respirator, and face shield) should be used, and the protocol should be approved by the institutional safety office.

INDIRECT ASSAY TO MEASURE PROTOPORPHYRINOGEN OXIDASE ACTIVITY

BASIC PROTOCOL

Preparation of the substrate, the most difficult step in this assay, begins with reduction of the deep red protoporphyrin solution, in a tightly closed container under nitrogen gas in the dark, by rapid addition of pulverized sodium amalgam. The colorless reduced solution is then removed from the amalgam and partially neutralized, taking care to minimize exposure to light and oxygen. Addition of an antioxidant helps prevent chemical reoxidation. The extent of reduction is monitored with a long-wave UV lamp; the best preparations will have no fluorescence. Even if the reduction is less than complete, however, as indicated by a faint red fluorescence (due to the presence of residual protoporphyrin), the substrate (protoporphyrinogen) solution may still be usable, as long as it remains colorless in visible light. A highly humid atmosphere will increase the difficulty of obtaining good reduction with sodium amalgam and should be avoided. Once the substrate is prepared it should be added to the assay without delay.

Materials

0.5 M Tris·Cl, pH 7.5 and pH 8.7 (*APPENDIX 2A*)
0.05 M Tris·Cl, pH 8.7 (*APPENDIX 2A*)
0.01 M EDTA in 0.05 M Tris·Cl, pH 8.7
0.05 M dithiothreitol (DTT) or glutathione in 0.5 M Tris·Cl, pH 7.5
Enzyme sample to be assayed, e.g., rat liver mitochondria, fibroblasts, or etiolated chloroplasts
Protein assay kit (Bio-Rad) or equivalent

Contributed by Judith M. Jacobs and Nicholas J. Jacobs
Current Protocols in Toxicology (1999) 8.5.1-8.5.13

Heat-inactivated control: enzyme sample that has been heated 15 min at 75°C
10% (v/v) Tween 20 or Tween 80 (optional)
~500 μM protoporphyrin stock solution (see recipe)
Ultra-high-purity nitrogen gas
0.01 N KOH
40% phosphoric acid, degassed with nitrogen
3.8% sodium amalgam (see Support Protocol 1)
2.7 N HCl

3-ml disposable, plastic, square spectrofluorometric cuvettes (12 × 45 mm; Fisher)
Fluorometer
Blak-Ray UV lamp (UVP 4-Watt, Fisher)
Filter funnel with fritted disc, fine porosity of 4 to 5.5 μm (Fisher)
Applicator sticks
pH paper (Hydrion pH test papers, range 6.0 to 8.0 and 8.0 to 9.5, Fisher)
Quartz spectrophotometer cuvettes

Prepare assay and measurement tubes

1. Prepare assay mixture by adding the following to small glass tubes:

   0.2 ml 0.5 M Tris·Cl, pH 7.5 to 8.7
   0.1 ml 0.01 M EDTA in 0.05 M Tris·Cl, pH 8.7 (1 mM EDTA final)
   0.1 ml 0.05 M glutathione or DTT in 0.5 M Tris·Cl, pH 7.5 (5 mM final)
   Enzyme sample containing 0.1 to 2 mg protein
   Milli-Q-H_2O to 0.74 ml.

   As well as sample tubes, prepare tubes without any enzyme and with heat-inactivated control sample (as controls for the rate of nonenzymatic protoporphyrinogen oxidation).

   Assay total protein by the Bio-Rad assay.

   The authors usually trisonicate mitochondria briefly using any low-power small sonic probe, although this is not required.

   A variety of pH values have been utilized satisfactorily over the 7.5 to 8.7 range, although protoporphyrinogen autooxidation is lower at higher pH values. Mammalian mitochondria are often assayed at pH 8.7. Plant organelles have been assayed at the lower values. The authors routinely assay rat liver mitochondria at pH 7.5 for effects of herbicide inhibitors. The final concentrations of protoporphyrinogen will be ~50 μM. Between 2 and 5 mM (final) DTT has been used in many current assays as an antioxidant in place of glutathione, since it minimizes the chemical autooxidation of protoporphyrinogen to protoporphyrin. Many enzymatic assays also employ a detergent (e.g., Tween 20 or Tween 80) at 0.03%, 0.1%, or 0.2% concentration. Detergent is not required for assay of sonicated mitochondria, and high detergent concentrations may be inhibitory to the enzyme; however, detergent is required for assay of the purified enzyme.

2. Determine the amount of measuring mixture required by multiplying the number of assay tubes by the number of time points by 1.45 ml; include an appropriate number of tubes for fluorescence standards (step 4). Prepare the appropriate quantity of measuring mixture according to the following recipe (per 100 ml):

   20 ml 0.5 M Tris·Cl, pH 8.7
   10 ml 0.01 M EDTA/0.05 M Tris·Cl, pH 8.7 (1 mM EDTA final)
   10 ml 0.05 M glutathione in 0.5 M Tris·Cl, pH 8.7 (5 mM glutathione final)
   1 ml 10% Tween 20 or Tween 80 (0.1% final)
   59 ml Milli-Q-purified H_2O.

   Dispense 1.45 ml per cuvette into 3-ml disposable spectrofluorometric cuvettes.

   The higher pH is used here to minimize chemical oxidation of protoporphyrinogen.

Prepare substrate stock and standards

3. Dilute 2 ml of ~500 μM protoporphyrin stock with 3 ml of 0.01 N KOH to obtain a working solution of ~200 μM.

4. In separate tubes, prepare protoporphyrin fluorescence standards by adding known amounts of protoporphyrin working solution to tubes of assay mixture (from step 1).

5. Set the excitation wavelength on the fluorometer to 405 nm and the emission wavelength to 633 nm. Add 50 μl of assay mixture without protoporphyrin to 1.45 ml measuring mixture and zero the fluorometer. Adjust the sensitivity of the fluorometer to read 100 fluorescent units (FU) using a 50-μl aliquot from an assay tube containing ~20 μM protoporphyrin.

   The standard should be measured in the presence of unheated as well as heated enzyme, since turbidity of the heated enzyme sample may affect fluorescence.

   The concentration of the standard will determine the sensitivity of the assay. For instance, for a very active enzyme preparation, 20 μM protoporphyrin can be used as the highest concentration. For less active material, a lower concentration is more appropriate. To assay protoporphyrinogen oxidase in fibroblasts, Brenner and Bloomer (1980) used a reference standard of 5 μM protoporphyrin that was adjusted to 25 FU. It is useful to set up a standard curve with a variety of protoporphyrin levels added to the assay mixture to test the linearity and sensitivity of the method.

Prepare protoporphyrinogen by reduction of protoporphyrin

6. Place 5 ml protoporphyrin working solution into a 25-ml rubber-stoppered Erlenmeyer flask. Deaerate the solution by flushing with nitrogen gas.

7. Grind 8 g sodium amalgam into a fine powder in the fume hood, using a mortar and pestle.

   With some amalgam preparations, larger amounts may need to be used. However, the solution becomes more difficult to neutralize if too much amalgam is used.

   IMPORTANT NOTE: *Steps 8 to 13 should be carried out under reduced light—i.e., using the minimal amount of light needed to conduct each step.*

8. Immediately add the amalgam to the protoporphyrin solution, replace the stopper, and shake vigorously using a gloved hand to secure the stopper. Gas is evolved, so point tube toward back of fume hood. Continue shaking for 2 to 5 min, venting as needed, until no fluorescence is observed when a long-wave UV lamp is shone on the solution. Add 0.25 ml of 0.05 M DTT or glutathione to the solution and remove the amalgam by filtration.

   The authors have most experience with a fritted-glass filter of fine porosity, but a syringe with a porous disc of 35-μm porosity also works. Dailey and Dailey (1997) recommend a syringe packed half full with glass wool.

9. Adjust the pH of the solution to 8.5 to 9 by dropwise addition of 40% phosphoric acid that has been degassed by bubbling with nitrogen.

   The pH should not go below 8, since autooxidation is enhanced by low pH. To determine the pH, put a drop of the solution on a strip of narrow-range pH paper using a wood applicator stick.

   Dailey and Dailey (1997) recommend neutralization with 2 M MOPS [3-(N-morpholino)propane sulfonic acid] for better pH control. The protoporphyrinogen solution should be used immediately whenever possible. Storage in the dark under nitrogen gas at room temperature for 1 hr may be possible with most preparations.

Begin assay and take spectrophotometric measurements

10. To start the reaction, add 260 µl of the protoporphyrinogen solution to each assay tube from step 1. Incubate at the appropriate temperature in a covered water bath.

    The final concentration of protoporphyrinogen added to the assay will be ~40 µM. Mammalian mitochondria are often assayed at 37°C, and plant organelles at 30°C or room temperature. If it is important to determine the actual concentration of the protoporphyrinogen solution, allow the solution to autooxidize overnight, dilute into 2.7 N HCl, determine the absorbance at 408 nm, and calculate the concentration, using the millimolar extinction coefficient (ε_{mM}) value of 297 cm^{-1} mM^{-1}. The recovery may be poor with autooxidation. For this reason, the stoichiometric recovery of protoporphyrinogen is rarely attempted. For best recovery of protoporphyrin from protoporphyrinogen, enzymatic oxidation of protoporphyrinogen with E. coli membranes should be used (see Support Protocol 2).

11. Agitate gently to mix and aerate, then remove a 50-µl aliquot of the assay mixture to 1.45 ml of measuring mixture in a disposable spectrofluorometric cuvette (prepared in step 2). Minimize exposure to light by using the least amount of light compatible with accurate pipetting. Thoroughly mix the contents of the cuvette and immediately read the fluorescence.

    Take the first aliquot as close as possible to the time of protoporphyrinogen addition.

12. Remove further 50-µl aliquots at 5- to 10-min intervals for 30 to 60 min, and measure the fluorescence as in step 11.

Calculate protoporphyrinogen oxidase activity of samples

13. Calculate the rate of protoporphyrin formation at each time interval by comparison with the reference standards, correcting for the rate of nonenzymatic protoporphyrinogen oxidation (based on the samples without enzyme and the heat-inactivated control).

    The following is a sample calculation showing how the data are used to calculate the enzyme activity in tissue preparations. If the fluorometer is adjusted to read 100 FU with measuring mixture to which 50 µl of standard (assay mixture containing 20 µM protoporphyrin) has been added (see step 4), then each FU increase in fluorescence during the assay is equivalent to 0.2 µM protoporphyrin formed from protoporphyrinogen. In a typical experiment with 1 mg/ml rat liver mitochondria, the authors observed a linear increase of 50 FU over 60 min. This is 10 µM protoporphyrin formed/hr/mg protein (50 FU × 0.2 µM = 10 µM). The heated control increased 10 FU or 2 µM in 60 min. Therefore, the rat liver mitochondria oxidized protoporphyrinogen at a rate of 8 µM/hr/mg protein. When it is necessary to verify that the product is protoporphyrin, scan the emission fluorescence from 600 nm to 650 nm (excitation 405 nm) and compare to the emission spectrum of the standard as shown in Figure 8.5.1.

14. After the assay is completed, verify that the pH of the assay mixture has not been altered by addition of an improperly acidified protoporphyrinogen solution by placing a drop of the reaction mixture on narrow-range pH paper. Dispose of all remaining pulverized sodium amalgam by adding a small amount of water. After several hours, dispose of mercury droplets formed as toxic mercury waste.

    If the pH is too high, redo the assay using a newly prepared, properly acidified protoporphyrinogen solution.

ALTERNATE PROTOCOL 1

DIRECT ASSAY TO MEASURE PROTOPORPHYRINOGEN OXIDASE ACTIVITY

In this assay, the rate of protoporphyrin formation is measured directly in a spectrofluorometric cuvette from the linear rate of increase in fluorescence as protoporphyrinogen is oxidized to protoporphyrin. A lower concentration of protoporphyrinogen is added as substrate and the pH of the protoporphyrinogen solution is decreased by use of a strongly buffered, concentrated solution of DTT. These variations eliminate the need for the technically difficult neutralization step.

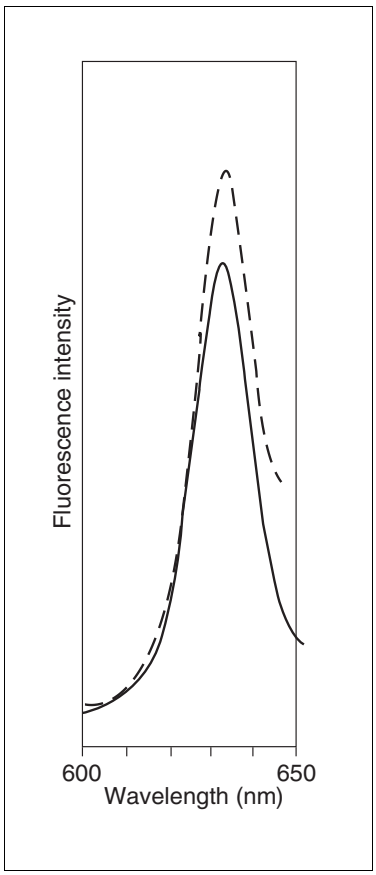

Figure 8.5.1 Fluorescence emission spectra of protoporphyrin and enzymatically oxidized protoporphyrinogen. The enzymatic reaction mixture was as described in Basic Protocol step 1 and contained (where indicated) 870 μg greening plastid protein/ml, protoporphyrin (13.5 μM), or protoporphyrinogen that had been enzymatically oxidized by the plastid enzyme. A 50-μl aliquot was added to 1.45 ml of measuring mixture as described in Basic Protocol steps 2 to 11. The fluorescence emission spectra were determined using an excitation wavelength of 410 nm with excitation and emission slits of 10 nm. The dashed line indicates the assay preparation with plasmids and oxidized protoporphyrinogen. The solid line indicates the protoporphyrin standard in the assay mix without added protoporphyrinogen or chloroplast enzyme preparation.

If enzyme sources cause turbidity, this can diminish protoporphyrin fluorescence. However, the authors have not found this to prevent measuring the relative increase in fluorescence even in the presence of relatively turbid suspensions of rat liver mitochondria or membranes from etiolated chloroplasts. The standard curve containing the enzyme should be linear. For enzyme preparations containing high background fluorescence or excessive amounts of turbidity, the indirect assay may be superior. See Critical Parameters and Troubleshooting for a discussion of interference by turbidity.

Materials

0.5 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.1 M EDTA in 0.05 M Tris·Cl, pH 8.7
10% (v/v) Tween 20
0.05 M and 0.1 M DTT in 0.5 M Tris·Cl, pH 7.5
Sonicated mitochondria or other enzyme sample to be assayed (see Basic Protocol)
Heat-inactivated control: enzyme sample that has been heated 15 min at 75°C
~500 μM protoporphyrin stock solution (see recipe)
Sodium amalgam (see Support Protocol 1)

3-ml, disposable spectrofluorometric cuvettes or 1.5-ml disposable semi-micro spectrophotometric cuvettes (Fisher 14-385-938; see Background Information)
Fluorometer
1-ml screw-cap microcentrifuge tubes, with securely fitted O rings
Mortar and pestle
Vortex mixer
Blak-Ray UV lamp (UVP 4-Watt, Fisher)
Applicator sticks
pH paper (Hydrion pH test papers with narrow range, Fisher)

Prepare assay and measurement tubes

1. Place spectrofluorometric cuvettes in an appropriate holder.

   Semi-micro spectrophotometric cuvettes that are clear on four sides can be used to assay volumes as small as 0.250 ml.

2. To each cuvette add the following reaction mix:

   0.1 ml 0.5 M Tris·Cl, pH 7.5
   0.1 ml 0.01 M EDTA in 0.05 M Tris·Cl, pH 8.7 (1 mM EDTA final)
   0.01 ml 10% Tween 20 (0.1% final)
   0.06 ml 0.05 M DTT in 0.5 M Tris·Cl, pH 7.5 (3 mM DTT final)
   Enzyme sample containing 0.1 to 0.4 mg protein
   Milli-Q-purified H_2O to 1 ml.

   After addition of the 0.04 ml protoporphyrinogen solution (step 7), which contains 50 mM DTT, the final DTT concentration will be 5 mM. Include controls without enzyme and with heated enzyme (see Basic Protocol, step 1).

Set up fluorometer and prepare standard curve

3. Set the fluorometer with the excitation wavelength at 405 nm, the emission wavelength at 633 nm, and the excitation slit at the narrowest setting to minimize exposure of the assay to light. Zero the instrument using a cuvette containing reaction mixture without protoporphyrin.

4. Add a dilution of ~500 μM protoporphyrin stock solution to an aliquot of reaction mixture so that the final porphyrin concentration is 0.25 μM (standard). Adjust the fluorometer so that the standard gives the maximum reading, usually 100 fluorescence units (FU).

5. Dilute the standard in reaction mixture to give final concentrations of 0.125 and 0.0625 μM, and check that these give readings 0.5 and 0.25 of the reading for the standard.

Reduce protoporphyrin to protoporphyrinogen

6. Place a small volume (0.8 ml) of ~500 μM protoporphyrin stock solution in a screw-capped 1-ml microcentrifuge tube.

7. Add 1 to 2 g very finely ground sodium amalgam rapidly with a spatula and immediately replace the cap on the tube. Vortex the tube vigorously until there is no fluorescence when viewed with a long-wave UV lamp, unscrewing the cap every 30 sec to release pressure.

   The reduction should not take longer than 3 to 5 min. Two grams of very finely ground amalgam per milliliter is usually optimal, but less can be used with the best amalgam preparations.

   Always keep the tube pointed away, since the top can be blown off by the gas generated. This procedure should be done in low light. The amalgam will settle to the bottom half of the tube after standing for several minutes. Using a dim light, check to see if settling is complete. If settling is insufficient, the authors discard and use less amalgam on the next attempt. This is rarely necessary. See step 8 for possible clarification methods.

Take spectrophotometric measurements

8. Draw off the reduced porphyrinogen with a pipet and dilute into an equal volume of 0.1 M DTT/0.5 M Tris·Cl, pH 7.5.

   The protoporphyrinogen solution can be clarified (see Basic Protocol, step 8) but the authors have not found this necessary due to the small volumes used in subsequent steps. The protoporphyrinogen should be protected from light and air. The solution should be used immediately (see Critical Parameters and Troubleshooting for storage suggestions).

9. Place cuvettes in the fluorometer and start the chart recorder or timer.
10. Add 0.04 ml protoporphyrinogen/ml reaction mixture to each cuvette to give a final concentration of 10 μM, with thorough agitation to mix and aerate.

    Since the substrate added at this concentration contains DTT to a final concentration of 2 mM, this should be taken into account when calculating the amount to add to the assay mixture to yield a final concentration of 5 mM DTT (see step 2).

11. Record the fluorescence at 633 nm of each cuvette in turn for 10 min or more at intervals of 30 sec using the chart recorder or a timer. Longer time intervals can be used with enzyme sources of low activity.

    Most fluorometers have a carrier for eight cuvettes. It is convenient to run seven samples and one heat-inactivated control to determine the nonenzymatic rate. The shutter should be opened just long enough to get a reading to minimize exposure of the sample to light.

12. Verify that the pH of the assay mixture is between 7.6 and 8.6. A pH above 8.8 is too far from the optimum pH of the enzyme.

    This can be done using a drop of the reaction mixture on narrow range pH paper .

Calculate protoporphyrinogen oxidase activity

13. Determine the increase in fluorescence units per minute for each sample and for the heat-treated control. Subtract FUs of the heated control from the FUs of the samples. The concentration of protoporphyrin in each sample can be calculated from the following (S = standard):

    sample concentration = (concentration of S/FU of S) × FU of sample

DETECTION OF ACCUMULATED PROTOPORPHYRINOGEN

ALTERNATE PROTOCOL 2

In the presence of diphenylether herbicides, protoporphyrinogen, as well as protoporphyrin, accumulates in cells that are actively synthesizing heme or chlorophyll. To detect the accumulation of protoporphyrinogen in samples treated with diphenylethers or other protoporphyrinogen oxidase inhibitors, advantage is taken of the facts that the *E. coli* enzyme for oxidation of protoporphyrinogen is not inhibited by diphenylethers and that protoporphyrinogen, but not protoporphyrin, is unstable and is degraded to undetectable non-porphyrin products in perchloric acid (PCA)/methanol.

This method should be applicable to detecting protoporphyrinogen accumulation in any tissue (crude lysates or homogenates) or enzyme assay where protoporphyrinogen is formed. The authors have used it to detect the accumulation of protoporphyrinogen in cultured hepatocytes and in suspensions of plant chloroplasts incubated with an excess of the porphyrin precursor 5-amino levulinic acid and the protoporphyrinogen oxidase inhibitor acifluorfen methyl.

Materials

Sample (reaction mixture or cell suspension) containing protoporphyrinogen (see Basic Protocol; Alternate Protocol 1)
E. coli membranes (see Support Protocol 2)
10% (v/v) PCA/methanol
~500 μM protoporphyrin stock solution (see recipe)
0.5 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)

3-ml, disposable spectrofluorometric cuvettes
Fluorometer

1. Transfer a 0.5-ml aliquot of the sample to be analyzed for protoporphyrinogen to a 1.5-ml microcentrifuge tube. Add 0.5 ml of 10% (v/v) PCA/methanol and hold on ice.
2. Transfer a second 0.5-ml aliquot of sample to another microcentrifuge tube and add 0.25 mg *E. coli* membranes (final concentration 0.5 mg/ml). Incubate 30 min in the dark at 37°C in an incubator or water bath.

   About 0.01 to 0.02 ml of the ~15 mg/ml E. coli membranes will be required.
3. Meanwhile, to the first tube (on ice), add a volume of 0.5 M Tris·Cl, pH 7.5, equal to the volume of *E. coli* membranes that was added to the second tube (to keep the volumes in the two tubes equal).
4. Prepare standards containing a range of known concentrations of protoporphyrin diluted in 10% (v/v) PCA/methanol.
5. After the 30-min incubation is over, add 0.54 ml of 10% (v/v) PCA/methanol to the second sample tube.
6. Centrifuge both samples 5 min at ~9000 × *g* (e.g., 2000 to 3000 rpm in a tabletop centrifuge), room temperature, to remove the precipitated protein.

   For whole cells centrifuging 5 min at 1000 × g will be sufficient.
7. Dispense 200 µl of each the supernatant and 800 µl of 10% (v/v) PCA/methanol into spectrofluorometric cuvettes. Determine fluorescence at excitation 405 nm and emission 605 nm.
8. Calculate the concentration of protoporphyrin in each sample by comparison with the reference standards.

   If protoporphyrinogen was present in the sample, the E. coli–treated aliquot will contain a higher concentration of protoporphyrin than the untreated aliquot. The difference in the concentration of protoporphyrin between the first aliquot and the second (E. coli–treated) aliquot is the concentration of protoporphyrinogen in the sample.

SUPPORT PROTOCOL 1

PREPARING SODIUM AMALGAM

The method of preparing sodium amalgam described in Fieser and Fieser (1967) is the classical procedure using complex enclosed glassware that is usually only available in organic chemistry laboratories, but should nonetheless be used whenever possible. The method of Nicolaus et al. (1993) is more similar to the authors' method and can also be recommended. The procedure presented here is slightly modified from Brenner and Bloomer (1980) and Jacobs and Jacobs (1982), but is not recommended for inexperienced investigators. It should be done in a chemical safety hood at high setting and proper protective gear (chemical protective gloves, face shield, and mercury respirator) must be worn, as hot mercury vapors are generated. The safety committee of the investigator's institution should approve the procedure.

Materials

Mercury metal
Nitrogen gas
Sodium metal
Light mineral oil
Phosphorus pentoxide

Chemical safety hood
Face shield

Chemical protective gloves (Fisher)
Mercury respirator (Fisher)
50-ml side-arm flask
Single-hole rubber stopper with glass tube vent

1. Weigh 75 g mercury into a 50-ml side-arm flask. Secure the flask to a ring stand; place on a hot plate and pass nitrogen gas gently though the side arm, allowing it to vent through the glass tube on the stopper. Warm the mercury at low heat, using the lowest setting on the hot plate.
2. Using a heavy knife, cut a piece from a lump of sodium metal stored under light mineral oil.

   The cut surfaces of the metal should be bright silver. Trim off and discard any oxidized (white-colored) sodium.

3. Trim the piece to weigh ~2.8 g, and cut it into smaller pieces (5 mm^3).

   The authors keep the sodium immersed in light mineral oil whenever possible. This can be done using a tared beaker containing the mineral oil. The weighed sodium lump is briefly removed to a glass plate for cutting and the cut pieces are returned to the oil immediately. Quantitative addition of sodium is not as important as protection of the cut surface from a moist atmosphere.

4. One at a time, blot each piece using a paper towel, then quickly remove the stopper from the flask of mercury and drop the sodium into it. Immediately replace the stopper and continue the flow of nitrogen.

   The sodium will melt into the mercury. The reaction is vigorous and releases mercury vapor.

5. Add the rest of the sodium rapidly, piece by piece.

   As the last pieces of sodium are added, the amalgam will begin to solidify, and it may be necessary to stir it using a heavy glass rod or spatula. The flow of nitrogen gas may be briefly interrupted during these procedures.

6. After all the sodium is added, remove the amalgam from the hot plate. Stir the amalgam during cooling to break it up into smaller chunks.
7. Remove the amalgam from the flask into a 50-ml beaker. Store in an evacuated desiccator over a large dish of phosphorus pentoxide.

   In the authors' experience, the amalgam will retain its ability to reduce porphyrins for several months when stored under vacuum over phosphorus pentoxide.

PREPARATION OF *E. COLI* MEMBRANES

SUPPORT PROTOCOL 2

E. coli membranes are used to detect accumulated protoporphyrinogen in Alternate Protocol 2. The membranes are prepared by sonication and centrifugation at 144,000 × *g*.

Materials

E. coli (ATCC #25922)
Bacterial Nutrient Broth (Difco)
0.5 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Protein assay kit (Bio-Rad) or equivalent

Centrifuge
Sonicator (e.g., Branson W185D or equivalent)
Ultracentrifuge

1. Grow *E. coli* in nutrient broth for 10 hr at 37°C with vigorous aeration.

2. Harvest cells. Centrifuge 20 min at 6000 × *g*, 4°C. Sonicate pellet using twenty 30-sec treatments and cooling cells on ice between treatments.
3. Remove unbroken cells by centrifugation for 20 min at 14,000 × *g*, 4°C.
4. Sediment the membranes 2 hr at 144,000 × *g*, 4°C. Wash once in 0.05 M Tris·Cl, pH 7.5, and resuspend in the same buffer to give a final protein concentration of ~15 mg/ml, as determined by the Bio-Rad assay.

Membranes can be stored in small aliquots at −70°C until needed.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Protoporphyrin stock solution, ~500 μM

Weigh ~2 mg of protoporphyrin into a 25-ml Erlenmeyer flask and add 7.5 ml of 0.01 N KOH in 20% ethanol. Stir 20 min away from direct light. Determine the exact concentration by adding 0.03 ml of the stock solution to 3 ml of 2.7 N HCl and measuring the absorbance at 408 nm, using the millimolar extinction coefficient (ε_{mM}) value of 297 cm^{-1} mM^{-1}.

Porphyrins are dissolved in base to facilitate reduction, but are more accurately quantitated in acidic solution. It is best to use freshly prepared protoporphyrin solutions to minimize aggregation of the protoporphyrin. The authors do not attempt to accurately weigh the protoporphyrin, but use the extinction coefficient to determine the exact concentration when this is needed. In practice, the authors' stock solutions have varied from 350 to 500 μM without any effect on enzyme activity.

COMMENTARY

Background Information

A variety of techniques have been used to measure the conversion of protoporphyrinogen to protoporphyrin. A spectrophotometric assay measuring the absorbance of protoporphyrin in both the visible and Soret (near 408 nm) regions was the first method used to show oxidation of the colorless porphyrinogen to the colored porphyrin (Poulson, 1976; Jacobs and Jacobs, 1979; Klemm and Barton, 1987). However, the distinct red fluorescence of protoporphyrin is more intense than its absorption, and is now utilized in a much more sensitive assay (Brenner and Bloomer, 1980; Jacobs and Jacobs, 1982; Labbe et al., 1985; Dailey and Karr, 1987; Camadro et al., 1993; Dailey and Dailey, 1997).

Almost any fluorometer and flurometric cuvette will be suitable for the assay; the authors have used a Perkin Elmer fluorometric spectrophotometer 650 10S equipped with a red-sensitive phototube. While the red-sensitive phototube increases sensitivity in the region of porphyrin fluorescence, it is not required. The volume of the assay will depend on the location of the light path of the spectroflurometer. It is only necessary to have 1 ml of liquid in a 3-ml cuvette to cover the light path of the Perkin Elmer 650. For assaying very small amounts of sample, the authors use disposable semi-micro spectrophotometric cuvettes that are clear on four sides. With the Perkin Elmer 650, it is possible to use as little as a 0.250-ml volume with these cuvettes by scaling down all reagents accordingly.

Critical Parameters and Troubleshooting

The most critical parameter in assays of protoporphyrinogen oxidase is the quality of the substrate, protoporphyrinogen. The authors have found that if complete reduction of protoporphyrin does not take place within 5 min, there is a problem with the sodium amalgam. Addition of more amalgam usually does not help, because the solution will become so basic that it is impossible to neutralize. On a humid day, the amalgam may take up moisture during grinding and become ineffective. Fresh amalgam is best, but stored amalgam that has remained completely dry is also suitable. Amalgam can be kept for several months in a desiccator, under vacuum, with phosphorus pentoxide used as desiccant.

Another major problem is the autooxidation of protoporphyrinogen. A variety of reducing agents have been added to the assay mixture and to the protoporphyrinogen solution in attempts to minimize chemical autooxidation. In the authors' experience, DTT is very effective at suppressing nonenzymatic protoporphyrinogen oxidation. The authors have most frequently used DTT at final concentrations of between 2 and 5 mM in the enzyme assay and also add DTT to protoporphyrinogen solutions to stabilize them before addition to the assay. Other reducing agents, such as glutathione and ascorbic acid, have been used by other researchers (Jacobs and Jacobs, 1982; Camadro et al., 1985; Camadro et al., 1993; Dailey and Dailey 1997). Protoporphyrinogen oxidase from some sources (especially plant sources) may be somewhat inhibited by DTT, and the presence of DTT also makes it more difficult to obtain quantitative recovery of protoporphyrin after chemical oxidation of protoporphyrinogen solutions by strong acids and/or light (Jacobs and Jacobs, 1982). However, the authors have found that use of an *E. coli* membrane preparation gives a good yield of protoporphyrin from protoporphyrinogen even in the presence of DTT (Jacobs and Jacobs, 1993).

Autooxidation may be more rapid with incompletely reduced protoporphyrinogen preparations, since these will contain a significant amount of unreduced protoporphyrin. Catalytic amounts of porphyrins have been reported to stimulate protoporphyrinogen autooxidation (Mauzerall and Granick, 1958). If no reductant is used, the rate of autooxidation will be substantial. A protoporphyrinogen oxidizing activity that is not inhibited by photobleaching herbicides (e.g., acifluorfen methyl), but that differs from autooxidation, has been described and may cause confusion if plant material is used (Jacobs et al., 1991; Lee et al., 1993; Yamato et al., 1994). This activity may be associated with plant peroxidases and is suppressed by DTT or ascorbate.

The preparation of protoporphyrinogen requires the reduction of protoporphyrin with 3% sodium amalgam. The authors have had little success in using other reductants, such as sodium borohydride. The method described here for making sodium amalgam must be carried out with extreme caution. The authors have not tried other methods, but preparation of small amounts of amalgam right before use by adding chips of sodium to a small amount of mercury in a beaker may be satisfactory. Other methods may be superior, if they result in less mercury vapor (Fieser and Fieser, 1967; Nicolaus et al., 1993). All procedures involving mercury, including use of the amalgam, must be done in a chemical safety hood and proper protective gear (chemical resistant gloves, mercury respirator, and face shield) should be used. The procedure should be approved by the institution's safety committee.

Determining the rate of nonenzymatic protoporphyrinogen oxidation can be another source of difficulty. Enzyme that has been heat-inactivated (15 min at 75°C) can be used, but when using crude sources of enzyme the heated preparations can become quite turbid. To partially decrease turbidity, disperse the heated enzyme with brief sonication, using a small sonic probe and a microcentrifuge tube. To correct for the quenching of protoporphyrin fluorescence by turbidity, standard curves should be set up without enzyme and in the presence of both unheated and heat-treated enzyme. The indirect assay (Basic Protocol) is less subject to interference from turbidity, since assay reactants are diluted in the measuring mixture. Turbidity can be minimized by solubilizing liver mitochondria with 1% sodium cholate (Birchfield and Casida, 1996).

Since the substrate, protoporphyrinogen, is difficult to prepare, it would be desirable to store it for several days or weeks. The authors have been able to store the substrate prepared as described in the direct assay above (see Alternate Protocol 1, step 8) by transferring it, after dilution into the DTT solution, to a 1-ml disposable tube appropriate for subsequent storage under liquid nitrogen. This gave satisfactory results in the assay after storage for several months. Other investigators have reported storage of protoporphyrinogen for many weeks frozen, under paraffin oil, discarding it only when the solution became colored (Birchfield and Casida, 1996; Camadro et al., 1993). Although the authors have no experience with this procedure, it should work for most purposes, since solutions which appear fluorescent, but remain colorless, will still contain mainly protoporphyrinogen. All frozen preparations should be thawed only once, and exposure to light and air must be minimized.

A new assay has been developed for dose-response studies of protoporphyrinogen oxidase inhibitors that eliminates the need for protoporphyrinogen as substrate (Birchfield and Casida, 1996). In this assay a radiolabeled probe, constructed from a protoporphyrinogen

oxidase–inhibiting herbicide, binds reversibly to the herbicide-binding site of the enzyme. The ability of other herbicides to interfere with binding of the labeled probe is a measure of their ability to inhibit the enzyme (Birchfield and Casida, 1996). In one recent study using a series of herbicides with variable potency, there was adequate correlation of enzyme inhibition with binding inhibition using mouse liver mitochondria as enzyme source (Birchfield and Casida, 1996). Protoporphyrinogen oxidase activity has also been assayed utilizing high-performance liquid chromatography (HPLC) with electrochemical detection to measure protoporphyrinogen disappearance (Li et al., 1987).

The decision to use the indirect (Basic Protocol) or the direct assay (Alternate Protocol 1) will depend on several factors. The indirect assay should be used if the enzyme source has high background fluorescence or high turbidity. However, the direct assay has been used for herbicide dose-response studies in both barley etioplast and rat liver mitochondrial preparations. In the direct assay, a small amount of concentrated protoporphyrinogen solution is added to the assay mixture, resulting in a final concentration of 10 μM. The 1/2 dilution of the protoporphyrinogen solution into 100 mM DTT and the 1/25 dilution of this solution (see Alternate Protocol 1, steps 8 and 10) into the assay mixture eliminates the neutralization step. If higher substrate concentrations are desired, the protoporphyrinogen solution must be neutralized before addition to the assay mixture. In the indirect assay, assay tubes can be incubated at any temperature desired. It may be preferable to use the indirect assay if the available fluorometer has no mechanism for temperature control and a specific temperature is required. Assay temperatures of between 37°C and room temperature have been used. Mammalian mitochondria are more active at 37°C, but can be assayed at room temperature for comparing effects of herbicide inhibitors.

Anticipated Results

In the indirect assay, sonicated rat liver mitochondria had a specific activity of 8 nmol protoporphyrin formed/hr/mg protein at 37°C. In the direct assay, sonicated rat liver mitochondria had a specific activity of 5 to 6 nmol protoporphyrin formed/hr/mg protein at 28°C. This specific activity is in the same range for another rat liver heme synthesis enzyme, coproporphyrinogen oxidase. Other heme synthesis enzymes show higher or lower specific activities (Bishop and Desnick, 1982).

Time Considerations

The indirect assay requires 3 hr; the direct assay 3 hr. Preparation of sodium amalgam requires 2 hr. Preparation of *E. coli* membranes requires 4 hr. These time estimates include only actual assay times after all protocols have been developed.

Measurement of δ-Aminolevulinate Dehydratase Activity

Vertebrate δ-aminolevulinate (ALA) dehydratase (ALAD), a cytosolic enzyme, catalyzes the second step of porphyrin formation, condensing two molecules of ALA to form one molecule of a monopyrrole, porphobilinogen (PBG). In contrast to ALA synthase (ALAS), the first and rate-limiting enzyme for porphyrin biosynthesis, ALAD activity is expressed abundantly in the liver and in erythroid tissues. The enzyme activity is also found in many other tissues. The proportion of ALAD activity to ALAS activity is ~1:100 not only in hepatic cells but also in erythroid cells. Thus, partial inhibition of ALAD activity is usually not associated with clinical symptoms.

This unit describes a colorimetric method for determining ALAD activity in mammalian blood and/or tissues (see Basic Protocol) and for measuring the extent of reactivation in lead-inhibited samples (see Alternate Protocol 1). The amount of PBG produced by the activity of ALAD can be measured by HPLC with UV detection (see Alternate Protocol 2), or the PBG can be converted to uroporphyrin and measured fluorimetrically (see Alternate Protocol 3).

Purified ALAD may be prepared from human erythrocytes (Anderson and Desnick, 1979), bovine liver (Tsukamoto et al., 1979), or rabbit or rat erythrocytes (Fujita et al., 1981). ALAD can be stored at 4°C in 55% (w/v) saturated ammonium sulfate, or in liquid nitrogen without loss of activity.

COLORIMETRIC MEASUREMENT OF ALAD ACTIVITY

BASIC PROTOCOL

ALAD activity in erythrocytes, spleen, liver, kidney, and brain can be determined using a colorimetric assay. Samples are incubated with ALA at 37°C for 60 min. The reaction is terminated with trichloroacetic acid/$HgCl_2$ and mixed well. The mixture is centrifuged and the supernatant is incubated with the modified Ehrlich's reagent. The amount of enzymatically synthesized porphobilinogen (PBG) is estimated as an Ehrlich-PBG color salt with a molar absorption coefficient of 6.2×10^4 at 555 nm (Mauzerall and Granick, 1956). One unit (U) of enzyme activity is defined as 1 μmol of PBG formed per hr at 37°C. Enzyme activity in erythrocytes or other tissues is expressed as U/ml packed cells or U/mg protein.

Materials

Blood or tissue sample
100 mM Tris-acetate buffer, pH 7.2
Protein assay dye reagent (e.g., Bio-Rad; see *APPENDIX 3*)
100 mM δ-aminolevulinic acid hydrochloride (ALA·HCl) in H_2O (Sigma; store up to 1 month at –20°C)
10% (w/v) trichloroacetic acid (TCA)/0.1 M $HgCl_2$, ice-cold (store at room temperature)
Modified Ehrlich's reagent (see recipe)

Heparinized Vacutainer
Heparinized precalibrated capillary tubes (Lancer)
Critoseal (Lancer)
Potter homogenizer
Microhematocrit centrifuge
1-ml semimicro cuvettes, 4-mm wide with 10-mm path length

Contributed by Hiroyoshi Fujita
Current Protocols in Toxicology (1999) 8.6.1-8.6.11

Prepare sample

For blood samples

1a. Collect blood samples in heparinized Vacutainer.

2a. Transfer a drop of blood to a heparinized precalibrated capillary tube, seal one end with Critoseal, and centrifuge 5 min at 10,000 × *g*, room temperature, using a microhematocrit centrifuge. Determine the hematocrit using the guide provided with the centrifuge.

3a. Lyse the remainder of the blood sample by freezing the cells 60 min or longer at –20°C and then thawing.

For tissue samples

1b. Suspend cut-up tissue in 3 vol of 100 mM Tris-acetate buffer, pH 7.2 (1:3 w/v suspension containing 25% homogenate).

2b. Homogenize by using a Potter homogenizer.

3b. Determine the protein concentration of tissue homogenates by the micro Bio-Rad assay.

Assay for ALAD

4. Set up assays in duplicate in 1.5-ml microcentrifuge tubes placed in an ice bucket. In each tube, add 50 µl lysate or homogenate to 238 µl of ice-cold 100 mM Tris-acetate buffer, pH 7.2, and mix well.

5. Add 12 µl of 100 mM ALA-HCl and incubate 60 min at 37°C.

   The reaction is usually linear for ~3 hr. An appropriate incubation time can be chosen based on the level of enzyme activity. For example, human erythroid ALAD activity is ~8 times higher than that of rats (see Anticipated Results). Therefore, for human erythroid samples the incubation could be shortened to 15 min.

6. To terminate the enzyme reaction add an equal volume (300 µl) of ice-cold 10% trichloroacetic acid (TCA)/0.1 M $HgCl_2$ and mix well. Centrifuge the mixture 5 min at ≥1000 × *g*, room temperature.

7. Transfer 500 µl of the supernatant to a fresh tube and mix with an equal volume (500 µl) of the modified Ehrlich's reagent. Prepare a blank consisting of equal volumes of 10% TCA/0.1 mM $HgCl_2$ and modified Ehrlich's reagent. Let stand 5 to 10 min at room temperature.

   The modified Ehrlich's reagent is used for these assays. The original Ehrlich's reagent gives only about half the absorbance.

8. Measure the absorbance of the Ehrlich-PBG color salt at 555 nm (A_{555}) using 1-ml semimicro cuvettes. Calculate the PBG concentration using a molar absorption coefficient of 6.2×10^4. Calculate the ALAD activity as in the following sample calculations.

   PBG concentration is calculated according to the following:

$$\frac{A_{555}}{extinction\ coefficient} \times \frac{assay\ volume}{sample\ volume} \times (dilution\ with\ TCA/HgCl_2) \times$$

$$(dilution\ with\ modified\ Ehrlich's\ reagent) \times \frac{60\ min}{15\ min} \times \frac{1}{hematocrit} \times 1000$$

When the A_{555} of normal human erythrocytes, whose hematocrit is 45%, is 0.6 after a 15-min incubation, ALAD activity is calculated as follows: $(0.6/6.2 \times 10^4) \times (300/50) \times 2 \times 2 \times 4 \times (1/0.45) \times 10^3 = (0.6 \times 6 \times 16 \times 10^3)/(6.2 \times 10^4 \times 0.45) = 2.06$ U/ml packed cells.

When A_{555} of normal rat liver is 1.1 after a 60-min. incubation, where the protein concentration of the homogenate (1:3 w/v) is 50 mg/ml, ALAD activity is calculated as follows: $(1.1/6.2 \times 10^4) \times (300/50) \times 2 \times 2 \times (1/50) \times 10^3 = (1.1 \times 6 \times 4 \times 10^3)/(6.2 \times 10^4 \times 50) = 8.5 \times 10^{-3}$ U/mg protein.

The volumes and incubation times described are suitable for measurements using 1-ml semimicro cuvettes. If micro or 100-µl ultramicro cuvettes are available, the procedure can be scaled down to 1/10.

ALAD ASSAY FOR DETECTING LEAD POISONING

ALTERNATE PROTOCOL 1

Lead poisoning has been known for centuries as an important metal poisoning in humans and is a major health problem, particularly in developing children. Because of a marked sensitivity of ALAD to lead, lead poisoning can be detected by measuring ALAD activity in a drop of blood. Another important feature is that ALAD activity can be restored to normal by treatment with dithiothreitol (DTT) or zinc (Fujita et al., 1981, 1982a). Heat treatment has also been reported to reactivate lead-inhibited ALAD activity (Chiba, 1976). Thus, the extent of inhibition by lead can also be determined as the extent of reactivation of the enzyme following incubation with DTT or Zn^{2+}, or after heat treatment.

Additional Materials *(also see Basic Protocol)*

1 M DTT (*APPENDIX 2A*; store up to 1 month at −20°C)
10 mM zinc acetate (store at room temperature)

1. Prepare hemolyzed blood samples (see Basic Protocol, steps 1a to 3a) or 25% tissue homogenates (see Basic Protocol, steps 1b to 3b).
2. To treat samples add 50 µl of sample, 3 µl of 1 M DTT, and 3 µl of 10 mM zinc acetate to 232 µl of 100 mM Tris-acetate buffer, pH 7.2, in a 1.5-ml microcentrifuge tube in an ice bath. Mix well and preincubate 15 min at 37°C.

   Prepare duplicate tubes for each assay condition. These will be the tubes with the reactivated enzyme (see step 7).

3. To prepare untreated samples (controls) add 50 µl sample to 238 µl Tris-acetate buffer, pH 7.2, in a 1.5-ml microcentrifuge tube. Place on ice.

   These will be the tubes with the nonreactivated enzyme.

4. Put the treated tubes on ice. Add 12 µl of 100 mM ALA·HCl to all (treated and untreated) tubes and incubate 60 min at 37°C.
5. Stop the enzyme incubation by adding an equal volume (300 µl) of 10% TCA/0.1 mM $HgCl_2$. Mix well and centrifuge 5 min at ≥1000 × *g*, room temperature.
6. Transfer 500 µl of supernatant to a fresh tube and add 500 µl modified Ehrlich's reagent. Let stand 5 to 10 min at room temperature. Determine the PBG concentration by reading the absorbance at 555 nm. Determine the ALAD activity in the treated (reactivated) and untreated (nonreactivated) tubes (see Basic Protocol, step 8).
7. Express enzyme activity as a ratio between the reactivated and nonreactivated enzyme. Alternatively express the activity as a ratio between the lead-bound activity to total activity, calculated as:

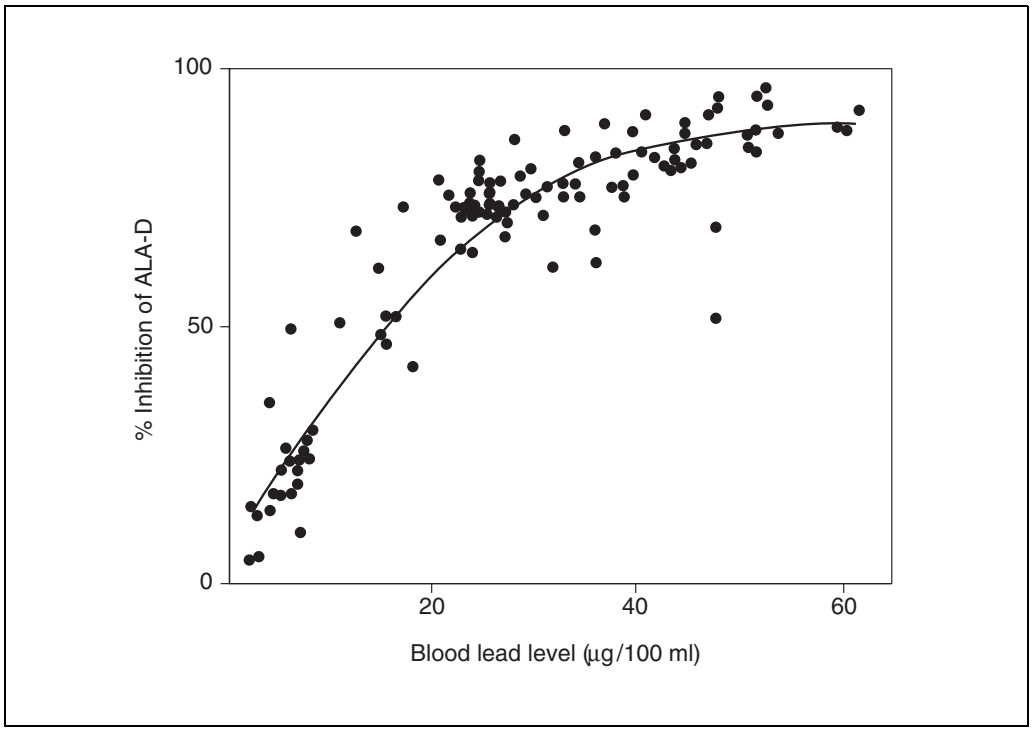

Figure 8.6.1 Correlation between inhibition ratio of ALAD and blood lead level. The inhibition ratio was calculated as described in Alternate Protocol 1. The regression curve was $y = 6.104 + 3.43x - 0.0336x^2$ (n = 108; multiple correlation coefficient 0.936; $F^2_{105} = 370.54$; $P < 0.005$). (Figure reprinted from Sato et al., 1982, with permission).

$$1 - \frac{\text{nonreactivated activity}}{\text{reactivated activity}}$$

See Figure 8.6.1. Each indicator has a good correlation with blood lead concentration.

In cases of styrene exposure (Fujita et al., 1986), trichloroethylene exposure (Fujita et al., 1984), type 1 tyrosinemia (Lindblad et al., 1977), and ADP (Doss et al., 1979), nonreactivated activity is essentially similar to reactivated activity.

ALTERNATE PROTOCOL 2

MEASUREMENT OF ALAD ACTIVITY BY HPLC

Crowne et al. (1981) reported HPLC determination of porphobilinogen after the termination of the enzyme reaction. By this HPLC method, an aliquot of the assay mixture (equivalent to ~1 µl of whole blood as enzyme source) is sufficient to determine the enzyme activity, demonstrating the extremely high sensitivity of this method.

In practice, the colorimetric determination of PBG is sensitive enough to determine ALAD activity in 5 µl of specimen when 100-µl ultramicro cuvettes are available. Thus, almost all assays are performed using spectrophotometry. However, PBG might be unstable on incubation at 37°C, so not only the amount of PBG formed but also the amount of PBG degraded should theoretically be taken into account to evaluate accurate ALAD activity. Under certain circumstances, therefore, the HPLC method should be superior to the colorimetric estimation, since ALA consumed PBG formed, and PBG degraded can be determined using the former method. According to the HPLC method, ALA consumption and PBG production in erythrocytes from 25 normal volunteers was reported to be 35.0 ± 7.7 µmol and 17.5 ± 3.84 µmol/liter RBC/min, respectively (Crowne et al., 1981). Thus, PBG degradation during incubation at 37°C for 60 min is demonstrated to be essentially nil.

Materials

5 to 50 µM PBG standards
Internal standard: 2-methyl-3-carbmethoxy-4-(3-propionic acid)-pyrrole (see recipe)
Mobile phase (see recipe)
Whole blood collected in heparinized Vacutainer
0.1 M sodium phosphate buffer, pH 6.8 (*APPENDIX 2A*) containing 10 mM δ-aminolevulinic acid hydrochloride (ALA·HCl; prepare just before use)
10% (w/v) trichloroacetic acid (TCA)/0.1 M $HgCl_2$, ice-cold (store at room temperature)
HPLC system with 5-µm particle Hypersil-SAS column (5 × 100–mm) and UV detector set at 240 nm and 0.02 AU (full scale; Shandon Southern)

1. Construct a calibration curve using standard solution of PBG ranging from 5 to 50 µM by mixing a 0.5-ml aliquot of each PBG standard with 0.1 ml of the internal standard and injecting 20 µl into the HPLC. Set the pressure at 80 bar with a flow-rate of 1.2 ml/min, and use a mobile phase consisting of 22:78 methanol/ion-pair reagent. Plot PBG concentration versus the ratio of the peaks of PBG/internal standard.

   The duration of the HPLC is <5 min.

2. Hemolyze 0.5 ml of whole blood to be tested for ALAD in 3.25 ml water.

3. Add 1.5 ml of the hemolysate (corresponding to 0.2 ml of whole blood) to 1 ml of 0.1 M sodium phosphate buffer, pH 6.8, containing 10 mM ALA. Incubate mixture 60 min at 37°C.

   ALA in 0.1 M sodium phosphate buffer should be prepared just before use because ALA is unstable under these conditions.

4. Terminate the enzyme reaction by adding 1 ml of 10% trichloroacetic acid/0.1 M $HgCl_2$, then centrifuge 5 min at ≥1000 × *g*, room temperature.

5. Mix the supernatant with the internal standard at a ratio of 5:1. Inject 20 µl of well mixed solution onto the HPLC and chromatograph as in step 1.

   Under the conditions employed, ALA, PBG, and the internal standard are well separated, with retention times of 114, 198, and 260 sec, respectively.

6. To determine ALAD activity, read PBG concentration in each assay mixture from the calibration curve.

FLUORIMETRIC DETERMINATION OF ERYTHROCYTE ALAD ACTIVITY BY HPLC

ALTERNATE PROTOCOL 3

Since PBG is considered to be sensitive to light and air oxidation, ALAD activity can be estimated after chemical conversion of PBG into stable and highly fluorescent uroporphyrin (Chakrabarti et al., 1975; Tomokuni, 1976). By fluorescence alone, however, it is difficult to separate fluorescence of the enzymatic product from fluorescence of other porphyrins in the reaction mixture. Thus, an HPLC method has been developed to enable this separation by which the amount of uroprophyrin can be used as a measure of ALAD activity .

Like the HPLC method as described in Alternate Protocol 2, the fluorometric determination is a few times more sensitive than the colorimetric determination, thus permitting ALAD assays in nonhepatic or nonerythoid tissues. The colorimetric determination is, however, sensitive enough to estimate ALAD activity in many cells.

Materials

Heparinized whole blood
0.2 M sodium phosphate buffer, pH 6.8 (*APPENDIX 2A*)
20 mM δ-aminolevulinic acid hydrochloride (ALA·HCl) in water
Authentic porphyrins: 500 μg/liter coproporphyrin I and appropriate concentration uroporphyrin I, dissolved in glacial acetic acid
10% (w/v) trichloracetic acid
Mobile phase: 500:500:10 (v/v/v) acetonitrile/aqueous 10 mM KH_2PO_4/glacial acetic acid

HPLC system with:
5-μm particle Shim-pack CLC-ODS reversed-phase column (6 × 150–mm; Shimadzu Ltd.)
Fluorescence detector with excitation wavelength of 400 nm (bandwidth 18 nm) and emission wavelength of 620 nm (bandwidth 22 nm)
100°C water bath

1. Hemolyze 0.1 ml heparinized whole blood with 1.4 ml of distilled water, then add 0.5 ml of 0.2 M sodium phosphate buffer, pH 6.8.
2. Add 0.5 ml of 20 mM ALA and incubate 60 min at 37°C.
3. Terminate the reaction by adding 1 ml of 10% trichloroacetic acid. Mix and centrifuge 5 min at ≥1000 × *g*, 4°C.
4. Transfer supernatant into fresh tube, heat 15 min at 100°C to yield uroporphyrin, then cool down in an ice bath.
5. Inject 10 μl of the assay mixture into HPLC with a flow rate of 1.5 ml/min to determine porphyrin separation and concentrations. Use mobile phase consisting of 500/500/10 acetonitrile/10 mM KH_2PO_4/glacial acetic acid. Run the authentic porphyrins to determine retention time. Also prepare a calibration curve using dilutions of coproporphyrin.

   Under these conditions, the retention times of uroporphyrin and coproporphyrin are 1.6 and 4.6 min, respectively.

6. Calculate the enzyme activity as $F_s/F_c \times 500/655 \times 3.5/0.1 \times 100$/hematocrit (mmol uroporphyrin/liter RBC/hr), where F_s = fluorescence of sample, F_c = fluorescence of coproporphyrin standard, and 655 = molecular weight of coproporphyrin.

   Since the fluorescence intensity of uroporphyrin is equal to that of coproporphyin at the same micromolar concentration under the conditions employed, the coproporphyrin standard, whose 5-μg vial is inexpensive and convenient, is used to calculate the activity instead of uroporphyrin.

   The relationship between ALAD activities determined by colorimetric assay (x) and by fluorometric assay (y) is reported as y = 0.125x – 38.761, with a correlation coefficient of 0.971 (n = 58; Tomokuni and Ichiba, 1988). Since a theoretical relationship should be y = 0.25x, more than 50% of produced PBG is lost during steps including chemical conversion into uroporphyrin.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ehrlich's reagent, modified

Dissolve 1 g of *p*-dimethylaminobenzaldehyde (Sigma) in a mixture of 30 ml glacial acetic acid and 16 ml 70% perchloric acid. Bring the volume to 50 ml with acetic acid. Store up to 1 week at 4°C in a dark brown bottle.

2-Methyl-3-carbmethoxy-4-(3-propionic acid)-pyrrole

Prepare an acetate buffer, pH 4.6, by diluting 57 ml of glacial acetic acid in 700 ml of water, adding 136 g of sodium acetate trihydrate, and bringing the final volume to 1 liter with water (store buffer indefinitely at room temperature). Dissolve 2 mg of δ-aminolevulinic acid hydrochloride (ALA·HCl) in 10 ml of water. Add 10 ml of the acetate buffer, pH 4.6, and heat the mixture 20 min at 100°C. Dry 1-ml aliquots and store at 4°C. Just prior to use, redissolve in 10 ml water.

Mobile phase

Dilute one 20-ml bottle of PIC-B7 (1-heptanesulfonic acid; Fluka) to 1 liter with water. Prepare this ion-pair reagent just before use or store at 4°C in the dark for a few days. Prepare mobile phase by mixing 78 parts of the ion-pair reagent with 22 parts methanol.

COMMENTARY

Background Information

ALAD activity was described for the first time by Shemin et al. (1954). Among the eight enzymes in the heme biosynthetic pathway of mammals, ALAD has one of the highest activities (Fujita et al., 1994). For example, mature human erythrocytes contain as much as 150 µg ALAD/ml packed cells (Fujita et al., 1987). While ALAD is present in erythrocytes, there is no heme synthesis in these cells since they lack mitochondrial ALA synthase, the first enzyme of heme biosynthesis.

Mammalian ALAD is a homodimer consisting of eight identical subunits, each with a molecular weight of ~35,000. Each of these subunits contains eight cysteinyl residues. Thus, one molecule of ALAD has 64 cysteinyl residues, and the enzyme activity is highly sensitive to oxidative agents (Tsukamoto et al., 1979). Furthermore, various metals, such as Ag^{+}, Hg^{2+}, Pb^{2+}, and Sn^{2+}, are known to strongly inhibit purified ALAD activity in vitro. Among these metals, Pb^{2+} and Sn^{2+} inhibit the enzyme activity also in vivo—an effect that accompanies clinical metal poisoning. Thus, the inhibition of ALAD activity is an important feature in divalent metal poisoning, and it is perhaps the most sensitive biological indicator of lead poisoning. In addition, ALAD is also inhibited by certain organic solvents, such as ethanol, trichloroethylene, bromobenzene, and styrene, and it is a useful biological index for environmental poisoning. Inhibition of ALAD by lead was originally reported by Koike (1959) and Lichtman and Feldman (1963). Since then, there have been many reports on the relationship between lead poisoning and ALAD inhibition.

Inhibition of ALAD activity is generally considered as the most sensitive indicator for low-level lead exposure. It should be noted, however, that enzyme activity in human erythrocytes has a wide range of variation which is thought to reflect different genetic backgrounds (Sassa et al., 1973). Thunell et al. (1987) reported that ~2% of 880 normal individuals have levels of ALAD activity ~50% of normal. Thus it is important to distinguish a lead-inactivated activity from a low normal activity. This distinction can be made by using DTT- and zinc-activated ALAD as described in Alternate Protocol 1.

Reactivation of lead-inhibited ALAD activity by treatment with glutathione (Haas et al., 1972), dithiothreitol (Granick et al., 1973), zinc (Finelli et al., 1975), heat treatment at 55° to 60°C (Chiba, 1976), or zinc and glutathione at 50°C (Mitchell et al., 1978) has been reported to be a useful index of lead exposure. Some methods have included DTT during enzyme incubation, and achieved an almost complete reactivation of lead-inhibited activity (Granick et al., 1973). A complete reactivation of ALAD

activity by 10 mM DTT and 100 μM zinc is more precisely documented by the comparison of ALAD protein and the completely reactivated specific activity of the protein (Fujita et al., 1981, 1982a).

The colorimetric determination of ALAD activity was first described by Gibson et al. (1955). In 1974, the European Standardized Method for ALAD assay was published (Berlin and Schaller, 1974), and it has become the main assay method. Commonly ALAD assay methods, including the European Standard method, are carried out in the presence of phosphate buffer. It should be noted, however, that lead-inhibited ALAD activity can be partially reactivated by a chelating activity of the buffer (Maes and Gerber, 1978). Thus, the use of buffers with chelating activity, such as citrate or phosphate buffers, should be carefully monitored or avoided when carrying out the assay for detecting lead poisoning (Alternate Protocol 1). This is the reason why Tris-acetate buffer, pH 7.2, is used instead of phosphate buffer, for certain assays (Fujita et al., 1981, 1982a,b). Jaffe et al. (1984) also described the use of TES-KOH buffer, pH 7.2. Thus, the ALAD assay from in vivo experiments indicates the magnitude of the inhibitory effect of a chemical hazard on ALAD. To understand the precise effect of a chemical hazard on ALAD, the in vitro relationship between the purified enzyme and the chemical hazard should be examined. Such studies will clarify, for example, the interaction between a chemical hazard and an essential SH residue of the enzyme.

Since the products of ALAD-catalyzed reactions are porphobilinogen and H^+, the purified enzyme activity can be determined as a change in pH. The formation of H^+ by ALAD can be colorimetrically monitored using bromothymol blue (5 mg/ml) at 617 nm. Under the conditions employed, a loss of 1 O.D. at 617 nm is equivalent to a formation of 0.019 M of H^+ (and PBG). The buffer for the reaction should be 10 mM Tris-acetate, pH 7.2, and ALA-HCl solution should be adjusted to pH 7.2 just before use.

In addition to toxicological inhibition, ALAD decreased activity is associated with inherited ALAD deficiency. ALAD porphyria (ADP), a rare hepatic porphyria, shows a marked deficiency in ALAD activity. This disease is due to a homozygous ALAD mutation; mutations identified in four patients to date indicate heteroallelic mutations of the ALAD gene. In one case of ADP, ALAD in erythrocyes was decreased to 45.8 μg/ml packed cells (Fujita et al., 1987b), which is markedly lower than that in normal controls (165 ± 56.8 μg/ml packed cells, $n = 18$; Fujita et al., 1987). ALAD in patients with type 1 tyrosinemia is also markedly decreased, and patients present with symptoms similar to ADP. In contrast to ADP, ALAD content in erythrocytes from a patient with type 1 tyrosinemia (~200 μg/ml packed cells) was within the normal range (Sassa et al., 1990). A comparison of ALAD concentration in the liver (ranging from 0.15 to 0.3 μg/mg protein) with that in erythrocytes (0.5 ± 0.17 μg/mg hemoglobin) suggests a preferential erythroid expression of the enzyme (Fujita et al., 1987; Sassa et al., 1990). ALAD activity in patients with tyrosinemia is inhibited by succinylacetone, an abnormal metabolite produced from tyrosine due to an inherited deficiency of fumarylacetoacetase activity. Recently, Bishop et al. (1996) reported that the tissue-specific expression of ALAD is due to a nonspecific promoter, which is located 5′ with respect to to exon 1a and an erythroid-specific promoter, 5′ with respect to exon 1b of the gene, in the liver and erythroid cells, respectively.

A genetic polymorphism of ALAD in man, with variants termed $ALAD^1$ and $ALAD^2$, was reported by Batistuzzi et al. (1981). Individuals with $ALAD^2$ phenotype were reported to have levels of blood lead higher than those with $ALAD^1$ phenotype (Astrin et al., 1987), and it has been suggested that $ALAD^2$ binds lead more effectively (Wetmur et al., 1991). A pair-matched study based on blood lead levels, however, showed that $ALAD^1$ protein and $ALAD^2$ protein were inhibited by lead to almost the same magnitude (Ziemsen, 1986). This observation suggests that lead may bind to $ALAD^1$ protein or $ALAD^2$ protein with similar affinity. Recently, a G^{177}-to-C transversion was shown in $ALAD^2$, which resulted in a Lys^{59}-to-Asn substitution (Wetmur et al., 1991). The Asn^{59} in the ALAD gene is also preserved in that position in the rat, mouse, and bovine enzyme (Wetmur et al., 1986; Bishop et al., 1986, 1989). The affinity of lead to ALAD in rat ($K_i = 6.0 \times 10^{-6}$ M) and bovine enzyme ($K_i = 2.8 \times 10^{-4}$ M) is lower than that to the human enzyme ($K_i = 1.7 \times 10^{-6}$ M); therefore, it might be possible that lead binds to the $ALAD^2$ protein, which has Asn^{59}, to a much lesser extent than to the $ALAD^1$ protein, which has Lys^{59} (Anderson and Desnick, 1979; Fujita et al., 1986). Recently, Bergdahl et al. (1997a) reported that ALAD polymorphism did not relate to lead levels but to kidney function.

In addition to genetic disease, styrene and trichloroethylene exposures are known to result

in lower ALAD activity. Styrene exposure is also associated with decreased protein, but this is presumably due to an irreversible deregulation of the enzyme by styrene and/or its oxide (Fujita et al., 1986, 1987).

Why mature erythrocytes contain a large amount of ALAD, in spite of the fact that mature erythrocytes no longer synthesize heme for hemoglobin, has not been well understood. Recently it was reported that ALAD is a 240-kDa proteasome inhibitor (CF-2; Guo et al., 1994). This may explain why ALAD is stable even after erythroid differentiation. The other possible role for ALAD protein in erythrocytes is as a 240-kDa lead-binding protein (Piomelli, 1993), since it has been reported to contain ~60% to 70% of blood lead (Bergdahl et al., 1997b). This observation is in good agreement with a regression curve between blood lead concentration (μM) as x and concentration of inhibited ALAD (subunit; μM) as y in lead-exposed workers; $y = -0.0547 + 1.448x - 0.3159x^2$, suggesting that 70% of lead is binding to ALA dehydratase when the blood lead level was lower than 3 μM (Fujita et al., 1982a).

Critical Parameters

There are a few critical points to be noted in the ALAD assay. Enzyme activity in erythrocytes can be markedly underestimated if hemolysis of the blood sample is incomplete. For example, samples frozen at −20°C for 30 min instead of 60 min show only ~50% of the complete activity. Freezing at −20°C for 60 min, or three quickly repeated freeze/thaw cycles in liquid nitrogen, is enough for complete lysis. Addition of 50% glycerol/DTT was reported to preserve ALAD activity and to facilitate detection of lead poisoning (Burns et al., 1994)

When a purified ALAD preparation is used, it loses activity rapidly because of oxidation of the sulfhydryl groups and loss of essential zinc. Therefore, activation of ALAD enzyme activity by DTT/zinc is essential. ALAD should be reactivated with 100 μM Zn^{2+} and 50 mM dithiothreitol prior to assay. Then, the reactivated enzyme should be applied to a Sephadex G-50 column (7 × 100–mm) under N_2 to remove excess dithiothreitol and zinc. Protein concentration of the reactivated enzyme is determined by measuring absorbance at 280 nm ($E^{1\%}_{1\ cm}$ = 11.8; Tsukamoto et al., 1979). Concentration of the purified enzyme, whose specific activity is 27 U/mg, in the assay mixture is usually 6 to 15 mg/ml. When the concentration of ALAD is 10 mg/ml, the absorbance of Ehrlich-PBG color salt after a 15-min reaction should be ~1. A relatively large amount of ALAD (6 to 15 mg/ml) should be used with N_2-saturated buffer and a short reaction time (15 min) to avoid oxidation during incubation.

Troubleshooting

Since the purified preparation is not stable under liquid nitrogen, it should be stored at 4°C with 55% saturated ammonium sulfate in the presence of 10 mM DTT and 100 μM zinc. In contrast to the purified enzyme, hemolysates or homogenized tissues can be stored in liquid N_2 without a significant loss of activity.

Contamination by metals may inhibit ALAD activity. Chemicals, reagents, tubes, and other items should be treated carefully to avoid contamination. Usually glass tubes and plastic labware from a freshly opened case do not present a problem When recycled glass tubes are used for assays, $HgCl_2$ should be thoroughly removed by washing with 0.1 N HNO_3 followed by exhaustive rinsing in deionized water.

Anticipated Results

When ALAD activity in human erythrocytes is determined according to the Basic Protocol, the enzyme activity for normal subjects is ~2 U/ml packed cells (Fujita et al., 1987). The ratio of nonreactivated activity to reactivated activity in normal controls is ~0.8. The relationship between nonreactivated activity and reactivated activity and blood lead concentration (μg Pb/100 ml blood) is $y = 0.0336x^2 - 3.43x + 93.90$, with a multiple correlation coefficient of 0.936, when the ratio of nonreactivated activity to reactivated activity is taken as y and the blood lead concentration is taken as x (Fujita et al., 1982a). Using hepatic biopsy tissue, ALAD activity of normal human liver is estimated to be 9×10^{-3} U/mg protein (Sassa et al., 1990). In Wistar rats after experimental lead exposure, erythrocyte nonreactivated activity in the control group (with a mean blood lead level of 9.3 μg/100 ml, $n = 6$) was 96×10^{-3} U/ml packed cells; in the low-lead-exposed group (with a mean blood lead level of 30.8 μg/100 ml, $n = 6$), 68×10^{-3} U/ml; and in high-lead exposed group (with a mean blood lead level of 90.9 μg/100 ml, $n = 6$), 20×10^{-3} U/ml packed cells. Reactivated activities for the same three groups were 136×10^{-3}, 258×10^{-3}, and 257×10^{-3} U/ml packed cells, respectively. Mean values of nonreactivated activity in the liver and in bone marrow cells in normal control rats were 8.3×10^{-3} and 8.8×10^{-3} U/mg protein, respectively; mean values of reactivated activity in the same liver and bone marrow cells were 9.5×10^{-3} and

18.9×10^{-3} U/mg protein, respectively (Fujita et al., 1985).

Time Considerations

To perform assays for ten samples in duplicate according to the Basic Protocol, it takes 3 hr, from enzyme preparation to colorimetric determination. For toxicological examinations, particularly screening for lead poisoning, it is necessary also to determine nonreactivated activity and reactivated activity. The assay for purified enzyme (from precipitation with ammonium sulfate to determination of activity) is completed within 2 hr. It takes ~2 hr to complete the preparation, preincubation, and incubation of the assay mixtures for HPLC analysis. In addition, HPLC with UV and fluorimetric detection take 5 min and 2 min, respectively, per sample. Each activity is determined in duplicate.

Measurement of Ferrochelatase Activity

Ferrochelatase, the terminal step in the heme biosynthetic pathway, catalyzes the insertion of ferrous ion into the protoporphyrin IX ring to form protoheme. The eukaryotic enzyme is located in the inner membrane of mitochondria with the active site facing the matrix. The enzyme activity is inhibited by heavy metal ions such as Pb^{2+} and Hg^{2+} and by *N*-alkylprotoporphyrins (degradation products of the heme moiety of cytochrome P-450). Although ferrochelatase cannot utilize ferric ion, it can insert zinc and cobalt ions into the porphyrin ring. Instead of protoporphyrin, artificial porphyrins including mesoporphyrin, deuteroporphyrin, and hematoporphyrin can serve as substrates (Taketani, 1994).

When zinc ion is used as a metal substrate, the enzyme reaction proceeds under aerobic conditions, and zinc-chelating activity is reflected in iron-chelating activity. Analysis of metalloporphyrins and porphyrin derivatives by high-performance liquid chromatography (HPLC) is now feasible. Also, detection of porphyrin fluorescence allows for a highly sensitive assay of ferrochelatase. Ferrochelatase can readily catalyze the insertion of ferrous, cobalt, and zinc ions into the porphyrin ring. Of these metalloporphyrins, only zinc porphyrin has fluorescence. Measuring fluorescence is a highly sensitive method compared with optical absorption. Therefore, reaction of zinc-chelation followed by analysis of zinc-porphyrins by HPLC makes for a simple and reproducible method to determine ferrochelatase activity (see Basic Protocol). It is also possible to measure cobalt-chelating activity by the same method (see Alternate Protocol 1), and to measure iron-chelating activity (see Alternate Protocol 2) spectrophotometrically. The reduced-minus-oxidized differential absorption spectra of pyridine-hemochromogen of formed heme can apply only to iron chelation (see Alternate Protocol 2). Measurement of iron- or cobalt-chelating activity was used in the past but requires large amounts of enzyme preparation for the assay. By zinc chelation it is possible to measure ferrochelatase activity on a small scale.

As described in the Commentary, measurement of zinc-porphyrin formation permits study of enzyme kinetics using small amounts of enzyme preparation. On the other hand, ferrous iron is a real substrate of ferrochelatase, and it is also informative to measure heme formation in vitro.

MEASUREMENT OF ZINC-MESOPORPHYRIN FORMATION

BASIC PROTOCOL

Mesoporphyrin and zinc ion are incubated at 37°C for 1 hr under aerobic conditions and the reaction is terminated by adding a mixture of methanol/dimethyl sulfoxide/EDTA. The resulting mixture is mixed and centrifuged, and the supernatant is withdrawn for measurement of zinc-mesoporphyrin with an HPLC equipped with a C18 column. Zinc-mesoporphyrin is measured by absorbance at 400 nm as well as by fluorescence intensity.

When zinc ion is used as a substrate, results can be altered by a nonenzymatic reaction. To prevent the nonenzymatic formation of zinc-mesoporphyrin, the molar ratio of zinc ion to mesoporphyrin should not exceed 4:1. The presence of detergents also suppresses the nonenzymatic formation of zinc-porphyrin. Tween 20 is an appropriate detergent because it does not contain fluorescence-absorbing contaminants. The addition of fatty acid to the reaction leads to a 4- to 8-fold increase in ferrochelatase activity, and some activities of ferrochelatase using homogenates from leukocytes and lymphocytes can be detected. Furthermore, saturated fatty acids such as palmitic and stearic acids will lower the nonenzymatic formation of metalloporphyrin.

Contributed by Shigeru Taketani

Current Protocols in Toxicology (1999) 8.7.1-8.7.8

Materials

1 mM mesoporphyrin solution (see recipe)
Tris/palmitate/Tween buffer (see recipe)
Enzyme source (see recipe): Mitochondrial preparation or cell homogenate (0.5 to 2.5 µg protein/µl)
2 mM zinc acetate
Stop solution: 3:7 (v/v) dimethyl sulfoxide/methanol with 0.1 mM EDTA
Ammonium acetate/methanol solution (see recipe)
Zinc-mesoporphyrin (Porphyrin Products)
Dimethylsulforide (DMSO)

Ultrasonicator
1.5-ml microcentrifuge tubes
37°C incubator
C18 column: 4-µm Novapak C18 silica column (4.6 × 150–mm; Waters) or Cosmosil 5C18-AR column (4.6 × 160–mm Nacalai Tesque)
0.2-µm precolumn filter (0.4 mm; Millipore)
HPLC system with 0.2-µm precolumn filter (2.5 × 2.5 cm), fluorescence spectrophotometric detector,and spectrophotometric visual detector

Prepare samples

1. Add 1 mM mesoporphyrin solution at a final concentration of 50 µM to Tris/palmitate/Tween buffer. Mix well and sonicate for 2 min as described in the recipe for mesoporphyrin and palmitic acid mixture in Reagents and Solutions.

   This mixture can be stored for up to 3 months in the dark at −20°C. Sonicate before use. Palmitic acid dissolved in ethanol can be used instead of sodium palmitate, but unsaturated fatty acids, including oleic acid and palmitoleic acid, are not suitable for the assay because the presence of unsaturated fatty acid leads to an increase in nonenzymatic formation of zinc-mesoporphyrin.

2. Add 20 µl cell homogenate or mitochondrial preparation (10 to 50 µg of protein) to 170 µl of the above mixture in a 1.5-ml microcentrifuge tube and mix well. Set up a second reaction mixture without enzyme as a negative control.

   As ferrochelatase is unstable below pH 7.8, the mitochondria must be prepared using solutions at pH 8.0. When using homogenates of lymphocytes or bone marrow cells as enzyme sources, solutions containing 10% to 20% glycerol should be used, as glycerol markedly stabilizes ferrochelatase.

3. Initiate reaction by adding 10 µl of 2 mM zinc acetate (final 100 µM) to each tube. Incubate 30 to 60 min in the dark at 37°C.

   The length of the incubation period depends on the enzyme preparation. When homogenates of lymphocytes or leukocytes are used, ≥60 min is needed, but prolonged incubation decreases the enzyme activity. When mitochondria from mammalian liver are used as enzyme sources, the incubation period can be <20 min because the mitochondria generally exhibit high ferrochelatase activity.

4. Terminate the enzyme reaction by adding 0.5 ml stop solution and mix by vortexing.

   After adding stop solution to the reaction mixture, the samples can be stored for up to one week at −70°C in the dark prior to HPLC analysis of zinc-mesoporphyrin.

5. Microcentrifuge samples 10 min at 14,000 × *g*, 4°C, and transfer the supernatants to new tubes.

6. Prepare standards containing various concentrations (100 to 500 nM) of zinc-mesoporphyrin dissolved in DMSO.

Perform HPLC

7. Equilibrate a C18 column with ammonium acetate/methanol solution at a flow rate of 1.5 ml/min.
8. Connect in tandem a fluorescence spectrophotometer outlet to a spectrophotometer. Adjust the detector of the spectrophotometer to 400 nm, and adjust the fluorescence spectrophotometer to excitation at 410 nm and emission at 580 nm.
9. Pass the sample through a 0.2-µm precolumn filter and then separately inject 10- to 15-µl sample onto the column.

   A precolumn filter will aid in expanding the life of the HPLC column by removing small precipitates. C18 columns such as the 4-µm Novapak C18 silica column and Cosmosil 5C18-AR column are suitable for use as a separation column.

   After all samples have been analyzed, the HPLC column should be washed with methanol for ≥30 min; maintenance of the column is of the greatest importance.
10. Read absorbance at 400 nm and fluorescence intensity of the formed zinc-mesoporphyrin. Prepare a standard curve by injection and analysis of the zinc-mesoporphyrin standards.

    Retention times of zinc-mesoporphyrin and mesoporphyrin are ~2.5 min and 3.9 min, respectively.
11. Calculate molar concentration from the different intensities of zinc-mesoporphyrin between values without or with enzyme since a small amount of zinc-mesoporphyrin is always formed nonenzymatically under the conditions described.

ASSAY OF COBALT-CHELATING ACTIVITY

ALTERNATE PROTOCOL 1

Instead of zinc acetate, this protocol uses 50 µM $CoCl_2$ as a metal substrate. Incubation conditions are the same as for zinc-chelating activity. The cobalt-mesoporphyrin formed is analyzed with an HPLC system by measuring spectrophotometric absorbance at 420 nm. As cobalt-mesoporphyrin is not fluorescent, the sensitivity of the cobalt-chelating activity is less than that seen for zinc chelation. Cobalt-mesoporphyrin is commercially available and can be used as a standard.

ASSAY OF IRON-CHELATING ACTIVITY

ALTERNATE PROTOCOL 2

In this protocol, a spectrophotometer is used to determine iron-chelating activity. The difficulty in measuring ferrochelatase activity with ferrous iron is that oxidation of ferrous ion to form ferric ion occurs in the presence of oxygen. During this reaction, hydroxy radical and peroxide are produced via a Fenton reaction, thereby destroying the porphyrin rings. Thus, oxygen must be removed from the reaction mixture by replacing oxygen gas with nitrogen or argon gas before the iron-chelating activity can be measured. A Thunberg tube is convenient and practical for obtaining anaerobic conditions.

Additional Materials *(also see Basic Protocol)*

1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1 mM mesoporphyrin solution (see recipe)
100 mM dithiothreitol (DTT)
10% (w/v) Triton X-100
Enzyme source (see recipe): Mitochondrial preparation or cell homogenate (0.5 to 2.5 µg protein/µl)
10 mM iron citrate (see recipe)
Nitrogen (N_2) gas
0.1 M iodoacetamide
1 N NaOH

continued

Pyridine
Sodium dithionite

Thunberg tube (Top Labo-Ware)
Spectrophotometer with scanning wavelength (i.e., Hitachi U-2010) and cuvettes

1. Prepare a 1-ml solution containing the following ingredients and add to the main tube of a Thunberg tube:

   0.1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
   50 µM mesoporphyrin
   1 mM DTT
   0.1% (w/v) Triton X-100
   0.1 to 0.2 ml enzyme source.

2. Prepare a 1-ml solution containing 100 µM iron citrate and 0.1 M Tris·Cl and add this to the side arm.
3. Remove O_2 gas from the reaction mixture by evacuating and flushing several times with N_2 gas, and then vacuum pump to obtain reduced conditions.

   The remaining trace O_2 is removed from the reaction mixture under reduced pressure.

4. Pour the solution of the side arm into the main tube and incubate the tube 30 min at 37°C.
5. Open the side arm and add 0.5 ml of 0.1 M iodoacetamide to stop the reaction.
6. Add 0.5 ml of 1 N NaOH and 0.5 ml pyridine.
7. Divide the mixture into two cuvettes. Add a few grains of fresh, free-flowing sodium dithionite to one cuvette and mix well to reduce mesoheme. Put the cuvette containing sodium dithionite–free mixture into the reference cell box of the spectrophotometer.

   Use fresh, dry sodium dithionite, as it is ineffective when old or damp.

8. Monitor the reduced minus oxidized differential absorption spectrum by scanning from 500 to 570 nm, and measure the difference in absorbance at 531 nm and 547 nm ($\Delta A = A_{547} - A_{531}$).
9. Calculate the mesoheme formed using the equation mesoheme (nmol) = $1000 \times 3.5 \times \Delta A + 21.7$, where 1000 is µmol/nmol, 3.5 is the final volume, and 21.7 is ε_{mM} ($\Delta A_{547-531\ nm}$ for mesoheme).

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Ammonium acetate/methanol solution

Adjust 1 M ammonium acetate to pH 5.18 with 6 M HCl. Mix 100 ml ammonium acetate with 900 ml methanol. Pass the solution through a 0.22-µm membrane filter (Millipore GVHP-type) under vacuum. Store up to several months at room temperature.

Enzyme source

For mitochondria: Suspend minced liver in 6 vol of 10 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*), containing 0.25 M sucrose and homogenize in a glass homogenizer with a Teflon pestle. Centrifuge the suspension 10 min at $600 \times g$, 4°C, to remove cell debris. Centrifuge the supernatant 10 min at $10{,}000 \times g$, 4°C, to sediment the mitochondria. Wash the pellet twice with 10 mM Tris·Cl, pH 7.8, and suspend the mitochondria in the same solution. Store at −70°C until use (up to 1 month).

For homogenates of cultured cells or peripheral blood lymphocytes: Suspend 5×10^6 cells in 500 µl of 10 mM Tris·Cl buffer, pH 7.8 (*APPENDIX 2A*), containing 20% glycerol and 1 mM DTT. Sonicate the suspension 2 min at 4°C, and centrifuge 5 min at $600 \times g$, 4°C. Use the resulting supernatant for enzyme assay or store at −70°C prior to use (stable for ≥1 month).

The sample of cells can also be stored at −70°C for 1 month.

Iron citrate solution, 10 mM

Dissolve 3.4 mg ammonium ferrous sulfate and 2.7 mg sodium citrate in 1 ml H_2O. Flush the solution with nitrogen gas for 2 min and store up to 3 months below 0°C.

Mesoporphyrin and palmitic acid mixture

100 µl of 1 mM mesoporphyrin (see recipe)
200 µl of 10 mM sodium palmitate
30 µl of 10% (w/v) Tween 20
100 µl of 1 M Tris·Cl buffer, pH 8.0 (*APPENDIX 2A*)
470 µl H_2O

Sonicate the mixture at room temperature for 2 min. Determine the concentration of mesoporphyrin spectrophotometrically in 0.1 N HCl, using the extinction coefficient $\varepsilon_{\mu M} = 445$ at 399 nm.

Mesoporphyrin solution, 1 mM

Dissolve 2 mg mesoporphyrin IX into 0.5 ml of 0.1 N KOH by vigorous vortexing. Add 0.5 ml ethanol and mix the resulting solution well. Store at −30°C until use (up to 1 year).

Tris/palmitate/Tween buffer

0.1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1 mM sodium palmitate
0.3% (v/v) Tween 20
Store up to several months at 4°C

COMMENTARY

Background Information

All living organisms can synthesize heme (Taketani, 1994). The activity of ferrochelatase was first demonstrated by Goldberg et al. (1956) with homogenates of chicken erythrocytes; they measured incorporation of iron-59 into protoporphyrin. Although mammalian tissues including liver, kidney, and bone marrow cells exhibit a relatively high ferrochelatase activity, microorganisms and plant cells generally exhibit low activity. Ferrochelatase is located in mitochondria of mammalian livers, and measurement of iron-chelating activity (see Alternate Protocol 2) with mitochondria is routine. The formed heme can be determined by difference spectra of pyridine-hemochromogen. With this procedure, it is difficult to do kinetic studies or to measure low ferrochelatase activity. Assay of zinc-chelating activity, followed by HPLC analysis, facilitates kinetic studies using small amounts of enzymes from bacteria, plants, and mammals. The protocol described here is a simple approach to measure ferrochelatase activity of various organisms. This procedure is highly reproducible and sensitive, so it can be applied using a very small amount of enzyme or when the enzyme source exhibits very low ferrochelatase activity.

HPLC analyses of porphyrins and metalloporphyrins for ferrochelatase were apparently first reported by Li et al. (1987), with a more detailed procedure later reported by Rossi et al. (1988). These procedures included measurement of ferrochelatase activity of human blood peripheral lymphocytes, which contain extremely low ferrochelatase activity. A blood sample is the only simple, viable material that can be used to examine human enzyme activities. For blood samples, the only method with sufficient sensitivity for measurement of ferrochelatase activity is incorporation of radioactive iron into the formed heme, which is then extracted for counting. However, the radiochemical assay presents technical difficulties. Iron-59 with specific radioactivity that decays over time is available in the form of ferrous

ion and is stored under anaerobic conditions. After incubation, labeled heme must be extracted with organic solvents to separate the free iron. The development of HPLC methods paved the way for simpler assays.

Activation of ferrochelatase activity by fatty acid was first performed when enzyme from rat liver mitochondria was solubilized and highly purified (Sawada et al., 1969). It was then demonstrated that ferrochelatase homogeneously purified from rat liver and yeast requires fatty acid to measure the enzyme activity (Taketani and Tokunaga, 1981; Camadro and Labbe, 1988). A later sensitive assay using HPLC showed that fatty acid suppresses nonenzymatic and activates enzymatic formation of zinc-mesoporphyrin when detergents such as Tween 20 (polyoxyethylenesorbitan monolaurate) and Tween 40 (polyoxyethylenesorbitan monopalmitate) are present in the reaction mixture (Rossi et al., 1988). Saturated fatty acids including palmitic and stearic acids are more effective and less expensive than unsaturated fatty acids. Phospholipids or neutral lipids are without untoward effects on the reaction. Mechanisms involved in activation of ferrochelatase activity by fatty acids remain unknown.

Critical Parameters

Zinc-chelatase activity is mostly reflected in iron-chelatase activity. The level of ferrochelatase activity determined by measuring the formation of zinc-mesoporphyrin is reliable. However, the kinetics of mesoheme formation are not always the same as those of zinc-mesoporphyrin formation. For example, sensitivity for ferrochelatase inhibitors such as Pb^{2+} and sulfhydryl agents is higher with heme formation than with zinc-porphyrin formation. When examining the kinetics of ferrochelatase, first confirm the results by comparing measurements of zinc-chelating and iron-chelating activities (see Alternate Protocol 2).

When effects of metals on ferrochelatase activity are examined, Tris·Cl buffer is not suitable for use because metal-chloride complexes frequently precipitate out, causing the concentration of metals to be nonhomogenous in the reaction mixture. Instead of Tris·Cl buffer, Tris·acetate buffer is recommended for use.

Although mesoporphyrin is an artificial porphyrin derivative that is a relatively stable porphyrin and can serve as a substrate of ferrochelatase, porphyrins should be handled in the dark because porphyrin is generally destroyed by light. Protoporphyrin, a natural substrate of ferrochelatase, is less soluble or stable than mesoporphyrin. Therefore, insertion of metals into protoporphyrin is much less than that into mesoporphyrin.

Ferrochelatase becomes unstable below pH 7.8 and the solubility of porphyrin decreases remarkably below pH 7.4. If enzyme activity is measured below pH 7.4, no activity can be detected even in the presence of fatty acid and glycerol. Thus, enzyme sources should be prepared at a pH of ~8.0 and the enzyme reaction must be carried out at pH 8.0.

Zinc-mesoporphyrin is easily destroyed because dissociation of zinc ion from the mesoporphyrin ring occurs under acidic conditions. Therefore, the use of acidic solutions (pH <4.5) should be avoided throughout all procedures described in this unit.

Sonication of the mixture containing sodium palmitate, mesoporphyrin, and Tween 20 is important to obtain reproducible results. When sonication is insufficient to completely disperse mesoporphyrin into the mixture, the amount of zinc-mesoporphyrin formed varies because the undispersed mesoporphyrin and zinc-mesoporphyrin are precipitated by the addition of methanol/DMSO/EDTA solution. The mixture of mesoporphyrin and palmitic acid should be sonicated prior to use.

Troubleshooting

The main reason for failure to obtain reproducible data of ferrochelatase activity is improper preparation of enzyme sources, especially when using homogenates from cultured cells, bone marrow cells, reticulocytes, and peripheral blood T lymphocytes. Solutions containing 20% glycerol at pH 8.0 are a sine qua non for preparation of homogenates. If an enzyme preparation without glycerol is used, the enzyme activity dramatically decreases with time. When mitochondria from rabbit reticulocytes are left on ice for 1 hr, the activity decreases to 50%; however, addition of glycerol to the enzyme solution markedly maintains the enzyme stability. When mitochondria from tissues are used for the assay, the solution containing glycerol is not needed for the preparation. However, ferrochelatase becomes unstable when mitochondria are solubilized with detergents. The presence of 20% glycerol and 1 mM DTT stabilizes the solubilized enzyme. Reasons for the different stability among enzyme sources are yet to be forthcoming.

Although the present method is the most sensitive and simplest currently available, $\geq 10^6$ cells are needed for triplicate assays. Even if the enzyme preparation is expected to have low activity that requires long incubation, >1 hr incubation time will not lead to a linear enzyme reaction.

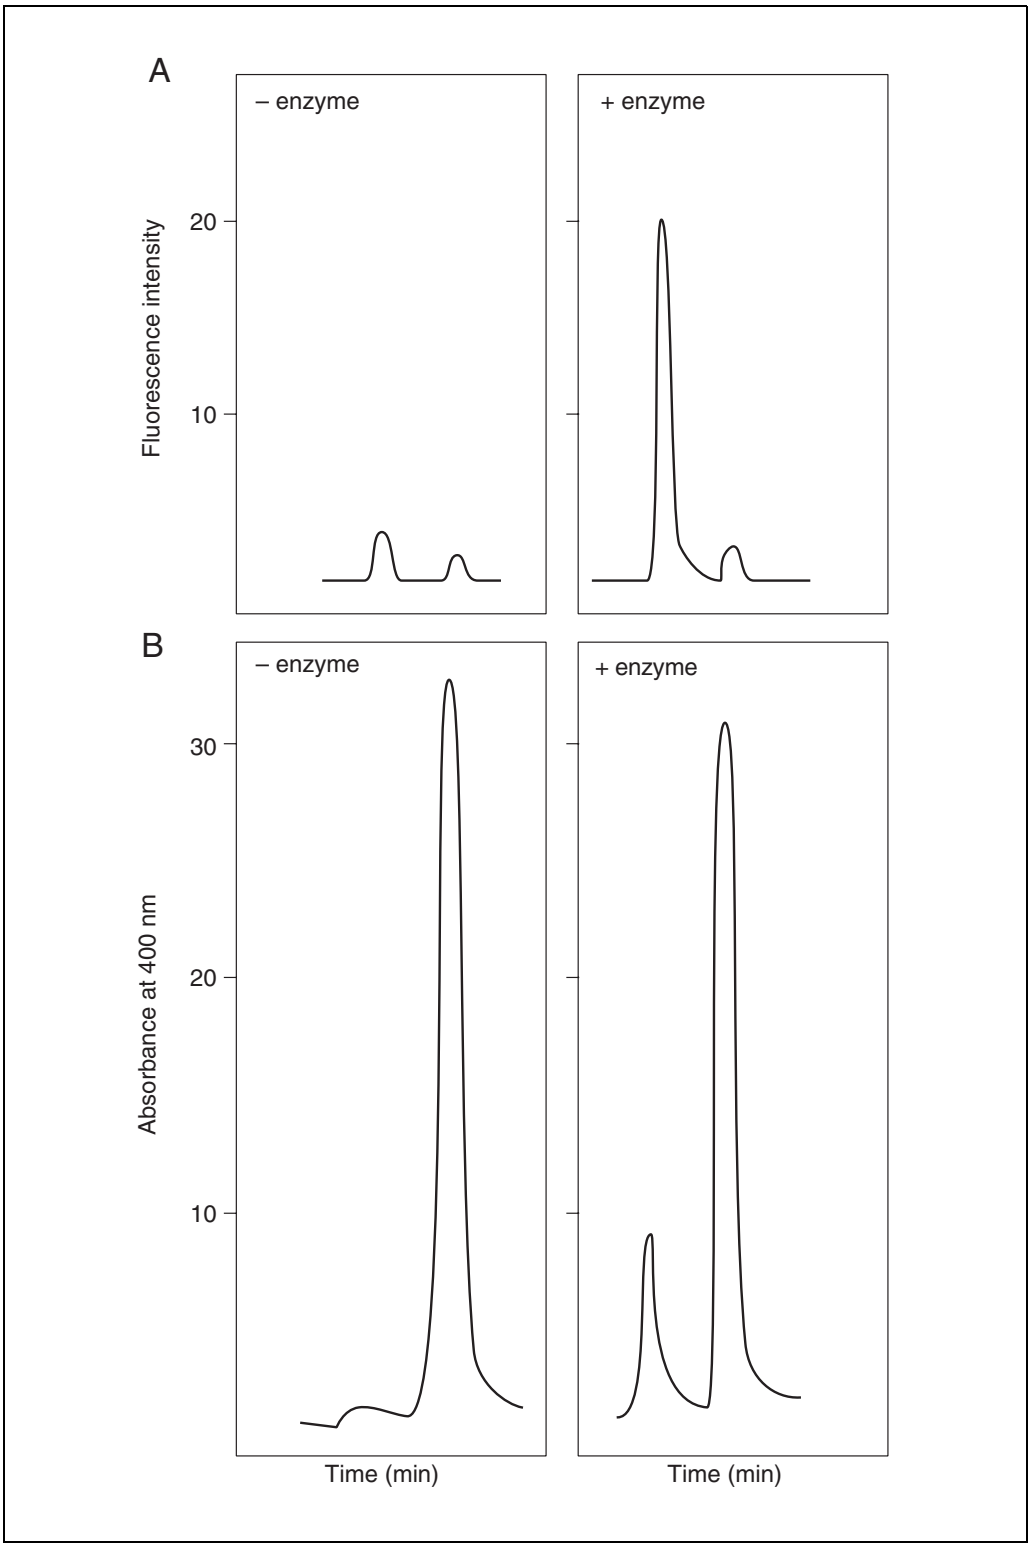

Figure 8.7.1 HPLC analysis of zinc-chelating activity with mouse macrophage RAW264.7 cells (left, no enzyme; right, with enzyme). (**A**) Fluorescence of zinc-mesoporphyrin (first peak) and mesoporphyrin (second peak) with excitation at 410 nm and emission at 580 nm. (**B**) Absorbance of zinc-mesoporphyrin and mesoporphyrin at 400 nm. Assay of ferrochelatase using homogenates (50 μg protein) of RAW264.7 cells and chromatographic conditions are described (see Basic Protocol).

Therefore, incubation time should be limited to 1 hr.

When the enzyme preparation contains a considerable amount of heme, absorbance of endogenous heme can be observed spectrophotometrically at ~400 nm. The retention time of heme by HPLC analysis is located between zinc-mesoporphyrin and mesoporphyrin, and the peak of heme sometimes overlaps that of zinc-mesoporphyrin. Since heme is nonfluorescent, fluorescence of zinc-mesoporphyrin can be measured.

Strong detergents such as Triton X-100 and Nonidet P-40 should never be used in any procedures used for measuring zinc-chelating activity because these compounds have several strong fluorescence-absorbing contaminants that interfere with measurement of zinc-porphyrin by HPLC. Tween 20 is recommended to solubilize porphyrins and to assay ferrochelatase activity because it does not interfere with fluorescence or with visual absorbance.

Anticipated Results

Zinc-chelating activity was measured with homogenates of a mouse macrophage cell line, and formation of zinc-mesoporphyrin was analyzed by HPLC under the conditions described in this unit. Figure 8.7.1 shows separation of zinc-mesoporphyrin from mesoporphyrin by HPLC. Even in the absence of ferrochelatase, a small peak of fluorescence of zinc-mesoporphyrin was observed with emission at 580 nm. Intensity of zinc-mesoporphyrin fluorescence is greatest with excitation at 410 nm and emission at 580 nm, while that of mesoporphyrin is greatest with excitation at 410 nm and emission at 630 nm. Therefore, adjusting the fluorescence spectrophotometer for emission at 630 nm causes a decrease in the intensity of zinc-mesoporphyrin fluorescence, in contrast to the increase in mesoporphyrin fluorescence. By increasing the amounts of ferrochelatase, the peak of zinc-mesoporphyrin increases linearly. At 400 nm, zinc-mesoporphyrin shows parallel increases in absorbance and the intensity of fluorescence. As a standard assay, the above adjustment is suitable for detection of zinc-mesoporphyrin, but the emission can vary between 580 and 630 nm when the enzyme preparation has high activity.

Time Considerations

With acquisition of the cells, triplicate HPLC assays of four samples will require 3 hr to complete. After terminating the assay, ≥30 min are needed to wash the HPLC column with 100% methanol. Preparation of all solutions used for the assay requires 2 to 3 hr, and all solutions can be stored at 4°C for several months. Alternate Protocol 1 requires 2 to 3 hr and Alternate Protocol 2 requires 2 hr.

Measurement of Erythrocyte Protoporphyrin Concentration by Double Extraction and Spectrofluorometry

The scope of this unit is limited to the determination of erythrocyte protoporphyrin (EP) for clinical diagnostic purposes using a primary reference method (see Basic Protocol). This method, which is used by the New York State Department of Health (NYS DOH), is based upon published methods and methods developed by other public health laboratories in the U.S., including the Centers for Disease Control (CDC) and the Wisconsin State Laboratory of Hygiene (WSLH). The method is very similar to that recommended by the National Committee for Clinical Laboratory Standards (NCCLS), except where indicated in the Commentary section (see Background Information). It is recommended for laboratory participants in the EP Proficiency Testing Program operated by the NYS DOH, and is also suitable for use in programs operated by the WSLH and the Pennsylvania Department of Health. This unit also contains protocols for assessing the presence of impurities in ethyl acetate (see Support Protocol 1) and for removing these impurities by glass distillation (see Support Protocol 2).

Procedures for determining EP via direct zinc protoporphyrin (ZPP) fluorescence in whole blood using portable instrumentation based on front-surface fluorometry (i.e., hematofluorometry) are relatively simple and are provided by the instrument manufacturers. Procedures for the separation and determination of specific porphyrin species using liquid chromatographic techniques are not well established and are beyond the scope of this unit.

MEASURING ERYTHROCYTE PROTOPORPHYRIN CONCENTRATION

BASIC PROTOCOL

Porphyrins and heme components are extracted from whole blood into an ethyl acetate/acetic acid mixture. Porphyrins are then separated from heme by back extraction into a hydrochloric acid solution and are quantitatively determined by molecular fluorometry using a spectrofluorometer calibrated with protoporphyrin IX (PPIX) standard solutions. Note, however, that the exact concentration of the standards must first be established using molecular absorbance, Beer's Law, and the millimolar absorptivity of PPIX.

Materials

5-µg protoporphyrin IX standards (Porphyrin Products)
Protosolv (Porphyrin Products)
1.5 M HCl (see recipe)
Blood specimens in 10-ml evacuated collection tubes with EDTA anticoagulant (purple-cap Vacutainers, Becton Dickinson or equivalent)
Quality control (QC) samples
4:1 (v/v) ethyl acetate/acetic acid solution (see recipe)

50-, 100-, and 200-µl fixed-volume micropipets
10-ml glass volumetric pipet (class A preferable)
Light-tight cabinet or box suitable for storing a rack(s) of culture tubes protected from light
UV/visible absorption spectrophotometer equipped with standard 1-cm^2 quartz cells
2-ml glass volumetric flasks (class A preferable) wrapped in aluminum foil
Adjustable or fixed-volume micropipets in the range 400 to 1600 µl

Contributed by Patrick J. Parsons
Current Protocols in Toxicology (1999) 8.8.1-8.8.12

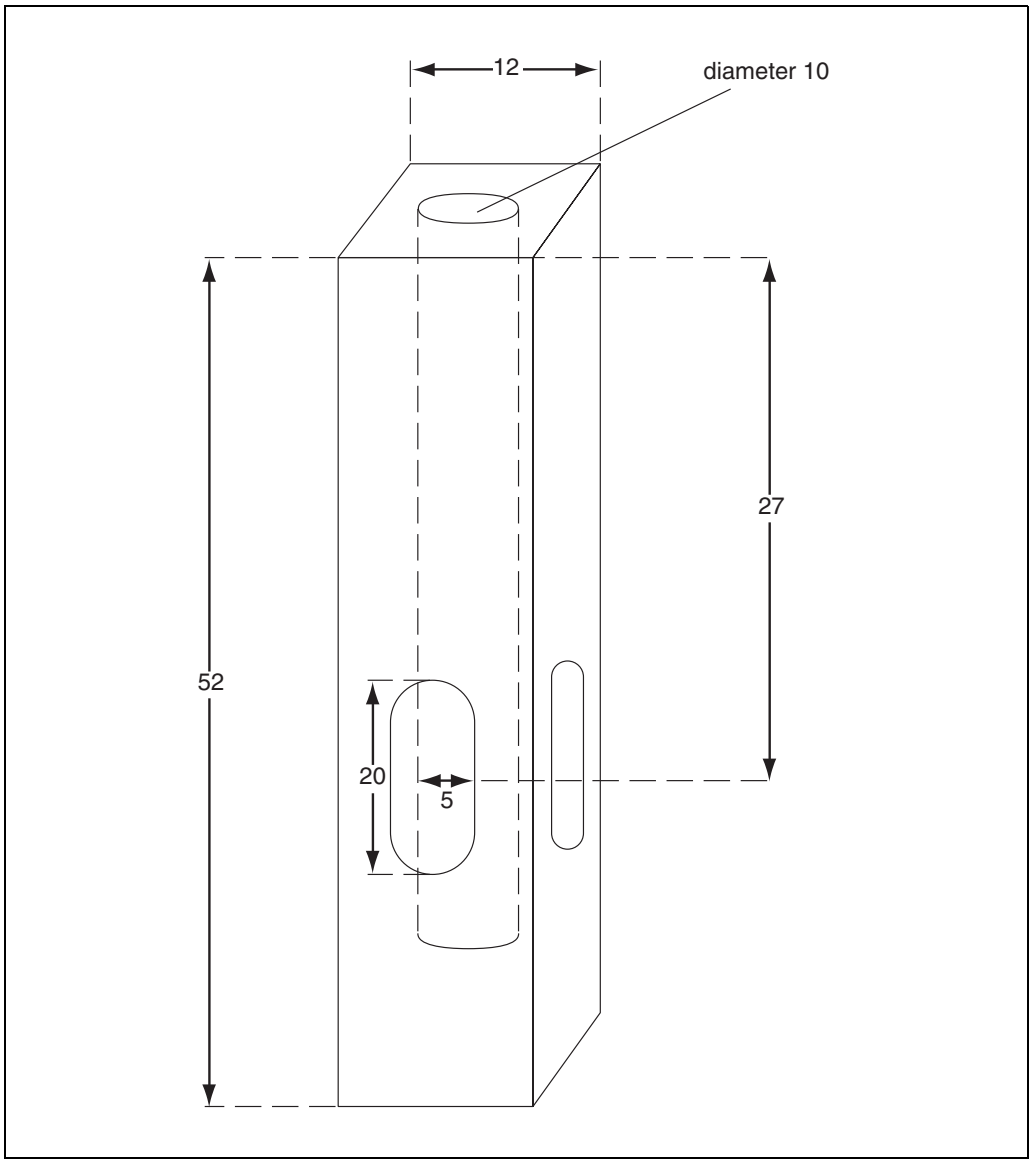

Figure 8.8.1 Schematic diagram of a cell holder modified to accommodate standard 10 × 75–mm glass culture tubes. Note that the holder, which can be easily machined from a 2 × 2 × 7–cm aluminum block, must have entrance/exit windows set at right angles to permit detection of fluorescence from the HCl phase of the extract. Dimensions (in mm) are reprinted from document C42-A (NCCLS, 1996) with permission from the NCCLS.

10 × 75–mm borosilicate glass culture tubes (Kimble, Corning or Scientific Products)

Microplate with 0.5-ml wells

1-liter actinic glass bottle-style pipets (Repipet, Barnstead/Thermolyne or equivalent) with 1-ml glass dispensers

Small benchtop centrifuge suitable for 10 × 75–mm glass culture tubes (Sero-Fuge, Clay Adams or equivalent)

Photographic dark room fluorescent tube filters (e.g., Macolite Toob Gard or EncapSulite safelite filters or equivalent)

Spectrofluorometer equipped with a red-sensitive photomultiplier tube (Hamamatsu R 928 or equivalent) and a cell holder modified to accommodate standard 10 × 75–mm glass culture tubes (Fig. 8.8.1)

NOTE: All plastic materials provided with the dispenser (i.e., uptake tubes and/or dispensing tips of the Repipet dispenser) must be replaced with glass devices to ensure the integrity of the ethyl acetate. This may require the services of a glassblower to modify commercially available devices.

NOTE: Standards and samples must be protected from exposure to bright light as much as possible throughout the procedure. Use yellow photographic filters for fluorescent tube lights. These tube-style filters are placed over standard fluorescent tube lights to reduce exposure from UV wavelengths.

Prepare PPIX calibration standard stock solution

1. Reconstitute 5 µg protoporphyrin IX by adding 100 µl Protosolv to the vial. Mix the contents gently without inverting the tube. Cap the vial and place in a darkened cabinet for 10 min to allow complete dissolution of the material.

   The vial should be capped to reduce loss of volatile components due to evaporation.

   Several alternative reagents may be used in place of the 5-µg PPIX standard, including protoporphyrin IX dimethyl ester or disodium salt (Porphyrin Products, Sigma). The exact concentration must be standardized using molecular absorbance as described below (see steps 3 to 5). Protoporphyrin IX dimethyl ester is hydrolyzed before use (Gunter et al., 1989).

   Some laboratories use coproporphyrin I or coproporphyrin III (Porphyrin Products) as secondary standards because of their greater stability compared to PPIX. Equivalent "protoporphyrin IX" values are assigned to these solutions, which are used to calibrate the spectrofluorometer on a daily basis. However, a correction factor for each new batch of coproporphyrin materials must be determined using PPIX.

2. Add 10 ml of 1.5 M HCl to the vial using a glass pipet and mix the contents by inverting the tube.

   The concentration of protoporphyrin IX is ~50 µg/100 ml.

Measure molecular absorbance of PPIX in the stock solution

3. Fill a 1-cm^2 quartz spectrophotometer cell with PPIX stock solution. Fill a 1-cm^2 spectrophotometer reference cell with 1.5 M HCl.

4. Place the sample and reference cells in an absorbance spectrophotometer and scan the spectrum between 395 and 420 nm. Record the maximum absorbance (A) at λ_{max} of the band relative to HCl.

   A sample spectrum is shown in Figure 8.8.2. Because there may be some variations in the spectrophotometer, it is safest to scan the sample and visually identify the peak to record the absorbance at its maximum.

   The exact mass of PPIX in the tube is not known and is only nominally estimated at 5 µg. Therefore, the molecular absorbance of PPIX in solution is required to calculate the true concentration of the stock solution.

5. Calculate the exact stock concentration (c) of PPIX using the equation c (µg/100 ml) = $A \times 233$.

   This equation is derived by molecular absorbance according to Beer's Law, which says that $A = m\varepsilon cl$, where A is measured absorbance at λ_{max}, $m\varepsilon$ is millimolar absorptivity (241 liters $mmol^{-1}$ cm^{-1}), and l is the cell path length in cm (1 cm). By rearrangement, c (mmol/liter) = $A/m\varepsilon l = A/241$. Using the PPIX relative molecular mass (562.3 g/mol), the equation then becomes c (µg/ml) = $A \times (562.3/241) = A \times 2.33$, or c (µg/100 ml) = $A \times 233$.

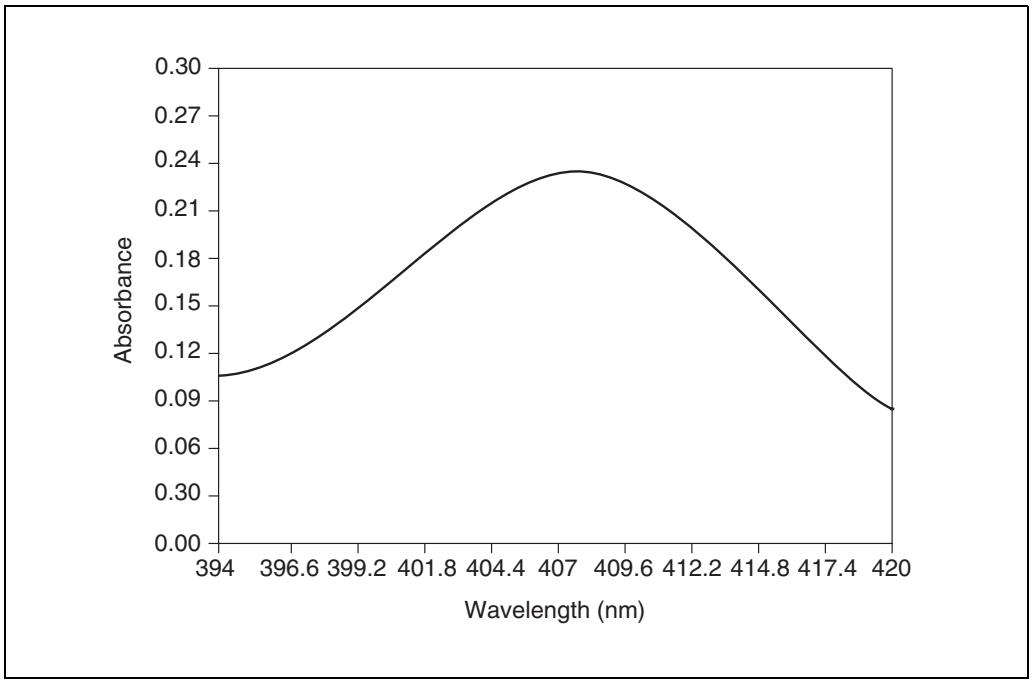

Figure 8.8.2 Typical absorbance band for a PPIX standard solution (51.8 µg/100 ml) in the 395- to 420-nm region of the spectrum. Note that λ_{max} is at 407.0 nm. Scan rate: 300 nm/min.

NOTE: *The 241 value for mε was adopted in the early days of EP testing and was based upon the best available data at the time. Although the correct mε value is now known to be 297 liter mmol^{-1} cm^{-1} (Gunter et al., 1989), the 241 value is still widely used. See Background Information for a more detailed discussion of this issue.*

Prepare working calibration standards

6. Wrap five 2-ml volumetric flasks in aluminum foil to protect the solutions from light.
7. Using an adjustable micropipet, transfer 1600, 1200, 800, and 400 µl stock solution into four flasks and label them 40, 30, 20, and 10 µg/100 ml, respectively. Label the fifth flask as the blank or zero standard.
8. Bring each flask to its 2-ml volume using 1.5 M HCl.

   This yields standards S_t, S_3, S_2, S_1, and S_b respectively, where S_t = top standard and S_b = blank.

9. Transfer 50 µl of each standard into duplicate 10 × 75–mm glass culture tubes. Prepare a third tube for the top standard, S_t.

   The extra S_t is used for adjusting and optimizing the spectrofluorometer.

10. Calculate the exact concentration of each PPIX working standard by multiplying the stock concentration (233 × A; step 5) by the dilution factor (volume of standard added/total volume).

Prepare blood specimens and QC samples

11. Bring all blood specimens and QC samples to room temperature and mix by inversion or by placing them on a rotator.

    Whole blood specimens are obtained either by venipuncture and collected in evacuated tubes (≥2 ml) with EDTA (Vacutainers; Becton Dickinson or equivalent) or by finger stick and collected in a microcollection tube with EDTA (Microtainers; Becton Dickinson or equivalent). Heparinized blood is also acceptable. QC samples are either lyophilized or frozen whole blood.

12. Transfer 200 µl deionized water into a 0.5-ml microplate well (dilution well).
13. Using a micropipet, withdraw 50 µl well-mixed whole blood. Remove any excess blood adhering to the pipet tip by wiping it with a laboratory tissue, being careful not to touch the open end of the tip.
14. Dispense the 50-µl blood sample into the dilution well and mix thoroughly by withdrawing and dispensing (i.e., pumping) the blood/water mixture several times until the solution in the tip appears clear.
15. Using a clean tip, transfer 50 µl diluted blood into a 10 × 75–mm glass culture tube. Prepare all blood specimens and QC samples in duplicate.

Extract calibration standards, blood specimens, and QC samples

16. Using a glass bottle–style pipet, add 1 ml of 4:1 ethyl acetate/acetic acid solution to all standards, QC samples, and blood samples. Thoroughly mix for 10 sec by vortexing.

    To ensure complete mixing, hold the glass tube at the top during vortexing.

17. Centrifuge 3 min at 1000 × *g* (~3000 rpm for a rotor radius of 10 cm), room temperature.
18. Decant each supernatant into a clean glass culture tube making sure the last drop is transferred by touching the two tubes. Discard the tube containing the cell debris.
19. Using another glass bottle–style pipet, transfer 1.0 ml of 1.5 M HCl to each sample and standard. Mix for 10 sec by vortexing.
20. Centrifuge 1 min at 1000 × *g*, room temperature.

    Two distinct liquid phases, ethyl acetate/acetic acid (brown) and HCl (clear), should be clearly visible.

21. Clean the surface of each tube with a laboratory tissue to remove any dust, grease, or fingerprints. Store extracted samples in a light-tight box while the spectrofluorometer is being calibrated.

    This tube will function as the sample cell when inserted into the cell holder of the spectrofluorometer.

Take fluorescence readings

22. Ensure that the excitation lamp of a spectrofluorometer is properly aligned. Set the slit width to 10 nm and adjust the gain accordingly.

    NOTE: *Spectrofluorometers vary from one manufacturer to another. Consult the operator's manual to optimize the various parameters. The instrument should be equipped with a red-sensitive detector (e.g., a photomultiplier tube) capable of enhanced sensitivity above 600 nm.*

23. For older spectrofluoromotors, where the monochromator is adjusted manually, set the excitation wavelength to 408 nm and use the extra S_t tube to scan the emission wavelength from 645 to 680 nm to locate the precise wavelength for maximum intensity. With modern computer-controlled instruments, this step may not be necessary.

    NOTE: *A scan of PPIX fluorescence spectrum shows two bands: one at 662 nm and another at 607 nm (Fig. 8.8.3). The 607-nm band is more intense than the one at 662 nm, which is broader and much easier to peak, although a little less sensitive. One consequence of the improved sensitivity of the 607-nm band is decreased precision. Since sensitivity is not a critical issue in this analysis, the improvement in precision at the 662-nm band is preferred.*

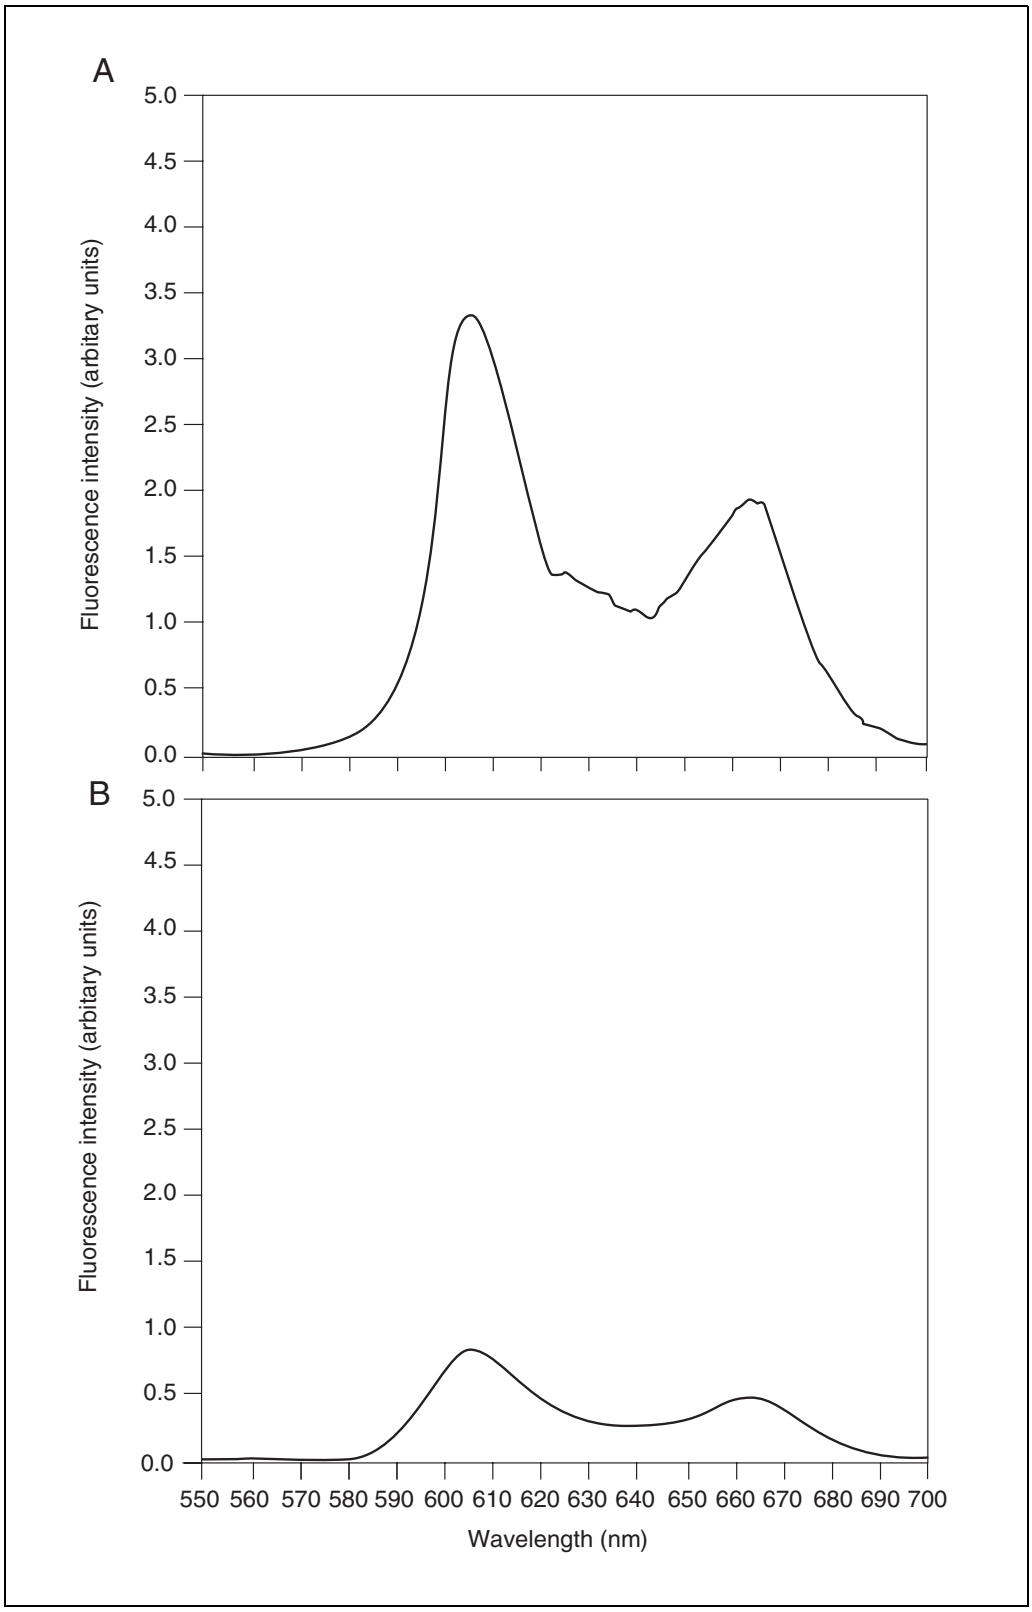

Figure 8.8.3 Typical fluorescence spectra for (**A**) a PPIX standard solution (52.9 μg/100 ml) and (**B**) an extracted human blood sample containing free erythrocyte protoporphyrin. Both measurements were made using a Perkin-Elmer LS5OB Luminescence spectrophotometer with excitation at 408 nm and a slit width of 10 nm.

24. Use one of the blank tubes (S_b) to "blank adjust" the instrument to zero. Check that the zero standard has no fluorescence relative to deionized water.

    If the blank does fluoresce, the reagents may contain interfering fluorescent materials.

25. Analyze standards in duplicate and in the sequence S_b, S_1, S_2, S_3, S_t.

26. Run any secondary standards or QC samples following the primary standards. Ensure that the results for any QC samples are within an acceptable range before continuing with blood samples for clinical testing.

    Acceptable standards are ±6 μg/100 ml or ±15%, whichever is greater.

27. Analyze all blood samples in duplicate.

Calculate PPIX concentration in samples

28. Prepare a standard curve by plotting the relative fluorescence intensity for each calibration standard (y axis) versus the exact PPIX concentration (step 10; x axis).

29. Compute the line of best fit ($y = mx + b$) by least-squares linear regression.

30. Calculate the PPIX concentration in diluted blood from the line of best fit. Multiply this value by 5.2 to account for the extraction efficiency (96% or 1.04 in whole blood) and the 5-fold dilution of blood with water.

    There are conflicting views on the efficiency of extracting porphyrins from whole blood samples. Unpublished data from the author's laboratory based on fifteen diluted blood samples repeatedly extracted with three successive aliquots of ethyl acetate/acetic acid solution showed that 96% ± 1% of the total extractable protoporphyrin was recovered in the first extraction. Thus, one can assume that the extraction efficiency is 96% provided that all extractable protoporphyrin was removed in the three successive extractions, and that the distribution of protoporphyrin IX between the aqueous and organic phases is the same for blood extracts and aqueous PPIX standards. At the present time, there are no reports of any residual protoporphyrin in the extracted cell debris.

    The top standard, S_t, is equivalent to a blood sample with an EP concentration ~200 μg/100 ml (taking into account the 5-fold dilution of blood samples). If any samples or control materials have fluorescence intensities above the top standard, additional dilution will be necessary. A 500-μl aliquot of the clear aqueous HCl phase of the final extract should be transferred, using a 500-μl fixed-volume pipet, into a clean glass culture tube. This is diluted with 2 ml of 1.5 M HCl and vortexed for 3 sec. The reduced fluorescence intensity is measured and the EP concentration is multiplied by another factor of 5 to correct for the additional dilution.

IDENTIFYING AND RESOLVING PROBLEMS WITH ETHYL ACETATE QUALITY

Some commercial supplies of ethyl acetate contain impurities such as oxidizing agents that can quench PPIX fluorescence, thus reducing relative fluorescence intensity. The problem almost always appears as low or inconsistent results for internal or external QC samples. Some problems can be traced to the use of plastic laboratory ware. All ethyl acetate solutions should be stored in glass bottles rather than plastic, as ethyl acetate can leach materials that quench fluorescence. Using clean, acid-washed, well-dried glass apparatuses for all reagents and procedures will eliminate many problems. If the problem cannot be traced to plastic ware, then the quality of the ethyl acetate used for the extraction is suspect. It is preferable to purchase bottles containing two liters or less because ethyl acetate that is left exposed to air may become oxidized, thus producing quenching agents. One test that can indicate the potential for a problem with quenching agents is the

potassium iodide (KI) test (see Support Protocol 1). If the KI test is positive, the ethyl acetate can be redistilled from glass in the laboratory (see Support Protocol 2).

SUPPORT PROTOCOL 1

Testing Ethyl Acetate Stock For Quenching Impurities

Materials

Potassium iodide
Ethyl acetate to be tested

1. Prepare a 10% (w/v) potassium iodide solution by dissolving 10 g KI in 100 ml water. Use only for the KI test and discard immediately after use.
2. Transfer 50 ml ethyl acetate into a 100-ml glass beaker and place it on a white surface (e.g., paper).
3. Add 10 ml of 10% KI solution, swirl to mix, and examine the color.

   A distinct yellow color, due to the oxidation of iodide, indicates that the ethyl acetate stock contains impurities that will quench PPIX fluorescence. Avoid using any ethyl acetate batch that yields a positive KI test. Use only supplies that do not produce a yellow color upon addition of 10% KI. If a suitable clean supply of ethyl acetate cannot be located, the material can be cleaned as described below (see Support Protocol 2).

SUPPORT PROTOCOL 2

Ethyl Acetate Cleanup by Glass Distillation

Materials

Ethyl acetate
2-liter round-bottom glass boiling flask (standard taper 24/40)
Teflon boiling stones
Column and condenser apparatus, including:
~15-inch glass fractionation column with standard taper 24/40 ground-glass joints, wrapped
in insulation and aluminum foil
~15-inch glass condenser with elbow to connect with collection vessel (standard taper 24/40)
2 ring stands and a lab jack
500-W heating mantle (Glas-Col or equivalent)
Rheostat (0-120 V output, 1500 W; Glas-Col or equivalent)
2-liter glass collection bottle with standard taper 24/40 ground glass joint opening

CAUTION: This is a hazardous procedure that must be done under a laboratory hood. Ethyl acetate and its vapors are highly flammable. When a bad batch of ethyl acetate has been identified, all pipet bottles should be washed with a clean batch to prevent cross-contamination.

1. Pour 1.5 liters commercial ethyl acetate into a 2-liter round-bottom flask. Add a few Teflon boiling stones.
2. Connect flask to a column and condenser arrangement. Turn on the water flow to the condenser.
3. Set the rheostat to an arbitrary setting of 75 until the ethyl acetate is almost boiling. Decrease heating to arbitrary setting 65.

   Don't heat the flask too rapidly at the start or ethyl acetate will be ejected directly up into the fractionating column.

   Condensed ethyl acetate should be produced steadily as rapid but distinct drops.

4. Discard the first 100 to 200 ml condensate. Use to rinse the collection/storage bottles.

   CAUTION: *Do not allow the flask to boil dry; this is not only hazardous but will require starting over. To avoid this problem, use a timer and decrease the heating rate further upon collecting ~800 ml.*

5. Collect ~1.0 to 1.2 liters condensed ethyl acetate and transfer to a clean, amber bottle. Store up to 1 month at room temperature.

   The procedure may be repeated one more time without emptying the round-bottomed flask.

   Even after redistillation, always check the ethyl acetate reagent before use by repeating the KI test.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ethyl acetate/acetic acid solution, 4:1 (v/v)

Pour 800 ml ethyl acetate into a 1-liter graduated cylinder. Add 200 ml glacial acetic acid (trace metal grade; Baker InstraAnalytical grade or equivalent). Stir well with a clean glass rod and pour into a 1-liter glass bottle–type pipet. Store up to 1 month at room temperature.

Hydrochloric acid (HCl), 1.5 M

Pour 500 ml water into a 1-liter class A volumetric flask. Carefully add 125 ml concentrated HCl (trace metal grade; Baker InstraAnalytical grade or equivalent) using a graduated cylinder. Dilute to volume with water, mix, and transfer to a bottle-type dispenser. Store up to 1 month at room temperature.

COMMENTARY

Background Information

The measurement of erythrocyte protoporphyrin (EP) for clinical testing purposes received much attention between 1970 and 1990, largely as a result of its application as a screening test for childhood lead poisoning. Lead interferes with the incorporation of iron into the porphyrin ring to form heme, a reaction catalyzed by the enzyme ferrochelatase (*UNIT 8.7*). This disruption of the final stage in heme biosynthesis leads to an accumulation of zinc protoporphyrin (ZPP) within the red blood cell. During the analysis for EP, the ZPP component, along with heme and any uncomplexed or "free" protoporphyrin, is extracted from blood using a mixture of ethyl acetate and acetic acid. The protoporphyrin is measured using fluorescence spectrometry. This method of analysis for EP has been in the literature for almost 40 years (Schwartz et al., 1960). In subsequent publications, the name "free erythrocyte protoporphyrin" (FEP) was coined to reflect that, in acid solution, the ZPP molecule dissociates to form "free" protoporphyrin IX and "free" zinc(II) ions. Thus, in ethyl acetate/acetic acid extraction methods, total EP is measured.

Working independently, several investigators (Kammholz et al., 1972; Piomelli, 1973; Sassa et al., 1973) published micromethods for EP analysis based on extraction with a mixture of ethyl acetate/acetic acid followed by determination using spectrofluorometry. Significant improvements to these methods were published (Chisolm and Brown, 1975) along with a recommendation to determine the exact concentration of the PPIX standard solutions using absorbance, Beer's Law, and a PPIX millimolar absorptivity of 241 liters $mmol^{-1}$ cm^{-1}.

The main advantage of these micromethods was that only small blood volumes (<50 µl) were required for the EP analysis, thus making it possible to conduct mass screening of children for exposure to lead. Other advantages were that the laboratory equipment required to set up the EP test was relatively inexpensive, and that the test did not suffer from the contamination errors that plagued early blood lead methods.

Prior to 1975, a blood lead concentration of ≥50 μg/dl was considered harmful to children. The EP test had good diagnostic sensitivity for predicting underlying exposure to lead at blood lead levels >30 μg/dl. The EP test was recommended by the CDC in 1975 for screening children for lead poisoning, and again in 1978, when the blood lead threshold was lowered to 30 μg/dl (CDC, 1975, 1978). In 1985, when the safe pediatric blood lead level was lowered to 25 μg/dl, the EP threshold was lowered from 40 to 35 μg/dl in line with concerns about the diagnostic accuracy of the test for predicting lower blood lead levels (CDC, 1985). When the CDC lowered the blood lead threshold to 10 μg/dl (CDC, 1991), it was evident that the EP test was no longer adequate as a predictor of underlying lead exposure (Parsons et al., 1991) and the CDC recommended that EP be replaced by a direct blood lead test.

During the 1970s, portable instrumentation was developed for the direct determination of ZPP in a single drop of blood (Blumberg et al., 1977a,b). These portable instruments, which were based on front-surface fluorometry, became known as hematofluorometers and were widely used to conduct on-site screening of children for lead poisoning. With the demise of the EP test in recent years, hematofluorometer use has declined, although the EP test still remains clinically useful in the identification of iron-deficiency anemia and in diagnosing inherited disorders of heme metabolism (e.g., erythropoietic porphyria).

Most recently, the National Committee for Clinical Laboratory Standards (NCCLS, 1996) has issued an approved guideline for EP testing. The NCCLS guideline includes a consensus method for determination of EP by ethyl acetate acetic/acid extraction that recommends using a millimolar absorptivity value (mε) of 297 liters $mmol^{-1}$ cm^{-1}. The 241 mε value was originally used by Chisolm and Brown (1975) and was based upon the best available data at the time, although numerous discrepancies were reported in the literature. However, it was not until 1989 that the correct mε value for PPIX (297 liters $mmol^{-1}$ cm^{-1}) was published (Gunter et al., 1989). Unfortunately, it has not been possible to change the long-standing practice of clinical laboratories and proficiency testing (PT) programs in the U.S. that are using the 241 value. In addition, as a vast literature and clinical database now exist for EP using the 241 mε value, there is little enthusiasm for correcting this "historical error" in the EP test.

Other differences between the NCCLS method and that described here are minor. They include decanting the product of the primary extraction of PPIX and heme components into a second culture tube for the back-extraction step with HCl, and the absence of an arithmetic correction for individual patient hematocrit or hemoglobin levels. All EP results obtained using the method described here are reported as μg/100 ml (μg/dl) of whole blood. Currently, there are three PT programs in the U.S., and all require that EP results be reported as μg/dl whole blood using the mε value of 241; no correction for hematocrit or hemoglobin is required.

Individual porphyrin species such as ZPP, PPIX, and coproporphyrin can be successfully determined in blood and urine by liquid chromatographic (LC) techniques. A number of early papers described LC methods based on separating porphyrin species on a reversed-phase column with fluorometric detection (Smith et al., 1980; Scoble et al., 1981; Chiba and Sassa, 1982). A comparison between fluorescence and absorbance detectors showed clearly that the former has better sensitivity, specificity, and reproducibility (Sagen and Romslo, 1985). Later papers have described improvements in LC methods that have used more selective extraction procedures (Ho et al., 1987) and have incorporated a more effective specimen pretreatment procedure coupled with gradient elution (Bowers et al., 1992). More recently, Sato et al. (1994) compared a conventional reversed-phased LC method (Smith et al., 1980) with a new LC method based upon elution of porphyrins on a porous polystyrene gel with a diisopropylamine/water/methanol mobile phase. They reported significant improvements over the conventional LC method including the ability to distinguish between the protoporphyrin emission peak and quenching due to heme, thus making removal of heme unnecessary. They also reported that the conventional LC method overestimated EP concentrations below 5 ng/100 ml, possibly due to dissociation of ZPP in an acid medium which yields additional protoporphyrin.

Critical Parameters and Troubleshooting

The most frequent source of problems with this analysis can be traced to the quality of the ethyl acetate supplies used for the extraction reagent (Doran and Mitchell, 1984). Impurities in this reagent can cause fluorescence quench-

ing, which leads to erroneously low results. The KI test for impurities (see Support Protocol 1) is generally reliable in this respect, but results can be misleading because of the subjective nature of the color intensity. If the quality of the ethyl acetate is suspect and the KI test is inconclusive or, perhaps weakly positive, the ethyl acetate should be redistilled or obtained from an alternative supply.

The protection of blood samples and reagents from exposure to bright lights, particularly sunlight or fluorescent tube light, is highly desirable as porphyrins are susceptible to photooxidation, which can result in erroneously low values. Blood samples are easily protected by wrapping them in aluminum foil. Avoid using plastic microcollection devices with protective filters for bilirubin measurements. These filters do not protect blood samples for the EP assay. In the laboratory, using low-cost photographic filters (which fit over standard fluorescent tubes) and reduced UV radiation are a convenient way of reducing photooxidation of samples and reagents. Extracted blood samples and standard solutions should be stored in a light-tight box while the spectrofluorometer is calibrated.

The use of plasticware in the laboratory should be avoided, as organic reagents may leach out impurities that can interfere in the analysis. This may require some modifications to ensure that all-glass pipet bottles are used. The key to success is to ensure that all laboratory ware is thoroughly clean and well dried before use. Access to reliable quality control materials is essential to assuring that clinical results are reliable. The availability of such materials is becoming more difficult as the test becomes less widely used. Thus, the onus is on the laboratory performing the test to develop such materials. The operators of the PT programs for EP may be able to help in this respect. One alternative is to prepare QC materials in house and to validate them through interlaboratory studies.

Anticipated Results

The absorbance measurement of PPIX standard solutions should result in a single band with λ_{max} at 407 nm as shown in Figure 8.8.2. The fluorescence spectra expected for PPIX in standard solutions and in extracted blood samples are shown in Figure 8.8.3. Quantitative results for EP quality control materials should fall within ±6 µg/dl of the target value for concentrations <40 µg/dl, or within ±15% of the target for values ≥40 µg/dl. These criteria are currently the same as those expected of participants in several U.S. PT for EP.

Normal clinical test results for EP vary slightly between men, women, and children based upon data derived from the Second National Health and Nutrition Examination Survey studies (NHANES II; Yip et al., 1984). However, the NHANES II data were calculated with an mε value of 297, and a correction must be made to convert those data into equivalent EP results measured using the 241 value. After excluding those subjects with iron-deficiency anemia and elevated blood lead levels (NCCLS, 1996), the 95th percentile NHANES data for men, women, and children yields rounded upper threshold values of 35, 37, and 38 µg/dl whole blood, respectively. Note that these values are close to the most commonly accepted upper threshold value for EP, 35 µg/dl whole blood, recommended by the CDC in their 1985 document for screening children exposed to lead.

Time Considerations

The limited stability of PPIX standards in acid solution (a matter of hours rather than days) requires some attention to timing. For example, it is unwise to perform sample extractions before the instrumentation has been set up, calibrated, and optimized. If at all possible, the sample and standard extractions and the fluorometric readings should be carried out in a single operation and not separated by a long interval (e.g., a lunch break). The entire procedure, including reporting results, can be easily accomplished in a typical 8-hr day if no problems are encountered. The number of blood samples that can be processed in a typical day will depend on the technologist's skills, but usually can be up to 50 in duplicate including calibration and quality control.

HPLC Methods for Analysis of Porphyrins in Biological Media

Porphyrins are formed as intermediates in the biosynthesis of heme (see Fig. 8.9.1). This process takes place in essentially all eukaryotic tissues. In mammalian, avian, and aquatic species, heme biosynthesis is characterized by formation of porphyrins with 8, 7, 6, 5, 4, and 2 carboxyl groups. Formation of 8-carboxylporphyrin(ogen), or uroporphyrinogen, is mediated by the catalytic activities of δ-aminolevulinic acid (ALA) synthetase, ALA dehydratase, porphobilinogen deaminase, and uroporphyrinogen III synthetase, while the successive decarboxylation and subsequent oxidation of 8-carboxylporphyrinogen to 2-carboxylporphyrin (protoporphyrin) are mediated by uroporphyrinogen decarboxylase, coproporphyrinogen oxidase, and protoporphyrinogen oxidase, respectively. Incorporation of ferrous iron (Fe^{2+}) into protoporphyrin to form heme is catalyzed by ferrochelatase (heme synthetase).

Differential alteration of heme biosynthetic pathway enzyme activities by drugs or environmental chemicals may result in changes in urinary, blood, fecal, and/or tissue porphyrin excretion patterns as well as in altered porphyrin concentrations in target tissues. Changes in tissue or excreta porphyrin levels are potentially useful, both in the diagnosis of chemical effects and as an indicator of toxicant exposure. The measurement of porphyrins in this manner requires a relatively rapid and efficient method of porphyrin recovery from biological media as well as a sensitive and readily applicable procedure for porphyrin separation and quantitation.

This unit describes analytical procedures for the extraction of porphyrins from urine, feces, blood, and tissues (Support Protocol 1 to 7). Each extraction procedure differs somewhat from the others, because biological media vary in the complexity of the matrix from which porphyrins must be extracted. The protocols described below maximize the recovery of porphyrins from the specific medium under consideration. An HPLC-spectrofluorometric procedure (see Basic Protocol) is also described which provides for the quantitative separation and analysis of porphyrins that have been extracted from any biological medium.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

SEPARATION AND QUANTITATION OF PORPHYRINS BY HPLC

BASIC PROTOCOL

Naturally occurring porphyrins may be separated according to the number of carboxyl groups. The analysis of porphyrins extracated from biological fluids and tissues (see Support Protocols 1 to 7) by HPLC provides characteristic profiles and facilitates rapid diagnosis of inherited or chemically induced disorders of porphyrin metabolism.

Materials

Porphyrin extract (see Support Protocol 5, 6, or 7)
Combined porphyrin standard: Porphyrin Acid Chromatographic Marker Kit (Porphyrin Products)
HPLC-grade methanol
0.05 M sodium phosphate buffer, pH 3.5 (see recipe)
Helium (for sparging or degassing mobile phase solutions)
HPLC system equipped with two programmable solvent-metering pumps, a gradient programmer, an automatic variable volume sample injector, and a fluorescence detector

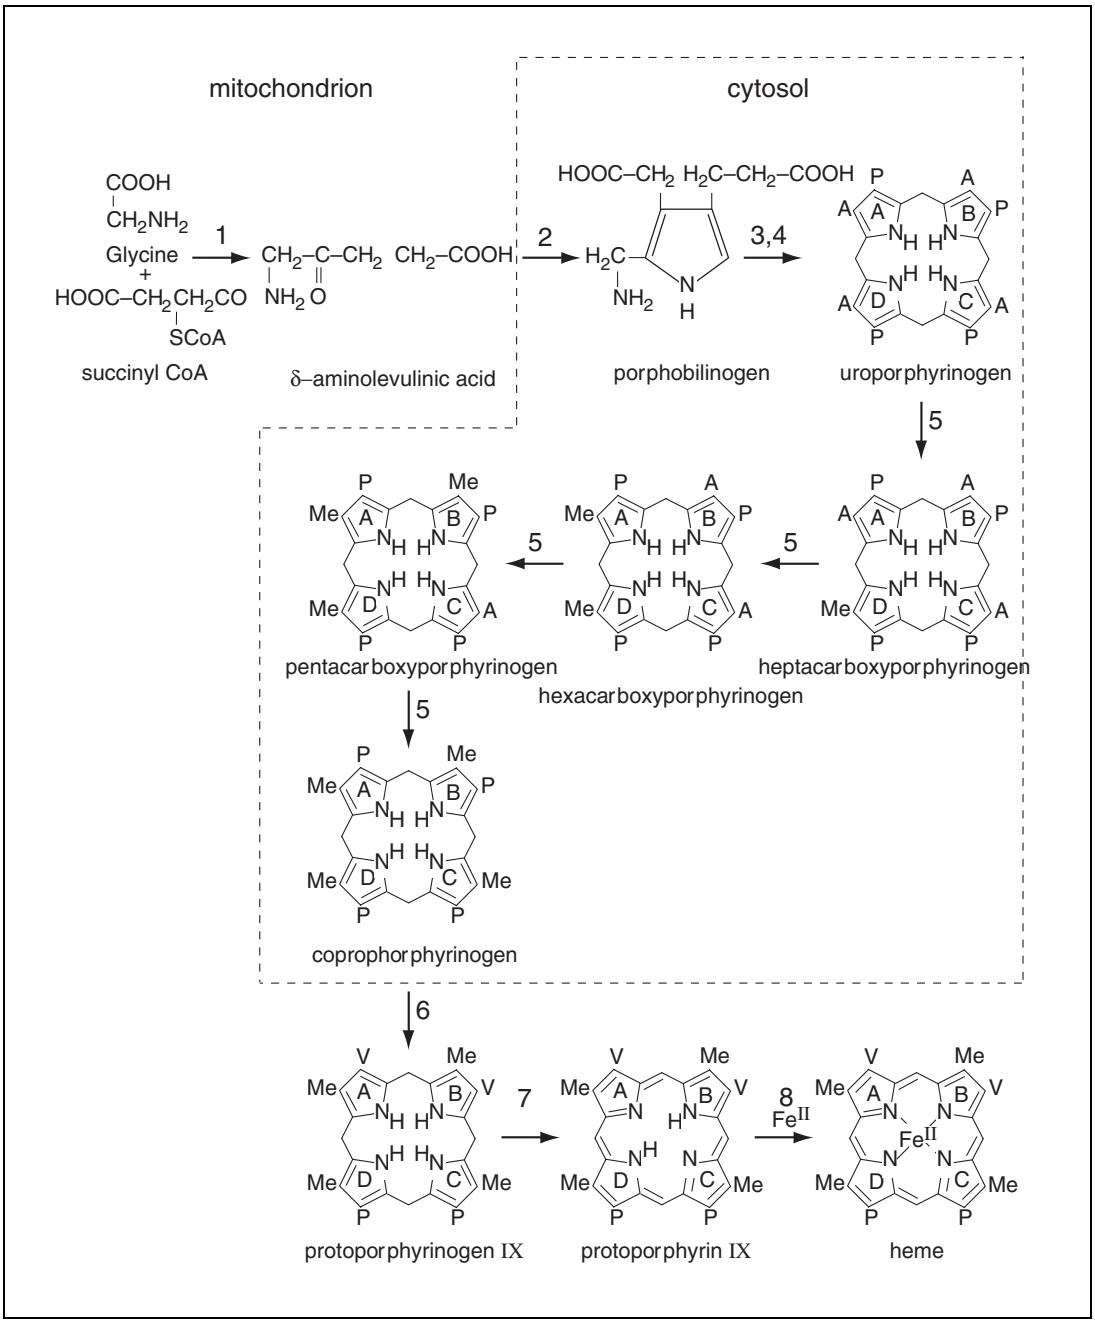

Figure 8.9.1 Role of porphyrins in biosynthesis of heme. Abbreviations: A, acetic acid; Me, methyl; P, propionic acid; V, vinyl.

C-18 250 × 4.6–mm 5-µm analytical HPLC column (e.g., Alltech Econosphere) and SS prefilter element (frit)
C-18 guard column
Column heater
Amber HPLC vials, caps and 300- to 500-µl inserts (size appropriate for specific instrument employed by the investigator)
Filters for mobile phase solvents (Millipore, type HVLP, 0.45-µm)

Perform HPLC separation

1. Initially, use a 10-µl (animal) or 50-µl (human) volume sample of the urinary porphyrin extract for HPLC-spectrofluorometric analysis. For tissue or excreta

Table 8.9.1 Mobile Phase Gradient Program[a]

Time (min)	Reservoir A (methanol)	Reservoir B (buffer)
0	50	50
4	65	35
8	85	15
22	99	1
27	10	90
28	10	90
30	50	50

[a]Filter and degas A and B just prior to use.

porphyrin determinations, use a 50- to 100-µl volume sample of porphyrin extract, whereas for blood, use a 10-µl sample.

Typically, porphyrin concentrations in rodent urine are up to 10-fold greater than those in human urine. Hence, a smaller volume of rodent urine extract may be employed for HPLC analysis. It may be necessary to determine empirically what volume of extract works best for porphyrin measurements by the analytical system employed by the individual investigator.

2. Prior to initiation of sample injections, calibrate the peak integration system by first injecting 50 µl of a combined porphyrin standard onto the column, with each of the six porphyrins in the standard mixture representing 50 pmol.
3. Inject the samples.

   Samples are most effectively injected onto the HPLC column using an autosampler that features an automatic injection system, such as the Waters 717 Plus Autosampler. For extended-run periods (overnight, week-ends) in which samples are loaded hours prior to the actual time of injection, employ an autosampler that has a temperature control feature, so that the samples can be maintained at a constant temperature (15°C or less) to prevent thermal decomposition of porphyrins prior to measurement.

4. Following injection, separate porphyrins using a gradient mobile phase in which reservoir A contains 100% HPLC-grade methanol and reservoir B contains 0.05 mM monobasic sodium phosphate, pH 3.5.
   a. Program the gradient as shown in Table 8.9.1. Use a flow rate of 1.0 ml per min.
   b. Maintain the column at 40°C during all operations using a column heater.
   c. Continuously sparge (degas) fluids in both reservoirs with helium throughout the HPLC operation in order to prevent gas build-up in the pump heads with subsequent erosion of solvent delivery and flow.

   This program provides for the separation and quantitation of 8-, 7-, 6-, 5-, 4-, and 2-carboxyl porphyrins with a sensitivity to detect 0.5 pmol. Complete resolution of all porphyrins is achieved within 25 min following sample injection (see Fig. 8.9.2).

Detect and quantitate porphyrins spectrophotometrically

5. Using a fluorescence monitor (such as the Waters model 474) that is interfaced with the outflow of the HPLC column, detect porphyrins by exciting at the wavelength of the Soret region, 390 to 410 nm, and measuring the emission at 600 to 630 nm.

   Each porphyrin responds maximally at slightly different excitation and emission wavelengths. Initially, set the excitation wavelength at 395 nm and the emission wavelength to 620 nm. Under most circumstances, these settings allow the determination of 8- through 2-carboxyl porphyrins, as well as zinc protoporphyrin, with enough sensitivity to detect 0.5 pmol. The investigator should determine empirically the optimal settings for the specific detection equipment employed.

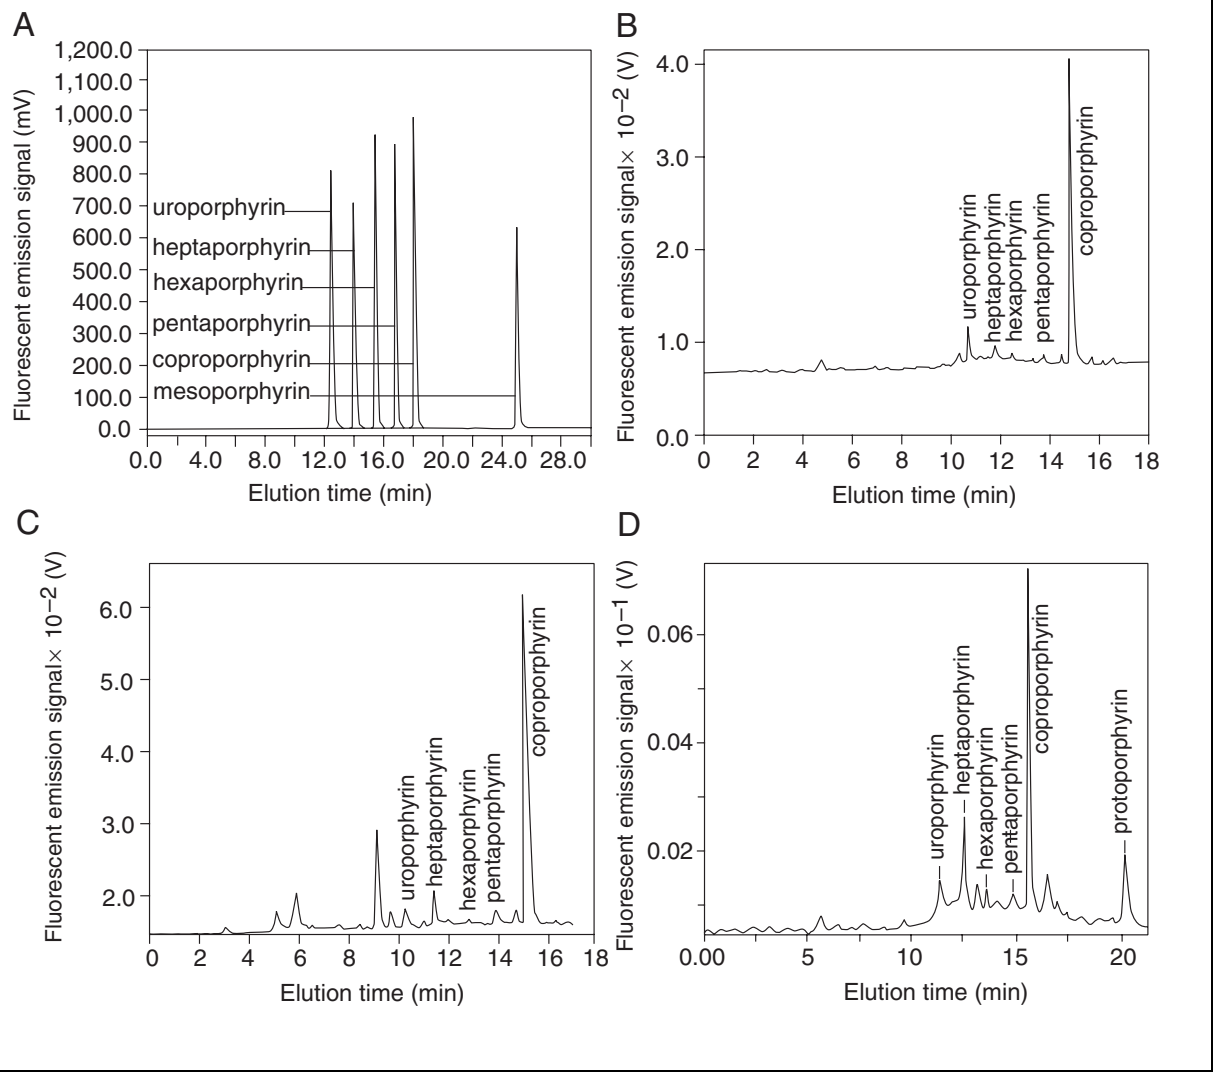

Figure 8.9.2 Anticipated chromatograms from: (**A**) porphyrin chromatographic acid standards, 100 pmol each, injection volume, 25 µl; (**B**) male human urine, injection volume, 50 µl (Bowers et al., 1992a); (**C**) Fischer 344 male rat urine, injection volume, 50 µl (Bowers et al., 1992a);(**D**) Fischer 344 male rat liver, injection volume, 50 µl (Woods and Miller, 1993).

SAMPLE COLLECTION PROCEDURES FOR PORPHYRINS

SUPPORT PROTOCOL 1

Animal Urine

Urine samples from rodents and other animal species are most effectively collected from metabolism cages that are designed to house individual animals and that permit separation of urine from feces, spilled food, hair, and other solid contaminants.

Materials

Sodium bicarbonate
Disodium EDTA
Test animals
Distilled water

Metabolism cages (Hoeltge, Inc.) that permit separation of urine from feces and other solid materials
Graduated polypropylene flasks (50-, 100-ml, or larger depending of size of animal used)

1. Before beginning urine collections, add ~50 mg sodium bicarbonate and ~4 mg disodium EDTA to each urine collection container.

   The bicarbonate prevents coprecipitation of porphyrins, which sometimes occurs at the acid pH of urine, and the EDTA precludes possible complexation of porphyrins with metals that might be present in the urine.

2. Collect a 24-hr urine sample under light-proof conditions (to avoid photochemical oxidation of urinary porphyrins over the collection period) using either dark colored or foil-wrapped glass or polypropylene flasks of sufficient size to permit collection of the entire sample. Position the flask immediately under the outlet of the collection funnel that is mounted beneath the floor of the wire-bottomed cage. Allow animals free access to drinking water during the collection period, but take care to ensure that drinking water cannot spill into the urine sample.

   For mice or rats, graduated 50- or 100-ml flasks are sufficient for the anticipated 10 to 30 ml 24-hr urine excretion volume. It is not necessary to keep the flasks on ice during the collection period if the room temperature is maintained at 21°C (70°F) or less.

3. At the end of the collection period, measure the total urine volume in each flask.

   If the total 24-hr sample is <10 ml and/or appears to be contaminated with feces, food, or other solid matter, it should not be used.

4. Either process the urine for porphyrin analysis immediately following collection (see Support Protocol 5), or freeze it at −20°C until analysis can be performed (preferably within 2 weeks).

   If it is anticipated that porphyrins will not be measured within a 2-week period following collection, freeze the samples at −80°C until analysis can be performed. Samples can be retained at −80°C for up to 6 months without significant porphyrin deterioration.

Human Urine

SUPPORT PROTOCOL 2

Human urine samples for porphyrin analysis can be collected in standard 100-ml clinical urine collection cups. While 24-hr samples are preferred for clinical studies, randomly collected "spot" urine samples are sufficient for porphyrin determination, if collected from all subjects at the same time of day.

Materials

Sodium bicarbonate
Disodium EDTA
Human subject(s)
100-ml clinical urine collection cups with orange screw-on lids (one per subject per void; Starplex Scientific, Fisher)
2.5-liter dark brown polypropylene bottles with screw-on lids (one per subject per 24-hr period; Biomedical Polymers, VWR)
Female urinals (as required; Commode Specimen Collection System, Fisher)

1. Add ~250 mg of sodium bicarbonate and ~25 mg of disodium EDTA to the containers that are used to collect human urine (either the clinical collection cup for spot samples or the larger 2.5-liter bottle for the 24-hr collection).

The bicarbonate prevents coprecipitation of porphyrins, which sometimes occurs at the acid pH of urine, and the EDTA precludes possible complexation of porphyrins with metals that might be present in the urine.

2. Collect urine samples from subjects in collection cups or female urinals. If 24-hr urine collections are required, then combine all separate urine voids that are collected over a 24-hr period in a single opaque (brown) 2.5-liter polypropylene bottle, and keep it refrigerated during the collection period.

   If a 24-hr collection is made, retain at least 25 ml for duplicate porphyrin analyses. For off-site collections made as part of field studies, freeze 25-ml aliquots and ship frozen samples on dry ice to the analytical laboratory by overnight delivery service.

SUPPORT PROTOCOL 3

Feces

Analysis of fecal polyphyrins is performed when determination of protoporphyrin, which does not appear in urine, and 4- through 6-carboxyl porphyrin excretion is required. Timing of collection is important for this purpose.

Materials

Metabolism cages (Hoeltge, Inc.) that permit separation of urine from feces and other solid materials *or* Commode Collection System (for human feces; Fisher)

For animal feces

1a. Collect animal feces as described above for urine collections, using individual metabolism cages that are designed to separate solid from liquid waste. Retain at least 0.5 g for duplicate porphyrin analysis.

For human feces

1b. Collect human feces using a Commode Specimen Collection System, such as that offered by Fisher (CMS/Fisher, Fisherbrand). Retain at least 0.5 g for duplicate porphyrin analyses.

SUPPORT PROTOCOL 4

Blood

Porphyrin determinations in blood focus primarily on ethrocyte protoporphyrin IX and zinc protoporphyrin IX concentrations. Proper collection of blood samples is essential for this purpose. Timing of collection is unimportant.

Materials

Sterile 10-ml syringe and needle or 10-ml Vacutainer tube (Becton Dickinson) with EDTA as anticoagulant

1. Draw subcutaneous venous blood samples from animals or humans using either a sterile 10-ml syringe or a 10-ml Vacutainer tube with EDTA as the anticoagulant. After the tube has been filled with blood, immediately invert several times to prevent coagulation.

   Whole blood collected in this manner can be stored at 10°C for up to 1 month.

   CAUTION: *Do not freeze, as this will lyse red cells, thereby precluding the ability to measure erythrocyte porphyrins independently from those in white blood cells or plasma. If only erythrocyte porphyrins are of interest, separate erythrocytes from other blood constituents prior to freezing.*

PORPHYRIN EXTRACTION PROCEDURES

Porphyrin extraction procedures vary somewhat depending upon the complexity of the biological matrix of the medium, e.g., urine, blood, feces, or tissue. Extraction of porphyrins from urine is relatively easily accomplished using polar solvents such as methanol and mineral acid (e.g., HCl), whereas extraction from feces, blood, or solid tissues such as liver or kidney, requires repetitive treatment with nonpolar solvents such as ethyl acetate or acetonitrile to ensure complete porphyrin recovery. The following porphyrin extraction procedures provide for efficient extraction of porphyrins from urine, tissues, fecal matter and blood.

CAUTION: These procedures must be carried out under reduced light, i.e., out of direct sunlight or fluorescent overhead lighting), to protect porphyrins from photo-oxidation. Preferred lighting is >560 nm (5600 Å). Acrylic red or yellow sheaths/tube guards (Platt Electric Supply) are available that slip over fluorescent light tubes and can be cut to fit.

Urine Porphyrin Extraction

SUPPORT PROTOCOL 5

Rodent urine differs from human urine in that it contains relatively high concentrations of riboflavin and other fluorescing materials that might potentially interfere with the spectrofluorescent detection of specific urinary porphyrins. The following analytical procedure was developed to permit separation of potentially interfering urinary contaminants as well as to provide for improved porphyrin recovery. This procedure is suitable for measurement of porphyrin levels in both animal and human urine as well as for detection of small changes in urinary porphyrin concentrations resulting from porphyrinogenic chemical exposures.

Materials
HPLC-grade methanol
10 mM sodium phosphate buffer, pH 3.5 (see recipe)
1 N and 6 N HCl
Urine sample (see Support Protocol 1 or 2)
35% (v/v) HPLC-grade methanol in 10 mM sodium phosphate buffer, pH 3.5 (see recipe for buffer)
10 mM sodium phosphate buffer, pH 7.5 (see recipe)
80% (v/v) HPLC-grade methanol/20% (v/v) 10 mM sodium phosphate buffer, pH 7.5 (see recipe for buffer)
Nitrogen source

C-18 Bond Elute columns with 10-ml reservoirs (size 10 ml/250 mg; Varian) *or* C-18 Sep-Pac columns (Waters) and 10-ml plastic syringes to be used as column barrel
Vacuum manifold system: e.g., Baker SPE 10 vacuum extraction system or Millipore 1225 Sampling Manifold
15-ml conical polystyrene centrifuge tubes with screw-on caps
Adjustable pipettor (Gilson 5000-µl) and tips to fit *or* 10-ml serological pipets and electric pipettor (Drummond)
Beckman J2-27 or equivalent centrifuge
20-ml glass or plastic scintillation vials with Mylar/Teflon-lined lid (Research Products International)
60°C water bath or heating block
Glass 5¾-in. Pasteur pipets
4-mm Millex-HV 0.45-µm membrane filters (Millipore)
1-ml plastic syringe
10-ml plastic syringe plunger

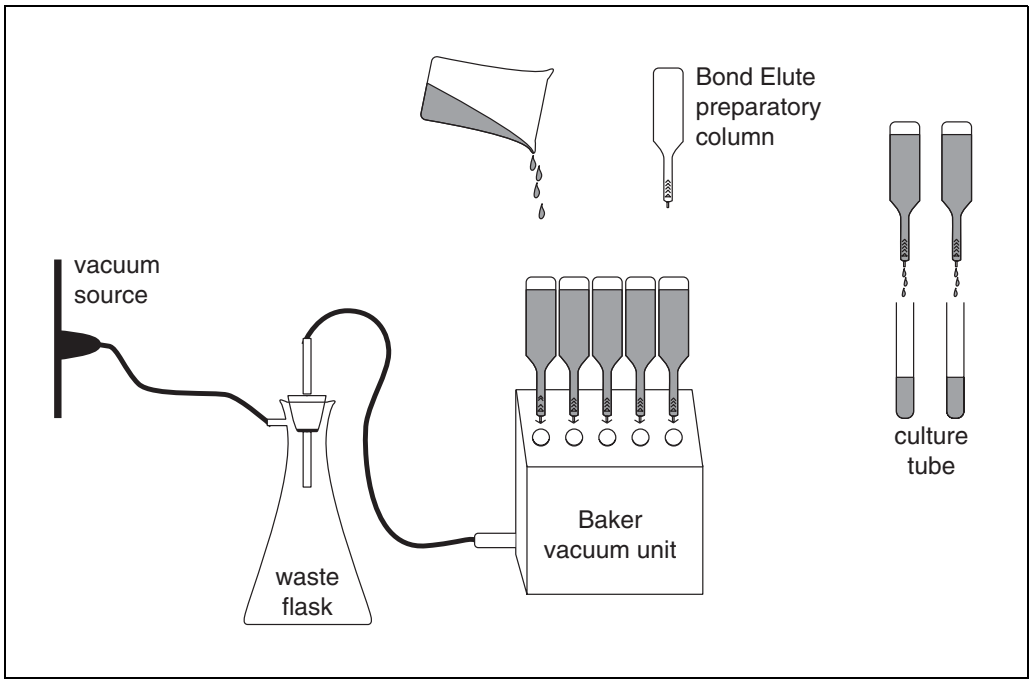

Figure 8.9.3 Setup for preparatory columns.

Amber HPLC vials to fit autosampler used (e.g., 1-ml amber shell vials for 96-position autosampler tray) and 300- to 500-µl inserts with bottom springs (Alltech Associates or Waters)

Pretreat the C-18 preparatory columns

1. For each urine sample, prepare one C-18 Bond Elute preparatory column (or C-18 Sep-Pak cartridge fitted to a 10-ml plastic syringe barrel), as shown in Figure 8.9.3.
2. Fit the outflow end of each preparatory column into one of the openings of a vacuum manifold system (Fig. 8.9.3).
3. Pass 10 ml of 100% HPLC-grade methanol through the column, followed by 10 ml of 10 mM sodium phosphate buffer, pH 3.5, under slight vacuum to facilitate flow.

   CAUTION: *Methanol is flammable and a cumulative poison. Work in a hood with safety glasses and protective gloves and clothing.*

4. Turn off the vacuum. Do not allow the cartridges to become dry.

   For rodent urinary porphyrin analysis, 6 ml is required for a single porphyrin determination. In most cases, it is desirable to analyze each individual sample in duplicate. Thus, 12 ml of urine is required for each animal determination. For human urine porphyrin determinations, use 10 ml for each individual assay (20 ml for duplicate determinations).

Extract porphyrins from urine

5. Separate a 6-ml aliquot (10 ml for human) of the urine sample into a capped 15-ml polystyrene conical centrifuge tube.
6. Centrifuge the sample 10 min at 2000 × *g*, room temperature, in Beckman J2-27 or equivalent centrifuge, to remove any insoluble and/or suspended matter.
7. Using an adjustable pipet, carefully transfer the supernatant to a 20-ml glass or plastic scintillation vial. Discard the sediment.

8. Using a pH meter or pH paper, adjust the solution to approximately pH 2.5 with a few drops of 6 N hydrochloric acid (HCl). Do not allow the pH to fall below 2.0.

   Use 10% NaOH to back-titrate, if necessary.

9. Pass the pH-adjusted urine solution through a preparatory column that has been preconditioned with methanol and phosphate buffer as described in steps 1 to 4.

   A small piece of gauze placed on top of the C-18 column is recommended to prevent clogging of the column.

10. Allow the urine solution to drip by gravity through the column until flow stops (a slight vacuum may be used if the solution fails to flow or stops flowing). Alternatively, use the 10-ml syringe plunger to assist the flow.

    CAUTION: *Do not apply continuous pressure or vacuum to facilitate this process initially, as this may cause small amounts of porphyrins to pass through the column. Porphyrins are retained on the column, while potentially interfering fluorescent contaminants, such as riboflavin, pass through and can be discarded.*

    At this stage, porphyrins are retained at the top of the column along with some contaminants. If high concentrations of porphyrins are present, they are visible with the naked eye as a dark red band. Lower concentrations can be visualized using a hand-held UV light.

11. To facilitate separation of remaining contaminants, wash the column sequentially as follows:

    a. First with 10 ml of 10 mM sodium phosphate buffer, pH 3.5.
    b. Second with 40 ml of 35% HPLC grade methanol in 10 mM sodium phosphate buffer, pH 3.5.
    c. Third with 3 ml of 10 mM sodium phosphate buffer, pH 3.5.
    d. Finally with 10 ml of 10 mM sodium phosphate buffer, pH 7.5.

    This final wash adjusts the column for elution of porphyrins.

    The preceding four wash steps may be facilitated by use of a moderate vacuum.

12. Place a 13 × 100–mm glass culture tube under each column to collect porphyrins to be eluted in the following steps.

13. To elute porphyrins, first pass 1 ml of 100% methanol, followed by 2 ml of a mixture of 80% methanol/20% 10 mM sodium phosphate buffer, pH 7.5, through the column.

    The initial drops of 100% methanol may be pushed through the column using the 10-ml syringe plunger to facilitate gravity dripping.

14. When porphyrin elution is completed, place the culture tube containing the porphyrin solution into a 60°C water bath or heating block. Discard the preparatory column.

15. Evaporate the methanol/buffer eluant to complete dryness under nitrogen gas.

    This step is best accomplished in a hood by attaching a Pasteur pipet to the nitrogen tank by flexible tubing and directing a slow stream of nitrogen through the tip of the Pasteur pipet against the inside of the test tube just above the surface of the liquid/porphyrin solution. Multiple samples may be dried simultaneously using a manifold, as shown in Figure 8.9.4.

16. Following complete evaporation of the liquid, dissolve the dried residue in the bottom of the tube that contains the concentrated porphyrins in 500 µl of 1 N HCl. Let stand at least 5 min, then vortex briefly (3 to 5 sec) to ensure complete dissolution of porphyrins.

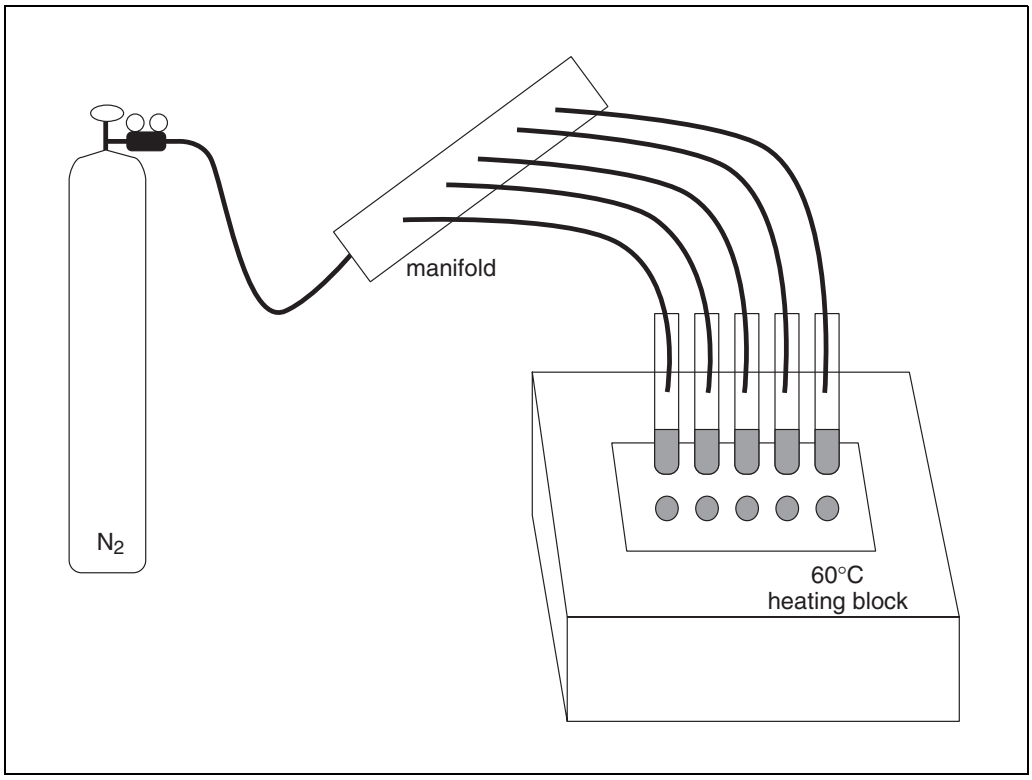

Figure 8.9.4 Setup for drying multiple samples using a manifold.

Up to 3 ml of HCl may be necessary to reconstitute the porphyrins if high concentrations are expected (such as when animals have been treated for prolonged periods with a porphyrinogenic drug or chemical).

17. Filter the reconstituted porphyrin solution through a 4-mm Millex-HV 0.45-µm membrane in order to remove small amounts of phosphate or other particulate matter that may have eluted with the porphyrins from the preparatory column and that could otherwise clog the HPLC injector system. Perform filtration in the following manner:

    a. Fit a 4-mm Millex-HV 0.45-µm membrane to a 1-ml plastic syringe with the plunger removed.

    CAUTION: *Larger filter sizes decrease percent recovery dramatically. Do not use nylon filters.*

    CAUTION: *Do not use nylon filters.*

    b. Using a 3-ml plastic pipet, transfer the reconstituted porphryin solution into the barrel of the syringe.

    c. Insert the plunger into the syringe and force the porphyrin solution through the attached 4-mm Millex-HV 0.45-µm membrane into an amber HPLC vial fitted with a 1.5-ml insert.

    Alternatively, any particulate matter can be removed by centrifugation for 10 min at 2000 × g. Centrifugation requires use of appropriate adaptors for the glass culture tubes to the centrifuge rotor employed.

18. Analyze solutions for porphyrin content (see Basic Protocol) or freeze at −20°C for up to 2 weeks prior to HPLC analysis.

Tissue and Fecal Porphyrin Extraction

Tissue or excreta porphyrin levels are of interest in the diagnosis of chemical effects on porphyrin metabolism and are also indicators of toxicant exposures. The following protocol may be employed as a relatively rapid and efficient method for porphyrin recovery from tissues as well as mammalian fecal or avian urofecal matter.

Materials

HPLC-grade acetonitrile
HPLC-grade distilled H_2O
Fecal (see Support Protocol 3) or tissue sample
1 N HCl
50:50 1 N HCl acetonitrile mixture
Nitrogen source

C-18 Bond Elute columns with 10-ml reservoirs (size 10 ml/250 mg; Varian) *or* C-18 Sep-Pac columns (Waters) and 10-ml plastic syringes to be used as column barrel
Vacuum manifold system: e.g., Baker SPE 10 vacuum extraction system *or* Millipore 1225 Sampling Manifold
Brinkman Power-Gen homogenizer (VWR) or equivalent
15-ml glass round-bottom centrifuge tubes, for homogenization
Beckman J2-27 or equivalent centrifuge
Adjustable pipettor (Gilson 5000-µl) and tips to fit *or* 10-ml serological pipets and electric pipettor (Drummond)
50-ml round bottom test tubes
32°C water bath or heating block
Glass 5¾-in. Pasteur pipets
50-ml glass round-bottom centrifuge tubes, for drying
4-mm Millex-HV 0.45-µm membrane filters (Millipore)
1-ml plastic syringe
10-ml plastic syringe plunger
Amber HPLC vials to fit autosampler used (e.g., 1-ml amber shell vials for 96-position autosampler tray) and 300- to 500-µl inserts with bottom springs (Alltech Associates or Waters)

Pretreat the C-18 preparatory columns

1. For each sample, prepare one C-18 Bond Elute preparatory column (or C-18 Sep-Pak cartridge fitted to a 10-ml plastic syringe barrel), as shown in Figure 8.9.3.
2. Fit the outflow end of each preparatory column into one of the openings of a vacuum manifold system (Fig. 8.9.3).
3. Pass 10 ml 100% HPLC-grade acetonitrile, followed by 15 ml HPLC-grade distilled water, through the column, under slight vacuum to facilitate flow.

   CAUTION: *Acetonitrile is flammable and a potential carcinogen. Work in a hood with safety glasses and protective gloves and clothing.*

4. Turn off the vacuum. Do not allow the cartridges to become dry.

Extract porphyrins from biological tissue or fecal matter

5. Working in a hood, place 0.1 to 0.2 g of tissue or fecal matter into a 15-ml round-bottom glass centrifuge tube containing 5 ml of a 50:50 mixture of 1 N hydrochloric acid (HCl) and concentrated acetonitrile.

6. Homogenize the tissue or fecal sample using a Power-Gen (or comparable) homogenizer.
7. Centrifuge the resulting homogenate 15 min at 3000 × *g*, 7°C, in a Beckman J2-27 or equivalent centrifuge.
8. Transfer 10 ml of the supernatant into a 100-ml beaker on ice, using a 10-ml serological pipet (or 5 ml twice with the 5000-µl pipettor).
9. Resuspend the pellet in an additional 6 ml of 50:50 1 N HCl acetonitrile mixture and vortex vigorously until the pellet is fully resuspended.
10. Centrifuge again for 15 min at 3000 × *g*, 7°C. Discard the pellet.
11. Combine the supernatant with the supernatant from the first spin in the 100-ml beaker.
12. Bring the total volume to 70 ml with HPLC-grade distilled water.
13. Pass the entire 70 ml of supernatant through a preparatory column that has been preconditioned with acetonitrile and water as described in steps 1 to 4.
14. Allow the supernatant to drip by gravity through the column until flow stops by continuously adding supernatant so that the liquid level remains above the top surface of the C-18 material, until the entire 70 ml of supernatant has passed through the column.

    A slight vacuum may be used to if the solution fails to flow or stops flowing. Do not apply pressure or continuous vacuum to facilitate this process initially, as this may cause small amounts of porphyrins to pass through the column.

15. When all of the extract has passed through the column, gently push (air purge) the excess solution through the cartridge using a 10-ml syringe plunger applied to the top of the column.
16. Dispose of the column eluate as hazardous waste.

    At this stage, porphyrins are retained at the top of the column along with some contaminants. If high concentrations of porphyrins are present, they are visible with the naked eye as a dark red band. Lower concentrations can be visualized using a hand-held UV light.

17. Place a 50-ml round-bottom test tube under each preparatory column and elute the porphyrins from the column into the test tube with 10 ml of acetonitrile.
18. When porphyrin elution is completed, place the test tube containing the acetonitrile-porphyrin solution into a 32°C water bath or heating plate and evaporate the acetonitrile to complete dryness under nitrogen gas.

    This step is best accomplished by attaching a Pasteur pipet to the nitrogen tank by flexible tubing and directing a slow stream of nitrogen through the tip of the Pasteur pipet against the inside of the test tube, just above the surface of the acetonitrile/porphyrin solution. Multiple samples may be dried simultaneously using a manifold, as shown in Figure 8.9.4.

19. Following complete evaporation of the acetonitrile, dissolve the dried concentrated porphyrins in the bottom of the tube in 500 µl of 1 N HCl. Let stand at least 5 min, then vortex briefly (3 to 5 sec) to ensure complete dissolution of the porphyrins.
20. Filter the reconstituted porphyrin solution through a 4-mm Millex-HV 0.45-µm membrane in order to remove small amounts of phosphate or other particulate matter that may have eluted with the porphyrins from the preparatory column and that could otherwise clog the HPLC injector system. Perform filtration in the following manner:

a. Fit a 4-mm Millex-HV 0.45-µm membrane to a 1-ml plastic syringe with the plunger removed.

CAUTION: *Larger filter sizes decrease percent recovery dramatically.*

CAUTION: *Do not use nylon filters.*

b. Using a 3-ml plastic pipet, transfer the reconstituted porphryin solution into the barrel of the syringe.

c. Insert the plunger into the syringe and force the porphyrin solution through the attached 4-mm Millex-HV 0.45-µm membrane into an amber HPLC vial fitted with a 1.5-ml insert.

Alternatively, any particulate matter can be removed by centrifugation for 10 min at 2000 × g. Centrifugation requires use of appropriate adaptors for the glass test tubes to the centrifuge rotor employed.

21. Analyze solutions for porphyrin content or freeze at −20°C for up to 2 weeks prior to HPLC analysis (see Basic Protocol).

Blood Porphyrin Extraction

SUPPORT PROTOCOL 7

Principal interest in blood porphyrins focuses on erythrocyte porphyrin measurements. Several methods for the analysis of erythrocyte porphyrins have been described. An extraction procedure that allows for analytical recoveries of protoporphyrin IX as well as zinc protoporphyrin IX is presented here. This procedure avoids extraction of porphyrins from the organic phase into aqueous HCl, thereby preventing conversion of Zn protoporphyrin to the free protoporphyrin IX.

Materials

Blood sample (see Support Protocol 4)
3:1 (v/v) ethyl acetate/glacial acetic acid containing 50 pmol mesoporphyrin IX (Porphyrin Products) as internal standard
Amber HPLC vials to fit autosampler used (e.g., 1-ml amber shell vials for 96-position autosampler tray) and 300- to 500-µl inserts with bottom springs (Alltech Associates or Waters)

1. Pipet 100 µl of whole blood into a microcentrifuge tube.
2. Working in a hood with protective clothing, gloves and safety glasses, add 300 µl of 3:1 ethyl acetate/acetic acid containing 50 pmol internal standard mesoporphyrin IX.
3. Vortex for 30 sec, then microcentrifuge 5 min at maximum speed.
4. Carefully remove the supernatant into an amber HPLC vial.
5. Analyze solutions for porphyrin content (see Basic Protocol) or freeze at −20°C for up to 2 weeks prior to HPLC analysis.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Sodium phosphate buffer, pH 3.5, 50 mM

Dissolve 6.9 g $NaH_2PO_4 \cdot H_2O$ in 1 liter of water. While stirring, adjust the pH to 3.5 with 20% (v/v) H_3PO_4 (phosphoric acid). Use 10% (w/v) NaOH to readjust the pH, if necessary. Store up to 1 month at 4°C.

Sodium phosphate buffer, pH 3.5, 10 mM

Dissolve 1.38 g $NaH_2PO_4 \cdot H_2O$ in 1 liter of water. While stirring, adjust the pH to 3.5 with 20% (v/v) H_3PO_4 (phosphoric acid). Use 10% (w/v) NaOH to readjust the pH, if necessary. Store up to 1 month at 4°C.

Sodium phosphate buffer, pH 7.5, 10 mM

Dissolve 1.38 g $NaH_2PO_4 \cdot H_2O$ in 1 liter of water. While stirring, adjust the pH to 7.5 with 10% (w/v) NaOH. Readjust to pH 7.5 using 20% (v/v) H_3PO_4 (phosphoric acid) if necessary. Store up to 1 month at 4°C.

COMMENTARY

Background Information

Chromatographic analytical techniques for measuring porphyrins in biological media were first developed to study porphyrins in urine, feces, and blood of patients with genetically inherited disorders of porphyrin metabolism (Nacht et al., 1970; *UNIT 8.1*). In more recent decades, numerous classes of drugs and environmental chemicals have been found to produce changes in tissue or excreta porphyrin levels (McColl and Moore, 1981; Maines, 1984; Marks, 1985; Woods, 1995), and HPLC techniques have evolved rapidly to accommodate the investigation of these effects (Ford et al., 1981; Scoble et al., 1981; Schreiber et al., 1983; Lim and Peters, 1984; Woods et al., 1984, 1991; Li et al., 1986; Kennedy and Maslen, 1989; Ho, 1990; Bowers et al., 1992a; Woods and Miller, 1993).

Although HPLC is a powerful technique for porphyrin separation and quantitation, the prechromatographic procedures employed in the extraction of porphyrins from biological media determine the accuracy of the total method to a large extent. Historically, extraction procedures involved the conversion of naturally occurring free porphyrin carboxylic acids to methyl esters, which were subsequently separated using normal-phase HPLC (Carlson and Dolphin, 1976; Seubert and Seubert, 1982). These procedures offered the advantage of increased stability and solubility in solution, but were tedious and time-consuming and often resulted in loss of porphyrins during the extraction and esterification procedures. Additionally, the esterification steps introduced problems such as incomplete and differential porphyrin esterification, as well as modification of vinyl side groups. In contrast, the use of procedures that permit the quantitative extraction of free porphyrins from biological media without esterification, as described in this unit, obviates many of these concerns and, additionally, allows analysis of porphyrins by the widely utilized and technically superior reversed-phase HPLC chromatographic columns employed today.

Free porphyrins, as well as the metalloporphyrin, zinc protoporphyrin, fluoresce intensely when irradiated with long-wave ultraviolet light. Hence, fluorescence detection is employed as a sensitive means for porphyrin quantitation. Detection of porphyrins is achieved by exciting at the wavelength of the Soret region, 390 to 410 nm, and measuring the emission at 600 to 630 nm. Each porphyrin responds maximally at slightly different excitation and emission wavelengths. Excellent results have been obtained in terms of the detection of all extracted porphyrins in biological substances using an excitation wavelength in the range of 395 to 400 nm and an emission wavelength of 620 nm (Woods et al., 1991; Bowers et al., 1992a,b; Woods and Miller, 1993). Spectrofluorometric analysis at these parameters permits the quantitative detection of 8- through 2-carboxyl porphyrins, as well as for zinc protoporphyrin, with a sensitivity to detect 0.5 pmol in the column effluent.

Critical Parameters

Porphyrins are subject to degradation by photo-oxidation. To protect porphyrins from photo-oxidation, use opaque or foil-wrapped collection bottles and store them in covered containers. Carry out all extraction procedures under reduced light, i.e., out of direct sunlight or fluorescent overhead lighting. Preferred lighting is >560 nm (5600 Å). Acrylic red or yellow sheaths/tubes guards are available that slip over fluorescent light tubes and can be cut to fit (Platt Electric Supply).

EDTA is added to prevent potential metal complexation of porphyrins. Care should be taken to use metal-free reagents to avoid introduction of metals into the porphyrin medium.

Do not freeze whole blood samples if erythrocyte porphyrin determinations are desired. Freezing will lyse the cells, making it impossi-

ble to separate erythrocyte porphyrins from those from other blood components.

In the urinary porphyrin extraction procedures, pH changes are used to maximize separation of porphyrins from fluorescent contaminants. A slightly alkaline pH during collection, storage, and centrifugation avoids porphyrin loss from oxidation and coprecipitation during centrifugation. Subsequently, the pH is lowered to ~2.5 just before application to the preparatory column to fully oxidize all reduced porphyrins (porphyrinogens) in the sample. A pH higher than 3.0 results in inconsistent binding to the C-18 preparatory column from one extraction procedure to another or between duplicate samples within the same trial. Undesirable contaminants are maximally removed from the preparatory column at pH 3.5. Caution must be exercized, since if the washing solution exceeds 35% methanol, porphyrins will be eluted from the C-18 packing material prematurely. Elution is highest at pH 7.5, so the last wash prepares the samples for elution into the collection tubes. Porphyrins precipitate out of solution at pH 4; therefore, samples must be kept above or below this pH value.

Urine samples should be slightly alkaline when centrifuged in step 2 to prevent coprecipitation of porphyrins out of solution. Usually, the sodium bicarbonate added as a preservative in the collection bottle (50 mg $NaHCO_3$ per 125-ml flask; 5 g $NaHCO_3$ per 2.5-liter amber bottle) is ample to achieve >pH 7.5. When samples are centrifuged, they should be at room temperature for maximum recovery. Ice-cold samples will have ~5% less recovery.

Sample solutions must pass through the preparatory columns slowly to be retained on the C-18 packing material; therefore, do not apply continuous pressure or vacuum to facilitate this process initially. If flow stops or fails to start, apply as little pressure as necessary to produce flow of 1 drop per sec.

Do not use nylon filters in the final porphyrin filtration step. Nylon completely retains porphyrins at low pH and partially at any pH. Increasing the Millex filter size also substantially reduces recovery. 4-mm filters decrease porphyrin recovery minimally, by ~3%.

Troubleshooting

During porphyrin extraction from tissues or excreta, sediment can build-up to such an extent that the solution will not pass through the preparatory column. If this occurs, precondition another column and pour the remaining sample into it. Continue with the wash steps. The flow usually improves after the first 35% methanol wash. After this is done there will be two columns that must be eluted into the same collection tube (6 ml total).

If the Millex syringe filters keep popping off the syringe when filtering the final porphyrin concentrate into the HPLC vial, too much pressure is being applied. If a filter plugs up, release pressure on the sample by pulling the plunger out half way, tip the syringe so the filter is up, remove the plugged filter and replace it with a new one, then continue to filter the remaining sample.

If no peaks or very small peaks are detected following injection of the porphyrin concentrate onto the analytical column, porphyrins could be present but undetectable due to a problem with the HPLC system. Check that the porphyrin standards can be detected. If even these are not apparent, the flow cell of the spectrofluorometric detector may be dirty. Try cleaning it per the manufacturer's instructions. On the other hand, the porphyrins can be lost during handling or in the extraction process. The most likely causes of this are incorrect collection or storage conditions (too much light, lack of refrigeration, or samples frozen in acidified state), or incorrectly made wash buffers (methanol higher than 35%, pH higher than 3.5). All aqueous buffers should be pH adjusted before organic solvents such as methanol are added.

Filter HPLC solvents and samples to remove particulates. Particulates can plug the HPLC pumping system and are very difficult to locate and remove. Degas the HPLC mobile phase solvents prior to use and sparge the reservoirs continuously with helium during analyses. If dissolved air is present in the solvents, it can come out of solution when the two solvents are combined in the HPLC mixing chamber and accumulate in the pump heads. Air is more compressible than the mobile phase liquids, so each stroke of the piston will deliver less solvent. As an air bubble grows, the gradient will deteriorate. Peaks may elute together, late, or not at all when this happens.

Change solvents and pressure gradually to protect the HPLC analytical column.

Abrupt solvent changes or high operating pressure can also damage the column. If the liquid that collects in the waste bottle becomes cloudy, high pressure may have forced C-18 packing material out of the column. In this case, the column must be replaced. Avoid getting air in the column. If air has built up in the pump heads or a solvent reservoir has inadvertently been allowed to run dry, disconnect the column

Table 8.9.2 Normal Values (Means ± SD) for Human Urinary Porphyrins (Bowers et al., 1992a)

Porphyrin	Amount detected	
	pmol/ml	μg/liter
Uroporphyrin	9.7 ± 5.7	8.4 ± 3.8
Heptaporphyrin	2.6 ± 2.4	2.0 ± 1.9
Hexaporphyrin	1.2 ± 0.3	0.9 ± 0.2
Pentaporphyrin	2.0 ± 1.0	1.4 ± 0.8
Coproporphyrin	61.1 ± 18.8	40.0 ± 13.5

Table 8.9.3 Normal Values (means ± SD) for Liver, Kidney, and Urine Porphyrins in the Male Fischer 344 Rat (Bowers et al., 1992a; Woods and Miller, 1993)[a]

Porphyrin	Liver (pmol/g)	Kidney (pmol/g)	Urine (pmol/24 hr)
Uro	1.9 ± 1.5	9.1 ± 1.5	373 ± 188
Hepta	2.8 ± 1.2	4.2 ± 1.8	211 ± 99
Hexa	0.2 ± 0.1	0.7 ± 0.3	68 ± 40
Penta	1.7 ± 1.5	6.0 ± 2.0	119 ± 76
Copro	44.5 ± 13.0	82.9 ± 3.2	1341 ± 280
Proto	4.2 ± 2.3	8.1 ± 3.2	0
Total	61.0 ± 14.3	107.5 ± 18.1	2112 ± 341

[a]Pay attention to strain, gender, and age variability (Bowers et al., 1992a).

while resolving the problem. Do not leave phosphate buffer in the column, as it will precipitate out and clog the column. Always flush the HPLC system by gradually, changing to 90% water/10% methanol for sufficient time—20 column volumes × flow (ml/min)—to thoroughly remove the phosphate buffer before changing to storage conditions (usually 100% methanol).

Apparently abnormally high uroporphyrin levels may be due to degradation of the C-18 packing material. This occurs when the silica packing material is subjected to pH <2.0, which results in degradative products from the C-18 HPLC column that coelute with uroporphyrin.

Drifting peak retention times are usually due to build-up of gas in pump heads. pH variations will also cause retention-time shifts.

Phosphate buffer precipitating in valves can cement moving parts together. Change phases gradually and flush thoroughly (20 columns volumes) with 50:50 methanol/H_2O after all runs to prevent phosphate buildup.

High back-pressure can be caused by blocked column frits. Try reversing the flow and flushing with methanol/H_2O or sonicating the frit to dislodge particles from the inlet frit. If the pressure remains high, replace the frit. High pressure can also mean it is time to change the HPLC guard column or the analytical column itself.

Poor separation of porphyrin peaks is mostly due to problems with the delivery of mobile phase solvents. Check for blocked frits, an empty helium gas tank, plugged check valves, leaks (often at a newly installed guard column) or air in the pump heads.

Anticipated Results

Tables 8.9.2 and 8.9.3 provide quantitative urinary and/or tissue porphyrin yields that have been achieved using the protocols described in this unit. Figure 8.9.2 presents anticipated chromatograms (HPLC elution profiles) of porphyrins extracted from various sources.

Time Considerations

Thirty tissue or urine samples can be effectively extracted in 1 day. Subsequently, each sample will require 33 min for HPLC analysis, once the HPLC is set up and equilibrated. Conversion of the output of the spectrofluorometric

detector to porphyrin concentrations (pmol/ml or other units) is readily accomplished using established computer software programs. The actual time will depend on the capabilities of the software available to the user.

CHAPTER 9
Heme Degradation Pathway

INTRODUCTION

The heme oxygenase (HO) system consists of three isozymes, members of the HSP32 family of oxidative stress–inducible proteins. Two, HO-1 and HO-2, are catalytically active and the third, HO-3, is marginally active. Unlike larger heat-shock proteins such as HSP70 and HSP90 that have chaperonin functions, HSP32 proteins catalyze degradation of the heme molecule. An overview of this degradative pathway is provided in *UNIT 9.1*.

Increased activity of HO isozymes can be used as an indication of exposure to oxidative stress. Catalytic activity of HO produces carbon monoxide (CO), biliverdin, and iron. To date there is no convenient method to detect iron release due to HO activity. For all practical purposes, however, the heme oxygenase system is the only biochemical system that produces CO and biliverdin; therefore, measurements of the formation of these compounds accurately reflect HO system activity. CO and biliverdin are produced in a 1:1 molar ratio, and experiments comparing production of the two compounds by in vitro reconstituted systems have shown good agreement in the molar quantities measured.

UNIT 9.2 describes the detection of CO production as an indication of HO activity. CO production can be measured directly by gas chromatography in cell- or tissue-expressed and purified preparations in vitro. It may also be measured in exhaled air, which can give a good indication of heme degradation activity of the organism. Instead of measuring biliverdin, it is more convenient to measure its reduction product bilirubin, which is produced in the next reaction in the heme degradation pathway, catalyzed by the enzyme biliverdin reductase.

UNIT 9.3 describes measurement of heme oxygenase activity by spectrophotometric analysis of bilirubin formation. There are other methods of measuring HO reaction products, including HPLC (*UNIT 9.6*). Because heme oxygenase isozymes are bound to the endoplasmic reticulum, isolated microsomal fractions can be used as the enzyme source, which reduces interference with the spectral analysis by other cellular constituents.

Measuring enzyme activity based on the formation of either CO or biliverdin/bilirubin does not distinguish the activities of HO-1 and HO-2. To estimate the relative contributions of the two proteins would require isozyme-specific inhibitors, which at this time are not readily available; metalloporphyrin inhibitors, which are commonly used to block HO activity, inhibit both isozymes. Fortunately, quite specific, non-cross-reacting antibodies to HO-1 (mono- and polyclonal) and HO-2 (polyclonal) are available commercially. A good estimate of the isozymes' relative contributions can therefore be obtained by immunoblotting, also described in *UNIT 9.3*. HO-1, HO-2, and HO-3 have been cloned and expressed as fusion proteins in *Escherichia coli*; a support protocol describes the purification of these fusion proteins for use in the assays or in other structure/function analyses. A second support protocol describes the isolation from tissues of microsomes that contain HO-1 and HO-2.

For studies of biliverdin reductase activity itself, *UNIT 9.4* describes an activity assay for detection of the enzyme at kinetic levels in either tissue extracts or cell extracts. (In

Current Protocols in Toxicology (2003) 9.0.1-9.0.2

contrast, in HO activity assays using cell homogenates, biliverdin reductase is usually not rate limiting for heme degradation because it is present in most tissues in excess of HO isozymes, and moreover an excess is added to the assay system.) The reductase has two pH optima and preferentially uses a different cofactor at each. Using pH-specific buffers make it possible to measure the enzyme activity at both optima. A second method of measuring biliverdin reductase levels is immunoblotting using commercially available, highly specific, high-titer polyclonal antibodies to the reductase. Finally, detection of the multiple isoforms of biliverdin reductase (which exhibits extensive microheterogeneity in both molecular weight and isoelectric point) by two-dimensional gel electrophoresis is also described. This assay is significant because the isoform population may be affected by an organism's exposure to chemicals.

As described in *UNIT 9.5*, the tissue distribution pattern of heme degradation pathway enzymes can be visualized by histochemical analyses at both the transcript level (by in situ hybridization) and the protein level (by immunodetection). Histochemical methods are invaluable for discerning which cell populations express which isozyme of heme oxygenase. The methods are also useful for detecting populations of cells that respond to a stimulus by expressing an isozyme of heme oxygenase. At the tissue level, the response of heme oxygenase genes to various stimuli can be detected by northern blot hybridization and RT-PCR, which will be covered in future supplements.

As noted above, the products of heme oxygenase activity are amenable to measurement by various techniques. *UNIT 9.6* describes a recently developed method for measurement of HO activity by HPLC. The method measures both biliverdin and bilirubin simultaneously and can be used with different cell and tissue preparations.

As described in *UNIT 9.1*, HO-1 is the stress/heat shock–inducible form of heme oxygenase, and its increased expression is primarily due to transcriptional activation of the *ho-1* gene. HO-2 is the glucocorticoid-responsive isozyme; the response is at both the level of transcription and translation. *UNIT 9.7* describes methods for the assessing transcriptional activation of the *ho-1* gene by analyzing promoter activity in transient and stable transfection systems. Transient transfection is the method most commonly used and involves transfection of cells using reporter genes. Stable transfection of the *ho-1* promoter has also been used, usually when *ho-1* promoter exhibits less-than-satisfactory behavior in transient transfection assays. This unit also contains a method for purification of high-quality plasmid DNA for cell transfection. Induction of HO-1 gene expression is generally considered an indicator of cellular stress response. HO-1 gene expression can be assessed by RT-PCR when limited tissue is available yet a high degree of sensitivity is required. *UNIT 9.8* describes an RT-PCR technique for quantification of HO-1 mRNA.

A critical factor in the biophysical characterization of a protein is its availability in a purified form. Because heme oxygenase functions in diverse physiological processes, it is of importance to characterize the protein from a mechanistic and a structural aspect. *UNIT 9.9* focuses on the human HO-1 isoform and describes high-yield expression and purification, as well as spectrophotometric techniques utilized in physical characterization of the protein.

Additional units will describe methods for quantitation of HO-2 and biliverdin reductase in human tissue samples by RT-PCR.

Overview of Heme Degradation Pathway

Heme—also called iron (Fe)-protoporphyrin IX or hemin (Fig. 9.1.1)—can be degraded through several enzymatic and chemical mechanisms. In mammals, the most efficient pathway for enzymatic heme degradation involves the heme oxygenase (HO) system. HO enzymes oxidatively cleave heme's porphyrin ring, generating stoichiometric quantities of biliverdin (Fig. 9.1.1) and carbon monoxide (CO). Chelated Fe is also released during the cleavage reaction (reviewed in Maines, 1992).

In mammals (and certain species of fish), biliverdin—the green pyrrolic product of HO activity—is subsequently converted to bilirubin by the cytosolic enzyme biliverdin reductase (Kutty and Maines, 1981). Bilirubin is the yellow pigment found in bile (Fig. 9.1.1).

The reduction of biliverdin by the reductase is coupled to the oxidation of the pyridine nucleotide cofactors NADH and NADPH. BVR reductase is unique among all enzymes described to date in that it has two distinct pH optima, 6.7 and 8.6, and it uses a different cofactor at each pH (Kutty and Maines, 1981). NADH is used at the acidic pH and NADPH is used in the basic range. The enzyme is highly conserved in its primary structure and biochemical properties as revealed by molecular characterization of the proteins from human and rat (Fakhrai and Maines, 1992; Maines et al., 1996). Biliverdin reductase has been identified as a zinc metalloprotein (Maines et al., 1996), and the protein shows extensive microheterogeneity due to post-translational modification (Huang et al., 1989).

Two catalytically active forms of HO, HO-1 and HO-2 (Maines et al., 1986), have been fully characterized. Recently a third isoform was identified (McCoubrey et al., 1997a), but its contribution to physiological heme degradation is likely to be minimal, because its HO activity in the presence of heme is low.

Both enzymatic and chemical mechanisms for heme degradation require molecular oxygen (O_2) and a reducing agent to activate the O_2 and reduce the heme iron from Fe^{3+} to Fe^{2+} (or maintain the iron in the Fe^{2+} state). In the HO-catalyzed reaction, NADPH acts as the reducing agent. In chemically catalyzed reactions, sodium dithionite or ascorbate provide the reducing equivalent.

For both enzymatic and chemical reactions, activation of O_2 by the electron donor initiates the multistep process of oxidative cleavage of the methene carbon bridges (Sano et al., 1986; Liu et al., 1997). The chemical mechanism, also called coupled oxidation, can cleave any one of heme's four carbon bridges, the α, β, γ, and δ carbon bridges. Thus chemical degradation leads to the formation of all four isomers of biliverdin. Biliverdin isomers are distinguished by which methene bridge was cleaved: e.g., biliverdin IXα is formed as a result of cleavage at the α-carbon bridge.

When heme b is the substrate, HO cleaves the molecule specifically at the α-methene bridge and the carbon atom is subsequently released as CO. For each molecule of heme oxidized by the HO system, three molecules of O_2 and NADPH are used. HO is designated a mixed-function oxidase, because it generates one mole of H_2O for each mole of O_2 consumed in the reaction.

Cells also use other minor enzymatic pathways to degrade heme. For example, in the mitochondria of heart tissue, an NADH-dependent heme-degrading system cleaves the heme molecule at the α-methene carbon bridge (Kutty and Maines, 1987). Heme can also be degraded by proteins such as xanthine oxidase (XO) and NADPH–cytochrome P450 reductase in the presence of H_2O_2. In the XO- or P450-catalyzed reactions, however, the products of heme degradation are not biliverdin or CO, but a mixture of pyrrolic complexes. A comprehensive description of the various heme-degrading systems is provided in Maines (1992).

HO-1 and HO-2 are produced by two different genes. The isozymes share little similarity in amino acid composition or sequence, and their genes differ in their nucleotide sequence, transcript size and number, organization and structure, and chromosomal location (Shibahara et al., 1985; Müller et al., 1987; Rotenberg and Maines, 1990; Sun et al., 1990; McCoubrey et al., 1992, 1995; McCoubrey and Maines, 1994). In addition, the two isoforms differ in their cell type and tissue distribution (Maines, 1992).

Both HO-1 and HO-2 are single-copy genes; however, HO-1 protein is produced from a single transcript of ~1.8 kb, whereas HO-2 is produced from two or more different-sized mRNAs. Most tissues and cell types in mammalian species express at least two different-

Current Protocols in Toxicology (1999) 9.1.1-9.1.5

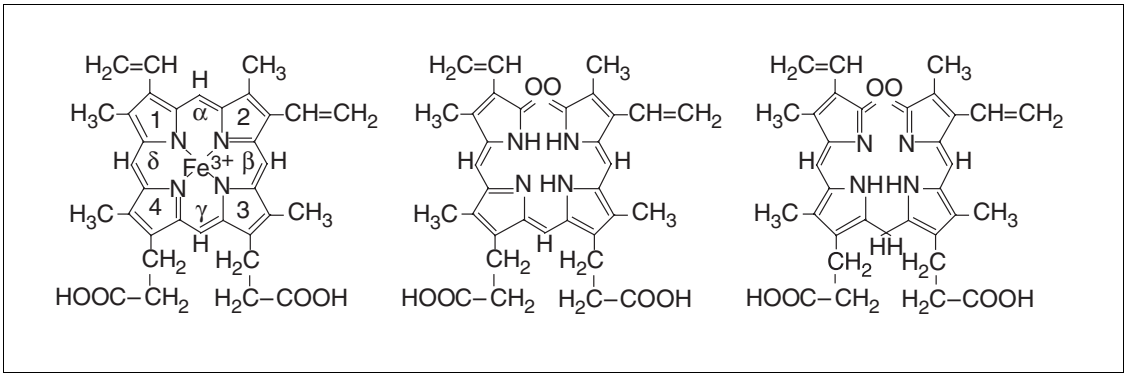

Figure 9.1.1 Chemical structures of heme (left), biliverdin (center), and bilirubin (right).

sized HO-2 transcripts, ~1.3 kb and ~1.7 to 1.9 kb. In the rat testis, however, five different transcripts for HO-2, ranging in size from ~1.3 to ~2.1 kb, have been identified. These transcripts show a developmentally regulated pattern of expression (McCoubrey et al., 1995). Different HO-2 transcripts arise from use of three different 5′ untranslated regions (UTRs) and two different polyadenylation signals (McCoubrey et al., 1992).

HO-1, also known as heat shock protein 32 (HSP32), was initially identified in 1974 as an enzyme that is induced by metals (Maines and Kappas, 1974). HO-1 expression is now known to be exquisitely sensitive not only to metals, but to all kinds of stimuli and agents that cause oxidative stress and pathological conditions, including heat shock, ischemia, glutathione depletion, radiation, hypoxia, hyperoxia, and cellular transformation and disease (Maines, 1992). In fact, no other enzyme studied to date is affected by as many diverse stimuli as is HO-1.

Induction of HO-1 by stress, such as heat shock, occurs in a coordinated fashion within different organs of an animal. The response is very rapid and fairly short-lived. For instance, in the heart, liver, kidneys, and brain of heat-shocked rats, HO-1 induction reaches its maximum in 1 hr, and the concentration of enzyme returns to normal ~6 hr after the stress (Maines, 1992).

HO-2, discovered in 1986 (Maines et al., 1986), is not induced by the factors that increase HO-1 expression (Trakshel et al., 1986a); HO-2 is responsive only to adrenal glucocorticoids (Weber et al., 1994). The consensus sequences necessary for binding regulatory factors—such as heat shock factors, AP-1 (activator protein-1), NF-κB (nuclear factor κB), and metal-dependent transcription factors—are present in the HO-1 gene promoter region (Müller et al., 1987; Alam et al., 1994), whereas the HO-2 gene contains only one functional glucocorticoid response element (GRE) consensus sequence (McCoubrey and Maines, 1994; Raju et al., 1997). Its GRE, however, is not a strong transcriptional promoter, and glucocorticoids exert a prominent regulatory effect on HO-2 expression at the protein level. At this time, it's not known whether glucocoticoids increase translation rate or protein turnover.

Total HO specific activity, which represents the sum of HO-1 and HO-2 activities, varies greatly among organs. The highest HO activity is usually found in the spleen, testes, and brain. In the brain and testes, HO-2 is the primary enzyme responsible for heme degradation. The spleen is the only organ in which HO-1 is the predominant HO isozyme under normal, unstressed conditions. The liver, however, displays an impressive level of HO-1 after exposure to oxidative stress.

As far as we know, HO-1 and HO-2 have similar catalytic mechanisms, substrate specificities, and cofactor requirements. The catalytic site of both enzymes consists of a conserved sequence of 24 amino acids that forms the "heme pocket" (Rotenberg and Maines, 1991). The heme pocket, which is hydrophobic and contains an essential histidine (McCoubrey et al., 1997b), recognizes the porphyrin ring of the metalloporphyrins but not the chelated metal. Therefore, various synthetic metalloporphyrins can bind to the heme pocket and prevent the natural substrate, Fe–protoporphyrin IX, from accessing the active site (Maines, 1981; Rublevskaya and Maines, 1994; McCoubrey et al., 1997b). Zn- and Sn-protoporphyrins have been used to inhibit heme degradation in clinical and laboratory settings (Vreman et al., 1993; Drummond et al., 1996). To a large degree such complexes are specific for HO isozymes, but they do not distinguish between HO-1 and HO-2. They can also affect nitric oxide (NO)

synthase and guanylyl cyclase activities. Metalloporphyrins can be used effectively to inhibit isolated purified protein preparations or to inhibit heme degradation altogether.

Recently an immunosuppressive peptide (D2702) has been identified as an effective inhibitor of HO-1 (Iyer et al., 1998). This peptide inhibits HO-1 in vivo and in vitro. The kinetics of its inhibition of HO-1 differ from its effects on HO-2, making the peptide a poor inhibitor of the latter isozyme. When using HO-1 inhibitors in vivo, however, it is important to note that inhibition is virtually always followed by a rebound induction at a later time point (Maines, 1984; Iyer et al., 1998).

Although major differences between HO-1 and HO-2 exist, each isozyme is evolutionarily conserved in its primary amino acid and nucleotide sequences. Therefore, antibodies and nucleotide probes can be used to study the proteins and genes from different species. HO-1 from rat, mouse, and human show >80% homology in their amino-acid sequences. For the HO-2 gene, the cDNA nucleotide sequence from rat, rabbit, and human is >90% homologous. Among the HO-1 and HO-2 proteins that have been sequenced, homology decreases to a mere 42% (Maines, 1992).

All of the products of HO activity are now suspected to be biologically active: CO, like NO, is thought to function as a signal molecule that regulates the generation of cGMP in biological systems (reviewed in Maines, 1997); Fe released by HO activity regulates the expression of genes, including the gene that encodes NO synthase; and biliverdin and bilirubin are both potent antioxidants (Stocker et al., 1987). In addition, the catalytic activity of the HO system plays a crucial role in maintaining homeostasis of cellular heme and hemoprotein levels (Maines, 1984, 1988); among the many hemoproteins and heme-activated enzymes are NO synthase, soluble guanylyl cyclase, and the cytochrome P450s.

In addition to its regular functions, HO-2 may have another, somewhat intriguing function: the protein may act as a cellular "heme or heme ligand sensor" (Maines, 1997; McCoubrey et al., 1997b). The 3′ UTR of HO-2 mRNA harbors two copies of a sequence 100% identical to the oxygen-sensing consensus sequence of erythropoietin, 5′-TTTTGCA-3′ (McCoubrey et al., 1992, 1997b). The sequence falls between the two poly(A) signals in the rat ~1.9-kb HO-2 transcript and in the equivalent ~1.7-kb transcript in humans. Moreover, in addition to its catalytic heme pocket, HO-2 possesses two additional high-affinity heme binding sites, called heme regulatory motifs (HRMs; McCoubrey et al, 1997a,b). Only seven cellular proteins identified to date contain HRMs (Rotenberg and Maines, 1991), including HO-2 and HO-3 (McCoubrey et al., 1997a). All HRMs have absolutely conserved cysteine-proline core residues. The cysteine residues of the HO-2 HRMs bind heme with high affinity but are not involved in heme catalysis. As a sensor, HO-2 may help regulate genes that are regulated by oxygen radicals, heme, or iron, including the ferritin, inducible NO synthase, and HO-1 genes. Also, by binding NO, HO-2 could function as an intracellular "sink" for NO.

Because HO-1 and HO-2 generate the same end products—biliverdin, CO, and Fe—measurement of any one of these products will reflect the combined activity of both isozymes. Detecting the activities of the individual isozymes is made even more difficult by the fact that both forms are present in all tissues examined to date, albeit in quite different proportions. Further, no inhibitors that are specific for one isozyme have yet been identified.

HO activity can be evaluated by measuring the generation of any one of the three different products of heme catalysis. For technical reasons, however, release of iron is seldom used to assess HO activity because this requires the use of radiolabeled Fe–protoporphyrin IX (heme).

Heme degradation by the HO isozymes requires the concerted activity of NADPH–cytochrome P450 reductase, which provides the reducing equivalents necessary for both the reduction of iron to the ferrous (Fe^{+2}) state (the form that binds oxygen) and the activation of molecular oxygen. The HO isozymes and the reductase colocalize to the endoplasmic reticulum. Therefore, the availability of the reductase can become limiting when measuring HO activity in tissues that have proportionally low concentrations of reductase and high concentrations of the HO isozymes, such as oxidatively stressed hepatic tissue or normal testis (Trakshel et al., 1986b).

Furthermore, other monooxygenase enzymes also rely on cytochrome P450 reductase to activate molecular oxygen using electrons provided by NADPH. Thus, the HO isozymes may have to compete with cytochrome P450 drug-metabolism systems for reducing equivalents. Awareness of the role of cofactors for HO activity becomes even more crucial when bilirubin is measured as the indicator of HO

activity. Biliverdin reductase, which must be present in such an assay system, also uses NADPH as a cofactor and has a rapid rate of reaction (Kutty and Maines, 1981). However, biliverdin reductase can also use NADH, whereas the HO system does not use NADH effectively.

Compounds that react with sulfhydryl groups, including metals such as Cd and Hg (Kutty and Maines, 1981; Maines, 1992), inhibit biliverdin reductase activity. Such inhibitors do not affect HO activity because HO-1 does not have any cysteine residues, and although HO-2 does contain cysteine residues, they are not involved in heme catalysis (McCoubrey et al., 1997b). Sulfhydryl reagents can inhibit overall heme degradation, however, by inhibiting biliverdin reductase. NADPH cytochrome P450 reductase is also inhibited by sulfhydryl reagents (Trakshel et al., 1986).

Immunoblotting can be used to assess the relative tissue concentrations of HO isozymes and their individual response to inducing agents. The two proteins have different predicted molecular weights: HO-1 is ~32 kDa and HO-2 is ~36 kDa. The commercially available antibodies to HO-1 and HO-2 do not cross-react and they have been used effectively for detecting individual HO isozymes by various analytical methods, including immunoblotting, immunohistochemistry, and radioimmunoassay (Sun et al., 1990; Ewing and Maines, 1992; Ewing et al., 1994).

Detection of Heme Oxygenase Activity by Measurement of CO

BASIC PROTOCOL

Heme oxygenase (HO, E.C. 1.14.99.3) is the first and rate-limiting enzyme in the heme degradation pathway. In the presence of NADPH–cytochrome P-450 reductase, HO catalyzes the following reaction, producing equimolar amounts of carbon monoxide (CO) and biliverdin:

$$\text{hemin (ferriprotoporphyrin IX)} + 6\text{NADPH} + 3\text{O}_2 \rightarrow \text{biliverdin} + \text{CO} + \text{Fe}^{3+} + 3\text{H}_2\text{O} + 3\text{NADP}^+$$

The biliverdin is immediately reduced to bilirubin, the pigment associated with jaundice. HO exists as two active isozymes, the inducible HO-1 and the constitutive HO-2. A third isozyme (HO-3) is ~90% identical to HO-2 in its amino-acid sequence but shows little HO activity (McCoubrey et al., 1997).

HO activity can be assayed by several methods, most of which rely on measurements of the rate of product formation. Bilirubin formation can be monitored in purified microsomal preparations by a coupled enzyme reaction using biliverdin reductase (see *UNIT 9.3*). Such assays require labor-intensive sample preparation and involve spectrophotometric quantification of the bilirubin formed in the aqueous phase or extracted into an organic phase.

A more direct procedure, described in this unit, involves the quantification, by gas chromatography, of HO-generated CO. This method is specific, sensitive, reproducible, and simple. CO determination can be used to study HO activity in all types of tissue at various stages of tissue fractionation and in tissue slices. The assay is also useful for studying, in vitro, the effects of various HO inhibitors, including the highly colored metalloporphyrin derivatives of heme.

HO activity in preparations from animal or plant tissue can be determined by measuring the production of CO. The protocol described in this unit measures the CO produced in a sealed reaction vial following the interaction of HO in a tissue preparation with hemin and NADPH.

Tissue homogenates are centrifuged at 13,000 × *g* and the supernatants (or other fractions purified to a greater or lesser extent) are incubated for 15 min at 37°C with 50 µM methemalbumin as substrate in the absence (blank) or presence (total) of NADPH in septum-sealed, CO-free vials. The reaction is terminated by quick-freezing samples to –78°C. The CO thus produced diffuses into the headspace of the reactor, where it can be quantified by gas chromatography (GC) on a molecular-sieve column with a reduction gas detector.

HO activity is expressed as nanomoles of CO produced per hour per milligram of protein. The method allows analysis of as little as 2 µl of rat tissue homogenate (20% w/v), prepared from 0.4 mg of liver (~40 µg total protein), for example. The assay measures the CO produced by all HO isozymes present in the sample.

When analyzing a large number of samples in 1 day, having two analysts work in conjunction can increase the sample throughput rate to up to ~300 vials per day. One analyst can isolate the tissues, perform the HO assays, and determine the amount of protein in the samples, while the other processes the tissues, prepares the samples, calibrates the instrument, and analyzes the CO content of the samples.

Current Protocols in Toxicology (1999) 9.2.1-9.2.10

NOTE: Because CO can be produced through photooxidative reactions between organic molecules in the samples and endogenous (e.g., riboflavin) or exogenous photooxidizers (e.g., metalloporphyrins), it is important that the steps involving CO generation and quantification be performed under conditions of reduced light.

Materials

Tissue or cell samples
0.1 M potassium phosphate, pH 7.4 (*APPENDIX 2A*)
0.9% (w/v) NaCl (optional, *APPENDIX 2A*)
HO substrate (see recipe)
4.5 mM NADPH (see recipe)
NADPH–cytochrome P-450 reductase (optional)
Anhydrous magnesium perchlorate (anhydrone; Fisher)
GC calibration gas: 10.8 µl CO/liter air (Scott Specialty Gases)
CO gas, 99.9% pure (e.g., Matheson Gas Products), optional

12 × 32–mm amber vials with polypropylene screw caps fitted with septa (e.g., Alltech Associates)
Vial racks (e.g., Fisher or equivalent)
Hamilton gas-tight syringe with repeating dispenser
2.5-mm-thick blue silicone sheets (Alltech Associates), for use in making septa
Hopcalite (CuO/MnO) catalytic converter (Trace Analytical)
Vial-purging assembly (see Fig. 9.2.1A)
Headspace-sampling assembly (see Fig. 9.2.1B)
0.0625-in. (1.59-mm) o.d. sleeve connector
18-G side-port needles, 5 and 7 cm
68 × 0.53–cm (i.d.) stainless steel column
40- to 60-mesh molecular sieve, 13X (Alltech Associates)
Gas-flow meter (J & W Scientific)
Gas-chromatograph system with reduction gas detector (Trace Analytical)
Sample injection valve with Model 451 Recycling Intervalometer (Gralab Instruments Division)
Recorder: 10-mV recorder (Linear Instrument) or integrating recorder (e.g., CR-3A, Shimadzu Scientific Instruments)
20-G side-port needle.

Additional reagents and equipment for determination of protein concentration (*APPENDIX 3*)

Prepare sample

1. Collect tissues or cells and rinse with ice-cold 0.1 M potassium phosphate, pH 7.4, or 0.9% NaCl. Keep tissue on ice.

   Whenever possible, flush or blanch tissue in situ or immediately after removal to eliminate circulating hemoglobin (a potential source of substrate). The assay can be performed on any cell or tissue type.

2. Homogenize fresh tissue in 4 vol ice-cold 0.1 M potassium phosphate (or 9 vol potassium phosphate for tissue with high levels of HO activity, e.g., spleen). Transfer tissue homogenates into microcentrifuge tubes.

3. Centrifuge homogenate 1 min at 13,000 × *g*, 4°C.

   A minimum of 100 µl of supernatant is needed for the assay, so prepare at least 200 µl of homogenate. The assay may be performed on crude enzyme preparations or on HO enzymes purified from specific subcellular compartments, e.g., from nuclear, mitochrondrial, microsomal, or soluble fractions. Purified isozymes can also be used.

4. Aspirate and discard any lipid from the supernatant surface. Transfer supernatant to a clean microcentrifuge tube without disturbing pellet.

5. Remove an aliquot of supernatant for determination of protein concentration.

Perform HO reaction

6. For each sample, assemble a set of five reaction vials into a rack. Label three vials "total" and the other two "blank."

   Total CO production (from HO activity and other sources) will be measured from the vials labeled "total," and the blanks will be used to measure any CO generated by non-HO activity.

   For conveniently handling large numbers of reaction vials, use commercially available 102-peg racks with 5 × 16 pegs, modified by shortening the pegs from 45 mm to 22 mm. These racks are also useful for storing clean vials.

7. Using 1.0-ml Hamilton syringes with repeating dispensers, add to all sample vials 20 µl HO substrate and 20 µl tissue preparation (from step 4). To the total samples, add 20 µl NADPH; to the blank samples, add 20 µl 0.1 M potassium phosphate, pH 7.4.

   Reactants should be pipetted in a manner that will prevent cross contamination: i.e., pipet substrate onto the bottom of the vial, tissue preparation onto the vial wall close to the bottom, and NADPH and buffer onto the wall just above the tissue preparation.

   The production of CO also requires the presence of NADPH–cytochrome P-450 reductase. This enzyme should be added when using highly purified tissue preparations from organs that have small amounts of reductase activity (e.g., brain or heart), or when reductase inhibitors are included in the reaction medium.

8. Seal vials with septum-fitted screw caps and mix liquids by swirling rack.

   Septa (8 mm diameter) are cut from 2.5-mm-thick, high-temperature blue silicone sheets (Alltech Associates).

9. Transfer rack to water bath and incubate 5 min at 37°C.

10. Prepare CO-free air by passing compressed air through a Hopcalite catalytic converter (see Fig. 9.2.1A).

11. Purge each vial for 2 sec with CO-free air at a flow rate of 200 to 300 ml/min using the vial-purging assembly (t = 0 min).

    If caps are wetted with distilled water prior to purging, the vial-purging assembly will penetrate the septa more smoothly (see Fig. 9.2.1A).

12. Incubate samples an additional 15 min at 37°C (t = 15 min). Remove vials from the water bath in the same sequence and at the same rate that they were purged. Dry vials with a towel and place them into a rack set in crushed dry ice.

13. Cover vials with a black plastic sheet and analyze headspace gas for CO as soon as possible.

    The septum material produces small amounts of CO at ambient temperatures, but the production rate is negligible at −78°C.

Quantify CO

14. Confirm that the GC injection-valve controller, detector, and recorder are functioning properly. Check and record carrier flow rate, column temperature, detector settings, and recorder settings. Verify that the carrier gas flow rate is ~30 ml/min and column temperature is 140°C.

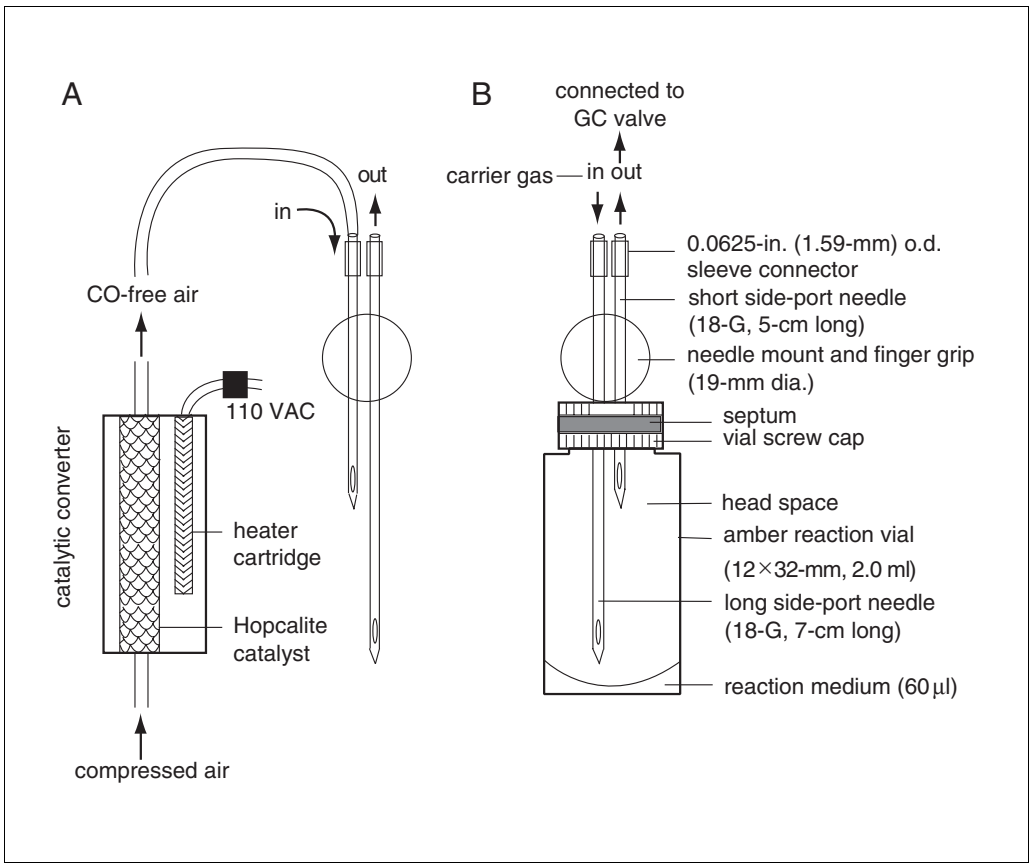

Figure 9.2.1 Double-needle assemblies for vial purging (**A**) or headspace sampling (**B**). The assemblies are identical except for the direction of the gas flow through the needles. (**A**) Compressed air is passed through a heated (~120°C) catalytic converter containing Hopcalite (CuO/MnO) catalyst. The catalyst oxidizes any CO to CO_2. The resulting CO-free gas is used to purge the headspace of the reaction vial just prior to incubation. When the assembly is removed from the vial after purging, the vial pressure will equilibrate to atmospheric pressure via the long needle after the shorter purging gas–inlet needle has been withdrawn. (**B**) The long needle introduces carrier gas into the vial and the short needle serves as an outlet. Such an arrangement will prevent vial liquid from being forced into the injection valve by the flow of carrier gas.

The ten-port pneumatic sample injection valve, fitted with a headspace-sampling assembly (Fig. 9.2.1B), injects the gas sample through a water-vapor trap filled with anhydrous magnesium perchlorate (Fisher), onto the 68 × 0.53–cm (i.d.) stainless steel column packed with 40- to 60-mesh molecular sieve 13X (Alltech Associates). The carrier gas flows through the column at a rate of ~30 ml/min to separate the vial gases on the basis of molecular size. The carrier gas then transports the reactor gas to the detector.

Under these operating conditions, the elution time for CO is ~90 sec, and as little as 1 pmol of CO is detectable. A 10-mV recorder can be used to chart the detector response (peak height) at a speed of 20 cm/hr. Integrating recorders are more efficient and convenient for determining CO peak areas accurately and rapidly.

15. Attach a clean, septum-fitted, capped vial to the headspace-sampling assembly (Fig. 9.2.1B) and turn on the valve controller to initiate the cycling of the valve between the injection phase (15 sec) and analysis phase (90 sec). Release carrier gas by puncturing the septum with a 20-G side-port needle.

Injection of the vial headspace gas onto the GC column will purge the vial of CO but will also leave the vial pressurized with carrier gas. This pressure must be released before standard gas is added to the vial.

16. Prepare a standard curve by injecting into the depressurized vial, one at a time, aliquots of 50, 100, 150, 200, and 250 µl standard gas (representing ~24, 48, 72, 96, and 120 pmol CO, respectively).

    If CO production is expected to be very high, greater volumes (up to 1000 µl) of CO standard gas may be introduced. However, with most GC systems, the standard curve ceases to be linear for quantities of CO >120 pmol. Higher quantities can be determined quite accurately through interpolation.

    Standard gas may be purchased or can be prepared by mixing 20 µl pure CO gas (99.9%; e.g., Matheson Gas Products) with 1000 µl of CO-free gas in a 1000-µl Hamilton acrylic syringe sealed with a septum fitted into an 18-G needle hub without the needle. The CO concentration in the syringe should remain stable for ~8 hr.

17. Plot the detector response (peak area, mV·sec) against pmol CO injected. Calculate the slope, in pmol CO per mV·sec.

    The plot for detector response should be linear from the origin up to 120 pmol.

18. Attach each HO reaction vial to the headspace-sampling assembly during the analysis phase of the previously injected sample. Record the detector response to CO as the area under the CO peak (retention time of ~0.7 min), expressed in mV·sec.

    If numerous samples are to be analyzed, check the slope of the standard curve hourly by injecting 250 µl CO standard gas into a CO-free depressurized vial. Compare with the peak area determined during the preparation of the initial standard curve.

19. Record data. Calculate the mean peak heights for total and blank samples during the analysis phase.

20. Measure protein content of processed tissue samples.

    HO activity can be expressed or normalized in several ways. The most widely accepted practice involves expressing activity as nanomoles of product formed (in this case CO) per hour per milligram protein. Thus determination of HO activity requires measurement of the protein concentration of the sample.

    Many protein determination methods can be used. Each methodology has its own sets of advantages and disadvantages and not all yield the same values for a given tissue preparation. The authors use the Lowry method (Lowry et al., 1951) because of its widespread use and sensitivity.

Calculate HO activity

21. Calculate HO activity as follows:

$$\text{HO activity (nmol/ hr/ mg protein)} = \text{total} - \text{blank (pmol CO)} \times \frac{\text{nmol}}{1000\ \text{pmol}} \times \frac{60\ \text{min/ hr}}{15\ \text{min}} \times \frac{\text{ml prep}}{\text{mg protein}} \times \frac{1}{0.02\ \text{ml prep}}$$

    The factor 15 min is the reaction time. In some instances, HO activity may be more appropriately expressed in terms of activity per unit (mg) fresh weight of tissue. Normalization of activity on the basis of fresh weight may be preferred, for example, when working with intact tissue slices, cells, and preparations with widely varying concentrations of HO-inactive protein. In such cases, calculate HO activity according to the following equation:

$$\text{HO activity (nmol/ hr/ mg fresh tissue)} = \text{total} - \text{blank (pmol CO)} \times \frac{\text{nmol}}{1000\ \text{pmol}} \times \frac{60\ \text{min/ hr}}{15\ \text{min}} \times \frac{\text{ml prep}}{\text{mg fresh tissue}} \times \frac{1}{0.02\ \text{ml prep}}$$

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HO substrate (150 μM heme/15 μM albumin)

Dilute 1 vol of 1.5 mM heme/0.15 mM albumin methemalbumin (see recipe) with 9 vol of 0.1 M potassium phosphate, pH 7.4 (*APPENDIX 2A*). Prepare fresh daily.

Methemalbumin, 1.5 mM heme/0.15 mM albumin

Dissolve 9.9 mg hemin (Sigma) in 2.5 ml of 0.4 M Na_3PO_4. Add H_2O to 8 ml and dissolve 100 mg of bovine serum albumin (A7030, Sigma). Gradually adjust to pH 7.4 using 1.0 N HCl (~0.75 ml) in a 1-ml gas-tight Hamilton syringe with a repeating dispenser while stirring vigorously. Add H_2O to 10.0 ml. Store up to 14 days at 4°C.

NADPH, 4.5 mM

4.3 mg β-nicotinamide adenine dinucleotide phosphate, reduced form (Na_4NADPH; Sigma)
1.0 ml 0.1 M potassium phosphate, pH 7.4
Prepare fresh daily

COMMENTARY

Background Information

Heme oxygenase plays an important role in homeostasis in cells and tissues. Not only does the enzyme play a key role in the degradation of heme (Maines, 1992), but it also produces CO, a gas with potential physiologically activity. Like nitric oxide, CO has been shown to modulate cyclic guanosine 5′-monoposphate concentrations (Maines, 1997). Furthermore, bilirubin, a prominent end product of the heme degradation pathway, has been shown to possess significant antioxidant properties, particularly in neonates just after birth (Dennery et al., 1995). Finally, HO has been shown to be a heat-shock protein and to respond to oxidative stress (Maines, 1997). Although activation of HO during heat shock or oxidative stress is being examined through measurements of HO gene transcription (mRNA) and translation (HO protein), it will be of interest to determine whether gene regulation and protein production also modulate HO activity. Thus, HO activity measurements are becoming increasingly relevant and important.

Several methods for the determination of HO activity in animal tissues have been described. The most commonly used method measures spectrophotometrically the amount of bilirubin produced by the sequential reactions of HO and biliverdin reductase in reconstituted microsomal preparations (Tenhunen et al., 1968; Tenhunen, 1972; Maines, et al., 1977). The use of a linked, multienzyme assay for the determination of HO presents difficulties for both experimental design and interpretation of results (Lodola et al., 1979). First, sample preparation and activity measurements are time consuming. Second, the spectrophotometric technique for the determination of the bilirubin produced requires a low absorptivity, transparent sample matrix, and an excess of biliverdin reductase. Furthermore, the molar extinction coefficient for bilirubin needed for the calculation of HO activity depends on the reaction matrix (aqueous or organic), and must be determined for each tissue preparation if accuracy is to be achieved (Tenhunen et al., 1968).

A different and more direct HO assay was first described by Cavallin-Stahl et al. (1978) using methodology initially developed for the determination of CO in blood. This method, which was subsequently modified by Sunderman et al. (1982), does not require biliverdin reductase and measures the CO produced from the oxidation of heme to biliverdin by HO. CO is trapped with added hemoglobin and is subsequently released into the headspace of a second reaction vessel by the action of potassium ferricyanide [$K_3Fe(CN)_6$]. The CO in the headspace is then reduced to methane and quantified by GC. HO activity measurements using the GC method are reported to correlate well with those of the spectrophotometric assay (Vreman et al., 1988).

The protocol presented in this unit provides a simpler, more sensitive, and better integrated method by omitting the trapping step. Instead, CO is measured directly from the reaction vial headspace by a reduction gas detector (Vreman et al., 1984; Vreman and Stevenson, 1988). The

detector can specifically measure trace levels (parts per billion or pmol) of reducing gases—i.e., those that are capable of combining with oxygen (O_2), including CO and hydrogen (H_2).

When directed through a heated bed of mercuric oxide (HgO), gases such as CO undergo the following reaction:

$$HgO + CO \xrightarrow{270°C} CO_2 + Hg \uparrow$$

The amount of mercury vapor produced during this reactions is directly proportional to the inlet CO concentration. It is detected by means of an ultraviolet light photometer located immediately downstream from the reaction bed. The high molar ultraviolet light absorption coefficient gives this detector its unusual sensitivity.

Further, because CO is the only gas generated, in equimolar quantities, from the degradation of heme to biliverdin or bilirubin in the presence of NADPH and O2 (Vreman et al., 1988), use of the reduction gas detector makes this assay specific for the detection of HO activity.

The procedure is rapid, simple, specific, and accurate. It permits the measurement of HO activity in an unlimited variety of tissue extracts and tissue slices (Meffert et al., 1994). Because no direct spectrophotometric measurements of HO reaction products are involved, highly colored or photosensitizing inhibitors, such as metalloporphyrins, can be studied using this method (Vreman et al., 1993). The original method (Vreman and Stevenson, 1988) involved using 20 µl of undiluted methemalbumin (2 mM heme/0.15 mM albumin) to yield a final reaction concentration of 800 µM heme. This concentration is much higher than that used for spectrophotometric methods (<100 µM). Because HO inhibition is competitive in nature, the authors have subsequently decreased the heme concentration to 50 µM; this change enabled the method to be more responsive to HO inhibitor studies.

Critical Parameters

This protocol is used to accurately detect and measure trace amounts of an odorless and invisible gas (Vreman and Stevenson, 1988). The handling and quantification of gases present unique problems in the laboratory. It is important to recognize that gas molecules are compressible, small, and mobile through Brownian motion. All these factors can promote rapid loss through the inappropriate handling of samples. The protocol describes the dispensing of gas with syringes open to the atmosphere. This technique works well, but must be completed as quickly as possible.

It is also important to recognize issues related to the permeability of gases through materials with relatively open molecular structure, including plastics such as polyethylene or polypropylene (in contrast to glass). Thus the composition of vessels used in the procedure may also play a role in CO losses. Furthermore, some organic materials (including some plastics, silicone, and rubber; see Levitt et al., 1995) may spontaneously produce CO at ambient temperatures or in the presence of light. This could contribute to falsely elevated assay results. Most problems of this nature can be kept to a minimum by keeping assay vials cool and dark, running appropriate blank controls, and by completing analyses as rapidly as possible.

HO activity in tissue samples may not remain stable. Stability varies from preparation to preparation. Timely assay of tissue preparations is important for reproducible and accurate results.

The GC system has great sensitivity towards CO, which readily passes through it. However, a large number of other, mostly organic, molecules can be retained on the molecular sieve column and can thereby affect its molecular separating characteristics or reduce the HgO in the reaction bed. Thus, it is important to keep the headspace gas as simple as possible by using, besides air, only inert gases such as nitrogen (N_2) and O_2 if the gaseous phase of the HO reaction needs to be altered. The use of organic solvent solutions for reactants (e.g., DMSO or pyridine) should be avoided or carefully researched in advance. Call Trace Analytical Customer Service (650-364-6895) with any questions about system compatibility. The system is absolutely and totally incompatible with the use of volatile halogenated hydrocarbons (e.g., chloroform and some anesthetics).

Some processes, such as photooxidation (Vreman et al., 1990a) or lipid peroxidation (Vreman et al., 1998), could contribute to CO generation in reaction vials. However, analysis of a blank reaction mixture will correct for these possible sources of error.

H_2, produced by microorganisms, is another reduction gas that may sometimes be present with CO. This potential interferant (with a retention time of 0.3 min) will be separated from CO (retention time of 0.7 min) on the molecular sieve column (Ostrander et al., 1982).

The combination of these discriminating steps contributes to the great specificity of this HO assay.

Table 9.2.1 GC Troubleshooting Guide

Problem	Possible cause	Solution
No CO peaks or peaks with erratic area and retention time	Faulty CO standard or poor sampling or transfer of standard	Check for plugged or leaky syringe
	Poor or no carrier flow through the vial or column	Check the detector outlet flow rate (which should be 30 ml/min) and peak retention time
		Check for proper position needle assembly through septum
	Reaction vial septum leaks when attached to headspace-sampling assembly	Check septum with soap solution with controller in inject mode
	Loose valve or carrier line fittings	Check valves and line fittings with soap solution
	Poor injection valve functioning	Check operation and actuation of valve and valve controller.
	Inappropriate column or detector temperature	Column temperature should be 140°C; detector temperature should be 270°C
	Ultraviolet light source burned out	Replace light source (Trace Analytical)
Gradual loss of sensitivity to CO	Introduction of water vapor onto column	Check column moisture trap or replace anhydrone and perform a new calibration curve
	Depletion of reaction bed	Replace reaction bed (Trace Analytical)
Baseline drift	Column contaminated	Recondition or replace column

Troubleshooting

Because CO is a gas, its quantification with the GC system poses unique problems. Unlike working with liquids, handling and transferring gases can result in a loss of material that cannot be detected until it is too late for recovery. However, loss of sample can be prevented through the careful use of well-planned techniques. The GC system itself can also, sometimes spontaneously, cause analysis failure.

When no CO peaks, or peaks with erratic area and retention times, emerge during analysis of CO-containing samples, the causes listed in Table 9.2.1 should be considered.

Table 9.2.1 also lists the possible causes and solutions for a gradual loss of sensitivity to CO in the GC system. Because the detection of CO depends on the chemical conversion of HgO to Hg gas, the reaction bed will become depleted of HgO as the Hg evaporates. Thus, the system will gradually (over ~2 year) lose its sensitivity to CO. This diminishing sensitivity should not affect daily CO analyses. With normal use, the column should be usable for up to 2 years. When the column fails, as detected by unstable and high baseline, it should be disconnected from the detector and reconditioned for 16 hr at 200°C, repacked with new column or replaced with a new column.

Anticipated Results

Table 9.2.2 shows representative results obtained using this methodology.

The results are not given as absolute values to be used for comparisons. They should be considered as representative values or trends for HO activity that may be encountered when different tissues from different species in various developmental stages are assayed. These results also represent HO activities in tissues observed after in vivo and in vitro perturbations that either increase (heme) or inhibit (metalloporphyrins) HO activity. In addition to these perturbations, there are many other parameters that may also play a significant role in the magnitude of the measured HO activities. These include, for instance, the route of administration of HO affectors (IP, IV, etc.), the time between administration and HO activity measurements, and the HO purification and concentration steps. It is our policy to always include an appropriate reference tissue as an assay check.

Table 9.2.2 Representative HO Activity Values Obtained Using the CO Method[a,b]

Treatment	HO activity (nmol CO/hr/mg protein)					
	Liver	Spleen	Brain	Kidney	Skin	Intestine
Newborn rhesus monkey (in vivo intravenous treatment)[c]						
Control	0.19 ± 0.10	0.62 ± 0.20	0.46 ± 0.14	0.12 ± 0.07	0.04[d]	0.30 ± 0.12
Heme	0.33 ± 0.23	0.78 ± 0.14	0.68 ± 0.28	0.32 ± 0.15	0.12 ± 0.02	0.41 ± 0.42
Heme + ZnPP[b]	0.08 ± 0.06	0.28 ± 0.03	0.60 ± 0.26	0.30 ± 0.13	0.10 ± 0.12	0.23 ± 0.12
Newborn Wistar rat (in vivo intraperitoneal treatment)[e]						
Control	0.43 ± 0.21	2.19 ± 0.66	—	—	—	—
CrMP	0.08 ± 0.04	0.98 ± 0.65	—	—	—	—
Adult Wistar rat (in vitro treatment)[f]						
Control	0.47 ± 0.10	2.23 ± 0.96	0.97 ± 0.34	0.17 ± 0.12	—	—
ZnBG	0.06 ± 0.03	0.04 ± 0.06	0.34 ± 0.20	ND	—	—

[a]Abbreviations: ZnPP, zinc protoporphyrin; CrMP, chromium mesoporphyrin; ZnBG, zinc deuteroporphyrin bis glycol; ND, not determined.

[b]All HO activity values measured from 1-min 13,000 × *g* supernatants from homogenized tissue using 50 μM heme as a substrate.

[c]Data taken from Vreman et al. (1990b). For each group of animals, control or treated, $n = 4$ except where otherwise noted.

[d]$n = 1$.

[e]Data taken from Vallier et al. (1993). For control animals, $n = 10$; for treated animals $n = 11$.

[f]Data taken from Vreman et al. (1992). For control and treated animals, $n = 3$.

Linearity. In preparations from rat liver and other tissues, HO activity is linear for up to 30-min of reaction time and up to 500 μg protein from the supernatant resulting from a 1-min 13,000 × *g* centrifugation. CO quantitation by this method is linear to 120 pmol.

Reproducibility. As an example of the within-run reproducibility of the method, assay of CO from 20-μl samples ($n = 10$) of adult rat liver and spleen yielded the following results [mean CO (pmol) ± SD (C.V.)]: for liver, 137 ± 4 (4%) total CO, 30 ± 4 (13%) blank, and 106 ± 4 (4%) net CO; for spleen, 440 ± 10 (2%) total CO, 49 ± 2 (4%) blank, and 391 ± 10 (2%) net CO.

Sensitivity. The limit of detection for CO is ~1 pmol. However, 10 pmol CO per vial is generally recommended as a practical working limit. Under current reaction conditions, ~1 μl (10 to 20 μg protein) of a 1-min 13,000 × *g* rat liver supernatant will produce 10 pmol of CO.

Time Considerations

The typical HO activity assay for ~6 tissue samples or 30 reactions requires ~4 to 5 hr. Sample preparation, including organ dissection and pretreatment, homogenization, and microsome isolation, should take 1 to 2 hr. Setting up and performing the HO reaction requires 1.5 hr. Quantitation of CO, including instrument calibration and sample analysis, requires 1.5 hr. Protein concentrations can be determined while CO is being measured. Finally, calculations can be performed in an hour, with most completed during the CO quantification phase.

An experienced analyst can perform and analyze ~160 HO reactions in a typical 8-hr day. With two analysts working together, the throughput rate can be increased to ~300 reactions per day.

Detection of Heme Oxygenase 1 and 2 Proteins and Bilirubin Formation

Changes in the amounts of the two heme oxygenase (HO) isozymes at the level of expressed protein may be detected by measurement of heme oxygenase activity (see Basic Protocol 1) or by immunoblot analysis (see Basic Protocol 2). Measurement of enzyme activity is useful for examining overall increases or decreases in total HO levels. The protocol described in this unit relies on a coupled assay, performed in the presence of excess biliverdin reductase, to measure the conversion of heme to bilirubin, which is quantified spectrophotometrically. The activity assay does not, however, distinguish between the contribution of HO-1 and HO-2, because, with minor exceptions, the substrates for both isozymes are the same and the products are identical. In contrast, immunoblotting provides a means to examine the expression of each protein individually. The differences in the primary amino acid compositions of the two isozymes is reflected in the specificity of their antisera: antibody prepared against HO-1 shows essentially no detectable cross-reactivity with antibody prepared against HO-2.

The two HO isozymes can be found in the microsomal fraction of cells and tissues and in the membrane fraction prepared from bacterial cells expressing full-length recombinant HO-1 or HO-2. This unit describes the preparation of microsomal fractions from tissue and cell extracts (see Support Protocol 1) or from bacterial cultures (see Support Protocol 2), the assessment of heme oxygenase activity by the measurement of bilirubin formation (see Basic Protocol 1), and the examination of HO protein levels by immunoblotting (see Basic Protocol 2).

SPECTROPHOTOMETRIC HEME OXYGENASE ASSAY

BASIC PROTOCOL 1

HO activity can be detected using a coupled heme degradation assay supplemented with biliverdin reductase (BVR). HO converts heme to biliverdin, which is subsequently reduced to bilirubin by BVR. The complete conversion of heme to bilirubin also requires the cofactor NADPH and cytochrome *c* (P450) reductase (CCR). The latter activity is high in fresh microsomal preparations, so addition of exogenous CCR is usually not necessary. However, if membrane fractions have been frozen and thawed, supplementing the assay with purified CCR is recommended to compensate for the loss of activity associated with storage. Bilirubin can be readily detected using a scanning spectrophotometer. The reactions should be carried out under reduced lighting to limit the destruction of bilirubin, which is photosensitive. The presence of Triton X-100 in the reaction prevents the formation of aggregates of enzyme and of heme, which can greatly reduce the efficiency of the reaction. It is essential that the final protein concentration in the assay be <1 mg/ml as higher concentrations can lead to spectral interference.

Materials

1 mM heme (see recipe), prepared fresh
30 U/ml biliverdin reductase (BVR; e.g., StressGen Biotechnologies) *or* kidney cytosolic fraction (see Support Protocol 1)
Cytochrome *c* reductase (CCR; e.g., Sigma or StressGen Biotechnologies), optional
Heme oxygenase (HO) assay buffer (see recipe)
Microsomal fraction (adjust protein concentration to <8 mg/ml with resuspension buffer)
Resuspension buffer (see recipe)
Triton X-100 (optional)

Contributed by William K. McCoubrey, Jr.
Current Protocols in Toxicology (1999) 9.3.1-9.3.9

2.75 mM NADPH (see recipe)
Chloroform, chilled on ice (optional)

Glass tubes, 13 × 100–mm or 12 × 75–mm
Scanning spectrophotometer

Perform reaction

1. Place three glass tubes in an ice bath to chill.
2. To one tube, add 18 µl of 1 mM heme and either 30 µl of 30 U/ml BVR (0.9 U total), *or* 100 µl kidney cytosolic fraction. If using bacterial cell extracts or microsomal preparations that have been frozen and thawed, add 0.12 U CCR to tube. Bring volume to 1.2 ml with HO assay buffer.

   When performing multiple assays it is best to prepare a master mix of buffer, heme, BVR, and CCR (if needed) and then to bring volume of tube to 1.2 ml. This ensures that conditions are identical for all samples.

   Addition of CCR is not necessary when freshly prepared microsomes are used, but will not interfere with the reaction.

3. Add 150 µl microsomal fraction. If necessary, dilute microsomal protein with resuspension buffer to <8 mg/ml, so that the final protein concentration in the assay is <1 mg/ml.

   If the protein sample being used is not in resuspension buffer, add Triton X-100 to the reaction mixture to a final concentration of 0.04%.

4. Mix tube briefly and return to ice bath. Label remaining two tubes as reference and test. Add 60 µl HO assay buffer to reference tube and 60 µl of 2.75 mM NADPH to test tube.
5. Add 600 µl reaction mixture (from step 3) to test and reference tubes.
6. Incubate test and reference tubes ≤30 min at 37°C in the dark with constant shaking.

   Incubation time will vary depending on the activity of the protein in the sample. A typical reaction time is 8 min, but the incubation could take as long as 30 min if HO activity is low. Longer incubations are not recommended, as they do not give quantitative results because of the thermal lability of the enzymes and product.

7. Stop the reaction by returning tubes to the ice bath. Cover the ice bath to protect bilirubin from photolysis.

Measure reaction product

8. Using the solution in reference tube, blank the scanning spectrophotometer between 410 and 610 nm.

   Using a scanning spectrophotometer rather than taking readings at two wavelengths is necessary because the maximum absorbance of bilirubin can vary between 460 and 475 nm, depending on conditions that cannot be optimized when using crude preparations. The continuous scan also allows measurement of a typical bilirubin peak rather than artifactual differences between the anticipated maximum and minimum wavelengths.

To measure bilirubin directly

9a. Scan the test reaction.

10a. Determine the difference in absorption between 470 and 530 nm. Calculate the concentration of bilirubin using an extinction coefficient of 40 mM^{-1} cm^{-1}.

   One unit of activity is defined as the amount that produces 1 nmol bilirubin/hr.

To extract bilirubin before measuring

9b. Add 1.5 vol cold chloroform to test reaction. Mix gently for a few seconds and return to ice. Repeat mixing two additional times.

Try to avoid forming an emulsion which will subsequently require separation. If an emulsion does form, hold the tube on ice or centrifuge at low speed until the phases separate.

Extracting bilirubin with chloroform prior to scanning increases the sensitivity of the assay by eliminating residual heme and raising the extinction coefficient of the product, which is higher in chloroform.

10b. Using chloroform as a reference, determine the difference in absorption of the chloroform phase between 450 and 530 nm. Calculate the concentration of bilirubin using an extinction coefficient of 58 mM^{-1} cm^{-1}.

Again, one unit of activity is defined as the amount that produces 1 nmol bilirubin/hr.

IMMUNOBLOTTING FOR HEME OXYGENASE 1 AND 2

BASIC PROTOCOL 2

Conditions for electrophoresis and immunoblotting are identical to those used for biliverdin reductase (see *UNIT 9.4 & UNIT 2.3*). The only modification is that acetone precipitation is performed on samples with low protein concentration (e.g., brain HO-1) prior to electrophoresis. To precipitate proteins, add 3 vol ice-cold acetone to samples and microcentrifuge 20 min at 10,000 × g, 4°C. Remove acetone and air dry the pellet for 5 min prior to adding 1× SDS-PAGE sample buffer.

Primary antibodies to rat HO-1 and HO-2 are commercially available (StressGen; see *SUPPLIERS APPENDIX*). The dilutions of the primary antibodies for each application need to be empirically determined, but a dilution of 1:100 to 1:250 usually works well for immunoblotting.

PREPARATION OF MICROSOMAL FRACTION FROM TISSUE

SUPPORT PROTOCOL 1

HO isozymes associate with intracellular membranes through their hydrophobic tails. Preparing HO isozymes involves homogenizing tissue samples and disrupting cell membranes. A low-speed centrifugation step removes particulates and the supernatant is then subjected to ultracentrifugation to separate the membrane fraction from the cytosol. The cytosolic portion can be used as a source of biliverdin reductase. The microsomes are resuspended in a buffer containing Triton X-100, which disrupts the hydrophobic interactions that bind the enzymes to the membranes.

Materials

Fresh or flash-frozen tissue
0.9% (w/v) NaCl in distilled H_2O, ice cold
Homogenization buffer (see recipe), ice cold
Resuspension buffer (see recipe)

Surgical scissors
Dounce homogenizer with tight-fitting Teflon pestle
Variable-speed drill
Centrifuge with fixed-angle rotor and tubes (e.g., Beckman J2 and JA20 rotor)
Ultracentrifuge with fixed-angle rotor (e.g., Beckman L8 and 50Ti rotor)

NOTE: Microsomes can be prepared from either fresh or frozen tissue. All steps must be carried out on ice or at 4°C unless otherwise noted.

1. Rinse fresh tissue or thaw frozen tissue in 50 ml ice-cold 0.9% NaCl, then weigh tissue.

   In general, 0.5 to 1 g of tissue is a convenient quantity for use in this protocol, although the amount may be scaled up or down depending on availability of tissue.

2. Add 5 vol (ml/g) ice-cold homogenization buffer to tissue.

   5 vol works well for most tissue. However, when working with liver, use 4 vol of buffer; for brain use 10 vol.

3. Using surgical scissors, mince tissue and then pour tissue and buffer into Dounce homogenizer. Homogenize sample until smooth using a Teflon pestle attached to a variable-speed drill. Set drill to ~200 rpm and homogenize tissue for 10 strokes.

4. Centrifuge 20 min at 10,000 × *g* (10,000 rpm in JA20 rotor), 4°C.

5. Transfer supernatant to an ultracentrifuge tube. Be careful to avoid transfering loose particulates.

6. Centrifuge 1 hr at 100,000 × *g* (50,000 rpm in 50Ti rotor), 4°C.

7. Transfer supernatant (cytosolic fraction) to appropriate storage tube and store at −80°C.

   When prepared from tissues that contain high concentrations of BVR (see UNIT 9.4), such as kidney, this fraction may be used as a source of BVR for HO assays (see Basic Protocol 1).

8. Resuspend microsomal pellet in a volume of resuspension buffer equivalent to 0.5 to 1 ml/g of tissue processed.

   It may be helpful at this step to use a small pestle on a drill to assist in disrupting the pellet.

9. Transfer microsomes to appropriate storage tube. Use immediately for determination of protein concentration and HO assay (see Basic Protocols 1 and 2) or store at −80°C.

SUPPORT PROTOCOL 2

PREPARATION OF BACTERIAL CELL EXTRACTS

HO fusion proteins, expressed from bacterial plasmids containing HO cDNAs coupled to vector-encoded sequences, are relatively stable in *E. coli.* Therefore, maximal yields of HO can be obtained following overnight growth of bacterial cultures to saturation. As is the case for the native HO proteins prepared from tissue, the hydrophobic tails of full-length cloned proteins cause association of the expressed recombinant HO with the membrane fraction of bacterial cell lysates. Lysates are prepared utilizing multiple cycles of freezing and thawing followed by brief sonication. In this protocol, Triton X-100 is included during lysis, so the HO protein is contained in the supernatant rather than in the pellet in the initial centrifugation step. The relatively high proportion of the fusion protein in the bacterial cells makes initial separation of membrane and cytosolic fractions unnecessary. However, as bacterial cells do not possess significant CCR activity, assays for HO activity require addition of that enzyme to the coupled reaction even when extracts have not been frozen before use. The protocol describes preparation of extracts from a 40-ml culture, but the volume can be scaled up or down as needed.

Materials

Bacteria on culture plate or in overnight culture
Liquid culture medium (e.g., 2× TY medium or superbroth; *APPENDIX 3A*) containing appropriate antibiotic (e.g., 50 to 100 µg/ml ampicillin)
Isopropyl-β-D-thiogalactopyranoside (IPTG), optional

0.1% (w/v) NaCl in distilled H_2O
Resuspension buffer (see recipe)

Centrifuge and rotor (e.g., Beckman J2 and JA20 rotor)
Water bath, room temperature
Sonicator

Additional reagents and equipment for culturing bacteria (*APPENDIX 3*)

1. Inoculate 40 ml of liquid medium containing the appropriate concentration of antibiotic with a single colony or with 0.4 ml (0.01 vol) of overnight culture. If vector requires IPTG for expression of recombinant protein, incubate culture 3 to 4 hr at 37°C before adding the appropriate concentration (1 to 3 mM) of inducer. Continue incubation overnight (16 to 18 hr).

   The flask used should be of sufficient volume (typically at least five times the volume of the medium) to allow for proper aeration.

   All subsequent steps must be carried out on ice or at 4°C unless otherwise noted.

2. Collect bacterial cells by centrifuging 12 min at 2000 × *g* (4000 rpm in JA20 rotor).

3. Wash pellet by resuspending in 4 to 5 vol of 0.1% NaCl (with respect to the volume of packed cells). Repeat centrifugation.

   The resuspended pellet may be transferred to a microcentrifuge tube if the volume allows. In this case, microcentrifuge 2 min at 6000 rpm.

4. Resuspend washed cells in 4 to 5 vol resuspension buffer and freeze in dry ice.

   The cells may be stored indefinitely at −80°C at this stage with virtually no loss of activity.

5. Thaw cells by immersing tube in cold tap water. Shake tube occasionally to mix sample and to minimize the time cells spend at elevated temperatures.

6. Repeat freeze-thaw cycle two additional times.

7. Sonicate samples three to four times using 15- to 20-sec bursts and allowing the suspension to cool for several minutes in between.

   There is usually a noticeable change in the opacity of the suspension when the cells have lysed sufficiently.

8. Centrifuge 20 min at 10,000 × *g*.

9. Transfer supernatant to an appropriate tube and use immediately for HO activity analysis or store at −80°C.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Heme, 1 mM

Dissolve 6.52 mg hemin (Sigma) in 250 µl of 0.1 N NaOH. Vortex until completely dissolved. Add 0.1 g Tris base, 132 mg bovine serum albumin (fraction V), and 9.5 ml H_2O. Vortex until BSA is completely in solution. Add 0.2 ml of 0.1 N HCl, vortex, and store on ice in the dark.

This solution should be used as soon as possible after preparation as aggregates of heme will form upon storage.

Heme oxygenase (HO) assay buffer

3.402 g KH_2PO_4
13.064 g K_2HPO_4
950 ml H_2O
Add 2 ml 0.5 N EDTA
Adjust to pH 7.4 with 1 N KOH
Filter and store up to 1 year at 4°C

Homogenization buffer

10 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
790 ml H_2O
Add 85.58 g sucrose
Stir to dissolve
Add H_2O to 1 liter
Filter sterilize and store up to 6 months at 4°C

NADPH, 2.75 mM

2.3 mg β-NADPH (Sigma)
1 ml HO assay buffer (see recipe)
Store on ice, protected from light, and use immediately

Alternatively, this solution may be stored frozen at −20°C for a week or more; however, repeated thawing and refreezing should be avoided.

Resuspension buffer

369 ml H_2O
10 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 ml glycerol
1 ml 0.5 M EDTA (*APPENDIX 2A*)
20 ml 10% (v/v) Triton X-100
Filter sterilize and store up to 6 months at 4°C

COMMENTARY

Background Information

In all mammalian species examined to date, heme oxygenase (HO) activity is produced largely by two isozymes: an inducible form, HO-1 (also known as heat shock protein 32; Keyes and Tyrell, 1989), and a constitutively expressed form, HO-2 (Maines et al., 1986). The proteins are encoded by distinct single-copy genes (Müller et al., 1987; McCoubrey and Maines, 1994), and they differ significantly in their amino acid composition and sequence (Shibahara et al., 1985; Rotenberg and Maines, 1990). Of particular note, HO-1 contains no cysteine residues, whereas HO-2 has three, two of which are present within its heme regulatory motifs (HRMs). HRMs are involved in heme-regulated functions in several proteins (Zhang and Guarente, 1995). They constitutively bind heme in HO-2 but are not involved in catalysis (McCoubrey et al., 1996). The differences in primary amino acid sequence between HO-1 and HO-2 are also reflected in the specificity of antibodies raised against each isozyme; polyclonal rabbit antisera are isozyme specific, exhibiting no cross-reactivity.

Both isozymes share an identical region of 24 amino acids, thought to be the heme-binding and catalytic pocket (Rotenberg and Maines, 1991). The recently described HO-3 (McCoubrey et al., 1997) differs from HO-1 and HO-2 in this domain and has almost no detectable heme oxygenase activity. Like HO-2, HO-3 is a hemoprotein that contains an HRM. Despite ≈90% amino acid identity between the two proteins, antiserum to HO-2 does not recognize HO-3. Although they diverge in amino acid composition, the carboxyl termini of all heme oxygenases so far sequenced have a conserved hydropathy profile. The terminal sequences are highly hydrophobic in nature and thus serve as a membrane binding domain (McCoubrey and Maines, 1993).

Heme oxygenase activity can be detected in most tissues, although the highest levels are found in spleen, testes, and brain. The relative contribution of the isozymes varies from tissue

to tissue. In spleen, HO-1 predominates, even under normal conditions. In contrast, although HO activity levels in the brain are comparable to that of spleen, HO-1 protein is nearly undetectable and is expressed in few neurons in the absence of induction. Exogenous stimuli have little effect on HO-2 levels. HO-1 activity, however, increases dramatically in many tissues in response to several factors, including heat shock and treatment with bromobenzene, hematin, lipopolysaccharide, or metal ions, such as cadmium.

Microsomal HO catalyzes the initial step in degradation of the heme moiety of hemoproteins: the cleavage of the α-meso carbon bridge to produce the open tetrapyrole, biliverdin (Tenhunen et al., 1968; Maines et al., 1977). In this reaction the bound iron is released and carbon monoxide (CO) is produced; HO activity is the sole source for the in vivo production of CO in mammalian systems (reviewed in Maines, 1992, 1997).

In principle, it is possible to quantify HO activity by measuring the production of any of the three products released after the oxidative cleavage of the heme molecule; all are produced in stoichiometric amounts by the enzyme. However, measurement of bilirubin formation using the coupled assay described in this unit is highly sensitive and more specific than measuring the other products. Direct measurement of biliverdin is possible, but, because it has a comparatively low extinction coefficient, detection of this product is less sensitive than for bilirubin. Although the release of chelated iron could be monitored using a radiolabeled derivative, any cleavage of heme has the potential to release the bound metal moiety. Because nonenzymatic cleavage occurs in microsomal preparations, this approach is not practical. Monitoring CO production (*UNIT 9.2*) would be more specific, but its measurement can be confounded by the release of the gas following the oxidative cleavage of any of heme's four meso-carbon bridges; HO-mediated cleavage is specific to the α-methane bridge and produces biliverdin IXα, for which BVR has a very high specificity. Thus, measuring the production of bilirubin is more specific than measuring the release of CO. In addition, measuring CO production requires expertise in gas chromatography; measurement of bilirubin concentration can be performed in any laboratory with a scanning spectrophotometer.

Critical Parameters

The simplest yet most common problem preventing the collection of usable data from the HO activity assay is inaccurate pipetting. These errors are magnified when samples have relatively low levels of HO activity. Heme has a very strong and broad absorption peak at ~390 nm (the Soret band). A slight error in the distribution of the reaction mixture between test and reference tubes can lead to differences in heme concentration and to detection of a heme peak when the tubes are compared. When activity is low, the heme peak remains large and the bilirubin peak is small. Under these conditions, the upper shoulder of the heme peak may obscure all or part of the bilirubin peak, making accurate determination of the magnitude of the latter difficult or impossible. Because of the small volume used for the assay and the amount of heme present (15 μM), even a few microliters difference can make a large difference in the quality of the assay.

Although the heme solution may be used over the course of more than 1 day if kept cold and in the dark, when quantitative results are required, daily preparation of fresh solution is necessary. Over time, visible aggregates will form in the solution and lead to a decrease in the concentration of available heme. More importantly, the presence of particulates in the assay may make obtaining an accurate spectrum impossible. Likewise, it is better to prepare fresh NADPH than to use a frozen stock, especially when the accuracy of absolute values is critical. Insufficient concentrations of detergent will also adversely affect the amount of bilirubin produced. A final concentration of 0.04% Triton X-100 in the assay is ideal and allows for a small margin of error without significant reduction in apparent activity. When assays are conducted on protein preparations that lack Triton X-100, the assay buffer should be supplemented to obtain a final detergent concentration of 0.04%.

For immunoblotting, selection of the appropriate antibodies and dilutions is essential. Follow suppliers' recommendations when possible. For untested applications, dilutions must be determined empirically.

Troubleshooting

As noted previously, the most common errors in the coupled HO assay are caused by poor pipetting technique. These inaccuracies often manifest themselves as abnormal spectra, in many cases causing an apparently linear increase or decrease in absorption between 450 and 600 nm. Careful examination and recalibration of pipettors will often rectify this problem. Mixing all of the reaction components,

except NADPH and buffer, with the microsomal preparation minimizes the number of different additions to the test and reference tubes.

It should be noted that a slight excess of the reaction mix is prepared so that a small amount remains in the mixing tube; this reduces the risk of pipetting unequal volumes into the test and reference tubes. When processing multiple samples, prepare a master mixture containing all the reaction components except protein. Use $(N + 0.5) \times$ the volume of each component (where N is the number of assays to be performed) and aliquot 1.2 ml of the mixture to each mixing tube. Such preparation allows more accurate comparisons of the HO activity values obtained because all the reactions are identical except for the protein added.

If the spectrum suggests a large contribution of residual heme, as can sometimes happen when HO activity is low, the concentration of heme in the reaction mix can be lowered as much as 3-fold (to 5 μM) without adversely affecting the kinetics or the magnitude of the bilirubin peak. Also, as noted in Basic Protocol 1, the incubation time can be increased to 30 min to boost the amount of bilirubin produced. Finally, when HO activity is extremely low, bilirubin may be extracted with chloroform and its spectrum obtained by comparison with a chloroform blank. Such extraction is also helpful when there is a contribution of a residual heme peak, as heme is not soluble in chloroform.

Measurement of less HO activity than expected is often an indication of insufficient CCR in the reaction. This is sometimes the case when performing an unsupplemented assay with fresh microsomal preparations that have been stored for an extended period following preparation, or when assay temperatures have been allowed to fluctuate above 4°C. Supplementing the assay with purified CCR usually alleviates this problem.

The presence of particulates in the microsomal preparation can also lead to irreproducible peaks or valleys in the spectral profile. This problem can be eliminated by centrifuging microsomes at $10{,}000 \times g$ prior to performing the HO assay (Support Protocol 1, step 4). HO proteins will remain in the supernatant and particulates should pellet under such conditions.

The most common problem in immunoblotting is uneven transfer of the protein to the membrane. This is generally due to the presence of bubbles in the transfer sandwich, which can be eliminated by careful layering of the components. Insufficient or excessive transfer times or voltages can also lead to decreased signal. Inclusion of prestained markers can allow monitoring of transfer efficiency.

Anticipated Results

The limits of detection of the HO assay depend on the sensitivity of the spectrophotometer being used and, in part, on the protein concentration of the microsomal preparation. Assuming that a ΔOD of 0.001 can be measured accurately, which is possible with many current spectrophotometers, the standard 8-min assay should accurately measure ≥1.7 U/ml HO activity in the microsomal preparation. If the protein concentration is the maximum 8 mg/ml, this corresponds to a specific activity of 0.2 U/mg. The assay sensitivity may be further increased by using a longer incubation time, so that <0.1 U/mg could be reliably detected. It should be noted that when protein concentration is low, it is possible to add a larger amount of the microsomal preparation by reducing the amount of assay buffer accordingly.

Microsomal HO activity varies greatly with tissue type. Microsomes prepared from the spleen, testis, and brain of an untreated rat may have activities of >10 U/mg. Small intestine, epididymis, and seminal vesicles yield specific activities from 0.4 to 0.7 U/mg, and HO activity in other tissues falls between these values (Maines, 1988). The activity of bacterial lysates depends on the activity of the promoter and the growth conditions, but can easily exceed that of tissue microsomes. Given the range of the assay, it is relatively easy to observe both increases and decreases in HO activity.

Using immunoblot analysis, HO-2 is readily detectable in most tissues. In untreated animals, the HO-1 level is at the limit of detection in many tissues, but can show dramatic increases in response to stress (Ewing and Maines, 1991).

Time Considerations

The time required for tissue preparation will vary with the number of animals being processed and the number of tissues to be collected, as well as the experience of the person doing the dissections. Microsomal preparation will require 2 to 3 hr depending on the number of samples. Preparation of the bacterial cell lysate following overnight growth will take ~1.25 to 1.5 hr for small cultures (25 to 100 ml) and ~2 to 2.5 hr for larger cultures due to the longer times necessary for the freeze-thaw cycles. Determination of protein concentration requires 30 to 60 min, and set up for 6 to 10 assays,

including preparation of fresh heme and NADPH, takes another hour. Calibration of the spectrophotometer can usually be accomplished during the incubation, and this period along with collection of spectra will take an hour. Thus, a single experimenter can obtain data in a single day if only a limited amount of dissection is required.

For immunoblotting, preparation of samples, electrophoresis, and transfer of proteins to the membrane can be accomplished by a single investigator in one day. For practical purposes, it is generally advisable to block overnight and to perform the antibody treatments and substrate development, which take 4.5 to 6 hr, the next day.

Detection of Biliverdin Reductase Activity

The initial step of the heme catabolic pathway is the oxidation of the porphyrin ring to form the open tetrapyrrole biliverdin IXα. In mammals, and in some species of fish, biliverdin is subsequently reduced to the bile pigment bilirubin. This reaction is catalyzed by the cytosolic enzyme biliverdin reductase (BVR). The enzyme is unique in that it has two pH optima, 6.7 and 8.7, and preferentially uses a different cofactor at each optimum—NADH and NADPH, respectively. BVR activity can be detected in nearly every tissue type, with the highest concentrations in liver and kidney. Purified from tissue, BVR exists as at least ten isoforms that differ in their isoelectric points and tissue distribution. BVR can be prepared from cytosolic fractions from tissue (see Basic Protocol 1) or from extracts from bacterial expression cultures (see Support Protocol). This unit presents a kinetic assay for the measurement of BVR activity at both pH optima (see Basic Protocol 1). In this assay, bilirubin is detected using a scanning spectrophotometer. BVR protein can be detected by immunoblotting (see Basic Protocol 2), and its isoelectric variants can be separated by two-dimensional isoelectric focusing (two-dimensional gel electrophoresis; see Basic Protocol 3). Subcellular localization of BVR should be determined by immunocytochemical analysis

KINETIC ASSAY OF BILIVERDIN REDUCTASE ACTIVITY

BASIC PROTOCOL 1

A cytosolic fraction is prepared from tissue and its BVR activity is determined by spectrophotometric measurement of the reaction product, bilirubin. To measure BVR activity at its different pH optima, two assay buffers are prepared: buffer of pH 8.7 is used when NADPH is the cofactor; buffer of pH 6.75 is used for NADH. Assays are performed under conditions of reduced lighting to prevent photolytic degradation of the substrate and product.

Materials

Fresh or flash-frozen tissue
0.9% (w/v) NaCl in distilled H_2O, ice cold
Homogenization buffer (see recipe)
BVR assay buffers, pH 8.7 and 6.75 (see recipes)
300 μM biliverdin (see recipe)
20 mg/ml bovine serum albumin (BSA)
Cofactor buffer (see recipe)
1 mM NADPH in BVR assay buffer, pH 8.7 (see recipe for buffer, store on ice; use within 2 hr)
10 mM NADH in cofactor buffer (see recipe for buffer; store on ice; use within 1 hr)

Surgical scissors
Dounce homogenizer with tight-fitting Teflon pestle
Variable-speed drill
Centrifuge with fixed-angle rotor and tubes (e.g., Beckman J2 with JA20 rotor)
Ultracentrifuge with fixed-angle rotor (e.g., Beckman L8 with 50Ti rotor)
13 × 100–mm or 12 × 75–mm glass tubes
Scanning spectrophotometer

NOTE: Microsomes can be prepared from either fresh or frozen tissue. Enzyme preparation is carried out on ice or at 4°C, and the assay is performed at room temperature.

Prepare cytosolic fraction

1. Rinse 0.5 to 1 mg tissue in 50 ml ice-cold 0.9% NaCl.
2. Add 9 vol (v/w) homogenization buffer to tissue.

Contributed by Tian-Jun Huang
Current Protocols in Toxicology (1999) 9.4.1-9.4.10

3. Using surgical scissors, mince tissue in buffer and pour into Dounce homogenizer. Homogenize sample until smooth using a Teflon pestle attached to a variable-speed drill. Set drill to ~200 rpm and homogenize tissue for 10 strokes.

4. Centrifuge 20 min at 10,000 × *g*, 4°C.

   In most cases, the specific activity of BVR in the 10,000 × g supernatant is sufficiently high that the activity assays can be performed at this point. If desired, an additional high-speed centrifugation step can be performed to separate heme oxygenase and other microsomal proteins from the cytosolic BVR.

5. Transfer supernatant to an ultracentrifuge tube, being careful to avoid transferring loose particulates.

6. Centrifuge 1 hr at 100,000 × *g*, 4°C.

7. Collect supernatant for BVR activity assay.

Perform BVR assay

8. At room temperature, prepare a combination solution containing 960 µl BVR assay buffer (pH 8.7 for use with NADPH or pH 6.75 for NADH), 10 µl of 300 µM biliverdin, and 10 µl of 20 mg/ml BSA. (If performing the assay in the absence of BSA, add an additional 20 µl assay buffer).

   NADH and NADPH assays are identical except that an assay buffer of pH 6.75 is used for NADH and a buffer of pH 8.7 is used for NADPH. Assays are performed under conditions of reduced lighting to prevent photolytic degradation of the substrate and product. BSA is included to stabilize BVR, but may be omitted in preparations that have a high concentration of total protein.

9. In cuvettes, prepare reference reactions as follows: Add 490 µl combination solution (step 8), 50 µl homogenization buffer, and 60 µl assay buffer, pH 8.7 (for assays using NADPH) *or* 60 µl cofactor buffer (for assays using NADH).

10. Place reference cuvette in scanning spectrophotometer and record the spontaneous change in absorbance at 468 nm (or 450 nm if BSA is not present) over 30 to 60 sec.

11. To test reaction cuvette add 490 µl combination solution, 50 µl cytosol, and 60 µl of 1 mM NADPH *or* 60 µl of 10 mM NADH. Mix sample and immediately record the change in absorbance at the same wavelength used for reference sample. Monitor rate over several time intervals (e.g., 4 × 15 sec) to ensure that reaction is linear. Correct the test spectrum for absorbance in the absence of cofactor by subtracting the reference spectrum (step 10).

    It is frequently necessary to dilute the cytosolic preparations in homogenization buffer to ensure that the reaction remains linear for the duration of the assay. If the reaction rate decreases over time, the substrate is becoming depleted. Repeat the assay with a diluted (1:10) enzyme.

12. Calculate concentration of bilirubin using an extinction coefficient of 63 $mM^{-1}cm^{-1}$ (or 53 $mM^{-1}cm^{-1}$ when assaying in the absence of BSA).

    One unit of activity is defined as the amount producing 1 nmol bilirubin/min.

BASIC PROTOCOL 2

IMMUNOBLOTTING ASSAY FOR BILIVERDIN REDUCTASE

Proteins are separated according to molecular weight by acrylamide gel electrophoresis and then transferred to a membrane. The membrane is incubated with a nonspecific blocking solution and then with a BVR-specific antiserum produced in rabbits. A secondary antibody, directed against rabbit immunoglobulin and conjugated to horseradish peroxidase, is then added. The location of protein-antibody complexes is then

visualized by adding a colorimetric substrate for the peroxidase. When selecting a primary antibody, note that BVR-specific antisera show pronounced species specificity. Antibodies raised against human BVR react very poorly with the rat reductase. Antibodies to a given species, however, will recognize all BVR isoforms from that species.

Materials

Protein samples in 1× SDS sample buffer (*APPENDIX 2A*)
Prestained or dye-labeled protein molecular-weight markers
Transfer buffer (see recipe)
1× and 5× PBS (see recipe)
Blocking solution (see recipe)
Rabbit anti-BVR antiserum (e.g., StressGen)
Antibody diluent (see recipe)
1× PBS containing 0.5% (w/v) sodium cholate (PBS/cholate)
Horseradish peroxidase–conjugated anti–rabbit IgG antiserum (e.g., Bio-Rad or Cappel)
4-Chloronaphthol
Methanol
30% (v/v) H_2O_2
0.2-μm-pore nitrocellulose sheets *or* nylon-backed equivalent

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (SDS-PAGE; *APPENDIX 3*) and electrotransfer of proteins (*UNIT 2.3*)

Perform electrophoresis and transfer proteins to membrane

1. Prepare a gel for SDS-PAGE using a 12.5% separating gel and a 3.5% stacking gel.
2. Load samples and molecular weight markers.
3. Run electrophoresis until bromphenol blue dye front reaches the bottom of gel.
4. Separate plates, cut stacking gel away with a clean razor blade, and submerge separating gel in transfer buffer.
5. Transfer proteins to nitrocellulose membrane (see *UNIT 2.3*).

Treat membrane with antibodies

6. Examine membrane to confirm transfer of proteins. Remove membrane and rinse briefly several times with 1× PBS.

   Before removing the membrane from the transfer chamber, confirm the effectiveness of transfer by noting the transfer of the molecular-weight markers to the membrane. If the process is incomplete, and the membrane and gel have not yet been separated, the transfer can be repeated.

7. Add sufficient blocking solution to completely cover the membrane and incubate overnight at 4°C with gentle rocking.

   The blocking step may also be carried out at 37°C for 1 to 2 hr.

8. Remove blocking solution and briefly rinse membrane twice with 1× PBS.

   The blocking solution can be stored at 4°C and reused at least a dozen times.

9. Dilute BVR antiserum 1:200 in antibody diluent. Add enough BVR antiserum to cover membrane (typically 10 ml) and incubate 1 to 2 hr at room temperature with gentle rocking.
10. Remove primary antibody and store solution at 4°C.

    The diluted antibody may be used up to five times without significant loss of sensitivity.

11. Rinse membrane briefly with PBS/cholate at room temperature. Cover membrane with PBS/cholate and incubate 10 min at room temperature with gentle rocking.
12. Remove PBS/cholate and cover membrane with 1× PBS. Incubate 10 min at room temperature with gentle rocking. Rinse membrane briefly with PBS/cholate.
13. Dilute horseradish peroxidase–conjugated goat anti–rabbit Ig serum 1:500 in antibody diluent. Add enough diluted secondary antibody to cover membrane. Incubate 1 to 2 hr at room temperature with gentle rocking.
14. Rinse membrane briefly with PBS/cholate. Cover with PBS/cholate and incubate 10 min at room temperature with gentle rocking. Repeat 10-min wash with fresh PBS/cholate.

    The diluted secondary antibody may be stored at 4°C and reused up to three times.

15. Rinse membrane briefly with 1× PBS. Cover with more 1× PBS and incubate 5 min at room temperature with gentle rocking. Repeat 5-min wash with fresh 1× PBS.

Detect antibody complexes

16. Prepare developing solution: Dissolve 15 mg 4-chloronaphthol in 5 ml methanol. Add 6 ml of 5× PBS and 19 ml H_2O.

    NOTE: *Solutions should be prepared on ice and the following steps carried out in reduced lighting.*

17. Place membrane in developing tray. Add 30 µl of 30% H_2O_2 to the chloronaphthol solution and immediately transfer solution to tray.
18. Incubate membrane at room temperature with gentle rocking in the dark. Check color development periodically. When band intensity is sufficient, transfer membrane to 1× PBS to stop the development.

    Developing time may vary from 1 to 30 min depending on the amount of BVR protein present. When the membrane begins to appear noticeably blue or violet in color, the probability of obtaining a good signal-to-background ratio decreases significantly.

BASIC PROTOCOL 3

TWO-DIMENSIONAL GEL ISOELECTRIC FOCUSING

Changes in BVR expression may be reflected by changes in the distribution of its isoforms, which can be resolved by two-dimensional isoelectric focusing. Protein samples are subjected to isoelectric focusing (IEF) in tube gels essentially by the method of O'Farrell (1975). After electrophoresis, the gel is removed from the tube and placed onto a denaturing polyacrylamide gel. Proteins are separated by SDS-PAGE and the resulting gel is either stained or developed as a immunoblot as described in Basic Protocol 2.

Materials

Urea
IEF acrylamide mix (see recipe)
Ampholytes pH 5-8, pH 4-6.5, and pH 3.5-10
10% (w/v) ammonium persulfate
TEMED
Lysis buffer (see recipe)
Overlay solution (see recipe)
Upper electrode buffer: 0.02 N NaOH
Lower electrode buffer: 0.01 M H_3PO_4
Sample for analysis
Gel equilibration buffer (see recipe)

3-ml syringe
10-cm gel tube–loading needle (e.g., Bio-Rad)
IEF tubes, 1.5 mm × 12.5 cm (e.g., Bio-Rad)
IEF apparatus (e.g., Bio-Rad)
Gel tube–extrusion needle (e.g., Bio-Rad)
Glass test tube, ≥15 cm in length

Additional reagents and equipment for SDS-PAGE (*APPENDIX 3*), electrotransfer (*UNIT 2.3*), staining proteins in gels (*APPENDIX 3*), and immunodetection (see Basic Protocol 2)

Prepare tube gels

1. Dissolve 5.5 g urea in 1.33 ml IEF acrylamide mix. Add 0.225 ml ampholyte pH 5-8, 0.225 ml ampholyte pH 4-6.5, and 0.05 ml ampholyte pH 3-10. Bring volume to 10 ml with H_2O. Warm to 37°C until urea is dissolved.
2. Degas solution for 15 min, then add 15 µl of 10% ammonium persulfate and 7 µl TEMED.
3. Pour solution into syringe fitted with gel tube–loading needle.
4. Seal bottom of gel tube with Parafilm, then fill tube with acrylamide solution to a depth of 10 cm. Add solution slowly to avoid introducing bubbles.
5. Overlay acrylamide solution with 20 µl H_2O by slowly pouring down the side of the tube to avoid mixing at the interface. Allow solution to polymerize for 1 hr.
6. Remove water from the top of the gel using a syringe with a pipettor. Add 15 µl lysis buffer followed by 15 µl overlay solution. Remove Parafilm from bottom of tube.
7. Carefully fill tube with upper electrode buffer.
8. Place tubes in holder in IEF apparatus. Fill top and bottom reservoirs with upper and lower electrode buffers, respectively.
9. Prefocus the gel by electrophoresing 15 min at 200 V, 30 min at 300 V, and 1 hr at 400 V.

Prepare sample and perform electrophoresis

10. In a microcentrifuge tube, add solid urea to protein sample until solution is saturated. Then add 1 µl lysis buffer for each 5 µl of sample.

    For purified BVR protein, 3 to 5 µg of sample can be easily detected on a stained gel. If using cytosolic extract, load 100 to 200 µg of protein and perform an immunoblot to detect BVR.

11. After prefocusing, remove IEF tube from apparatus and remove overlay and lysis buffer.
12. Load sample onto top of gel and carefully overlay with 15 µl overlay buffer. Fill remainder of tube with upper electrode buffer.
13. Return tube to IEF apparatus and electrophorese 17 hr at 400 V.
14. Increase voltage to 800 V and electrophorese for an additional 1 hr.
15. Shut off power. Remove upper chamber and then tube.
16. Attach a gel tube–extrusion needle to a 3-ml syringe and fill the syringe with H_2O.

17. Insert the needle into the tube, running the tip against the tube's inside surface, until the tip rests between the gel and the tube.

    Allow the tip to penetrate only a few millimeters below the top of the gel. Do not push the gel with the needle.

18. Very slowly apply pressure to the syringe, carefully rotating the tube at the same time.

    The gentle stream of water will detach the gel from the tube.

19. As the gel is extruded from the bottom of the tube, allow the needle to advance further into the tube. When the needle has been inserted as far as it will go, remove it and use air pressure to expel the gel into a large tray of water.

20. Collect gel in a test tube submerged in the water.

    It is essentially impossible to handle the gel directly without damaging it.

21. Decant the water from the tube and replace with gel equilibration buffer.

22. Incubate tube 20 min with gentle rocking.

Electrophorese the SDS-PAGE dimension

23. Pour a separating gel and stacking gel for SDS-PAGE using 1.5-mm spacers and a preparative comb that produces a loading well that is wider than the length of the tube gel (see *APPENDIX 3*).

24. Remove most of the equilibration buffer from the tube and allow gel to slide out onto a piece of Parafilm. Use a spatula to straighten the gel out on the Parafilm.

25. Carefully slide the gel into the loading well. Try to avoid trapping air bubbles.

26. Perform electrophoresis and transfer proteins to a nitrocellulose membrane (see *UNIT 2.3*). Stain gel for proteins or develop as an immunoblot (see Basic Protocol 2, steps 6 to 18).

SUPPORT PROTOCOL

PREPARATION OF BVR FUSION PROTEIN FROM BACTERIAL CELL EXTRACTS

BVR expressed from plasmids containing cloned BVR cDNA is not stable in some strains of *Escherichia coli* if the cells are grown past log phase. However, significant yields of the BVR–β galactosidase fusion protein can be obtained from cultures grown to relatively late log phase. As is the case for native BVR, the fusion protein is found in the cytoplasmic fraction of the lysates. Lysates are prepared by several cycles of freezing and thawing followed by sonication and centrifugation at 10,000 × *g*. Preparation of bacterial cell lysates is identical to that described in *UNIT 9.3,* Support Protocol 2, except that homogenization buffer is substituted for resuspension buffer in the lysis step. BVR activity is then analyzed as described in Basic Protocol 1 (steps 8 to 12).

These crude lysates have sufficient BVR activity that they can be used to supplement heme oxygenase assays (see *UNIT 9.3*) without the further purification.

Because the stability of the fusion protein varies from one bacterial strain to another, a preliminary time-course study should be performed determine the optimal harvest time for the bacteria.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibody diluent

6 g bovine serum albumin
40 mg Thimerosal (Sigma)
40 ml 5× PBS (see recipe)

Add 10 ml normal goat serum and bring volume to 200 ml with H_2O. Centrifuge 15 min at 20,000 × *g*, 4°C. Filter sterilize and store up to 6 months at 4°C.

Biliverdin, 300 µM stock

1 mg biliverdin dihydrochloride (Sigma)
5.08 ml methanol
Keep on ice in reduced light
Prepare fresh daily

Blocking solution

6 g bovine serum albumin
40 mg Thimerosal (Sigma)
40 ml 5× PBS (see recipe)

Add 20 ml normal goat serum and bring volume to 200 ml with H_2O. Centrifuge 30 min at 20,000 × *g*, 4°C. Filter sterilize and store up to 6 months at 4°C.

BVR assay buffer, pH 6.75

Dissolve 3.95 g KH_2PO_4 and 3.66 g K_2HPO_4 in 400 ml H_2O. Add 5 ml 0.1 M EDTA (*APPENDIX 2A*) and adjust to pH 6.75 with KOH. Bring volume to 500 ml with H_2O. Autoclave to sterilize and store at 4°C for up to 6 months.

BVR assay buffer, pH 8.7

Dissolve 6.057 g Tris base in 400 ml H_2O. Add 5 ml 0.1 M EDTA (*APPENDIX 2A*) and adjust to pH 8.7 with HCl. Bring volume to 500 ml with H_2O. Store up to 6 months at 4°C.

Cofactor buffer

Adjust 2 ml BVR assay buffer, pH 6.75 (see recipe), to pH ~7.8 by adding 0.1 ml of 1 N NH_4OH. Bring volume to 4 ml with H_2O.

If preparing larger volumes, buffer can be stored up to 6 months at 4°C.

Gel equilibration buffer

10 ml glycerol
4 ml 2-mercaptoethanol
16 ml 10% (w/v) SDS
10 ml 0.5 M Tris·Cl, pH 6.8
2 ml 0.05% (w/v) bromphenol blue
40 ml H_2O
Store up to 1 year at 4°C

Homogenization buffer

10 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
790 ml H_2O
85.58 g sucrose
H_2O to 1 liter
Filter sterilize and store up to 6 months at 4°C

IEF acrylamide mix

141.9 g acrylamide
8.1 g bisacrylamide
H_2O to 500 ml
Filter through Whatman no. 1 filter paper
Store up to 1 year at 4°C

Lysis buffer

5.7 g urea
2 ml 10% Nonidet P-40
0.2 ml pH 5-8 ampholytes
0.2 ml pH 4-6.5 ampholytes
0.1 ml pH 3-10 ampholytes
0.5 ml 2-mercaptoethanol
H_2O to 10 ml
Prepare fresh daily

Overlay solution

5.5 g urea
0.1 ml pH 5-8 ampholytes
0.1 ml pH 4-6.5 ampholytes
0.05 ml pH 3-10 ampholytes
H_2O to 5 ml
Prepare fresh daily

Phosphate-buffered saline (PBS), 5×

10.8 g KH_2PO_4
55.7 g K_2HPO_4
175.3 g NaCl
3 liters H_2O
Adjust pH to 7.4 with KOH
Bring volume to 4 liters with H_2O
Store indefinitely at room temperature
To obtain 1× PBS, dilute 4:1 with H_2O before use

Transfer buffer

25 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
192 mM glycine
20% (v/v) methanol
Store up to 1 year at room temperature

COMMENTARY

Background Information

In mammals and some species of fish, the cytosolic enzyme biliverdin reductase (BVR) reduces biliverdin IXα—the open tetrapyrole product of the oxidative cleavage of heme by heme oxygenase—to bilirubin (Singleton and Laster, 1965; Colleran and O'Carra, 1970; Tenhunen et al., 1970). In mammals, bilirubin is subsequently glucuronidated by bilirubin UDP-glucuronosyltransferase and excreted. BVR reduces the γ bridge of biliverdin using either NADH or NADPH as a cofactor. The optimal pH for BVR activity differs for each of the pyridine nucleotides. Optimal activity is seen at pH 6.75 with NADH and at 8.7 when NADPH is used as the cofactor for the enzyme purified from rat (Kutty and Maines, 1981). Human biliverdin IXα reductase also shows similar cofactor specificity and pH optima, although the pH optimum for NADH is broader for human BVR than for the rat enzyme (Maines and Trakshel, 1993; Maines et al., 1996).

Whether isolated from rat or human tissue, BVR is strongly inhibited by thiol agents, suggesting that cysteine residues are important for

enzymatic activity. Both rat and human BVRs have been cloned and expressed in *E. coli* (Fahkrai and Maines, 1992; Maines et al., 1996) and the critical nature of the cysteine residues has been confirmed by site-directed mutagenesis of the rat enzyme (McCoubrey and Maines, 1994). Rat and human BVRs share 83% identity in amino acid sequence and differ in length by a single additional amino acid residue present in the human protein. On SDS-PAGE the rat enzyme has a mobility comparable to its predicted size (~34 kDa); however, human BVR migrates anomalously, yielding an apparent size of 39 to 42 kDa. Human BVR expressed from the cDNA also shows an abnormal mobility. The explanation for this phenomenon remains to be elucidated. Despite the relatively strong sequence homology between rat and human BVR, antisera raised to the enzymes show pronounced species specificity. Antibodies raised against the human form have extremely low immunoreactivity toward the rat protein.

Purified BVR exists as a large number of isoelectric variants. At least ten isoforms can be detected by two-dimensional gel electrophoresis using protein purified from various tissues (Huang et al., 1989); the relative abundance of isoforms varies among tissues. Several variants are also detected when the enzyme is expressed in bacteria (Maines et al., 1996), which suggests that at least some variants may be the result of post-translational modifications common to both prokaryotes and eukaryotes. Recently it has been demonstrated that differential phosphorylation plays a significant role in generation of the variant isoforms (Huang et al., manuscript in preparation). It is likely that phosphorylation regulates enzyme activity. Thus, changes in the distribution of the variants may reflect a regulation of BVR at the post-translational level.

Critical Parameters

The most common error in detection of BVR activity results from improper preparation or storage of reagents. Biliverdin is not soluble in aqueous solutions, and failure to completely dissolve the substrate in methanol before adding it to the reaction mixture may result in spectral interference and an inaccurate measurement of BVR activity. Similarly, exposing biliverdin to light may cause it to degrade, thus altering the kinetics of the reaction.

Cofactor instability can also lead to spurious results. Although NADPH solutions remain stable for many hours if kept on ice, they should be prepared as close to the time of use as possible. Rapid use is even more essential for NADH, which is comparatively unstable in solution and should be used immediately after preparation.

For Basic Protocol 2, all of the critical parameters normally pertinent to immunoblotting will apply. Of particular note for BVR blots is the species specificity of antisera. Polyclonal sera prepared against rat BVR recognize the human enzyme poorly, and antisera prepared against human BVR recognize the rat protein to an extremely limited degree. Thus selecting the appropriate antibody is essential for success of the procedure.

For two-dimensional gel electrophoresis (Basic Protocol 3), all considerations relevant to electrophoresis and immunoblotting apply. In particular, caution should be used to avoid introduction of air bubbles into the gels. Bubbles are frequently trapped between the tube gel and the surface of the second gel and can prevent an even transfer of the protein, which leads to artifacts. The small-diameter IEF tubes must be cleaned scrupulously and rinsed well prior to use to avoid the buildup of bubbles, which can effectively block the tube. Care must be taken when overlaying solutions in the tubes to avoid similar problems. As noted in the protocol, extrusion of the gel is accomplished using the water in the syringe, not the needle, as the latter can easily tear the gel.

Troubleshooting

As noted above, degradation of the cofactor solutions, especially NADH, can decrease the success and reproducibility of the assay. As a general rule, when activities appear lower than anticipated, it is wise to repeat the assay with fresh cofactor. Also, BVR activity is maximal when the substrate concentration is in the 3- to 5-μM range. Use of concentrations above or below this range will yield reduced estimates of activity. Thus, care should be taken in the preparation of stock and reaction solutions.

When sample preparations may contain very high levels of BVR activity, it is possible that addition of too much protein will lead to inaccurate estimates of activity. If too much BVR is present, so much substrate may be converted to product initially that the reaction will no longer be in the linear range during the spectrophotometric scan. In some cases the biliverdin may be virtually exhausted before the scan begins. Such a situation sometimes occurs when using purified protein or bacterial cell extracts that express high concentrations of

BVR fusion protein. Frequently, dilution of the protein preparation will remedy this problem. Additionally, the reaction rate should be determined by taking an average of activities measured during several short periods, rather than a single long period (e.g., four readings over 15 sec rather than one reading lasting 1 min). A decrease in the initial activity rate during the later intervals would suggest nonlinear kinetics, and the assay should be repeated with a reduced amount of protein.

In addition to the critical parameters noted above, most difficulties in immunoblotting and IEF arise from the technical problems typical of SDS-PAGE or to problems with the antibody solutions. Upon initial use, polyclonal antisera may detect proteins in addition to BVR. Such activity is particularly likely when crude bacterial extracts are used, as the hosts (generally rabbit) are frequently exposed to *E. coli* antigens and may develop antibodies to some of them. These antibodies are generally relatively low in titer compared to the antibodies raised against the immunogen and their activity is reduced with subsequent reuse of the serum. However, excessive reuse of the working antibody solutions eventually results in decreased signal sensitivity. If maximum sensitivity is required in examining bacterial lysates, it may be necessary to preabsorb the serum with lysates prepared from the same *E. coli* strain lacking BVR cDNA.

Anticipated Results

Preparations of rat liver and kidney cytosol generally yield specific activities in the range of 1 U/mg of total protein. Bacterial cell extracts typically have 10 to 20 times the specific activity of tissue preparations. The number and relative distribution of isoelectric variants will differ depending on the tissue being examined and the treatment regimen. In general both kidney and liver will show five or six isoform bands.

Time Considerations

Dissection of tissue and preparation of cytosolic fractions or collection of bacterial cells and preparation of lysate requires ~2 hr. Determination of protein concentrations and preparation of reagents for the kinetic assay takes ~1 hr, and the assay and calculations require 1 to 2 hr depending on the number of samples. Immunoanalysis is typically performed over the course of 2 days but can be accomplished in 1 day if the blocking step is carried out at 37°C. The first phase of two-dimensional gel electrophoresis requires a full day, due to the 17-hr electrophoresis step. The second dimension and immunoblotting usually takes 2 days.

Histochemical Analysis of Heme Degradation Enzymes

Histochemical analysis of the heme degradation system provides critical insights into the cellular localization, expression, and regulation of enzymes responsible for catabolism of the heme molecule. Assessment of the expression and regulation of select mRNAs and protein by in situ hybridization histochemistry (ISH; see Basic Protocol 1) and immunohistochemical approaches (IHC; see Basic Protocol 2 and Alternate Protocols 1 to 3) allows, respectively, for visualization and analysis of specific cellular sites of expression. Immunohistochemistry represents an important adjunct to gross biochemical, molecular, and activity measurements of tissue enzyme protein and transcripts (see *UNITS 9.2, 9.3 & 9.4*). Successful application of histochemical technique is as much an art as it is science. As such, the protocols described here constitute basic histochemical procedures for analysis of the heme degradation system, but some empirical modifications may be necessary to optimize the application for the special requirements of a particular experimental design, tissue source, or type of tissue. Additional protocols describe preparation of tissues for ISH and IHC (see Support Protocol 1) and adsorbing antibody with antigen to demonstrate specificity of staining (see Support Protocol 2).

DETECTION OF HEME OXYGENASE 1 AND 2 TRANSCRIPTS BY ISH

BASIC PROTOCOL 1

Cloning and characterization of the genes for rat heme oxygenase 1 (HO-1; Shibahara et al., 1985) and heme oxygenase 2 (HO-2; Rotenberg and Maines, 1990) have allowed for derivation of specific cDNA probes and characterization of transcripts coding for HO isozymes from a variety of tissue sources across mammalian species, including rodent and human (reviewed in Maines, 1992, 1997). ISH has been successfully applied to reveal the cellular localization of HO gene expression in brain (Ewing and Maines, 1992; Verma et al., 1993) and testis (Maines and Ewing, 1996). This nonisotopic approach, using digoxigenin labeling of cDNA, affords a highly sensitive technique without the hazards inherent in using radioisotopes. Furthermore, immunochemical detection of the HO-1/HO-2 cDNA-mRNA hybrids can be completed in 1 day, whereas techniques utilizing autoradiographic detection of radiolabeled probes can take weeks to obtain proper exposure. Using this method, specific mRNA can be detected in a heterogeneous cell population where only a subpopulation may be transcribing the HO-1/HO-2 gene.

This protocol describes in situ detection of HO-1 or HO-2 mRNAs. Selective cDNA probes that encode complementary sequence to either HO-1 or HO-2 mRNAs are produced and tagged with digoxigenin. Paraffin-embedded tissue is prepared under conditions that preserve the integrity of the target mRNAs and is then treated to allow penetration of the digoxigenin-labeled HO-1/HO-2 cDNA probes. Prepared tissue is incubated overnight with the appropriate cDNA probe to allow formation of cDNA/mRNA hybrids. The tissue is washed under conditions of sufficient stringency to reduce nonspecific adherence of cDNA probes with tissue components. Finally, the authentic cDNA/mRNA hybrids are immunochemically visualized.

Materials

10× PCR buffer (see recipe)
2 mM dNTP mix (2 mM each of dATP, dGTP, dCTP, and dTTP)
100 mM stocks of HO-1 or HO-2 sense and antisense primers (Midland Certified Reagent Co.):
HO-1 primers: 5′-TGCACATCCGTGCAGAGAAT-3′ (+71 to +90) and 5′-AGGAAACTGAGTGTGAGGAC-3′ (+814 to +833)
HO-2 primers: 5′-GAAGTGAGGGCAGCACAAAC-3′ (−32 to −13) and 5′-CTTCTTCAGCACCTGGCCT-3′ (+486 to +504)
5 U/µl *Taq* DNA polymerase (U.S. Biochemical)
10 to 20 µl/ml template plasmid DNA
Mineral oil
Chloroform
1% (w/v) agarose gel (see recipe)
1× TAE buffer (see recipe) containing 0.5 µg/ml ethidium bromide (added from 5 mg/ml ethidium bromide stock; see recipe)
3 M sodium acetate, pH 5.2 (*APPENDIX 2A*)
70% and 100% ethanol
TE buffer, pH 8 (see recipe)
GeneClean kit (Bio 101)
Digoxigen-dNTP labeling mix (see recipe)
Slides containing paraffin-embedded tissue sections of interest (see Support Protocol 3)
Xylene
Graded ethanol series: 50%, 60%, 70%, 80%, 90%, and 100% (v/v) ethanol
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
0.2 N HCl
2×, 1×, 0.5×, 0.25×, and 0.05× SSC (see recipe for 20×)
10 µg/ml proteinase K working solution (see recipe; preincubate 45 min at 37°C before use)
4% (w/v) paraformaldehyde
Prehybridization buffer (see recipe)
Buffer I (see recipe)
Blocking solution (see recipe)
Anti-digoxigenin antibody-alkaline phosphatase conjugate (Fab fragments; Boehringer Mannheim)
Buffer II (see recipe)
Developer solution (see recipe)
Aqueous mounting medium

Programmable thermal cycler
Coplin jars
Humidified chambers: large plastic culture dishes lined with RNase-free H_2O-saturated Whatman filter paper
Glass coverslips

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.2* & *APPENDIX 3*)

Prepare double-stranded templates for HO-1/HO-2 by PCR

To exclude vector sequence and yield a probe with defined ends, the target is amplified from double-stranded template prior to generation of single-stranded probes.

1. Combine the following in a 0.5-ml microcentrifuge tube:

   76.5 µl distilled water
   10 µl 10× PCR buffer
   10 µl 2 mM dNTP mix
   1 µl 100 mM HO-1 or HO-2 sense primer stock solution (100 pmol)
   1 µl 100 mM HO-1 or HO-2 antisense primer stock solution (100 pmol).

2. Add 0.5 µl of 5 U/µl *Taq* DNA polymerase and 1 µl (20 ng) of the appropriate template plasmid.

   Appropriate negative controls may include a reaction mixture without Taq DNA polymerase enzyme and another without template plasmid. The template plasmid can be generated by RT-PCR of mRNA from rat spleen (HO-1) or rat testes (HO-2).

3. Vortex mixture and gently overlay with 70 µl mineral oil.

4. Carry out PCR in a programmable thermal cycler using the following amplification cycles:

1 cycle:	2 min	94°C	(denaturation)
30 cycles:	1 min	94°C	(denaturation)
	1.5 min	57°C	(annealing).
	4 min	70°C	(extension)
Final step:	10 min	70°C	(hold)

5. Cool at 4°C, add 100 µl chloroform, then vortex for 15 sec. Transfer the top (aqueous) phase to a clean microcentrifuge tube.

   Upon chloroform addition the mineral oil will settle to the bottom of the microcentrifuge tube.

6. Remove 5 µl of the aqueous phase and analyze by electrophoresis on a 1% (w/v) agarose gel in 1× TAE buffer containing 0.5 µg/ml ethidium bromide (see *UNIT 2.2* & *APPENDIX 3A*).

7. After electrophoresis, visualize the amplified fragment using a UV light source (see *UNIT 2.2* & *APPENDIX 3*). A bright fluorescent band should be visualized on the gel following amplification relative to negative controls.

Purify the double-stranded DNA template

8. If the HO-1/HO-2 cDNA has been suitably amplified, add 10 µl of 3 M sodium acetate, pH 5.2, and 300 µl of ice-cold 100% ethanol to the remainder of the aqueous phase to precipitate the amplified DNA fragment. Vortex and place on dry ice for 10 to 20 min.

9. Microcentrifuge 15 min at 10,000 × *g*, 4°C. Decant the supernatant and rinse the pellet containing the cDNA by adding 70% ethanol and microcentrifuging 5 min at 10,000 × *g*, 4°C. Decant the supernatant, air dry the pellet, and resuspend it in 20 µl TE buffer, pH 8.

10. Electrophorese sample on two lanes of a 1% (w/v) standard agarose gel in 1× TAE buffer containing 0.5 µg/ml ethidium bromide (see *UNIT 2.2* & *APPENDIX 3A*).

11. Visualize the purified material using a UV-light source and excise the bands corresponding to the size of the desired HO-1 (763-bp)/HO-2 (563-bp) fragment.

12. Purify the fragment away from the agarose using the GeneClean kit, according to the manufacturer's instructions.

13. Quantitate the final DNA concentration of the sample by comparison with standards in a 1% agarose gel, and store sample at −20°C.

Label single-stranded probes

14. Starting with the double-stranded template, prepare single-stranded sense and antisense probes by asymmetric PCR and purify as described above for preparation of the double-stranded template (steps 1 to 13), with the following modifications at the indicated steps.

    a. In step 1, for each single-stranded probe (sense and antisense), use only one of the two HO-1/HO-2 primers in the reaction mixture.

       HO-1 primer, +71 to +90, is used to generate the sense orientation, whereas the complement of +814 to +833 is used for antisense. HO-2 primer, −32 to −13, is used to generate the sense orientation, whereas the complement of +486 to +504 is used for antisense.

    b. Also in step 1, use 10 µl digoxigenin-dNTP labeling mix instead of 10 µl of the standard 2 mM dNTP stock in the reaction mix.

    c. In step 2, use 5 µl (2 ng/µl) of the double-stranded HO-1/HO-2 fragment from (step 13) as the template, instead of the plasmid template.

    d. The total volume of the reaction is maintained at 100 µl by the addition of the appropriate amount of RNase-free water.

       The probe is stored at −20°C and is stable for at least 6 months.

Experimental day 1: Pretreat tissue

15. To increase diffusion of HO-1/HO-2 cDNA probes into cells, clear tissue of paraffin by placing slides twice sequentially, each time for 10 min, in Coplin jars containing xylene.

    See Support Protocol 1 for preparation of tissue.

16. Rehydrate the tissue by sequential incubations of 3 min each in graded ethanol solutions from 100% to 50% in increments of 10%.

17. Equilibrate the tissue in PBS with three sequential incubations for 3 min each.

18. Denature the tissue by immersing in in 0.2 N HCl and incubating 20 min.

19. Incubate tissue for 15 min in 2× SSC.

20. Equilibrate the tissue in PBS with two sequential incubations for 3 min each.

21. Apply 10 µg/ml proteinase K to the tissue section on the slide and incubate 30 min at 37°C in a humidified chamber.

    Depending on the tissue type the length of digestion may have to be optimized for maximal probe penetration.

22. Rinse the deproteinated tissue with PBS to remove excess enzyme, then incubate tissue in 4% (w/v) paraformaldehyde for 5 min at 4°C . Rinse tissue briefly in PBS, then air dry for 10 min.

    Depending on the tissue type the length of fixation may have to be optimized.

Prehybridize and hybridize tissue

23. Pipet prehybridization buffer onto the dry tissue section and incubate the slides in a humidified chamber for 1 hr at room temperature.

24. Rinse tissue in 2× SSC for 15 min. Dehydrate slides by sequential incubations of 3 min each in graded ethanol solutions from 50% to 100% in increments of 10% (i.e., in the opposite order from step 16).

25. Dilute the HO-1/HO-2 cDNA probe (from step 14) to 2 ng/ml in prehybridization solution. Pipet this hybridization solution onto the dry tissue.

In addition to the HO-1/HO-2 antisense probe, the appropriate HO-1/HO-2 sense probe should be run in parallel and at the same concentration. The latter constitutes a negative test, or control, for HO-1/HO-2 mRNA. Also, a control in which no probe is applied to the tissue should be tested under in situ hybridization conditions to confirm the absence of endogenous alkaline phosphatase activity in tissue sections.

26. Gently apply Parafilm coverslips, taking care to exclude all air bubbles. Transfer slides to humidified chambers, seal the cover of each chamber with Parafilm, and incubate 16 hr at 37°C.

    "Parafilm coverslips" are applied as follows. Gently grasp the end of a precut rectangular piece of Parafilm with a pair of forceps. Lay the edge of the Parafilm at the end of the slide and gently place the coverslip onto the tissue by slowly decreasing the angle between the Parafilm and the slide. This technique will allow even distribution of probe solution and displacement of air bubbles.

Experimental day 2: Post-hybridize and perform immunohistochemistry

27. Perform post-hybridization treatment of tissue by sequentially incubating in Coplin jars containing: 2× SSC (40 min, 25°C), 1× SSC (40 min, 25°C), 0.5× SSC (40 min, 37°C), 0.25× SSC (40 min, 25°C), and 0.05× SSC (40 min, 25°C), respectively, prior to immunochemical localization.

    Time and stringency may have to be varied depending on the tissue source.

28. Rinse tissue briefly in buffer I, then block tissue by treating for 30 min with blocking solution at 25°C.

29. Dilute anti-digoxigenin antibody–alkaline phosphatase conjugate 1/500 in blocking solution. Replace the blocking solution from the previous step with this diluted primary antibody and incubate 1 hr at 25°C in a humidified chamber.

30. Rinse the tissue twice with buffer I, each time for 10 min at 25°C to remove excess primary antibody.

31. Equilibrate the tissue for 10 min in buffer II, then begin incubating in developer solution in the dark, while monitoring color development in the tissue every 30 min using a microscope. If the staining intensity is not sufficient, return the slide to the developer for another 30-min incubation period. Otherwise proceed to step 32.

    Slides may either be immersed in developer or the developer applied to the section directly.

    The hybrids of HO-1/HO-2 cDNA and mRNA will be indirectly visualized as deposits of purple formazan dye in cells within the tissue.

32. When staining intensity is satisfactory, terminate reaction by rinsing slides in distilled water.

33. Coverslip (glass) slides using aqueous mounting medium and store in a light-tight container.

IMMUNOHISTOCHEMICAL ANALYSIS OF HEME DEGRADATION SYSTEM IN FREE-FLOATING SECTIONS

BASIC PROTOCOL 2

Immunohistochemistry (IHC) has been widely applied to reveal the cellular localization of HO gene expression in a variety of tissues (see Table 9.5.1). Using this method, specific sites of protein expression can be detected in a heterogeneous cell population where only a subset of cells may be translating the HO-1/HO-2 gene. The IHC procedures describe how to localize HO system components with specific antibody preparations that are commercially available.

Briefly, frozen tissue is prepared under conditions that preserve both the integrity of the tissue and the select antigenic proprerties of the target protein needed for antibody binding. Tissue is treated to allow entry of antibody directed against the target protein. The tissue is washed under conditions of sufficient stringency to reduce nonspecific adherence of antibody with tissue components. Tissue is then incubated with secondary antibody and washed. Finally, the authentic antibody-antigen complexes are visualized using an immunochemical detection system typically consisting of a tertiary antibody conjugated to peroxidase followed by diaminobenzidine treatment. Consequently, sites of protein expression are stained brown.

NOTE: Tissue preparations for IHC primarily fall into two categories, depending on the method used for handling post fixation: paraffin-embedded sections and frozen sections. In turn, frozen tissue sections may be subjected to IHC procedure as mounted sections or free-floating sections. This latter format is commonly applied to analysis of components of the heme degradation system in brain tissue.

Materials

Frozen tissue sections (Support Protocol 1)
0.1 M sodium phosphate buffer, pH 7.3 (*APPENDIX 2A*)

PBTX: 0.3% (v/v) Triton X-100 in 0.1 M sodium phosphate buffer, pH 7.3 (store up to 1 month at 4°C)
Antibody buffer: PBTX (see above) containing 10% (v/v) normal goat serum (NGS)—filter through 0.45-µm filter fitted to a syringe; prepare fresh
Primary antibody: HO-1, HO-2, or BVR antibody (StressGen)
Secondary antibody: goat anti-rabbit γ-globulin (Organon Teknika Cappel)
Tertiary antibody: peroxidase-anti-peroxidase antibody (Organon Teknika Cappel)
0.05 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.5% (w/v) 3,3-diaminobenzidine tetrahydrochloride dihydrate (DAB) in 0.05 M Tris·Cl, pH 7.5 (prepare fresh; filter through Whatman filter paper)
3% (v/v) hydrogen peroxide (prepare fresh from 30% hydrogen peroxide)
Graded ethanol series: 50%, 60%, 70%, 80%, 95%, and 100% (v/v) ethanol
Xylene
Cytoseal 60 mounting medium

Small paint brushes
Netted compartments (Brain Research)
Tabletop shaker
60 × 15–mm tissue culture dishes (Falcon)
Superfrost Plus slides (Fisher)
Slide warmer
Glass coverslips
Large crystallization dishes

Experimental day 0

1. On the night before the experiment is to begin, soak tissue for 16 hr in 0.1 M sodium phosphate buffer, pH 7.3, at, 4°C with gentle agitation on a tabletop shaker.

   Tissue is transferred to netted compartments which are then placed in large crystallization dishes containing 0.1 M sodium phosphate buffer, pH 7.3.

   This incubation serves to remove the cryoprotectant from the sections.

Experimental day 1: Expose to primary antibody

2. With a small paintbrush, transfer tissue into netted compartments and then place the compartments into a large crystallization disk containing 0.1 M sodium phosphate buffer, pH 7.3.

   Many sections may be processed in a single netted compartment.

3. Wash sections three times with 0.1 M phosphate buffer, pH 7.3, each time by incubating 5 min at room temperature with shaking.

   All washes are performed on a tabletop shaker at room temperature unless otherwise specified. The speed of shaking should allow for gentle movement of the tissue within the netted compartment.

4. Wash sections three times in PBTX, each time by incubating 5 min.

5. Block the tissue by incubating 20 min in antibody buffer.

6. Transfer tissue into 60 × 15–mm culture dishes containing primary antibody (HO-1, HO-2, or BVR) diluted to the appropriate concentration in antibody buffer. Incubate from overnight to ≤4 days in a cold room (4°C).

   The final concentration of antibody depends on the specific antibody preparation being used and may need to be empirically determined.

Experimental day 2: Expose to secondary antibody

7. Transfer the tissue out of the dishes containing the primary antibody into netted compartments with PBTX. Wash tissue with eight changes of PBTX, at room temperature, over a period of 2 to 3 hr.
8. Preincubate the tissue sections in antibody buffer for 20 min.
9. Transfer the tissue out of the netted compartments into 60 × 15–mm culture dishes containing goat anti-rabbit γ-globulin (GAR) secondary antibody diluted 1/1000 (v/v) in antibody buffer.

   If a primary antibody is derived from a source other than rabbit, then the choice of secondary antibody should be adjusted accordingly for specificity.

10. Incubate tissue in secondary antibody overnight in a cold room.

Experimental day 3: Expose to tertiary antibody

11. Transfer the tissue into netted compartments containing PBTX. Wash the tissue with eight changes of PBTX over a period of 1.5 to 3 hr.
12. Preincubate tissue sections in antibody buffer for 20 min.
13. Transfer tissue sections into culture dishes containing peroxidase-anti-peroxidase tertiary antibody diluted 1:500 (v/v) in antibody buffer. Incubate tissue in tertiary antibody for 1 hr at room temperature.
14. Transfer tissue into netted compartments containing 0.1 M sodium phosphate buffer, pH 7.3. Wash tissue with eight changes of 0.1 M sodium phosphate buffer, pH 7.3, over a period of 1 to 2 hr.
15. Wash tissue twice, each time for 10 min, in 0.05 M Tris, pH 7.5.

Detect bound antibodies

16. Incubate tissue in 0.5% DAB/0.05 M Tris·Cl, pH 7.5.

    CAUTION: *Development reagents should be prepared and used in a fume hood. 3,3-diaminobenzidine tetrahydrochloride dihydrate (DAB) is a carcinogen. DAB solutions may be inactivated by addition of full-strength bleach. Furthermore, DAB-tainted glassware should be decontaminated by rinsing with bleach prior to further cleaning. All DAB-containing solutions should be handled as chemical waste in accordance with institutional guidelines.*

17. Add 33 ml of 3% hydrogen peroxide to 100 ml of freshly prepared 0.5% DAB/0.05 M Tris·Cl, pH 7.5. Immediately begin incubating tissue in this developer solution and continue incubation up to 15 min, visually inspecting selected sections under a microscope frequently to assess the progress of development.

    The reaction product is brown.

18. Terminate the development process by washing the tissue sections three times, each time for 10 min, in 0.05 M Tris, pH 7.5.
19. Wash tissue sections three times, each time for 15 min, in 0.1 M sodium phosphate buffer, pH 7.3. Store sections in 0.1 M sodium phosphate buffer, pH 7.3, at 4°C until further processing.

Process tissue sections

20. Mount sections onto Superfrost Plus slides with a paintbrush.
21. Dry the mounted sections covered at 37°C on a slide warmer.
22. Dehydrate the tissue by immersing the slides successively, each time for 3 min, in Coplin jars containing 50%, 60%, 70%, and 80% (v/v) ethanol solutions, respectively.

Then, immerse slides twice, each time for 3 min, in 95% ethanol, and finally three times, each time for 3 min, in 100% ethanol.

23. Immerse slides three times in xylene, each time for 15 min, to clear the sections.

    Removal of water content and treatment with xylene is required for good resolution of the cellular architecture of the tissue.

24. Coverslip slides using Cytoseal 60 mounting medium.

ALTERNATE PROTOCOL 1

IMMUNOFLUORESCENCE LOCALIZATION OF HEME DEGRADATION SYSTEM USING FREE-FLOATING FROZEN SECTIONS

Generally, there are two primary approaches to the visualization of protein/antibody complexes: colorimetric and fluorimetric. Fluorimetric detection is an extremely powerful strategy that has been elegantly applied to visualize a wide variety of target proteins.

This procedure details the detection of the heme degradation system by fluorimetric detection using goat anti-rabbit γ-globulin (GAR) secondary antibody conjugated to fluorescein isothiocyanate. These procedures are a modification of those described in Basic Protocol 2.

Additional Materials *(also see Basic Protocol 2)*

Secondary antibody: fluorescein (FITC)-conjugated goat anti-rabbit γ-globulin (Organon Teknika Cappel)
70% (v/v) glycerol
Fluorescence microscope

1. For frozen sections, carry out steps 1 to 8 of Basic Protocol 2.

   From this point onward, tissue sections should be manipulated under conditions of dimmed lighting to avoid photobleaching of the fluorescent signal. All incubations are performed in the dark. It is convenient to cover incubation vessels with aluminum foil to ensure light-tight conditions.

2. Transfer the tissue out of the netted compartments into culture dishes containing FITC-conjugated goat anti-rabbit γ-globulin diluted 1/10,000 (v/v) in antibody buffer.

   If a primary antibody is prepared from a source other than rabbit, then the choice of secondary antibody should be adjusted accordingly for specificity. Also, appropriate dilution of the fluorescently labeled secondary antibody and optimal duration of incubation may have to be empirically determined.

3. Incubate tissue in secondary antibody overnight in a cold room.

4. Transfer the tissue into netted compartments containing 0.1 M sodium phosphate buffer, pH 7.3. Wash the tissue with eight changes of 0.1 M sodium phosphate buffer, pH 7.3, over a period of 1.5 to 3 hr.

5. Mount tissue on Superfrost Plus slides and dry overnight on a slide warmer at 37°C.

6. Briefly rehydrate tissue by placing slides in a Coplin jar containing 0.1 M sodium phosphate buffer, pH 7.3, for 2 to 3 min.

7. Apply a glass coverslip using 70% (v/v) glycerol.

8. Wrap completed slides in foil and store at 4°C until ready to visualize using a fluorescence microscope.

IMMUNOHISTOCHEMICAL LOCALIZATION OF HEME DEGRADATION SYSTEM USING PARAFFIN-EMBEDDED TISSUE

Infiltration of tissue with paraffin wax (paraffin embedding) is a popular way to preserve tissue for IHC. In the hands of a skilled practitioner, paraffin-embedded tissue can be sectioned much more thinly than frozen tissue. As a result, paraffin sections typically yield superior resolution of individual cells than that obtained using frozen sections. However, it is noteworthy that paraffin embedding requires harsher chemical treatment of tissue than does processing of frozen sections. Consequently, with paraffin embedding there is greater risk for disruption of target protein such that antibody recognition is lost. Many antibodies that work perfectly well in procedures using frozen sections are useless with paraffin sections.

The following IHC procedures detail localization of HO system components in sections preserved by fixation and paraffin embedding. Briefly, paraffin is removed from the tissue using xylene and the sections are rehydrated. Tissue is incubated with primary antibody, washed, incubated with a biotinylated secondary antibody, and washed again. Finally, tissue is incubated with streptavidin conjugated with peroxidase, and washed prior to visualization of antibody-antigen complexes.

Additional Materials *(also see Basic Protocol 2)*

Paraffin-embedded sections on slides (Support Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Endogenous peroxidase inhibitor (see recipe)
PBS containing 0.3% (v/v) Triton X-100
PBS containing 0.3% (v/v) Triton X-100 and 10% (v/v) normal goat serum (NGS)
HO-1, HO-2, or BVR antibody (StressGen)
Zymed histological staining kit containing biotinylated goat anti-rabbit antiserum (secondary antibody) peroxidase-streptavidin conjugate, and development solution (Zymed)
Humidified chambers: large plastic culture dishes lined with H_2O-saturated Whatman filter paper
Glass coverslips

Prepare sections

1. Incubate paraffin-embedded tissue (5- to 10-µm thick) three times in xylene, each time for 3 min.
2. Incubate tissue three times in 100% ethanol, each time for 3 min.

   Once a bottle of ethanol is opened it will take up moisture from the atmosphere, rendering it less than absolute. It is advisable to replace the bottle of ethanol on a weekly basis, depending upon use.

3. Incubate tissue for 3 min in 80% ethanol, then for 3 min in 70% (v/v) ethanol.
4. Incubate tissue for 5 min in PBS, then in endogenous peroxidase inhibitor for 7 min.
5. Wash tissue four times in PBS, each time for 5 min.
6. Incubate tissue twice in PBS containing 0.3% Triton X-100, each time for 5 min.

Block tissue

7. Apply 250 µl of PBS containing 0.3% Triton X-100 and 10% NGS to each slide, transfer to a humidified chamber, and incubate 20 min at 25°C .

   This step is intended to block nonspecific binding sites in the tissue. Depending on the tissue type and source or the antibody being employed, the duration of the blocking step may have to be optimized.

8. Drain slides of excess blocking solution.

   It is convenient to tilt slides at a 45° angle onto a paper towel to remove the bulk of the solution. The remainder of the blocker may be removed by carefully placing a Kimwipe adjacent to the tissue to absorb remaining solution. However, it is important that the slides not be allowed to dry, or high background will be observed. Thus, prompt replacement of blocker with primary antibody is necessary. It is advisable to process a limited number of slides through each step to ensure timely and consistent tissue treatment.

Expose to primary antibody

9. Apply 100 µl of primary antibody diluted to the appropriate concentration in PBS containing 0.3% Triton X-100 and 10% NGS.

   The optimal primary antibody concentration will vary among antibody preparations and tissue type; so this needs to be empirically determined. For most antibody preparations, a 1/250 (v/v) dilution gives good results.

10. Apply Parafilm coverslips to each slide.

    "Parafilm coverslips" are applied as follows. Gently grasp the end of a precut rectangular piece of Parafilm with a pair of forceps. Lay the edge of the Parafilm at the end of the slide and gently place the coverslip onto the tissue by slowly decreasing the angle between the Parafilm and the slide. This technique will allow even distribution of antibody and displacement of air bubbles.

11. Transfer slides to a humidified chamber, seal with Parafilm, and incubate overnight at 4°C .

Expose to secondary antibody

12. Remove humidified chamber from refrigerator or cold room and equilibrate to room temperature for 1 hr.

13. Wash tissue four times with PBS, each time for 3 min.

    Parafilm coverslips may be efficiently removed by immersing the slides in a Coplin jar containing PBS. Thereafter, excess primary antibody is rinsed from the slides by placing them in Coplin jars containing PBS.

14. Drain sections and place slides back in humidified chambers. Pipet 100 µl of biotinylated goat anti-rabbit secondary antibody onto the sections, close chamber, and incubate 20 min at room temperature.

15. Wash slides four times with PBS, each time for 3 min. Drain sections and place them back in the humidified chambers.

Expose to conjugate

16. Pipet 100 µl of peroxidase-streptavidin conjugate onto each section, close the humidified chambers and incubate 15 min at room temperature.

17. Transfer sections to Coplin jars containing PBS and wash four times with PBS, each time for 3 min.

Develop slides

18. Prepare development solution (Zymed kit) immediately prior to use, in accordance with the manufacturer's instructions, and keep in the dark.

19. Pipet developer onto sections and incubate at room temperature for up to 15 min.

20. Terminate development by rinsing sections twice with distilled water, each time for 10 min.

21. Apply glass coverslips with mounting solution provided with the Zymed kit.

Mounting solution should be warmed to 37°C prior to use.

22. Examine slides for cells giving a positive (brown) reaction.

IMMUNOFLUORESCENCE LOCALIZATION OF HEME DEGRADATION SYSTEM FOR PARAFFIN-EMBEDDED SECTIONS

ALTERNATE PROTOCOL 3

This procedure details the fluorimetric detection of enxymes of the heme degradation system using goat anti-rabbit γ-globulin (GAR) secondary antibody conjugated to fluorescein isothiocyanate. The procedures are modified from Alternate Protocol 2.

Additional Materials *(also see Basic Protocol 2 and Alternate Protocol 2)*

Secondary antibody: fluorescein isothiocyanate (FITC)–conjugated goat anti-rabbit γ-globulin (Organon Teknika Cappel)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
70% (v/v) glycerol

Humidified chambers: large plastic culture dishes lined with H_2O-saturated Whatman filter paper
Glass coverslips
Fluorescence microscope

1. Carry out steps 1 to 14 of Alternate Protocol 2.

   From this point onward, tissue sections should be manipulated under conditions of dimmed lighting to avoid photobleaching of the fluorescent signal. All incubations are performed in the dark. It is convenient to cover incubation vessels with aluminum foil to ensure light-tight conditions.

2. Transfer slides to a humidified chamber and apply 100 µl of FITC-conjugated goat anti-rabbit antibody diluted 1/1000 in antibody buffer. Apply a Parafilm coverslip and seal the humidified chamber.

   "Parafilm coverslips" are applied as follows. Gently grasp the end of a precut rectangular piece of Parafilm with a pair of forceps. Lay the edge of the Parafilm at the end of the slide and gently place the coverslip onto the tissue by slowly decreasing the angle between the Parafilm and the slide. This technique will allow even distribution of antibody and displacement of air bubbles.

   If a primary antibody is derived from a source other than rabbit, then the choice of secondary antibody should be adjusted accordingly for specificity. Also, appropriate dilution of the fluorescently labeled secondary antibody and optimal duration of incubation may have to be empirically determined.

3. Incubate tissue in secondary antibody for 20 min at room temperature.
4. Remove slides from the humidified chamber and wash tissue four times with PBS, each time for 3 min.

   Excess secondary antibody is rinsed from the slides by placing them in Coplin jars containing PBS.

5. Drain sections and mount glass coverslips on each slide with 70% glycerol.
6. Wrap completed slides in foil and store at 4°C until ready to visualize using a fluorescence microscope.

PREPARATION OF TISSUE FOR ISH AND IHC

SUPPORT PROTOCOL 1

Tissue fixation and subsequent chemical treatment(s) are critical to the preservation of cellular architecture and target integrity (i.e., mRNAs and protein). The ultimate quality of histochemical data is greatly influenced by conditions used at this stage.

This protocol details the procedures for perfusion and fixation of tissue from both adult and neonatal rats. Optimal conditions for fixation treatment will vary and may have to be empirically determined.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for care and use of laboratory animals.

Materials

Adult or neonatal rat
Sodium pentobarbital
0.9% (w/v) NaCl
Perfusion fixative (see recipe)
Graded sucrose solutions: 0.1 M sodium phosphate buffer (*APPENDIX 2A*) containing 10%, 20%, and 30% (w/v) sucrose (store up to 1 week at 4°C)
Cryoprotectant (see recipe)

Dissecting instruments
Intravenous catheter (18-G for adult rat; 22-G for 14- to 28-day neonate; Becton Dickinson) or 30-ml syringe with 25-G needle (for 7-day neonate)
Superfrost Plus slides (Fisher)
Perfusion apparatus including peristaltic pump
Microtomes (Reichert-Jung)
Compartmentalized boxes

Anesthetize the animal

1. Weigh the adult or neonatal rat and anesthetize it by intraperitoneal injection of 50 mg/kg sodium pentobarbital.
2. After the animal is asleep, firmly pinch the foot with a pair of forceps.

   If there is no response, then proceed with the surgery.
3. Place the animal on its back. Open the abdominal cavity with a midline incision to the sternum.

   Positioning the animal on a refrigerator rack placed over a sink or basin is convenient for animal manipulation and drainage of perfusate.

Insert the catheter

4. Make a diagonal cut to each side of the sternum through the rib cage, extending to either side of the neck.

   Care should be taken not to sever any vessels or puncture the heart.
5. Clamp the sternum back with hemostatic forceps to give access to the heart.
6. Cut the connective tissue surrounding the diaphragm and make a lateral cut on each side of the animal to allow proper drainage of the perfusate.
7. Lift the lungs to expose the descending aorta and occlude the vessel using hemostatic forceps.

   Only occlude the descending aorta if the organ(s) of interest are in the upper body. Full-body perfusion is obtained by omitting this step.
8. Make a small incision in the right atrium.

   Be sure to have the intravenous catheter at hand and perfusion apparatus set up and functional prior to this step.

9. Insert the intravenous catheter into the left ventricle. Remove the needle and carefully position the catheter so that the tip of the device resides within the aortic arch.

The optimal size of the catheter for transcardial perfusion is either 18-G for adult rats or 22-G for 14- to 28-day-old neonatal animals, respectively. For 7-day-old neonates transcardial perfusion may be performed manually using a 30-ml syringe fitted with a 25-G needle. Manual perfusion of these young animals is technically demanding since the heart is very small and great care must be taken not to pierce through the organ. Extra time should be allotted for these manual procedures.

Begin perfusion

10. Connect the catheter to the perfusion apparatus and begin a flow of 0.9% (w/v) NaCl into the animal.

For an adult animal, infuse 250 ml of 0.9% (w/v) saline over 15 min. For a 7- to 28-day-old animal, infuse 60 to 70 ml over 10 min. Manually infuse the 7-day-old neonate with 20 to 30 ml 0.9% NaCl over ~3 min. Monitor the progress of the perfusion by assessing the animal's eyes and gums for a blanched appearance at the end of this step.

11. Switch the flow to perfusion fixative.

It is common to see turgor and twitching of the upper extremities at the initial flow of fixative. Perfuse the adult with 500 ml of fixative over 30 min. Perfuse 14- to 28-day-old rats with 200 ml of fixative over 30 min. For 7-day-old neonates, infuse ~100 ml of fixative. After this step, the extremities and tip of the nose should be stiff.

Collect and section tissue(s)

12. Disconnect the animal from the perfusion apparatus and collect tissue.

For many tissues, post-fixation is recommended following initial perfusion/fixation procedure. Post-fixation times and temperature vary considerably among tissues. For example, adult rat brain tissue is post-fixed for 1 hr at room temperature, whereas post-fixation of this tissue from 7- to 28-day-old animals is extended to 16 to 24 hr at 4°C. Similarly, adult testis is post-fixed up to 16 hr at 4°C prior to further processing. In many cases, fixation time must be empirically determined to optimize detection of HO protein or mRNAs. For ISH application, overfixation of tissue severely diminishes HO mRNA signal obtained.

For brain tissue to be used for IHC of frozen sections

13a. Post-fix 1 hr at room temperature (adult rat brains) or 16 to 24 hr (for brains from 7- to 28-day-old rats) by allowing the tissue to remain submerged in the fixative. Cryoprotect following post-fixation by placing the organ in graded 10% increments of sucrose solutions (from 10% up to 30% w/v sucrose) for 1 to 2 days each at 4°C.

The organ is completely equilibrated with each solution when it sinks to the bottom of the vessel.

14a. Section brain tissue for IHC using a freezing sliding microtome. Cut the brain into 30- to 50-µm thick sections. Store intact brain or sections in cryoprotectant in compartmentalized boxes at −20°C until immunohistochemical staining is to be performed.

Best recovery of brain tissue from 7- to 14-day-old rat is obtained using sections >40-µm-thick. Furthermore, neonatal cerebellar tissue remains intact throughout the procedure if cut in sagittal orientation.

For other tissues

13b. After fixation and optional post-fixation, paraffin-embed tissue and section at 5- to 10-µm thickness onto Superfrost Plus glass slides using a microtome.

A typical processing schedule for paraffin-embedding of tissue is 10% (v/v) neutral buffered formalin (1.5 h); 10% neutral buffered formalin (1.5 h); 60% (v/v) ethanol (30 min); 80%

(v/v) ethanol (45 min); 95% (v/v) ethanol (50 min); absolute ethanol (50 min); absolute ethanol (30 min); absolute ethanol (30 min); xylene (1 h); xylene (30 min); paraffin (30 min); paraffin (30 min); paraffin (1 h).

14b. Store slides at ambient temperature in slide cases until use.

SUPPORT PROTOCOL 2

PREPARATION OF PREADSORBED SERUM CONTROL

Appropriate reagent controls should be run in parallel with histochemical procedures. The use of preadsorbed antisera is an important control for the authenticity of antibody-antigen complexes detected by IHC procedure. Below is the procedure for preparation of preadsorbed antisera for IHC of the heme degradation system, along with notes on their use.

Materials

Primary antibody (see appropriate protocol)
Purified HO-1, HO-2, or BVR protein (StressGen)
Antibody buffer (see Basic Protocol 2)

1. Pipet equal amounts of primary antibody into two 1.5-ml polypropylene microcentrifuge tubes.
2. Add pure antigen to give a final protein concentration >1 mg/ml to the antiserum to be adsorbed. Add an equal amount of diluent without antigen to the control antiserum.
3. Incubate the mixtures for 2 hr at room temperature.
4. Dilute mixtures to their final working concentration with antibody buffer. Store aliquots at −20°C until use. Incubate serum aliquots overnight at 4°C prior to use.
5. Use the control and preadsorbed antisera in parallel throughout histochemical procedures.

Adsorption of antisera may be confirmed in a dot-blot format. Briefly, dilute antigen serially in 10-fold increments. Apply known quantities of diluted antigen to small strips of nitrocellulose blotting medium and air dry. Process strips for immunoblotting (UNIT 2.3). Preadsorbed antibody should no longer yield signal observed with unadsorbed antisera. Likewise, use of preadsorbed antisera under histochemical conditions should abolish signal observed in sections treated with control antiserum. No further processing is necessary.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Agarose gel, 1% (w/v)

Suspend 1 g low-melting agarose in 100 ml 1× TAE buffer (see recipe) containing 0.5 μg/ml ethidium bromide (added from 5 mg/ml stock; see recipe). Heat with stirring until solids are dissolved. Allow to cool in a 60°C water bath prior to pouring the gel (see *UNIT 2.2* & *APPENDIX 3*).

Agarose solutions can be prepared ahead of time and stored at room temperature. It is often convenient to melt the agarose in a microwave oven prior to each use.

Blocking solution

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
2% (v/v) normal sheep serum
0.5% (w/v) bovine serum albumin (BSA)
Store up to 1 week at 4°C

Buffer I

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
Store up to 1 month at 25°C

Buffer II

100 mM Tris·Cl, pH 9.5
100 mM NaCl
50 mM $MgCl_2$
Store up to 1 month at 25°C

Cryoprotectant

Dissolve 300 g sucrose in 500 ml 0.1 M sodium phosphate buffer, pH 7.3 (*APPENDIX 2A*). Add 300 ml ethylene glycol and stir until solution is thoroughly mixed. Make solution up to 1 liter with 0.1 M sodium phosphate buffer, pH 7.3. Store at 4°C.

CAUTION: *Ethylene glycol is hazardous.*

Final concentrations: 0.05 M sodium phosphate, pH 7.3, containing 30% (w/v) sucrose and 30% (v/v) ethylene glycol.

Denhardt's solution, 50×

Dissolve 1 g polyvinylpyrrolodone, 1 g BSA, and 1 g Ficoll in 77 ml RNase-free water (see recipe). Bring volume up to 100 ml with RNase-free water and filter sterilize. Divide solution into aliquots and store at −20°C for up to several months.

Final concentrations are 1% (w/v) polyvinylpyrrolidone, 1% (w/v) BSA, and 1% (w/v) Ficoll.

Developer solution

Prepare a stock solution of 0.122 M nitroblue tetrazolium chloride (NBT) in 70% (v/v) DMSO. Prepare a stock solution of BCIP (5-bromo-4-chloro-3-indolyl phosphate *p*-toluidine salt) by dissolving 10 mg of BCIP in 200 µl *N*,*N*-dimethylformamide. Prepare the solutions immediately prior to use and keep in the dark.

Mix 250 µl of the NBT stock solution (0.61 mM final), 177 µl of the BCIP stock solution (0.52 mM final), and 12 mg levamisole (0.024% w/v final) with 50 ml buffer II (see recipe). Prepare immediately prior to use and keep in the dark.

Digoxigenin-dNTP labeling mix

Mix 285 µl RNase-free water (see recipe), 350 µl 1 mM digoxigenin-11-dUTP, 65 µl 10 mM dTTP, and 100 µl each of 10 mM dATP, dGTP, and dCTP. Store frozen in aliquots at −20°C for several months.

Final concentrations: 1 mM dATP, 1 mM dCTP, 1 mM dGTP, 0.65 mM dTTP, and 0.35 mM digoxigenin-11-dUTP

Endogenous peroxidase inhibitor

Combine 40 ml phosphate-buffered saline (PBS; *APPENDIX 2A*), 5 ml 30% (v/v) H_2O_2, and 5 ml methanol. Prepare immediately prior to use.

Final concentrations: 3% (v/v) H_2O_2, and 10% (v/v) methanol.

Ethidium bromide, 5 mg/ml

Dissolve 50 mg ethidium bromide in 10 ml RNase-free water (see recipe). Store at room temperature protected from light up to several months.

CAUTION: *Ethidium bromide is a carcinogen. Gloves should be worn at all times to avoid contact. Solutions should be discarded in accordance with institutional guidelines.*

Fish sperm DNA

Dissolve fish (salmon) sperm DNA (Sigma) in RNase-free water (see recipe) to 10 mg/ml. Shear by passing through tuberculin syringes sequentially fitted with 18- to 27-G needles, then sonicate briefly. Store in aliquots frozen at −20°C until use.

Formamide, deionized

Stir formamide with 1% (w/v) Bio-Rad AG501-X8 resin for 1 hr at room temperature. Separate the formamide from the resin by filtration through general-use filter paper. Aliquot and store at −20°C prior to use.

PCR buffer, 10×

Mix 5 ml of 1 M Tris·Cl, pH 8.3, 12.5 ml of 2 M KCl, 750 µl of 1 M $MgCl_2$, and 2.5 ml of 2% (w/v) gelatin. Adjust volume to 50 ml using RNase-free water (see recipe). Filter sterilize and store frozen in aliquots indefinitely.

Final concentrations of components in the 10× buffer are: 100 mM Tris·Cl, 500 mM KCl, 15 mM $MgCl_2$, and 0.1% (w/v) gelatin. The 1× buffer is 10 mM Tris·Cl, pH 8.3, 50 mM KCl, 1.5 mM $MgCl_2$, and 0.01% (w/v) gelatin.

Perfusion fixative

Heat 500 ml of distilled water to 90°C. Turn off heat, add 40 g paraformaldehyde to the water, and stir until the solids are dissolved (the solution will now appear milky white). Clarify the solution with dropwise addition of 1 N NaOH.

Dissolve 15 g sucrose in 500 ml 0.2 M sodium phosphate buffer, pH 7.3 (*APPENDIX 2A*). Add this solution to the clarified paraformaldehyde solution. Filter the mixture using Whatman general-use filter paper. Store overnight at room temperature or up to 1 week at 4°C.

CAUTION: *Paraformaldehyde is toxic and all procedures should be performed in a fume hood.*

Final concentrations: 0.1 M phosphate buffer containing 4%(w/v) paraformaldehyde and 1.5% (w/v) sucrose

Prehybridization buffer

Mix 25 ml deionized formamide (see recipe), 10 ml 20× SSC (see recipe), 1 ml 50× Denhardt's solution (see recipe), and 12.8 ml RNase-free distilled water (see recipe). Heat denature an aliquot of 10 mg/ml fish sperm DNA (see recipe) by boiling for 10 min followed by quenching on ice. Add 1.25 ml denatured fish sperm DNA just prior to use.

Final concentrations are 50% (v/v) formamide, 4× SSC, 1× (v/v) Denhardt's solution, and 0.25 mg/ml heat-denatured fish sperm DNA

Proteinase K, 10 µg/ml

Stock solution: Prepare 10 mg/ml proteinase K in RNase-free water. Divide into convenient aliquots and store up to several months at −20°C.

Working solution: Add 10 µl of 10 mg/ml proteinase K to 10 ml phosphate-buffered saline (PBS; *APPENDIX 2A*). Warm the fresh solution to 37°C for 30 min before use.

RNase-free water

Add 1 ml diethylpyrocarbonate (DEPC) to 1 liter distilled water. Shake well and autoclave.

SSC, 20×

Dissolve 88.2 g sodium citrate and 173.3 g NaCl in 800 ml distilled water. Adjust solution pH to 7 with 10 N NaOH and adjust volume to 1 liter with distilled water. Add 1 ml diethylpyrocarbonate (DEPC), mix well, and sterilize by autoclaving.

Store at room temperature up to 1 month. From this stock prepare 4×, 2×, 1×, 0.5×, 0.5×, 0.25× and 0.05× SSC by appropriate dilution with RNase-free water (see recipe).

TAE buffer, 1×

Dissolve 4.84 g Tris base in 700 ml RNase-free distilled water (see recipe). Add 1.14 ml glacial acetic acid and 2 ml 0.5 M EDTA, pH 8. Adjust volume to 1 liter with RNase-free distilled water. Filter sterilize or autoclave and store at room temperature up to several months.

TE buffer, pH 8

Dissolve 158 mg Tris hydrochloride in 80 ml RNase-free distilled water (see recipe). Adjust pH to 8 with 1 N NaOH. Add 200 µl 0.5 M EDTA, pH 8 (*APPENDIX 2A*). Adjust volume to 100 ml with RNase-free water, sterilize by autoclaving, and store at room temperature up to several months.

COMMENTARY

Background Information

Rabbit anti-rat polyclonal antibody preparations (HO-1, HO-2, and BVR) and HO cDNA(s) are utilized in the above protocols to localize immunoreactive protein and transcripts, respectively, of enzymes of the heme degradation system. These protocols represent the first comprehensive compendium of current histochemical methodologies used to define the pattern of expression of the HO system in the newborn (Maines et al., 1996) and adult rat brain (Ewing et al., 1993). The procedures described herein have the virtue of being nonradioactive, and are applicable to systemic organs, such as the cardiovascular system (Ewing et al., 1994) and the male reproductive system (Maines and Ewing, 1996), as well as to cultured cells (Raju et al., 1997). Visualization of the cellular HO system aids in assessment of potential sites of carbon monoxide, iron, and bile pigment production.

Heme is synthesized in a complex series of enzymatic steps that begin with Δ-aminolevulinate synthase and end with ferrochelatase. The resultant metalloporphyrin, Fe-protoporphyrin IX (Fe-PP, heme, hemin, protoheme, ferro-protoporphyrin, ferri-protoporphyrin) is utilized in a variety of functions when associated with proteins (reviewed in Maines, 1992). Heme is integral to life, and it carries out oxidative reactions and electron-transfer processes and delivers molecular oxygen (O_2) to cells. In addition, this essentially square-planar tetrapyrrole is the molecular cornerstone of gaseous cell signaling, wherein it serves as source of carbon monoxide (CO) and is a general cellular target for this monoxide and nitric oxide (NO). In most cases, mammalian tissue has a very high capacity to generate CO and in some organs, such as the brain, it overwhelmingly exceeds the NO generating capacity (reviewed in Maines, 1997).

Recent findings regarding the diverse biological properties of the products of heme metabolism have challenged the previous view of these entities as mere physiological waste products (reviewed in Maines, 1992, 1997). In mammals, the heme molecule can be degraded by both enzymatic and chemical means. Enzymatic catabolism of heme by the HO system utilizes NADPH as a source of reducing equivalents, leading to the activation of O_2 and initiation of a multistep process of oxidation of the methene bridges of the porphyrin ring, ultimately generating CO, biliverdin, and Fe. A comprehensive description of the various heme-degrading systems was provided by Maines (1992).

In mammals three forms of HO have been identified to date. The first form, now known as HO-1, was identified as a distinct enzyme entity nearly two decades ago (reviewed in Maines, 1992). The second enzyme, now known as HO-2, was recognized about a decade later (Trakshel et al., 1986). The third form, now known as HO-3, was most recently described (McCoubrey et al., 1997).

HO-1, HO-2, and HO-3 are different gene products (McCoubrey et al., 1997). The isoenzymes display distinct nucleotide sequences, amino acid composition, transcript number and size. HO-1, also known as the stress protein HSP32 (Keyse and Tyrrell, 1989), is the smallest of the three and has a molecular weight of ~30,000 (Shibahara et al., 1985); HO-2 and HO-3 have molecular weights of ~36,000 (Ro-

tenberg and Maines, 1990) and ~33,000 Da (McCoubrey et al., 1997), respectively.

HO-1 and HO-2 vastly differ in cell type, tissue distribution, and regulation (reviewed in Maines, 1992); in these areas little is currently known about HO-3. At this time, it is believed that all three HO enzymes have similar mechanisms of heme-based catalysis, substrate specificity, and cofactor/coenzyme requirements (McCoubrey et al., 1997), although HO-3 is a poor heme catalyst (McCoubrey et al., 1997). HO-1 is exquisitely sensitive, not only to metals, but to all kinds of stimuli and agents that cause oxidative stress and pathological conditions—e.g., heat shock, ischemia, GSH loss, radiation, hypoxia, hyperoxia, and cellular transformations and disease states (reviewed in Maines, 1992, 1997). In fact, there is no other enzyme described to date that is affected by so many stimuli of diverse nature as is HO-1. HO-2 is not induced by the factors that increase HO-1; the only chemical inducers of HO-2 identified to date are adrenal glucocorticoids (Raju et al., 1997).

All products of heme degradation are now suspected to be biologically active. CO is suspected to be, like NO, a signal molecule for generation of cGMP in biological systems. Iron released by HO activity regulates genes, including those of HO-1 (reviewed in Maines, 1992), and NO synthase (NOS; Weiss et al., 1994). Bilirubin, which is formed when biliverdin is reduced by biliverdin reductase (reviewed in Maines, 1992), is a potent antioxidant (Stocker et al., 1987). Aside from the important biological functions of HO activity products, the catalytic activity of the system plays a crucial role in maintaining cellular heme homeostasis and hemoprotein levels (reviewed in Maines, 1992); among the many hemoproteins and heme-activated enzymes are NOS and soluble guanylate cyclase. In addition, HO protects the cell from the deleterious effects of the heme molecule, which is the most effective promotor of lipid peroxidation and oxygen free radical formation (Tappel, 1961).

Critical Parameters and Troubleshooting

The IHC portion of this protocol has been optimized for use with rabbit polyclonal antibody preparations directed against HO-1, HO-2, or BVR. Any polyclonal antibody preparation may vary in character among sources and should be optimized for working concentration. The results of histochemistry should be validated by use of preadsorbed or preimmune serum as a negative control. Incomplete perfusion of tissue will result in nonspecific spotting of sections, particularly prominent within the microvasculature of the tissue. Treatment of tissue with endogenous peroxidase inhibitor (EPI) for 5 to 8 min and thorough rinsing prior to blocking and incubation with primary antibody generally solves this problem.

As with all molecular techniques utilized for visualization of mRNAs in cells and tissue, the sensitivity of target transcripts to degradation is worthy of note. It is therefore essential to maintain all reagents free of RNase, which will abolish signal via destruction of target mRNA. Furthermore, fixation time for tissue from multiple species and obtained from animals of different ages may have to be optimized for best results. In the hands of the authors, overfixation of tissue has resulted in loss of HO cDNA:mRNA signal using the digoxigenin labeling technique described in this protocol.

The heme degradation pathway is an exquisitely regulated system responsive to developmental factors, endogenous stimuli (i.e., drugs and toxins), and seemingly subtle exogenous stimuli (i.e., handling, general environment). As such, careful attention to animal handling and tissue collection procedures should be maintained throughout the execution of experimental protocols to ensure accurate and reproducible results. In retrospective studies where tissues are obtained for comparison from sources utilizing different collection and fixation protocols, caution is advised. In turn, tissue samples for analysis should be processed in parallel throughout all histochemical procedures, along with appropriate reagent controls.

Finally, the critical but little discussed subject of data collection deserves attention. As mentioned in the beginning of this unit, application of histochemistry is as much an art as a science. Proper use of these procedures requires a critical and objective eye to minimize subjectivity in data collection. A double-blind format for analysis should be used wherever possible. Furthermore, photographic documentation of histochemical data should be performed under uniform conditions of lighting, exposure, and magnification for all specimens to be compared. This is particularly critical when using immunofluorescent endpoints where photobleaching may preclude repetition of photography. A custom photolab may be utilized to obtain photomicrographs of highest fidelity to the original image.

Reagent and tissue preparation

Successful outcome of the ISH procedure (Basic Protocol 1), requires care to ensure that all glassware and reagents are free of RNase, which will destroy target mRNAs. Human skin is a common source of RNase contamination of equipment and reagents, so gloves should always be worn whenever handling anything that will come into contact with tissue samples over the course of analysis. It is common practice to designate glassware for sole use in these histochemical procedures.

For either ISH or IHC, time invested in meticulous preparation and sectioning of tissue is paramount to the overall quality of data ultimately derived. In particular, the quality of tissue perfusion, choice of fixative, and duration of fixation are often overlooked as critical determinants to successful application of these techniques.

While many of these important details are described here, the novice practitioner is encouraged to review more general considerations found in a good quality histochemistry textbook.

Probe design for HO-1/HO-2 cDNA

The HO-1/HO-2 cDNA probes are prepared by adaptation of the polymerase chain reaction (PCR) technique using digoxigenin-dUTP as previously described (Iwamura et al., 1994), with the modifications detailed in Basic Protocol 1. The probe design and amplification procedures described here specifically pertain to analysis of rat HO mRNA. Application of these probes for analysis of tissue from other species should be undertaken with appropriate caution, because complete probe homology may not exist between the rat and the species of interest. Furthermore, gene products other than HO-1/HO-2 mRNA targets may be expressed in other species which bear select sequence homology to HO-1/HO-2 cDNA probes and could yield artifacts. To avoid these problems, it is expedient to perform a search of GenBank to identify known mRNAs that could yield interference prior to initiating analysis of sections from a unique type or source of tissue. Additionally, assessment of cDNAs intended for use in ISH may be very effectively applied in a Northern blot format to confirm hybridization of probe to mRNA(s) of appropriate size and abundance in a sample representing total extract of mRNA from the tissue of interest. Northern blot analysis of HO-1/HO-2 mRNAs has been presented before (Ewing, 1996).

The digoxigenin-labeled HO-1 cDNA most successfully used for ISH is a 763-bp fragment corresponding to HO-1 nucleotides +71 to +833, as described by Shibahara et al. (1985). The two nucleotide primers used were 5′–TGCACATCCGTGCAGAGAAT–3′, homologous to HO-1 cDNA nucleotides +71 to +90, and 5′–AGGAAACTGAGTGTGAGGAC–3′, complimentary to HO-1 cDNA nucleotides +814 to +833. This HO-1 cDNA probe was selected so that it would not hybridize to HO-2 mRNA.

The digoxigenin-labeled HO-2 cDNA most successfully used for ISH is a 536-bp fragment corresponding to HO-2 nucleotides −32 to +504, as described by Rotenberg and Maines (1990). The two nucleotide primers used were 5′–GAAGTGAGGGCAGCACAAAC–3′, homologous to HO-2 cDNA nucleotides −32 to −–13, and 5′ CTTCTTCAGCACCTGGCCT–3′, complimentary to HO-2 cDNA nucleotides +486 to +504. This HO-2 cDNA probe was selected so that it would not hybridize to HO-1 mRNA. The HO-2 probe was, however, complimentary to regions common to both 1.3- and 1.9-kb homologous transcripts. Thus, HO-2 ISH utilizing this probe reflects total HO-2 mRNA expression.

Anticipated Results

Since the first presentations of histochemical analysis of heme degradation system in rat brain (Ewing and Maines, 1991) and systemic organs (Ewing et al., 1994; Ewing and Maines, 1995), the application of these IHC and ISH techniques (or variations thereof) has been extended to include a variety of mammalian tissues and species including man. Many of these studies are summarized in Table 9.5.1 and are provided as a convenient source for anticipated results from these procedures, as well as support protocols for the application of these techniques in a plethora of experimental settings and with select tissue types.

Time Considerations

The total time for ISH procedures is approximately 4 to 5 days (Basic Protocol 1). IHC analysis of free-floating sections requires 3 days (Basic Protocol 2 and Alternate Protocol 1). However, this does not take into account the time required for mounting of the frozen sections onto slides prior to final processing. IHC of a heme degradation system using paraffin sections requires 2 days (Alternate Protocols 2 and 3). Tissue perfusion and fixation are typi-

cally conducted over 2 days (Support Protocol 1). Cryopreservation of frozen tissue is performed over 2 to 4 days. Time required to section tissue will vary with the number of samples to be processed.

An HPLC Method to Detect Heme Oxygenase Activity

Heme oxygenase (EC 1.14.99.3, HO), in a coupled reaction with NADPH:cytochrome P-450 reductase (EC 1.6.2.4), oxidizes heme (ferriprotoporphyrin-IX) to form biliverdin-IXα (BV), ferrous iron, carbon monoxide (CO), and water. NAD(P)H:biliverdin reductase (BVR; EC 1:3:1:24) completes the sequence of heme degradation by reducing BV to bilirubin-IXα (BR). The HO reaction fulfills an important metabolic function in regulating intracellular heme concentrations.

The classical HO assay depends on the spectrophotometric determination of bilirubin (see *UNIT 9.3*). Because BV cannot be detected by this assay, the reactions must be supplemented with an excess of exogenous BVR activity, to convert all residual BV to BR.

This unit describes a method for measuring HO activity by the simultaneous quantification of BV and BR using high performance liquid chromatography (HPLC; see Basic Protocol). The principal advantage of this technique is that it permits calculation of total HO activity even if BVR activity is limiting or absent. Thus, the protocol does not require supplementation with a BVR extract, which is not commercially available and is time-consuming to prepare. The Basic Protocol may be easily transformed into an assay for BVR activity (see Alternate Protocol).

This protocol has been developed using microsomal extracts from cultured cells (see Support Protocol). Optionally, crude cellular extract may be substituted for microsomal protein (see Support Protocol). In principle, protein preparations from organ tissue may also be used (see *UNIT 9.3*).

DETERMINING HEME OXYGENASE ACTIVITY USING HPLC

BASIC PROTOCOL

The HO enzymatic reaction consists of a microsomal extract from tissue culture cells combined with a heme substrate and β-NADPH, at 37°C. The BV and BR produced in the reaction are then extracted, separated on a reversed-phase C18 column by HPLC, and detected in the elution volume by visible spectroscopy at 405 nm. HO activity is then expressed as the picomoles of bilirubin equivalents formed (BV + BR) per fixed reaction time at 37°C and fixed protein mass.

CAUTION: Methanol is required for the assay. Use appropriate precautions for the use and storage of flammable liquids. Avoid skin and eye contact with this reagent.

NOTE: All protein extraction procedures must be performed at 4°C with precooled solutions and equipment. The photosensitive materials, including the reaction samples, should be handled under dark ambient conditions.

NOTE: The assay is labor-intensive and best performed with a team of two investigators.

Materials

Microsomal protein extract from cultured cells (see Support Protocol)
Solution A (see recipe)
Partially purified biliverdin reductase (BVR; optional)
20 mM β-NADPH (see recipe)
40 mM glucose 6-phosphate (see recipe)
1 U/μl glucose-6-phosphate dehydrogenase (see recipe)
2.5 mM protoporphyrin IX (Sn PPIX; see recipe; optional)

Contributed by Stefan W. Ryter and Rex M. Tyrrell
Current Protocols in Toxicology (2000) 9.6.1-9.6.14

2.5 mM hemin stock solution (see recipe)
Stop solution with mesoporphyrin internal standard (see recipe)
HPLC buffer A (see recipe)
HPLC buffer B: methanol (HPLC grade; Fisher; degassed 2 min with compressed He)
20 μM biliverdin and bilirubin standards (see recipes)

1.5- and 0.5-ml microcentrifuge tubes
High performance liquid chromatography (HPLC) system with two solvent reservoirs and pumps (e.g., Kontron or equivalent)
Data acquisition system (e.g., MT 450 MS-DOS or higher; Kontron or equivalent)
Autosampler (e.g., HPLC 360; Kontron, or equivalent)
Visible detector (e.g., UVIKON 720 LC microdetector; Kontron or equivalent)
Reversed-phase C18 steel cartridge HPLC column (e.g., Novapak 3.9 mm × 15 cm) *or* phenyl reversed-phase column (both available from Waters Chromatography)
Compressed helium tank

Assemble HO reaction

1. Assemble the reagents on ice in microcentrifuge tubes. Add 500 μg fresh microsomal protein extract per sample tube in a volume of 50 to 88 μl (see Support Protocol).

   Optionally, BVR may be included in the reaction. Add both microsomal (500 μg) and partially purified BVR extract (50 to 200 μg) in a volume of <88 μl. The BVR may be prepared as described by Tenhunen et al. (1970).

2. Adjust volume to 88 μl with solution A. Also add the following:

   5 μl 40 mM glucose-6-phosphate solution
   5 μl 20 mM β-NADPH
   1 μl 1 U/μl glucose-6-phosphate dehydrogenase.

   Prepare negative controls by assembling the reaction mixtures as described above with the substitution of 5 μl solution A for the NADPH solution; alternatively, substitute boiled protein extract for fresh microsomal protein. A competitive inhibitor of HO activity, such as Sn PPIX, may be introduced into the reaction as a negative control (e.g., add 1 μl of 2.5 mM Sn PPIX solution to a complete reaction to a final concentration of 25 μM).

3. Preincubate the incubation mixtures for 5 min at 37°C.

4. To initiate the reactions, add 1 μl of 2.5 mM hemin stock solution and vortex 5 sec.

   The final reaction concentrations are 5 mg/ml fresh microsomal protein, 0.5 to 2 mg/ml BVR extract (optional), 1 mM β-NADPH, 2 mM glucose-6-phosphate, 1 U/100 μl glucose-6-phosphate dehydrogenase, 25 μM hemin, 0.25 M sucrose, 20 mM Tris·Cl, pH 7.4, in a final volume of 100 μl.

5. Place tubes in a circulating water bath at 37°C in the dark.

6. Incubate reactions at 37°C for a chosen time interval, typically 5 to 60 min.

   The linear range for measured activity must be determined. A 20-min reaction time is suggested from previous studies with various human cell types. Reaction time may have to be increased up to 1 hr to detect activity from control (uninduced) cells that express low basal activity.

Prepare samples for HPLC

7. Terminate the HO reactions under dark ambient conditions by adding 1 vol (100 μl) stop solution to each tube at 20°C. Vortex 5 sec.

8. Centrifuge the stopped reaction mixtures 10 min at 15,000 × *g*, 20°C.

   The resulting colored pellet retains ~80% to 85% of the heme. The supernatant is clear with a faint yellow color.

9. Recover supernatants and transfer to 0.5-ml microcentrifuge tubes.

   These are the ethanol/DMSO extracts. Ensure that samples are free of suspended particles.

10. Place the tubes containing ethanol/DMSO extracts into an autosampler with a dark cover, and begin the sample run as soon as possible.

    If manual injection is used, store uninjected samples at room temperature protected from light until injection. If an autosampler is used, ensure that the microcentrifuge tubes are compatible with the sampling apparatus.

    Freeze-thawing the alcohol-extracted HO reaction mixtures (final step) at −70° may decrease the quality of the sample. The resulting bile pigment and internal standard (mesoporphyrin) decomposition products will appear as additional chromatographic peaks.

Prepare the HPLC apparatus

11. Connect the HPLC apparatus to a reversed-phase C18 steel cartridge HPLC column.

    A phenyl reversed-phase column also gives a good separation of reaction products.

    IMPORTANT NOTE: *This part of the protocol is best performed in advance by a second investigator.*

12. Program the HPLC to perform a linear gradient that starts from 100% HPLC buffer A at time zero and reaches 100% buffer B at 14 min, and which then reverts to 100% buffer A and remains constant until the termination at 19 min. Set the total flow rate to 1.5 ml/min.

13. Set the detector for continuous absorbance monitoring at 405 nm.

14. Degas both HPLC solutions with compressed helium for ≥2 min. Fill one reservoir with HPLC buffer A. Fill the second reservoir with buffer B.

    Ensure that the solutions are free of particles and that the pump intake heads are clean.

15. Purge the intake hoses free of air by pumping from each buffer reservoir through an open precolumn check valve.

16. Prime the HPLC column with 100% HPLC buffer A for ≥2 min prior to the first injection. Check system for leaks.

    Include a tube of mixed standards as the first sample in the run to ensure that the system is operating correctly. Prepare mixed standards in HPLC buffer A in the following final concentrations: 1 μM hemin, 1 μM BR IXα, 1 μM BV, and 0.4 μM mesoporphyrin. For assay calibration, however, prepare standards as described in steps 18 to 26.

17. After the sample analysis is complete, wash the column 60 min with 100% methanol.

Construct BR and BV standard curves

18. Dilute the 20 μM biliverdin and bilirubin standard solutions with 100% DMSO to generate a series of 10× standard solutions in the range of 2 to 20 μM.

    Perform this step under dark ambient conditions.

    Biliverdin standards may be omitted if biliverdin reductase has been added to the samples.

19. To microcentrifuge tubes at room temperature, add 500 μg microsomal protein (in <100 μl) and adjust to 100 μl with solution A.

20. Heat the protein to 37°C for 10 min in a circulating water bath.

21. Add 100 μl stop solution with internal standard and vortex 10 sec.

22. Centrifuge at 15,000 × *g* for 5 min at room temperature.
23. Transfer 135 µl of the supernatant to a fresh microcentrifuge tube.
24. Before each injection, in the dark, add 15 µl BV or BR standard from 10× concentrated stock solutions (prepared in step 18) to final concentrations ranging from 0.2 to 2 µM.

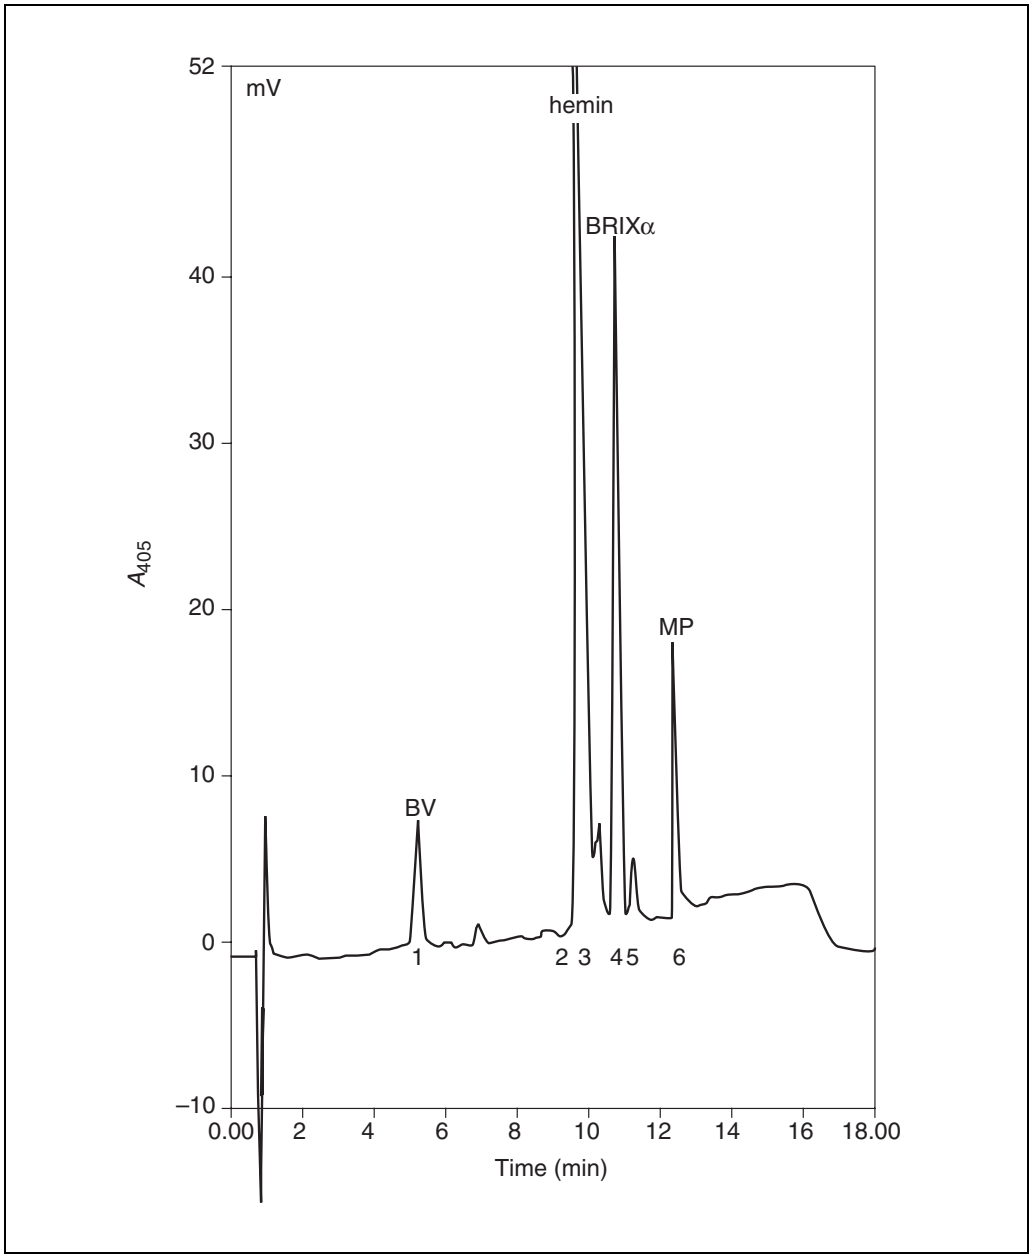

Figure 9.6.1 HPLC chromatogram showing the resolution of tetrapyrrole standards in an alcohol extract of sonicated microsomal protein solution. Final concentrations were 2 µM biliverdin (BV), 2 µM bilirubin-IXα (BRIXα), 0.35 µM BRIIIα, 0.27 µM BRXIIIα, 12.5 µM hemin, 0.4 µM mesoporphyrin (MP), corresponding to injected amounts of 240 pmol BV, 240 pmol BRIXα, and 48 pmol MP. The tetrapyrroles eluted with the following typical retention times: (1) biliverdin (BV), 5.29 min; (2) hemin, 9.8 min; (3) bilirubin structural isomer (IIIα or XIIIα), 10.39 min; (4) bilirubin-IXα (BRIXα), 10.9 min; (5) bilirubin structural isomer (IIIα or XIIIα), 11.38 min; and (6) mesoporphyrin (MP), 12.54 min. Optical density was detected at 405 nm. Reprinted from Ryter et al. (1998), with permission from Elsevier Science.

25. Inject immediately into the HPLC system.
26. Plot the detector response (integrated peak area) as a function of BV or BR concentration.

The assay protocol assumes that 100% of the BV and BR will be recovered from HO reactions by extraction in 95:5 (v/v) ethanolDMSO (in the stop solution), which is the case for HO reactions containing 500 μg protein and <2 μM BV or BR. To determine recovery efficiency, dissolve 20 μl 10× standard in 80 μl protein solution at 37°C (0.2 to 2 μM assuming a final volume of 200 μl). Add 100 μl 95:5 (v/v) ethanol/DMSO. Centrifuge 5 min at 15,000 × g. Inject the supernatant immediately into HPLC. Compare with result obtained in steps 18 to 26.

Calculate HO activity

27. Record the integrated peak areas of biliverdin-IXα, bilirubin-IXα, and mesoporphyrin from each sample chromatogram (see Fig. 9.6.1).

If an integration program is not available, then detector response in peak height (arbitrary units) may also be used.

28. From the linear standard curves, calculate the concentrations of BV and BR in an injected sample in μM (pmol/μl).
29. Calculate bilirubin equivalents (BReq) using the following formula, assuming a stopped reaction volume of 200 μl.

BReq = (pmol/μl BV + pmol/μl BR) × (200 μl).

The BReq value is equivalent to the picomoles of substrate oxidized.

In the presence of an excess of BVR activity, the equation simplifies to:

BReq = (pmol/μl BR) × (200 μl).

30. Normalize the BReq value against the relative mesoporphyrin recovery for each sample, using the following formula:

BR′eq = BReq (MP*/MP_S)

where MP* = average mesoporphyrin recovery for the entire run, and MP_S = sample mesoporphyrin recovery. Calculate the mesoporphyrin ratio directly from arbitrary detector units.

31. Calculate HO activity using the following formula:

BR′eq/(mg protein) (hr)

where hr = reaction time in linear range of assay, expressed in hours.

32. Express the final result with the units pmol BR/mg protein/hr.

PREPARATION OF MICROSOMAL PROTEIN EXTRACTS FROM CULTURED CELLS

SUPPORT PROTOCOL

This protocol is used to prepare microsomal protein extracts from cultured cells. Crude cellular extract may optionally be prepared by following steps 1 to 5 and 11 to 12 only.

Materials

Cultures of cells
Phosphate-buffered saline (PBS), pH 7.4 (*APPENDIX 2A*), ice-cold
PBS/EDTA solution (see recipe), ice-cold
Solution A (see recipe)
1000× protease inhibitor stock solutions (see recipe)

Rubber cell scrapers
15-ml centrifuge tubes (e.g., 16 × 125–mm tissue culture tubes with screw caps; Corning)
Refrigerated tabletop centrifuge (e.g., GPK centrifuge; Beckman, or equivalent)
Sonicator (e.g., Branson sonifier B-12 sonicator; Branson Ultrasonics, or equivalent)
Ultracentrifuge (e.g., Centrikon T20-60 ultracentrifuge; Kontron, or equivalent)
Fixed-angle rotor capable of 105,000 × *g* (e.g., TFT65.13 rotor; Kontron, or equivalent)
Polyallomar ultracentrifuge tubes, (e.g., 13.5-ml; Kontron)

Additional reagents and equipment for determination of protein concentration (*APPENDIX 3*)

NOTE: Perform all steps at 4°C.

Prepare crude extract

1. Place petri dishes containing cells on ice. Aspirate culture medium and rinse the monolayers twice with ice-cold PBS and drain. To each dish, add 1.0 ml ice-cold PBS/EDTA. Detach the cells with a rubber cell scraper. Recover the suspension from each dish and combine into 15-ml centrifuge tubes. Rinse each dish with an additional 1.0 ml of PBS and pool.

   Cell culture parameters must be determined experimentally for cell type and for the degree of purification desired. Microsomal preparations require ~5 × 10^7 cells pooled from two to four 150-mm monolayer cultures grown to 80% to 90% confluence. This approximation yields 1 to 2 mg microsomal protein from human HeLa cells. If crude extract is chosen for the assay, then two to three 100-mm near-confluent plates should be sufficient to yield 1 to 2 mg protein. Although this protocol has been developed using monolayer tissue cultures, in principle, any cell type may be applied.

2. Centrifuge cells 5 min at 500 × *g*, 4°C.

3. Resuspend each pellet 1:1 (v/v) in solution A containing protease inhibitors.

   Add the protease inhibitors to solution A from 1000× stock solutions immediately before use.

4. Transfer the suspension to 1.5-ml microcentrifuge tubes and sonicate on ice twice for 15 sec, at low power (20 W).

   When operating the sonicator, keep the tube completely embedded in ice. Use adequate ear protection.

5. Centrifuge the homogenates 20 min at 15,000 × *g*, 4°C. Transfer the supernatant to a clean 1.5-ml microcentrifuge tube. Repeat the centrifugation step if necessary to obtain a clear supernatant.

   The protein extraction procedure may be stopped at this point, and the crude supernatant used in the enzyme assay instead of microsomal protein (proceed to step 11). The crude extract contains HO activity and may contain BVR activity depending on the cell type. The use of crude extract is discouraged since it may accelerate column aging.

Prepare microsomal protein extract

6. Transfer the supernatant to ultracentrifuge tubes. Balance the tubes by adding solution A.

7. Centrifuge at 1 hr at 105,000 × *g*, 4°C, in fixed-angle ultracentrifuge rotor.

8. Drain the microsomal pellets at 4°C. Resuspend the pellet in 100 to 200 µl buffer A by vigorous manual pipetting (20 to 50 times) on ice. Transfer the suspension to microcentrifuge tubes. If necessary use another 100 to 200 µl buffer A to recover residual particles, and pool.

   The resulting pellet will be difficult to resuspend, due to high viscosity.

9. Sonicate the crude suspensions 10 sec on ice at low power (20 W).

10. Centrifuge the suspensions 5 min at 15,000 × *g*, 4°C.

    The final suspensions should be homogenous, with a small amount of pellet. If the supernatant is not homogenous, or if the pellet is too large, repeat steps 9 and 10.

11. Decant the supernatant to a fresh microcentrifuge tube and store on ice until use.

12. Calculate the protein concentration of the supernatant using a commercial protein assay reagent kit according to the manufacturer's instructions. Dilute microsomal protein to 6 to 10 mg/ml with solution A.

    If the microsomal protein preparations are too dilute (<6 mg/ml) increase starting material or reduce protein resuspension volume.

DETECTION OF BVR ACTIVITY

ALTERNATE PROTOCOL

The HPLC technique can be readily adapted to an assay for BVR activity with a simple transformation as described below.

Additional Materials *(also see Basic Protocol)*

Protein sample to be analyzed for BVR activity
2.5 µM biliverdin (BV) solution in DMSO (see recipe for 20 µM stock)

1. Assemble the reagents on ice in microcentrifuge tubes.

2. Add 500 µg of a protein sample to each tube in <88 µl volume.

3. Adjust volume to 88 µl with solution A, then add the following:

   5 µl 40 mM glucose-6-phosphate solution
   5 µl 20 mM β-NADPH
   1 µl 1 U/µl glucose-6-phosphate dehydrogenase.

4. Preincubate reaction mixtures 5 min at 37°C.

5. To initiate the reactions, add 1 µl of 2.5 µM BV and vortex 5 sec.

   If DMSO is used as the solvent for BV, do not exceed a final concentration of 0.25% in the reaction mixture. A buffer such as 0.1 M potassium phosphate, pH 7.4, may be substituted for solution A.

   The final reaction concentrations—dissolved in solution A—are 5 mg/ml protein extract, 1 mM β-NADPH, 2 mM glucose 6-phosphate, 1 U/100 µl glucose 6-phosphate dehydrogenase, and 25 µM biliverdin.

6. Place tubes in a circulating water bath at 37°C in the dark.

7. Incubate reactions at 37°C for a chosen time interval, typically 5 to 60 min.

8. Terminate the reactions and perform HPLC separations (see Basic Protocol, steps 7 to 17).

9. From the linear standard curves (see Basic Protocol, steps 18 to 26), calculate the concentration of BR in an injected sample in µM (pmol/µl). Calculate BVR activity

using the following formula, where MP* = average mesoporphyrin recovery for the entire run, MP_S = sample mesoporphyrin recovery, and hr = reaction time expressed in hours:

$$(\text{pmol}/\mu\text{l BR}) \times (200\ \mu\text{l})(MP^*/MP_s)$$

Express the final result in the units pmol BR/mg protein/hr.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Ammonium acetate, 1 M, pH 5.2

Weigh 77.0 g ammonium acetate
Add 26.0 ml glacial acetic acid
Adjust volume to 1.0 liter with Millipore-filtered water
Adjust pH to 5.2 with glacial acetic acid
Filter through 0.2-µm filter
Store up to 3 months at 4°C

Bilirubin IXα standard, 20 µM

Prepare 1.0 mM bilirubin-IXα in 100% DMSO (Sigma) by calculating the required weight of bilirubin mixed isomers (Sigma) according to percent composition (by weight) of the IXα isomer, using the following formula: [(5.84 mg × 100)/percent composition of IXα isomer], and weighing the result in milligrams. Dissolve in 10 ml DMSO. Prepare fresh immediately before use. Add 20 µl of 1.0 mM bilirubin stock to 980 µl DMSO, for a final concentration of 20 µM.

Do not store bilirubin solutions.

The BR IIIα or BR XIIIα structural isomers will appear as minor peaks on either side of the BR IXα peak in standard chromatograms, but will not interfere with the analysis.

Biliverdin IX standard, 20 µM

Weigh 6.19 mg biliverdin IX hydrochloride (Sigma). Dissolve in 10 ml 100% DMSO for a final concentration of 1.0 mM. Divide into aliquots and store up to 3 months at −20°C. Add 20 µl of the 1.0 mM stock to 980 µl 100% DMSO, for a final concentration of 20 µM.

Glucose-6-phosphate, 40 mM

Weigh 11.3 mg D-glucose-6-phosphate monosodium salt (Sigma) and dissolve in 1.0 ml solution A. Prepare fresh daily.

Glucose-6-phosphate dehydrogenase, 1 U/µl

Dissolve commercial preparation of glucose-6-phosphate dehydrogenase (G6PDH; EC 1.1.1.49, Type XV from Baker's yeast, lyophilized, sulfate free; Sigma) to a final concentration of 1 U/µl in solution A (see recipe). Divide into aliquots and store up to 3 months at −20°C.

Hemin stock solutions, 2.5 mM

Weigh 6.5 mg bovine hemin (Sigma). Dissolve in 1.0 ml 100% DMSO, for a final concentration of 10 mM. Store up to 3 months at −20°C. Immediately before use, gradually dilute the stock 1:3 (v/v) by addition of distilled water, for a final concentration of 2.5 mM.

HPLC buffer A

Pour 100 ml of 1.0 M ammonium acetate, pH 5.2 (see recipe), into a clean glass cylinder. Add 600 ml methanol (HPLC grade). Fill to 1.0 liter with Millipore-filtered water from the source. Degas 2 min with compressed helium.

Mesoporphyrin stock, 200 µM

Working in the dark, weigh 6.39 mg mesoporphyrin (Sigma). Dissolve in 10.0 ml 100% DMSO, for a final concentration of 1.0 mM. Dilute to the stock solution 1:4 (v/v) by addition of 100% DMSO, for a final concentration of 200 µM. Divide into aliquots in foil-wrapped tubes. Store up to 3 months at −20°C, protected from light. Avoid repeated freeze-thaw cycles.

β-NADPH, 20 mM

Weigh 16.7 mg nicotinamide adenine dinucleotide phosphate, reduced form (β-NADPH, tetrasodium salt; Sigma). Dissolve in 1.0 ml solution A (see recipe), for a final concentration of 20 mM. Prepare fresh daily.

PBS/EDTA solution

To 500 ml phosphate-buffered saline (PBS), pH 7.4 *(APPENDIX 2A*), add 0.5 ml of 1.0 M EDTA, pH 8.0 (*APPENDIX 2A*). Store up to 1 month at 4°C. To an aliquot add AEBSF (see recipe for protease inhibitor stock solutions) to a final concentration of 50 µg/ml immediately before use.

Protease inhibitor stock solutions, 1000×

AEBSF: Weigh 50 mg 4-(2-aminoethyl) benzolsulfonylfluoride hydrochloride (AEBSF, Pefabloc SC; Boehringer Mannheim). Dissolve by vortexing in 1.0 ml water. Store up to 2 months at −20°C.

Leupeptin: Weigh 4 mg leupeptin (Boehringer Mannheim). Dissolve by vortexing in 1.0 ml water. Store up to 6 months at −20°C.

Pepstatin: Weigh 4 mg pepstatin (Boehringer Mannheim). Dissolve by vortexing in 1.0 ml 100% DMSO. Store up to 1 month at −20°C.

Divide solutions into 20- to 50-µl aliquots for storage. See above.

Sn Protoporphyrin-IX (Sn PPIX)

Working in the dark, weigh 7.5 mg Sn PPIX dichloride (Porphyrin Products). Dissolve in 1.0 ml 100% DMSO for a final concentration of 10 mM. Divide into aliquots in foil-wrapped tubes and store up to 3 months at −20°C, protected from light. Immediately before use, gradually dilute the stock solution 1:3 (v/v) with distilled water, to a final concentration of 2.5 mM.

Solution A

Weigh 85.6 g sucrose (Sigma). Add 20 ml of 1 M Tris·Cl, then add water to 800 ml and adjust pH to 7.4 with 2 N NaOH. Adjust volume to 1.0 liter with water, autoclave, and store up to 1 month at 4°C. Add protease inhibitors (see recipe) just before use.

Stop solution with mesoporphyrin internal standard

Add 20 µl of the 200 µM mesoporphyrin stock solution (see recipe) to a 10-ml aliquot of a mixture of 95 parts ethanol 5 parts dimethylsulfoxide (v/v). Prepare immediately before use; Do not store.

COMMENTARY

Background Information

HO, a microsomal monooxygenase activity, provides the rate-limiting step in heme degradation (Tenhunen et al., 1969). HO facilitates the disposal of hemoglobin heme during the turnover of erythrocytes in the reticuloendothelial system. Furthermore, HO regulates an intracellular free heme pool that exists in equilibrium with the synthesis and degradation of hemoproteins (Maines, 1992). HO may provide an antioxidative function in the removal of free heme, a potentially harmful iron chelate (Keyse and Tyrrell, 1989). The three biologically active reaction products of HO activity—iron, BR, and CO—imply multiple physiological consequences that can arise from a single enzymatic reaction. By degrading heme, HO activity may directly affect the balance of cellular redox-active iron pools (Ryter and Tyrrell, 2000). The iron-dependent stimulation of ferritin synthesis, coupled with the equilibration of the released iron to the ferritin pool, may also represent an antioxidative process associated with HO activity (Vile and Tyrrell, 1993). Furthermore, BR, which has antioxidant properties, may affect serum antioxidant balance (Stocker et al., 1987), though its intracellular function remains obscure. The CO released by HO may act as a second messenger molecule. The coordination of CO to the heme iron of soluble guanylate cyclase activates the enzyme, resulting in the increased synthesis of 3′,5′-cyclic guanosine monophosphate (cGMP). This mechanism of action resembles that proposed for the endothelium-derived relaxing factor, nitric oxide, NO. The possible consequences of HO/CO/cGMP–dependent signaling include the regulation of vascular function (platelet aggregation, vasodilation, smooth muscle proliferation) and neurotransmission (reviewed in Maines, 1997; Durante and Schafer, 1998). Three distinct HO isozymes, representing three different genes, have been characterized (Maines et al., 1986; McCoubrey et al., 1997a): an inducible form (HO-1), and two constitutive noninducible forms (HO-2) and (HO-3). All three forms can contribute, to various extents, to the total HO activity measurable by current methods. HO-2, which occurs abundantly in testes, nervous tissue, and vascular systems, may conceivably function in CO/cGMP-dependent signaling in these tissues (Maines, 1997). Both HO-1 and HO-2 catalyze the identical biochemical reaction, but they differ in physical properties and reaction rate toward heme (Maines et al., 1986). HO-3, which is highly homologous to HO-2, has weak HO activity (McCoubrey et al., 1997a). Both HO-2 and HO-3 contain two additional heme regulatory domains (HRD) distinct from the catalytic domain (McCoubrey et al., 1997a,b).

The inducible isozyme, HO-1, may be classified as a stress protein, since its elevated synthesis occurs in cultured cells following adverse environmental conditions. Among the agents that trigger the HO-1 response are physical conditions (hyperthermia, shear stress, hypoxia, and 320- to 380-nm ultraviolet-A radiation), inflammatory mediators (cytokines, endotoxins, nitric oxide), and chemical xenobiotics (including heavy metals, thiol-reactive substances, and various oxidants). The alteration of cellular reducing potential by depletion of cellular glutathione may represent a common mechanism by which many agents, including oxidants, trigger induction of the *HO-1* gene (reviewed in Maines, 1992; Ryter and Tyrrell, 1997).

Enzymatic activity assays are important tools in studying the functional significance of the HO system. A conventional method for the detection of HO activity involves the spectrophotometric detection of BR (Schacter, 1978; Tenhunen et al., 1969) directly in micosomal protein by NADPH difference spectroscopy (λ max 464 to 468 nm). The direct measurement of BR in complex protein mixtures can be complicated by spectral interference and the fact that the molar extinction coefficient of BR varies with the consistency of the protein extract. A variation of this method, as described by Kutty and Maines (1982; also see *UNIT 9.3*), extracts the BR from the aqueous phase using chloroform. The concentration of BR is subsequently calculated from the A_{464} to A_{530} of the chloroform extract relative to a chloroform blank. The chloroform extraction of BR, however, may be inefficient. Furthermore, the use of this assay with protein from cultured cells often yields results near the lower limit of spectrophotometric detection. As a source of enzymes (HO and P-450 reductase), the assay requires an 18,000 × *g* supernatant fraction (crude extract) derived from organ, tissue, or cultured cells, which then may be further purified as the 104,000 × *g* microsomal pellet. The spectrophotometric HO assays require supplementation with exogenous tissue extracts to provide BVR activity. Since BV, the proximal product of HO activity, is difficult to measure

Table 9.6.1 Troubleshooting Guide for HPLC Measurement of HO Activity

Problem	Possible cause	Solution
No peaks in chromatogram	HPLC system malfunction	Check detector signal cable. Check detector lamp and settings.
		Check for precolumn leaks.
	Autosampler malfunction	Ensure sampling mechanism is injecting properly.
Unstable baseline	Air in system	Degas buffers and purge system.
Split peaks	Flow obstruction	Replace precolumn filter.
Peak spreading	Column wear	Invert or replace column.
Heme and mesoporphyrin peaks visible, but no BV or BR peaks appear	No detectable enzymatic activity	Review protein extraction procedures, and ensure that all steps are performed at 4°C.
		Ensure a reaction temperature of 37°C. Check quality of reaction components, especially heme and NADPH. Increase reaction time.
Additional peaks in chromatograph	Mesoporphyrin degradation	Replace mesoporphyin stock solution.
	BR degradation	Ensure dark conditions for post-reaction processing.

by spectrophotometry due to spectral interference from other reaction components, the success of the assay depends on the complete conversion of the BV to BR. BVR may be obtained from animal tissues (i.e., bovine or rat liver) in the 30,000 to 105,000 × *g* supernatant, or in partially purified form (Tenhunen et al., 1970).

Derivatives of the HO assay have included radiochemical methods, which typically use [^{14}C]heme as the HO substrate. The [^{14}C]bilirubin formed as the final product is either extracted into chloroform (Tenhunen, 1972) or isolated by thin-layer chromatography (Sierra and Nutter, 1992). The detection of CO by gas chromatography provides another alternative for estimating HO activity (see *UNIT 9.2*).

High-performance liquid chromatography (HPLC) may be conveniently used to detect bile-pigment formation. Bonkovsky et al. (1986) and Lincoln et al. (1989) developed reversed-phase HPLC methods for resolution of BV, BR, and heme extracted from biological materials, using an ammonium phosphate/methanol gradient. HPLC has been employed for the detection of BR formed in HO reactions (Lee and Ho, 1994; Lincoln et al., 1988), and has been demonstrated to be more sensitive than the spectrophotometric assay when analyzing HO activity in hepatocytes (Lincoln et al., 1988). An HPLC method was used to identify BV IXα as the product of the HO reaction (Noguchi et al., 1982). The protocol described in this unit integrates the previous methods to provide an HPLC-based HO assay that measures both BV and BR produced in the HO reaction mixture, using an ammonium acetate/methanol gradient (Ryter et al., 1998, 2000).

Critical Parameters and Troubleshooting

Bilirubin can be easily detected by HPLC and is relatively stable if reasonable precautions are taken to avoid photodegradation. While the 405 nm employed as the detection wavelength is suboptimal for detection of BV or BR, it allows simultaneous detection of both pigments, as well as hemin, at picomole sensitivity. If BVR is present in the reaction mixtures in excess, or added from an exogenous source, the BV peak will disappear to favor a single BR peak, which will simplify quantification. Protein extracts prepared from HeLa cells were found to contain substantial BVR activity in the 18,000 × *g* supernatant, which even cosedimented in 105,000 × *g* pellets. The amount of endogenous BVR present in protein samples will vary with cell type and degree of protein purification used.

Successful performance of this assay requires a high-quality protein extraction (see Table 9.6.1). To safeguard against protein degradation, a broad spectrum of protease inhibitors should be employed in all extraction solutions. Perform all steps at 4°C using pre-

Table 9.6.2 Measurement of HO Activity in Human Cell Types[a]

Cell type	Treatment condition	HO activity (pmol BR/mg microsomal protein/hr)
HtTA-1 (Hela)[b]	Control[b]	25 ± 11
HtTA-1 HO-2 overexpressing clone[b]	72 hr culture[c]	727 ± 150
HtTA-1[b]	Hemin, 10 μM[d]	278 ± 20
FEK-4 Human skin fibroblast	Control[e]	120 ± 2.5
FEK-4 Human skin fibroblast	Na-Arsenite, 50 μM[f]	350 ± 38
FEK-4 Human skin fibroblast	UVA radiation (250 kJ/m^2)[g]	450

[a]Sample values were obtained by HPLC determination of HO activity as described previously (Ryter et al., 1998, 1999). Microsomal protein derived from cultured cells was used for all determinations. Values reflect mean and standard deviation from three independent determinations.

[b]Human HeLa HtTA-1 were cultured in Earle's minimal essential medium (EMEM) supplemented with 10% FBS, 0.2% sodium bicarbonate, and antibiotics, under standard conditions (37°C, 95% air/5% CO_2) for 4 days.

[c]The heme oxygenase-II (HO-2) overexpressing HtTA-1 subclone (9D5) was cultured for 72 hr in antibiotic-free medium and then harvested for activity analysis.

[d]HtTA-1 were treated with hemin (10 mM in DMSO) applied directly to complete medium to a final concentration of 10 μM, and incubated at 37°C for 16 hr before harvest.

[e]The normal human foreskin fibroblast line FEK-4 was cultured to confluence in EMEM supplemented with 15% FCS, and 0.2% sodium bicarbonate, under standard conditions (37°C, 95% air-5% CO_2).

[f]Sodium *m*-arsenite was applied to confluent FEK-4 monolayers in PBS at 50 μM for 30 min. Subsequently, the cultures were rinsed twice with PBS, fed again with original conditioned complete medium, and restored to 37°C incubators for an additional 14 hr prior to harvest.

[g]For ultraviolet-A (UVA) radiation treatments, confluent FEK-4 monolayers were irradiated at room temperature in PBS supplemented with 0.01% Ca^{2+} and Mg^{2+}. The UVA radiation (250 kJ/m^2) was applied using a broad-spectrum (350 to 400 nm) Sellas 4 KW UVA lamp (Sellas Medizinische Gerate). The light dose was determined using an IL-1700 radiometer (International Light). Following irradiation, cells were rinsed with PBS, restored to complete conditioned medium, and incubated at 37°C for an additional 10 hr.

cooled solutions and equipment. For best results, finish the entire assay on the day of protein extraction. Freezing microsomal or crude extracts at −20°C may cause activity loss.

Assay failure may also commonly arise from mechanical problems with the HPLC apparatus (see Table 9.6.1). These problems can be avoided by proper maintenance of the equipment, including routine inspection for leaks and replacement of precolumn filters. Special care should be used to ensure that buffers and injected samples are free of particulate contamination. HPLC columns have a limited lifetime and require periodic replacement, which can drive up the cost of performing this assay. The columns must be rinsed thoroughly with methanol immediately after completion of the run. Repeated injection of the samples leads to progressive column wear, which manifests as peak spreading. The use of crude protein extract as starting material may cause accelerated column wear. Reversing the column direction when peak spreading occurs can extend column lifetime. Excess injected hemin may be retained in the column and elute during subsequent methanol rinsing. The binding of excess heme inside the column may also affect column lifetime.

A slight dark decay of BR IXα occurs when the samples are stored for long periods of time in plastic tubes. The cause of this has not been determined, but may be due to air oxidation or binding of the pigment to the plastic. Thus, long serial repetitions of equivalent samples in an autosampler result in gradual signal reduction. The authors recommend limiting autosampler runs to 20 samples. The rate of dark decay can be determined experimentally from the serial repetition of BR standards.

A weakness of HO activity assays is that they do not differentiate between HO-1 and HO-2 activity. Theoretically, based on known mRNA and protein expression patterns, basal HO activity is generally assumed to reflect constitutive HO-2 expression with a negligible contribution from HO-1. Inducible HO activity reflects the additional contribution of HO-1 activity to the background of HO-2 activity.

There are rare cases, however, where HO-2 contributes to inducible activity, such as stimulation of nervous tissue with glucocorticoid hormones (Weber et al., 1994). A thorough analysis of HO expression, therefore, might involve a combination of activity assay data supplemented with immunoblot or northern blot analyses of the protein or mRNA levels of the different isozymes.

Furthermore, in vitro enzyme assays provide only a comparative estimate of functional enzyme protein levels under the artificial condition of excess exogenous substrate. However, the availability of endogenous heme for HO activity in tissue samples cannot be addressed by the assay. Absolute activity values reported will vary depending upon the degree of protein purification used. Therefore, for comparative purposes, one should use a consistent protein extraction protocol.

Anticipated Results

Figure 9.6.1 shows a sample standard chromatogram. As little as 10 pmol of BV or BR can be detected using the HPLC parameters described. Most mammalian cell types should contain basal HO activity. Basal values from cultured cells should be in the range of 30 to 200 pmol/mg protein/hr. Table 9.6.2 shows typical results from analyses of cultured cells exposed to several inducing agents.

Time Considerations

The preparation of tissue culture samples is typically initiated 2 to 3 days prior to the assay. Treatment with inducing chemicals or other manipulations of cell culture conditions is typically performed during the 12-hr period preceding the cell harvest. These parameters will vary depending on individual experimental design. Cell scraping and preparation of crude extract typically requires 1.5 to 2 hr for 20 to 30 petri dishes. The preparation of microsomal fractions from crude extract requires an additional 1.5 hr. Allow ≥0.5 hr for determination of protein concentrations. Allow 0.5 to 1 hr for assembly of reaction mixtures, if all reagents are prepared. Allow up to 1 hr reaction incubation time. Allow 15 min for post-reaction processing. Allow an analysis time of 20 min per sample (if an autosampler is used, the investigator need not be present after the first injection). Allow several hours for manual peak integration (this may be automatic on newer HPLC systems) and calculation of HO activities.

Functional Analysis of the Heme Oxygenase-1 Gene Promoter

Heme oxygenase (HO) enzyme activity is stimulated by a diverse array of chemical compounds, bioactive agents, and environmental conditions. This stimulation is a consequence of increased expression of the HO-1 enzyme resulting primarily from an enhanced rate of *ho-1* gene transcription.

Understanding the mechanism of inducer-dependent *ho-1* gene activation requires measurement of the transcriptional activity of the *ho-1* gene promoter. Promoter activities are most commonly measured in vivo by transient transfection assays utilizing reporter genes. In such assays, plasmid DNA bearing a reporter gene under the control of the test promoter is introduced, or transfected, into target cells by chemical or other means. The cells are subsequently exposed to vehicle or inducing agents and reporter enzyme activity is measured in extracts from treated and untreated cells, generally within 24 to 72 hr after transfection. By examining reporter gene constructs containing different regions (and mutants) of the *ho-1* gene promoter in this manner, it is possible to localize the exact DNA regulatory sequences necessary for *ho-1* gene activation by a particular agent. In certain circumstances, the *ho-1* gene promoter exhibits suboptimal or aberrant regulation in transient transfection assays. Integration, or stable transfection, of an *ho-1* promoter/reporter gene construct into chromosomes, which provides a more normal chromatin environment for gene regulation, often overcomes this limitation.

The *Photinus pyralis* (firefly) luciferase gene is arguably the most commonly used reporter gene for promoter analyses. Often, in transient transfection analyses, a second reporter gene under the control of a strong, constitutively active promoter is cotransfected with the primary construct. Normalization of the primary enzyme activity in each cell extract to the activity of the secondary reporter enzyme activity corrects for any potential variations in transfection efficiency between different cell populations. The *E. coli lacZ* gene encoding β-galactosidase is commonly used as the secondary reporter gene.

This unit describes procedures necessary for transient transfection analysis of the *ho-1* gene promoter (see Basic Protocol); these include transfection of cells using calcium phosphate–DNA precipitates and measurement of luciferase and β-galactosidase activities in the same cell extract by chemiluminescence-based assays. The calcium phosphate precipitation technique is also used to generate stable transfectants (see Alternate Protocol). Finally, a method is presented for purification of high-quality plasmid DNA necessary for cell transfection (see Support Protocol).

TRANSIENT TRANSFECTION OF REPORTER GENE CONSTRUCTS INTO MAMMALIAN CELLS AND MEASUREMENT OF REPORTER ENZYME ACTIVITIES

BASIC PROTOCOL

Transient transfection analysis is the preferred method for promoter function studies, as transfections can be carried out in 1 day and the entire experiment completed within 3 to 4 days. In contrast, 3 to 4 weeks are required for generation and expansion of stably transfected cell lines (see Alternate Protocol). In the present method, a precipitate containing calcium phosphate and DNA is formed by slowly mixing a HEPES-buffered saline solution with a solution containing calcium chloride and the reporter gene plasmid DNA, and this is applied to the cells. The $CaPO_4$-DNA complexes adhere to the surface of cells and are internalized. The transfected cells are exposed to the HO-1 inducer being tested and subsequently lysed directly on the plate with a detergent-containing buffer.

Current Protocols in Toxicology (2000) 9.7.1-9.7.21

Aliquots of lysates are used to measure luciferase and β-galactosidase activities with a single-tube luminometer.

Materials

Adherent eukaryotic cells: e.g., HeLa (human cervical epithelial adenocarcinoma), MCF-7 (human mammary epithelial adenocarcinoma), NIH 3T3 (mouse embryo fibroblast), L929 (mouse connective tissue fibroblast-like), Hepa (mouse hepatoma), or RAW 264.7 (mouse peritoneal macrophage)
Complete medium (depending on cell line used)
Plasmid containing luciferase gene under control of *ho-1* promoter (see Table 11.9.1) purified by CsCl gradient (see Support Protocol)
Plasmid containing β-galactosidase gene (see Table 11.9.1) purified by CsCl gradient (see Support Protocol)
Carrier CsCl-purified plasmid DNA (see Support Protocol)
3 M sodium acetate, pH 5.2 (see recipe)
95% ethanol
2.5 M $CaCl_2$ (see recipe)
2× HEPES-buffered saline (HeBS; see recipe)
Glycerol/PBS solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
HEPES-buffered, serum-free medium (appropriate to cell line; see recipe) containing inducing agent of interest
Cell lysis buffer (see recipe)
Luciferase assay buffer (see recipe)
0.2 mM luciferin solution (see recipe)
β-galactosidase chemiluminescent substrate solution (see recipe)
Light emission accelerator (Tropix)

6-well tissue culture plates
14-ml polystyrene round-bottom tubes (Falcon)
Platform shaker or rocker
Luminometer with measuring tube
48°C bath or heating block

Additional reagents and equipment for mammalian cell culture (*APPENDIX 3B*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Transfect cells with $CaPO_4$-DNA precipitates

1. The day before transfection, plate 5×10^5 cells per well of 6-well tissue culture plates and place in CO_2 incubator under standard growth conditions. Just prior to transfection, replace culture medium with 2.0 ml complete medium.

   The number of cells plated may be adjusted to account for differences in cell size and morphology and the cell density requirements at the time of induction. In general, on the day of transfection, it is important that cells be visibly separated in the wells (~50% confluent), as the ability to take up DNA is related to the surface area of the cell exposed to medium.

   APPENDIX 3B describes techniques for mammalian cell culture.

2. Ethanol precipitate DNA to be transfected as follows.

   a. In a 1.5-ml microcentrifuge tube, mix appropriate amounts of:

      CsCl-purified luciferase reporter/*ho-1* promoter plasmid DNA
      CsCl-purified β-galactosidase plasmid DNA
      CsCl-purified carrier DNA

   b. Adjust the volume to 90 µl with water.

   c. Add 10 µl of 3 M sodium acetate, pH 5.2, and 250 µl 95% ethanol.

   d. Mix and place 15 min at −70°C or overnight at −20°C.

   Ethanol precipitation sterilizes the DNA to be transfected. Plasmid DNA should be purified by two rounds of CsCl gradient centrifugation (see Support Protocol), as impurities in the DNA preparation can be deleterious to transfection efficiency.

   The total amount of DNA that is optimal for transfection will vary with cell line, from ~5 to 15 µg per well of a 6-well plate. The amount of individual reporter plasmids used for transfection will depend largely on the strengths of the ho-1 promoter (generally 5 µg) and the promoter driving expression of the lacZ gene in the cell line transfected (generally 1 to 5 µg, typically less but never more than the ho-1/luc plasmid because the β-gal plasmid contains a strong constitutive promoter). Surprisingly, the most important consideration here is the total amount of DNA used, which is determined empirically and is cell-line dependent. The range of 5 to 15 µg is based on observation and published reports. General cloning plasmids, E. coli DNA, or salmon sperm DNA are commonly used as carrier DNA.

3. Pellet DNA by microcentrifuging 5 min at 12,000 × *g* (12,000 rpm), 4°C, and remove the supernatant by aspiration or by inverting the microcentrifuge tube on a fresh Kimwipe inside a tissue culture hood. Air dry the pellet.

4. Resuspend the pellet in 450 µl sterile water and add 50 µl of 2.5 M $CaCl_2$. Mix by pipetting.

   DNA is difficult to dissolve in high salt solutions and should be resuspended completely prior to addition of $CaCl_2$.

5. Place 500 µl of 2× HeBS in a sterile, 14-ml polystyrene round-bottom tube. Add the DNA/$CaCl_2$ solution dropwise with a Pasteur pipet, mixing the solutions after every 4 to 5 drops by gentle agitation of the tube. Incubate 15 to 20 min at room temperature.

   Agitation (2 to 3 sec each) should be of sufficient strength to permit mixing but not so strong as to generate bubbles. A vortex mixer may also be used. Clear polystyrene tubes, in contrast to opaque tubes, permit easier visualization of the precipitate. The mixture should appear cloudy, similar to very dilute milk. The volume of precipitate is sufficient for two wells; if more than one inducer, or multiple concentrations of the same inducer, are being tested, adjust the amount of DNA and solution volumes proportionally. Do not prepare more than 2 ml of precipitate in a single tube of this size. Higher volumes do not permit adequate mixing, and result in suboptimal precipitation. Combine all precipitates of the same DNA mixture into a single tube prior to aliquoting into replicate wells.

6. With a 1-ml pipettor, transfer 0.45 ml of each precipitate prepared to each of 2 wells in a 6-well plate of growing cells (see step 1). Distribute the precipitates dropwise over the entire well and gently agitate to mix precipitate and medium.

7. Incubate the cells 4 to 6 hr under standard growth conditions.

   The amount of time that the precipitate should be left on the cells will vary with cell type. For hardy cells such as HeLa, L929, and NIH 3T3, the precipitate can be left on for 16 to 24 hr with concomitant enhancement in DNA uptake and reporter enzyme activities. Other cell types will not survive this amount of exposure to the precipitate. As a general rule, expose cells for the minimum amount of time sufficient to attain reasonable levels of reporter enzyme activity.

8. Remove the medium from each well, add 1 ml sterile 37°C glycerol/PBS, and leave for 1 to 2 min, room temperature. Remove the glycerol solution and wash cells twice with 2 ml 37°C PBS, then feed cells with 2 ml 37°C complete medium.

   For most cell lines, transfection efficiency is increased to varying degrees by "shocking" the cells with either glycerol or DMSO (10% to 20%). DMSO tends to be somewhat less harmful to the cells, but also may not be as effective. Shocking is unnecessary when cells are exposed to the precipitate overnight. Wash cells quickly with PBS as excessive exposure to glycerol will kill cells.

9. Incubate cells for 16 to 40 hr under standard growth conditions.

Expose cells to inducing agent

10. Remove medium by aspiration and wash each well with 1 ml 37°C PBS.

11. To duplicate wells, add 2 ml HEPES-buffered, serum-free medium containing the inducing agent or the vehicle used for the inducing agent (control). Return plates to the CO_2 incubator for 5 hr.

    For many HO-1 inducers, such as heme and heavy metals, the highest induction levels are achieved in serum-free medium, as serum proteins bind and retard cellular uptake. In serum-free medium, the optimal exposure time is generally between 3 and 8 hr, which represents a balance between the need to translate sufficient levels of reporter gene products and to maintain cell viability, as many HO-1 inducers are toxic. HO-1 inducers that are not toxic or whose actions are not inhibited by serum proteins can be added in complete medium for extended periods. In such circumstances, addition of inducing agent immediately after transfection (at the end of step 8) may provide for higher induction levels.

12. Remove induction medium by aspiration and wash each well twice with PBS.

    If luciferase assays cannot be carried out immediately, freeze plate at −70°C after removal of PBS.

Prepare cell extract

13. Add 0.5 ml cell lysis buffer to each well and agitate the plate on a platform shaker or rocker for 15 min at moderate speed, room temperature.

    Cell lysis can be monitored by examining the cells under a microscope. Lysed cells will appear shrunken and circular. Detachment of cells from the plate is not necessary for lysis and release of reporter enzymes.

Measure luciferase activity

14. Pipet 0.4 ml luciferase assay buffer into each luminometer measuring tube and an appropriate volume of luciferin solution (depending upon the luminometer) into the injection vial.

    Perform all assays in duplicate.

15. Pipet 5 to 50 µl cell lysate directly into the assay buffer within each tube and mix by gentle agitation.

16. Place tube in the luminometer and inject 100 µl luciferin solution. Measure luminescence by integrated light analysis (typically 10 to 20 sec).

    Dilute or reduce cell extract to maintain reaction within the linear range of the instrument. Reaction buffer, lysate, and substrate volumes will vary depending on instrument used. Compared to peak height analysis, integrated analysis is less affected by noise fluctuations, thus reducing variability, and this generally can detect lower levels of light emission.

    Integrated light analysis is "built into" all luminometers used for promoter analysis. Most luminometers permit adjustment of integration period (i.e., 10, 20, or 30 sec).

Measure β-galactosidase activity

17. Transfer 0.25 ml of each cell lysate (from step 13) to a 1.5-ml microcentrifuge tube and heat at 48°C for 50 min. Place tubes on ice 5 min and then microcentrifuge 5 min at 12,000 × *g*, 4°C.

    Perform all assays in duplicate.

    All mammalian cells exhibit varying degrees of endogenous β-galactosidase activity. Depending on the level, this activity may lead to background, which will decrease the overall sensitivity of the assay by lowering the signal-to-noise ratio. Mammalian and E. coli β-galactosidases exhibit differential sensitivity to heat inactivation. Because endogenous β-galactosidase activity may not be completely eliminated by heating, it is useful to measure the heat-insensitive activity in control extracts (from mock-transfected cells). For cells with low endogenous activity, such as HeLa and L929, this step may be omitted if exogenous activity is relatively high. Heated samples may be frozen at −70°C for up to 1 week without loss of activity.

18. Transfer 2 to 20 µl of each clarified cell lysate into a luminometer measuring tube. Add 100 µl β-galactosidase substrate solution (containing chemiluminescent β-Gal substrate) to each sample and gently mix. Incubate 60 min at room temperature.

    The amount of cell extract required may vary depending on the amount of expression and the instrument used. It is important to vary the concentrations of extract or time of reaction to keep the signal within the linear range of the assay. Measurements are time dependent. Substrate solution should be added to sample extracts in the same time frame as they are counted in the luminometer. For example, if it takes 20 sec to completely count a sample, then substrate solution should be added to tubes at 20-sec intervals.

19. Transfer an appropriate volume of light emission accelerator to the injection vial. Place tube with lysate/substrate solution (step 18) in luminometer and inject 100 µl accelerator. Measure integrated light emission over a 10- to 20-sec period.

STABLE TRANSFECTION OF REPORTER GENE CONSTRUCTS INTO MAMMALIAN CELLS

ALTERNATE PROTOCOL

Nonspecialized DNA transfected into mammalian cells lacks functional centromeres and is lost from the cell population with first-order kinetics. A small fraction will integrate into cellular chromosomes and be stably maintained as chromosomes replicate during subsequent cell divisions. Regulatory sequences within "transient" DNA molecules generally do not assume proper chromatin/nucleosomal structures and may exhibit suboptimal or aberrant gene regulation, particularly with respect to gene activation or repression. Differences in transcriptional activity between "transient" and "stable" sequence conformations have been observed for several promoters, including that of the *ho-1* gene and, in certain cellular contexts, some agents only activate integrated promoter sequences. Additionally, stably transfected cell lines permit rapid screening of agents (and conditions) that modulate promoter activity without repeated transfections.

To select for stable transfectants, generally representing ≤0.01% of the original population, the reporter gene plasmid is cotransfected with a second plasmid encoding a dominant selectable marker at a molar ratio of at least 5:1. Because transfected DNAs form large concatemers inside the cells, this ratio practically ensures that cells with the integrated marker gene will also incorporate the reporter gene. Cells are cultured in selection medium that permits survival only of those cells expressing the dominant marker. Resistant cells are allowed to grow until colonies are readily visible to the naked eye, and they are then collected and expanded. Several selectable marker genes are available for use in mammalian cells. The bacterial *aph* (*neo*) gene, encoding aminoglycoside phosphotransferase, is frequently used to select stable transfectants.

Additional Materials *(also see Basic Protocol)*

20 mg/ml G418 (see recipe)
Mammalian expression plasmid encoding *neo* gene and control expression vector lacking *neo* gene (e.g., pBSSK)
Bicinchoninic acid kit for protein determination (Sigma; optional)

10-cm tissue culture dishes
12- to 96-well tissue culture plates

Determine the minimum concentration of G418 necessary to prevent cell growth

1. Plate 5×10^5 cells in each of six 10-cm tissue culture dishes. After 24 hr, add serial dilutions of G418 (from 20 mg/ml stock) to individual plates at final concentrations of 0 to 1000 µg/ml in increments of 200 µg/ml and incubate under standard growth conditions.

2. Culture cells for 2 weeks, feeding with the appropriate selective medium every 3 to 4 days.

   APPENDIX 3B describes techniques in mammalian cell culture.

3. After 2 weeks, examine dishes for viable cells and determine the minimum concentration of G418 required to significantly inhibit cell growth.

   Cells differ in their susceptibility to killing by G418 and some may require even higher concentrations of the drug to evince cell death within a reasonable period of time. Cells will divide once or twice in the presence of lethal doses of G418, so the effects of the drug take several days to become apparent. The rate of cell killing diminishes dramatically if the cells reach confluency before the selection can take full effect. If necessary, plate lower numbers of cells (here and for transfection below).

Precipitate DNA and transfect cells

4. The day before transfection, plate 5×10^5 cells in a 10-cm tissue culture dish and incubate under standard growth conditions. Just prior to transfection, replace culture medium with 9.0 ml complete medium.

   Most cell lines can grow in isolation, a requirement for selecting stably transfected cells. If in doubt about the cell line being used, plate ~50 to 100 cells on a 10-cm tissue culture dish and feed every 4 days for 12 to 14 days. Examine for number of colonies by looking from underneath the plate or using a microscope. Colonies may also be quantified by removing the medium and staining the plate with 2 to 3 ml of 2% methylene blue in 50% ethanol. Colonies become visible after removal of the excess stain.

5. Ethanol precipitate the DNAs to be transfected as follows (see Basic Protocol, steps 2 to 3).

   Experimental plates—13.5 µg *ho-1* promoter/luciferase plasmid + 1.5 µg of *neo* expression vector plasmid.

   Control plate—13.5 µg *ho-1* promoter/luciferase plasmid + 1.5 µg of expression vector lacking the *neo* gene.

   Use a molar ratio between 5:1 and 15:1 of the reporter plasmid to the neo plasmid. For promoter analysis studies, it is best not to physically link the selective marker to the reporter gene transcription unit in a single plasmid. Any potential interference by the strong, constitutive promoter controlling expression of the marker gene with the regulation of the test sequences will be more pronounced at the 1:1 molar ratio in the linked plasmid. For control plates, any DNA lacking the selectable marker (e.g., pBSSK) will suffice.

6. Transfect the DNAs into the cells (see Basic Protocol, steps 4 to 9).

   For each sample, prepare 1 ml of $CaPO_4$-DNA precipitate and distribute entire volume on to a single 10-cm culture dish. For post-transfection shock, use 5 ml glycerol/PBS solution and PBS per 10-cm culture dish. Do at least two independent transfections (i.e., independent precipitates) of the experimental DNA in case one of the transfections fails.

7. Twenty-four hours after transfection, add G418 at the concentration determined in steps 1 to 3. Replace selection medium every 3 to 4 days.

   Some investigators propagate cells under nonselective conditions for 36 to 48 hr and then split the cells 1:15 into multiple plates containing selective medium. This is useful when it is necessary to isolate individual clones or to determine the number of transfectants, as one of the plates can be stained to facilitate counting. This strategy, however, is more cumbersome and less economical and usually not necessary for promoter studies.

   Different lots of G418 can have different potencies. If cell death occurs slowly or cells reach confluency, increase the G418 concentration incrementally by 100 μg/ml at each change of the medium until cell death is obvious.

Culture and expand cells

8. Culture cells in selective medium until colonies are 1 to 2 mm in diameter and readily visible to the naked eye (e.g., ~3 to 4 weeks).

9. Collect all colonies from a single plate as a pooled mixture, expand, and prepare frozen stocks at the earliest passage possible.

   Analysis of pooled clones is recommended to dilute or equalize any potential effects of specific integration sites on promoter regulation. If isolating and testing individual colonies, ≥2 to 3 such clones need to be analyzed. The number of resistant colonies obtained will depend on the efficiency of transfection, but ideally each mixture should contain ≥100 individual transfectants.

Measure luciferase activity

10. Plate stably transfected cells in multiwell plates (e.g., 12- or 96-well tissue culture plates) and culture under standard growth conditions for 2 days. Treat cells and measure luciferase activity (see Basic Protocol, steps 14 to 16).

    The use of multiwell plates allows for analysis of multiple inducers at various concentrations and periods of treatment. For example, 96-well plates are particularly advantageous for analysis of stably transfected cells if a 96-well plate format luminometer is available. The number of cells plated and volumes used for cell culture, induction, and cell lysis will vary with cell type and well format used. (See Anticipated Results for specific numbers).

11. *Optional:* Measure protein content of cell extract using a bicinchoninic acid kit to normalize luciferase data with respect to protein.

    Because the same number of cells are plated in each well, extracts are prepared with minimal manipulation, and the inducers are unlikely to significantly affect cell growth within the brief period examined, there is little variation in the amount of protein between individual cell extracts (in a given experiment), and normalization is generally unnecessary. If measuring protein, use a procedure, such as the bicinchoninic acid method, that is compatible with the concentrations of DTT and Triton X-100 in the lysis buffer.

SUPPORT PROTOCOL

PLASMID DNA PURIFICATION

High-quality plasmid DNA is essential for efficient transfection by calcium phosphate precipitation. Plasmid DNA prepared by simple or quick methods do not work well with this protocol. Best results are obtained with supercoiled plasmid DNA purified on silica or other DNA-binding matrices or by banding in cesium chloride gradients. The latter method is described here.

Materials

Plasmid-bearing *E.coli* colonies on agar plate
2× YT bacteria culture medium (see recipe)
Antibiotic (e.g., ampicillin, kanamycin)
Glucose solution (see recipe)
NaOH/SDS solution (see recipe)
Potassium acetate solution (see recipe)
Isopropanol
TE buffer, pH 8.0 (see recipe)
CsCl
10 mg/ml ethidium bromide (see recipe)
CsCl/TE buffer solution (see recipe)
CsCl/TE buffer–saturated isopropanol (see recipe)
3 M sodium acetate, pH 5.2 (see recipe)
95% or 100% and 70% ethanol

Sterile toothpicks
Culture tubes
37°C shaker incubator
2-liter flask
250-ml ultracentrifuge bottles (for a Sorvall GSA rotor)
Sorvall RC-5B superspeed centrifuge and Sorvall GSA rotor (or equivalent)
10-ml heat sealable ultracentrifuge tubes
Beckman L-70 ultracentrifuge and Beckman VTi 65 rotor (or equivalent)
Stand and clamp
18-G (or wider) needles
3- to 5-ml sterile syringes
15-ml screw-cap polypropylene tubes
Sorvall SS-34-rotor with rubber adapters (or equivalent)
1.5-ml microcentrifuge tubes

Culture E. coli cells and prepare cleared cell lysates

1. Propagate a small-scale culture of plasmid-bearing *E. coli* cells by stabbing an isolated colony from an agar plate with the end of a sterile toothpick and dropping it into a 15-ml polypropylene tube containing 2 ml of 2× YT medium and the appropriate antibiotic. Culture overnight at 37°C in a shaking incubator (200 to 250 rpm).

2. On the following day, pour all of the overnight culture into a 2-liter flask containing 500 ml of 2× YT medium and antibiotic. Culture for 12 to 18 hr at 37°C with shaking.

   Large-scale cultures may also be initiated from a single colony, bypassing step 1. In such cases, culture for 24 hr.

3. Transfer cultures into two 250-ml bottles and collect cells by centrifuging 10 min at 9000 × *g* (7500 rpm in a Sorvall GSA rotor), 4°C, using a Sorvall RC-5B superspeed centrifuge.

   Type of bottle, rotor, and centrifuge used will depend on availability.

4. Discard supernatant and resuspend each pellet in 5 ml glucose solution. Combine duplicate pellets and keep on ice.

   Use a rubber policeman or glass rod to break up pellet; incomplete resuspension will reduce plasmid DNA yield.

5. Add 20 ml NaOH/SDS solution (i.e., two times total volume of glucose solution) to lyse cells. Mix by swirling and keep on ice for 5 min.

   Lysates will be pale brownish-yellow and relatively clear. Incomplete clarification will reduce plasmid DNA yield, and generally results from excess cells. In such cases, reduce culture incubation time or proportionally increase volumes of glucose, NaOH/SDS, and potassium acetate (see below) solutions.

Partially purify plasmid DNA

6. Add 15 ml potassium acetate solution (1.5 times total volume of glucose solution). Mix by swirling and keep on ice for 5 min.

   A flocculent precipitate forms immediately and contains, along with other cellular debris, much of the E. coli chromosomal DNA.

7. Centrifuge samples as in step 3. Transfer the supernatant into a clean 250-ml centrifuge bottle.

   Some low-density particulate remains in the supernatant; it will not affect plasmid DNA purification.

8. Add 0.6 volumes of isopropanol to supernatant to precipitate DNA. Swirl or invert to mix and keep at room temperature for 5 min. Centrifuge samples as in step 3. Discard supernatant and wipe inside of bottle with Kimwipes.

   After adding isopropanol, do not store mixture at −20°C or −70°C as additional contaminating material may precipitate and affect subsequent purification.

Purify plasmid DNA by banding in a CsCl gradient

9. Resuspend pellet in exactly 8.8 ml TE buffer, pH 8.0, and add 10 to 10.2 g CsCl. Swirl or vortex to completely dissolve CsCl.

10. Transfer sample to a 10-ml heat sealable ultracentrifuge tube and add 100 µl of 10 mg/ml ethidium bromide solution to the top. Seal tube, and mix by inversion.

    Remember to balance tubes prior to sealing. Use CsCl/TE solution to increase weight. Check seal by squeezing tubes.

11. Ultracentrifuge overnight (i.e., 14 to 24 hr) at 238,000 × *g* (50,000 rpm in a Beckman VTi 65.1 rotor), 20°C.

    If the rotor or ultracentrifuge is in use or otherwise unavailable, store tubes indefinitely in the dark wrapped in aluminum foil at room temperature.

12. Remove centrifuge tubes from the rotor and immobilize with a clamp attached to a stand.

    Care should be taken not to disturb the CsCl gradient and DNA band(s) formed during centrifugation.

13. Puncture the top of the tube with an 18-G (or wider) needle (which can be left or removed). Insert an 18-G needle connected to a 3- to 5-ml sterile syringe into the side of tube, ~0.5 to 1 cm below DNA band, and move needle so that the bevel is pointed upwards and is just touching the bottom of the DNA band. Extract DNA slowly into the syringe.

CAUTION: *When inserting needle into the side, do not place fingers behind the tube. Ideally, there should be a single DNA band near the middle of the tube; RNA will be at the bottom and any precipitates will form a solid film on one side of the tube. If there are two DNA bands, remove the lower, closed-circular plasmid DNA. If the DNA band is toward the bottom of the tube, the sample withdrawn will be contaminated with RNA. The plasmid DNA is easily separated from the RNA on the second CsCl gradient. Do not use a higher-gauge needle as they tend to get clogged and may also shear large plasmid DNAs. Withdraw DNA in the smallest volume possible (e.g., ~2 to 3 ml) and do not attempt to collect the entire band. A thin band is always left behind no matter the volume removed.*

14. Transfer plasmid DNA to another ultracentrifuge tube, top with CsCl/TE solution, and seal tube. Ultracentrifuge for 6 hr at 342,000 × *g* (60,000 rpm in a Beckman VTi 65.1 rotor), 20°C.

    If it is more convenient, centrifuge overnight at 238,000 × g (50,000 rpm in Vti65.1 rotor).

15. Remove the plasmid band as described in step 13, note approximate volume, and transfer to a 15-ml screw-cap polypropylene tube. Extract three times with 1 to 2 vol CsCl/TE buffer–saturated isopropanol. Remove and discard the upper (pink), isopropanol phases containing ethidium bromide.

    The lower, DNA-containing layer should be clear after the final extraction. If necessary, carry out additional extractions. The upper phase is most easily removed using a Pasteur pipet. Any lower layer removed by pipetting is easily visible in the stem of the pipet and should be returned to the tube.

Precipitate DNA

16. Measure volume of the final lower phase and add 2 vol TE buffer, pH 8.0. Mix, then add 3 vol isopropanol (50% final concentration) and mix again. Place tubes at −20°C for 30 min to overnight to precipitate DNA.

17. Collect DNA by centrifuging for 10 min at 7600 × *g* (8000 rpm in a Sorvall SS-34 rotor with rubber adapters), 4°C.

18. Decant or aspirate supernatant and invert tube onto Kimwipes to drain any residual liquid. Be careful not to let any loosened pellet drain along with the liquid. Resuspend the pellet in 400 µl TE buffer, pH 8.0, and transfer to a 1.5-ml microcentrifuge tube. Add 0.1 vol (i.e., 40 µl) of 3 M sodium acetate, pH 5.2, and 2.5 vol (i.e., 1 ml) of 95% or 100% ethanol. Mix to precipitate DNA.

19. Pellet DNA in a microcentrifuge for 5 min at 12,000 × *g* (12,000 rpm). Decant or aspirate supernatant and wash pellet with 1 ml of 70% ethanol. Air dry pellet and resuspend in 1 ml TE buffer, pH 8.0.

    Because of the compactness of the pellet, vigorous pipetting is necessary to break up the pellet and facilitate resuspension. Alternatively, the pellet can be stored overnight in TE buffer at 4°C to allow dissolution.

20. Quantify DNA and store at 4°C.

    This procedure yields ~2 to 3 mg DNA/500 ml culture for high-copy plasmids.

REAGENTS AND SOLUTIONS

Use autoclaved Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

$CaCl_2$, 2.5 M

Dissolve 18.4 g $CaCl_2 \cdot 2H_2O$ in 50 ml water. Sterilize solution by filtering through a 0.22-µm filter and distribute into 5-ml aliquots. Maintain working aliquot at 4°C for up to 6 months and store remainder indefinitely at −20°C.

Cell lysis buffer

Add 1 µl of 100 mM PMSF (see recipe) and 5 µl of 0.1 M DTT (see recipe) to each milliliter of cell lysis reagent (see recipe). Prepare just before use and only the amount necessary (final concentration: 0.1 mM PMSF/0.5 mM DTT).

Cell lysis reagent

Weigh 1.23 g $MgSO_4$, 0.38 g EGTA, and 2.6 g HEPES (*N*-2-hydroxylthylpiperazine-*N*′-2-ethanesulfonic acid; sodium salt). Add water and adjust pH to pH 8.0 with NaOH. Add 5 ml Triton X-100 and adjust with water to a final volume of 500 ml (final concentration: 10 mM $MgSO_4$/2 mM EGTA/20 mM HEPES, pH 8.0/1% (v/v) Triton X-100). Store up to 6 months at 4°C.

CsCl/TE buffer–saturated isopropanol

Dissolve 240 g CsCl in 200 ml TE buffer, pH 8.0 (see recipe). Add to 300 ml isopropanol. Mix and allow the phases to separate. Use the upper phase. Store indefinitely at room temperature.

After depletion, additional isopropanol may be added and used as long as distinct phases form. Conversely, CsCl/TE solution may be added to assist phase separation.

CsCl/TE buffer solution

Dissolve 48 g CsCl in 40 ml TE buffer, pH 8.0 (see recipe). Store up to 1 month at room temperature.

Dithiothreitol (DTT), 0.1 M

Dissolve 0.15 g DTT in 10 ml water. Dispense into 0.5-ml aliquots and store indefinitely at −20°C.

Ethidium bromide, 10 mg/ml

Dissolve 1 g ethidium bromide in 100 ml water. Store indefinitely in a dark bottle or a bottle wrapped in aluminum foil at room temperature.

CAUTION: *Ethidium bromide is a powerful mutagen and is moderately toxic. Gloves should be worn when working with solutions that contain this dye, and a mask should be worn when weighing it out.*

G418, 20 mg/ml

Dissolve 1 g G418 in 50 ml complete tissue culture medium. Sterilize by filtering through a 0.22-µm filter and distribute into 10-ml aliquots. Maintain working aliquot at 4°C for up to 3 months and store remainder indefinitely at −20°C.

β-Galactosidase chemiluminescent substrate solution

1 M sodium phosphate, monobasic: Dissolve 13.8 g $NaH_2PO_4 \cdot H_2O$ in water and adjust volume to 100 ml. Store at room temperature.

1 M sodium phosphate, dibasic: Dissolve 26.8 g $Na_2HPO_4 \cdot 7H_2O$ in water and adjust volume to 100 ml. Store at room temperature.

Substrate diluent: Mix 0.7 ml of 1 M monobasic sodium phosphate and 9.3 ml of 1 M dibasic sodium phosphate stock solutions. Add 100 µl of 1 M $MgCl_2$ (*APPENDIX 2A*) and adjust volume to 100 ml (final concentration: 0.1 M sodium phosphate, pH 8.0/1 mM $MgCl_2$). Store up to 3 months at 4°C.

Substrate solution: Dilute chemiluminescent β-Gal substrate (Galacton; Tropix) 1:500 with diluent. Prepare just before use and only the amount necessary.

Glucose solution

Dissolve 9.8 g dextrose monohydrate in 955 ml water. Add 25 ml of 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*), and 20 ml of 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*). Dispense into 100- to 500-ml portions and sterilize by autoclaving and store up to 6 months at 4°C (final concentration: 50 mM glucose/25 mM Tris·Cl, pH 8.0/10 mM EDTA).

Glycerol/PBS solution

Mix 130 ml glycerol with 130 ml phosphate-buffered saline (PBS; *APPENDIX 2A*). Sterilize mixture by filtering through a 0.45-µm filter. Add 125 ml of mixture to each of two 500-ml bottles of sterile PBS. Mix and store indefinitely at 4°C (final concentration: 10% v/v glycerol).

HEPES-buffered saline (HeBS) solution, 2×

Dissolve 4.1 g NaCl, 3.0 g HEPES acid, and 0.053 g Na_2HPO_4 in 200 ml water. Adjust pH to 7.05 with concentrated NaOH. Adjust volume to 250 ml with water, sterilize by filtering through a 0.22-µm filter, and test for transfection efficiency (final concentration: 50 mM HEPES, pH 7.05/280 mM NaCl/1.5 mM Na_2HPO_4). Dispense 40-ml aliquots into sterile 50-ml plastic tubes. Maintain working aliquot up to 2 months at 4°C and store remainder indefinitely at −20°C.

Efficient precipitates form only within the narrow pH range of 7.05 ± 0.05, and there can be wide variability in the efficiency of transfection obtained between batches of 2× HeBS. Precipitate formation should be checked with each new batch by mixing 0.5 ml of 2× HeBS with 0.5 ml of 250 mM $CaCl_2$ and vortexing. A fine precipitate should develop that is readily visible in the microscope.

HEPES-buffered serum-free medium

Add 10 ml of sterile 1 M HEPES, pH 7.2 (commercially prepared) to a sterile 500-ml bottle of serum-free medium appropriate to the cell line to be used (final concentration: ~20 mM HEPES). Store at 4°C until expiration date of medium.

Luciferase assay buffer

Add 1 µl of 1 M DTT (*APPENDIX 2A*) and 20 µl of 100 mM ATP (*APPENDIX 2A*) to each milliliter of luciferase reagent buffer (see recipe). Prepare just before use and only the amount necessary (final concentration: ~1 mM DTT/2 mM ATP).

Luciferase reagent buffer

Weigh 1.65 g glycylglycine, 1.85 g $MgSO_4$, 0.76 g EGTA, and 1.02 g KH_2PO_4; add water and adjust pH to 7.8 with concentrated KOH. Adjust with water to a final volume of 500 ml (final concentration: 25 mM glycylglycine/15 mM $MgSO_4$/4 mM EGTA/15 mM KH_2PO_4). Aliquot and store up to 1 year at 4°C.

Discard if excessive precipitate forms upon storage.

Luciferin solution, 0.2 mM

Dissolve 10 mg luciferin (sodium salt; Analytical Luminescence Laboratory) in 165 ml water. Transfer 10-ml aliquots into 15-ml screw-cap tubes, wrap with aluminum foil and store at −20°C for up to 1 year.

NaOH/SDS solution

Mix 0.1 volume each of 2 N NaOH (*APPENDIX 2A*) and 10% SDS (*APPENDIX 2A*) with 0.8 volume water (final concentration: 0.2 N NaOH/1% SDS). Prepare just before use and only in the amount necessary.

Phenylmethylsulfonyl fluoride (PMSF), 100 mM

Dissolve 0.17 g of PMSF in 10 ml anhydrous isopropanol and store indefinitely at 4°C.

Potassium acetate solution

Dissolve 294.4 g potassium acetate in ~600 ml water. Adjust pH to 5.0 with glacial acetic acid (~120 ml). Adjust volume to 1 liter with water (final concentration: 3 M potassium/5 M acetate). Autoclave and store indefinitely at room temperature.

Sodium acetate, pH 5.2, 3 M

Dissolve 204 g of sodium acetate trihydrate in 400 ml water. Adjust the pH to 5.2 with glacial acetic acid and adjust volume to 500 ml with water. Sterilize by autoclaving and store indefinitely at room temperature. Decant working aliquots into 50-ml screw-cap plastic tubes.

TE buffer, pH 8.0

Mix 10 ml of 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*), 2 ml of 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*), and 988 ml water. Aliquot and autoclave (final concentration: 10 mM Tris·Cl/1 mM EDTA). Store indefinitely at room temperature. Decant working aliquots into 50-ml screw-cap plastic tubes.

YT bacteria culture medium, 2×

Weigh and mix 16 g tryptone, 10 g yeast extract, and 5 g sodium chloride. Dissolve in 1 liter water. Aliquot into bottles or flasks and sterilize by autoclaving. Store indefinitely at room temperature. Discard if medium turns cloudy at any time after sterilization.

COMMENTARY

Background Information

Heme oxygenase (HO) enzymes catalyze the initial and rate-limiting reaction in heme catabolism—the oxidative cleavage of b-type heme molecules to yield equimolar quantities of biliverdin IXα, carbon monoxide, and iron. This activity was identified and initially characterized in the mid- to late 1960s. Soon thereafter, several studies demonstrated that HO activity is stimulated not only by the substrate heme or during erythrophagocytosis, but also in response to agents unrelated to heme including endotoxin and heavy metals. Initial investigations using RNA synthesis inhibitors hinted at the requirement of de novo RNA synthesis, and studies with isolated polysomes confirmed that induction of enzyme activity resulted from increased levels of the mRNA encoding the isozyme now classified as HO-1. The availability of cDNA and genomic clones has established, by direct measurement of transcription rates, that induction of HO-1 expression by many if not all stimuli is regulated primarily at the level of transcription initiation. Additionally, the list of HO-1 inducers has expanded dramatically to include, among others, UV irradiation, hyperthermia, inflammatory cytokines, nitric oxide, disease states, and therapeutic drugs (Maines, 1992; Choi and Alam, 1996).

The basic mechanism of transcription is essentially identical for all genes and involves the initiation and procession of RNA synthesis by RNA polymerase and the basic transcription machinery. Temporal, spatial, tissue-specific, and inducer-dependent variations in gene expression result primarily from the binding of specific transcription factors to their target DNA sequences (*cis* elements) located within the body of the gene, downstream of the gene or, more commonly, upstream of the gene in the proximal and/or distal promoter regions. These sequence-specific DNA binding proteins, in turn, modulate the rate of transcription initiation by interacting directly, or indirectly via coactivators, with the basic transcription machinery.

Aside from the obvious requirement of procedures to isolate and sequence select eukaryotic genes, identification and functional analysis of *cis*-elements has been greatly facilitated by two technological developments: (1) the ability to transfect DNA into cells, and (2) the use of reporter genes to monitor the transcription activity of regulatory sequences.

Transfection

Naked DNA can be introduced into mammalian cells directly by microinjection, or, more commonly, by methods that promote cellular uptake. DNA uptake can be facilitated by generation of pores in the cellular membrane with electrical impulses (i.e., electroporation),

by lipid-mediated fusion to cell membranes, or with the use of chemical agents such as DEAE-dextran or calcium phosphate. The calcium phosphate coprecipitation technique has evolved from the observations of Graham and van der Eb (1973) that $CaCl_2$ enhances DEAE-dextran-mediated cellular uptake of adenovirus DNA. Further analysis indicated that enhanced uptake resulted as a consequence of the formation and cellular adsorption of DNA-$CaPO_4$ coprecipitates (the phosphate was fortuitously present in the DNA dilution buffer). Calcium phosphate precipitation is a relatively simple and inexpensive procedure, and, unlike the DEAE-dextran method, is equally effective in transient and stable transfections. Because effective precipitates form under relatively specific conditions, variability in transfection efficiencies is a potential and not infrequent problem. Another disadvantage is that this technique is not particularly effective with suspension or primary cells. Lipids, on the other hand, expedite DNA uptake into a wide variety of cells. This property, and the commercial availability of various formulations, have made lipid-mediated transfection a popular methodology in promoter function analysis, in spite of the inherently higher cost of commercial reagents.

Reporter genes

The transcriptional activity of putative regulatory sequences can be studied using homologous systems in which the test sequence directs the expression of its corresponding gene. In this approach, cloned genomic fragments encompassing the coding and flanking regions or minigenes are transfected into cells and activity is assayed by mRNA analysis. The transcripts derived from the exogenous, transfected gene can be distinguished from the endogenous mRNA by using a heterologous cell line (i.e., from a different species) or by modification of the cloned gene (i.e., deletion or insertion of foreign sequences) that generates a slightly altered product. The advantage of this strategy is that RNA measurements provide a relatively direct assessment of transcriptional activity and utilize genetic configurations similar to the endogenous gene, minimizing any potential effects of post-transcriptional processes on gene expression. Measurement of RNA levels, however, can be quite cumbersome and time-consuming, especially considering that identification of *cis* elements requires examination of numerous deletion and site-directed mutant constructs, and the homologous strategy has been superseded by a heterologous approach utilizing reporter genes. With the heterologous system, transcriptional activity is most commonly scored indirectly by measuring reporter gene product levels or enzyme activity. Such assays are generally quicker and more easily quantifiable, and the assumption that protein levels are directly proportional to transcription activity appears to be valid under most circumstances. An important criterion for a reporter gene is that it encode a protein (activity) that is not present in the target cell, or, if present, that can be distinguished from the endogenous activity. Even some mammalian genes, such as those encoding human growth hormone and interleukin 2, which are expressed in a tissue-restricted manner, or placental alkaline phosphate, which can be distinguished from most other phosphatases by its heat stability, satisfy this criterion and have been used in such a capacity. The most commonly used reporter genes, however, are derived from nonmammalian sources. For most of the 1980s, the bacterial genes encoding chloramphenicol acetyl-transferase (Gorman, 1985) and, to a lesser extent, β-galactosidase, were most frequently used for promoter analysis. Because of the construction and availability of numerous promoter/CAT plasmids, this reporter gene is still widely used. Its popularity, however, has gradually and significantly diminished since the introduction of the firefly luciferase reporter gene in 1987 (de Wet et al., 1987). The preference for luciferase is obvious when one compares the characteristics of the enzyme assays; the luciferase reaction is simpler and can be carried out in a matter of minutes as opposed to several hours, does not utilize radioisotopes (as is the case with the most common CAT assays), is more sensitive by at least 3 to 4 orders of magnitudes, and is more economical (Alam and Cook, 1990).

Genomic clones encoding HO-1 from several species have been isolated, and regulatory sequences of these genes have been characterized to varying degrees. Mouse (Alam et al., 1999), rat (Immenschuh et al., 1998; Pellacani et al., 1998), human (Takeda et al., 1994), and chicken (Elbirt et al., 1998) *ho-1* gene promoter/luciferase fusions and their derivatives have been constructed by several investigators and may be obtained from these sources. If necessary, however, *ho-1* promoter sequences may be obtained by other means such as: (1) by screening genomic libraries with traditional methods; (2) by PCR amplification of genomic DNA of species for which sequence data is available; (3) by PCR amplification of commer-

cially available genomic library arrays; and (4) from individuals (or affiliated repositories) involved in large-scale genome sequencing, after first having identified the appropriate clone(s) from sequence information in various databases. With the *ho-1* promoter sequence in hand, standard cloning into a luciferase reporter gene vector will provide the necessary chimera for transfection experiments. Initial analysis should be carried out with largest promoter construct available. Subsequent deletion and mutation of the *ho-1* sequences will localize the inducer-responsive *cis*-element(s).

Critical Parameters and Troubleshooting

The use of luciferase and the development and enhancement of chemiluminescent-based assays for other commonly used reporter enzymes, such as β-galactosidase and alkaline phosphatase, has significantly reduced the lower limit of detection for reporter proteins, in some cases to as few as 10^3 molecules (Alam and Cook, 1990). Because of this increased sensitivity, optimization of protocols to achieve maximum transfection efficiency is less of a consideration in promoter regulation analysis. Nonetheless, reasonable levels of DNA uptake are still useful, for example, when analyzing weak promoters, and particularly with the $CaPO_4$ precipitation technique, as small variations in the size and quality of the precipitate can have dramatic effects on transfection efficiencies.

The initiation, growth, and physical characteristics of precipitate complexes, and ultimately transfection efficiencies, are influenced by many factors, including the concentrations of calcium and phosphate, DNA concentration, and reaction temperature and time (Graham and van der Eb, 1973; Jordan et al., 1996). With the Basic Protocol, however, poor transfection efficiency can most often be attributed to the 2× HeBS solution or the plasmid DNA sample. Optimal transfection—and presumably the formation of highly effective $CaPO_4$-DNA complexes—occurs within the extremely narrow pH range of 7.05 ± 0.05 for the 2× HeBS solution. Values outside this pH range can result in highly dense precipitates that are toxic to cells, large complexes that are not readily internalized, or little to no precipitate (i.e., not visible under a microscope). Given these narrow limits, it is necessary to carefully calibrate the pH meter, using freshly prepared standards, just before preparation of the 2× HeBS solution. Furthermore, the pH of the 2× HeBS solution will migrate outside of the optimal range upon prolonged storage at 4°C. If deterioration in reporter enzyme activities and/or variability in the size, uniformity, or density of the precipitate complex is observed over a period of several transfections, replacement of the 2× HeBS solution should be the first step in the troubleshooting process. While some investigators have also noted deterioration of the 2.5 M $CaCl_2$ solution over time, the author has observed no decay in efficacy of such solutions stored for up to a year at 4°C.

DNA prepared by simple or quick methods should not be used for transfection by the $CaPO_4$ precipitation technique. Impurities in such preparations inhibit initiation and growth of precipitate complexes, reduce internalization of the complex by host cells, and/or promote cellular toxicity. Plasmid DNA purified by CsCl banding is generally considered the "gold standard" and DNA purified as described in the Support Protocol is rarely the source of poor transfection efficiencies. DNA purified by single banding exhibits somewhat reduced efficacy. Plasmid DNA purified by adsorption to silica or other matrices is purported to yield transfection efficiencies equal to or better than those observed with CsCl-purified DNA. In the authors' experience, such preparations are adequate but slightly less effective and give more inconsistent results when used in transfections by $CaPO_4$ precipitation.

For induction studies, another important but less obvious parameter is the molecular nature of the luciferase reporter gene and vector. Firefly luciferase is normally translocated to the peroxisomes in the firefly photocytic cells and also in transfected mammalian cells. As a consequence, this reporter enzyme has a relatively short half-life, ~3 hr in mammalian cells. A commonly used, commercially available luciferase reporter vector encodes a modified luciferase in which the peroxisome targeting sequence has been inactivated, resulting in cycloplasmic retention of the enzyme, and consequently increased stability. Other modifications within the luciferase cDNA and the vector backbone have the net effect of providing high-level, stable expression of luciferase in mammalian cells, 10- to over 100-fold greater than observed with typical vectors encoding wild-type luciferase. The modified luciferase vector is extremely useful when testing regulatory sequences with weak transcriptional activity or measuring basal expression. Promoter sequences cloned into the modified vector, however, may exhibit reduced apparent

inducibility; with the identical *ho-1* promoter sequences, wild-type luciferase constructs generate "fold induction" values 3 to 10 times higher than the modified luciferase plasmid. Presumably, this difference is a consequence of the increased basal activity observed with the modified luciferase reporter plasmid and will be more pronounced when the induction period is brief and not initiated immediately after transfection.

Test DNA

For purposes of this unit, the promoter is broadly defined as all the sequences of a gene necessary for correct transcription initiation and modulation of the rate of such initiation. Proper transcription initiation is controlled primarily by the initiation region itself and the TATA box (or analogous sequences in genes lacking identifiable TATA boxes), generally located 20 to 30 bp upstream of the transcription start site. This short region is operationally referred to as the core promoter. The rate of transcription initiation, as noted earlier, is controlled by discrete *cis* elements that may be located proximal or distal to the core promoter within the body of the gene (either in introns or exons) or in the 5′ or 3′ flanking regions. In the literature, the term "promoter" is often synonymous with the 5′ flanking region as transcription regulatory sequences are most commonly located within this segment. For instance, in the case of *ho-1* genes, all the regulatory *cis* elements thus far identified are situated in the upstream region. Therefore as a general rule, the initial reporter gene construct to be tested should contain the largest contiguous portion of the 5′ flanking region available (and clonable) including the transcription initiation site. Because not all *cis* elements may reside within such a contiguous region, another common strategy is to clone individual subfragments spanning the entire gene into a reporter plasmid containing either a homologous (i.e., derived from the gene under study) or a heterologous core promoter. This latter strategy is possible because of the modular nature of *cis* elements. With either cloning strategy, higher reporter enzyme activity resulting from the test construct relative to the parent reporter plasmid is indicative of the presence of regulatory sequences that confer basal and/or inducible transcription activity. These elements can be further localized by testing either subfragments or systematic deletion mutants of the original DNA. Confirmation of the role of a discrete element in transcription regulation generally requires site-directed mutation of that sequence in the context of the native promoter and/or the function of the element in isolation.

While the above strategies are generally applicable to all promoters, it should be noted that, as no two genes are identical, neither are two promoters alike. Even within the limited class of stress-responsive genes, mechanistic and structural differences are readily evident. For example, activation of the *ho-1*, *c-fos*, *hsp 70*, and metallothionein genes by cadmium is mediated by the cadmium- or stress-responsive, serum-responsive, heat shock, and metal regulatory elements, respectively, each of which has a unique sequence and binds to distinct transcription factors. Furthermore, while the cadmium-responsive sequences of the *c-fos*, *hsp 70*, and metallothionein genes are located relatively close to the transcription start site, those for the *ho-1* gene are situated ~4 kbp upstream. In addition, while some *ho-1* gene promoters contain sequence motifs similar to the heat shock and metal regulatory elements, none of these sequences have been shown to be activated by cadmium. Indeed, identification of elements based on similarity to consensus sequences is not necessarily indicative of function, and each promoter and each element must be tested individually and in the proper context.

Target cells

HO-1 expression is stimulated by one or more agents in practically all tissues tested, and in theory, any cell type can be used for *ho-1* promoter analysis. Consequently, the choice of cell type and its tissue of origin is dependent largely on the interests of the investigator and the physiological relevance of the inducing agent to that particular cell type. For any chosen cell type, the obvious and overriding requirement is that the test inducer activate transcription of the endogenous *ho-1* gene, a characteristic that should be confirmed prior to initiation of promoter analysis experiments. Furthermore, among different cells, those exhibiting the highest levels of induction are generally better suited for inducible promoter activity measurements, all other factors, such as transfectability, being similar. Analysis of the *ho-1* promoter, as of other promoters, is most frequently carried out using transformed or immortalized cells, since these cells are readily available, easily cultured and in general, quite conducive to DNA transfection. In most immortalized cell lines, for most inducers, the mechanisms of *ho-1* gene activation appear to be preserved. In certain circumstances, how-

ever, the transformed phenotype may result in the loss or abatement of part or all of the induction mechanism. For instance, while bromobenzene potently stimulates expression of rat hepatic HO-1, no induction is observed in several transformed hepatoma cell lines (J. Alam, unpub. observ.). One possible explanation for this discrepancy is that induction of HO-1 requires transformation of bromobenzene by one or more cytochrome P-450s, whose constitutive expression and/or activities are generally attenuated in hepatoma-derived cell lines. In theory, the absence of a particular cytochrome P-450 in immortalized cells may be overcome by ectopic expression of the enzyme or the use of the active bromobenzene metabolite, but this will require identification of the metabolizing enzyme or the actual metabolite responsible for gene induction. In such and similar circumstances, promoter analysis will require the use of primary cells or possibly even the use of transgenic mice. Finally, it should be noted that primary cells and suspension cells are generally not easily transfected with the $CaPO_4$-DNA coprecipitation technique.

Inducing agent

As noted earlier, a wide array of agents and conditions, both physiological and nonphysiological, stimulate transcription of the *ho-1* gene. A substantial list of such agents can be found in Maines (1992). These inducers are chemically and structurally diverse, ranging from such ephemeral entities as nitric oxide gas and shear stress resulting from blood flow in the vasculature to more concrete substances including heavy metals and polypeptide cytokines. This diversity is reflected in the mechanism of *ho-1* gene activation as distinct, inducer-specific *cis*-elements have been identified within *ho-1* promoters (Choi and Alam, 1996). Furthermore, additional differences are inevitable, as some agents, such as inflammatory cytokines or polypeptide growth factors, initiate the induction process by stimulation of cell-surface receptors, whereas other, membrane-permeable inducers, including heme and hydrogen peroxide, are likely to utilize a less circumscribed route to the nucleus. Most, but maybe not all inducers, however, share a common characteristic in that they promote cellular oxidative stress, either directly by generating reactive oxygen species or indirectly by depleting cellular antioxidant functions. This commonality is also reflected in the mechanism of *ho-1* gene activation by some inducers, as they utilize a common *cis*-element and its cognate DNA-binding protein (Choi and Alam, 1996).

Some practical considerations in the use of *ho-1* inducers are outlined as follows. (1) Many inducers are cytotoxic and the degree of toxicity can be cell dependent. Consequently, it is useful to establish dosage and temporal profiles for cell toxicity and HO-1 induction with each agent (in each cell line). The ultimate goal is to establish experimental conditions that permit reasonable induction of reporter gene expression without the confounding variable of cellular dysfunction. A time course is also useful because some agents can activate the *ho-1* gene in a relatively direct manner (i.e., within a few hours) whereas others evince a more delayed response, possibly because such induction is indirect, requiring the prior synthesis or generation of intermediary activators. (2) In examining the mechanism of inducer-dependent gene activation, it is often necessary to identify pharmacological compounds, such as antioxidants, steroids, or kinase inhibitors, that further modify the response. These compounds are generally added at the same time as or prior to (i.e., 0.5 to 24 hr) the addition of the inducing agent. (3) One should also consider the possibility that the test agent (either inducer or induction modifier) directly modulates the reporter enzyme activity/assay. For instance, the author has observed that PD098059, a commonly used inhibitor of mitogen-activated protein kinase kinases 1 and 2, and resveratrol, an antioxidant, inhibit the luciferase reaction, whereas hemin potently suppresses the chemiluminescent-based β-galactosidase assay described in this unit. Because it is often difficult to measure the actual intracellular concentration of test agents, the simplest and proper way to determine any modulatory effects of such compounds (at the concentrations used) on enzyme activity is to assay cell extract mixtures containing a constant amount of lysate from cells transfected with the reporter gene and varying amounts of lysates from untransfected cells exposed to the vehicle or the test agent. Purified enzyme may also be substituted for the former. (4) Many agents are soluble only in nonaqueous solutions. It goes without saying that data should be collected for transfected cells treated with the proper "vehicle" control, especially since some solvents, such as dimethyl sulfoxide and ethanol, are known to modulate HO-1 activity in certain settings. (5) Most *ho-1* inducers activate other genes and the protocol described herein (along with the caveats) is generally applicable to the functional

Table 9.7.1 Troubleshooting Guide for Transfection and Promoter Analysis

Problem	Potential cause	Possible solution
Basic Protocol		
No enzyme activity: luciferase and β-Gal	Instrument malfunction	Repeat assay using purified enzymes as positive control; repair instrument if necessary
	Incorrect plasmid used	Check integrity of plasmid by restriction endonuclease analysis
No enzyme activity: luciferase	ATP omitted from luciferase assay buffer	Prepare new assay buffer
Low activity: luciferase and β-Gal[a]	Poor transfection efficiency	Optimize transfection (Kingston et al., 1996; Rose, 1996); change cell line; change transfection method
	Incomplete cell lysis	Monitor cell lysis under microscope; prepare new lysis buffer if necessary
	Inducer is toxic to cells	Decrease concentration
Low activity: luciferase[a]	Precipitation (probably magnesium phosphate) in luciferase reagent buffer	Prepare new buffer; make sure pH and phosphate concentration are correct
	Luciferin solution old or of improper pH	Luciferin is most stable at pH between 6.1 and 6.5; discard if yellow
Low activity: β-Gal[a]	Promoter exhibits weak activity in cell line	Use β-galactosidase construct with different promoter
	Inducer inhibits activity (i.e., hemin)	Omit β-galactosidase measurements; normalize to protein content. Use different secondary reporter (i.e., CAT, AP).
Variable activity: luciferase and β-Gal	Contaminated injector lines	Thoroughly wash injectors
Variable activity: β-Gal	Incomplete inactivation of endogenous β-galactosidase activity	Reheat extract; check temperature
No or low induction of luciferase activity	*ho-1* promoter does not contain inducer-responsive element	Test other regions of *ho-1* gene
	Induction requires chromatin structure	Test stable transfectants
	Inducer must be metabolized prior to induction	Test metabolic derivatives or use cells capable of metabolizing agent
	ho-1 gene not responsive to inducer in cell line tested	Check induction of endogenous HO-1; use different cell line
	Induction occurs by a post-transcriptional mechanism	
Alternate Protocol		
Few or no stable transfectants	Cells are extremely sensitive to G418	Use different selectable marker gene and antibiotic (Mortensen et al., 1997)
	Selectable marker DNA degraded or omitted.	Check integrity of plasmids
	Poor transfection efficiency	See above

continued

Table 9.7.1 Troubleshooting Guide for Transfection and Promoter Analysis, continued

Problem	Potential cause	Possible solution
Stable transfectants on control plate	Plasmid DNAs contaminated	Check DNA stock
	Cell line contaminated with previous stable transfectants	Transfect new batch of cells from frozen stock
Support Protocol		
No plasmid band	Band at top of tube: too much CsCl	
Band at bottom of tube: too little CsCl	Carefully weigh CsCl; bake at 100°C to evaporate any moisture	
Low plasmid yield[b]	Incomplete lysis of cells	Prepare new NaOH stock
	Insufficient removal of chromosomal DNA and cellular protein	Check pH of potassium acetate solution; may not have been adjusted with acetic acid
	Low-copy plasmid	Use chloramphenicol amplification to prepare plasmid DNA (Sambrook et al., 1989)

[b]100 to 200 µg.

analysis of other promoters. One should bear in mind, however, that certain adjustments may be necessary because of promoter-specific mechanistic differences (see above for cadmium-mediated gene regulation).

The problems commonly observed with the protocols, their most likely causes, and potential solutions are outlined in Table 9.7.1.

Anticipated Results

Results from a typical transient transfection analysis and from an experiment using stable transfectants are shown in Tables 9.7.2 and 9.7.3, respectively. For the former, 5×10^5 cells were plated in each well of 6-well plates and each well was transfected with a DNA mixture consisting of 2 µg of pHO15 luc (which contains 15 kbp of the mouse *ho-1* gene promoter), 1 µg of pCMV β-gal (*lac Z* gene under the control of cytomegalovirus regulatory sequences), and 2 µg of pBluescript II SK$^-$ (Stratagene) for 6 hr. "Mock" transfections were carried out with 5 µg of pBluescript II SK$^-$ per well. After glycerol shock, cells were incubated for 36 hr and treated with vehicle or inducing agent for 5 hr. 8% (~40, 25, and 20 µg of protein for HeLa, Hepa, and L929 cells, respectively) and 4% of the cell extracts were used for luciferase and β-galactosidase assays, respectively. The data is the average of duplicate measurements. Hepa cells stably transfected with pHO15 luc were plated in a 24-well cluster (1×10^5 cells/well) and cultured for 66 hr. Cells were treated with vehicle or inducer for 5 hr and 3.3% of each extract (~7 µg of protein) was used for luciferase assays. For each treatment, the data represent the average from triplicate wells. Several aspects of the data are noteworthy. (1) Even though the same precipitate is used, basal luciferase activity varies considerably among different cell lines. This is in part due to cell-specific differences in *ho-1* promoter activity, but mostly reflects the transfection efficiency of the calcium phosphate precipitation method in these cells. (2) For a given inducer, the level of induction will vary with cell type and the optimal concentration of a given inducer is also cell-dependent (compare effect of cadmium concentration on induction levels in HeLa or Hepa cells with that in L929 cells). (3) When using the same $CaPO_4$-DNA precipitate, transfection efficiency between populations (i.e., wells) should be similar for a given cell line, as exemplified by the consistency in the β-galactosidase activities in HeLa or Hepa cell extracts. The variations in β-galactosidase activity observed in L929 cells indicates that the inducers, at the concentration used, are toxic to these cells. (4) Some agents can affect the reporter enzymes reaction; note the reduced β-galactosidase activity in extracts from hemin-treated cells. A direct effect of hemin, but not of arsenite or $CdCl_2$, on this reaction has been confirmed with the use of purified β-galactosidase. (5) β-galactosidase activity in HeLa cell extracts is near the upper

Table 9.7.2 Transient Transfection Assay

Inducer	Conc. (μM)	Luciferase ($\times 10^3$ RLU)[a]			β-galactosidase ($\times 10^5$ RLU)[a]		
		HeLa	Hepa[b]	L929	HeLa	Hepa	L929
Arsenite	25	219	100 (8)	2.23	95.9	30.9	0.81
	50	323	108 (8)	1.57	93.6	33.6	0.32

limit of detection for the instrument (1×10^7 RLU) and may not be in the linear range for the assay. These extracts should be diluted and reassayed. (6) For *ho-1* promoter-directed reporter genes, induction levels are almost invariably greater in stably transfected cells than in transiently transfected cells.

Time Considerations

Transient transfection analysis is generally carried out over a period of 3 to 5 days. This range reflects the variability in the lengths of the transfection (4 to 24 hr), of the incubation period prior to induction (typically 0 to 48 hr), and of the induction and post-induction incubations (4 to 24 hr). The hands-on time is, of course, considerably less. With practice, a given cell line can be trypsinized, counted, and plated in ~30 min. It will take a similar amount of time to ethanol precipitate 6 to 12 DNA samples. To facilitate this process, all plasmid stocks should be stored at 4°C, not frozen, and at consistent and convenient concentrations (e.g., 1 μg/μl) that permit simple, mental calculations to determine volumes used for precipitation. Most protocols recommend that cells be incubated for 2 to 4 hr in fresh medium prior to transfection. This step allows sufficient time to carry out ethanol precipitations on the same day as transfections. Because this incubation period has been eliminated in these protocols, it is more convenient to precipitate the DNA samples on the day before transfections. The actual transfection procedure, from pelleting of DNA by centrifugation to the application of $CaPO_4$-DNA precipitates on the cells, will take ~1 hr. With experience, the actual mixing of the $CaCl_2$-DNA and the 2× HeBS solutions will take ≤1 min per sample. Therefore, 6 to 12 precipitates (for 12 to 24 wells when testing one inducer) can easily be prepared before the first precipitate is ready for addition to cells.

Measurement of luciferase and β-galactosidase activities, if carried out in the same day, will take ~3 hr. The longest steps in these procedures are heat-inactivation of endogenous β-galactosidases and incubation of extracts with the β-galactosidase substrate, each of which requires ~1 hr. Therefore, after preparation of cell lysates, the first step should be to initiate the heat-inactivation procedure with a portion of the extract. The luciferase measurements can easily be carried out during this period. Once the luciferase assay buffer has been aliquoted into individual tubes, addition of extract and measurement of light output will

take ~30 sec/sample with a single tube luminometer set for a 10-sec integrated light analysis. Consequently, 24 samples can be measured in duplicate in ~30 min. There will be sufficient time to clean the luminometer before the heated extracts are ready for β-galactosidase measurements. Actual luminometer readings for β-galactosidase, as for luciferase, will take ~30 sec/sample. Often, it is more convenient to carry out the luciferase and β-galactosidase measurements on separate days. In this case, cell extracts can be frozen at −70°C prior to or after heating, although activities are slightly higher with the latter strategy.

For the Alternate Protocol, where applicable, the time required for individual manipulations is similar to that of the Basic Protocol. The main difference between these protocols is the time required to select (~3 to 4 weeks) and expand (~1 to 2 weeks) stable transfectants.

Quantitation of Human Heme Oxygenase (HO-1) Copies by Competitive RT-PCR

Heme oxygenase 1 (HO-1) is an indicator of stress conditions. The goal of this unit is to describe a microsensitive assay for human HO-1 mRNA molecules, since most clinical samples are of limited cell number and/or limited mRNA copy number. Conventional methods of mRNA analysis, such as northern blot analysis and nuclease protection mapping (*APPENDIX 3E* and *APPENDIX 3A*, respectively), are insufficient in sensitivity and/or accuracy. Competitive RT-PCR is suitable and has become the most widely used form of quantitative RT-PCR. Using competitive RT-PCR, it is not necessary to assay products exclusively during the exponential phase of the amplification procedure (Murphy et al., 1990; Cross, 1995). Serial dilutions of the sample are used with a fixed amount of competitor template (internal standard) cDNA, and this mixture is subjected to amplification. This approach is used to determine the levels of HO-1 in normal human tissues—i.e., cerebral brain, cerebellum, kidney, spleen, and fetal liver. The results of this study demonstrate that human spleen basal levels of HO-1 mRNA copies were markedly higher than the levels in fetal liver, which are higher than the kidney, which are higher than the brain (Goodman et al., 1996).

This unit describes RT-PCR analysis of tissues in a quantitative assay (see Basic Protocol). It also includes protocols to verify that the amplified product is distinguishable from the product amplified from the internal standard (see Support Protocol 1) and that the internal standard and the sample are amplified with equivalent efficiency (see Support Protocol 2).

QUANTITATIVE RT-PCR TO MEASURE HO-1 mRNA

BASIC PROTOCOL

This protocol is designed to quantitate human HO-1 mRNA in samples limited in cell number and/or mRNA copies. Varying amounts of total RNA from human tissues are used for reverse transcription. The sequences are then amplified by PCR in a tube that also contains an internal standard, equivalent in amplification efficiency (see Support Protocol 2), obtained by deleting 50 bp from the original human HO-1 gene (Yoshida et al., 1988). After amplification, templates are resolved and, when the internal standard is present in the reaction mixture, the ratio of the amplified sample versus the standard template is proportional to the amount of RNA; therefore, it is possible to calculate the number of specific mRNA molecules.

Materials

pCMV-HHO-1 plasmid (Yoshida et al., 1988)
1 U/µl *Eco*R47III and buffer (Promega)
1 U/µl *Bal*31 nuclease and buffer
2% (w/v) agarose gel (*APPENDIX 3A*)

Tissue sample (e.g., human liver)
First-Strand cDNA Synthesis Kit (Clontech Laboratories):
DEPC-treated H_2O (*UNIT 2.9*)
10 µM oligo$(dT)_{18}$
0.1 M Tris·Cl, pH 8.3 (*APPENDIX 2A*)
0.1 M KCl
0.1 M $MgCl_2$
100 mM dNTPs in sterile deionized H_2O (Promega)
2 U/ml RNase inhibitor
100 U/ml Moloney murine leukemia virus reverse transcriptase (Bethesda Research Laboratories)
0.001% (w/v) gelatin
1 µM sense primer: 5′-CAG GCA GAG AAT GCT GAG TTC-′ (Kutty et al. 1992; CER)
1 µM antisense primer: 5′-GAT GTT GAG CAG GAA CGC AGT-3′ (Kutty et al., 1992; CER)
2.5 U/µl *Taq* DNA polymerase (Stratagene)
5 Ci/µl (185 GBq/µl) [α-^{32}P] dCTP (3000 Ci/mmol)
Mineral oil (optional)
6% (w/v) 37.5:1 acrylamide/bisacrylamide gel (*APPENDIX 3A*)
25 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)/200 mM glycine/1 mM EDTA
Thermocycler

Additional reagents and equipment for restriction endonuclease digestion, agarose gel electrophoresis, ethidium bromide staining, bacterial transformation, cell culture, phenol/chloroform extraction, determination of RNA purity by UV spectroscopy, polyacrylamide gel electrophoresis, plasmid amplification and purification (*APPENDIX 3A*), RNA isolation (Chomczynski and Sacchi, 1987; *APPENDIX 3A*), and autoradiography (*APPENDIX 3D*)

Prepare internal standard plasmid

1. In each of three 1.5-ml microcentrifuge tubes, linearize 1 µg pCMV-HHO-1 plasmid with 2 U *Eco*R47III 2 hr at 37°C, in appropriate buffer, using equal aliquots for each tube. Stop on ice.

   There is a single restriction site in human HO-1 cDNA at position 420 bp.

2. Add 2 to 5 µl plasmid to 10 µl appropriate restriction enzyme buffer to each tube and digest 5 min with 2 µl of 1 U/ml *Bal*31 nuclease, 37°C (*APPENDIX 3A*).

3. Stop the reaction by placing the tubes on ice.

4. Analyze 2 µl linearized plasmid on a 2% (w/v) agarose gel alongside 100-bp DNA molecular weight marker VI and stain with 10 mg/ml ethidium bromide (*APPENDIX 3A*). If not linearized, repeat steps 1 to 3.

5. Add 2 µl linearized plasmid to each of five 1.5-ml microcentrifuge tubes containing 10 µl *Bal*31 buffer. Add 1 to 3 µl of 1 U/µl *Bal*31 to each tube.

6. Incubate at 22°C, stopping the reaction at 5, 10, 15, 20, and 30 min by transferring the tube to ice or by adding 5 µl of 0.5 M EDTA.

   This reaction digests nucleotides and creates a truncation in the plasmid.

Ligate plasmid

7. Analyze 2 µl of each reaction on a 2% agarose gel and stain with ethidium bromide to confirm digestion has occurred.

8. Transfer 2 to 5 µl of each of the digested plasmids to a fresh tube. Ligate by adding 10 µl T4 DNA ligase buffer and 1 µl T4 DNA ligase to each tube. Incubate overnight at 16°C.
9. Stop the reaction by placing the tubes on ice.
10. Analyze 2 µl of each reaction on a 2% agarose gel and stain with ethidium bromide to confirm ligation (i.e., DNA is larger).

Transform E. coli

11. Transform 2 to 5 µl construct DNA into 1 ml JM109 *E. coli* transformation-competent bacteria (*APPENDIX 3A*).
12. Heat shock cells by incubating 5 min at 95°C.
13. Place the cells on ice.
14. Spread the bacteria on an LB plate or equivalent containing 10 mg/ml ampicillin (*APPENDIX 3A*). Incubate overnight at 37°C.

    Only the cells that are transformed with the plasmid containing the ampicillin-resistance gene will survive and form colonies.

Identify internal standard

15. Pick several colonies and extract the DNA with 1:3 phenol/chloroform (*APPENDIX 3A*).

    Alternatively, perform PCR directly on the colonies.

16. Digest the clones with *Bal*31. Analyze the digests on a 2% agarose gel to determine the size of the truncated plasmids.
17. Confirm that the plasmid contains a mutated HO-1 gene by digesting with *Eco*R47III and analyzing on a 2% agarose gel stained with ethidium bromide to confirm fragment and DNA size.
18. Select a clone with ~50 bp truncated from the original cDNA of HHO-1. Amplify the selected clone by transferring cells from the colony to 3 ml LB broth containing 10 mg/ml ampicillin. Incubate overnight in a 37°C shaker.

Purify the plasmid for internal standard

19. Extract the DNA using a Qiagen miniprep kit according to manufacturer's instructions.
20. Excise the insert from the vector by digesting as described (see steps 1 to 3), except use 2 U *Hind*III endonuclease and buffer per microgram DNA. Purify by gel electrophoresis on a 1% (w/v) low-melting-temperature agarose gel.

    This insert is used as the internal standard in the PCR reactions.

21. Cut out the appropriate band with a razor blade or scalpel, and purify DNA by phenol/chloroform extraction.

    Alternatively, the DNA can be purified using a centrifuge filtration kit (Millipore), and centrifuging 25 min at 10,000 rpm, 5°C.

Prepare RNA

22. Isolate total RNA from 1 mg of the tissue sample (e.g., human liver) using the method of Chomczynski and Sacchi (1987; *APPENDIX 3A*).

23. Quantify RNA by UV spectrophotometry (i.e., A_{260}/A_{280}; *APPENDIX 3A*). Check the quality of the RNA on a 2% (w/v) agarose gel stained with ethidium bromide.

    The ratio should be ~1.6:1.0.

Reverse transcribe RNA

24. To a microcentrifuge tube add (20 µl total volume):

    0.1 to 2 µg RNA
    12.5 µl DEPC-treated H_2O
    1 µl of 10 µM oligo $(dT)_{18}$ (0.2 µM final).

    To determine the appropriate amount of RNA to add, use an RT-PCR assay with an internal competitive RNA standard to quantify HO-1 expression. Set up a series of five RT-PCR reactions with each reaction containing a serial amount of total cellular RNA. Adjust the concentration of cellular RNA so that the PCR signal falls within the range of the internal standard RNA used.

25. Denature RNA 2 min at 70°C and place on ice.

26. Prepare reverse transcription mixture containing (30 µl total volume):

    50 mM Tris·Cl, pH 8.3
    75 mM KCl
    3 mM $MgCl_2$
    0.5 mM (each) dNTP
    1 U/µl of RNase inhibitor
    200 U Moloney murine leukemia virus reverse transcriptase.

27. Add 5 µl reverse transcription mixture to the denatured RNA and incubate 1 hr at 42°C.

28. Stop the reaction by heating 5 min at 95°C. Place the tube on ice.

Amplify RNA

29. Prepare PCR mixture (50 µl total volume):

    10 mM Tris·Cl, pH 8.3
    50 mM KCl
    0.001% (w/v) gelatin
    1.5 mM $MgCl_2$
    250 µM (each) dNTP
    1 µM (each) sense and antisense primers
    10 fg internal standard (step 21)
    2.5 U *Taq* DNA polymerase per reaction
    1 µCi [α-^{32}P]dCTP

    The primers are designed to amplify a 555-bp stretch (79 to 633 bp) of the published cDNA of the human HO-1 (Yoshida et al., 1988).

30. Add PCR mixture (80 to 100 µl) to RT reaction tube to 100 µl final volume. If the thermocycler does not have a heated lid, overlay with two drops of mineral oil.

31. Amplify by PCR using the following program:

40 cycles:	1 min	95°C	(denaturation)
	1 min	55°C	(annealing)
	2 min	72°C	(extension)
Final step:	10 min	72°C	(final extension).

Characterize amplified products

32. Analyze amplified products on a 6% (v/v) 37.5:1 acrylamide/bisacrylamide gel in 25 mM Tris·Cl, pH 8.3/200 mM glycine/1 mM EDTA (*APPENDIX 3A*).
33. After drying, analyze the gel by autoradiography (*APPENDIX 3A*).
34. Analyze autoradiogram by densitometry (*APPENDIX 3A*), or excise bands from the gel and count the radioactivity (e.g., in a scintillation counter).
35. Identify amplified templates (see Support Protocol 1) and verify that the internal standard is amplified as efficiently as the HO template (see Support Protocol 2).
36. Use the areas of HHO-1 mRNA and internal standard bands in densitometry graphs to calculate the area ratios of mRNA to the internal standard for each RT-PCR reaction.

    Where the ratio of mRNA to internal standard products equals 1 (Log_e ratio = 0), the number of mRNA molecules is the same as the known number of internal standard RNA molecules. This gives a value for the expression of HHO-1 mRNA in molecules per microgram total cellular RNA. The results are used for calculating mRNA levels when they fall within the range of internal standard RNA products. For example, at the point of RNA species equivalence, the HHO-1:mHHO-1 ratio = 1 and y = Log_e (area HHO-1/area mHHO-1) = 0, area under the curve, Asx = Log_e (molecules internal standard RNA). When y = 0, and molecules internal standard RNA = −7.969/−0.538 = 14.812, the actual number of HHO-1 mRNA molecules = $e^{14.812} = 2.71 \times 10^6$. Therefore, there are 2.71×10^6 molecules HHO-1 mRNA in 1.5 g total cellular RNA, which equates to 1.81×10^6 molecules HHO-1 mRNA/g total RNA.

DISTINGUISHING BETWEEN THE AMPLIFIED TEMPLATES

SUPPORT PROTOCOL 1

To perform quantitative analysis, it is necessary to be able to distinguish between the product from the sample tissue and that of the internal standard. Analyze several clones for the size of the mutated cDNA (mHHO-1) resulting from the digestion by *Bal*31 and for the presence of an *Eco*47III restriction site. After transformation into competent bacteria by the mutated plasmid, obtain PCR products from several clones with the indicated primers (see Basic Protocol) and analyze them on a 6% acrylamide/bisacrylamide gel (Fig. 9.8.1). For these experiments, clone 2 (lane 2) is chosen and designated pCMV-mHHO-1. This clone is also examined for size (Fig. 9.8.2). The difference in size between the original and mutated plasmids is ~50 bp (Fig. 9.8.1, lanes 2 and 3). To better evaluate the size of the PCR products, the two inserts (HHO-1 and mHHO-1) are amplified by PCR and analyzed on a 2% agarose gel. The difference in size, 50 bp, should be demonstrated as expected from the previous sizing results (Fig. 9.8.2).

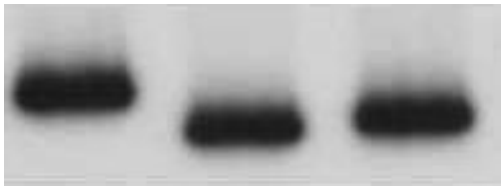

Figure 9.8.1 Analysis of different clones for the internal standard of HHO-1. A representative RT-PCR autoradiogram showing PCR products obtained from the amplification of several clones selected after modification of the Eco47III site as described. Lane 1: PCR product from pCMV-HHO-1 as a positive control for the reactions on and as a marker for original size. Lanes 2 and 3: different clones tested after mutation.

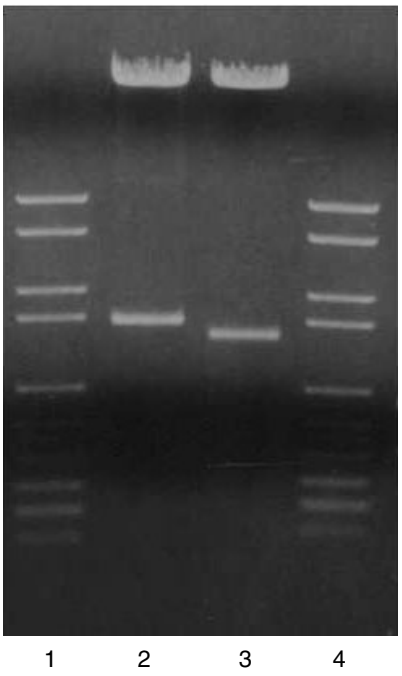

Figure 9.8.2 Analysis on 1% agarose gel of clone 2 (Fig. 9.8.1), which was selected as an internal standard. Lanes 1 and 4: 100-bp DNA molecular weight marker. Lane 2: HHO-1 insert digested with Eco47III. Lane 3: mHHO-1 insert digested with Eco47III.

SUPPORT PROTOCOL 2

COMPETITIVE VERSUS NONCOMPETITIVE AMPLIFICATION

In order to achieve a reliable quantitation, it is critical to demonstrate that the internal standard and sample template or templates are amplified equally under the reaction conditions. To determine this, examine whether the 10% (50 bp) difference in the sequence between the two templates causes a difference in amplification efficiency. Subject various amounts of total RNA (e.g., from human liver) to RT-PCR alone or as a mixture with a fixed amount (10 fg) of the mutated insert (mHHO-1). For combined PCR, add mHHO-1 to the PCR step. Reverse transcribe the RNA samples using oligo$(dT)_{18}$ primers. Identify respective templates by their difference in size examined by electrophoresis on an acrylamide/bisacrylamide gel, and quantify the amount of product by densitometry of the bands on the autoradiogram.

In Figure 9.8.3A there is a concentration dependence associated with the amount of mRNA added to the RT-PCR incubation mixture shown in the autoradiogram band. In Figure 9.8.3B, when the internal standard (mHHO-1) is included in the PCR mixture (the same amount, 10 fg and 0.1 to 2 μg of the reference RNA, were added to each reaction), the amount of amplified standard decreased as the amount of kidney RNA increased. These results indicate that the sample and internal standard templates are both amplified in the same manner and are competing for amplification: as the amount of one template increases, the chance of the other template being amplified declines.

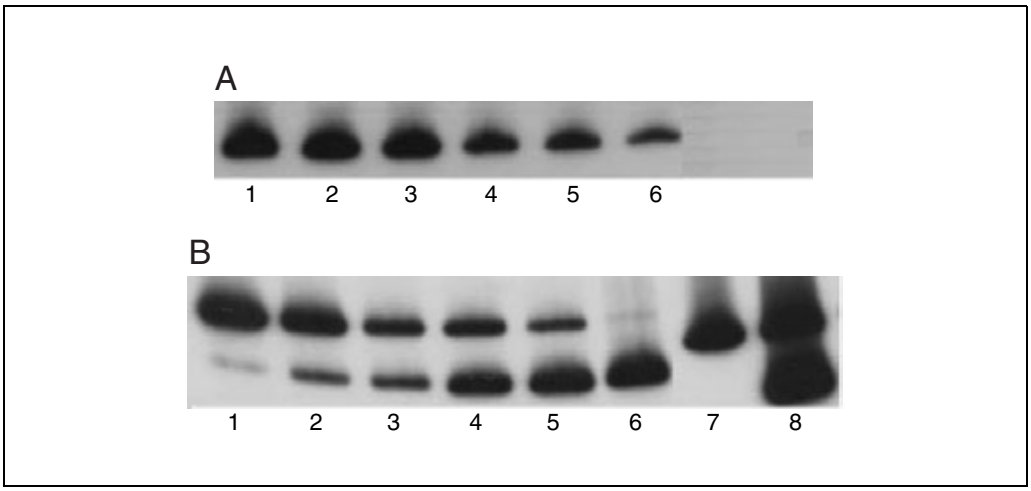

Figure 9.8.3 (**A**) Analysis of RT-PCR products obtained from total RNA of human kidney. Lane 1: 200 ng; lane 2: 100 ng; lane 3: 50 ng; lane 4: 25 ng; lane 5: 5 ng; and lane 6: 1 ng. (**B**) Competitive amplification of human kidney total RNA and mutated insert (mHHO-1). Internal standard (mHHO-1) at 10 fg is mixed with human kidney total RNA at 200, 100, 50, 25, 5, and 1 ng in lanes 1 to 6, respectively.

COMMENTARY

Background Information

The rate-limiting enzyme in heme catabolism, heme oxygenase (HO), is a stress protein, and its induction has been suggested to represent an important protective response in numerous biological processes, including defense against oxidative stress produced by heme and hemoglobin, since unmetabolized heme is a source of free radicals (Wagener et al., 1999; Yang et al, 1999; Quan et al., 2001). It is also involved in the inflammatory process (Laniado-Schwartzman et al., 1997; Otterbein et al., 2000) and it contributes to the regulation of vascular tone (Levere et al., 1990). HO-1 knockout mice (Poss and Tonegawa, 1997) and the recently reported first human case of HO-1 deficiency (Yachie et al., 1999) were both shown to have exaggerated inflammatory status. Induction of HO decreases cellular heme (pro-oxidant) content and elevates bilirubin (antioxidant) levels (Nath et al., 1992; Abraham et al., 1995). Elevation of HO activity in tumor-bearing rats (Schacter and Kurz, 1986) and in partial hepatectomized rats (Solangi et al., 1988) also results in a decrease in the content of renal and liver heme proteins such as cytochrome P450.

To date, three HO isoforms, HO-1, HO-2, and HO-3, have been identified that catalyze this reaction. HO-1 is a 32-kDa heat-shock protein, which is inducible by numerous noxious stimuli. HO-2 is a constitutively synthesized 36-kDa protein, which is abundant in brain and testes. HO-3 is related to HO-2 but is the product of a different gene, and its ability to catalyze heme degradation is much less than that of HO-1. (McCoubrey et al., 1992; Maines et al., 1997).

This unit describes a protocol designed to measure the amount of HO-1 mRNA in a given tissue sample (see Basic Protocol). Once the RT-PCR system has been shown to be specific for designated targets and the sample and the internal standard templates can be amplified with an equivalent efficiency, the quantitative nature of the system can be examined. In the course of testing for the competitiveness of the sample and internal standard templates for amplification, the authors found that 10 fg of standard was the appropriate amount required in the reaction mixture for RNA from various human tissues at the range of 1 to 100 ng to be amplified and unambiguously quantified. Because the internal standard and sample templates have been shown to be amplified equally efficiently under the conditions described (see Support Protocol 2), it is possible to determine the human HHO-1 mRNA content. The number of molecules of HHO-1 in human spleen was 3755 per nanogram total RNA, and in the fetal liver was 2440 per nanogram total RNA (Fig. 9.8.4). In contrast, cerebellum expressed the least amount of HO-1 mRNA followed by human whole cerebral brain and kidney.

In summary, it is believed that, after all proper normalizations, this competitive RT-PCR method will be a sensitive and truly quantitative way to measure the level of HO-1

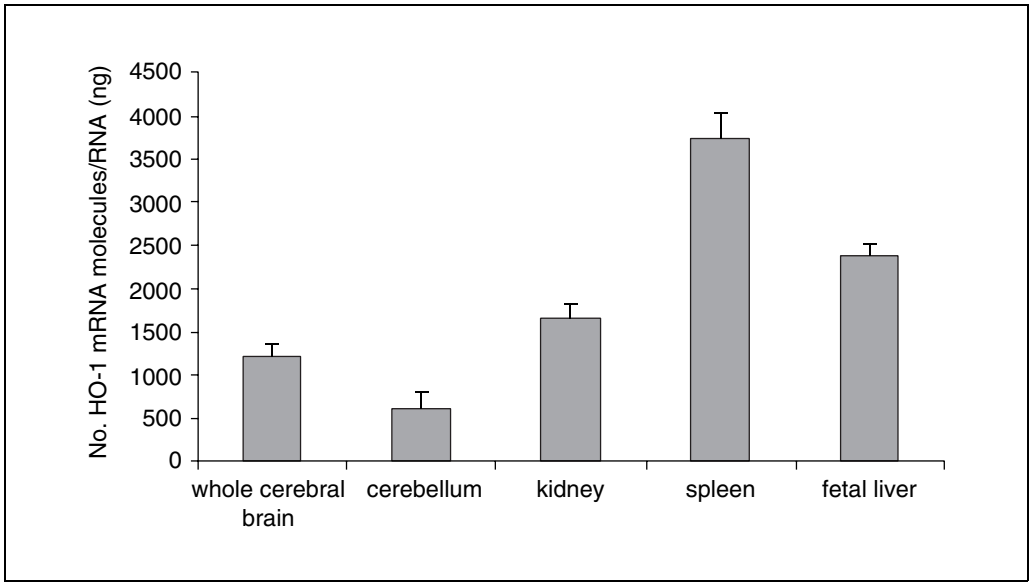

Figure 9.8.4 HHO-1 mRNA molecules in different human tissues. RT-PCR products were subjected to autoradiography and densitometric analysis to detect the number of mRNA molecules of HHO-1 compared to a known internal standard molecule as described (see Basic Protocol). See Figure 9.8.5 for the standard curve.

mRNA copies not only in normal tissues but also in other systems where HO-1 is an indicator for stress conditions.

Critical Parameters

The great power of amplification of PCR presents a challenge when the technique is used to quantify copy numbers of genes and mRNAs. Minute differences in any of the variables that affect the efficiency of amplification can dramatically alter product yield. This problem can be circumvented by co-amplifying a target sequence with a standard template so that the reaction is completed in the presence of an internal control (Becker-Andre and Hahlbrock, 1989; Wang et al., 1989; Gilliland et al., 1990). Accordingly, this system, which is used to evaluate the genetic expression of HHO-1, was developed with the following considerations in mind. First, the internal standard used was identical to the sample template in the target region; the difference being 10% in length due to mutation. Second, the primers were derived from regions where the standard and the original templates have identical sequences. Consequently, differences in the melting temperatures of cDNA templates and primer/template duplexes, which can greatly influence the amplification, are of no consequence. Furthermore, the standard and sample templates can be easily distinguished on an acrylamide gel due to their difference in size (50 bp).

As expected, the great sequence similarity between the standard and sample templates

Table 9.8.1 Troubleshooting Guide to Quantitative RT-PCR

Problem	Possible cause	Solution
The intensity of the band is not related to the concentration	Improper RNA concentration used due to error in measurements of the RNA samples	Make accurate measurements of RNA and/or perform a rapid GAPDH PCR to determine the discrepancy of the spectrophotometer and the estimated total RNA samples
Autoradiography bands appear in different positions	The water used in the PCR or RT-PCR is contaminated	Water used for preparation of various reagents must be highly purified

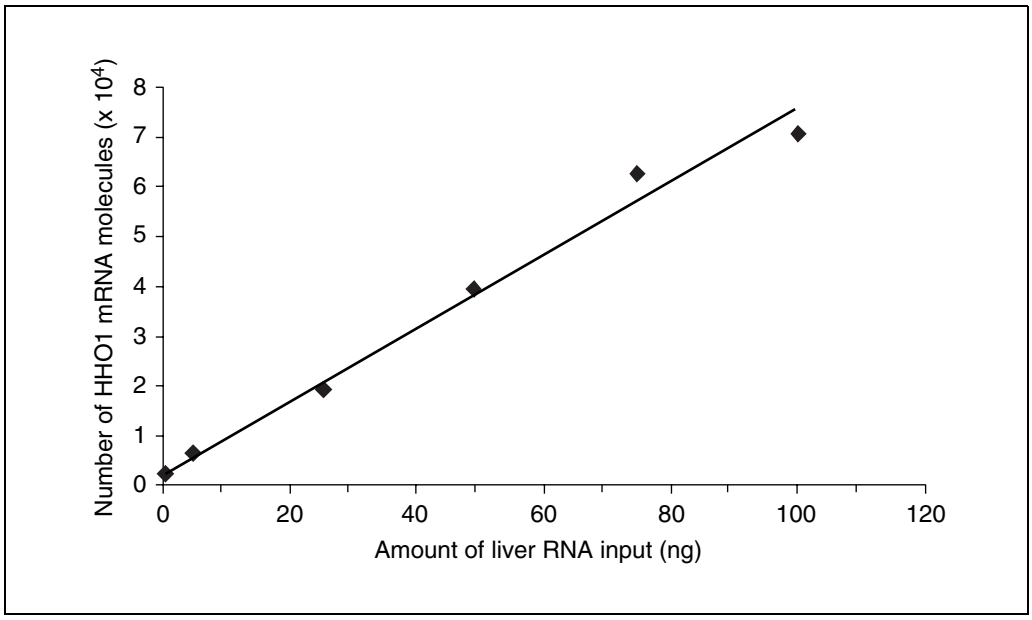

Figure 9.8.5 Competitive amplification of human kidney total RNA and mutated insert (mHHO-1). Internal standard (mHHO-1) at 10 fg is mixed with human kidney total RNA at 100, 50, 5, and 1 ng, respectively. Reaction products are analyzed on a 6% acrylamide/bisacrylamide gel. The amount of amplification human template is identified by densitometry on the autoradiogram and by counting the radioactivity of various bands after excision from the gel (the methods were compared in their results). The ratio of human RNA versus the internal standard is used to calculate the amount of HHO-1 mRNA content and this is plotted against the amount of input sample RNA. Reproduced from Abraham (1998).

rendered them good candidates for amplification. The input ratio of internal standard versus sample RNA was therefore critical for a clear-cut measurement of the amount of each template amplified. This required that RNA in each sample be individually determined. When the ratio was appropriate, a linear relationship existed between the amount of input sample RNA and the amount of amplified sample template after the latter had been normalized against the amplified internal standard. It is estimated that there are ~1670 HHO-1 mRNA molecules in each nanogram of total RNA from human kidney using this technique.

Troubleshooting

For the most common problems and solutions, see Table 9.8.1 (also see *APPENDIX 3C*).

Anticipated Results

The authors studied the HO-1 transcript expression in normal human liver tissue. Total RNA from this tissue showed a PCR cycle–dependent linear relationship with the concentrations of GAPDH mRNAs. A linear relationship also was seen between the optical density of the PCR band and the concentration of the mRNAs after RT reactions (unpub. observ.). As seen in Figure 9.8.5, the number of molecules formed under these conditions was dependent on the RNA input. Thus, optimum conditions were used to determine HO-1 expression.

The human RNAs extracted from five organs were obtained from Clontech Laboratories and were quantified by spectrophotometry. Using 15 μg of each organ RNA, the RNAs were checked by 1% agarose gel electrophoresis and ethidium bromide staining, RT-PCR, and Southern blotting, and filters were hybridized with a human HO probe (Fig. 9.8.5). The five different human organ RNAs were whole brain, cerebellum, whole kidney, whole spleen, and fetal liver. GAPDH was used to assess the quality of RNA.

Time Considerations

Three to six hours is required to generate PCR products.

Acknowledgment

The authors wish to thank Dr. Hatem Sabaawy for allowing his research results to be included in this discussion.

Purification and Characterization of Heme Oxygenase

Heme oxygenase (EC 1.14.99.3) catalyzes the NADPH–cytochrome P450 reductase, O_2-dependent degradation of heme to biliverdin, carbon monoxide (CO), and iron (Fig. 9.9.1; reviewed in Ortiz de Montellano, 2000; Ortiz de Montellano and Wilks, 2000). Heme oxygenase (HO) is highly unusual in that it uses heme as a cofactor for its own degradation, and it is therefore unlike classic hemoproteins such as the cytochrome P450, peroxidase, or catalase enzymes. The reaction requires a total of seven electrons and three oxygen molecules for the conversion of one heme molecule to biliverdin, CO, and iron (Liu and Ortiz de Montellano, 2000). All mammalian heme oxygenases regiospecifically cleave heme at the α-*meso*-carbon to yield biliverdin IXα which, by the action of biliverdin reductase, is converted to bilirubin. The existence of two isoforms of heme oxygenase, designated HO-1 and HO-2, respectively, has been known for some time (Maines et al., 1986; Rotenberg and Maines, 1990; Shibahara et al., 1993). HO-1, a heat shock protein also known as HSP32, is induced by a number of factors including heme, heavy metals, and oxidizing agents (Maines, 1992). HO-2, which is primarily located in the brain, spleen, and testis, is largely resistant to induction, except by the adrenal glucocorticoids (Weber et al., 1994). A third isoform, HO-3, has been described recently, and a lack of catalytic activity has suggested that its function may largely be regulatory (McCoubrey et al., 1997).

In mammals, the heme oxygenase pathway is the only defined mechanism for the degradation of heme. The oxidative cleavage of heme, in addition to removing a potentially toxic agent, also provides a mechanism for the reutilization of iron. Iron recovery and reutilization is of major physiological importance, as 97% to 99% of the iron in red blood cell synthesis comes from iron recycled from heme and iron-binding proteins (Bothwell et al., 1995). The critical role of heme oxygenase in iron reutilization was further demonstrated in recent experiments with genetic HO-1 knockout mice (Poss and Tonegawa, 1997a). The HO-1 deficient adult mice developed chronic anemia associated with low serum levels, but also an increased hepatic and renal iron content resulting in oxidative damage, chronic inflammation, and tissue injury. Earlier studies had demonstrated that HO-1 is induced as a response to oxidative challenge, and that the up-regulation was an adaptive response to protect cells from such oxidative challenge (Balla et al., 1993; Otterbein et al., 1995). More recently, murine cells lacking HO-1 were found to be

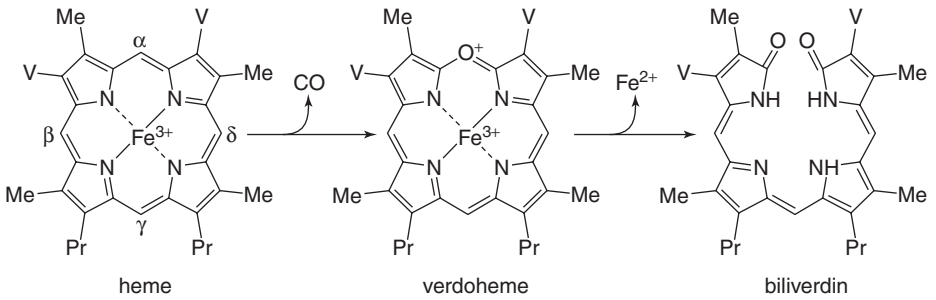

Figure 9.9.1 Enzymatic conversion of heme to biliverdin. Abbreviations are as follows; Me, methyl ($-CH_3$), V, vinyl ($-CH=CH_2$), and Pr, propionate ($-CH_2-CH_2-COOH$). The *meso*-carbons are labeled α, β, δ, γ.

Current Protocols in Toxicology (2003) 9.9.1-9.9.17

more susceptible to the accumulation of free radicals and oxidative damage both in vivo and in vitro, confirming the role of HO-1 as an important antioxidant system (Poss and Tonegawa, 1997b). The critical role of HO-1 in both antioxidant protection and iron homeostasis highlights the unique interest in HO-1 from areas of study as diverse as cardiovascular physiology, the central nervous system, renal and hepatic function, inflammation, and transplant surgery (Immenschuh and Ramadori, 2000; Otterbein and Choi, 2000). Indeed the overexpression of HO-1 activity brought about by pharmacological agents or specific gene transfer has been postulated as having therapeutic benefits (Immenschuh and Ramadori, 2000).

Bilirubin, the final product of the oxidative cleavage of heme, has long been known as a neurotoxic agent when it rises above physiological levels, as in neonatal jaundice or Crigler-Najjar syndrome (Maines, 1992). However, bilirubin can also act as a lipid-soluble antioxidant that may have physiological relevance in the protection against intracellular oxidative damage due to free-radical formation (Stocker et al., 1987; Stocker, 1990; Dore et al., 1999; Barañano et al., 2002).

The oxidative cleavage of heme by HO releases CO as a product of the reaction, which has been proposed as a neural messenger in processes such as long-term memory potentiation, neuroendocrine regulation, and vasodilation through the action of soluble guanylyl cyclase, or sGC (Stevens and Wang, 1993; Verma et al., 1993; Snyder et al., 1998). More recently, evidence has indicated that the anti-inflammatory response and inhibition of apoptosis by CO is independent of sGC and results from direct activation of the mitogen-activated protein (MAP) kinase pathway (Otterbein et al., 2000).

Given the unique role of heme oxygenase in many diverse physiological functions, it is of fundamental importance to characterize the heme oxygenase protein from a mechanistic and structural aspect. This unit will focus on the human HO-1 isoform, on which most of the biophysical data has been obtained, and describes both high-yield expression (see Basic Protocol 1) and purification (see Basic Protocol 2) as well as spectrophotometric techniques utilized in physical characterization of the protein (see Support Protocols 2 and 3). A protocol for the preparation of NADPH–cytochrome P450 reductase, used in assays for HO, is also included (see Support Protocol 1).

A critical factor in the biophysical characterization of any protein is the ability to generate a sufficient amount of material for such studies. The advent of heterologous expression systems for HO-1 greatly advanced the biophysical and mechanistic characterization of the protein. Truncated genes for both the rat and human HO-1 were constructed lacking the C-terminal 23 amino acids corresponding to the hydrophobic membrane anchor (Wilks and Ortiz de Montellano, 1993; Wilks et al., 1995). The enzymes were expressed at high levels as catalytically active soluble forms that caused the bacterial cells to accumulate biliverdin (Wilks and Ortiz de Montellano, 1993; Wilks et al., 1995).

HIGH-YIELD EXPRESSION OF HUMAN HO-1 IN *E. COLI*

BASIC PROTOCOL 1

The expression vector for the human HO-1 gene is constructed in pBAce, a pBR322 derivative carrying the alkaline phosphatase promoter *phoA* (Craig et al., 1991). The gene is generated by the polymerase chain reaction (PCR) from the respective full length cDNA in an Okayama-Berg vector (Shibahara et al., 1985). The 5′-sense oligonucleotide encodes an *Nde*I site at the N-terminus and the 3′-antisense oligonucleotide encodes a stop codon (TAA) at the proline 23 amino acids from the C-terminus, immediately followed by a *Sal*I site (Wilks et al., 1995). The PCR product is cloned into pBAce following restriction digest with *Nde*I and *Sal*I to generate pBHO1.

The expression of HO-1 is carried out in low-phosphate induction medium containing 75 μg/ml ampicillin. A 3-ml inoculum in LB medium is set up from fresh colonies of pBHO-1-transformed *E. coli* DH5αF′ grown on LB-ampicillin plates. A 100-μl aliquot is taken from the mid-log-phase cultures grown at 30°C, and this is used to inoculate four 1-liter cultures of the same medium containing 75 μg/ml ampicillin. Cells are grown for a further 18 hr at 30°C, or until the medium becomes green.

It was noted in early experiments that *E. coli* DH5αF′ cells containing pBHO1, when grown in LB medium containing 100 μg/ml ampicillin, grew with green coloration. The expression yields in both the low-phosphate medium and LB medium under identical conditions were found to be within the same range. The advantages of using LB medium are the simpler protocol and cost effectiveness.

Materials

pBHO-1 vector (P.R. Ortiz de Montellano; *ortiz@cgl.ucsf.edu*)
E. coli DH5αF′ (Life Technologies)
LB medium and plates containing 100 μg/ml ampicillin (see recipe)
Low-phosphate induction medium (see recipe) containing 75 μg/ml ampicillin
Temperature-controlled shaking incubator (New Brunswick Model G20 or equivalent)
UV/visible spectrophotometer (Varian Cary Bio-100 or equivalent)
Low-speed centrifuge (Beckman Avanti J25-I with JA-10 rotor or equivalent model)

1. Transform (see *APPENDIX 3A*) *E. coli* DH5αF′ cells with pBHO-1 and grow the transformed cells on a fresh LB-ampicillin plate overnight at 37°C. Pick a single colony and use it to inoculate 3 ml of LB medium containing 75 μg/ml ampicillin.
2. Grow the 3-ml culture at 30°C in a shaking incubator to mid-log phase (OD_{600} ~0.5 to 0.6) by monitoring the optical density at 600 nm in a UV/visible spectrophotometer.
3. Take 100 μl of the mid-log phase cells and inoculate 1 liter of LB medium or low-phosphate induction medium containing 75 μg/ml ampicillin.
4. Grow the cells for a further 16 to 18 hr at 30°C in a shaking incubator or until the cells turn green in color. Harvest the cell pellets by centrifuging 20 min at 10,000 × *g* (5,000 rpm in a JA-10 rotor), 4°C. Store the harvested cell pellets at −80°C prior to purification of the protein (see Basic Protocol 2).

   Do not grow the cells for longer than 24 hr as partial proteolysis of the 30 kDa HO-1 to a 28-kDa inactive fragment occurs (see Critical Parameters and Troubleshooting).

PURIFICATION OF HO-1 PROTEIN

BASIC PROTOCOL 2

The purification of HO-1 by ion-exchange chromatography yields the biliverdin-bound protein. For preparations of HO-1 that are to be reconstituted with heme, the addition of heme readily displaces biliverdin from the protein to yield the heme-HO-1 complex. To obtain the apoprotein free of biliverdin, a modification to the purification protocol is required (see steps 6b to 9b).

Materials

Cell pellets (see Basic Protocol 1)
Lysis buffer I (see recipe)
Ammonium sulfate
10, 20, and 100 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*)

250 mM potassium chloride (KCl)
10 mM diaminopropane
Gradient from 0 to 250 mM KCl in 10 mM diaminopropane
1.5 mM hemin solution (see recipe)
NADPH–cytochrome P450 reductase (see Support Protocol 1)
2.5 to 3.0 μmol/min/mg biliverdin reductase (Mahin D. Maines; *Mahin_Maines@urmc.rochester.edu*)
Hemin/BSA solution (see recipe)
1 mM NADPH: dilute 1 M NADPH stock (see recipe) in 100 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*)

Fisher Scientific 60 Sonicator Dismembrator (or equivalent)
Low-speed centrifuge (Beckman Avanti J25-I with JA-10 and JA-20 rotors or equivalent) and corresponding 50-ml centrifuge tubes
Dialysis membrane, MWCO 10 kDa (also see *APPENDIX 3H*)
FPLC system (Amersham Pharmacia Biotech) with Mono-Q (HR 10/10) column *or* conventional chromatography system (peristaltic pump, fraction collector, and gradient maker) with 3 × 10–cm Q-Sepharose column (also from Amersham Pharmacia Biotech)
3 × 10–cm chromatography column packed with QAE anion-exchange resin (Amersham Pharmacia Biotech) and equilibrated with 10 mM diaminopropane, pH 9.0
1.5 × 6.0–cm chromatography column packed with Bio-Gel HTP hydroxyapatite resin (Bio-Rad) and equilibrated with 10 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
UV/visible spectrophotometer (Varian Cary Bio-100 or equivalent)
Amicon filtration unit with YM10 membrane (10 kDa molecular weight cut-off)

Additional reagents and equipment for dialysis (*APPENDIX 3H*) and SDS-PAGE (*APPENDIX 3F*)

NOTE: All procedures should be carried out at 4°C.

Disrupt cells

1. Resuspend the harvested cells in 150 ml lysis buffer I, 4°C. Stir the cell suspension for 30 min at 4°C.
2. Sonicate the cell suspension for three 1-min cycles at 2-min intervals, keeping the suspension on ice.
3. Transfer the sonicated cell suspension to four 50-ml centrifuge tubes and centrifuge 60 min at 27,000 × *g*, 4°C, to remove the cell debris.

Perform ammonium sulfate precipitation

4. Transfer the supernatant to a 250-ml graduated beaker and slowly add solid ammonium sulfate to a final concentration of 40% (w/v), stirring continuously. Stir the solution for a further 30 min, then centrifuge 20 min at 27,000 × *g*, 4°C.

   This ammonium sulfate precipitation is referred to as the "40% cut."

5. Transfer the supernatant to a 250-ml graduated beaker and add ammonium sulfate to a final concentration of 70%. Stir the suspension for 30 min and collect the precipitate by centrifugation at 27,000 × *g*, 4°C.

To obtain biliverdin-bound HO-1

6a. Resuspend the ammonium sulfate precipitates in a total of 30 to 50 ml of 10 mM potassium phosphate buffer, pH 7.4, and dialyze 4 to 6 hr (*APPENDIX 3H*) against three 3-liter changes of that buffer using an MWCO 10 kDa dialysis membrane.

7a. Purify protein by anion-exchange chromatography as follows:

i. Set up the FPLC system to produce a linear gradient of 10 mM potassium phosphate buffer, pH 7.4/250 mM KCl.

ii. Equilibrate the Mono-Q (HR 10/10) column with 10 mM potassium phosphate buffer, pH 7.4, at a flow rate of 2 ml/min.

iii. Load the dialyzed fraction (from step 6) on to the column. Wash the column with a further 50 ml of 10 mM potassium phosphate buffer, pH 7.4.

iv. Elute the protein (collecting 3-ml fractions) with a linear gradient from 0% of 250 mM KCl (100% of 10 mM potassium phosphate buffer, pH 7.4) to 25% of 250 mM KCl (75% of 10 mM potassium phosphate buffer, pH 7.4) over 20 min, hold at 25% for 10 min, and then increase linearly over 20 min to 100% of 250 mM KCl.

The fractions containing heme oxygenase elute in the first half of the gradient.

If an FPLC chromatography system is not available, a 3 × 10–cm Q-Sepharose column can be substituted using the same buffer system and a linear KCl gradient from 10 to 200 mM KCl.

8a. Remove 10-µl samples from every third fraction and run on SDS-PAGE (*APPENDIX 3F*) to determine the peak heme oxygenase–containing fractions.

9a. Pool the peak heme oxygenase fractions and dialyze (*APPENDIX 3H*) against three changes (4 to 6 hr) of 4 liters of 10 mM potassium phosphate buffer, pH 7.4, using an MWCO 10 kDa dialysis membrane. Store proteins up to 12 months at −80°C.

At this stage the protein should be 95% pure.

To obtain biliverdin-free HO-1 apoprotein

6b. Resuspend the ammonium sulfate precipitate from step 5 in 10 mM diaminopropane, pH 9.0, dialyze against three 4 liter changes of the same buffer, and apply to a 3 × 10–cm QAE anion-exchange column previously equilibrated with the same buffer.

7b. Elute the protein from the column with a gradient of 0 to 250 mM KCl in 10 mM diaminopropane, pH 9.0. Collect 3.0-ml fractions and analyze every third fraction for the HO-1 protein by SDS-PAGE (*APPENDIX 3F*).

The green biliverdin pigment remains bound to the column and the apo-enzyme is eluted.

8b. Pool the fractions containing HO-1 protein and dialyze (*APPENDIX 3H*) against three 4- to 6-hr changes of 4 liters of 20 mM potassium phosphate buffer, pH 7.4, using an MWCO 10 kDa dialysis membrane.

9b. Store the protein up to 12 months at −80°C.

Prepare the heme-HO-1 complex

10. Add 1.5 mM hemin solution to the dialyzed protein from either step 9a or 9b in a quantity sufficient to give a final molar ratio of 2:1 heme:protein.

The hemin solution should be prepared fresh and used within 30 min.

11. Apply the heme/protein solution to a 1.5 × 6.0–cm Bio-Gel HTP column previously equilibrated with 10 mM potassium phosphate buffer, pH 7.4. Wash the column with a further 50 ml of the same buffer or until no heme can be detected in the eluate. Monitor the heme by measuring the absorbance at 402 nm.

12. Elute the heme-HO-1 complex with 100 mM potassium phosphate buffer, pH 7.4, collecting 2.0 to 3.0 ml fractions. Pool the peak fractions by monitoring the absor-

bance of the heme-HO-1 complex at 405 nm. Calculate the total yield of protein from the millimolar extinction coefficient of 128 mM^{-1}.

13. If necessary, concentrate the heme-HO-1 protein to 10 mg/ml by filtration on an Amicon filtration unit with a 30-kDa MWCO YM10 membrane. Divide protein solutions into 100- to 1000-µl aliquots, and store up to 12 months at –80°C.

Assay heme oxygenase activity

14. Add the following to a 1-ml cuvette:

    10 to 50 µl heme oxygenase–containing solution (step 13; ~0.1 nmol enzyme)
    5 to 20 µl NADPH–cytochrome P450 reductase (prepared as in Support Protocol 1; 0.3 nmol)
    5 to 20 µl of biliverdin reductase (0.3 nmol)
    100 µl hemin/BSA solution (final concentration 15 µM heme/1 µM BSA)
    100 mM potassium phosphate buffer, pH 7.4, to give a final volume of 900 µl.

15. Mix the contents of the cuvette by inverting gently and zero the absorbance at 468 nm.

16. Add 100 µl of 1 mM NADPH (final concentration 100 µM), mix, and monitor the change in absorbance with time at 468 nm for 10 min. Calculate the specific activity using the millimolar extinction coefficient (ε) of 43.5 mM^{-1} cm^{-1} and the following relationships:

    $\Delta A = \varepsilon cl$

    where ΔA represents the change in absorbance per min (in the linear phase), ε represents the millimolar extinction coefficient and l represents the path length (a path length of 1 cm is routinely used). Rearranging this equation, the number of mmol of bilirubin formed per min can be calculated from:

    $c = \Delta A/\varepsilon$

    where the units are mM/min, and:

$$\text{activity (mmol/min)} = c \times \frac{\text{µl protein solution}}{1000}$$

    Finally, divide by the concentration of protein (mg) used in the assay to give the specific activity in mmol/min/mg.

SUPPORT PROTOCOL 1

PREPARATION OF NADPH–CYTOCHROME P450 REDUCTASE

NADPH–cytochrome P450 reductase is used in assays for HO-1 such as that described in steps 14 to 16 of Basic Protocol 2. The purified NADPH–cytochrome P450 reductase is obtained by a slight modification of the method of Yasukochi and Masters (1976). The pETOR vector used in the heterologous expression of the protein is described in Wilks et al. (1995).

Materials

E. coli BL21(DE3)
pETOR (pET vector containing gene for human NADPH cytochrome P450 reductase; *wilks@tx.maryland.edu*)
LB medium containing 100 µg/ml ampicillin (see recipe)
Terrific broth containing 100 µg/ml ampicillin (see recipe)

1 M IPTG stock (see recipe)
Lysis buffer II (see recipe)
Resuspension buffer (see recipe)
Bio-Rad protein assay kit
Lubrol PX detergent (polyoxyelthylene 9 lauryl ether; Sigma-Aldrich)
Column wash buffers I and II (see recipes)
Elution buffer: column wash buffer II (see recipe) containing 2.5 mM 2′-AMP
20 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*) containing 20% (v/v) glycerol
300 mM potassium phosphate buffer, pH 7.7 (*APPENDIX 2A*)
1 mM bovine cytochrome *c*
1 mM NADPH: dilute 1 M NADPH (see recipe) with 300 mM potassium phosphate buffer, pH 7.7 (see *APPENDIX 2A* for buffer)

UV/visible spectrophotometer (Varian Cary Bio-100 or equivalent model)
Temperature-controlled shaking incubator (New Brunswick Model G25 or equivalent model)
Low-speed centrifuge(Beckman Avanti J25-I with JA-10 rotor or equivalent model)
Fisher Scientific 60 Sonicator Dismembrator (or equivalent)
High-speed centrifuge (Beckman L8-70 with 45 Ti rotor, or equivalent)
1 × 10–cm chromatography column packed with 2′,5′-ADP-Sepharose and equilibrated with equilibration buffer (see recipe for buffer)

Grow E. coli in E. coli BL21(DE3)

1. Transform (see *APPENDIX 3A*) *E. coli* BL21(DE3) with pETOR and grow the transformed cells in 3 ml LB-ampicillin medium overnight to saturation.
2. Inoculate three 1-liter cultures of terrific broth containing 100 μg/ml ampicillin with 1 ml of the overnight culture from step 1, and grow the cells to an OD_{600} of 0.4 at 37°C in a shaking incubator.
3. Reduce the temperature of the incubator to 22°C and induce the cells by adding 1 M IPTG stock to a final concentration of 0.4 mM.
4. Grow the cells for a further 16 hr, then harvest by centrifuging 20 min at 10,000 × *g* (5,000 rpm in a JA-10 rotor), 4°C.

Purify NADPH cytochrome P450 reductase

All of the following steps should be carried out at 4°C.

5. Resuspend the cell pellets in 100 ml lysis buffer II. Stir the resuspended cells for 1 hr to ensure lysis of the cells.
6. Sonicate the lysed cells four times for 30 sec, at 1-min intervals. Centrifuge 30 min at 18,000 × *g* (10,000 rpm in JA-10 rotor), 4°C, to remove cell debris.
7. Collect the supernatant and centrifuge it again for 1 hr at 185,000 × *g* (40,000 rpm in a Beckman 45 Ti rotor), 4°C. Resuspend the pellets from this high-speed centrifugation in 30 ml resuspension buffer.
8. Determine the protein concentration by Bio-Rad protein assay kit and adjust the concentration to 3 mg/ml with resuspension buffer. Add Lubrol PX to a final concentration of 0.2 % (v/v) and stir for 1 hr.
9. Clarify the solubilized protein solution by centrifuging 1 hr as in step 7. Retain the resulting supernatant.

10. Load the supernatant onto a 1 × 10–cm 2′,5′-ADP-Sepharose column equilibrated in equilibration buffer.

11. Wash the column with an additional 50 ml of equilibration buffer followed by 50 ml of column wash buffer I. Finally wash the column with 50 ml of column wash buffer II.

12. Elute the protein from the column using elution buffer, collecting 1-ml fractions. Assay the fractions for activity using the reduction of cytochrome *c* (see steps 14 to 17). Pool the fractions containing the peak activities.

13. Dilute the pooled fractions with sufficient 20 mM potassium phosphate buffer, pH 7.4, containing 20% (v/v) glycerol, to reduce the concentration of 2′-AMP 100-fold. Remove the 2′-AMP by successively concentrating the diluted solution over an Amicon YM30 membrane.

Assay NADPH-cytochrome P450 reductase activity

14. In a spectrophotometer cuvette, add 0.1 to 1.0 μg of NADPH–cytochrome P450 reductase (usually 1 to 10 μl of the solution obtained from step 12) and 100 μl 1 mM bovine cytochrome *c* to 300 mM potassium phosphate buffer, pH 7.7, adjusting the volume of buffer to give a final volume of 900 μl.

15. Seal the cuvette with Parafilm, mix the contents gently by inversion, and zero the absorbance at 550 nm.

16. Add 100 μl of 1 mM NADPH (from 1 M stock solution) in 300 mM potassium phosphate buffer, pH 7.7, and mix the contents immediately. Monitor the increase in absorbance with time over a 5-min period or until the activity reaches a plateau.

17. Measure the initial rate and, using the millimolar extinction coefficient of 21.1 mM^{-1} cm^{-1}, calculate the specific activity (see Basic Protocol 2, steps 14 to 16).

A typical specific activity would be in the range of 1 to 15 μmol/min/mg.

SPECTROPHOTOMETRIC ANALYSIS OF THE HEME-HEME OXYGENASE COMPLEX

The unique chromophore of heme-binding proteins allows the use of a number of spectrophotometric techniques to yield detailed information on the nature of the heme ligands. Although individual spectroscopic techniques can yield valuable information, it is the combined use of techniques such as UV/visible, magnetic circular dichroism (MCD), resonance Raman, and nuclear magnetic resonance (NMR) that can provide great insight into the nature of the coordination and ligation of the heme. It is beyond the focus of this review to provide detailed methodology for all such techniques, and therefore the focus will be on the characterization of the heme-HO-1 complex by UV/visible spectroscopy. A synopsis of the information that can be gained in a more extensive spectroscopic analysis will be given below (see Background Information).

SUPPORT PROTOCOL 2

UV/Visible Spectra of the Heme-HO-1 Complex

Materials

10 to 20 μM heme-HO-1 complex (see Basic Protocol 2)
20 mM potassium phosphate buffer, pH 7.0 (*APPENDIX 2A*)
Carbon monoxide (CO) gas source
1 mM (17.4 mg/ml) sodium hydrosulfite (sodium dithionite) in 10 mM potassium phosphate buffer, pH 7.0 (see *APPENDIX 2A* for buffer), prepared immediately before use

1-cm quartz cuvettes
UV/visible spectrophotometer (Varian Cary Bio-100 or equivalent model)
1 × 10–cm Bio-Gel P-10 desalting column (Bio-Rad), equilibrated with 20 mM potassium phosphate buffer, pH 7.0 (see *APPENDIX 2A* for buffer)

1. In a 1-cm quartz cuvette, dilute heme-HO-1 complex to a final concentration of 10 μM in a final volume of 1 ml of 20 mM potassium phosphate buffer, pH 7.0. Record the spectrum of the ferric (Fe^{3+}) heme-HO-1 complex, scanning from 250 to 750 nm in a UV/visible spectrophotometer.

   The spectrum of the oxidized heme-HO-1 complex has a Soret maximum at 404 nm and a high spin marker band in the visible region at 628 nm (Fig 9.9.2).

   The Soret maxima at 404 nm for a 10 μM concentration of the heme-HO-1 complex should give an absorbance of 1.3 to 1.4.

2. To obtain the reduced, ferrous (Fe^{2+}) carbon monoxy (CO) spectrum of the heme-HO-1 complex, take the 1-ml sample and gently bubble with CO for 1 to 2 min, to saturate the solution and ensure a high content of CO in the cuvette.

   CAUTION: *CO is a poisonous gas. Carry out the CO saturation in a ventilated hood. Do not bubble vigorously or foaming and precipitation of the protein may occur.*

3. Following CO saturation, add 1 equivalent (5 to 10 μl) of a fresh 1 mM sodium hydrosulfite solution, and mix by inverting the cuvette.

   The ferrous CO heme-HO-1 complex should immediately change color from brown to red, indicating reduction and binding of the CO ligand.

4. Again record the spectrum of the ferrous CO-bound heme-HO-1 complex, scanning from 250 nm to 750 nm.

   The spectrum should increase in intensity with a Soret maximum at 420 nm and the visible α/β bands at 567 and 537 nm, respectively (Fig 9.9.2).

5. To obtain the ferrous oxy (O_2)-complex, pass 1 ml of the ferrous CO-heme-HO-1 complex over a Bio-Gel P-10 desalting column equilibrated with 20 mM potassium phosphate buffer, pH 7.0, to remove the sodium hydrosulfite.

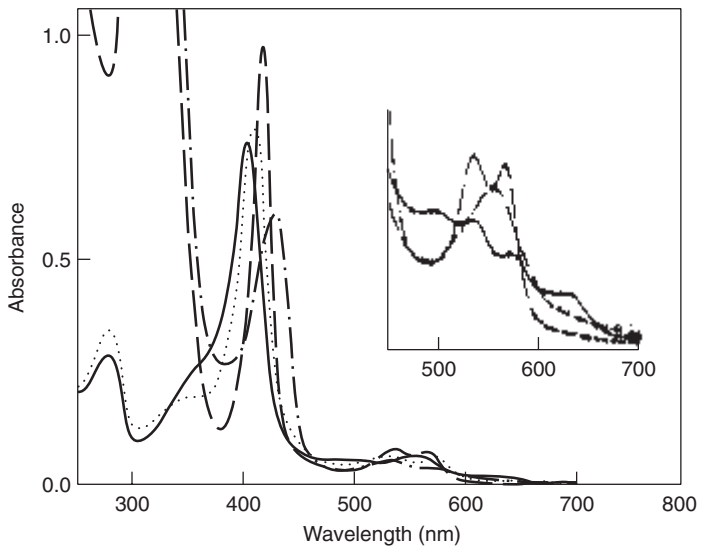

Figure 9.9.2 Absorption spectra of the purified heme-HO-1 complex: ferric heme-HO-1 (solid line); ferrous deoxy heme-HO-1 (line of alternating dots and dashes); ferrous O_2 heme-HO-1 (dotted line); ferrous CO-heme-HO-1 (dashed line).

6. Elute the ferrous O_2-heme-HO-1 complex (~2 ml) with 20 ml potassium phosphate buffer, pH 7.0.
7. Record the spectrum of the eluted ferrous O_2-heme-HO-1 complex, scanning from 250 to 750 nm.

   The spectrum of the ferrous O_2-heme-HO-1 complex has a Soret maximum at 412 nm and α/β bands at 573 and 539 nm respectively (Fig 9.9.2).

SUPPORT PROTOCOL 3

UV/Visible Spectra of Heme Oxygenase Reaction Intermediates

It has previously been shown that in the presence of CO inhibition of the heme oxygenase reaction results in the accumulation of the ferrous CO-verdoheme intermediate (Wilks and Ortiz de Montellano, 1993; Yoshida et al., 1980, 1982). The conversion of the heme-HO-1 complex to the ferrous CO-verdoheme complex can be monitored spectroscopically in the presence of the NADPH–P450 reductase system.

Materials

NADPH–cytochrome P450 reductase (see Support Protocol 1)
Heme-HO-1 (see Basic Protocol 2)
100 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
Carbon monoxide (CO) gas source
1 M NADPH (see recipe)

1-cm cuvette
UV/visible spectrophotometer (Varian Cary Bio-100 or equivalent model)

1. In a 1-cm cuvette, prepare a solution of 30 μM NADPH–cytochrome P450 reductase and 10 to 15 μM heme-HO-1 in a final volume of 1 ml of 100 mM potassium phosphate buffer, pH 7.4. Record the spectrum of the resting state ferric heme-HO-1 complex from 300 to 750 nm. Saturate the heme-HO-1 complex with CO by gently bubbling.

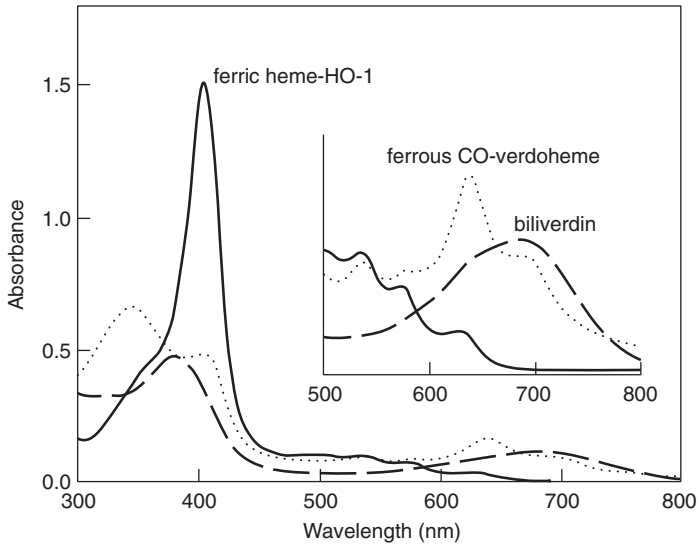

Figure 9.9.3 Conversion of the ferric heme-HO-1 complex to biliverdin-IXα in the presence of NADPH cytochrome P450 reductase: ferric heme-HO-1 (solid line); ferrous CO-verdoheme HO-1 (dotted line); biliverdin (dashed line).

2. Initiate reaction by the addition of NADPH in 10-µM increments to a final concentration of 100 µM. Monitor the spectral changes between 300 and 750 nm over a 20-min period at 1-min intervals. Add NADPH increments between scans.

   Increments are added to avoid interference with heme soret—the NADPH absorbs at 350 to 360 nm.

   The characteristic shift in Soret maximum from 404 nm to 420 nm, with the appearance of a band at 638 nm in the visible region is characteristic of the ferrous CO-verdoheme complex (Fig 9.9.3).

3. Bubble the reaction intermediate with oxygen and record the final spectrum which is typical of the final product, biliverdin (Fig. 9.9.3).

REAGENTS AND SOLUTIONS

Use autoclaved Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ampicillin, 100 mg/ml stock solution

Add 10 ml of H_2O to 1 g ampicillin. Once the ampicillin is completely in solution, filter sterilize through a 22-µm disposable syringe filter. Store in 1 ml aliquots up to 3 months at −20°C.

Column wash buffer I

300 mM potassium phosphate, pH 7.4 (*APPENDIX 2A*)
20% (v/v) glycerol
0.1 mM EDTA
Store up to 2 weeks at 4°C

Column wash buffer II

20 mM potassium phosphate, pH 7.4 (*APPENDIX 2A*)
0.15% (w/v) sodium deoxycholate
Store up to 2 weeks at 4°C

Equilibration buffer

20 mM potassium phosphate, pH 7.4 (*APPENDIX 2A*)
20% (v/v) glycerol
0.1 mM EDTA
Store up to 2 weeks at 4°C

Hemin/BSA solution

Prepare 100 µl of 1.5 mM hemin solution (see recipe) and add 0.68 mg of BSA as a carrier. Store up to 1 week at 4°C.

Although free hemin will form µ-oxo dimers, hemin bound to BSA does not form such inactive dimers.

This solution when used in the HO-1 assay gives a final concentration of 15 µM heme and 1 µM BSA.

Hemin solution, 1.5 mM

Dissolve 10 µg of hemin in 100 µl of 0.1 N NaOH. Once the hemin is completely dissolved, increase the volume to 10 ml with 10 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*). Filter through 0.45-µm disposable syringe filter. Prepare fresh before each use; use within 30 min of preparation.

IPTG stock solution, 1 M

Dissolve 2.38 g isopropylthio-β-D-galactoside (IPTG) in 8 ml water. Adjust the volume to 10 ml and filter sterilize through a 0.22-µm disposable filter. Store up to 8 weeks at −20°C.

LB (Luria-Bertani) medium and plates containing 100 µg/ml ampicillin

For liquid LB medium:

950 ml deionized H_2O
10 g Bacto tryptone (Difco)
5 g Bacto yeast extract (Difco)
10 g NaCl
Adjust pH to 7.0 with 5 N NaOH
Adjust volume to 1 liter
Sterilize by autoclaving 20 min on liquid cycle

For LB plates:

Add 15 mg of Bacto-agar (Difco) to 1 liter of liquid LB medium prior to autoclaving. Pour into sterile 150-mm-diameter petri dishes and allow to cool.

For LB medium or plates containing 100 µg/ml ampicillin:

After autoclaving the medium (with or without agar), allow it to cool to ~50°C and add 1 ml of 100 mg/ml ampicillin stock (see recipe) per liter for a final concentration of 100 µg/ml. Mix thoroughly. If preparing plates, pour them at this point as described above.

Low-phosphate induction medium

Prepare 1 × 10^6 stock solution of micronutrients:

37 mg $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$
247 mg H_3BO_3
84 mg $CoCl_2$
25 mg $CuSO_4$
158 mg $MnCl_2{\cdot}4H_2O$
18 mg $ZnSO_4$
H_2O to 10 ml
Filter sterilize

Prepare 1 × 10^6 stock solution of salts:

370 ml H_2O
400 ml 1 M MOPS (83.72 g/400 ml, adjusted to pH 7.4 with KOH)
40 ml 1 M Tricine (7.17 g/40 ml, adjusted to pH 7.4 with KOH)
10 ml 10 mM $FeSO_4{\cdot}7H_2O$ (27.8 mg/10 ml)
50 ml 1.9 M NH_4Cl (5.08 g/50 ml)
10 ml 276 mM K_2SO_4 (0.48 g/10 ml)
10 ml 0.5 mM $CaCl_2$ (0.74 mg/10 ml)
10 ml 528 mM $MgCl_2$ (0.5 g/10 ml)
100 ml 5 M NaCl (29.22 g/100 ml)
Add 10 ml of the 1 × 10^6 micronutrients from the above stock, filter sterilize and store at 4°C as 10× MOPS salts to be used below.

Prepare 1 liter of low-phosphate induction medium:

895 ml of sterile H_2O
100 ml 10× MOPS salts (from above)
2 g glucose
2 g casamino acids (vitamin assay grade from Difco)
75 mg ampicillin

continued

100 ml 1 M sodium phosphate (equimolar mix of Na_2HPO_4 and NaH_2PO_4)
1 ml 1.5 mM thiamine (0.506 mg/ml)
20 mg adenine
Sterilize by filtration
Store up to 1 month at 4°C

Lysis buffer I

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*; sterilize by autoclaving 20 min on liquid cycle)
1 mM EDTA (add from 0.5 mM EDTA, pH 8.0 stock; *APPENDIX 2A*; sterilize by autoclaving 20 min on liquid cycle)
1 mM phenylmethylsulfonyl fluoride (PMSF; add from 1 M PMSF stock; see recipe)
10 µg/ml lysozyme
Use immediately

Lysis buffer II

100 mM Tris-acetate, pH 8.1
20% (v/v) glycerol
1 mM EDTA
1 mM PMSF (add from 1 M PMSF stock solution; see recipe)
1 µg/ml pepstatin
10 µg/ml leupeptin
0.1 µg/ml antipain
50 µg/ml lysozyme
Use immediately

NADPH, 1 M

Dissolve 833 mg NADPH in 1 ml of the reaction buffer for either the HO-1 assay (100 mM potassium phosphate buffer, pH 7.4; *APPENDIX 2A*) or the NADPH–cytochrome P450 reductase assay (300 mM potassium phosphate buffer, pH 7.7; *APPENDIX 2A*). Store in 100-µl aliquots for 8 weeks at −80°C

PMSF, 1 M

Dissolve 1.74 g of phenymethylsulfonyl fluoride (PMSF) in 10 ml isopropanol. Store up to 3 months in 1-ml aliquots at −20°C.

Resuspension buffer

20 mM potassium phosphate, pH 7.4 (*APPENDIX 2A*)
20% (v/v) glycerol
1 mM EDTA
1 mM PMSF (add from 1 M PMSF stock solution; see recipe)
1 µg/ml pepstatin
10 µg/ml leupeptin
0.1 µg/ml antipain
Use immediately

Terrific broth containing 100 µg/ml ampicillin

900 ml H_2O
12 g Bacto tryptone (Difco)
24 g Bacto yeast extract (Difco)
4 ml glycerol

continued

Sterilize by autoclaving for 20 min. Allow the medium to cool to 60°C and add 100 ml of 0.17 M KH_2PO_4/0.72 M K_2HPO_4 (see annotation). Finally, add 1 ml of 100 mg/ml ampicillin stock (see recipe) per liter for a final concentration of 100 μg/ml. Mix thoroughly.

The 0.17 M KH_2PO_4/0.72 M K_2HPO_4 solution is made by dissolving 2.31 g of KH_2PO_4 and 12.54 g of K_2HPO_4 in 90 ml of H_2O. After the salts have fully dissolved adjust the volume to 100 ml with H_2O and sterilize by autoclaving for 20 min.

COMMENTARY

Background Information

The methods described in this unit have set the stage for many subsequent biophysical studies of the human HO-1. The expression system and purification protocol described here routinely yield 20 to 30 mg of purified protein per liter of cells. Consequently, it has been possible to characterize heme oxygenase on a mechanistic and structural level. Such characterizations include biochemical studies and the use of biophysical techniques such as X-ray crystallography, NMR, resonance Raman, and magnetic circular dichroism (MCD).

Initial UV/visible spectra of the heme-HO-1 complex as described in this unit have provided preliminary information on the nature of the ligation. At pH 6.0, the heme-HO-1 complex has a Soret maximum at 404 nm and a charge transfer band at 632 nm, characteristic of a high-spin species. On increasing the pH from 6.0 to 10.0, the heme Soret shifts from 404 to 409 nm and the charge transfer band decreases with the appearance of α/β-bands at 539 and 574 nm respectively (Sun et al., 1993; Hawkins et al., 1994). These data suggest that a water molecule occupying the sixth ligand position is being titrated to a hydroxide with increasing pH. The UV/visible spectrum of the ferrous complex in the presence of CO with the Soret at 420 nm and α/β bands at 567 and 537 nm, respectively (Fig 9.9.2), is consistent with a histidine as the proximal ligand.

The limited information gained from the UV/visible spectrum on the nature of the proximal ligand is far from conclusive, and much more information can and has been gained from more sophisticated spectroscopic techniques including MCD. MCD, because it is a difference technique that has both positive and negative components, yields a more detailed spectrum than the corresponding UV/visible spectrum. The increased sensitivity of MCD makes it an effective "fingerprinting" technique for the determination of the ligand coordination, oxidation state, and spin state of heme-binding proteins (Cheek and Dawson, 2000). Assignment of the proximal ligand in a heme protein of unknown function is based on comparison to a protein whose proximal ligand is known. The sample to be analyzed is prepared with a known ligand such as cyanide or azide, which can then be compared to the ferric-cyano complex of heme proteins with known ligands, such as myoglobin or cytochrome *c* peroxidase. The cyanoferric heme-HO-1 complex is very similar to that of cyanoferric myoglobin, thus confirming the proximal histidine ligation (Hawkins et al., 1996).

Raman spectroscopy is a vibrational spectroscopy technique that can detect transitions between different ligation states of porphyrins as the spin-state changes (Spiro and Czernuszewicz, 1995). As in MCD experiments, the resonance Raman spectra of the heme-HO-1 complex show a marked change in the heme axial coordination and spin state with changing pH, supporting the ionization of a coordinating water molecule (Sun et al., 1993). Resonance Raman studies, as well as providing direct confirmation of histidine as the proximal ligand, has provided more detailed information on the nature of the proximal histidine. The position of a characteristic marker band for the iron-histidine stretching frequency has implications for the ionization state of the proximal histidine. The band at 216 cm^{-1} in the heme-HO-1 complex (Sun et al., 1993) is close to that of myoglobin (221 cm^{-1}; Kitagawa et al., 1979), where the proximal ligand is only weakly hydrogen bonded. The presence of a strong hydrogen bond, such as that in cytochrome *c* peroxidase, shifts the iron-imidazole stretching frequency to 233 cm^{-1}, while complete ionization gives a value closer to 246 cm^{-1} (Smulevich et al., 1988). The relatively low value for the heme-HO-1 complex can therefore be interpreted as a proximal histidine that is weakly hydrogen-bonded.

The weakly hydrogen-bonded proximal histidine in the heme-HO-1 complex has strong implications for the mechanism of oxygen activation. The ability to form an activated ferryl

by destabilizing the dioxygen bond is largely dependent on the electron density present on the proximal ligand. As the electron density increases by partial or complete deprotonation of the proximal histidine, the ability to carry out dioxygen cleavage increases. Biochemical studies have shown that a ferryl species is not an intermediate in the heme oxygenase–catalyzed degradation of heme (Wilks and Ortiz de Montellano, 1993; Wilks et al., 1994). The mechanism proposed in these studies was that of an electrophilic addition of the terminal oxygen of the protonated peroxo intermediate (Fe-O-OH) to the α-*meso*-carbon. The proposed electrophilic mechanism is consistent with the presence of a proximal ligand that is neither ionized nor hydrogen-bonded. Indeed, recent NMR studies of the heme-HO-1 complex have identified an increased electron density at the α-*meso*-carbon, which would facilitate such a mechanism (Hernandez et al., 1994).

The extensive characterization of the heme-HO-1 complex by spectroscopic techniques such as MCD, resonance Raman, and NMR has greatly aided biochemical studies in elucidating the mechanism of action of HO-1. It is also gratifying that the recently determined crystal structure of the human heme-HO-1 complex (Schuller et al., 1999) has confirmed many aspects of the previous spectroscopic studies. The successful development of high-yield expression and purification protocols has enabled the majority of such studies to be carried out. Understanding of regiospecificity and catalysis will be greatly advanced with ongoing biophysical studies on both the wild-type HO-1 and site-directed mutants.

Critical Parameters and Troubleshooting

Although expression of HO-1 in high yields is feasible in both LB-ampicillin and low-phosphate induction medium, the key factor in obtaining viable protein is to minimize proteolysis to the 28-kDa fragment. This 28-kDa protein, while readily taking up heme, is inactive and can significantly lower the specific activity of the preparation. Therefore, for preparations in which it is imperative that no proteolytic fragment be present, the expression of the protein should be monitored to determine optimal conditions for obtaining the intact protein.

The purified apo-HO-1 or the biliverdin-HO-1 can both be used to reconstitute the heme-HO-1 complex (see Basic Protocol 2). The critical factor in successful reconstitution of the protein is the preparation of the hemin solution. As emphasized in the protocol, the heme solution must be freshly prepared immediately before use, as on standing it will form μ-oxo-dimers in which two heme molecules are coordinated through their iron centers by an oxygen molecule. Hemin is not soluble in aqueous buffer at pH 7.4 and must first be dissolved in alkaline conditions. It is important to dissolve the heme in a minimal amount of 0.1 N NaOH (100 μl), so that on dilution with aqueous buffer (pH 7.4) the pH remains close to neutral. If the pH of the heme solution is too alkaline (pH 8.5 to 9.0), significant denaturation of HO-1 may occur on addition of the hemin solution to the protein.

The HO-1 activity assay relies on the successful coupling of the NADPH cytochrome P450 reductase and HO-1 enzymes, as well as the conversion of biliverdin to bilirubin by biliverdin reductase. The molar ratio of cytochrome P450 reductase to heme oxygenase should be at least 3:1; however, a large excess will result in significant uncoupling in which H_2O_2 will be produced at the expense of NADPH consumption, resulting in nonenzymatic heme degradation. In some instances it may be necessary to titrate the concentration of NADPH–cytochrome P450 reductase required to give the maximum rate of bilirubin production. An excess of biliverdin reductase is required to ensure that the conversion of biliverdin to bilirubin is not the rate-limiting factor in the assay. In the author's laboratory, both purified and partially purified biliverdin reductase have been used successfully in the reconstituted assay.

Anticipated Results

The protocol outlined for the purification of HO-1 routinely yields 100 mg of purified protein with a specific activity 3 to 6 μmol/hr/mg. Purified protein obtained from a 6-liter expression is sufficient to carry out a number of biophysical and biochemical assays, including spectroscopic analysis and X-ray crystallography. The purification of NADPH cytochrome P450 reductase routinely yields 20 mg of purified protein with a specific activity of 15 μmol/min/mg, which is sufficient to reconstitute 100 heme oxygenase activity assays.

Time Considerations

The transformation and expression of HO-1 protein (Basic Protocol 1) requires 2 days for growth and harvest of the cells. Purification of HO-1 (Basic Protocol 2) from lysis of the cells to reconstitution of the protein with heme re-

quires 3 to 4 days. Preparation of the biliverdin-free protein requires 2 days when not reconstituting with heme. The purification of the NADPH cytochrome P450 reductase (Support Protocol 1) requires 5 days for the expression and subsequent purification steps. In both Basic Protocol 2 and Support Protocol 1 a 4 to 6 hr dialysis step can be carried out overnight for convenience. Characterization of the heme-HO-1 complex by UV/visible spectroscopy (Support Protocol 2) can be carried out in 2 to 4 hr. Similarly, the turnover of the heme-HO-1 complex in the presence of NADPH cytochrome P450 reductase (Support Protocol 3) can be carried out over 2 to 3 hr.

CHAPTER 10
The Nitric Oxide/Guanylate Cyclase Pathway

INTRODUCTION

No other single molecule has such a multiplicity of biological effects as nitric oxide (NO). This simple molecule, which acts in a fairly specific manner, is now recognized as playing an integral part in various homeostatic mechanisms—including those of the central and peripheral nervous systems and cardiovascular system, as well as host-defense interactions—where it can directly alter vital functions; it also affects gene expression. Among NO's most crucial roles are its activities as a brain neurotransmitter and in the regulation of blood pressure. NO was cited in over 8000 papers in the 1990s. Its importance is underscored by the fact that within a few years after its production in the body was first demonstrated, it had become the most heavily studied molecule in the history of modern science. It was declared molecule of the year by *Science* in 1992; in 1998, the Nobel Prize for physiology and medicine was awarded to key investigators in the field.

UNIT 10.1 initiates this chapter by providing an overview of the NO formation pathway and elaborating on the molecule's many functions, with emphasis on those relating to the immune and vascular systems.

The next several units cover methods for detecting NO activity in a wide range of biological systems using a variety of different approaches. In *UNIT 10.2*, NO synthase activity is measured—as an indication of NO production—by a radiometric assay in which labeled arginine is used as the enzyme substrate. This approach can be applied to all types of biological systems, from cells in culture to tissue extracts.

A second strategy is based on NO's status as a free radical, possessing an unpaired electron that can react with amino acid side chains and cause nitrosylation of proteins. Detection of nitrosated proteins is an effective means to assess NO production and activity. *UNITS 10.3 & 10.4* describe several methods that can be used to detect NO metabolites and protein derivatives. Also discussed in *UNIT 10.4* is the direct detection of NO in cellular systems and chemical reactions.

An indirect means to measure NO production while directly assessing the its biological function is to measure cGMP, which is produced by activation of soluble guanylyl activity. *UNIT 10.5* describes methods for determining tissue levels of cGMP and measuring guanylyl cyclase activity. Experimenters should be cautioned that cGMP is produced by the activation of guanylyl cyclase through interaction with NO or CO. Therefore, tissue cGMP level should not be directly equated with NO synthase activity or NO production.

Histochemical analysis is a nearly indispensable tool for detecting the pattern of NO synthase expression in tissues. This method of analysis is of similar value to the visualization of the cyclic nucleotide cGMP in tissues. Protocols for such analyses are provided in *UNIT 10.6* and *UNIT 10.7*, respectively.

Current Protocols in Toxicology (2000) 10.0.1-10.0.2

Nitric oxide, being a highly reactive molecule, is capable of forming various derivatives in biological systems. The biological effect of nitrogen oxide species depends on the chemistry of the intermediates formed and the chemical reactions they are involved in. Determination of which reactions are relevant to different toxicological mechanisms is challenging. *UNIT 10.8* provides methods for distinguishing between oxidative and nitrosative chemistry of different nitrogen oxide species.

Because of the centrol role of NO in host defense mechanisms and the molecule's ability to alter expression of stress-responsive genes, measurement of the transcriptional regulation of inducible NO synthase (iNOS) is often needed to assess the impact of environmental stimuli on the cell. When stimulated, high levels of iNOS are expressed, and its expression can be specifically measured by northern blot analysis and, conveniently, from nitrite formation. *UNIT 10.9* provides procedures for mRNA analysis as well as a rapid method using the Greiss reaction to measure nitrite accumulation.

Overview of the Pathway and Functions of Nitric Oxide

WHAT IS NO?

Nitric oxide (NO) has been recognized for many years as a toxic, reactive free radical gas. Initially, most research on NO focused on its role in air pollution, as a component of cigarette smoke, and as a byproduct of microbial metabolism. More recently, however, NO has been discovered to be present in a wide variety of biological systems. NO was first shown to be the species previously defined as endothelium-derived relaxing factor (EDRF), which mediates the ability of substances such as acetylcholine and bradykinin to dilate blood vessels (Furchgott and Zawadski, 1980; Ignarro et al., 1987; Palmer et al., 1987). NO was then discovered to be the molecule responsible for the tumoricidal and bactericidal actions of macrophages (Hibbs et al., 1987). NO was also found to be released from cerebellar granule cells after exposure to glutamate analogs, suggesting a role in nervous system function (Garthwaite et al., 1988). These and subsequent studies indicate that NO is a unique biological molecule that functions in a variety of metabolic and signaling pathways.

NO is present in biological systems as a dissolved nonelectrolyte (except in the lung and paranasal sinus where it is present as a gas) that is not stored in any subcellular compartments. It is synthesized on demand and simply diffuses from the site of formation to the site of action. NO forms covalent and noncovalent linkages with protein and nonprotein targets, including the enzyme guanylate cyclase. NO is inactivated by diffusion away from its targets and by the formation of covalent linkages to the superoxide anion or scavenger proteins. Because the biological actions of NO are not controlled by conventional means, NO depends on its small size, diffusibility, membrane permeability, and reactivity to exert its effects (Dawson and Snyder, 1994). Furthermore, because the cell cannot sequester and regulate the local concentration of NO, regulation of NO synthesis is the key to regulating its biological activity.

PATHWAY OF NO FORMATION BY NITRIC OXIDE SYNTHASE

NO is formed directly from the guanidino nitrogen of L-arginine by the enzyme nitric oxide synthase (NOS) through a process that consumes five electrons and results in the formation of L-citrulline (Fig. 10.1.1). NOS is unusual among oxidative enzymes in that most other enzymes consume one or two electrons for similar functions. Initial attempts to purify NOS were unsuccessful, owing to the rapid loss of enzymatic activity upon purification. The loss of NOS activity was eventually attributed to separation from its necessary cofactor, calmodulin; this knowledge led to its purification to homogeneity from cerebellum (Bredt and Snyder, 1990). NOS was then isolated from macrophages and endothelial tissue (Jaffrey and Snyder, 1995). Purification of NOS led to

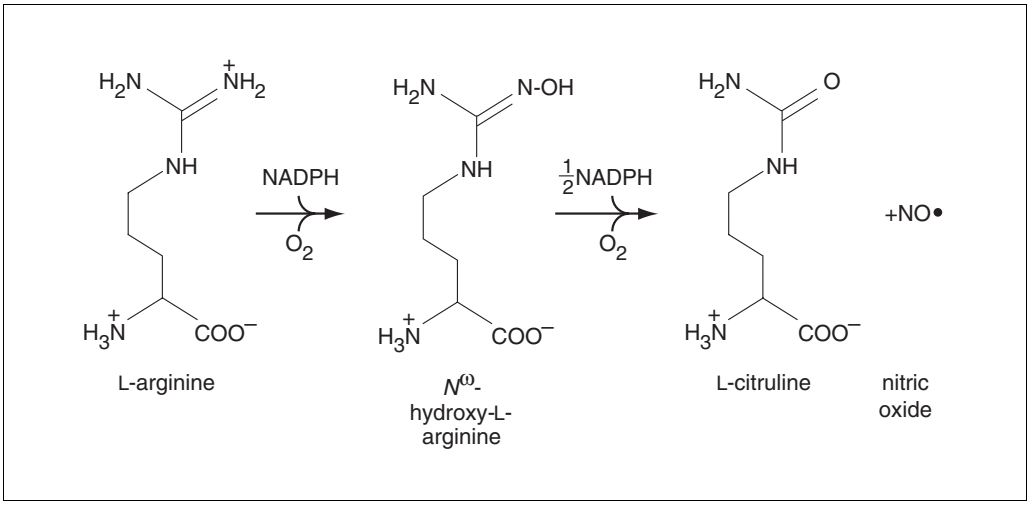

Figure 10.1.1 Biosynthesis of nitric oxide. NO is formed from L-arginine in two successive reactions. Both steps require NADPH, O_2, Ca^{2+}, and calmodulin and are enhanced by tetrahydrobiopterin.

Current Protocols in Toxicology (1999) 10.1.1-10.1.6

cloning of the cDNA for neuronal NOS (nNOS, type I; Bredt et al., 1991), which facilitated the subsequent cloning of macrophage NOS—also referred to as inducible NOS or immunologic NOS (iNOS, type II)—and endothelial NOS (eNOS, type III; Jaffrey and Snyder, 1995).

Cloning of NOS revealed 60% homology to cytochrome P-450 reductase (CPR) at the C-terminal portion of nNOS (Fig. 10.1.2; Bredt et al., 1991). The homology with CPR is shared by all NOS isoforms cloned and reflects the oxidative nature of NO biosynthesis. Both NOS and CPR contain specific recognition sites for NADPH, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD), which bind NOS stoichiometrically. These are the only mammalian enzymes known to contain recognition sites for NADPH, FMN, and FAD (Dawson and Snyder, 1994). NOS also uses tetrahydrobiopterin as a cofactor. Tetrahydrobiopterin helps transform NOS into a catalytically active conformation and may also act as an oxidative-reductive cofactor. NOS contains heme, which reacts with CO. CO inhibits purified NOS, which is consistent with the participation of a cytochrome-P-450-type heme in the reaction. Moreover, NO itself appears to interact with the enzyme's heme and inhibit its own formation, thus exerting feedback inhibition (Marletta, 1994).

The catalytic form of NOS is a dimer. Dimerization requires the presence of heme, tetrahydrobiopterin, and arginine; heme and tetrahydrobiopterin become associated with the dimer during assembly. Dimerization alone is not sufficient for electron flow; calmodulin binding is also required. The mechanism of electron transfer is likely to be similar to that of the cytochrome P-450 enzymes, in that NADPH reduces FAD, which subsequently reduces FMN, which in turn transfers electrons to the ferric heme, promoting the interaction with molecular oxygen (Dawson and Snyder, 1994). Calmodulin binding appears to permit electron transfer both from NADPH to the flavins and from the flavins onto heme. The calmodulin-binding site lies between the putative P-450 oxygenase domain, which contains the heme-, tetrahydrobiopterin-, and arginine-binding sites, and the CPR domain, located in the C-ter-

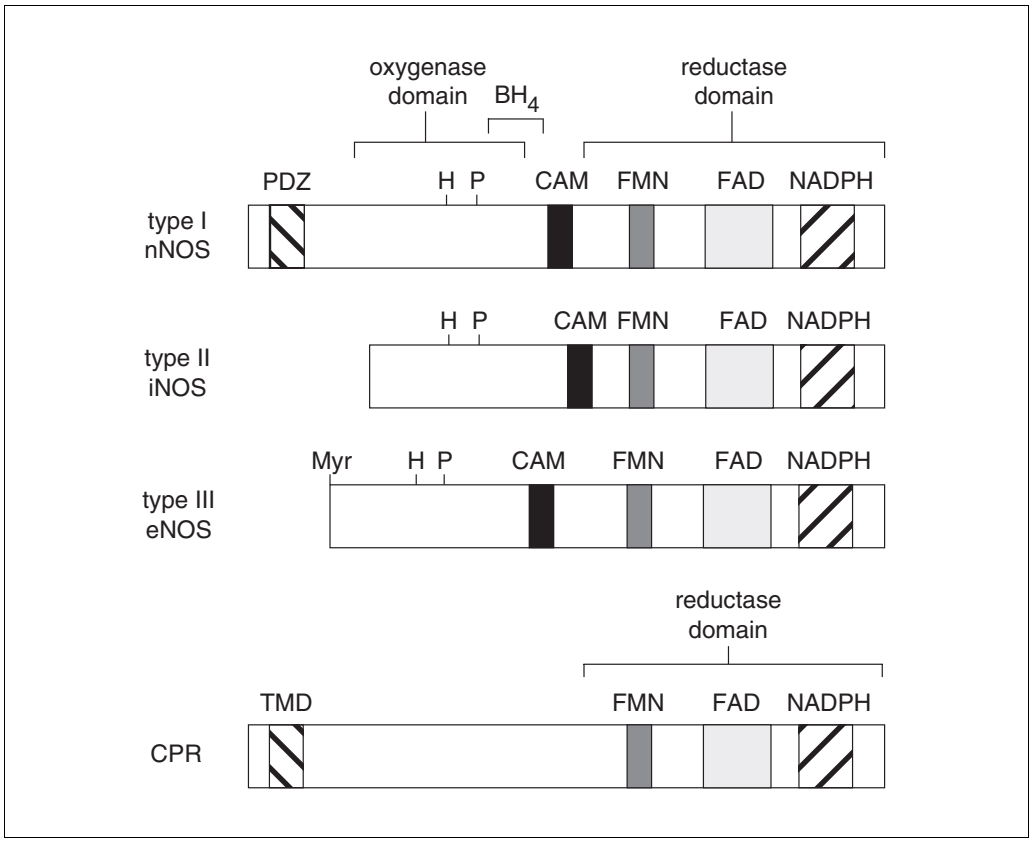

Figure 10.1.2 Isoforms of NOS compared to CPR. PDZ, PDZ domain; H, heme binding site; P, consensus sequence for phosphorylation by cAMP-dependent protein kinase; BH_4, tetrahydrobiopterin binding site; CAM, calmodulin binding site; FMN, flavin mononucleotide binding site; FAD, flavin adenine dinucleotide binding site; NADPH, NADPH binding domain; TMD, transmembrane domain; Myr, myristoylation site.

minal 60% of NOS. Elevation of intracellular calcium levels allows calmodulin to bind calcium and become competent to bind eNOS and nNOS. In contrast, the calmodulin of iNOS is very tightly bound, and thus is constitutively capable of transferring electrons to heme even in the absence of elevated intracellular calcium (Marletta, 1994).

eNOS and nNOS are constitutive, and are sometimes designated cNOS because substantial levels of basal enzyme protein exist in cells; in contrast, macrophages contain negligible levels of iNOS enzyme, and new enzyme is formed in response to stimuli. The categories defining the NOS isoforms are not absolute. Although constitutive forms of NOS were thought to be activated only by calcium-calmodulin interactions and not by new enzyme synthesis, recent findings show dramatic increases in nNOS synthesis in response to nerve damage and other stimuli. Recently, nNOS was found in non-neuronal tissues, such as skeletal muscle, respiratory and gastrointestinal epithelium, white blood cells, and pancreatic and uterine tissues. eNOS occurs in neuronal subpopulations in the brain. iNOS occurs in many tissues besides macrophages (Jaffrey and Snyder, 1995).

The constitutive and inducible forms of NOS are controlled differently. nNOS and eNOS are activated by increases in intracellular calcium. In the brain, glutamate acting at *N*-methyl-D-aspartate (NMDA) receptors triggers an influx of calcium that binds to calmodulin to activate nNOS. Glutamate can triple nNOS activity in brain slices in a matter of seconds. In endothelial cells, acetylcholine or bradykinin receptor activation stimulates the phosphoinositide cycle, generating the calcium that activates eNOS. iNOS is catalytically active in the absence of calcium, because calmodulin is tightly bound to the enzyme. Under basal conditions, macrophages have no detectable iNOS activity, whereas stimuli such as lipopolysaccharide and interferon γ stimulate new iNOS protein formation in a few hours (Nathan and Xie, 1994).

FUNCTIONS OF NO

NO in the Nervous System

NO is a regulator of neurotransmitter release. NOS inhibitors block neurotransmitter release in brain slices and synaptosomes. In synaptosomes, neurotransmitter release evoked by stimulation of NMDA receptors is blocked by NOS inhibitors, whereas release by potassium depolarization is unaffected. Presumably, glutamate acts at NMDA receptors located in NOS nerve terminals, stimulating the formation of NO, which diffuses to adjacent terminals to augment neurotransmitter release. In contrast, potassium depolarizes all terminals so that effects of the limited populations of NOS terminals are not detectable (Jaffrey and Snyder, 1995).

Stimulating NMDA receptors in cerebellar slices with glutamate or NMDA itself augments NOS activity and cGMP levels as rapidly as one can measure, and both increases are blocked by NOS inhibitors. Whether NO is the primary regulator of cGMP throughout the brain is unclear, because localization of nNOS and guanylate cyclase differ. Localizations of guanylate cyclase more closely parallel those of heme oxygenase 2, the enzyme that synthesizes carbon monoxide, which can also stimulate guanylate cyclase (Dawson and Snyder, 1994).

Initial immunohistochemical mapping of nNOS detected specific staining in many parts of the peripheral autonomic nervous system. Neurons of the myenteric plexus throughout the gastrointestinal pathway possess NOS. These nitrergic neurons, formerly termed nonadrenergic and noncholinergic (NANC) neurons, are involved in the relaxation phase of peristalsis. NOS inhibitors selectively block NANC neurotransmission (Bult et al., 1990; Desai et al., 1991). Furthermore, nNOS knockout mice display markedly enlarged stomachs with hypertrophy of the pyloric sphincter, a syndrome that resembles the human disease infantile hypertrophic pyloric stenosis (Huang et al., 1993).

Autonomic neurons of the pelvic plexus and its axonal processes that form the cavernous nerve, which innervates penile blood vessels, also contain nNOS, as do the projections of the nerve plexus into the arterial sinusoids in the periphery of the corpora cavernosa, the erectile tissue of the penis. NANC neuronal stimulation relaxes isolated cavernosal strips, and this effect is blocked by NOS inhibitors. Penile erection elicited by electrical stimulation of the cavernous nerve is blocked by low doses of NOS inhibitors (Burnett et al, 1992; Rajfer et al., 1992). nNOS knockout mice, however, display normal copulatory activity, procreate normally, and obtain erections upon stimulation of the cavernous nerve. Therefore, other mechanisms must compensate for the loss of nNOS (Huang et al., 1993).

NO may also participate in nervous system development. nNOS is expressed transiently in the cerebral cortical plate of rats, especially at

embryonic days 15 to 19, when the majority of the cells in the plate stain along with their processes, which project to the thalamus. The innervation gradually decreases after birth and is absent in adults. Similarly, embryonic sensory ganglia all stain for nNOS, as do embryonic olfactory neurons, whereas in both cases, staining is absent in adults (Jaffrey and Snyder, 1995). In long-term potentiation (LTP), enhancement of transmitter release by Schaeffer collaterals is thought to require release by pyramidal cells of a retrograde messenger. NOS inhibitors interfere with the establishment of LTP, as does hemoglobin, which binds NO. Some NOS inhibitors are active when injected directly into pyramidal cells (O'Dell et al., 1991; Schuman and Madison 1991; Haley et al., 1992). Recently, strong evidence supporting a role for NO in LTP has been obtained using transgenic mice null for both eNOS and nNOS (Son et al., 1996) and in hippocampal cultures using NOS inhibitors, NO scavengers, and photoactivatable NO donors (Arancio et al., 1996).

Studies in nNOS knockout mice provide insight into behavioral roles for NO (Nelson et al., 1995). Male knockout mice mount females indiscriminately, regardless of whether the females are in estrus or not. When wild-type male mice are housed together, they fight; but within an hour or so they establish appropriate hierarchical relationships. By contrast, male knockout mice fight almost incessantly, sometimes to the death. Thus nNOS knockouts appear to lose behavioral inhibition.

Excess production of NO in the nervous system is neurotoxic. NO has been shown to mediate glutamate excitotoxicity, which is the primary mode of neurotoxicity in cerebral ischemia (Dawson et al., 1991). nNOS knockout mice are more resistant to cerebral ischemia than are wild-type controls (Huang et al., 1994). The neurotoxic effects of NO are mediated by its interaction with the superoxide anion, which forms the highly neurotoxic species peroxynitrite, leading to the activation of pathways that deplete cellular energy substrates and result in cell death (Dawson and Snyder, 1994).

NO in the Immune System

NO is effective against various microbes, tumor cells, and alloantigens. iNOS is not detectable in healthy tissue but is expressed after immunologic challenge or injury. The induction of iNOS can be mediated by cytokines and by microbial products. In addition to macrophages and microglia, iNOS under pathologic conditions can be expressed in most tissues, including neurons, astrocytes, and endothelial cells (Nathan and Xie, 1994).

NO formation is increased during inflammation (e.g., arthritis), and several classic inflammatory symptoms are reversed by NOS inhibitors. Furthermore, unregulated NO synthesis becomes self-destructive and may play a role in disorders such as autoimmune disease, immune rejection of allografted organs, graft-versus-host disease, and sepsis. These proinflammatory effects of NO are not evident under acute physiologic conditions, in which NO can mediate anti-inflammatory functions, such as inhibition of neutrophil adhesion, cyclooxygenase activity, and cytokine formation (Schmidt and Walter, 1994). Induction of iNOS can take place under neuropathologic conditions (Iadecola, 1997). iNOS knockout mice have markedly reduced defenses against microorganisms (e.g., *Listeria* and *Leishmania*), and against the proliferation of lymphoma tumor cells. These animals are, however, resistant to carrageenan inflammation and hypotension elicited by endotoxin (MacMicking et al., 1995; Wei et al., 1995).

NO in the Vascular System

NO is a major regulator of vascular hemodynamics and is the primary messenger molecule mediating blood vessel relaxation (Ignarro et al., 1987; Palmer et al., 1987). Attempts to understand the vasodilatory effects of organic nitrates and the mechanisms of acetylcholine-induced relaxation of vascular smooth muscle led to the discovery that endothelially derived NO is critical in the regulation of vascular hemodynamics and that NO represents the long-sought endothelium-derived relaxing factor (EDRF). NO relaxes blood vessels by binding to iron in the heme at the active site of guanylate cyclase, thereby activating the enzyme to generate cGMP. Both shear stress and deformation of vascular endothelium, which accompany pulsatile flow through blood vessels, stimulate NO release through poorly defined mechanisms (Moncada and Higgs, 1993).

eNOS knockout mice exhibit deficient acetylcholine vasodilation, and their mean blood pressure is higher than that of control animals (Huang et al., 1995). eNOS may play a protective role in cerebral ischemia by maintaining regional cerebral blood flow, because transgenic mice that lack eNOS experience increased infarct volumes after middle cerebral artery occlusion (Huang et al., 1995). Endothelial functions, including NO release and action,

are clearly impaired or dysregulated in important vascular diseases such as atherosclerosis; hypertension; diabetes; reperfusion injury; and vasculopathy associated with angioplasty, bypass surgery, and transplantation, although the molecular mechanisms are as yet unclear.

SUMMARY

In a relatively short period of time, understanding of the diverse functions of NO in mammalian systems has grown immensely. Having been recognized as a bona fide cellular signaling molecule, NO has changed our understanding of what constitutes a physiologic signal. Undoubtedly, new roles for NO will be found in an even greater number of biological processes.

Assay of Tissue Activity of Nitric Oxide Synthase

Nitric oxide synthase (NOS) activity can be assayed by several techniques that are based on the formation of either NO or L-citrulline. Among these methods, which include the quantitation of NO (or NO-derived metabolites) by UV/VIS spectroscopy, fluorescence spectroscopy (*UNIT 10.4*), electron paramagnetic resonance (EPR) spectroscopy, chemiluminescence or bioassay, the conversion of radiolabeled L-arginine to L-citrulline is the most widely used. The assay is very sensitive, simple to perform, and relatively robust. As described in this unit, it can be used to determine NOS activity in either intact cells (see Basic Protocol 1) or cell and tissue extracts (see Basic Protocol 2). Both protocols are based on the separation of [^{3}H]L-citrulline from [^{3}H]L-arginine by cation-exchange chromatography, a simple and time-saving technique that allows parallel processing of many samples. Detailed instructions for preparation and maintenance of the chromatography columns are also provided (see Support Protocol 1). Because the sensitivity of the assay depends critically on the purity of the radiolabeled substrate, an additional support protocol is supplied that describes the purification of [^{3}H]L-arginine by HPLC (see Support Protocol 2). Throughout all protocols, [^{14}C]L-arginine can be substituted for [^{3}H]L-arginine if desired. These procedures have been successfully applied to a broad range of cell types (see Anticipated Results for examples).

DETERMINING NOS ACTIVITY IN INTACT MONOLAYER CELLS

BASIC PROTOCOL 1

This protocol describes the determination of NOS activity in freshly isolated or cultured cells, and provides a simple and rapid means for assessing the responsiveness and sensitivity of cellular NOS to different stimuli. The method is based on the conversion of incorporated [^{3}H]L-arginine to [^{3}H]L-citrulline and can be applied to adherent or suspended cells. After appropriate isolation and/or culture procedures, cells are washed with buffer and incubated with [^{3}H]L-arginine and the compound(s) to be tested. After removal of extracellular [^{3}H]L-arginine, the reaction is terminated by lysis of the cells with HCl. To determine the amount of [^{3}H]L-arginine incorporated, a sample of the cell extract is removed and radioactivity is measured by liquid-scintillation spectrometry. The remaining extract is subjected to cation-exchange chromatography followed by the quantification of [^{3}H]L-citrulline in the eluate. Results are calculated as percent conversion of incorporated [^{3}H]L-arginine to [^{3}H]L-citrulline and corrected for blank levels obtained in the presence of a NOS inhibitor.

The procedure described here is for cell monolayers cultured in six- or twelve-well plates. It is recommended that the experiment be performed in triplicate wells for each test condition. Moreover, each set of assays requires control incubations in the presence of a NOS inhibitor, e.g., 100 µM N^G-nitro-L-arginine (L-NNA) or N^G-monomethyl-L-arginine (L-NMA).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (see *APPENDIX 1A*).

NOTE: Because unlabeled L-arginine diminishes the uptake of [^{3}H]L-arginine, experiments should be performed in L-arginine-free buffer to achieve maximum sensitivity of the assay.

Materials

Confluent monolayer culture
HEPES-buffered salt solution, pH 7.4 (see recipe), prewarmed to 37°C
10 mM N^G-nitro-L-arginine (L-NNA) or N^G-monomethyl-L-arginine (L-NMA) in water
[2,3,4,5-^{3}H]L-arginine (HPLC-purified, see Support Protocol 2) in HEPES-buffered salt solution (~10,000 cpm/µl)
Stock solution of compound to be tested, prepared as 20× stock solution in HEPES-buffered salt solution or an appropriate solvent (see step 3 annotation)
0.01 N HCl
Scintillation cocktail
Sodium acetate buffer with L-citrulline (see recipe)
[^{3}H]L-citrulline in 0.01 HCl
Dowex 50W cation-exchange columns (for preparation and maintenance of columns, see Support Protocol 1)

Incubate cells with test compound and [^{3}H]L-arginine

1. Aspirate the culture medium and wash confluent monolayer twice with 1 ml of 37°C HEPES-buffered salt solution.

   Because culture media usually contain 0.3 to 3 mM L-arginine, at least two washes are required to minimize contamination of the buffer with residual L-arginine.

2. Add 0.9 ml HEPES-buffered salt solution to the washed cells. To determine blank levels, add 9 µl of 10 mM L-NNA or L-NMA to three wells. Agitate the plate, then place it into an incubator or onto a thermostated heating block, and incubate it 10 min at 37°C.

3. Add 50 µl of 10,000 cpm/µl [^{3}H]L-arginine in HEPES-buffered salt solution (~500,000 cpm) and 50 µl of a 20-fold stock solution of the compound to be tested. Agitate the plate, then incubate it 10 min at 37°C.

   In general, stock solution(s) of test compound(s) should be prepared in HEPES-buffered salt solution. If not possible, substances may be dissolved in 0.01 N HCl, 0.01 N NaOH, or an organic solvent (e.g., dimethyl sulfoxide), but proper controls are then required to exclude solvent effects.

4. Aspirate the incubation medium, and wash monolayer twice with 1 ml ice-cold HEPES-buffered salt solution.

   CAUTION: *Incubation medium is radioactive—pay attention to correct waste disposal!*

   For complete removal of extracellular [^{3}H]L-arginine, two washing steps are required. The use of ice-cold washing buffer is strongly recommended to stop cell metabolism rapidly. In the washing buffer, 1 mM ethylene glycol bis(β-aminoethylether-N,N,N′,N′-tetraacetic acid) (EGTA) may be substituted for $CaCl_2$ to block Ca^{2+}-dependent NOS activity.

5. Add 1 ml 0.01 N HCl to the washed cells. Leave plates at least 1 hr at room temperature to ensure complete release of intracellular [^{3}H]L-arginine and [^{3}H]L-citrulline.

Determine [^{3}H]L-arginine incorporation and [^{3}H]L-citrulline formation

6. Agitate the plate; then transfer 0.1 ml HCl extract to a scintillation counting vial and sequentially add 1.9 ml water and 5 ml scintillation cocktail. Mix, then count radioactivity in a liquid scintillation spectrometer to determine the amount of incorporated [^{3}H]L-arginine.

   Typically, 5 ml scintillation cocktail will be sufficient to achieve a homogenous solution, but a larger volume may be required if a scintillation cocktail with a low sample load capacity is used.

7. Add 0.1 ml sodium acetate buffer with L-citrulline to the remaining HCl extract.

   After adding the sodium acetate buffer with L-citrulline, the pH of the samples should be between 5.0 and 5.5. Thus each time a fresh solution of either HCl or sodium acetate buffer with L-citrulline is prepared, mix 0.9 ml HCl and 0.1 ml buffer and check the pH. If necessary, change the pH of the sodium acetate buffer with L-citrulline, mix it again with HCl, and measure the pH. Repeat this procedure until the desired pH is obtained.

8. Agitate the plate; then transfer the supernatant to the cation-exchange column and collect the effluent in a scintillation counting vial. Elute residual [^{3}H]L-citrulline with 1 ml water into the same vial, and add 5 ml scintillation cocktail. Mix, then count radioactivity to determine the amount of [^{3}H]L-citrulline formed.

   Treatment of cells with HCl disrupts cell membranes, but the resulting cell debris usually remains attached to surface of the culture dishes. If, however, loosening of the cell debris is observed, samples should be centrifuged 5 min at 10,000 to 15,000 × g before being transferred to the cation-exchange column.

Determine L-citrulline recovery

9. Prepare a solution of ~10,000 cpm/ml [^{3}H]L-citrulline in 0.01 N HCl. Mix 0.9 ml of this solution with 1.1 ml water and 5 ml scintillation cocktail in a scintillation counting vial; count radioactivity (= total cpm).
10. Mix another 0.9 ml of the [^{3}H]L-citrulline solution with 0.1 ml sodium acetate buffer with L-citrulline in a test tube and transfer the sample to the cation exchange column. Elute, and determine radioactivity as described in step 8 (= recovered cpm).
11. Divide recovered cpm by total cpm to calculate recovery of L-citrulline.

    The recovery of L-citrulline is usually between 0.8 and 0.9 (i.e., 80% to 90%). Because the elution profile may vary after prolonged use or storage of the columns, it is recommended that the recovery be checked periodically (e.g., each month).

Calculate results

12. Calculate the total radioactivity of incorporated [^{3}H]L-arginine:

$$\frac{\text{cpm (step 6)} \times \text{total volume of HCl extract (1 ml)}}{\text{sample volume (0.1 ml)}}$$

$$U: \frac{1100 \text{ cpm} \times 1 \text{ ml}}{0.1 \text{ ml}} = 11{,}000 \text{ cpm } (S: 12{,}000 \text{ cpm}, I: 11{,}500 \text{ cpm})$$

NOS activity in intact cells is expressed as percent conversion of incorporated [^{3}H]L-arginine into [^{3}H]L-citrulline. As an example, results from a typical assay performed with endothelial cells in six-well plates are given (U, unstimulated; S, stimulated with a Ca^{2+} ionophore; I, stimulated with a Ca^{2+} ionophore in the presence of L-NNA).

13. Calculate the total radioactivity of [^{3}H]L-citrulline formed:

$$\frac{\text{cpm (step 8)} \times \text{total volume of HCl extract (1 ml)}}{\text{sample volume (0.9 ml)} \times \text{recovery of L-citrulline}}$$

$$U: \frac{230 \text{ cpm} \times 1 \text{ ml}}{0.9 \text{ ml} \times 0.95} = 270 \text{ cpm } (S: 2600 \text{ cpm}, I: 150 \text{ cpm})$$

14. Calculate conversion of incorporated [^{3}H]L-arginine into [^{3}H]L-citrulline:

$$\frac{[^3\text{H}]\text{L-citrulline formed}}{\text{incorporated } [^3\text{H}]\text{ L-arginine}}$$

$$U: \frac{270 \text{ cpm}}{11{,}000 \text{ cpm}} \times 100 = 2.5\% \ (S: 21.7\%, I: 1.3\%)$$

15. Subtract the value of the NOS-inhibitor control (*I*) from those of the samples (*U*, *S*) to obtain NOS-dependent conversion of L-arginine into L-citrulline:

    Unstimulated: 1.2% conversion;
    Stimulated: 20.4% conversion.

ALTERNATE PROTOCOL 1

DETERMINING NOS ACTIVITY IN INTACT SUSPENSION CELLS

NOS activity can also be measured for cells that grow in suspension. It is recommended that the experiment be performed in triplicate for each test condition. Moreover, each set of assays requires control incubations in the presence of a NOS inhibitor (e.g., 100 µM NNA or L-NMA). Materials required for this procedure are the same as those used when assaying monolayer cells (see Basic Protocol 1).

1. Collect cells from suspension cultures and centrifuge 5 min at 400 × *g*, room temperature. Wash the pellet twice with 37°C HEPES-buffered salt solution and resuspend the final pellet to a concentration of 0.2–1 × 10^6cells/ml.
2. Transfer 0.9-ml aliquots of the cell suspension to 1.5-ml microcentrifuge tubes. To determine blank levels, add 9 µl of 10 mM L-NNA or L-NMA to three tubes. Mix sample, and place tube into a 37°C water bath or heating block. Incubate cells 10 min at 37°C.
3. Add 50 µl [^{3}H]L-arginine solution and 50 µl of a 20-fold stock solution of the compound to be tested. Incubate cells 10 min at 37°C, shaking the tube occasionally.
4. Sediment cells by centrifugation, 4°C, and wash the pellet twice with 1 ml ice-cold HEPES-buffered salt solution.

   CAUTION: *Incubation medium is radioactive—pay attention to correct waste disposal!*

   According to the authors' experience with various types of cells, centrifugation can be performed at 10,000 to 15,000 × g without disruption of cell membranes. Centrifugation at high speeds reduces the time required for sedimentation (~10 sec) and thus minimizes cell metabolism during the washing procedure.
5. Resuspend the pellet in 1 ml of 0.01 N HCl, and leave tube at least 1 hr at room temperature to ensure complete release of intracellular [^{3}H]L-arginine and [^{3}H]L-citrulline.
6. Vortex sample 5 to 10 sec. Transfer 0.1 ml cell suspension to a scintillation counting vial, and sequentially add 1.9 ml water and 5 ml scintillation cocktail. Mix, then count the radioactivity in a liquid scintillation spectrometer to determine the amount of incorporated [^{3}H]L-arginine.
7. To the remaining cell suspension (0.9 ml), add 0.1 ml sodium acetate buffer with L-citrulline. Mix the sample and centrifuge 5 min at 10,000 to 15,000 × *g*, room temperature, to sediment cell debris.
8. Transfer the supernatant to the cation-exchange column, and collect the effluent in a scintillation counting vial. Elute residual [^{3}H]L-citrulline with 1 ml water in the same vial and add 5 ml scintillation cocktail. After mixing, count radioactivity to determine the amount of L-[^{3}H]citrulline formed.
9. Calculate the results (see Basic Protocol 1, steps 9 to 15).

DETERMINING NOS ACTIVITY IN CELL OR TISSUE EXTRACTS

This protocol describes a sensitive enzyme assay that allows the determination of NOS activity in cell or tissue extracts. The assay can be carried out with cell homogenates, subcellular fractions, or (partially) purified NOS. Several methods are available for disrupting the cell membranes, but the efficacy of each technique may vary, depending on the type of cells or tissues used. In general, a mechanical homogenizer is a good choice for homogenizing intact tissues, whereas isolated and cultured cells are often more efficiently disrupted by sonication. After appropriate homogenization and centrifugation, NOS activity is assayed in the presence of [^{3}H]L-arginine, NADPH, Ca^{2+}/calmodulin, flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and (6*R*)-5,6,7,8-tetrahydro-L-biopterin (H_4biopterin). Following termination of the reaction, [^{3}H]L-citrulline is separated from [^{3}H]L-arginine by cation-exchange chromatography, and [^{3}H]L-citrulline is quantified in the eluate by liquid scintillation spectrometry. Results are corrected for blank and column recovery, and NOS activity is expressed as formation of L-citrulline per minute and milligram of protein.

NOTE: Tissues should be either used immediately on collection or rapidly frozen and stored at −70°C. Preparation of tissue extracts should be performed at 4°C to avoid loss of enzyme activity.

Materials

Cells or tissue of interest
Phosphate-buffered saline (PBS; *APPENDIX 2A*), prewarmed to 37°C
Triethanolamine buffer with EDTA (see recipe)
Assay buffer with [^{3}H]L-arginine (see recipe)
Sodium acetate buffer with EDTA (see recipe)
Scintillation cocktail
[^{3}H]L-citrulline in sodium acetate buffer with EDTA (~10,000 cpm/ml)

Ultrasonic generator *or* mechanical tissue homogenizer (e.g., Polytron, Brinkman)
Cheesecloth or 100-μm-pore-size cell strainer
Protein assay kit (e.g., Bio-Rad kit for Bradford protein assay)
Dowex 50W cation exchange columns (for preparation and maintenance of columns, see Support Protocol 1)

Prepare extracts

For cell extracts

1a. Suspend adherent cells using a rubber policeman or cell scraper, and centrifuge cells 5 min at 400 × *g*, room temperature. Wash the pellet twice with 37°C PBS, and resuspend the final pellet in a small volume (typically 2 ml per ml pellet) of ice-cold triethanolamine buffer with EDTA

2a. Disrupt the cells by sonication (typically, four 10-sec pulses).

CAUTION: *Prolonged sonication will increase the temperature of the cell extract. Thus, sonicate cells in short bursts (~10 sec); allow sample to cool 50 sec in ice water in between bursts.*

For tissue extracts

1b. Working at 4°C, weigh a portion of the tissue (typically 0.5 to 5 g) and put it into a beaker. Add a measured volume of ice-cold triethanolamine buffer with EDTA (typically 5 ml/g tissue) and mince the tissue with scissors.

Perform steps 1b, 2b, and 3 to 5 at 4°C.

2b. Disrupt the chopped tissue using a standard mechanical homogenizer.

Depending on the type of tissue, the time required for homogenization may vary from 20 (brain or liver) to 60 sec (muscle). Alternatively, soft tissues (e.g., brain and liver) may be homogenized by six to eight strokes with a Potter-Elvehjem homogenizer (800 rpm).

For tissue and cell extracts

3. Filter homogenate through multiple layers of cheesecloth or a cell strainer (pore size 100 μm) to remove cell debris.

4. Either use the homogenate immediately to determine NOS activity (step 6 onward; keep preparations on ice until just before use) or store it at −70°C.

Alternatively, use the fresh homogenate for subcellular fractionation (Castle, 1995).

Depending on the type of tissue, homogenates may be stored up to 6 months at −70°C without considerable loss of enzyme activity.

5. Determine the protein concentration by a standard protein assay (e.g., Bradford assay, kit available from Bio-Rad).

Perform NOS assay

6. Put assay tube into a test tube rack on ice. Add 50 μl assay buffer with [^{3}H]L-arginine and 10 μl of a 10-fold stock solution of the compound to tested.

It is recommended that the experiment be performed in triplicate for each test condition. Moreover, each set of assays requires incubations in the absence of enzyme extract to obtain blank values.

7. Add 40 μl homogenate (enzyme extract; 1 to 10 mg protein/ml) and vortex the sample for ~5 sec. Put the tube into a 37°C water bath or heating block, and incubate the sample for 10 min.

To determine blanks, add 40 μl water instead of enzyme extract.

8. Terminate the reaction by adding 0.9 ml ice-cold sodium acetate buffer with EDTA. Vortex sample ~5 sec, and put tube on ice.

The stopped assays can be left on ice until the batch of incubations has been completed.

9. Transfer sample to the exchange column, and collect effluent in a scintillation counting vial. Elute residual [^{3}H]L-citrulline with 1 ml water in same vial, and add 5 ml scintillation cocktail. Mix, then count radioactivity in a liquid scintillation spectrometer to determine amount of [^{3}H]L-citrulline formed.

10. To determine the radioactivity of the [^{3}H]L-arginine added to the assay, mix 50 μl assay buffer with [^{3}H]L-arginine with 2 ml water and 5 ml scintillation cocktail in a scintillation counting vial; count radioactivity.

Determine L-citrulline recovery

11. To determine the recovery of L-citrulline, prepare a solution of authentic L-[^{3}H]citrulline in sodium acetate buffer with EDTA (~10,000 cpm/ml). Mix 1 ml of this solution with 1 ml water and 5 ml scintillation cocktail in a scintillation counting vial; count radioactivity (= total cpm).

It is recommended that the experiment be performed in triplicate.

12. Load another 1 ml [^{3}H]L-citrulline solution onto the cation-exchange column. Elute, and determine radioactivity as described in step 9 (= recovered cpm). Divide recovered cpm by total cpm to obtain recovery of L-citrulline.

The recovery of L-citrulline is usually between 0.8 and 0.9 (i.e., 80% to 90%). Because the elution profile may vary after prolonged use or storage of the columns, the recovery should be checked periodically (e.g., each month).

Calculate results

13. To correct values for blank and L-citrulline recovery, subtract radioactivity of the blank from that of the sample, and divide this value by the L-citrulline recovery:

$$\frac{1200 \text{ cpm} - 80 \text{ cpm}}{0.9} = 1244 \text{ cpm}$$

NOS activity is usually expressed as picomoles of L-citrulline formed per minute per milligrams of protein. As an example, results from a typical assay performed with a cytosolic fraction of cytokine-activated murine macrophages are as follows:

Assay volume: 100 µl
Final concentration of L-arginine: 100 µM (amount per tube: 10,000 pmol)
Radioactivity of [^{3}H]L-arginine added: 67,000 cpm
Radioactivity of blank: 80 cpm
Radioactivity of sample: 1200 cpm
Recovery of L-citrulline: 90%
Amount of protein added: 0.14 mg.

14. Multiply this value by the amount of L-arginine per assay, and divide by the radioactivity of the [^{3}H]L-arginine added to obtain the amount of L-citrulline formed:

$$\frac{1244 \text{ cpm} \times 10{,}000 \text{ pmol}}{67{,}000 \text{ cpm}} = 186 \text{ pmol L-citrulline}$$

15. Divide this value by the incubation time and the amount of protein to obtain the specific NOS activity:

$$\frac{186 \text{ pmol}}{10 \text{ min} \times 0.14 \text{ mg}} = 133 \text{ pmol L-citrulline} \times \text{min}^{-1} \times \text{mg}^{-1}$$

PREPARATION AND REGENERATION OF DOWEX 50W CHROMATOGRAPHY COLUMNS

SUPPORT PROTOCOL 1

The strongly acidic cation exchanger Dowex 50W can be used to achieve a simple and efficient separation of L-citrulline from L-arginine. This protocol describes preparation of chromatography columns and regeneration of the resin.

Materials

Cation-exchange resin (Dowex 50W, H^+ form, 200 to 400 mesh, 8% cross-linked)
Chromatography columns (bed volume 1 to 2 ml, e.g., Poly-Prep columns from Bio-Rad)
Ethanol
0.5 M and 1 M NaOH
1 M HCl

1. Suspend 100 g cation-exchange resin in 500 ml water. Allow the resin to settle for 20 to 30 min and decant the supernatant. Repeat this procedure as follows:

Four times with 500 ml water
Twice with 200 ml ethanol
Twice with 200 ml water
Once with 500 ml 0.5 M NaOH
Once with 500 ml 0.5 M NaOH, preheated to ~80°C
Three times with 500 ml water
Twice with 500 ml 1 M HCl
Three times with 500 ml water.

2. Resuspend the resin in 100 ml water and pipet 1.5-ml aliquots of the suspension into chromatography columns.

   The final volume of the settled resin in the column should be 0.6 to 0.8 ml.

   With 100 g resin, 80 to 100 columns of 1- to 2-ml bed volume can be filled. The suspension of the resin can be stored with sodium azide (~0.02% w/v) at 4°C.

3. Wash columns three times with 3 ml of 1 M NaOH to transform the resin into the Na^+ form.

4. Before use, wash columns three times with 10 ml water.

   Chromatography columns are most conveniently used if they are mounted in racks with spacing identical to that of the racks of the scintillation vials to be used.

5. After each experiment, regenerate the resin by washing once with 3 ml of 1 M NaOH and store columns dry at room temperature. Repeat the treatment with NaOH once or twice a week until the next use of the columns (step 4).

   CAUTION: *NaOH wash is radioactive—pay attention to correct waste disposal!*

   According to experience, flow rates may be markedly reduced when columns are not reused within a few days. This problem can be avoided by treating unused columns with NaOH every few days (see Critical Parameters and Troubleshooting).

SUPPORT PROTOCOL 2

PURIFY [^{3}H] L-ARGININE BY HPLC

Commercially available batches of [^{3}H]L-arginine often contain radiolabeled impurities that will coelute with [^{3}H]L-citrulline on Dowex 50W cation-exchange columns. Because this results in high blank levels (up to 5%) and thus decreased sensitivity of the NOS assay, [^{3}H]L-arginine should be purified before use. This protocol describes a simple and efficient method of purifying of [^{3}H]L-arginine by HPLC that reduces blank levels in the NOS assay to 0.1% to 0.2 %.

Materials

HPLC system
50 mM sodium acetate buffer, pH 6.4 (*APPENDIX 2A*)
[2,3,4,5-^{3}H]L-arginine (100 µCi)
Scintillation cocktail
Methanol
HPLC column (Nucleosil 100 10 SA, 4 mm × 250 mm)

1. Equilibrate the HPLC column with 50 mM sodium acetate buffer (pH 6.4) for 2 to 3 hr (flow rate 0.1 ml/min). Before the run, increase the flow rate gradually to 1.5 ml/min.

2. Set up the fraction collector to obtain 20-sec (= 0.5-ml) fractions in plastic vials.

3. Inject 100 µl of the [2,3,4,5-^{3}H]L-arginine solution (100 µCi) onto the equilibrated column and start the fraction collector. Collect 50 fractions.

   Typically, the retention time of L-arginine is ~12 min, but it may increase to up to 25 min after prolonged use of the column.

4. Transfer 10 µl of each fraction into a scintillation counting vial, add 2 ml scintillation cocktail to each vial, and count radioactivity in a liquid scintillation spectrometer. Pool all fractions with a radioactivity of >100,000 cpm/10 µl, and store the solution at 4°C until use.

   IMPORTANT NOTE: *Solutions of ^{3}H-labeled compounds should not be stored frozen, as this will accelerate the exchange of ^{3}H with water.*

5. Wash the HPLC column at a flow rate of 0.1 ml/min for ~3 hr with 50 mM sodium acetate buffer (pH 6.4), then for 12 to 24 hr with Milli-Q-purified water.

   CAUTION: *Washing buffer is radioactive—pay attention to correct waste disposal!*

   If the column is not reused within the next few days, an additional wash with methanol (~1 hr) is recommended to avoid bacterial contamination of the resin. Before use, remove the methanol by washing the column for ~12 hr with Milli-Q-purified water.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer with [^{3}H]L-arginine

200 µl 500 mM triethanolamine/HCl, pH 7.4
200 µl 5 mM $CaCl_2$
100 µl 2 mM L-arginine
20 µl 1 mg/ml calmodulin
10 µl 1 mM FAD in 50 mM triethanolamine/HCl, pH 7.4
10 µl 1 mM FMN in 50 mM triethanolamine/HCl, pH 7.4
200 µl 2 mM NADPH in 50 mM triethanolamine/HCl, pH 7.4
20 µl 1 mM H_4biopterin in 0.01 N HCl
~1,000,000 cpm (50 to 150 µl) HPLC-purified [^{3}H]L-arginine (see Support Protocol 2)
H_2O to 1 ml
Prepare just before use

Stock solutions of triethanolamine/HCl (pH adjusted with 5 M NaOH), $CaCl_2$, L-arginine, and calmodulin can be stored indefinitely at –20°C. Stock solutions of FAD, FMN, NADPH, and H_4biopterin should be prepared daily.

HEPES-buffered salt solution

50 mM HEPES (free acid)
100 mM NaCl
5 mM KCl
2.5 mM $CaCl_2$
1 mM $MgCl_2$
Adjust pH to 7.4 with 5 N NaOH
Store up to 1 month at 4°C

Sodium acetate buffer with L-citrulline

Prepare a solution of 0.2 M sodium acetate and 10 mM L-citrulline. Adjust pH to 13.0 with 5 N NaOH and store up to 1 month at 4°C.

Sodium acetate buffer with EDTA

20 mM sodium acetate
2 mM EDTA
10 mM L-citrulline
Adjust pH to 5.0 with 5 N HCl
Store up to 1 month at 4°C

Triethanolamine buffer with EDTA

Prepare a solution of 50 mM triethanolamine hydrochloride and adjust the pH to 7.4 with 5 N NaOH. Add 0.1 ml of 0.5 M EDTA (*APPENDIX 2A*) per 100 ml buffer (0.5 mM EDTA final) and store up to 1 month at 4°C. Immediately before use, add 0.1 ml 2-mercaptoethanol per 100 ml buffer (12 mM final).

COMMENTARY

Background Information

NO is a widespread messenger molecule that regulates biological processes as diverse as blood vessel relaxation, neuronal cell-to-cell communication, and immune function (*UNIT 10.1*). It is formed enzymatically by three NOS isoforms, which differ in tissue distribution and mechanisms of regulation (Mayer and Hemmens, 1997; Stuehr, 1997). The endothelial (eNOS) and neuronal (nNOS) isozymes are constitutively expressed and activated by Ca^{2+}-dependent calmodulin binding, whereas the inducible isozyme (iNOS)—which is expressed after stimulation of cells with cytokines or endotoxin—is largely Ca^{2+} independent. Although differently regulated, all isozymes catalyze the same reaction, namely an NADPH- and O_2-dependent oxidation of L-arginine to form L-citrulline and NO. Accordingly, the catalytic activities of all NOS isoforms can be measured by monitoring the formation of either L-citrulline or NO.

In this unit, a radiochemical assay is described that is based on the conversion of [^{3}H]L-arginine to [^{3}H]L-citrulline to determine tissue activity of NOS. The earliest form of this assay was reported by Iyengar et al. (1987) and was used for sequential chromatography with Dowex 50W (Na^+) and Dowex 50W (H^+) columns (method adapted from Gopalakrishna and Nagarajan, 1980) for isolation of the product. Bredt and Snyder (1989) simplified the separation procedure to a single step with Dowex 50W (Na^+), which then became the standard method for separating L-citrulline from L-arginine. As demonstrated in this unit, the radiochemical assay can be used to determine NOS activity in both intact cells and broken cell preparations. Applied to intact cells, the method provides a rapid and sensitive measure for the responsiveness of the cells to external stimuli. The values obtained, however, are not measures of absolute NOS activity, because of the difficulty of controlling the intracellular concentrations of the substrates, cofactors, and Ca^{2+}. Therefore, the whole-cell assay cannot be used to compare directly the total NOS activity in different cell types. For a reliable assay of total NOS activity, cell or tissue extracts must be prepared.

Besides the radiochemical assay, several other techniques are available for determining NOS activity. In intact cells, for instance, accumulation of intracellular cyclic guanosine 5′-monophosphate (cGMP) can be used as biochemical marker for NO formation and thus NOS activity. This method is based on the stimulation of soluble guanylyl cyclase by endogenously formed NO and the determination of cGMP by radioimmunoassay (Schmidt et al., 1989, 1992). The assay is a highly sensitive detector of NO; but like the radiochemical assay in intact cells, it does not provide an absolute measure of NOS activities.

Another commonly used method for detecting NO is the oxyhemoglobin assay. This is based on the NO-induced conversion of oxyhemoglobin to methemoglobin, which can be monitored photometrically at 401 (Feelisch and Noack, 1987) or 577 nm (Murphy et al., 1991). The assay can be used to quantify both the release of NO from cells or tissues and the NOS activity in cell or tissue extracts. The sensitivity of this method is lower than that achieved with the radiochemical assay, and proper controls with a NOS inhibitor are required to account for the possible interference of superoxide or H_2O_2 (Winterbourn et al., 1976).

Tissue activity of NOS can also be monitored by measuring the accumulation of nitrite and nitrate in culture supernatants and body fluids. First, nitrate is reduced to nitrite (by either enzymatic conversion or reduction with metallic cadmium or zinc); then the total nitrite is measured via a diazotization reaction with the Griess reagent and photometric quantitation of the azo dye at 550 nm. Owing to its low sensitivity, the assay is not suitable for detecting eNOS and nNOS activity; but it represents one of the standard procedures for determining the tissue activity of iNOS.

Not described here are alternative, more sophisticated detection methods, including bioassays, fluorescent spectroscopy, EPR spectroscopy, chemiluminescence, and electrochemical techniques. For detailed descriptions of these methods see Key References for suggested reading.

Critical Parameters and Troubleshooting

Experiments with cultured cells

When working with cell monolayers, the major concern is to avoid detaching the cells from the substratum. The most critical step is the washing procedure, because parts of the monolayer may be washed away if the buffer is poured directly onto the cells. The best way to avoid damaging the monolayer is to pipet the

buffer slowly onto the wall of the well. Because most cells require divalent cations for attachment, dissociation of the monolayer may also be observed in Ca^{2+}/Mg^{2+}-free buffers. If experiments must be performed in Ca^{2+}-free buffer, it might help to increase the Mg^{2+} concentration to 2.5 to 10 mM. EGTA, a chelator with a pronounced Ca^{2+} preference, should used instead of EDTA. If dissociation of the monolayer is still observed, the dishes should be coated with polylysine before use. For coating, dissolve 5 mg polylysine in 50 ml Milli-Q-purified water and sterilize the solution by filtration (0.22-µm filter). Add 1 ml of this solution to each well, and leave the plates for 10 min at room temperature. Remove the solution (which can be reused for further coatings) and wash the dishes twice with sterile Milli-Q-purified water. Wait until the residual water has evaporated, and use the coated plates for cell culture.

Uptake of radiolabeled L-arginine and lysis of the cells after incubation are also critical parameters when determining NOS activity in intact cells. For the protocol described, the percentage of incorporated L-arginine should be in the range of 1% to 10%. One cause of low incorporation is the presence of (residual) L-arginine or other basic amino acids, which compete with radiolabeled L-arginine at the transport site. Apparently low incorporation of L-arginine may also result from incomplete lysis of the cells. According to the authors' experience with different types of cells (e.g., endothelial cells, macrophages, and neuronal cell lines), treatment with 0.01 N HCl is sufficient for complete cell lysis. The advantage of this method is that the cell debris remains attached to the wells so the supernatant can be applied onto the columns without further centrifugation. Because treatment with 0.01 N HCl might be insufficient for disruption of other cells, lysis should be checked by solubilizing the cells with 1 N NaOH after removing the HCl extract. If substantial radioactivity is found in the NaOH extract, more concentrated HCl (e.g., 0.1 N) should be used. For column chromatography, the pH of the sample should be between 5.0 and 5.5, so the ionic strength and the pH of the sodium acetate buffer and L-citrulline must be adjusted accordingly.

Preparation of cell and tissue extracts

Although NOS activity may vary slightly depending on culture conditions (e.g., medium composition, removal of serum prior to experiments, number of cells/well during the assay), these effects are usually only marginal and any standard culture conditions are generally acceptable.

Because NOS is very labile, temperature is the most critical parameter when preparing cell and tissue extracts. Accordingly, the materials required (such as buffers, homogenization tube, rotor, and centrifuge) should be precooled and all working steps performed in a 4°C cold room. During the homogenization, tubes should be placed in ice; and if the time required for cell rupture exceeds 15 to 20 sec, the procedure should be performed in intervals and samples recooled on ice to avoid any rise in temperature.

Several methods are available for cell rupture, but the efficiency of most techniques varies, depending on the type of cells or tissues used. The mild shearing forces generated by mechanical homogenizers are usually sufficient to disrupt intact tissues but may be inappropriate for an efficient homogenization of isolated cells. For most types of cells, sonication is the best alternative, but the efficiency of the treatment must be checked by microscopy. If incomplete homogenization is observed, increase the number of bursts but not their duration, because prolonged sonication will rapidly increase the temperature of the cell extract. Alternatively, a pressure homogenizer or a bead mill can be used to disrupt the cells.

NOS assay

In general, the authors perform the assay in the presence of 100 µM L-arginine, a concentration far above the K_M value of NOS, which allows a reliable determination of maximal enzyme activity. The use of such a high substrate concentration has the additional advantage of minimizing the interference of endogenous L-arginine present in homogenates and cytosolic fractions. When low NOS activities are expected, however, the concentration of unlabeled L-arginine should be reduced to 10 µM, which will increase the amount of [^{3}H]L-arginine that is converted to [^{3}H]L-citrulline and thus the sensitivity of the assay.

All isozymes require enzyme-bound H_4biopterin, FAD, and FMN for catalytic activity. These cofactors are usually present in sufficient amounts in intact cells but should be added to the incubation buffer when assaying NOS activity in cell or tissue extracts. If not available, one or more cofactors may be omitted, but their absence will reduce NOS activity to 30% to 50%. When iNOS is assayed, $CaCl_2$ and calmodulin can be omitted.

Column chromatography

Prolonged use or storage of the Dowex columns may result in decreased flow rates, usually caused by clogged column filters or air bubbles in the column bed. This problem can usually be avoided by washing the columns with 1 N NaOH once or twice a week to prevent drying of the resin and precipitation of protein in the column filter. If poor flow rates are observed, resuspend the resin with a spatula during the washing procedure to remove any air bubbles present in the column bed. To clean clogged filters, close the outlet of the columns and leave columns filled with 1 N NaOH for 2 to 4 hr. If flow rates are still slow, suck NaOH through the column by applying vacuum to the outlet.

Anticipated Results

The NOS family consists of three isoforms, which differ in enzymatic activity, mechanism of regulation, and cellular distribution. The endothelial isoform is a membrane-bound low-output NOS that is expressed primarily in vascular endothelial cells but also in epithelial cells and cardiomyocytes. Enzyme activity requires Ca^{2+}-dependent binding of calmodulin and is, therefore, regulated by changes in Ca^{2+} concentration. In intact endothelial cells (e.g., isolated from aortas or umbilical veins) conversion of [^{3}H]L-arginine to [^{3}H]L-citrulline will be in the range of 1% to 5% under control conditions and up to 40% upon stimulation of the cells with Ca^{2+}-mobilizing agonists (e.g., bradykinin, histamine, ATP, or Ca^{2+} ionophores). In broken cell preparations (e.g., homogenates or membrane fractions of endothelial cells) maximal enzyme activity will be in the range of 5 to 20 pmol L-citrulline $\times$ min^{-1} $\times$ mg protein^{-1}.

The neuronal isoform is a cytosolic low-output NOS that is expressed primarily in neuronal cells but also in skeletal muscle. Similar to eNOS, enzymatic activity of nNOS requires Ca^{2+}-dependent binding of calmodulin. In intact neuronal cells (e.g., N1E-115 neuroblastoma cells or 108CC15 neuroblastoma $\times$ glioma hybrid cells), conversion of [^{3}H]L-arginine to [^{3}H]L-citrulline will be in the range of 1% to 5% under control conditions and up to 30% on stimulation of the cells with Ca^{2+}-mobilizing agonists. In broken cell preparations (e.g., cytosolic fractions of porcine or rat brain) maximal enzyme activity will be in the range of 20 to 150 pmol L-citrulline $\times$ min^{-1} $\times$ mg protein^{-1}.

The inducible isoform is a cytosolic high-output NOS whose expression is induced by cytokines and endotoxins in virtually all mammalian cells. In contrast to the other isoforms, iNOS binds calmodulin Ca^{2+} independently and is, therefore, not regulated by changes in Ca^{2+} concentration. Accordingly, enzymatic activity of iNOS can easily be distinguished from that of eNOS and nNOS by performing parallel experiments in the absence and presence of Ca^{2+}. The highest activity of iNOS (200 to 700 pmol L-citrulline $\times$ min^{-1} $\times$ mg protein^{-1}) can be found in the cytosolic fraction of activated macrophages (e.g., isolated alveolar or peritoneal macrophages or cell lines J774 or RAW 264.7).

Time Considerations

Determination of NOS activity in intact cells (24 samples). The entire procedure can be done in ~2 hr plus the time required for liquid scintillation spectrometry. The assay takes ~30 min; cell lysis with HCl, ~1 hr; neutralization and transfer of the samples on the Dowex column, ~10 min; and elution of L-citrulline, ~20 min.

Preparation of cell or tissue extracts. The entire procedure can be done in 30 to 90 min. Homogenization takes ~10 min; centrifugation (optional), ~1 hr; and protein determination, ~20 min.

NOS assay (24 samples). The entire procedure can be done in ~1 hr plus the time required for liquid scintillation spectrometry. The assay takes ~30 min; transfer of the samples on the Dowex column, ~10 min; and elution of L-citrulline, ~20 min.

Preparation and regeneration of Dowex columns. Initial preparation of the columns (washing the resin, filling the columns, treating with NaOH) takes ~8 hr. Washing the columns before use takes ~2 hr, and regeneration of the resin takes ~30 min.

Purification of [^{3}H]L-arginine by HPLC. Equilibration of the HPLC column requires 2 to 3 hr, separation takes ~30 min, and washing the column requires 12 to 24 hr.

Detection of Nitrosated Proteins

Several methods have been used to analyze nitroso compounds: the Saville assay (Saville, 1958), spectrophotometric analysis, the quinine fluorescence quenching assay (Gabor and Allon, 1994), the diaminonaphthalene assay (Cook et al., 1996), chemiluminescence analysis, and mass spectrometry analysis. Among these methods, the Saville assay is the most widely used, because it is less sensitive to interference than are the fluorescence methods and because it requires only simple chemical reagents and a spectrophotometer. The diaminonaphthalene assay (a fluorescence method) and chemiluminescence analysis are the methods of choice when high sensitivity is required; their detection limits are 10^{-7} M and 10^{-8} M, respectively, which are 10 and 100 times more sensitive than for the Saville assay. Spectrophotometric analysis is mainly used for the structural characterization of nitroso compounds, but can also serve as a rapid method for estimating the -NO content of unknown samples. Mass spectrometry analysis is employed for precise structural analysis. This unit describes the Saville assay, spectrophotometric analysis, and the quinine fluorescence quenching assay (the diaminonaphthalene assay is discussed in *UNIT 10.4*). For discussion of the principles of chemiluminescence and mass spectrometry methods, which require special instrumentation, see Commentary.

SAVILLE ASSAY TO DETECT NITROSATED PROTEINS

BASIC PROTOCOL 1

The Saville assay is the most widely used method for detecting *S*-nitroso (S-NO) compounds. It was developed by Saville (1958) and is based on the nitrite detection method of Griess (1879). In the Saville assay, the mercuric ion (Hg^{2+}) substitutes for the -NO group in S-NO, and the released -NO (in the form of HONO) is subsequently detected by the Griess reaction, which involves diazotization with sulfanilamide (SN) and subsequent derivatization with *N*-1-(naphthyl)ethylenediamine dihydrochloride (NEDD). To distinguish the released HNO_2 from free nitrite in the sample, ammonium sulfamate (ASM) and HCl are added to the sample before the Hg^{2+} substitution reaction. ASM rapidly reacts with HNO_2 to form NH_3, N_2, and H_2SO_4 but does not affect *S*-nitrosothiol (RSNO) species. It also cannot compete with SN, which is added later to react with the HNO_2 produced after Hg^{2+} is substituted for -NO. SN forms a diazonium salt with HNO_2, which then couples to NEDD to form a purple-pink azo dye.

Although the detection limit of the Saville assay is 1 μM (the final concentration of *S*-nitroso compounds in the assay mixture), the initial -NO concentration must be >5 μM, because the sample is diluted a minimum of 5-fold in the assay (as in this protocol). To analyze samples of limited quantity, use a microtiter-plate assay in which the sample is diluted 2-fold in the assay and the total assay volume is 0.2 ml (see Alternate Protocol).

Materials

Sample to be tested (nitroso compounds, nitrosated proteins, cell homogenates)
100 μM $NaNO_2$ (freshly prepared)
0.5% (w/v) ammonium sulfamate (ASM; Aldrich) in water (store at room temperature; stable 1 year or more)
2 N HCl
Hg/sulfanilamide (Hg/SN) solution (see recipe)
N-1-(Naphthyl)ethylenediamine dihydrochloride (NEDD) solution (see recipe)

1. Add 0.4 ml water to two 10-ml test tubes for blanks. For standards, add 15, 30, 60, 120, 180, 240, and 300 μl of 100 μM $NaNO_2$ to 16 × 100–mm test tubes, and dilute with water to a final volume of 0.4 ml.

Contributed by Ying-Yi Zhang and Joseph Loscalzo
Current Protocols in Toxicology (1999) 10.3.1-10.3.8

The final concentration of the standards in the total assay mixture will be 1, 2, 4, 8, 12, 16, and 20 μM, respectively.

The standard curve is linear up to 40 μM. If needed, prepare the standards in the range of 2 to 40 μM using a 200 μM $NaNO_2$ solution. Do not use HNO_2 in place of $NaNO_2$. Once solubilized, HNO_2 slowly decomposes in water into H_2O and NO.

2. Add each unknown sample (up to 0.3 ml) to its corresponding test tube, and dilute with water to a final volume of 0.3 ml.

3. Add 0.1 ml of 0.5% ASM to the unknown sample tubes; mix well.

   Do not add ASM to the standards. See annotation to step 4.

4. Add 0.1 ml of 2 N HCl to all test tubes; mix. Wait 1 to 2 min.

   This step yields two different reactions. In the tubes with standards, HCl reacts with $NaNO_2$ to form HNO_2, which will react with SN and NEDD in step 5 to form a chromophore. In the tubes with unknowns, the HNO_2 formed from the reaction of HCl and free nitrite is removed by ASM (added in step 3). This reaction takes ~1 min. To avoid significant degradation of HNO_2 in the standards, do not let this incubation step exceed 3 min.

5. Add 0.5 ml Hg/SN solution and 0.5 ml NEDD solution to all test tubes; mix. Leave at room temperature 10 min.

   A purple-red color should be visible in the standards immediately after addition of the NEDD solution. Maximum color development occurs within a few minutes and is stable for at least 1 hr.

6. Read absorbance at 540 nm against blank.

7. Use the readings for the standards to prepare a standard curve, and calculate the actual concentration of each sample as follows: actual concentration = concentration read from standard curve × 1.5/sample volume (ml).

   N-Nitrosotryptophan releases NO slowly but spontaneously. It can, therefore, be detected by the Griess reaction used in the Saville assay if the reaction time (after addition of SN and NEDD) is extended to 30 min. In this case, the presence of $HgCl_2$ does not affect the detection of the nitroso group.

ALTERNATE PROTOCOL

MICROTITER-PLATE SAVILLE ASSAY TO DETECT NITROSATED PROTEINS

The basic steps in the microtiter-plate Saville assay are the same as those of the standard assay. The annotations in the standard assay (see Basic Protocol 1) apply equally to the steps in this protocol.

Additional Materials (also see Basic Protocol 1)

40 μM $NaNO_2$ (freshly prepared)
Hg/SN/NEDD solution (see recipe)

96-well microtiter plate
Microtiter plate reader

1. Devote two columns of wells on a microtiter-plate to blanks and standards by adding 0, 5, 10, 20, 40, 60, 80, and 100 μl of 40 μM $NaNO_2$ to wells A1 to H1, and the same volume to wells A2 to H2 for duplicates. Dilute with water to a final volume of 130 μl.

   The final concentration of the standards in the total assay mixture will be 1, 2, 4, 8, 12, 16, and 20 μM, respectively.

   Standards can be made up in the range of 2 to 40 μM using an 80 μM $NaNO_2$ stock solution.

2. Add up to 100 µl of each unknown sample to an empty well; dilute with water to a final volume of 100 µl. Set up wells containing unknown samples in duplicate or triplicate.
3. Add 30 µl of 0.5% ASM to the wells with unknown samples; mix well.
4. Add 30 µl of 2 N HCl to all wells; mix. Wait 1 to 2 min.
5. Add 40 µl Hg/SN/NEDD solution to all wells; mix. Incubate 10 min at room temperature.
6. Read absorbance at 540 nm or 550 nm with standard-cutoff filter. Use wells A1 and A2 as blanks to zero the instrument.
7. Use the readings for the standards to construct a standard curve, and calculate the actual concentration of sample as follows: actual concentration = concentration read from standard curve × 0.2/sample volume (ml).

SPECTROPHOTOMETRIC ASSAY TO DETECT NITROSATED PROTEINS

BASIC PROTOCOL 2

The nitroso group in nitrosocysteine and nitrosotryptophan generates chromophores that absorb at 300 to 350 nm. By analyzing the absorption spectrum and the intensity of absorption, one can determine both the structural characteristics of the nitroso group and the concentration of -NO in the sample. Spectrophotometric analysis is not sufficiently sensitive for concentration determinations in typical biological samples, owing to the low extinction coefficient of the -NO; detection requires a minimum sample concentration of 10 µM. Nitrosoproline has a low-intensity absorption peak at 343 nm and an extinction coefficient of 91 M^{-1} cm^{-1}. Thus it is not detectable by this protocol at concentrations <100 µM.

Materials

Appropriate reference solution (see step 4 annotation)
Sample to be tested

1. Set spectrophotometer to wavelength scan mode.
2. Take baseline of the blank.

   For example, if the sample contains GSNO, then the corresponding blank will contain glutathione. In this case, the glutathione reference solution should be scanned (the blank) before the sample solution is scanned.

3. Scan the absorption of the sample from 200 to 600 nm.
4. Read absorbance at the wavelength of maximum absorption.

   The critical step in this analysis is the preparation of the reference (blank), which greatly affects the interpretation of the sample spectrum. When the reference contains only water, the observed spectrum represents the sum of the absorption of all the components in the sample. When the reference contains the same solution components as the sample except for the nitrosated molecule of interest, the spectrum reflects the absorption of the nitrosated molecule. If the reference contains all sample components including the precursor molecule that is not nitrosated, the spectrum reflects -NO group absorption exclusively.

5. Calculate the concentration of nitroso equivalents in the sample by dividing the maximum absorbance by the extinction coefficient for the specific nitroso group.

BASIC PROTOCOL 3

QUININE FLUORESCENCE QUENCHING ASSAY TO DETECT NITROSATED PROTEINS

Quenching of fluorescence emission by a chromophore that absorbs at the wavelength of a fluorophore's excitation or emission is known as the inner filter effect (primary or secondary, respectively). Gabor and Allon (1994) developed a method that exploits the inner filter effect to measure -NO content. The fluorophore used is quinine sulfate, which has an absorption spectrum that overlaps with the absorption spectra of -NO in *S*-nitroso-cysteine and *N*-nitrosotryptophan. The sensitivity of the method is 1 μM; however, because the sample must be diluted in the assay solution 10- to 100-fold (depending on the interference of other components in the biological sample), the original sample concentration must be >10 μM.

Materials

Sample to be tested
100 μM *S*-nitrosoglutathione (GSNO) solution (see recipe)
10 μM quinine sulfate
0.1 M H_2SO_4

Spectrofluorometer
Cuvettes or microcuvettes

1. For standard curve measurements, prepare mixtures containing 1 to 20 μM GSNO and 0.1 μM quinine sulfate in 0.1 M H_2SO_4, in a final volume of 3 ml (standard cuvette) or 0.3 ml (microcuvette).
2. For each standard, excite solution at 334 nm and read emission at 453 nm using spectrofluorometer.
3. For sample measurement, prepare a mixture containing unknown sample (1% to 10% of final volume) and 0.1 μM quinine sulfate in 0.1 M H_2SO_4, in the appropriate final volume (as defined in step 1). Read fluorescence as described in step 2.
4. Plot the standard curve, and read the sample nitroso concentration from the curve.

Because the quinine assay is based on the inner filter effect, any molecule that absorbs light in the 300 to 500 nm range will interfere with the assay. Myoglobin, for example, absorbs at 300 to 450 nm; at 40 μg/ml; it reduces quinine fluorescence by 30%.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

GSNO solution

Mix equimolar concentrations of glutathione (Sigma) and $NaNO_2$ in 0.2 M HCl. Prepare fresh.

Hg/SN solution

0.25% (w/v) $HgCl_2$ (Sigma)
3% (w/v) sulfanilamide (Aldrich)
0.4 N HCl
Store at room temperature (stable 6 months or more)

CAUTION: *Hg^{2+} is toxic. Care should be taken not to contaminate the environment or one's hands. Sulfanilamide and $HgCl_2$ have limited solubility in H_2O; dissolve them in HCl directly.*

Hg/SN/NEDD solution

Prepare 0.4 % (w/v) $HgCl_2$ (Sigma) and 5% (w/v) sulfanilamide (Aldrich) in 0.4 N HCl, and store indefinitely at room temperature. Before use, add 20 mg NEDD (Aldrich) to 10 ml of the Hg/SN solution. Use immediately.

NEDD solution

0.1% NEDD (Aldrich)
0.4 N HCl
Keep in dark at room temperature (stable for a few days)
Discard when the solution becomes dark

COMMENTARY

Background Information

NO, NO metabolites (NO_2, N_2O_3, HNO_2, $ONOO^-$), and NO donor compounds react with proteins via three types of reactions: nitrosylation, nitration, and nitrosation. In nitrosylation reactions, NO coordinates with a metal ion in a protein to form a nitrosyl-metal complex, such as the nitrosyl-heme-Fe complex. In nitration and nitrosation reactions, a nitro (-NO_2) or nitroso (-NO) group covalently binds to an amino acid residue in a protein to form the corresponding nitroamino acid (such as nitrotyrosine) or nitrosoamino acid (such as nitrosocysteine). The likelihood of these reactions occurring in a specific protein depends on the structural characteristics of the protein and the particular NO species involved in the reaction. Thus a systematic examination of all possible reaction products is important for understanding the molecular mechanisms underlying various NO-mediated biological effects. This unit presents methods for detecting nitrosation of proteins.

Depending on the atom to which the nitroso group is attached, nitrosation is classified as *C*-, *O*-, *N*-, and *S*-nitrosation. Studies on model peptides have shown that nitrosation can occur on a cysteinyl thiol group (*S*-nitrosation); on a tyrosine phenol ring (*C*-nitrosation); or on a side-chain amine group in proline, tryptophan, arginine, lysine, glutamine, and asparagine (*N*-nitrosation). Because many of these nitrosation products are very unstable under physiologic conditions, only three nitrosoamino acids are commonly observed: *S*-nitrosocysteine, *N*-nitrosoproline, and *N*-nitrosotryptophan. The specificity of *N*-nitroso (N-NO) and *S*-nitroso (S-NO) detection is noted for each method. In addition to N- and S-specificity, the methods described in this unit are applicable to the detection of N-NO and S-NO groups in proteins and in other compounds. Thus when a biological sample is found to be nitroso positive, further structural analysis should be performed to identify the specific nitroso derivative.

Chemiluminescence

Chemiluminescence is defined as light emitted by a molecule in the course of a chemical reaction. NO generates light when it reacts with ozone by the following reaction sequence:

$$NO + O_3 \rightarrow NO_2^* + O_2$$
$$NO_2^* \rightarrow NO_2 + h\nu\ (590 - 2800\ nm)$$

Fontijin and colleagues (1970) built the first chemiluminescence detector to detect NO in air as an environmental pollutant. The sensitivity of the detector is quite high: 4 parts per billion (v/v, NO/air), corresponding to 1×10^{-13} mol/liter.

Chemiluminescence methods cannot be used to detect nitroso compounds directly, because NO must enter the reaction chamber in the gas phase. Several methods have, therefore, been developed to liberate the NO moiety from the nitroso compound in a gas form ($NO^\cdot$) and subsequently to detect it by chemiluminescence.

TEA (thermal energy analyzer)

The TEA was developed by Fine and colleagues (1975a) to detect N-NO compounds; it consists of a pyrolytic unit and a chemiluminescence detector. In the pyrolytic unit, the nitroso compound is vaporized with a flash of heat (300°C) and is homolytically cleaved in a catalytic pyrolyzer containing a mixture of WO_3 and $W_{20}\ O_{58}$. The sudden increase in thermal energy cleaves the molecule at its weakest bond. Because N-NO bonds generally have lower energy (10 to 50 kcal/mol) than the C-N, C-C, and C-H bonds (70 to 90 kcal/mol), they will be cleaved preferentially. The generated NO is carried by argon to the chemiluminescence detector for analysis. The TEA can detect nitroso compounds in the range of 10

pmol (1 μM in 10 μl), with a specificity of 100 μg/kg (nitroso compounds/total mass). Although it was originally designed to detect N-NO compounds, TEA can also detect S-NO, nitrosyl metal complexes, some nitroalkanes, nitrate esters, nitroaromatics, and inorganic nitrite and nitrate.

HPLC-TEA and GC-TEA

To improve the detection selectivity of the TEA, Fine and colleagues made two other instrumental modifications, which involve linking an HPLC unit (1976) or a gas chromatography (GC) unit (1975b) to the TEA. The GC-TEA was designed to detect volatile *N*-nitroso compounds and the HPLC-TEA nonvolatile compounds. In this instrument, the sample is first separated by HPLC and then enters the pyrolysis unit for liberation of $NO^{\cdot}$. Because both the carrier solvent and the nitroso molecule are vaporized during pyrolysis, the products leave the pyrolyzer in a vapor or gas form. The two cold traps (at 0° and −70°C)—in sequence after the pyrolyzer—condense the vapor first to liquid and then to solid, while NO is carried by argon into the chemiluminescence detector. The HPLC separation makes nitroso detection more selective; but it does not, of course, alter the sensitivity of TEA.

HPLC-photolysis-chemiluminescence

The solvent used in the HPLC-TEA-chemiluminescence instrument must be sufficiently volatile to be vaporized instantaneously to liberate NO efficiently; however, separation of biological samples is commonly performed in aqueous solution. Conboy and Hotchkiss (1989) developed a device that releases NO from nitroso compounds by photolysis at room temperature. The photolysis device, interfaced between an HPLC and a chemiluminescence detector, consists of a 3-m × 1-mm-i.d. borosilicate glass tube coiled around a 200-W mercury vapor lamp. The sample enters the glass coil after HPLC separation and helium purging (to remove O_2) and is then photolyzed by the energy provided by the UV lamp. The resulting NO is separated from the liquid matrix when passing through the two cold traps, after which it is carried by helium to the chemiluminescence detector for analysis.

Photolysis detects nitroso compounds (N-NO, S-NO), nitrosyl-metal complexes, and inorganic nitrite. The nitrite can be separated from nitroso compounds on HPLC. Without separation, the use of a 495-nm-cutoff filter can also eliminate interference from nitrite in the assay (Alpert et al., 1997). The detection limit of this method is 10 pmol (10 nM in 1 ml).

Denitrosation-chemiluminescence detection

The denitrosation-chemiluminescence method releases NO from nitroso compounds by chemical reaction and was developed by Downes and colleagues (1976) based on a denitrosation reaction. In this method, the nitroso compound is refluxed with hydrogen bromide in an acidic nonaqueous solution. The resulting nitrosyl bromide product, a gas, is carried by nitrogen to a tube containing silica heated at 350°C. The nitrosyl bromide is converted to $NO^{\cdot}$, which is then separated from the halogenated material in a cold trap and detected by chemiluminescence. The original method was later modified in several ways to distinguish thermal and acid-labile contaminants from N-NO compounds and to accelerate the analysis (for a review, see Walters, 1996). This method is still used for analysis of nitroso compounds in gastric fluid and has a detection limit of 10 pmol; it does not distinguish N-NO from S-NO compounds, because the latter can also be denitrosated by hydrogen bromide.

Mass spectrometry analysis

Mass spectrometry (MS) measures the mass of a molecule or fragments of a parent molecule in concert with the molecule's charge. The analysis is achieved by first ionizing the molecule in a gas phase and then differentiating the resulting ions according to their mass/charge ratio (*m/z*). Traditional mass spectrometers carry out the ionization step by thermal vaporization and electron bombardment, which is not suitable for proteins and thermolabile molecules, because these molecules cannot be transformed to the gas phase intact. To analyze nitrosoproteins, the mass spectrometer must be equipped with a milder ionization source, such as an electrospray ionization (ESI) or matrix-assisted laser desorption/ionization (MALDI) unit. The ionization process in the ESI unit is carried out by spraying the sample into a drying chamber through a high-voltage syringe tip; and in the MALDI unit, by desorption of the sample molecule from the sample/matrix crystal on a high-voltage metal surface with a UV laser beam. The ESI unit has the advantage of being able to interface with an HPLC-UV unit. Thus the products in a reaction mixture can be first chromatographically separated and then consecutively analyzed by ESI-MS.

NO has a relative mass of 30 Da. During nitrosation, a proton of a protein or peptide is

substituted by a -NO group; thus the mass increase of the nitrosation product will be 29 Da. MS also detects the results of other NO_x-dependent reactions, including nitration (mass increase of 45 Da) and oxidation of thiol groups (SH) into sulfonic acid groups (SO_3H) (mass increase of 49 Da). Several examples of the application of MS analysis to nitrosated peptides have been published (Mirza et al., 1995; Zhang et al., 1996; Lander et al., 1997). The S-NO bond in nitrosocysteine and the N-NO bond in nitrosotryptophan are weak bonds. Although ESI is used in the MS analysis, these bonds are still readily cleaved during ionization. Mirza and colleagues (1995) found that 50% of the S-NO bonds are cleaved at a drying gas temperature of 125°C and 100% cleaved at 200°C. The sensitivity of MS analysis is in the femtomole to picomole range.

Troubleshooting

The Saville assay and spectrophotometric analysis are straightforward and highly reproducible. In the Saville assay, if the color (pink to purple-red) is not visible after addition of all the reagents, the formation of HNO_2 in the standard tubes during Basic Protocol 1 step 4 should be confirmed. Two factors could account for lower HNO_2 concentrations in the standards than expected: (1) the pH of the $NaNO_2$ solution used in step 1 is below pH 5 or (2) there is a long delay between step 4 (addition of HCl) and step 5 (addition of Hg^{2+}/SN and NEDD). $NaNO_2$ is converted to HNO_2 in acidic solution, and HNO_2 decomposes gradually once formed. The freshness of the NEDD could also affect color development.

In the quinine fluorescence quenching assay, if HCl is used in place of H_2SO_4, the intensity of the standard emission peak is significantly reduced.

Anticipated Results

The lower limits of the Saville assay is 1 μM. With 1 to 20 μM nitroso species present in the assay solution, the corresponding absorption range is expected to be 0.05 to 1.00 OD units in the standard assay, and 0.02 to 0.40 OD units in the microtiter plate assay. Over this range of concentrations and absorptivities, the standard curve should be absolutely linear. The molar extinction coefficients of various low-molecular-weight nitroso derivatives range from 500 to 1200 cm^{-1} M^{-1}. For *N*-nitroso compounds, the molar extinction coefficients vary greatly between aromatic and nonaromatic derivatives. For example, the molar extinction coefficient for *N*-nitrosotryptophan at 335 nm is 7000 cm^{-1} M^{-1}; the molar extinction coefficient for *N*-nitrosoglutamine, by contrast, is 76 cm^{-1} M^{-1} at the same wavelength.

The concentration of nitrosoproteins in biological samples is reported to be in the micromolar range (Stamler et al., 1992; Upchurch et al., 1996), and the concentration varies with disease states (Hilliquin et al., 1997) and in different bodily fluids (Gaston et al., 1993). For example, Hilliquin and co-workers (1997) found that rheumatoid arthritis patients have an average serum *S*-nitrosoprotein concentration of 3.2 ± 2.3 μM, but their synovial fluid *S*-nitrosoprotein concentration is significantly higher at 10.1 ± 2.9 μM.

Time Considerations

When stock reagents are prepared, both the standard and microtiter-plate Saville assays take ~30 to 60 min. Dilution and pipetting of samples take 10 to 30 min to complete. Addition of the reagents requires ~10 min; color development and reading take ~15 to 20 min. The quinine assay, spectrophotometric analysis, and chemiluminescence analysis each requires 2 to 3 min for each sample reading.

Fluorometric Techniques for the Detection of Nitric Oxide and Metabolites

The explosion of interest in the biology of nitric oxide (NO) over the past decade has led to the development of different methods for detecting metabolites of NO under a variety of biological conditions. Numerous techniques, ranging from chemiluminescence to electron spin resonance (ESR), have been employed to evaluate this diatomic radical and other chemical intermediates associated with NO metabolism. The assay most widely used to determine the presence of NO is the measurement of nitrite (NO_2^-) via the classical Griess reagent method (Granger et al., 1996; *UNIT 10.3*). This takes advantage of the formation of a nitrosating species in acidified nitrite solutions that will react with sulfanilamide to form a diazonium adduct. The diazonium adduct then couples with *N*-(1-naphthyl)ethylenediamine dihydrochloride (NEDD) to form a colored azo dye. The absorbance of the resulting solution is read by a UV/VIS spectrophotometer. More recently, fluorometric techniques have been developed using similar nitrosation chemistry; these techniques provide improved sensitivity for nitrite determination (Miles et al., 1996, and references therein). Both fluorometric and colorimetric techniques to determine NO (Miles et al., 1996; Nims et al., 1995) and *S*-nitrosothiols (Cook et al., 1996) at neutral pH, using the same chemical reactions, have been devised. These are useful for numerous biological experiments, especially those concerned with temporal factors. This unit describes fluorometric techniques for the detection and quantification of NO, nitrosating

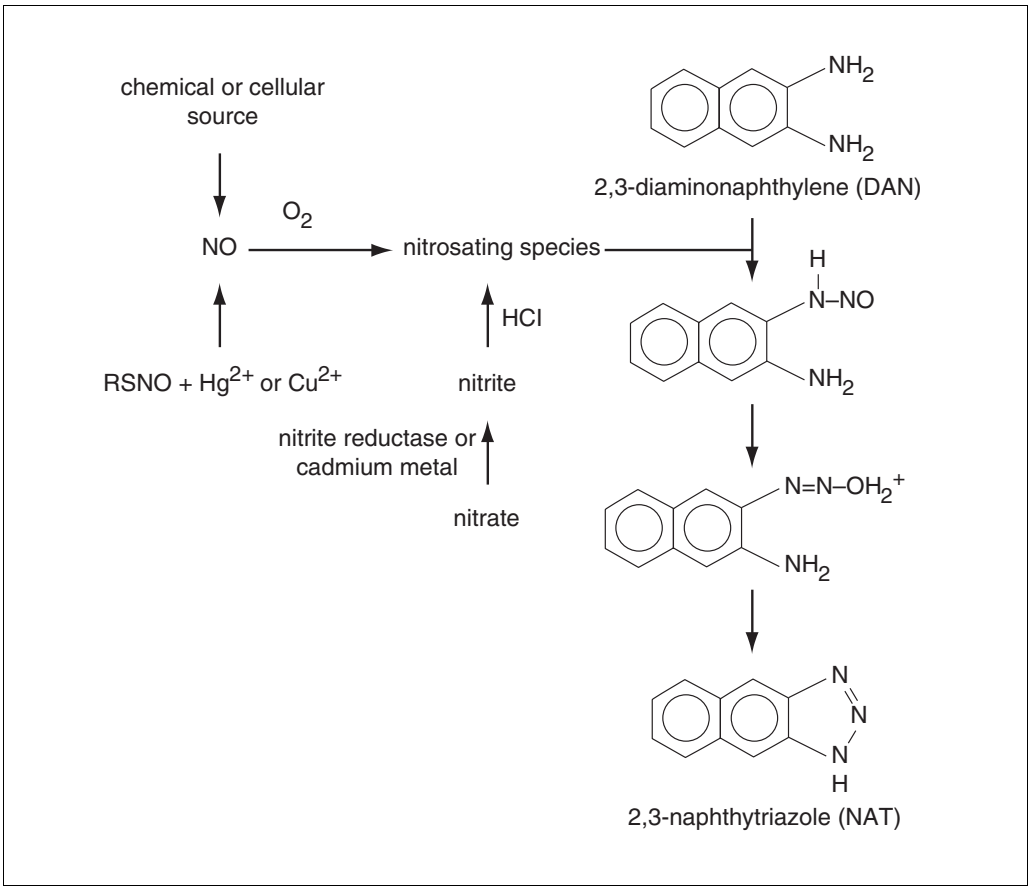

Figure 10.4.1 Reactions for analyzing nitric oxide.

Current Protocols in Toxicology (1999) 10.4.1-10.4.12

species, nitrite/nitrate (NO_3^-), and *S*-nitrosothiols in chemical, biochemical, and cellular experiments (Fig. 10.4.1).

This method involves the detection of nitrosating agents produced either chemically or from cellular sources. In the presence of oxygen, NO decomposes via an autoxidation reaction to form the nitrosating agent N_2O_3.

$$4\ NO + O_2 \rightarrow 2\ N_2O_3$$

The reactive intermediate can then be chemically trapped and will serve as a direct indication of the level of NO present. The reaction can be readily followed quantitatively over specified time intervals (Miles et al., 1996). The same chemical reactions can be used to detect *S*-nitrosothiol via a displacement reaction with mercury or copper (Cook et al., 1996). The fluorescence detection method described here employs the reactions whereby 2,3-diaminonaphthylene (DAN) is nitrosated to yield the fluorescent compound 2,3-naphthyltriazole (NAT; Fig. 10.4.2).

$$N_2O_3 + DAN \rightarrow NAT + NO_2^- + H^+$$

When NAT is excited with 375-nm light, it fluoresces with a maximum emission between 425 and 450 nm. For quantification, it is important to note, when calculating the amount of NO present, that one molecule of NAT is formed for every two molecules of NO (Miles et al., 1996). It is advised, however, that standard curves be prepared for all conditions.

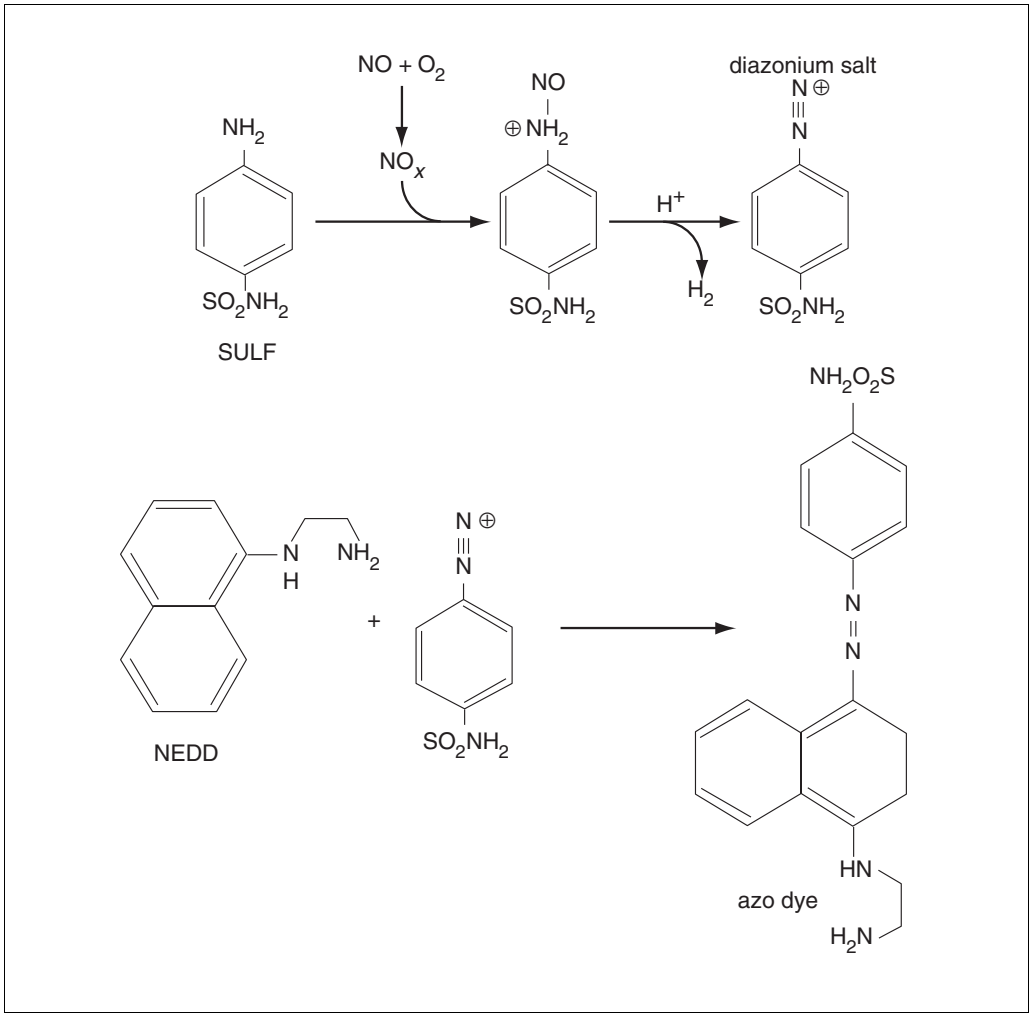

Figure 10.4.2 Reactions for chemically trapping reactive N_2O_3.

DETECTION OF NO FROM CHEMICAL REACTIONS

In the procedure that follows, DAN-containing solutions (prepared without reductants, phenol red, GSH, or vitamins, which may interfere with the assay) are exposed to either a chemical or a biological source of NO. The fluorescence is determined using a fluorometer with both excitation and emission slit widths adjusted depending on the desired sensitivity. Table 10.4.1 shows an approximate concentration range for each slit width. There is some variation among instruments, and the appropriate sensitivity level must be determined for each one.

One of the most useful aspects of this fluorescence technique is that it can be used to monitor the release of NO over the course of an experiment. For instance, one can readily determine the NO release profile over a specific time interval that results from exposing an NO-generating compound to a cell culture. This gives an indication of the temporal NO profile during the biological experiment. This protocol is a basic means of measuring NO released from different chemical or biochemical systems.

Materials

Cell culture medium with no phenol red or vitamins (see recipe)
2,3-Diaminonaphthylene (DAN)
Dimethyl formamide (DMF) or dimethylsulfoxide (DMSO)
20 to 100 mM sodium phosphate, pH 7.4 (*APPENDIX 2A*)
Nitrogen or argon gas
NO gas
Concentrated NaOH (1 or 10 M; *APPENDIX 2A*)
Sulfanilamide
N-(1-Naphthyl)ethylenediamine dihydrochloride (NEDD)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
NO-generating system to be tested

Fluorescent cuvettes (preferably quartz)
Airtight 100-µl syringe
NO gas cylinder
Fluorometer
Airtight syringe
Plastic tuberculin syringe
Syringe needles

1. Dissolve 15 mg DAN in either DMF or DMSO to give ~100 mM DAN stock solution.
2. Dissolve 200 µl DAN stock solution in 100 ml desired buffer to achieve a 0.2 mM DAN solution.

   Most common buffers can be used, such as Tris, HEPES, and PBS. Generally phosphate buffers with metal chelators such as diethylenetriaminepentaacetic acid (DETAPAC) are used.

Table 10.4.1 Relationship Between Fluorometer Slit Width and Concentration Range[a]

Slit width (nm)		Triazole concentration range (nm)
Excitation	Emission	
2.5	2.5	250-10,000
5.0	5.0	40-1500
10	10	10-40

[a]For Perkin-Elmer LS-50B.

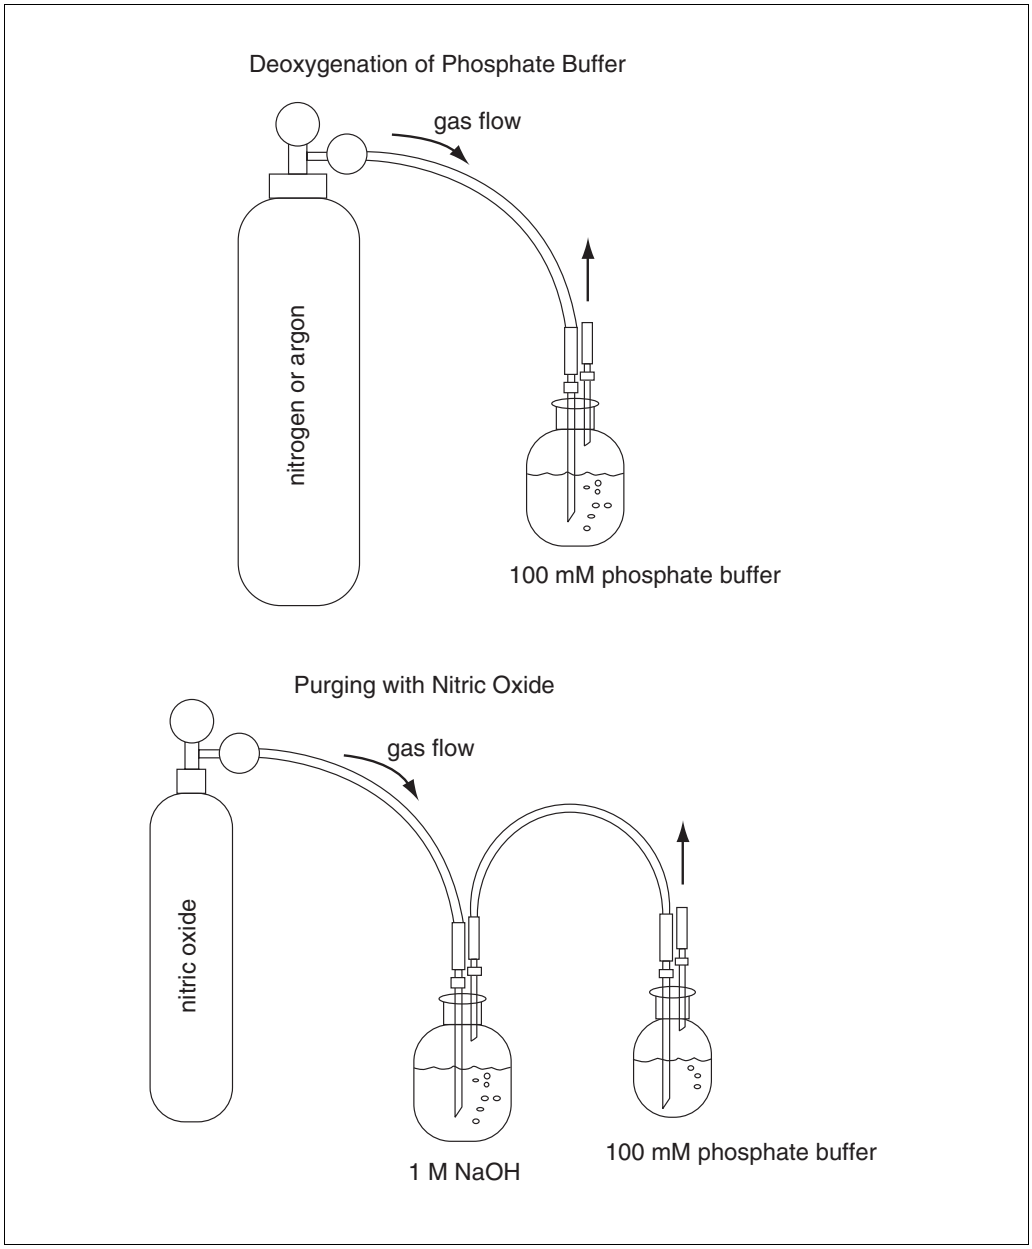

Figure 10.4.3 Apparatus used to degas buffer (top diagram) and prepare NO stock solution (bottom diagram). First degas the vial containing 100 mM sodium phosphate buffer solution by bubbling argon through the solution. Degas the solution 1 min for every milliliter of buffer. Remove the exhaust syringe needle first, then the inlet needle. The 100-mM buffer is now ready for introduction of NO. To prepare the NO-saturated phosphate buffer, connect Tygon tubing from an NO tank to a 6-in. needle (spinal tap needles are useful), and then cut a plastic 1-ml tuberculin syringe and insert into the end of the tubing. Place the needle on the tip. Fill a 500- to 1000-ml flask or bottle that can be fitted with a rubber septum halfway with 1 M NaOH. Place a rubber septum on the opening of the bottle. Stick the needle from the tank through the septum and into the solution, allowing NO to bubble through the solution. Then attach a piece of Tygon tubing to two modified plastic syringes, one with a 2-in. needle and one with a 6-in. needle. Stick the 2-in. needle through the septum into the NaOH solution container, keeping it above the level of the liquid to collect gas; stick the 6-in. needle through the septum into the container of degassed phosphate buffer. Vent the gas from the phosphate buffer into a hood using another 2-in. needle.

Compounds that absorb at wavelengths >350 nm, including phenol red, may interfere with this assay. Media should be prepared without phenol red and some vitamins.

3. To prepare NO stock solution, place 20 to 100 mM sodium phosphate, pH 7.4, in a vial with a rubber septum, and bubble nitrogen or argon through the buffer for 1 min per milliliter of buffer (a convenient setup for accomplishing this is shown in the top diagram of Fig. 10.4.3).

   The concentration should protect the solution from sudden changes in pH. Sometimes small exposure to oxygen will generate acid. A high buffer concentration prevents an acidic pH, which can nitrosate DAN, leading to potentially erroneous results.

4. Set up an apparatus to bubble NO gas first through 1 M NaOH and then through the degassed phosphate buffer (see the bottom diagram of Fig. 10.4.3). Bubble NO through this apparatus for 20 min.

   Alternatively, an NO donor, such as $[(C_2H_5)_2NN(O)NO]Na$ (DEA/NO), can be used to calibrate the fluorometric technique (Keefer et al., 1996). The solid is dissolved in 0.01 mM NaOH. Approximately 20 mg/ml will yield a 10-mM stock solution. To verify the exact concentration, take a UV/VIS spectrum of the base. The wavelength maximum at 250 nm has an extinction coefficient of 8000 M^{-1} cm^{-1}.

5. Prepare colorimetric assay solution (for standardizing the NO stock solutions or DEA/NO) by dissolving 0.5 g sulfanilamide and 30 mg NEDD in 100 ml PBS. Stir and gently heat; then filter if necessary through a 0.22- to 0.45-µm-pore-size paper or syringe filter.

   This colorimetric assay is as described by Nims et al. (1995, 1996).

6. Add a 100-µl aliquot of NO stock solution via an airtight syringe to 1 ml colorimetric solution. Allow to stand 2 min; then read the absorption at 500 nm using a UV/VIS spectrophotometer. Divide the absorbance reading by 0.012 to get the concentration of NO in the stock solution.

   Airtight syringes are required to reduce the exposure of oxygen to the NO solution. NO is unstable under aerobic conditions, and airtight syringes protect the NO from degradation before it is introduced to the colorimetric solution. To introduce the NO into the airtight syringe, first puncture the septa of the NO-saturated buffer; then draw the buffer into the syringe. Place the needle of the airtight syringe at the bottom of the air-exposed test tube that contains the colorimetric solution; then introduce the buffer.

   To standardize the amount of NO released by DEA/NO, add 10 µl to 1 ml colorimetric solution. Allow to stand at room temperature for 1 hr or at 37°C for 20 min. Read the absorption at 500 nM, and divide by 0.012 to get the amount of potential NO released by DEA/NO at neutral pH. The division accounts for the extinction coefficient and the 10× dilution. The maximum DAN concentration is 400 µM, which limits the amount of NO that can be detected. Under conditions in which large amounts of nitrosation occurs, the fluorescence intensity at 450 nm is saturated. To correct for this, simply shift to a wavelength >500 nm. This shift to a lower emission wavelength reduces the fluorescence reading per mole of NAT, providing a spectral region that will not go off scale. The lower the wavelength, the less sensitive the assay; therefore, systems that generate higher NO can be monitored. Remember to redo the standard curve at the new wavelength.

7. Add 1-, 2-, 5-, and 10-µM aliquots of NO stock solution to different test tubes via an airtight syringe to DAN solution. Allow to stand for 10 min at room temperature. To read fluorescence, excite the solutions at 375 nm and read the emission at 450 nm, to obtain a standard curve for the particular buffer or medium.

   Reducing agents such as NADPH, dithiothreitol (DTT), GSH, ascorbate, and 2-mercaptoethanol can interfere with this reaction. Be sure to obtain the standard curve with NO and the exact buffer system in which the experiment is conducted. Phenol red and vitamins also interfere with the assay and should be omitted.

8. Determine NO concentration in the NO-generating system of interest by adding 0.01 ml of the system to a tube containing 1 ml DAN buffer as described in step 6. Follow the reaction by exciting the solutions at 375 nm and reading the emissions at 450 nm.

Temporal experiments can be readily conducted to obtain real-time profiles of NO production.

BASIC PROTOCOL 2

DETECTION OF NO IN CELLULAR SYSTEMS

Basic Protocol 1 can be readily used to detect NO derived from cells (Miles et al., 1995, 1996) by testing the cell supernatant. Supernatants can be from almost any buffer system that does not contain vitamins or phenol red. Cells such as stimulated murine macrophages or rat neutrophils can generate considerable amounts of nitrite in a short period of time, which under some conditions can be detected by fluorescence methods. This protocol describes how to use the fluorescent technique to detect NO produced by cells.

Materials

Cells thought to produce NO
Cell culture medium (see recipe)
2,3-Diaminonaphthylene (DAN; see Basic Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Concentrated NaOH (1 or 10 M; *APPENDIX 2A*)

1. Plate cells at 0.2–1 $\times 10^6$ cells/ml in cell culture medium. Allow the cells to attach for 1 to 2 hr.

   Cytokines or other stimuli can be introduced at this time.

2. Place 0.2 ml of DAN stock solution in 100 ml of cell culture medium. Remove the full medium, and wash the cells with PBS twice. Remove the final rinse, and place the cell culture medium with DAN on the cells and incubate for the required time.

   IMPORTANT NOTE*: For long-term storage of the medium, filter it, but omit DAN from the buffer. Add DAN just before conducting the experiment. No phenol red should be present. Vitamins commonly added to media can also interfere.*

3. After cell incubation is complete, take between 0.5 and 1 ml of cell supernatant and add sufficient 10 mM NaOH to obtain a total volume of 2 ml.

   The volume can be adjusted if a plate reader is used.

4. To read fluorescence, excite the solution at 375 nm and read the emission at 450 nm.

   This may not be an effective method for detecting NO derived from cells that use low concentrations of NO, such as bradykinin-stimulated endothelial cells. However, cells that are stimulated to generate iNOS are potentially good candidates.

5. Generate a standard curve for the buffer or medium used to grow the cells, as described in the previous protocol (see Basic Protocol 1, steps 3 to 7).

BASIC PROTOCOL 3

DETECTION OF *S*-NITROSOTHIOLS

S-nitrosothiol complexes are important metabolites in the biology of nitric oxide. This method first removes the nitrosyl from *S*-nitrosothiol adducts by mercury or copper and then oxidizes it to form a nitrosating agent that readily reacts with DAN (Cook et al., 1996).

Materials

Mercuric chloride or copper sulfate
Dimethyl formamide (DMF) or dimethylsulfoxide (DMSO)

2,3-Diaminonaphthylene (DAN)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Glutathione
Sodium nitrite
Hydrochloric acid (HCl)
Cell extracts
Buffer samples

Rubber gloves
Fluorometer

1. Prepare a stock solution of 10 mM mercuric chloride in DMF or a 10 mM copper sulfate aqueous solution.

   CAUTION*: DMF/$HgCl_2$ solutions are highly toxic, and should be handled using rubber (not latex) gloves. Copper is less toxic; however, its sensitivity is considerably less.*

2. Prepare 0.4 mM DAN in PBS and add 1 vol of this solution to the sample.

   It is most convenient to use 1 ml of sample and 1 ml of 0.4 mM DAN.

3. Add 10 µl of either mercuric chloride or copper sulfate solution per 100 µl of sample. Allow the mixture to stand for 20 to 30 min at room temperature.

4. Dilute to 2 ml with PBS.

   Add buffer to reach the needed volume for the fluorometer. Volumes of 2 to 3 ml are generally required when using cuvettes; plate readers require less.

5. To prepare a standard curve, first generate *S*-nitrosoglutathione by mixing 33 mg glutathione with 6.9 mg sodium nitrite in 10 ml of 100 mM HCl. Allow the solution to stand 5 min at room temperature.

6. Dilute the solution 1:10 (0.1 ml to 1 ml) in PBS and read fluorescence on a UV/VIS spectrophotometer at 338 nm. Divide the absorbance by 0.09 to obtain the concentration of GSNO in the stock solution.

7. Take the stock solution and serially dilute it in PBS so that the GSNO concentrations range from 0.1 to 10 µM in the same final volume (the same volume as for the sample) and read fluorescence.

   This provides an approximation of the total amount of S-nitrosothiols in the sample.

DETERMINATION OF NITRATE BY FLUORESCENT TECHNIQUES

BASIC PROTOCOL 4

As discussed, acidified nitrite produces a powerful nitrosating agent, which can be trapped by different aromatic amines such as DAN. Nitrate can also be quantified by fluorescent methods, but only after enzymatic or cadmium pellet reduction. Kits are currently available for the enzymatic reduction of nitrate to nitrite. This section describes a protocol involving the nitrosation of DAN. Samples to be tested can be derived from biochemical, cell culture media, or in vivo fluid samples.

Materials

Hydrochloric acid (HCl)
Sample to be tested
2,3-Diaminonaphthylene (DAN)
Concentrated NaOH (1 or 10 M; *APPENDIX 2A*)
5000 U/ml lactate dehydrogenase (Sigma) diluted 1:10 in phosphate-buffered saline (PBS; *APPENDIX 2A*)
100 mM sodium pyruvate
Hydrogen peroxide

100 U/ml GSH peroxidase (Sigma)
10 U/ml *Aspergillus nitrate* reductase
Flavin adenine dinucleotide (FAD)
β-Nicotinamide adenine dinucleotide phosphate (NADPH)

1. Prepare 0.2 mM DAN in 1 N HCl.
2. Add 0.9 ml of sample to 1 ml DAN/HCl and allow the solution to stand for 2 min.
3. Add 100 µl of 10 N NaOH.
4. To read the fluorescence, excite the solution at 375 nm and read the emission at 450 nm.

   A standard curve containing nitrite can be produced by diluting various concentrations of nitrite (from 0.1 to 20 µM) in PBS and repeating steps 1 to 3. Plot nitrite concentration versus fluorescence to obtain the standard curve.

5. If the sample medium or buffer contains >10 µM NADPH or GSH, remove them by the following methods: to oxidize NADPH, add 10 µl lactate dehydrogenase in PBS and 1 µl of 100 mM pyruvate per 1 ml sample. To eliminate GSH, add 10 mM hydrogen peroxide and 5 µl of 100 U/ml GSH peroxidase and incubate 10 min. Then add DAN/HCl as in step 2.
6. Prepare a 1 mM solution of FAD and a 10 mM solution of NADPH. To 1 ml sample, add 10 µl *Aspergillus nitrate* reductase*, 5* µl of 1 mM FAD, and 3 µl of 10 mM NADPH. Incubate 30 min at 37°C.

   The sample size can be changed as long as the proportion of milliliters to liters is maintained.

   Nitrate determination uses reduction by Aspergillus nitrate reductase (1000 U/ml; Grisham et al., 1996).

7. Add 20 µl of 5000 U/ml lactate dehydrogenase and 1 µl of 100 mM sodium pyruvate and let sit 5 min. Add 1 ml DAN/HCl solution, as described in step 2, and proceed to step 4 to obtain a reading without the NADPH and GSH.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cell culture medium

Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing:
10 mM HEPES, pH 7.4
20 mM glucose
4 mM glutamine
1 mM L-arginine
50 U/ml penicillin
50 U/ml streptomycin
Store up to 7 days at 4°C

The medium must be prepared without phenol red, as this and any other compound that absorbs at wavelengths >350 nm (such as some vitamins) will interfere with the assay. The medium should not contain serum, because it will interfere with the fluorometric assay. Solutions containing either colorimetric components or DAN can be stored at room temperature for several days. The medium should be stored in the refrigerator without DAN or the colorimetric components.

COMMENTARY

Background Information

The protocols described here provide a fluorescence method for the determination of nitrosation chemistry—which serves as an indicator of the presence of nitric oxide from either chemical, biochemical, or cellular sources—as well as the determination of *S*-nitrosothiol complexes. The protocols use the specificity of the nitrosation of 2,3-diaminonaphthylene (DAN) to yield a fluorescent triazole (Fig. 10.4.2). Although not a direct method of detecting NO, this is a sensitive indicator of its presence at neutral pH. Basic Protocol 4 was specially designed to detect NO derived from cells.

The basic principle underlying the method is that the generation of nitrosating agents at neutral pH involves the formation of nitric oxide. This can be useful for real-time quantification of NO produced from different sources. For instance, NO released from NO donors, such as NONOates, can result in nitrosative chemistry (Wink et al., 1997). As seen in Figure 10.4.4, 10-, 20-, 50-, and 100-μM samples of DEA/NO release NO over a 1-hr period, indicating the formation of NO, which then further reacts.

Critical Parameters and Troubleshooting

When starting to compare different sources of NO in the presence of a substance such as superoxide, NO may be produced, but nitrosation may be limited (Miles et al., 1995; Wink et al., 1997). Therefore, if NO is being produced, nitrosation chemistry may be diverted. If the presence of superoxide is suspected, then add superoxide dismutase (SOD) at 0.2 mg/ml. As shown in Figure 10.4.5, nitrosation is suppressed in the presence of superoxide. The addition of SOD readily restores the nitrosation. When doing cell culture experiments, be sure that SOD does not harm the cells.

Other substances that can limit the assays are sodium azide, dithiothreitol, 2-mercaptoethanol, and ascorbate. To test whether any of these substances are a problem in a medium, obtain a simple standard curve using NO-saturated aqueous solutions or NO donor drugs,

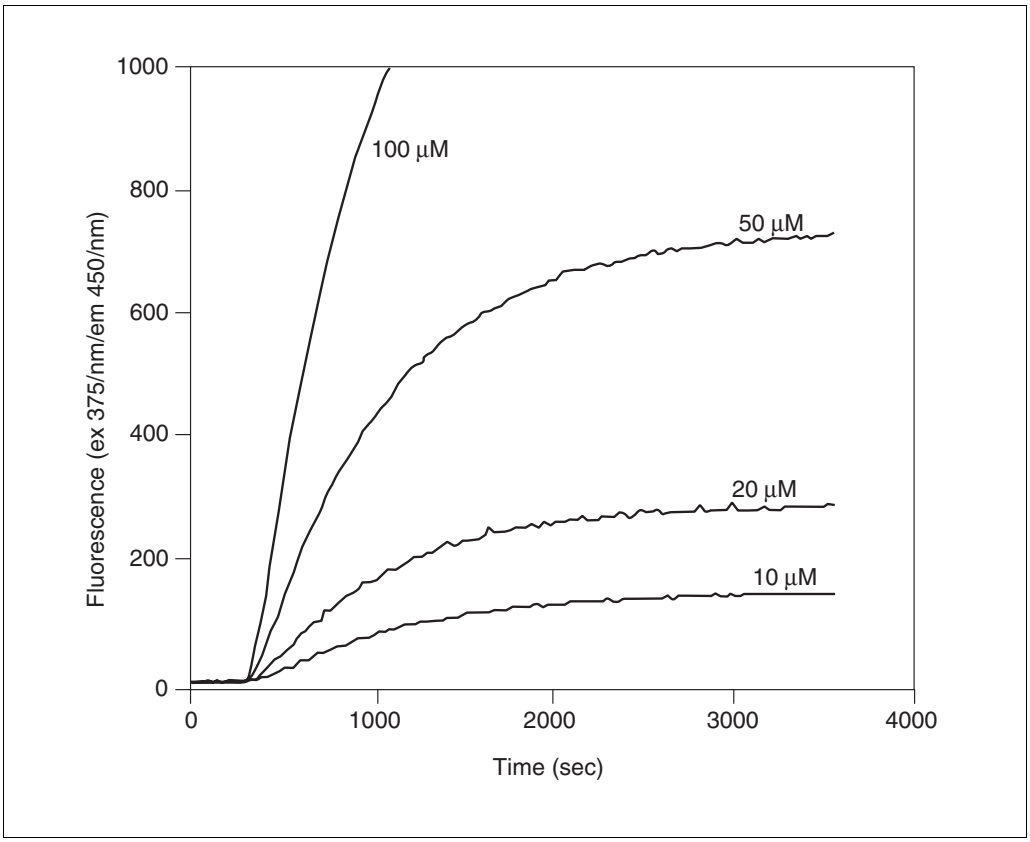

Figure 10.4.4 The formation of NAT is mediated by different concentrations of the NONOate DEA/NO in PBS buffer at room temperature.

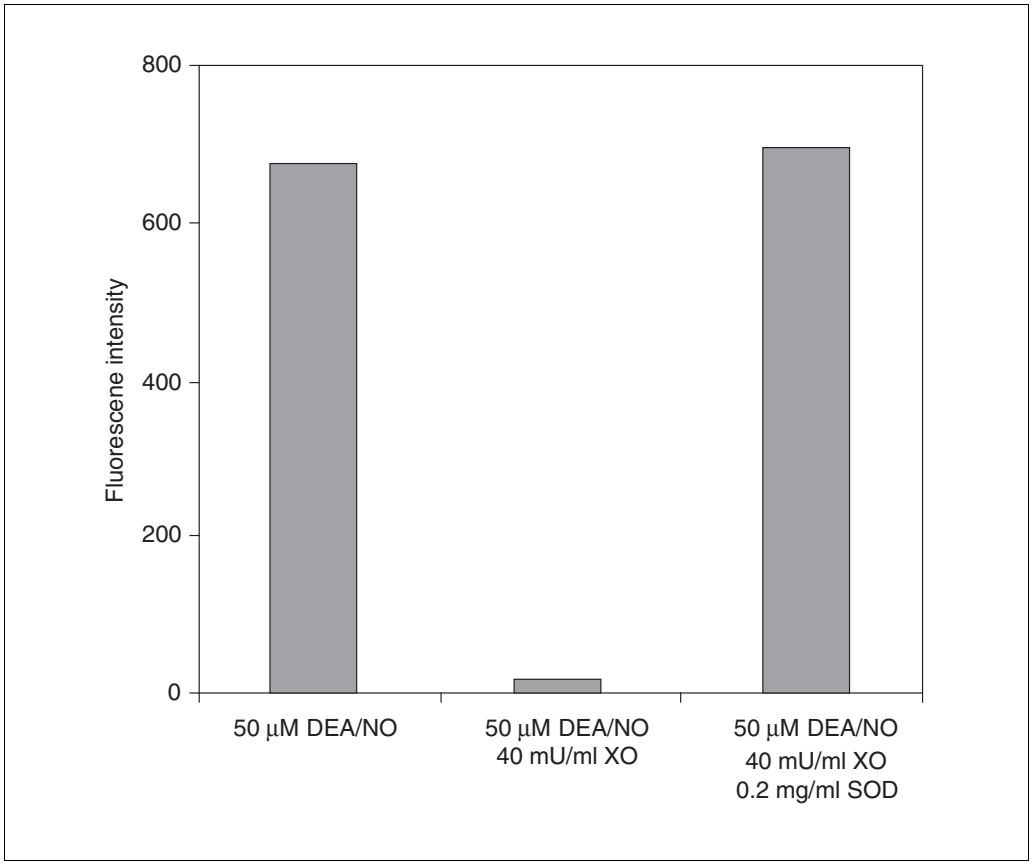

Figure 10.4.5 The effect of superoxide on nitrosation reaction by NO sources; data reported in Wink et al. (1997). The PBS buffer solution included 10 mM HEPES, 0.1 mM DETAPAC, and 0.5 mM hypoxanthine. The solutions were incubated for 1 hr at 37°C.

such as DEA/NO. Another possible source of interference is heme proteins, such as oxyhemoglobin. Heme proteins at concentrations >10 μM can interfere by creating a filter effect or by scavenging NO directly. Using NO gas or NO donors can be a reliable method.

Determining of *S*-nitrosothiol takes advantage of the fact that mercury or copper ions can readily displace NO from these adducts (Cook et al., 1996). NO is oxidized by O_2 to N_2O_3, which then nitrosates DAN. The mercuric salts are very toxic, and extreme care should be taken when handling them. Like low-molecular-weight *S*-nitrosothiol, protein *S*-nitrosothiol can be readily detected; however, BSA and other proteins are not as sensitive as low-molecular-weight *S*-nitrosothiol (Cook et al., 1996). The level of protein *S*-nitrosothiol indicates the lower limit of the actual concentration of total *S*-nitrosothiol. Colorimetric assays have also been described for these procedures (Cook et al., 1996).

Cellular determination of NO via nitrosative chemistry can be readily done using media without phenol red. Dulbecco's minimum essential medium (DMEM; Sigma) without phenol red and with L-arginine and glucose, is a good medium in which to monitor nitrosation for 24 hr (Miles et al., 1995). Under optimal conditions, 500,000 cells per 1 ml medium will give ~0.8 μM NAT in 4 hr. At slit widths of excitation/emission at 5/5 or 2.5/2.5 nm, the reading is significant. Murine macrophages that have been stimulated by interferon (INF) and lipopolysaccharide (LPS; Fig. 10.4.6) or rat neutrophils stimulated with phorbol esters generate detectable nitrosation for 4 to 8 hr after treatment.

Nitrite and nitrate can also be determined using the DAN fluorescence assay. In acidic solutions nitrite can readily nitrosate DAN. The addition of a 1 N HCl solution containing 0.2 mM DAN readily nitrosates DAN with any nitrite. There is a potential of interference from NADPH or GSH, which is a problem for experiments in which biochemical assays such as NOS are used and when nitrate is converted to nitrite via nitrite reductase. The addition of lactate dehydrogenase for 5 min readily converts these proteins. It is important to obtain standard curves each time, to ensure that the

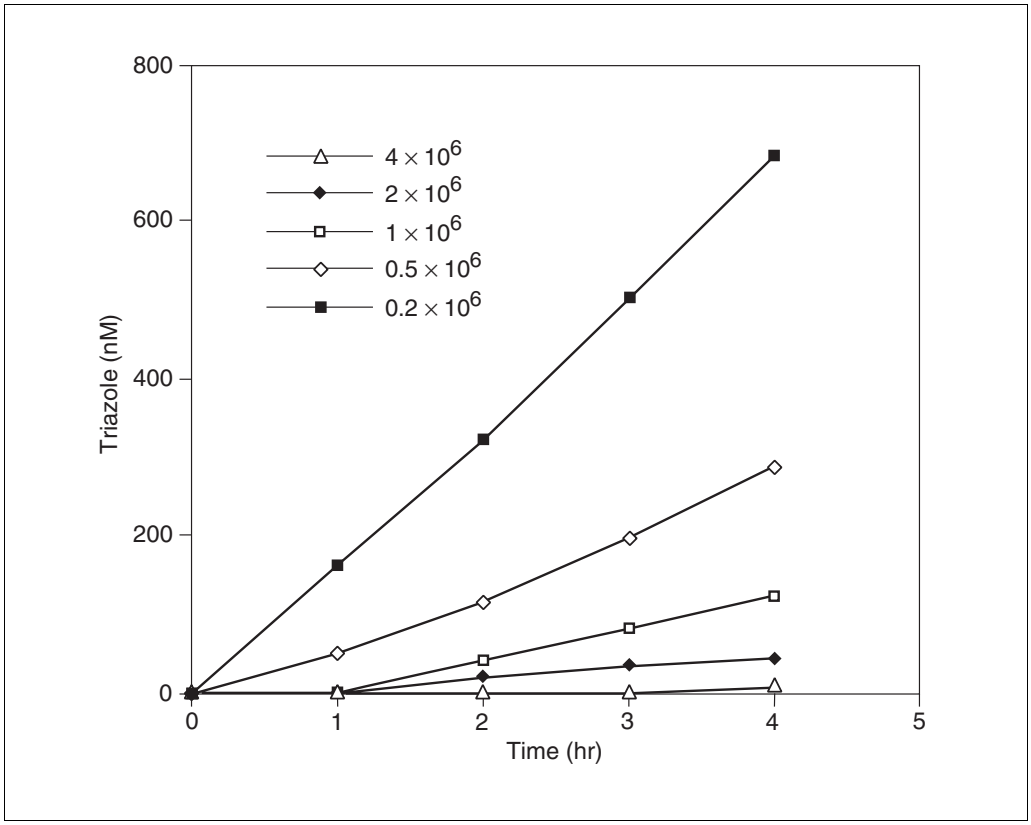

Figure 10.4.6 Nitrosation of DAN by different cell densities of RAW macrophages. Macrophages were plated in 10-cm dishes and treated overnight with interferon-γ. LPS was then added for 4 hr. The cells were rinsed, and the medium was replaced with 10 ml DMEM containing 0.2 μM DAN, 20 mM HEPES, 4 mM glutamine, 10 mM glucose, and 1 mM L-arginine.

specific experimental conditions do not interfere with the assay.

The protocols described here provide several methods for determining a variety of metabolites of NO. Although these protocols measure the analyte indirectly through nitrosating agents, they provide a good indication of the presence of NO metabolism. These protocols may need to be modified to fit the particular experiment being conducted.

Anticipated Results

The detection limit of the DAN assay is about 10 nM; however, some of the procedures described here require dilutions of 10 to 100 times, reducing sensitivity. A typical experimental detection limit ranges from 50 nM to 200 μM. Nitrosation from cell cultures has a lowest detection limit of 50 nM, and the detected nitrite concentration may be as low as 10 nM. Be sure to check for and subtract any background nitrite. The limits of detecting NO from donors and *S*-nitrosothiol range from 50 nM to 100 μM. Again, the sensitivity is determined by the type of dilution made.

Time Considerations

The assays described in this unit are not in themselves time consuming, taking 1 hr or less to perform. However, preparation and treatment of the cells prior to making these measurements may take variable amounts of time.

Measurement of cGMP and Soluble Guanylyl Cyclase Activity

Guanosine 3′,5′-cyclic monophosphate (cGMP) was originally identified more than three decades ago, but little headway was made in elucidating its physiologic role(s) until it was established that the synthesizing enzyme, soluble guanylyl cyclase, could be activated by nitric oxide (NO; Waldman and Murad, 1987) and that NO mediated the cGMP response to excitatory amino acid receptor activation in the brain (Garthwaite et al., 1988). Since then, the ideas that NO is an important intercellular messenger molecule and that soluble guanylyl cyclase is its best characterized target have gained wide acceptance (Mayer et al., 1993). Thus measurement of tissue cGMP levels and soluble guanylyl cyclase activity have become important tools in the investigation of the NO-cGMP signal transduction pathway. Methods for both are described in this unit. cGMP levels may be determined either ex vivo or in tissues that have been maintained in vitro. Guanylyl cyclase activity may be estimated for both crude and purified enzyme preparations.

For measuring the cGMP content of tissues, radioimmunoassay (RIA) is the method of choice (Steiner et al., 1972; see Basic Protocol 1). This technique has recently been simplified by the introduction of scintillation proximity assay (SPA) technology (see Alternate Protocol 1). Two approaches are generally used to determine the activity of soluble guanylyl cyclase. In the first, unlabeled (cold) guanosine 5′-triphosphate (GTP) is the substrate, and the cGMP formed is measured by RIA (Troyer et al., 1978; see Basic Protocol 2). In the second, the conversion of radiolabeled substrate ([α-^{32}P]GTP) to product ([^{32}P]cGMP) is monitored (Schultz and Böhme, 1984; see Alternate Protocol 2).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (see *APPENDIX 1A*).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to government regulations regarding the care and use of laboratory animals.

DETERMINATION OF TISSUE cGMP LEVELS BY RIA

BASIC PROTOCOL 1

This technique is based on the competition for binding to cGMP antiserum between a known concentration of [^{3}H]cGMP and the unlabeled cGMP contained within samples. Therefore, after the removal of unbound radiolabeled ligand and the addition of scintillant, the counts per minute (cpm) will be inversely proportional to the concentration of cGMP in the sample.

Tissue maintained in vitro is inactivated by plunging it into a small volume of boiling hypotonic homogenization buffer (aiming for a protein concentration of ~1 mg/ml) contained in a microcentrifuge tube and heating it for 3 to 5 min. Alternatively, the cGMP content of tissues may be determined ex vivo after rapidly removing and freeze clamping. Most tissues possess quanylyl cyclase activity, but liver and brain are particularly good sources of the soluble isoform.

NOTE: A cGMP RIA kit containing [^{3}H]cGMP, antiserum, cGMP standards, 10 µM cGMP, and ammonium sulfate solution is commercially available (Amersham).

Contributed by Eric Southam

Current Protocols in Toxicology (1999) 10.5.1-10.5.8

Materials

Tissue to be analyzed
Tris/EDTA buffer: 50 mM Tris/4 mM EDTA, pH 7.6 (prepare from Tris base and EDTA, and adjust pH with 1 M HCl)
~5.9 kBq/ml [^{3}H]cGMP (Amersham)
Rabbit antiserum specific for cGMP (raised according to the method of Steiner et al., 1972)
80, 40, 20, 10, and 5 nM unlabeled cGMP (standards)
10 µM cGMP (for determining nonspecific binding)
0.39 g/ml ammonium sulfate [$(NH_4)_2SO_4$], ice cold
Water-compatible scintillation fluid

Probe sonicator
Aspirator (a narrow-gauge syringe needle attached to a vacuum line works well)

Prepare soluble cGMP-containing fraction

1. Homogenize the tissue by sonication in Tris/EDTA buffer, pH 7.6.
2. Remove an aliquot of homogenate (e.g., 50 µl) for protein determination by standard methods. Centrifuge the remainder 5 min at 10,000 × *g*, room temperature, and then determine the cGMP content of the soluble fraction.

Perform the RIA

3. Place 50 µl of [^{3}H]cGMP, 100 µl of sample, and 50 µl of rabbit anti-cGMP antiserum into an appropriate number of 1.5-ml microcentrifuge tubes. For total counts, nonspecific binding, and standards, set up tubes in similar fashion in which the 100 µl of sample is replaced with 100 µl of either Tris/EDTA buffer, 10 µM cGMP, or standard dilutions of cGMP, respectively. Perform each determination in duplicate.
4. Vortex mix each tube and incubate ≥1.5 hr on ice.

   There is no disadvantage to overnight incubation, as long as all tubes are treated indentically.

5. Precipitate bound [^{3}H]cGMP by adding 1 ml ice-cold 0.39 g/ml ammonium sulfate. Vortex mix, and leave 5 min on ice.
6. Centrifuge 75 sec at 10,000 × *g*, 4°C.
7. Aspirate the supernatant, which contains unbound [^{3}H]cGMP; dissolve the precipitate by adding 1 ml distilled water and vortex mixing.

   From this stage on, tubes can be safely left at room temperature.

8. Transfer 950 µl of the resuspended precipitate to a scintillation vial, and add 10 ml scintillation fluid. Mix thoroughly.
9. Count for 5 min in a scintillation counter.

Calculate results

10. Subtract nonspecific binding from all of the other counts. Then calculate, for each standard or sample cGMP concentration, the fraction C_0/C_x, where C_0 = total counts and C_x = counts for the standard or sample.
11. To obtain the standard curve, plot C_0/C_x on the ordinate against standard concentrations of cGMP (0.5 to 8.0 pmol/100 µl) on the abscissa.

    The resulting curve is a straight line that intercepts the ordinate at 1.0 and is, therefore, described by equation:

$$C_0/C_x = (\text{slope} \times \text{cGMP concentration}) + 1$$

12. To determine unknown cGMP concentrations, rearrange the equation:

$$\text{cGMP concentration} = \frac{(C_0/C_x - 1)}{\text{slope}}$$

13. The resultant cGMP concentration has the units picomoles of cGMP per 100 µl; divide by the protein content of 100 µl of homogenate to arrive at a tissue concentration measured in picomoles per milligram of protein.

DETERMINATION OF TISSUE cGMP LEVELS BY SCINTILLATION PROXIMITY ASSAY

ALTERNATE PROTOCOL 1

Like RIA, this procedure is based on competition between a known concentration of [^{3}H]cGMP and unlabeled sample cGMP for binding to cGMP antiserum; results are calculated as for the RIA. Unlike in the RIA, the scintillant is contained within microspheres that bear anti-rabbit antibodies on their surface (SPA antibody binding beads). This means that only the [^{3}H]cGMP bound to antibody—which itself becomes bound to the fluomicrospheres—will be in close enough proximity to the scintillant within the spheres to generate a signal. There is, therefore, no need to separate bound radiolabeled ligand from unbound.

Additional Materials *(also see Basic Protocol 1)*

Anti-rabbit SPA antibody binding beads (fluomicrospheres, Amersham)
96-well microtiter plate and sealer (e.g., T-tray, Wallac)
β-plate scintillation counter

1. Dispense 50 µl of [^{3}H]cGMP, 100 µl of buffer, standards, or sample (see Basic Protocol 1, step 3), and 50 µl of rabbit anti-cGMP antiserum into each well of a 96-well plate.
2. Add 50 µl of fluomicrospheres to each well. Seal the plate and mix.

   The manufacturer recommends a 3-hr incubation at room temperature, but experience has proved this to be unnecessary.

3. Count for 5 min using a β-plate scintillation counter.
4. Calculate cGMP binding activity (see Basic Protocol 1, steps 10 to 13).

SOLUBLE GUANYLYL CYCLASE ASSAY USING RIA TO QUANTIFY cGMP PRODUCT

BASIC PROTOCOL 2

In this assay, based on the method of Troyer et al. (1978), the quantity of cGMP product formed from GTP substrate by soluble guanylyl cyclase, maintained at 37°C, is measured by RIA (or SPA). This method is suitable for either crude or purified enzyme preparations. Crude soluble guanylyl cyclase is prepared simply as described here. Typically, liver or brain tissue is used for the preparation of a crude enzyme extract. The enzyme may be purified to homogeneity as described elsewhere (Mülsch and Gerzer, 1991).

Materials

Animals whose tissues are to be analyzed
Tris/DTT buffer, ice cold: 10 mM Tris/1 mM dithiothreitol, pH 7.4 (prepare with Tris base and adjust pH with 1 M HCl; *APPENDIX 2A*)
Reaction buffer containing unlabeled GTP (see recipe)
0.1 M EDTA (*APPENDIX 2A*)
Motorized homogenizer, 4°C
Refrigerated centrifuge capable of 48,000 × *g*

Prepare a crude enzyme extract

1. Quickly remove tissue and immerse it in ~10 vol ice-cold 10 mM Tris/DTT buffer, pH 7.4, aiming for a final protein concentration of <10 mg/ml.
2. Thoroughly homogenize (~15 sec, high power) using a prechilled motorized homogenizer, 4°C.
3. Centrifuge 30 min at 48,000 × *g*, 4°C.
4. Decant the soluble fraction and keep on ice until used, or divide into aliquots and snap freeze in liquid nitrogen for long-term storage at −70°C.

Perform the enzyme assay

5. Dispense 150-µl aliquots of reaction buffer containing unlabeled GTP into 1.5-ml microcentrifuge tubes and prewarm to 37°C in a water bath.
6. Add 50 µl crude enzyme extract.
7. Incubate 10 min at 37°C.
8. To determine enzyme activity, add 40 µl of 0.1 M EDTA, and heat to 100°C in a block heater for 3 to 5 min.

   Nonspecific activity is determined by adding EDTA to the enzyme extract and heating before adding the GTP substrate.

9. Determine the cGMP content of the reaction mixture via RIA as described above (see Basic Protocol 1, steps 3 to 9).

Calculate results

10. Calculate the cGMP generated by the enzyme as described above (see Basic Protocol 1, steps 10 to 13), expressing enzyme activity as moles cGMP formed per milligram of protein per minute.

ALTERNATE PROTOCOL 2

SOLUBLE GUANYLYL CYCLASE ASSAY USING [α-^{32}P]GTP AS SUBSTRATE

Soluble guanylyl cyclase activity may also be determined by monitoring the conversion of [α-^{32}P]GTP to [^{32}P]cGMP (Schultz and Böhme, 1984). [^{32}P]cGMP must be separated from unused radiolabeled substrate by precipitating out the latter with zinc carbonate and running the sample on an alumina column. Tritium may be used in place of the very high-energy beta emitter ^{32}P as a label for this assay.

Additional Materials *(also see Basic Protocol 2)*

Reaction buffer containing [α-^{32}P]GTP (see recipe)
125 mM zinc acetate [$Zn(C_2H_3O_2)_2 \cdot 2H_2O$]
125 mM sodium carbonate ($Na_2CO_3 \cdot 10H_2O$)
Neutral alumina column (see recipe)
0.1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
[^{3}H]cGMP containing ~5.9 kBq/ml (Amersham)
Water-miscible scintillation fluid

Perform the enzyme assay

1. Prepare the crude enzyme extract (see Basic Protocol 2, steps 1 to 4).
2. Dispense 75-µl aliquots of reaction buffer containing [α-^{32}P]GTP into 1.5-ml microcentrifuge tubes and prewarm to 37°C.
3. Prepare two additional tubes to be used for determining the efficiency of recovery (ER) in step 6. Prepare two blank tubes by adding 75 µl reaction buffer containing label, 400 µl of 125 mM zinc acetate, and 500 µl of 125 mM sodium carbonate.

4. Add 25 µl crude enzyme extract to each tube, including blank and ER tubes. Briefly vortex mix.
5. Incubate 10 min at 37°C.
6. Add 400 µl of 125 mM zinc acetate followed by 500 µl of 125 mM sodium carbonate to terminate the assay. Add 5,000 to 10,000 cpm [^{3}H] cGMP to ER tubes.

Isolate the [^{32}P]cGMP

7. Centrifuge 10 min at 2000 × *g*, room temperature.
8. Transfer 800 µl of supernatant to a neutral alumina column.
9. Elute [^{32}P]cGMP with 5 ml of 0.1 M Tris·Cl, pH 7.5; drain and repeat with a further 5 ml buffer.
10. Collect entire eluates into 20-ml scintillation vials. Add 10 ml water-miscible scintillation fluid to each vial.
11. Determine activity of samples using a scintillation counter. Also prepare two 50-µl aliquots of reaction buffer containing label (i.e., 50 pmol GTP) and count those to determine the specific activity (SA) of the labeled substrate.

Calculate results

12. Calculate soluble guanylyl cyclase activity as the ratio of recovered counts (minus blank) divided by specific activity of labeled substrate and corrected for efficiency of product recovery, per milligram of protein per minute.

$$\text{activity} = \frac{\text{cpm} - \text{blank}}{\text{SA} \times \text{ER} \times \text{mg protein} \times \text{min}}$$

where blank = counts per minute when zinc carbonate is added before the addition of the enzyme; SA = specific activity of radiolabeled substrate; and ER = efficiency of recovery of cGMP (the fraction of added cGMP recovered in the eluate) for the ER tubes.

A recovery of ~0.6 is usual. [^{3}H]cGMP is suitable for this purpose.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Neutral alumina column

Fill glass or plastic columns (7 mm i.d.) with dry neutral alumina (100 to 200 mesh) to a height of 2.5 cm. Add 8 ml of 0.1 M Tris·Cl buffer, pH 7.5 (*APPENDIX 2A*); allow buffer to drip through and the alumina to resettle. Wash with a further 2 ml of 0.1 M Tris·Cl buffer, pH 7.5.

Columns should be freshly prepared.

Reaction buffer containing [α-^{32}P]GTP

4.0 ml 2 × reaction buffer stock solution (see recipe)
0.5 ml 24 mM $MnCl_2$ (4.75 mg/ml $MnCl_2 \cdot 4H_2O$ in 50 mM Tris·Cl)
0.5 ml 8 mM [α-^{32}P]GTP (1.134 mg/ml GTP in 50 mM Tris·Cl, spiked with [α-^{32}P]GTP to arrive at ~5×10^6 cpm/ml)
1.0 ml 50 mM Tris·Cl, pH 7.5

Prepare 50 mM Tris·Cl from Tris base, adjusting the pH to 7.5 with 1 M HCl.

Final concentrations in the reaction buffer are 50 mM Tris·Cl, 4 mM IBMX, 5 mM creatine phosphate, 0.15 mg/ml creatine phosphokinase, 0.5 mg/ml BSA, 2 mM cGMP, 3 mM $MnCl_2$, and 1 mM [α-^{32}P]GTP. The working solution is diluted 3:1 in the assay.

Reaction buffer containing unlabeled GTP

2.5 ml 2× reaction buffer stock solution *without* cGMP (see recipe)
3.05 mg guanosine 5′-triphospate (GTP; sodium salt)
50 µl 0.3 M $MnCl_2$ (5.937 g $MnCl_2 \cdot 4H_2O$/100 ml 50 mM Tris·Cl)
1.20 ml 50 mM Tris·Cl, pH 7.5
Keep stirred

Prepare 50 mM Tris·Cl from Tris base, adjusting the pH to 7.5 with 1 M HCl.

Final concentrations in the reaction buffer are 50 mM Tris·Cl, 4 mM IBMX, 5 mM creatine phosphate, 0.15 mg/ml creatine phosphokinase, 0.5 mg/ml BSA, 1 mM GTP, and 3 mM $MnCl_2$. The working solution is diluted 3:1 in the assay.

Reaction buffer stock solution, 2×

Combine (per milliliter):
6.05 mg Tris base (to 50 mM)
H_2O to dissolve
1 M HCl (*APPENDIX 2A*), pH 7.5
1.776 mg 3-isobutyl-1-methylxanthine (IBMX; warm and stir to dissolve; to 8 mM)
2.551 mg creatine phosphate (disodium salt, hydrate; to 10 mM)
0.30 mg creatine phosphokinase (type I, rabbit muscle, 150 to 250 U/mg protein)
1.0 mg BSA (lay on top of buffer and let dissolve without agitation)
0.734 mg guanosine 3′,5′-cyclic monophosphate (cGMP; sodium salt; to 2 mM)
Add H_2O to full volume
Divide stock solution (e.g., 50 ml) into aliquots and store up to several weeks at −20°C

For reaction buffer with unlabeled GTP, omit cGMP from the stock solution.

COMMENTARY

Background Information

There are two isoforms of guanylyl cyclase: a membrane-bound particulate form and a soluble form. Soluble guanylyl cyclase is a heterodimer consisting of α and β subunits and is activated by the interaction of NO with its heme moiety (Mayer et al., 1993). Many tissues contain both isoforms of the enzyme, but the two are readily separated by centrifugation. Investigators should be aware, however, that the resultant soluble fraction contains other enzymes in addition to soluble guanylyl cyclase. Components of the assay reaction buffers are included to take account of some of these. 3-isobutyl-1-methylxanthine (IBMX) is a broad-spectrum inhibitor of phosphodiesterases (PDE), except the calcium/calmodulin-dependent PDE I (Mayer et al., 1993), and will, therefore, minimize the degradation of cGMP. The GTP-regenerating system, consisting of creatine kinase and creatine phosphate, is included to counteract the activity of 5′ nucleotidases and thus protect the supply of substrate. Unlabeled cGMP is included in the reaction buffer containing [α-^{32}P]GTP to minimize any loss of the labeled cyclic nucleotide product.

Essential for the activity of soluble guanylyl cyclase is the presence of a divalent metal cofactor, either Mg^{2+} or Mn^{2+}. The former cation facilitates a more pronounced response when the enzyme is stimulated by NO; the latter results in higher basal activities. It will be noted from Basic Protocol 2 that enzyme activity may terminated by chelating the metal cofactor with EDTA. Soluble guanylyl cyclase is extremely sensitive to oxidation, and the reducing agent DTT (or another equivalent thiol) is an essential additive to the homogenization buffer.

In intact tissues, the activity of soluble guanylyl cyclase depends on the various physiologic stimuli that result in the synthesis of NO. In rat brain slices, for example, cGMP levels are raised after stimulation with the excitatory amino acid glutamate in a NO-dependent manner (Southam et al., 1991). Indeed, the cGMP response is an excellent biochemical marker for glutamate receptor activation. In the absence of such stimuli—for example, when assaying crude or purified preparations of soluble guanylyl cyclase—basal levels of activity may be very low, necessitating the inclusion of a NO-donor com-

pound in the reaction mixture (see Critical Parameters and Troubleshooting).

Critical Parameters and Troubleshooting

Perhaps the greatest source of variability when estimating the cGMP content of tissues, either by RIA or by SPA, is the treatment of the tissues themselves. The effects of the animal's behavior immediately before death and of the method of killing should be considered. For example, cGMP levels in the cerebellum are influenced by stress, motor activity, and respiratory depression (Wood, 1991). Basal and stimulated cGMP levels in tissues maintained in vitro highly depend on the viability of the tissue and, therefore, on the method of preparation and maintenance. The cGMP response to 10 mM glutamate in adult rat brain slices, for example, is 10-fold greater in hand-cut slices than in chopped slices (Garthwaite et al., 1979). It should also be remembered that the cGMP content of intact tissues reflects not only the activity of guanylyl cyclases but also that of phosphodiesterases. When the NO-cGMP pathway is studied in tissues maintained in vitro, it may be desirable to promote the cGMP response by incubating in the presence of a broad-spectrum PDE inhibitor (e.g., 1 mM IBMX).

cGMP antiserum provided in cGMP RIA kits is claimed by the manufacturers to bind to cGMP with ~ 150,000 and 30,000 times greater affinity than to cAMP and guanine nucleotides, respectively, so that cross-reactivity should not be a problem. Investigators who prepare their own antiserum must carefully characterize its properties before use. Reconstituted antiserum should be stored frozen; and although it will withstand a small number of freeze-thaw cycles with minimal loss of activity, these should be minimized by dividing it into small aliquots before storage. Thawed antiserum must be thoroughly mixed before use.

Optimum antiserum-cGMP binding is achieved at low temperatures; care should be taken that the temperature does not rise above 4°C during incubation, precipitation with ammonium sulfate (which itself must be ice cold), and centrifuge steps of the RIA procedure. Because the SPA does not require separation of bound from unbound radiolabeled ligand, this protocol may be performed at ambient temperatures.

It is essential for both RIA and SPA that standards be included with each assay to control for an interassay variation. When plotted as described in the Basic Protocol 1, the standard curve should produce a straight line. This linearity should not be assumed to hold true for higher cGMP concentrations, at which the curve tends to flatten out. If the cGMP content exceeds 8 pmol/100 µl then samples should be diluted. Generally, though, provided good experimental practice is observed (accurate pipetting, for example), RIA and SPA assays of cGMP are highly reproducible. The sensitivity of the RIA technique may be enhanced from the picomole to the femtomole range by acetylating the samples and standards (Harper and Brooker, 1975).

To ensure that consistent results are obtained when assaying soluble guanylyl cyclase activity, it is essential that the conversion of substrate to product per milligram protein (or unit of purified enzyme) is constant, i.e., within the initial velocity phase. It is, therefore, necessary to demonstrate that the quantity of cGMP formed is directly proportional to time and to protein concentration, within the limits of the experimental protocol. If they are not, the most likely explanations are that the enzyme is unstable or the quantity of substrate is limiting. The following steps may be taken to optimize enzyme stability: (1) ensure that the enzyme is used as quickly as possible once prepared and stored on ice in the meantime; (2) reduce oxidation of the enzyme by incorporating a reducing agent, such as DTT, in the homogenization buffer and, if necessary, the reaction buffer; (3) add BSA to the reaction mix (particularly when using purified enzyme); and (4) inhibit dephosphorylation of the enzyme by adding a phosphatase inhibitor. In addition, the reaction period may be reduced from the 10 min indicated in the protocol. Substrate should be present in excess; but if high concentrations of enzyme (high protein content) are present, then it could conceivably become limiting. In this case, the simplest solution is to dilute the enzyme preparation.

Obtaining reproducible values for basal soluble guanylyl cyclase activity may prove problematic because the basal activity levels are low (which makes inhibition studies, in particular, difficult) and also because of spontaneous activation of the enzyme, presumably caused by variable concentrations of endogenous NO. These problems may be overcome by ensuring that sufficient NO is present in the reaction mix to cause a consistently elevated level of enzyme activity. There are several NO-donor compounds available that may be used to stimulate soluble guanylyl cyclase activity (Southam and Garthwaite, 1991). For example, 100 µM sodium nitroprusside (SNP, Sigma) is reported to increase purified bovine lung-soluble guanylyl cyclase activity 174-fold (Humbert et al., 1990).

Anticipated Results

The cGMP content of tissues is influenced by many factors (see Critical Parameters and Troubleshooting), but typical basal concentrations in rat brain slices are in the range of 1 to 5 pmol/mg protein and may rise 100-fold or more upon stimulation by glutamate receptor agonists (Southam et al., 1991). Soluble guanylyl cyclase activity measurements vary, depending largely on whether a crude extract or purified enzyme is assayed and the makeup of the reaction buffer. The basal activity of purified bovine lung enzyme, with Mg^{2+} present as a metal ion cofactor, is reported to be 12 nmol/mg/min, rising to 2100 nmol/mg/min in the presence of 100 μM SNP (Humbert et al., 1990).

Time Considerations

Tissue homogenates to be assayed for cGMP content can be safely kept frozen for several weeks without any loss of the cyclic nucleotide. About 60 samples can comfortably be assessed by RIA in 3 to 4 hr. This does not include time taken for scintillation counting but does include a 90-min incubation period. SPA is considerably quicker, because an extended incubation period is not necessary and the need for separating bound from unbound radiolabeled ligand is eliminated: the same number of samples can be assayed in ~1 hr (again, not including time taken for scintillation counting). A crude extract of soluble guanylyl cyclase takes 1 hr to prepare, and the enzyme assay a further 2 hr. If Alternate Protocol 2 has been followed, eluates from the chromatography column are counted directly. When nonradioactive cGMP is the product, either an RIA or SPA assay must be performed. Preparation of a crude enzyme extract, the assay, and determination of cGMP by RIA can all be done in a single day.

Histochemical Analysis of Nitric Oxide Synthase by NADPH Diaphorase Staining

Since Hope at al. (1991) and Dawson et al. (1991) first showed that neuronal nitric oxide synthase (NOS) and NADPH diaphorase are identical, NADPH diaphorase staining has been widely used to detect NOS-containing neurons in tissue sections and cell cultures. Throughout the brain and peripheral tissues, all NOS-staining cells also stain for NADPH diaphorase, and in most areas the great majority of NADPH diaphorase–containing cells also exhibit immunoreactivity for NO synthase (Dawson et al., 1991). In some tissues, such as the adrenal cortex, NADPH diaphorase can be detected where NOS cannot. However, the coincidence of neurons staining positive for NOS and NADPH diaphorase is dramatic, especially in areas such as the cerebral cortex and corpus striatum, where only ~1% to 3% of cells are positive for NOS and NADPH diaphorase and the two enzymes are co-localized in all instances (Dawson et al., 1991). The extraordinary concurrence of NOS and NADPH diaphorase implies that NOS accounts for the diaphorase staining. Transfection of NOS cDNA into the 293 human kidney cell line showed that diaphorase staining of transfected cells reflects and is proportional to the amount of NOS cDNA transfected. Moreover, the proportion of NOS and NADPH diaphorase staining in individual neurons is the same as observed for cells transfected with NOS cDNA (Dawson et al., 1991). Thus, the NOS content of each neuron can fully account for its diaphorase activity. Macrophage or immunological or inducible NOS (iNOS) and endothelial (eNOS) also have NADPH diaphorase activity.

This unit describes the procedure for NADPH diaphorase staining of neurons, but the procedure works equally well for non-neuronal cells (e.g., macrophages and endothelial cells).

This procedure describes a histochemical analysis of nitric oxide synthase through NADPH diaphorase staining (Dawson et al., 1991) in which the diaphorase enzymatic activity reduces tetrazolium dyes to a dark blue formazan precipitate in the presence of NADPH. NOS-containing cells are visualized by incubating fixed tissue or cell cultures for 30 to 90 min at 37°C in a solution containing NADPH/nitroblue tetrazolium/Tris·Cl/Triton X-100. The progress of the reaction can be observed under a microscope. NOS containing cells stain dark blue-purple. The reaction is stopped by washing off the staining solution and adding buffered salt solution.

NOTE: The key to success with this procedure is freshness of the reagents used. All solutions should be made fresh prior to use.

Materials

Cultured cells, free-floating tissue sections, or slide-mounted tissue sections
Tris-buffered saline (TBS): 50 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)/1.5% (w/v) NaCl
0.2 M sodium phosphate buffer, pH 7.4 (PB; see recipe; prepare fresh)
4% (w/v) paraformaldehyde in 0.1 M PB (see recipe; prepare fresh)
0.2% or 0.4% (v/v) Triton X-100 in TBS
NADPH diaphorase staining solution (see recipe; prepare fresh)
TBS containing 0.05% (w/v) sodium azide (optional)
Sonicating water bath

Contributed by Mirella Gonzalez-Zulueta, Valina L. Dawson, and Ted M. Dawson
Current Protocols in Toxicology (1999) 10.6.1-10.6.4

Fix tissue sections or cell cultures

1. If cell cultures are being used, aspirate off culture medium and wash cells by letting them stand in 0.5 ml of TBS per 15-mm well.

   Good positive controls are cultures or tissue sections from cerebellar granule cells.

2. Fix cells or tissue sections by covering them with 4% paraformaldehyde/0.1 M PB and letting them stand 30 min at 4°C.
3. Aspirate off paraformaldehyde and wash with TBS three times for 10 min each time by letting the cells stand in 0.5 ml of TBS per 15-mm well.

Permeabilize cells

4. Permeabilize cells by incubating them 5 min at room temperature in 0.2% Triton X-100 in TBS.

   Free-floating or slide-mounted tissue sections should be permeabilized for 30 min at room temperature in 0.4% Triton X-100 in TBS.

5. Aspirate off solution and rinse once with TBS.

Stain cells

6. Apply 0.5 ml NADPH diaphorase staining solution per 15-mm well.
7. Float dish or plate in a 37°C water bath and allow staining to proceed.

   For slide-mounted tissue sections, incubation in the staining solution should be performed for 30 to 90 min in a 37°C incubator or oven.

8. Check staining under a light microscope at 30 min and at 15-min intervals thereafter.
9. When cells stained dark blue-purple become visible, stop the reaction by washing off staining solution and adding TBS.

   The stained cells are those containing NOS. If the solution itself turns pink-purple the reaction should be stopped; the authors routinely get optimal NADPH diaphorase staining prior to this point. If the reaction is allowed to proceed beyond this point, high background staining may appear.

   Stained cultures can be kept for a few days at 4°C in TBS containing 0.05% sodium azide.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

NADPH diaphorase staining solution

Prepare buffer solution, β-NADPH and NBT solutions (in separate tubes), and staining mix as follows:

Buffer solution

0.1 M Tris·Cl (pH 7.2)
0.2% (v/v) Triton X-100
0.02% (w/v) NaN_3

2 mM β-NADPH solution: 16.66 mg β-NADPH reduced form in 10 ml buffer solution.

0.4 mM NBT solution: 3.28 mg nitroblue tetrazolium in 10 ml buffer solution (the mixture may need to be sonicated for 10 to 15 min to dissolve the NBT).

Staining mix: Mix together β-NADPH and NBT solutions 1:1 (v/v). Just before application to cells, filter through a 0.22-μm filter unit (to prevent formation of dark blue precipitate).

The final concentration of the stain mix is 1 mM reduced β-NADPH and 0.2 mM NBT.

4% (w/v) paraformaldehyde/0.1 M PB

1. Prepare 8% (w/v) paraformaldehyde in distilled water (8 g in 100 ml water). Depolymerize solution by heating to 80°C and letting it stand 30 min at that temperature while stirring.

Do not exceed 80°C. If paraformaldehyde boils, start over.

CAUTION: *Wear gloves and mask while weighing and preparing paraformaldehyde. While solution is being heated, cover it with aluminum foil.*

2. Clear paraformaldehyde solution by adding 1 or 2 drops of 10 M NaOH.

Solution will change from a turbid appearance to clear.

3. Check volume and replace water that has evaporated.

4. Add 1 vol of 0.2 M PB (pH 7.4; see recipe) to make a final solution of 4% paraformaldehyde/0.1 M PB.

5. Just before use, filter solution through a 0.22-μm filter unit.

Sodium phosphate buffer (PB), 0.2 M, pH 7.4

Stock solution A: 0.2 M NaH_2PO_4 (12 g NaH_2PO_4 in 500 ml water or 13.9 g $NaH_2PO_4 \cdot H_2O$ in 500 ml water).

Stock solution B: 0.2 M Na_2HPO_4 (28.4 g Na_2HPO_4 in 1 liter water).

0.2 M PB working solution: Mix 1 part solution A with 4 parts solution B (e.g., 100 ml of A and 400 ml of B). Prepare fresh before use.

COMMENTARY

Background Information

The procedure described in this unit is a simple histochemical analysis of NOS-containing cells. It is highly reproducible if the solutions are freshly prepared before each use and the protocol is followed accurately. This approach is based on the enzymatic diaphorase activity that nitric oxide synthase possesses. NADPH diaphorase was first identified histochemically through the reduction of tetrazolium dyes in the presence of NADPH but not NADH (Thomas and Pearse, 1964). The co-localization of NOS-staining neurons and NADPH diaphorase–staining neurons is well documented (Bredt et al., 1991), and in 1991 both activities were shown to reside in the same protein (Dawson et al., 1991; Hope et al., 1991). Definite demonstration that NOS accounts for diaphorase staining came from experiments in which cells of the human kidney cell line 293 that lacked both NOS and diaphorase activities were transfected with NOS cDNA (Dawson et al., 1991). The transfected cells showed extremely similar levels of immunoreactivity for NOS and diaphorase, and the diaphorase staining correlated with the amount of transfected cDNA. Another approach taken by Hope et al. (1991) to link NOS and NADPH diaphorase was to purify diaphorase activity and show that it possesses NOS activity.

Under appropriate fixation conditions, NADPH diaphorase staining can be used to identify all NOS isoforms. For an unknown reason, NOS is resistant to paraformaldehyde fixation, whereas all other NADPH-dependent oxidative enzymes are inactivated by fixatives. The choice of fixation and permeabilization can influence the specificity of the staining and favor one isoform over another (Vaid et al., 1996). For example, the CA1 hippocampal pyramidal neurons stain prominently when tissue sections are fixed in high concentrations of glutaraldehyde (2%), but when fixed in the presence of paraformaldehyde CA1 pyramidal cells do not stain for diaphorase.

Critical Parameters and Troubleshooting

The largest source of failure in obtaining good NADPH diaphorase staining is the use of solutions that have not been freshly made before each use. This is particularly true for the paraformaldehyde solution and the staining mix. A long enough fixation time (at least 30 min) is also important.

Trouble usually arises if the staining solution is not filtered before addition to the cells, which leads to formation of abundant dark blue precipitates that greatly interfere with observation of stained cells. The pH of the buffer is not

critical, but pH 7.2 limits nonspecific NADPH diaphorase staining. A staining solution that is not light yellow immediately after preparation should be discarded. NBT may not go into solution easily, requiring sonication for 10 to 15 min. If NBT is not dissolved adequately, very poor or no staining will be obtained.

A high background staining may be seen that may impede accurate assessment of NOS-containing cells. This is usually due to an excessively long incubation time of cells in the staining solution. Moreover, if the reaction takes place for an abnormally long period of time, dark blue precipitates form that obstruct the detection of stained cells. Therefore, the progress of the reaction should be observed every 15 min. Incubation for 30 to 90 min is usually necessary, depending on the tissue and the level of NOS expression.

Anticipated Results

NADPH diaphorase staining is a simple technique that gives reproducible results if the protocol is followed carefully. Cells that contain NOS should stain dark blue-purple, and are clearly distinguishable from unstained cells. The dark blue stain is intense and homogenously distributed in the cytoplasm. The nucleus of the cell is clearly devoid of blue stain. The number of diaphorase staining cells varies with the tissue type. A good positive control are cerebellar granule cells for the high number of cells expressing NOS at high levels.

In the brain, the highest density of diaphorase staining neurons is evident in the cerebellum and the olfactory bulb. In most brain regions, diaphorase staining can be detected in 1% to 2% of the cells. In the cerebellum, positive staining is detected in up to 80% of granule cells. Other areas of high staining include the supraoptic nucleus, the superior and inferior colliculi, the caudate-putamen, and the dentate gyrus of the hippocampus. Microglia and astrocytes can also stain positive. Throughout the gastrointestinal tract, diaphorase-staining neurons are present in the myentric plexus. Staining also occurs in discrete ganglia cells and fibers in the adrenal medulla. Disphorase staining is prominent within the posterior pitutiary gland. It has also been found in the macula densa of the kidney. In the periphery, diaphorase staining is localized to the endothelium of blood vessels, in neutrophils and macrophages. In primary cultures of mature (14 days in vitro) cortical neurons, the authors routinely are able to count 100 to 120 diaphorase-positive neurons per 15 × 15–mm culture well, where cells are plated at a density of 4×10^5 cells/well.

Time Considerations

The entire procedure can be done in ~3 hr plus the time required to observe and quantify NOS positive cells under the microscope. Preparation of the 4% paraformaldehyde/0.1 M PB solution takes ~1 hr, cell fixation and permeabilization requires about 40 min, and staining takes ~1 hr.

Immunocytochemical Analysis of Cyclic Nucleotides

Within certain limits, immunocytochemical detection of cyclic nucleotides makes it possible to study dynamic alterations in cyclic nucleotide levels under conditions that are at least partly reflective of those in living tissue. Changes in cAMP or cGMP levels can be pinpointed in cells in heterogeneous tissue. In combination with (immuno)histochemical characterization of these cells, or cells that are in contact with cyclic nucleotide–immunopositive cells, this can give insight into the regulation of cyclic nucleotides in a complex tissue. Such studies are limited by the strategy chosen to study the living tissue or cells. In principle, any approach can be used that allows for fixation of cyclic nucleotides to the protein matrix at some point in the experiment. It should be realized that immunocytochemical analysis of cyclic nucleotides is time consuming, especially when physiological or pharmacological factors are to be studied.

The first choice to be made is whether to use an in vivo or an in vitro approach. Biochemical studies of cyclic nucleotide metabolism in vivo have shown that changes in cAMP or cGMP may be very rapid, and unless special precautions are made, cyclic nucleotides levels will change during the process of isolating the tissue (Guidotti et al., 1974). Nevertheless, excellent results have been obtained using cGMP immunocytochemistry in in vivo experiments in invertebrates (e.g., Bicker et al., 1996; Ewer et al., 1994; Truman et al., 1997). In vertebrates the number of in vivo studies has been limited (Berkelmans et al., 1989; Southam and Garthwaite, 1993), and it is probably best to use tissue slices or isolated organs when different conditions, e.g., drugs or time periods, are to be studied.

This unit includes protocols for preparation and characterization of antibodies to conjugated cAMP and cGMP (see Support Protocol) and in vitro immunostaining of brain slices for cyclic nucleotides (see Basic Protocol) with modifications for in vivo fixation for immunocytochemistry (see Alternate Protocol). The basic principles are the same for cAMP and cGMP immunocytochemistry, and the relevant variations in procedural details have been indicated.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

IMMUNOCYTOCHEMISTRY FOR CYCLIC NUCLEOTIDES USING IN VITRO FIXED BRAIN SLICES

BASIC PROTOCOL

Freshly dissected brains are sectioned and treated, then fixed in vitro for staining with cGMP- or cAMP-specific antibodies. Alternatively, the tissue can be fixed in vivo before sectioning and staining (see Alternate Protocol).

Materials

Animal source of tissue
Krebs buffer, oxygenated with 5% CO_2/95% O_2 (see recipe), ice cold
Cyanoacrylate glue
Drug or toxin to be tested for effects on cGMP or cAMP levels
Formaldehyde fixative (see recipe), ice cold
Formaldehyde fixative containing 10% sucrose (see recipe)
10% (w/v) sucrose
Optimal cutting (OCT) compound (cryostat embedding medium)

Contributed by J. de Vente and H.W.M. Steinbusch
Current Protocols in Toxicology (1999) 10.7.1-10.7.17

Acrolein fixative (see recipe)
Glycine
0.1 M phosphate buffer, pH 7.0, containing 10% sucrose
TBS (see recipe)
10 mM $NaCNBH_3$ in 0.1 M sodium acetate, pH 7.45
Anti-cGMP-formaldehyde-protein *or* anti-cAMP-acrolein-protein antiserum (see Support Protocol)
TBS-T: TBS containing 0.3% Triton X-100
Secondary and tertiary antibodies conjugated with reporter molecules (e.g., FITC or Cy3; see Troubleshooting)
1:3 (v/v) TBS/glycerol
DAB staining solution (see recipe)

Grid glued to a firmly fitting teflon support ring into the multiwell tissue culture plate
12-well plates
Vibrating tissue knife: Vibratome (Technical Products) or Vibroslicer (WPI)
Cryostat
Chrome-alum-coated glass microscopic slides

Prepare brain slices

1. Sacrifice animal, then remove the brain from the skull as quickly as possible.

   This protocol describes the procedure for brain slices, but the method is, in principle, suitable for any tissue (also see Commentary). However, experience is limited with other tissues, which means that many parameters governing cyclic nucleotide metabolism, factors important for correct interpretation of the immunocytochemical results, still need to be explored.

   Probably the fastest way to remove the brain from the skull is by decapitating the animal followed by removal of the skull bones. Lift the brain upward in a rostral to caudal direction and sever the optic nerves just rostral to the optic chiasm. It is necessary to sever the optic nerves, otherwise they will dislodge the optic chiasm and the ventral part of the hypothalamus will be damaged. There are many possible modifications of this basic procedure. Some groups recommend that the animal be anesthetized and allowed to inhale pure oxygen prior to decapitation and opening of the skin layers on top of the skull. These precautions are recommended to prevent ischemic cell damage. For further details see Garthwaite et al. (1979) and Aitken et al. (1995). The complete June 1995 issue of Journal of Neuroscience Methods focuses on problems related to isolating, preparing, and maintaining brain tissue slices in vitro.

2. Cool the brain immediately by dropping it in ice-cold continuously oxygenated Krebs buffer.

3. Dissect the area(s) of interest and glue this part on a cooled support using cyanoacrylate glue.

   Do not touch the brain with your fingers. The maximum size of the brain slice is determined by dimensions of the culture wells.

4. Prepare brain slices of 300- to 400-µm thickness using a Vibratome or Vibroslicer, while the tissue is immersed in ice-cold continuously oxygenated Krebs buffer.

   Speed is the key to success in this procedure. It is also very important to handle the slices with utmost care. Two different ways of obtaining slices are commonly in use, i.e., the McIlwain tissue chopper and the Vibratome or Vibroslicer. In the authors' experience, slicing is preferred as the gentler method, resulting in better morphology (see also Garthwaite et al., 1979). Many different protocols for handling and incubation of brain slices are to be found in the literature, each advocating modifications of this basic protocol (Aitken et al., 1995). It is doubtful whether any of these recipes will save the slice when the slicing process is too slow.

The quality of a slice is most often defined operationally. Routine histochemistry to assess the quality of the slice is necessary, using histochemical stains such as hematoxylin-eosin or toluidine blue staining. Preferably, this should be done for each experiment, and it is necessary to do this when effects of drugs are studied for the first time using this approach. For a detailed discussion on the quality of the slice the reader is referred to Aitken et al. (1995).

Incubate brain slices

5. Place slices on a grid glued to a support ring in a multiwell culture plate containing 2 ml ice-cold continuously oxygenated Krebs buffer.
6. Slowly and continuously bubble 5% CO_2/95% O_2 through the buffer solution. Place culture plates in a water bath and gradually raise the temperature to 35°C.
7. Incubate slices 30 to 60 min at room temperature in the presence or absence of drug.
8. Add drug to the wells and continue the incubation for the desired period of time.

Depending on the design of the experiment, drugs may alternatively be present from the start of the incubation.

Incubation duration for the tissues in vitro is determined by the experimental setup Hoever, it is necessary to let the tissue equilibrate in buffer under the conditions used in the final experiment for ≥30 min. This equilibration time varies considerably in the literature (Garthwaite et al., 1979; Aitken et al., 1995). The necessity to include a phosphodiesterase inhibitor will be readily apparent when there is no cGMP immunostaining observed in the absence of such an inhibitor. At present, it is impossible to give definite guidelines on this point as the involvement of phosphodiesterases in cell signalling is a rapidly developing field (see Background Information).

Cyclic nucleotides are rapidly broken down by phosphodiesterases, so it may be necessary to include a phosphodiesterase inhibitor in the incubation buffer. Isobutylmethylxanthine (IBMX) at 1 mM concentration has been most commonly used (see Background Information).

Fix brain slices for immunocytochemistry and cryostat sectioning

For cGMP analysis:

9a. Place slices in ice-cold formaldehyde fixative containing 10% sucrose for 2 hr.

The cGMP-formaldehyde-protein conjugate is not indefinitely stable. However, at 4°C dissociation is negligible. Fixation of cGMP to the protein is not 100% complete. The indicated fixation time has proved to be sufficient for brain slices but may be prolonged. Slices may be kept overnight in 10% sucrose in the cold before being sectioned on a cryostat.

10a. Wash the slice 30 min in ice-cold 10% sucrose in 0.1 M phosphate buffer, pH 7.4.

It is necessary to wash out the formaldehyde because otherwise it may form an insoluble precipitate when slices are frozen with CO_2.

11a. Align slices in a plane and quick-freeze them in OCT compound using CO_2.

Aligning brain slices in a plane can be accomplished as follows. Cover a glass microscope slide with Parafilm. Place the slices on the Parafilm, positioning them carefully with a soft brush so that they will fit on the cryostat chuck. Remove adhering buffer with a piece of filter paper. Push the glass slide, face down, into Tissue-Tek OCT compound already applied to the cryostat chuck using a vertical adjustment attachment. Freeze the slices into the OCT compound with CO_2. The Parafilm ensures that the slices can be easily removed from the glass slide.

12a. Cut 5- to 20-µm sections on a cryostat and thaw-mount them onto chrome-alum-coated glass slides.

Any type of coating commonly in use to adhere sections to glass slides will do. Chrome-alum has the advantage of low cost.

13a. Store sections at −20°C.

Sections can be stored for considerable time. The authors have successfully stained sections that had been stored frozen >2 years.

For cAMP analysis:

9b. Place slices in 2 ml acrolein fixative for 2 hr.

IMPORTANT NOTE: *Special precautions must be taken for cAMP immunocytochemistry because acrolein is used as a fixative. Acrolein is a very aggressive and highly toxic compound. Addition of glycine to the fixative solution will inactivate the acrolein.*

10b. Add 20 mg glycine at room temperature and leave for 30 min more.

11b. Remove the solution and postfix the slices in formaldehyde fixative containing 10% sucrose for 1 hr.

12b. Place slices in 0.1 M phosphate buffer (pH 7.0) containing 10% sucrose for 30 min.

13b. Freeze and section as described in steps 11a to 13a.

Immunostain for cyclic nucleotides

14. Airdry the cryostat sections by letting them stand for 15 to 20 min at room temperature.

15. Wash in TBS three times, 5 min each.

16. *For cAMP only:* Treat the sections for 30 min with 10 mM $NaCNBH_3$ in 0.1 M sodium acetate, pH 7.45.

For cGMP, skip to step 17.

The cyanoborohydride treatment is necessary to reduce double bonds produced by acrolein, which may give a very high background signal when epifluorescence is used.

17. Apply the appropriate anti–cyclic nucleotide antiserum to the sections at the necessary dilution in TBS-T.

The dilution of the primary antibodies depends on the particular antiserum and the detection method used. In conjunction with the avidin/biotin detection system, use of a 1:40,000 dilution of a primary anti-cGMP antibody has been reported.

18. Leave the sections at 4°C overnight.

19. Wash 15 min each with TBS, TBS-T, and TBS.

It is advisable to limit the time of the initial washing steps as much as possible in view of the labile nature of the cGMP-formaldehyde-protein bond. These precautions are no longer necessary when the primary antibody is bound to the cGMP-epitope, as this binding is tenacious.

20. Apply the secondary antibody containing the fluorescent reporter molecule and incubate 1 hr at room temperature.

21. Repeat step 19.

22. Mount sections with 1:3 (v/v) TBS/glycerol.

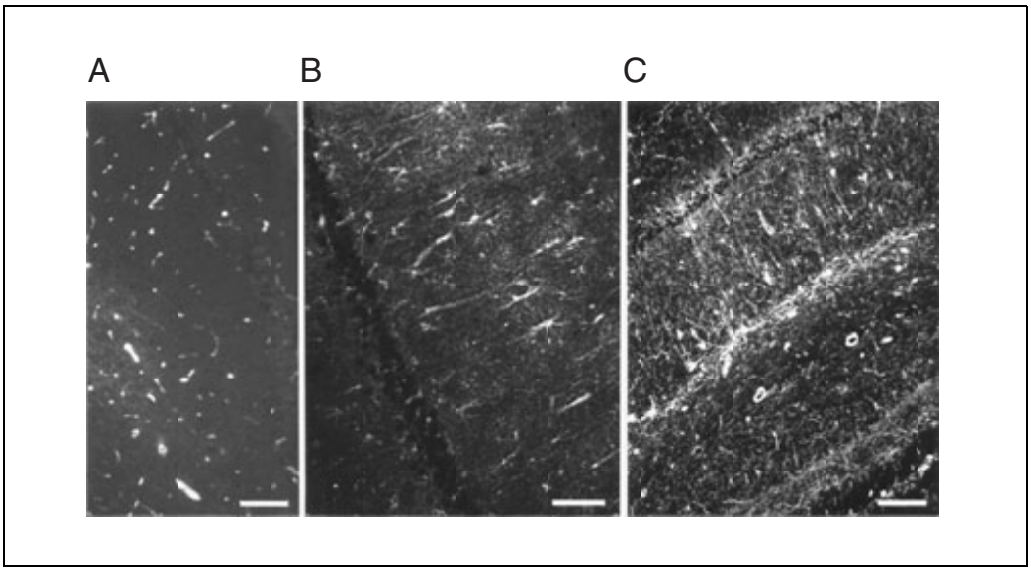

Figure 10.7.1 Cyclic nucleotide immunocytochemistry: the different localization of sGNC and pGNC using cGMP immunocytochemistry in the hippocampus. Tissue was (**A**) unstimulated; (**B**) incubated 10 min in the presence of 100 nM ANF; (**C**) incubated 10 min in the presence of 0.1 mM sodium nitroprusside. All in vitro incubations were performed in the continuous presence of 1 mM IBMX to inhibit phosphodiesterase activity. Bars represent 50 μm.

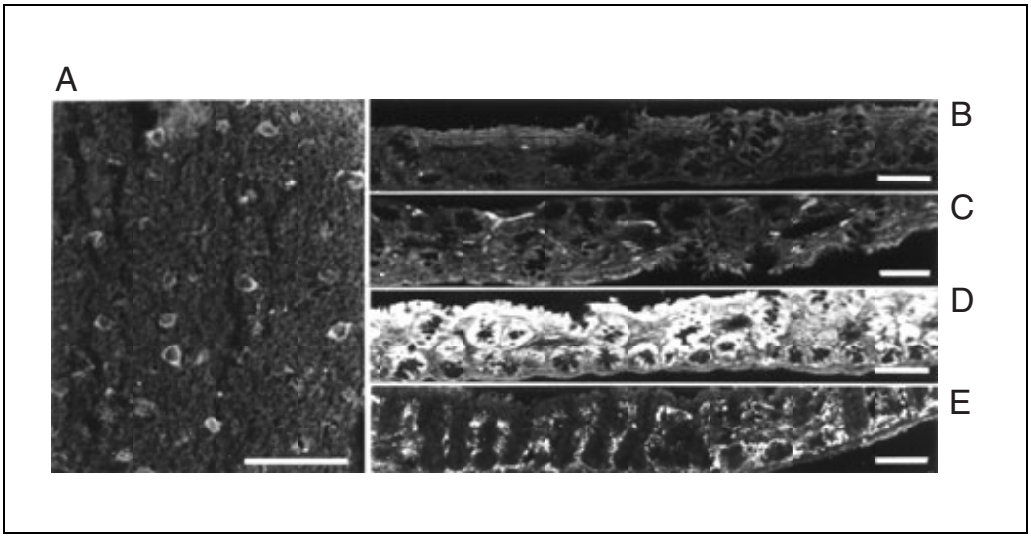

Figure 10.7.2 cAMP immunocytochemistry in (**A**) in a slice from the frontal cortex of the rat incubated 5 min in the presence of 10 μM dopamine. Demonstration of the differential localization of cGMP in the rat colon after stimulation of three different types of GNC is shown in: (**B**) unstimulated proximal colon; (**C**) proximal colon incubated 10 min in the presence of 1 μM ANF; (**D**) proximal colon incubated 10 min in the presence of 0.1 μM *Escherichia coli* enterotoxin STa; (**E**) distal colon incubated 10 min in the presence of 0.1 mM sodium nitroprusside. All in vitro incubations were performed in the continuous presence of 1 mM IBMX to inhibit phosphodiesterase activity. Bars represent 50 μm.

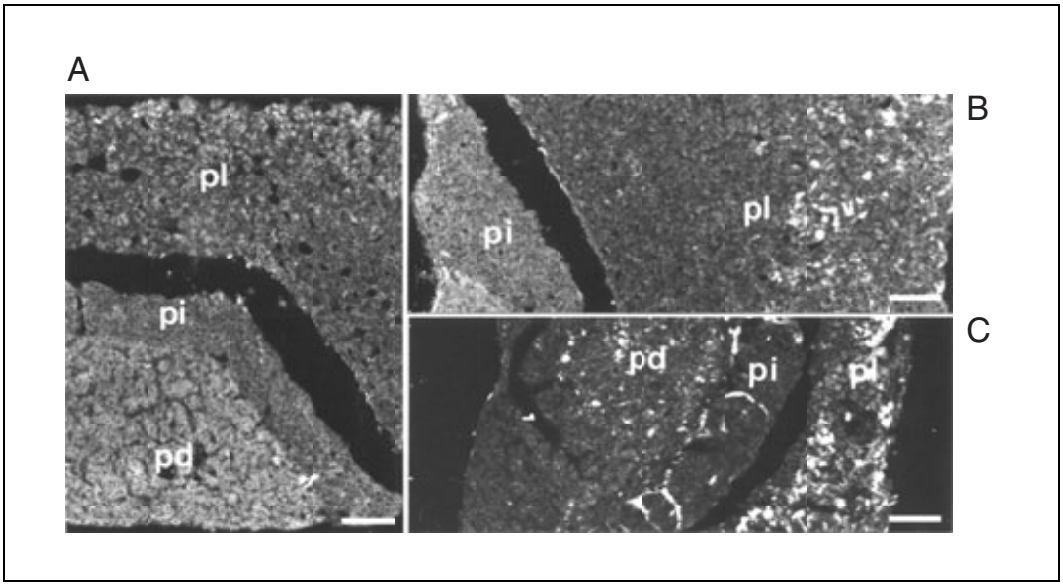

Figure 10.7.3 Differential localization of sGNC and pGNC in the hypophysis of the rat using cGMP immunocytochemistry. (**A**) unstimulated; (**B**) stimulated with 100 nM ANF; (**C**) stimulated with 0.1 mM sodium nitroprusside (pl - pars lateralis; pi - pars intermediate; pd - pars distalis). All in vitro incubations were performed in the continuous presence of 1 mM IBMX to inhibit phosphodiesterase activity. Bars represent 50 μm.

Any detection system in use with other immunocytochemical procedures can be used to visualize cGMP or cAMP. In this respect there is no difference between cyclic nucleotide immunocytochemistry and other immunocytochemical procedures. For example, the peroxidase-antiperoxidase method with diaminobenzidine visualization may also be used.

See Figures 10.7.1, 10.7.2, and 10.7.3 for examples of results.

ALTERNATE PROTOCOL

IN VIVO FIXATION FOR CYCLIC NUCLEOTIDE IMMUNOCYTOCHEMISTRY

The tissue of interest is perfused with fixative in vivo, then used for immunocytochemistry with cyclic nucleotide–specific antisera.

Additional Materials *(also see Basic Protocol)*

Animal source of tissue
Pentobarbital sodium (Nembutal)
Krebs buffer (see recipe) prepared without calcium, oxygenated with 5% CO_2/95% O_2
Drug to be tested for effects on cGMP or cAMP levels
Formaldehyde fixative (see recipe)
TBS (see recipe) containing 10% (w/v) sucrose
0.9% (w/v) NaCl (*APPENDIX 2A*)
Chrom-alum- or lysine-coated slides

1. Weigh animal, and anesthetize by i.p. injection of the appropriate volume of pentobarbital sodium (50 mg/kg).
2. Open the rib cage and transcardially perfuse the animal with 150 ml oxygenated calcium-free Krebs buffer containing the appropriate concentration of drugs.

   This should be done by someone with experience in performing perfusions (for additional perfusion details see UNIT 9.5). In the process of fixation the animal will be killed.

Fix tissue

For cGMP analysis:

3a. Perfuse the animal with 500 ml formaldehyde fixative.

4a. Remove the brain from the skull and postfix the tissue for 2 hr in the same fixative.

For cAMP analysis:

3b. Perfuse the animal with 200 ml of acrolein fixative followed by 500 ml saline solution containing 10 mg/ml glycine to inactivate the acrolein.

> IMPORTANT NOTE: *Whole-body perfusion with acrolein requires a high-quality fume hood, the use of a gas mask and special gloves, and immediate inactivation of the acrolein fixative using a saturated solution of glycine in water.*

4b. Postfix the tissue for 2 hr in formaldehyde fixative.

5. For cryostat sectioning, immerse the tissue overnight in TBS containing 10% sucrose in the cold.

> *As an alternative, the tissue can be sectioned immediately after postfixation with a Vibratome slicer. In this case, keep the tissue and the sections in a cold TBS solution.*

6. Thaw cryostat sections onto chrome-alum- or lysine-coated glass slides.

7. Proceed with immunostaining (see Basic Protocol, steps 14 to 22).

PREPARATION AND CHARACTERIZATION OF ANTISERA TO CONJUGATED CYCLIC NUCLEOTIDES

SUPPORT PROTOCOL

The key to successful visualization of cyclic nucleotides in fixed tissue is the use of antisera directed against the fixed forms of the nucleotides. This is accomplished by treating the nucleotide antigen with the appropriate fixative when generating the antiserum. The antisera against (unfixed) cyclic nucleotides that are commonly used in radioimmunoassays may be of some utility; however, their performance can be capricious, and the results are disappointing in comparison with those obtained with antibodies against fixed nucleotides.

Because of their small size, cyclic nucleotides must be fixed and conjugated to a carrier protein for use as an immunogen. After the antisera are produced, their specificity is characterized using a peroxidase-based immunodot procedure.

Materials

Carrier protein (e.g., bovine thyroglobulin, BSA, hemocyanin)
3′,5′ cGMP or 3′,5′ cAMP (sodium salt)
0.2 M sodium phosphate buffer, pH 7.0 (*APPENDIX 2A*)
Formaldehyde fixative (see recipe)
0.1 M sodium phosphate buffer, pH 7.0 (*APPENDIX 2A*), 4°C
0.1 M sodium acetate, pH 4.75 (*APPENDIX 2A*)
Acrolein fixative (see recipe)
Glycine
$NaCNBH_3$
Rabbits (or other species in which to raise antibodies)
0.9% (w/v) NaCl (*APPENDIX 2A*)
Complete and incomplete Freund's adjuvant
Fixative-treated carrier protein
Glycerol

Blocking solution: 1% (w/v) gelatin and 1% (w/v) nonfat dry milk in water
TBS (see recipe)
TBS-T: TBS containing 0.3% (v/v) Triton X-100
Anti–rabbit Ig (secondary antibody)
Rabbit peroxidase-antiperoxidase antibody
0.05 M Tris·Cl, pH 7.0 (*APPENDIX 2A*)
DAB staining solution (see recipe)

Dialysis equipment
Homogenizer, either standard Potter system or high-speed-blade (Polytron-type) system
Nitrocellulose or nylon membrane
Glass capillary micropipets

Prepare and purify cyclic nucleotide–protein conjugate

For cGMP-formaldehyde-protein conjugate:

1a. Dissolve, while stirring, 20 mg carrier protein (thyroglobulin or BSA) and 45.8 mg of cGMP (25 mM) in 5 ml of 0.2 M phosphate buffer, pH 7.0.

2a. Add 5 ml of 8% (w/v) freshly depolymerized formaldehyde in water and stir solution at least 2 hr at room temperature.

The solution will turn slightly opaque. No precipitate should develop.

3a. Purify conjugate at 4°C by dialysis against several volumes of 0.01 M phosphate buffer, pH 7.0, or by repeated ultrafiltration with the same buffer.

Purification of the conjugate should be done in the cold because of the labile nature of the cGMP-formaldehyde bond (de Vente et al., 1987).

When selecting dialysis tubing or ultrafiltration filters, take into account the molecular weight of the carrier proteins when selecting the MWCO—e.g., thyroglobulin has a molecular weight of >600,000; with BSA it is possible to use a MWCO of 65,000. Consult the manufacturer's documentation to select the proper membranes.

4a. Freeze-dry the conjugate and store at −20°C.

For cAMP-acrolein-protein conjugate:

1b. Add 10 mg carrier protein (thyroglobulin, hemocyanin, or BSA) and 25 mg cAMP to 10 ml of 0.1 M sodium acetate, pH 4.75. Add 40 µl acrolein fixative under vigorous stirring. Continue stirring 4 hr at room temperature in the dark.

CAUTION: *Acrolein is an aggressive and toxic chemical; use gloves and a fume hood.*

2b. Add 200 mg glycine and leave under the same conditions for 30 min. Add 130 mg $NaCNBH_3$ and stir for another 30 min.

Glycine neutralizes the acrolein, and $NaCNBH_3$ reduces double bonds, which may give a very high background signal when epifluorescence is used.

3b. Dialyze the conjugate solution against three changes of distilled water for 24 hr at 4°C.

When selecting dialysis tubing or ultrafiltration filters, take into account the molecular weight of the carrier proteins when selecting the MWCO—e.g., thyroglobulin has a molecular weight of >600,000; with BSA it is possible to use a MWCO of 65,000. Consult the manufacturer's documentation to select the proper membranes.

4b. Freeze-dry the conjugate solution and store desiccated at −20°C.

Collect preimmune samples

5. Collect a preimmune blood sample from the rabbit or other animal to be immunized in normal glass tubes.

   See Donovan and Brown (1999a,b) for animal care and handling and Donovan and Brown (1999c) for blood collection.

6. Leave the sample for 1 hr at room temperature. Free the clotted blood from the glass wall and place tubes at 4°C overnight.

7. Isolate the serum and store in aliquots at −80°C.

Raise antibodies against cyclic nucleotides

8. Suspend 0.5 mg of conjugate in 0.5 ml of 0.9% NaCl. Add 0.5 ml complete Freund's adjuvant and emulsify using a Potter homogenizer system or Polytron-type system.

   Other adjuvants may be used in place of Freund's adjuvant, which is considered to be a rather painful means of immunization because of the ulcers it produces. However, not all will give results as good as those obtained with Freund's, although the response of the animals is very individual. See Cooper and Paterson (1999) for general details of immunizing and collecting serum.

9. Inject the conjugate suspension (1 ml total volume) intradermally at six to eight sites on the back of the animal.

   In the specific case of raising antibodies to cGMP, it is the authors' experience that not all rabbits respond to the antigen. About one out of three rabbits responds to some extent, and only about one out of six produces a high-quality serum. In the authors' experience, the quality of the serum does not improve after five booster injections.

10. At 3-week intervals, prepare a booster injection as described above (step 8) using incomplete instead of complete Freund's adjuvant, and administer this booster injection (1 ml) intramuscularly at four sites (250 µl per site).

11. Collect immune serum 7 to 10 days after each booster injection. Isolate the serum and store it in aliquots at −80°C as described in steps 6 and 7.

    Antibodies have been raised in rabbits, mice, and sheep. Although some differences in recognition of cGMP epitopes in different cells might be expected because cGMP is fixed to different matrix proteins (de Vente et al., 1989), this problem can be overcome by combining different antisera. Antibodies against cGMP raised in rabbits and in sheep have been observed to stain exactly the same, as demonstrated by double immunostaining (de Vente, unpub. observ.).

Purify antiserum

12. Incubate the immune serum 30 min at 56°C.

13. Add 3 mg fixative-treated carrier protein to each milliliter of serum. Incubate 30 min at 37°C and then overnight at 4°C.

    As the cyclic nucleotides are fixed to the carrier protein using formaldehyde (cGMP) or acrolein (cAMP), it is necessary to study the effects of these fixatives on the carrier protein itself in the absence of the cyclic nucleotide. Therefore, the carrier protein is treated in exactly the same way as described for preparation of the conjugate except that the cyclic nucleotides are not added. This protein is used either to remove excess antibodies (those not specific for the cyclic nucleotides) from the sera or to provide a constant carrier protein concentration for conjugate dilutions in preabsorption experiments.

14. Centrifuge the serum for 15 min at 10,000 × *g*, 4°C.

15. Dilute the serum 1:1 (v/v) with glycerol and store at −20°C.

    Antisera can be stored this way for prolonged periods of time.

Test specificity of antibodies

16. Prepare conjugates as described above (steps 1 to 4), using a range of nucleotides selected for specificity testing and a carrier protein different from the one used to immunize the animals.

17. Prepare serial dilutions (1:10) of these conjugates in TBS, starting at 1 mg/ml, at constant down to 0.1 µg/ml concentration of the unconjugated protein.

    This constant concentration of unconjugated protein assures identical conditions.

18. Spot 2 µl each of these solutions onto nitrocellulose or nylon blotting membrane using glass capillary micropipets. Let dry at room temperature.

19. Soak the blot 1 hr in blocking solution.

    Blocking of the binding capacity of the blot is necessary, as otherwise the blot will be saturated with antiserum. Gelatin usually works satisfactorily and has the advantage of low cost.

20. Wash in three changes of TBS, 5 min each.

21. Incubate blot with primary antibodies (from step 15) at an appropriate dilution in TBS overnight at 4°C.

22. Wash 15 min each with TBS, TBS-T, and TBS.

23. Incubate with anti–rabbit Ig secondary antibody diluted in TBS for 30 min, then repeat step 22

    Dilution is usually as indicated by the manufacturer, otherwise it needs to be determined for each antibody separately.

24. Incubate with rabbit peroxidase-antiperoxidase antibody diluted in TBS for 30 min, and repeat step 22.

    Dilution is usually as indicated by the manufacturer, otherwise it needs to be determined for each antibody separately.

25. Wash 5 min in 0.05 M Tris·Cl buffer, pH 7.4. Add DAB staining solution and wait until the brownish color has developed sufficiently.

    The brownish color must be visible within 10 min and should be complete within 20 to 30 min. In exceptional cases it is necessary to wait longer; however, a certain nonspecific precipitation of the color might occur, and this is likely to interfere with the immunocytochemical staining when prolonged incubations are used.

26. Wash at least three times, 10 min each, with 0.05 M Tris·Cl buffer, pH 7.4. Let the blots dry at room temperature.

    Interaction of the antiserum with the spotted proteins will produce brown spots.

    Careful analysis of the results will yield information about the specificity of the antiserum. Preimmune sera must be negative. Antisera preabsorbed with antigen-protein conjugates will be negative, but at a limiting dilution of the antigen-protein conjugate, the reaction product will become visible again. Using the antiserum in different dilutions will give some indication of the antiserum dilution that might give a result with tissue samples. The dilution of antiserum used for tissue immunocytochemistry will generally be less by a factor of three to ten. A good performance of antiserum on nitrocellulose dot blots or immunoblots (western blots) is no guarantee of good performance in tissue immunocytochemistry.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acrolein fixative, 1% (v/v)

Working in a high-capacity fume hood, dissolve 1% (v/v) double-distilled acrolein (as supplied) under vigorous stirring in 0.1 M sodium acetate, pH 4.8 (*APPENDIX 2A*).

This solution is prepared just prior to use and cannot be stored.

CAUTION: *Acrolein is highly toxic. Use gloves and a mask. Acrolein distillation needs to be carried out by a very experienced organic chemist.*

DAB staining solution

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.01% (v/v) hydrogen peroxide
0.5 mg/ml diaminobenzidine (DAB)

This solution is prepared just prior to use and cannot be stored.

Formaldehyde fixative (4% w/v), freshly depolymerized

Add 4 g powdered paraformaldehyde to 50 ml water and add 3 drops of 1 N NaOH. Stir gently and heat the solution at 65°C until it has cleared completely. Add 50 ml of 0.2 M sodium phosphate buffer (pH 7.4).

To obtain sucrose-containing fixative, add 10% (w/v) sucrose to the prepared formaldehyde solution.

These solutions can be kept for at least 4 hr. No upper limit for storage can be given; however, it is advised to prepare them fresh for each experiment.

Other formaldehyde-based fixatives such as Zamboni (containing picric acid) or Bouin (containing picric acid, acetic acid, and commercial formalin solution) can be used equally well. There may be particular circumstances in which one of these fixatives is preferred. However, this issue has not been investigated in detail.

Krebs buffer, oxygenated

1.2 mM $CaCl_2$
121.1 mM NaCl
1.87 mM KCl
1.15 mM $MgCl_2$
24.9 mM $NaHCO_3$
11.0 mM glucose
Adjust pH to 7.4, if necessary, with 0.01 M HCl or 0.01 M NaOH.
Oxygenate with 5% CO_2/95% O_2

This buffer is best prepared by making a 10× concentrated solution of the salts without glucose, $CaCl_2$, and $NaHCO_3$. When required, the concentrated solution is diluted and oxygenated, and glucose and $NaHCO_3$ are added. Aeration is continued and the $CaCl_2$ is added from a concentrated stock solution as the final ingredient. This procedure prevents the formation of insoluble $CaCO_3$. If well oxygenated, this buffer can be kept for one working day.

In some cases it may be desirable to include phosphodiesterase inhibitors in this buffer (see Basic Protocol, step 8 annotation). Many phosphodiesterase inhibitors are rather insoluble in water and in such a case a concentrated stock solution needs to be prepared in DMSO. A final concentration of 1% DMSO in the incubation buffer has no effect on the concentration of cyclic nucleotides in rat brain tissues. IBMX dissolves slowly in aqueous medium; it will take at least 1 hr to reach a concentration of 1 mM IBMX.

Tris-buffered saline (TBS)

50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.9% (w/v) NaCl (*APPENDIX 2A*)
Store at 4°C

Phosphate-buffered saline (PBS; APPENDIX 2A) can be used equally well.

This solution is stable for prolonged times when kept cold; at room temperature it is not advised to keep it longer than 5 days.

COMMENTARY

Background Information

Cyclic nucleotides are second messengers. They relay many different signals involved in regulating growth, development, metabolism, memory formation, and memory storage. Signaling molecules either stimulate or inhibit the synthesis or breakdown of cAMP or cGMP.

cAMP is synthesized by the enzyme adenylate cyclase (ADC). Presently, eight species of ADC are known (Cooper et al., 1995), and these species are uniquely regulated by a variety of different ligands. In addition, different types of ADC show discrete expression patterns throughout the organism. For studying the role of cAMP in different cell types in heterogeneous tissue, immunocytochemical detection greatly expands the possibilities for assessing the compound's distribution. Moreover, such a technique might be able to show a discrete regulation of cAMP within different parts of a single cell.

Similar considerations apply to cGMP metabolism. cGMP is synthesized by two different classes of enzymes, the so-called particulate and soluble guanylyl cyclases (pGNC and sGNC). Both forms of cyclases are activated by different ligands and have very different structures, and both are found in vertebrates as well as in invertebrates (Wedel and Garbers, 1997).

pGNC contains an extracellular hormone-receptor domain, a membrane-spanning region, and an intracellular catalytically active portion (Wedel and Garbers, 1997). Six membrane-bound forms of GNC have been recognized in mammals. To date, some but not all endogenous ligands for these receptors have been identified. pGNC-A and -B receptors are activated by natriuretic peptides. pGNC-C is activated by guanylins and by the heat-stable fragment of *Escherichia coli* endotoxin (Wedel and Garbers, 1997). Recently, GNC activating peptides have been described in the retina, which act on both pGNC-D and -E (e.g., Gorczyca et al., 1994). The activating ligand for the neuroepithelial pGNC-F is still unknown. In invertebrates, activation of pGNC by eclosion hormone is important for the initiation of specific behavioral programs (Truman et al., 1997). From cloning studies of GNC in *Caenorhabditis elegans* came the surprising result that at least 29 gene products could be identified that appeared to encode a protein with GNC activity (Yu et al., 1997). Therefore, many more pGNCs may be discovered in mammals.

sGNC is a heterodimeric protein. In rats, two α (α_1, α_2) and two β (β_1, β_2) subunits are presently known (Harteneck et al., 1991), whereas in humans a β_3 subunit has been identified (Giuili et al., 1992). sGNC contains a prosthetic heme group and is activated by NO (Murad, 1994). Although other activators of sGNC are known—e.g., CO, OH^-, and arachidonic acid—their physiological significance is not known. NO is synthesized by nitric oxide synthase (NOS) from L-arginine and molecular oxygen, with citrulline as a coproduct (Bredt et al., 1990; Knowles and Moncada, 1994; Moncada et al., 1991). In the past 10 years several isoforms of NOS have been characterized (Moncada et al., 1991). Apart from the constitutive forms, another isoform of the enzyme can be induced by combinations of cytokines and immunostimulants. The constitutive forms of NOS are all activated through a calcium/calmodulin-dependent pathway, whereas the inducible form of NOS is intrinsically active (Knowles and Moncada, 1994). As NO has a very high affinity for sGNC (Traylor and Sharma, 1992), it is easily conceivable that sGNC might be an important target for endogenously synthesized NO (Garthwaite, 1991).

Cyclic nucleotide levels in tissue are controlled by the rates of synthesis through ADC or GNC and breakdown through phosphodiesterase (PDE) activity. The 3′,5′-cyclic nucleotide phosphodiesterases comprise a large family of enzymes that can be classified on the basis of kinetic and structural characteristics into at least eight subfamilies (Beavo and Reifsnyder, 1990). Several of these subfamilies

also contain a considerable number of isoforms (Houslay and Milligan, 1997). Recently, it has been demonstrated that members of several of these subfamilies have a specific localization in cells in restricted areas of the brain and peripheral tissues (Juilfs et al., 1997). These findings, together with known properties relating to substrate specificity (cAMP and/or cGMP) and inhibitor selectivity, point to an important role for PDE activity in regulating cyclic nucleotide–mediated signal transduction.

In addition, it has been shown that cGMP has an important role in regulating cAMP hydrolysis. cGMP stimulates PDE-2 and inhibits PDE-3 activity (both enzymes preferentially hydrolyze cAMP). The PDE-1 class of enzymes is calcium dependent, and both cAMP- and cGMP-specific forms of this type PDE are known (Beavo and Reifsnyder, 1990; Houslay and Milligan, 1997). As there is considerable PDE activity in most tissues and certainly in the brain, it is advisable to choose a suitable inhibitor of PDE activity when cyclic nucleotide immunocytochemistry is attempted.

In summary, cyclic nucleotides are important second messengers regulating ion-channel activity, protein function, cell interactions, and gene transcription, thus controlling cell structure and function. In recent years it has become clear that the cyclic nucleotide signaling cascade is more complex than was previously thought. Great variety has been observed in enzymes synthesizing cAMP or cGMP, and in addition, the number and disparity of classes of PDEs increasingly reveal their complexity. Thus evidence is accumulating that individual cells in complex tissues like the brain can have a distinct set of cyclic nucleotide synthesizing and hydrolyzing enzymes, leading to unique responses even when the receptor set of the cells are similar. Modern cyclic nucleotide immunocytochemistry can play an important role in identifying these cells in an environment that is at least partly intact. This can give clues to the function of single cells in a complex response.

Visualization of second messenger molecules is a powerful approach in studying the role of second messengers in relation to the (sub)cellular localization and/or kinetics of the second messenger response. During the last decade, technical improvements in Ca^{2+} imaging have yielded a wealth of information about the second messenger role of this ion in time and space. For cyclic nucleotides, there is presently no method available that has the same resolution as Ca^{2+} imaging. The localization of cyclic nucleotides can be studied using conventional immunohistochemical techniques. However, if the kinetics of the cyclic-nucleotide response are very fast, as in the case of odor or photon transduction (Baylor, 1996; Boekhoff and Breer, 1992), advanced biochemical techniques are necessary.

Immunocytochemical and biochemical analysis of cyclic nucleotides both require antibodies raised against cAMP or cGMP. Indeed, when antibodies against the cyclic nucleotides first became available (Steiner et al., 1972), they were immediately used in immunocytochemical studies (Wedner et al., 1972). These antibodies were raised against a 2′-succinylated cyclic nucleotide, which was coupled to a carrier protein by means of a carbodiimide reaction. All immunoassays for cAMP or cGMP presently available use this type of antibody. Although the early immunocytochemical studies showed for the first time a discrete localization of cAMP or cGMP in complex tissues, some drawbacks of the method were soon recognized. For cAMP immunocytochemistry it was necessary to use unfixed tissue material, with the accompanying severe losses of the readily water-soluble cyclic nucleotide from the tissue (Cumming et al., 1980). Although tissue fixation was shown to be compatible with cGMP immunocytochemistry (Chan-Palay and Palay, 1979), cyclic nucleotide immunocytochemistry did not find wide application. Visualization of the active pool of cyclic nucleotides proved difficult, and it was hypothesized that these antibodies recognized cAMP and cGMP bound to the respective protein kinases (Steiner et al., 1976).

Successful immunocytochemical visualization of small, water-soluble molecules requires fixation of these molecules to tissue-matrix proteins, as otherwise they will be lost during the subsequent procedural steps. The fixatives most commonly used in immunocytochemistry are formaldehyde and glutaraldehyde, which are both rather reactive chemicals. During fixation, the original structure of the hapten may be modified, as has been demonstrated for serotonin (Schipper and Tilders, 1983). Therefore, as these small molecules are nonimmunogenic, antisera should be raised against conjugates that have been prepared following a procedure similar to that used for tissue fixation (de Vente et al., 1987; Schipper and Tilders, 1983). For cAMP and cGMP, different fixation procedures

had to be worked out, which finally resulted in the raising of antisera specifically directed against acrolein-fixed cAMP and formaldehyde-fixed cGMP.

Critical Parameters

When working with isolated tissue, the isolation procedure is probably the most difficult, and most controversial, step (Aitken et al., 1995). In general, routine pharmacological methods for preparing tissues can be used and have met with success (e.g., Berkelmans et al., 1989; Chevalier et al., 1992; de Vente et al., 1989; Vaandrager et al., 1992). For the preparation of brain tissue, speed is of utmost importance. The thickness of the slice should be not more than 400 µm, and oxygenation of the slice should be optimal on all sides (Aitken et al., 1995).

As fixation of cyclic nucleotides is necessary for a reliable visualization, the choice of the fixative is critical. cAMP is not very reactive towards formaldehyde or glutaraldehyde, therefore it is necessary to use the highly reactive and highly toxic cross-linker acrolein (de Vente et al., 1993; Wiemelt et al., 1997). In the case of cGMP, the methylene bridge formed between the protein and hapten by use of formaldehyde is sufficiently stable to permit raising highly selective antibodies (de Vente et al., 1987). The reaction conditions for conjugating cGMP to a protein have been investigated in some detail. Fixation of cGMP was optimal between pH 6.0 and 7.0. A fixation time of 2 hr was taken to be sufficient as the reaction between cGMP, formaldehyde, and thyroglobulin approached equilibrium at this time point. As the retention of cGMP in a model system was improved at pH 7.4 compared to pH 6.0, a routine fixation of cGMP at pH 7.4 is indicated (de Vente et al., 1987).

Troubleshooting

The immunostaining procedure itself is reliable and there are no real pitfalls other than the normal problems related to proving specificity in immunocytochemistry. Therefore, always include negative controls. Specificity can further be studied by preabsorbing the antibodies with either cyclic nucleotides free in solution or in conjugated form (de Vente et al., 1989). As the antibodies are raised against conjugated cAMP or cGMP, it is preferred to preabsorb the primary antibodies with the respective conjugates. To avoid false positive results in the specificity test, it is necessary to use a conjugate protein different from the one used for immunizing the animal. In the authors' experience nonspecific staining of the primary antibodies is very low, and if there are problems in this direction, they are most probably related to the fixative.

In theory, the secondary and tertiary antibodies should not be a cause of erroneous results. However, in the authors' experience they are the largest source of trouble in immunocytochemistry. Large differences have been observed in the quality of immunostaining with various batches of labeled antibodies, even when they originated from the same manufacturer. Especially large differences have been noted in the nonspecific immunofluorescence associated with FITC- and Cy3-conjugated secondary antibodies. This nonspecific immunofluorescence has been observed in myelinated tissue in particular, and the authors have not been able to identify a pretreatment that removes such nonspecific staining if it is present. When double or triple immunostaining is to be performed, the experimenter must be aware that interactions between secondary antibodies may occur or that there may be nonspecific interactions between primary and unrelated secondary antibodies. False-positive reactions may also be observed when tertiary antibodies are used. Double and triple immunostaining reactions must be validated by controls for all the different combinations of antibodies that are used.

Anticipated Results

Cyclic nucleotide immunocytochemistry should result in the visualization of cGMP or cAMP in cell somata and in tissue fibers. How cGMP or cAMP immunostaining will present itself depends on the stimulus and the kind of tissue. Most experience has been obtained with the stimulation of the soluble guanylyl cyclase using a nitric oxide–donor compound, like sodium nitroprusside, and with the stimulation of the particulate form of the enzyme using atrial natriuretic factor (ANF) in mammals and eclosion hormone in insects (e.g., Bicker et al., 1996; de Vente et al., 1996; Ewer et al., 1994; Shuttleworth et al., 1993; Southam and Garthwaite, 1993; Truman et al., 1997). The effect of stimulation of cGMP synthesis in the central nervous system and in peripheral tissue slices incubated in vitro with sodium nitroprusside or ANF is demonstrated in Figure 10.7.1, 10.7.2, and 10.7.3. In the hippocampus, sodium nitroprusside stimulates soluble guanylyl cyclase

primarily in varicose fibers, a few interneurons and in some astrocytes. In contrast the effect of ANF is primarily shown in astrocytes (de Vente et al., 1989). A certain number of astrocytes contains both the soluble and the particulate guanylyl cyclase (de Vente, unpub. obs.). In the intestine it was possible to demonstrate the presence of three different types of guanylyl cyclase activity by stimulating different pieces of tissue with three different specific ligands (e.g., Vaandrager et al., 1992). In the hypophysis the authors could demonstrate that sGNC and pGNC have a different localization in the three different parts of this tissue. Activation of adenylate cyclase by dopamine is shown in the frontal rat brain, where cAMP accumulation is observed in neuronal cell somata (de Vente et al., 1993).

A sharply defined immunostaining of cGMP has been demonstrated in almost all studies using antibodies against formaldehyde-fixed cGMP and, therefore, is anticipated. Presently, it is unknown whether diffusion of cGMP out of the cellular structures has a significant role. The retention of cGMP in biological tissue is almost certainly much higher than the 30% reported for a model system (de Vente et al., 1987; de Vente et al., unpub. observ.). If some diffusion of cAMP or cGMP occurs, as described in the literature for cultured cells (Wu et al., 1993) or in in vivo microdialysis studies (e.g., Luo et al., 1994), the immunostaining of this extracellular nucleotide will be part of the background staining. It might be argued, on the basis of the sharp delineation of the cyclic GMP immunostaining that diffusion out of the tissue is negligible, which is in agreement with the published data (Tjörnhammar et al., 1986).

It may be anticipated that the use of different phosphodiesterase inhibitors may give insight into the distribution of these enzymes in tissues. It has to be realized that none of these inhibitors is a very specific drug; in the best case they are highly selective. Thus it has been shown that zaprinast, a rather selective inhibitor of the PDE-5 (cGMP hydrolyzing), in combination with a NO donor results in the accumulation of cGMP in a restricted area of the hippocampus of the rat (de Vente et al., 1996). Similarly, zaprinast was effective in raising cGMP levels in canine colon smooth muscle cells (Shuttleworth et al., 1993). As already discussed in Background Information, immunocytochemical studies on the tissue distribution of phosphodiesterases (PDEs), although limited (e.g., Juilfs et al., 1997), have provided convincing evidence that various isoforms of this class of enzymes may have a very specific distribution in subsets of cells of functionally assigned areas of every tissue. It is becoming apparent that cells can have an individual expression of a set of PDEs. Therefore, the study of cyclic nucleotide localization in heterogeneous tissue may yield different results when the same experiment is performed twice using different PDE inhibitors. Thus, although IBMX has been the PDE inhibitor of choice in many studies, it will always be necessary to study the effects of other PDE inhibitors in a particular setup when the aim is to provide definite conclusions about the involvement of cyclic nucleotides in signal transduction using the approach described in this unit.

Time Considerations

The entire procedure, incubation of the slices, fixation, sectioning, and immunostaining, can be done in 1.5 working days. The most time consuming step, incubation of the sections with the primary antibodies, can be done overnight. It takes ~4 months to raise primary antibodies in rabbits.

Methods for Distinguishing Nitrosative and Oxidative Chemistry of Reactive Nitrogen Oxide Species Derived from Nitric Oxide

The chemistry of nitric oxide (NO) may have profound effects on biological systems depending on the reactive intermediates involved (Wink et al., 1996a). These NO-derived intermediates formed under aerobic conditions may engage in complex chemical reactions with biologically important molecules. The outcome of these reactions, as well as their ultimate effect on biological systems, depends on the selectivity of the reactive chemical species and the concentration of different substances present. For instance, the reaction between nitric oxide and oxygen can lead to a variety of chemical intermediates, depending on the phase of the reaction. In the gas phase normally associated with air pollution, the autoxidation requires two NO molecules and one oxygen molecule to form two molecules of NO_2 (nitrogen dioxide), which can further react with NO to form N_2O_3 (dinitrogen trioxide).

$$2\ NO + O_2 \rightarrow 2\ NO_2$$
$$NO_2 + NO \rightarrow N_2O_3$$

However, in aqueous solution, there appears to be a fundamental difference in the intermediates produced in the NO/O_2 reaction. Trapping experiments appear to indicate that there is no formation of free NO_2 in aqueous solution (Wink et al., 1993). Furthermore, it has been suggested that the major reactive intermediate in aqueous solution is an isomer of N_2O_3 that differs from that formed in the gas phase (Pires et al., 1994). Competitive kinetic experiments have shown that peptides containing thiols have a high affinity for N_2O_3 (Wink et al., 1994). These results indicate that the primary target of N_2O_3 in vivo is thiols, and suggest that proteins such as those containing zinc-finger motifs are susceptible to reaction with the intermediate (Kroncke et al., 1994; Wink and Laval, 1994). This reaction can affect numerous cellular functions, possibly resulting in cytotoxicity.

Other reactive intermediates formed during the metabolism of NO under in vivo conditions may have important consequences. Peroxynitrite ($ONOO^-$) is readily formed from the reaction between O_2^- and NO (Huie and Padmaja, 1993). Studies have indicated that, unlike N_2O_3, peroxynitrite does not directly nitrosate substrates (Miles et al., 1995; Wink et al., 1997). However, peroxynitrite does oxidize different substrates (lipids, DNA, proteins), which is the primary mode of reactivity in biology (Beckman et al., 1990; Pryor and Squadrito, 1996).

In this unit, conversion of two different compounds to fluorescent products will be used to distinguish between oxidative and nitrosative chemistry of different reactive nitrogen oxide species. In addition, methods will be described for determining the relative selectivity of different substances with these reactive intermediates. Conversion of 2,3-diaminonaphthylene (DAN) to 2,3-naphthyltriazole (NAT) will be used to determine the chemistry of nitrosation (see Basic Protocol 1). The oxidation of 123 dihydrorhodamine (DHR) to 123 rhodamine will be used as a probe for oxidation (see Basic Protocol 2).

DETERMINATION OF NITROSATION REACTIONS

BASIC PROTOCOL 1

The two parts of this protocol provide information necessary to determine the amount of nitrosation, as well as the relative selectivity of the nitrosating intermediates for other substances (Wink et al., 1996a). Buffers and medium often contain an array of substances, and it is not always clear when designing experiments whether these agents might interfere with an assay or experiment. The first part (consisting of steps 1 to 7) is useful

Contributed by David A. Wink, Sungmee Kim, Allen Miles, David Jourd'heuil, Matthew B. Grisham
Current Protocols in Toxicology (2000) 10.8.1-10.8.12

for determining whether substances are present in medium or buffers that limit nitrosation in a particular experiment.The second part (consisting of steps 8 to 12) is used to distinguish the relative chemical affinity for nitrosating intermediates. This is useful in determining the order of reactivity of different substances with nitrosating agents, and can be used to find efficient scavengers for nitrosating agents.

Materials

2,3-diaminonapthylene (DAN; Aldrich)
Dimethylformamide (DMF) or dimethylsufoxide (DMSO)
Buffer or medium under investigation
PBS without calcium or magnesium (*APPENDIX 2A*)
20 to 100 mM sodium phosphate, pH 7.4 (*APPENDIX 2A*)
Nitrogen or argon gas (see Fig. 10.4.3 for setup)
NO gas cylinder (see Fig. 10.4.3 for setup)
1 M NaOH
Sulfanilamide
N-(1-naphthyl)ethylenediamine dihydrochloride (NEDD; Aldrich)
Substrate to be evaluated

Bubbling apparatus for nitrogen or argon and for NO (Fig. 10.4.3), consisting of:
  Glass vials with rubber septa
  Tygon tubing
UV/visible spectrophotometer and quartz cuvettes
100-µl airtight syringe
Spectrofluorometer
13 × 75–mm glass test tubes

Determine Extent of Nitrosation in Different Buffering Systems

Prepare stock solutions

1. Prepare 100 mM DAN stock solution by dissolving 15.6 mg of DAN in 1 ml of either DMSO or DMF.
2. Dissolve 0.2 ml of the DAN stock solution in 100 ml of the buffer or medium under investigation, to make a 0.2 mM DAN/buffer solution.

   IMPORTANT NOTE: *No phenol red should be present. Also, vitamins commonly added to media can interfere as well. It is important that a standard curve be done in the medium of interest to check if any interferences are present.*
3. Prepare comparison buffer by adding 0.2 ml of DAN stock solution to 99.8 ml of PBS (without calcium or magnesium).
4. Prepare NO stock solutions as follows.
   a. Place 20 to 100 mM sodium phosphate, pH 7.4, in a vial with a rubber septum (Fig. 10.4.3).
   b. Bubble nitrogen or argon through the phosphate solution for 1 min per 2 ml of buffer.
   c. Bubble NO through the solution for 20 min per 2 ml of buffer using an apparatus such as that illustrated in Figure 10.4.3 to first bubble the NO through 1 M NaOH to purify the gas and then collect the gas in 100 mM sodium phosphate, pH 7.4.

      Alternatively an NO donor such as $(C_2H_5)_2N(NO)(NO)Na$ and DEA/NO can be used (Keefer et al., 1996). Approximately 20 mg/ml DEA/NO solid should dissolved in 0.01 mM NaOH to yield a 10 mM stock solution. To verify the exact concentration, take a UV-vis spectrum in base. The maximum absorbance at 250 nm has an extinction coefficient of 8000 cm^{-1} M^{-1}.

Standardize using colorimetric method (Nims et al., 1995)

5. Dissolve 0.5 g of sulfanilamide and 30 mg NEDD in PBS to form the colorimetric solution. Stir and gently heat. Filter if necessary.

6. Add a 100-µl aliquot of the NO stock solution via an airtight syringe to 1 ml of colorimetric solution. Allow to stand for 2 min then read the absorption at 500 nm in a UV/vis spectrophotometer. Divide the absorbance reading by 0.012 (for a 1-cm pathlength cuvette) to get the concentration of NO in the stock solution in mM.

   Alternatively, to standardize the amount of NO released by DEA/NO, add 10 µl of the stock solution of that compound (see annotation to step 4) to 1 ml of the colorimetric solution. Allow to stand 1 hr at room temperature or 20 min at 37°C. Read the absorbance at 500 nm. Take the absorbance and divide by 0.0012. This is the concentration of NO released at neutral pH by the DEA/NO stock solution.

Determine the extent of nitrosation in buffer

7. Add 100 µl of the NO stock solution (prepared in step 4) through an airtight syringe to 2 ml of the test buffer containing DAN (prepared in step 2) in the spectrofluorometer. Allow to stand for a few minutes, then read the fluorescence with excitation of 375 nm and emission of 450 nm. Repeat with the comparison buffer (PBS containing DAN; prepared in step 3). Compare fluorescence intensity.

   IMPORTANT NOTE: *The difference in fluorescence between the medium and PBS indicates the amount of potential nitrosative scavenging agents.*

Determine Relative Selectivity of Different Substances

Prepare DAN and substrate solutions

8. Make a 0.2 mM DAN solution in PBS as described in step 3.

   10 to 20 mM HEPES, phosphate, or Tris can be added for additional buffering capacity if required. If the amount of added stock NO or NO donor is <1% of the reaction volume, there should be no effect on the pH. Otherwise, check the pH.

9. Place 2 ml DAN solution (prepared in step 8) into each of a series of 13 × 75–mm glass test tubes. Add substrate to be evaluated at concentrations from 0 to 50 mM (if solubility permits).

   Samples should be analyzed in triplicate. The range of concentrations includes positive and negative controls.

Read fluorescence and analyze results

10. Read the fluorescence at 375 nm excitation and 450 nm emission.

11. Plot concentration of substrate (x-axis) versus 1/fluorescence (y-axis). Divide the slope of the line by the y intercept. Multiply the x intercepts by −1 to give the concentration of substrate required to quench 50% of the reaction with DAN.

    This is the concentration where the 50% of the intermediate is nitrosating DAN and 50% is being scavenged by the substrate. Therefore, the rates of the two pathways are identical and the rate constants can be derived from the concentration (see Background Information).

12. Compare different substrates and their relative $-x$ intercepts at a single concentration of DAN to provide the relative affinity of different substrates for a particular substrate.

BASIC PROTOCOL 2

DETERMINATION OF THE SELECTIVITY FOR DHR OXIDATION

Some reactive nitrogen oxide intermediates formed during NO metabolism can oxidize different substrates. The oxidation of different fluorescent dyes by reactive chemical species such as peroxynitrite can be used to detect these species (Crow, 1997). One such reaction is that of DHR oxidation (Kooy et al., 1994; Miles et al., 1996). This is not a specific dosimeter for a particular intermediate such as hydroxyl radical or peroxynitrite, but instead represents the presence of oxidation chemistry under a given set of conditions. Addition of different trapping agents provides a method for deciphering the species responsible for oxidation. For instance, azide is an excellent trap for nitrosating reactive nitrogen oxide species (RNOS) such as N_2O_3 (Williams, 1988). Metal chelators such as DETAPAC prevent oxidation of DHR by metal-catalyzed reactions mediated by O_2^- and H_2O_2. The following provides a method to determine selectivity, as well as the effect of scavengers on oxidation.

Materials

123 dihydrorhodamine (DHR)
Dimethylformamide (DMF)
PBS (*APPENDIX 2A*) or sample buffer
Oxidizing substances under investigation
123 rhodamine

13 × 75–glass test tubes
Spectrofluorometer

1. Dissolve 25 mg solid DHR in 5 ml of DMF. Dilute this solution three-fold in DMF to yield a 5 mM DHR stock solution.
2. Prepare dilutions of the stock solution (2 ml samples in 13 × 75–mm glass test tubes) with concentrations ranging between 5 and 200 μM DHR in medium, PBS, or sample buffer.

   DHR alone is the negative control; 123 rhodamine is the positive control.
3. Add the oxidizing substances or system to the solution and incubate for the designated time of the experiment. Prepare standard solutions using 123 rhodamine in the exact buffer used in the experiment.
4. Place the 2-ml samples in the spectrofluorometer. Excite at 500 nm and read the emission at 570 nm.
5. Plot 1/[DHR] (*x*-axis) versus 1/fluorescence intensity (*y*-axis). Divide the *y* intercept by the slope and multiply it by −1.

   This value is the concentration of DHR required to trap 50% of the chemical oxidant.

   If the reaction is competitive with DHR oxidation—i.e., formation of nitrite/nitrate—division of the first-order rate constant by this value can give the second-order rate constant for the reaction between the oxidant and DHR.
6. Once the concentration of DHR required to trap 50% of oxidant is determined, prepare a stock solution with the concentration of DHR five times that determined in step 5.

   For example, if 20 μM DHR was required to achieve 50% fluorescence, make a 100 ml stock solution of 100 μM DHR. This will ensure that most of the chemical oxidant is reacting with DHR.

7. Place 2 ml of the DHR solution prepared in step 6 into a series of glass test tubes. Add the substrate that is being evaluated at concentrations from zero to five or ten times the concentration of DHR.

   For example, if 100 μM DHR is present in the solution, then a concentration range of quenching substrates should be from 0 to 1 mM. However, this may depend on the solubility of substrate.

   Samples should be run at least in triplicate for each point for accuracy.

8. Read the resulting fluorescence by exciting the solution at 500 nm and reading the emission at 570 nm.

9. Plot the concentration of substrate (*x*-axis) versus 1/fluorescence (*y*-axis). Divide the slope of the line by the *y* intercept.

   This will give the x intercept which, when multiplied by −1, gives the concentration of substrate required to quench 50% of DHR.

10. Compare different substrates and their relative *x* intercept at a single concentration of DHR to provide the relative selectivity of different substrates for oxidants.

COMMENTARY

Background Information

The mechanism of toxicology that NO is involved in depends on the chemistry of this diatomic radical. Nitrosative and oxidative chemistry resulting from these intermediates can determine specific toxicological mechanisms (Wink et al., 1996a, 1998). Therefore, it is important to understand the reactive chemical species present and the influences they may have on various biological components both from a mechanistic standpoint and an experimental one. As discussed below, there are two ways of interrogating these intermediates. The first is a dose-dependent analysis using either DAN or DHR, which gives the relative reactivity of the RNOS with each compound with respect to other reactions such as nitrite and nitrate formation. The second allows the comparison of different compounds and their effect on scavenging nitrosative and oxidative species.

Product formation analysis

The limiting reaction for the oxidation or nitrosation mediated by different RNOS is the reaction mechanism that ultimately forms nitrite/nitrate. For example, the hydrolysis of N_2O_3 in aqueous solutions will limit the reactions this molecule can undergo with various substrates:

$$N_2O_3 + H_2O \rightarrow NO_2^-$$
$$N_2O_3 + \text{substrate} \rightarrow \text{products}.$$

From these equations, it is possible to derive an expression that will provide the ratio of rate constants for a variety of reactions. Such information should provide a better understanding of the selectivity of RNOS.

A mathematical model can be used to determine the relative affinities of various substrates for NO_x. The reaction rate constant for the substance is defined as k_s, while the reaction rate constant for the formation of nitrite is defined as k_H. The ratio of rate constants, k_s/k_H, determines the affinity of substrate (S) and the amount of product (P) that will be formed at specific substrate concentrations, or, in other words, the fraction of total NO_x that is scavenged by S. The ratio of k_s to k_H can be assessed by analyzing product formation as a function of substrate concentration. This is analogous to the Lineweaver-Burke plots commonly employed in the study of enzyme kinetics. The following mathematical derivation for scheme 1 (see Fig. 10.8.1A) will aid in the determination of the selectivity.

The ratio of product formed versus nitrite concentration is proportional to the rates of formation for each reaction pathway such that: $(dP/dt)/(d[N]/dt)$ = ratio of product formation to nitrite formation. Since $dP/dt = k_s[NO_x]S$, and nitrite formation is unimolecular because water is the solvent,

$$dN/dt = k_H[NO_x].$$

Then,

$$dP/dN = (k_s[NO_x]S)/(k_H[NO_x]).$$

Simplifying the equation gives

$$P/N = k_sS/k_H.$$

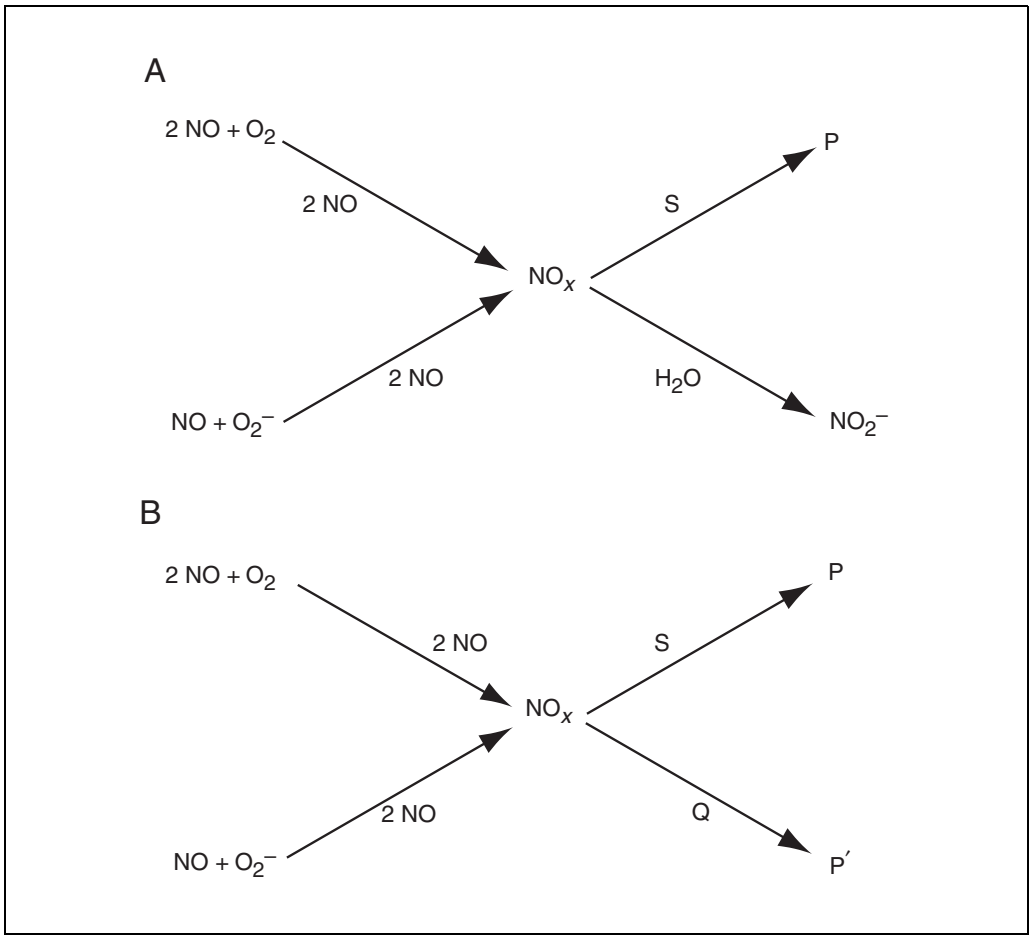

Figure 10.8.1 Reaction schemes. (**A**) Scheme 1. (**B**) Scheme 2.

Since the amount of P as it relates to amount of nitrite formed via hydrolysis is:

$$P_o = P + N$$

where P_o is equal to the maximum total amount of P formed at infinite S concentration or, in other words, the total amount of available NO_x formed. If one solves for N:

$$N = P_o - P$$

and by substitution:

$$P/(P_o - P) = k_s S/k_H$$

This can then be solved algebraically in terms of $1/P$ to yield:

$$1/P = (k_H/(k_s S) \times 1/P_o) + 1/P_o.$$

A plot of $1/S$ versus $1/P$ will give a linear plot with slope $= k_H/(k_s) \times (1/P_o)$ and y-intercept $= 1/P_o$. Therefore,

$$k_s/k_H = y\text{-intercept/slope or } -(x\text{-intercept}).$$

Using this methodology, the $-(1/x$-intercept) represents the concentration of substrate required to scavenge 50% of the available NO_x. An alternative way to express this is that the concentration of substrate required is such that the rate of product formation is equal to the rate hydrolysis of NO_x. Hence,

$$k_H = k_s[S_{0.5}],$$

which can be solved as follows:

$$k_H = k_s[S_{0.5}] = -1/x \text{ intercept.}$$

Product quenching

Another approach is to design a study of the competition between two different substrates, S and Q (for quencher) for NO_x.

The rate constant for the reaction of substrate (detection compound) is k_s, while the rate constant for the quencher is k_Q. A mathematical expression can be derived for scheme 2 (see Fig. 10.8.1B) which can yield the ratio of rate constants for k_s and k_Q. As above, the ratio of P/P' is proportional to the ratio of their rates of formation:

$$(dP/dt)/(dP'/dt) = dP/dP'.$$

Since

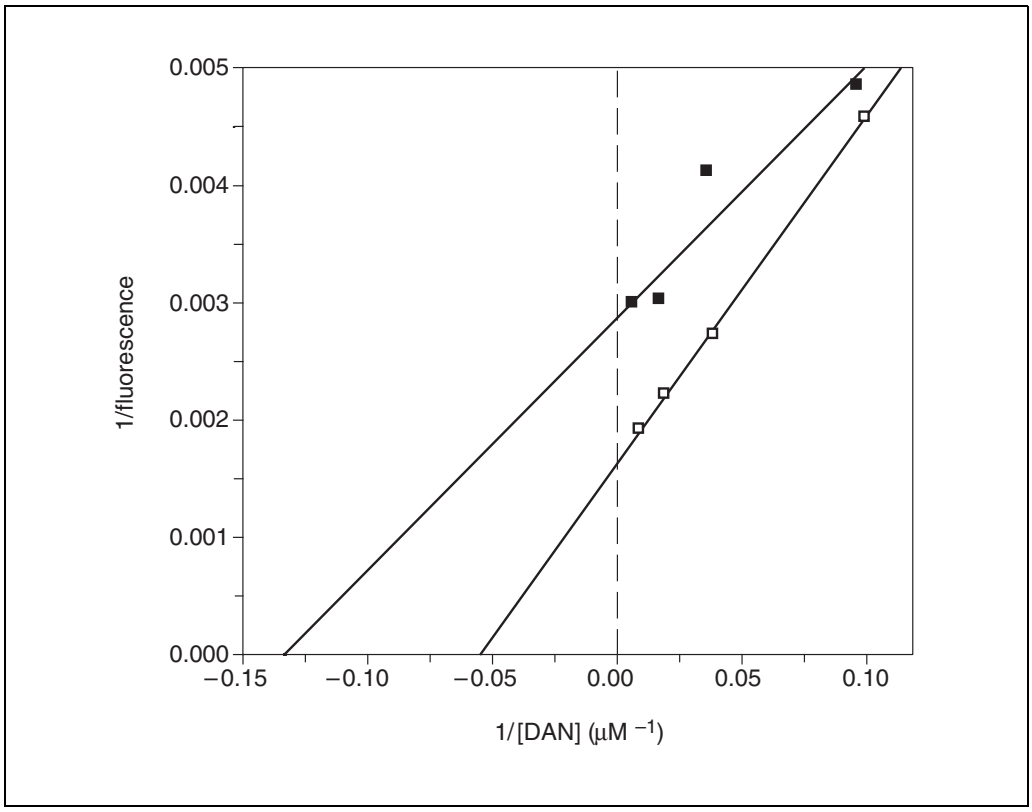

Figure 10.8.2 The effect of different concentrations of DAN on the fluorescence intensity mediated by the NO/O_2 reaction or acidic nitrite. Increasing DAN was placed in a 10 mM phosphate solution, pH 7, where NO concentration was 10 μM (open squares). Another 10 mM phosphate solution at, pH 5, with 10 mM $NaNO_2$ was exposed to different DAN concentrations (closed diamonds).

$$dP/dt = k_s[NO_x]S$$
$$dP'/dt = k_Q[NO_x]Q$$

then

$$P/P' = (k_s[NO_x]S)/(k_Q[NO_x]Q)$$

Often it is inconvenient to measure product, P'. Therefore, P' can be expressed in terms of P. In the absence of Q, P_T represents the total NO_x which is scavenged

$$P_T = P + P'$$

therefore

$$P' = P_T - P;$$

then

$$P/(P_T - P) = (k_sS)/(k_QQ).$$

Solving the above equation for $1/P$:

$$1/P = [\ (k_QQ)/(k_sS) \times 1/P_T] + 1/P_T.$$

In this type of experiment, the substrate concentration remains constant while the amount of quencher, Q, is varied. A plot of $1/P$ versus the concentration of Q yields a linear graph with slope = $(k_Q)/(k_sS) \times 1/P_T$ and y-intercept is $1/P_T$. Therefore if S is known:

$$k_Q/k_s = S \times (\text{slope}/y\text{-intercept}) \text{ or}$$
$$S \times x\text{-intercept}.$$

It is important to note that with this type of experiment, the substrate concentration should be such that >90% of the NO_x is scavenged by S.

Chemical biology of NO

There are numerous chemical reactions involving nitric oxide that are thought to be operative in biological systems. Determining which reactions are relevant to different toxicological mechanisms has been a challenge. In order to decipher the complexity of these reactions, a description known as the chemical biology of NO was formed, which equates the pertinent chemical reactions to specific biological situations (Wink et al., 1996b, 1998). The chemical biology of NO is divided into two major categories, consisting of direct and indirect effects. The direct effects are those that involve direct reactions of NO with biological targets—e.g., the reaction between NO and heme proteins such as guanylate cyclase and oxyhemoglobin. These reactions require low concentrations of NO and occur very rapidly.

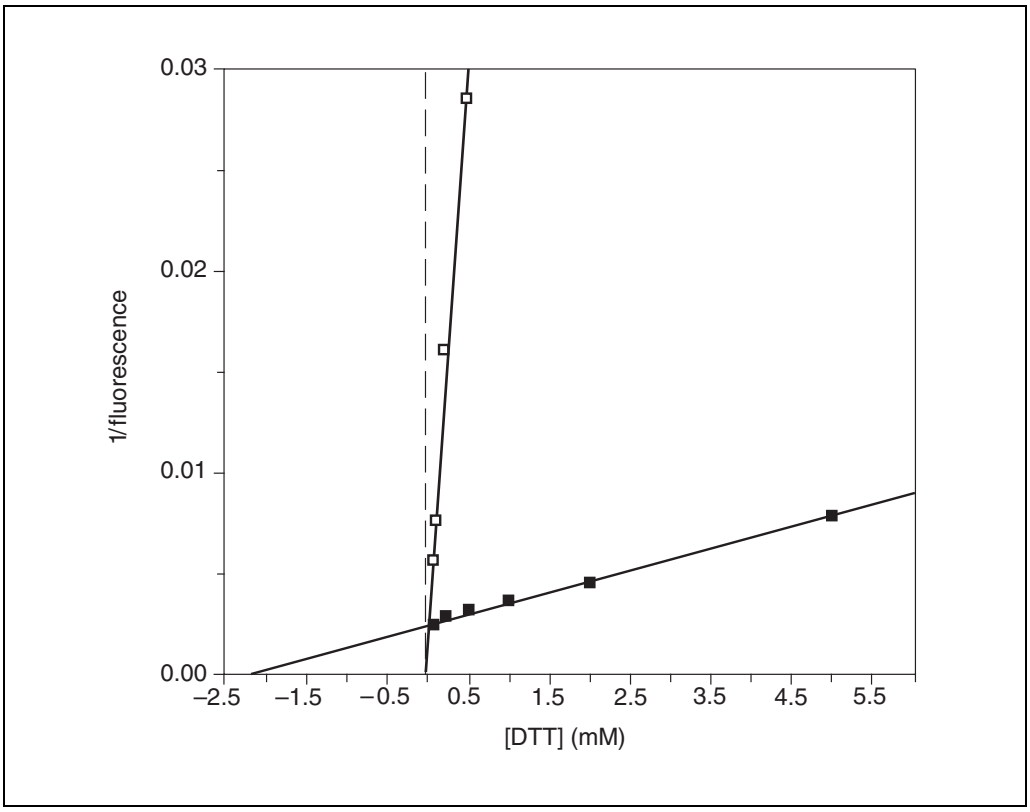

Figure 10.8.3 The effect of different amounts of DTT on the nitrosation of DAN, mediated either the NO/O_2 reaction or acidic nitrite. A 10 mM phosphate solution, pH 7, with 100 μM DAN and varying amounts of DTT was exposed to 10 μM NO (closed squares). A 10 mM phosphate solution, pH 5, with 100 μM DAN and varying amounts of DTT was exposed to 10 μM $NaNO_2$ (open squares).

Table 10.8.1 Selectivity of NO_x Toward Reaction with Various Substrates in Aqueous Solution[a]

Substrate	$k_s/k_H(M^{-1})$	Concentration required to scavenge 90% of NO_x (mM)
Amino acids	<5	2000
5-Aminosalicylic acid	2×10^3[b]	5
Ascorbate	3×10^4	0.3
Azide ion	10^5	0.1
Cysteine	5×10^3	2
Cytosine	<0.005	2×10^5
DAN	3×10^4	0.3
Dopamine	1×10^3[c]	10
Ferrocyanide	5×10^2	20
Glutathione	10^4	1
Phosphate	25	400
Tyrosine	25	400

[a]Data from Wink et al., 1996c.

[b]Obtained by monitoring of the resultant product with absorbance at 400 nm.

[c]Obtained by monitoring the formation of the resultant oxidized product by absorbance at 475 nm.

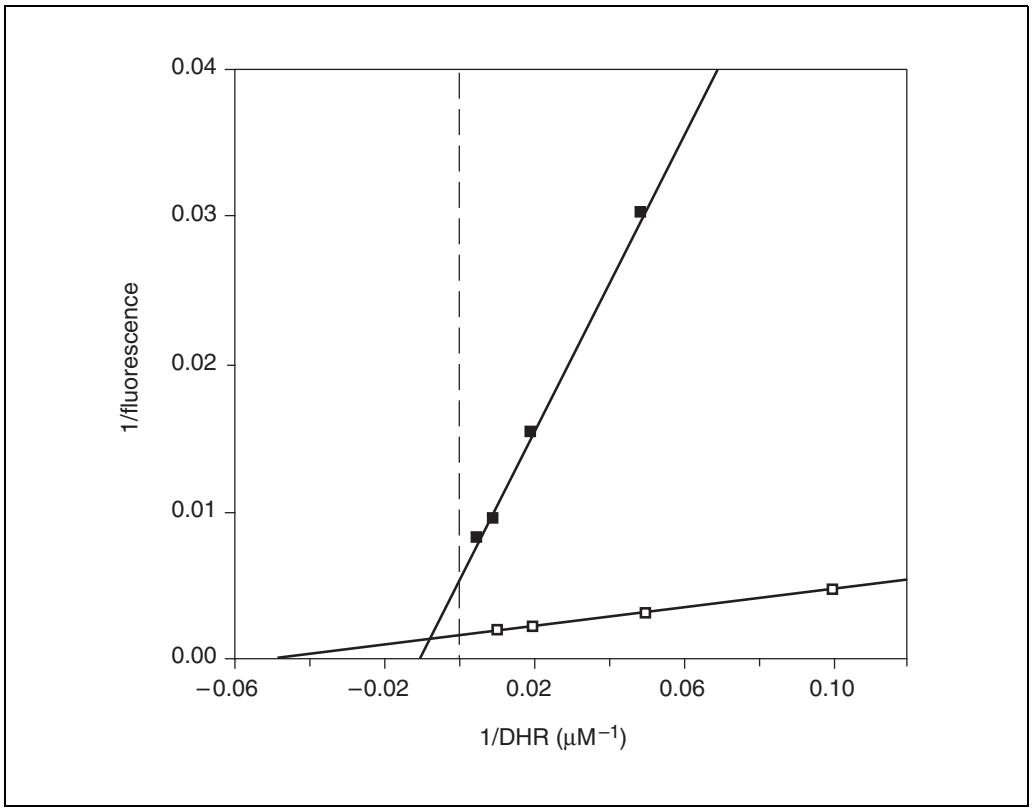

Figure 10.8.4 Concentration dependency of DHR treated with peroxynitrite or DEA/NO. PBS solutions containing 50 μM DETAPAC and 10 mM HEPES with varying concentrations of DHR was exposed to 10 μM DEA/NO (closed squares). PBS solutions containing 50 μM DETAPAC and 10 mM HEPES with varying concentrations of DHR was exposed to 10 μM peroxynitrite (open squares).

Indirect effects do not involve NO itself, but rather RNOS derived from the reaction between NO and oxygen or superoxide. These reactions require high localized concentrations of NO, generally for a prolonged period of time, and primarily generate N_2O_3 from the reaction with oxygen, while $ONOO^-$ is the preliminary product from the NO/O_2^- reaction. N_2O_3, as discussed above, mediates nitrosation reactions, while $ONOO^-$, and, to lesser extent, N_2O_3, mediate oxidative chemistry. With this in mind, the indirect effects can be cataloged into nitrosative and oxidative stress. As presented here, DAN distinguishes nitrosative pathways, while DHR indicates oxidation, allowing the determination of both categories of the indirect effects.

Nitrosation reactions in biological systems occur primarily with amines and *S*-nitrosothiols. These reactions with a variety of proteins (e.g., DNA repair proteins, ligase, alkylyltransferase, GAPDH, metallothionein, and zinc finger proteins such as Fpg and SP-1) can have profound effects such as inhibition of DNA repair proteins and formation of vasoactive substances (Wink et al., 1996a,b). The formation of N_2O_3 in vivo is primarily from three sources. Reactions such as the autoxidation of NO (Ford et al., 1993), acidic nitrite solutions (Williams, 1988), and NO reaction with peroxynitrite can all result in nitrosation reactions (Wink et al., 1997). There appear to be two isomers of N_2O_3 that differ in affinity for different substrates. The autoxidation of NO in the gas phase proceeds through the intermediate NO_2, which reacts at near diffusion control to yield N_2O_3 (Pires et al., 1994). Mildly acidic nitrite solutions can also generate N_2O_3. It has been presumed that the $ON\text{-}NO_2$ isomer of N_2O_3 is formed in both gas phase autoxidation and acidic nitrite reactions (Williams, 1988). However, the autoxidation in aqueous solution is thought to form a different isomer of N_2O_3 perhaps ONONO (Pires et al., 1994). With the methods described above, it is possible to probe the relative reactivity of these intermediates under different conditions.

When NO is exposed to a solution with varying DAN concentrations, there is an increase in fluorescence with increasing concentration of DAN. A plot of 1/[DAN] versus 1/fluorescence is linear, with $-1/x_{int} = 18$ μM

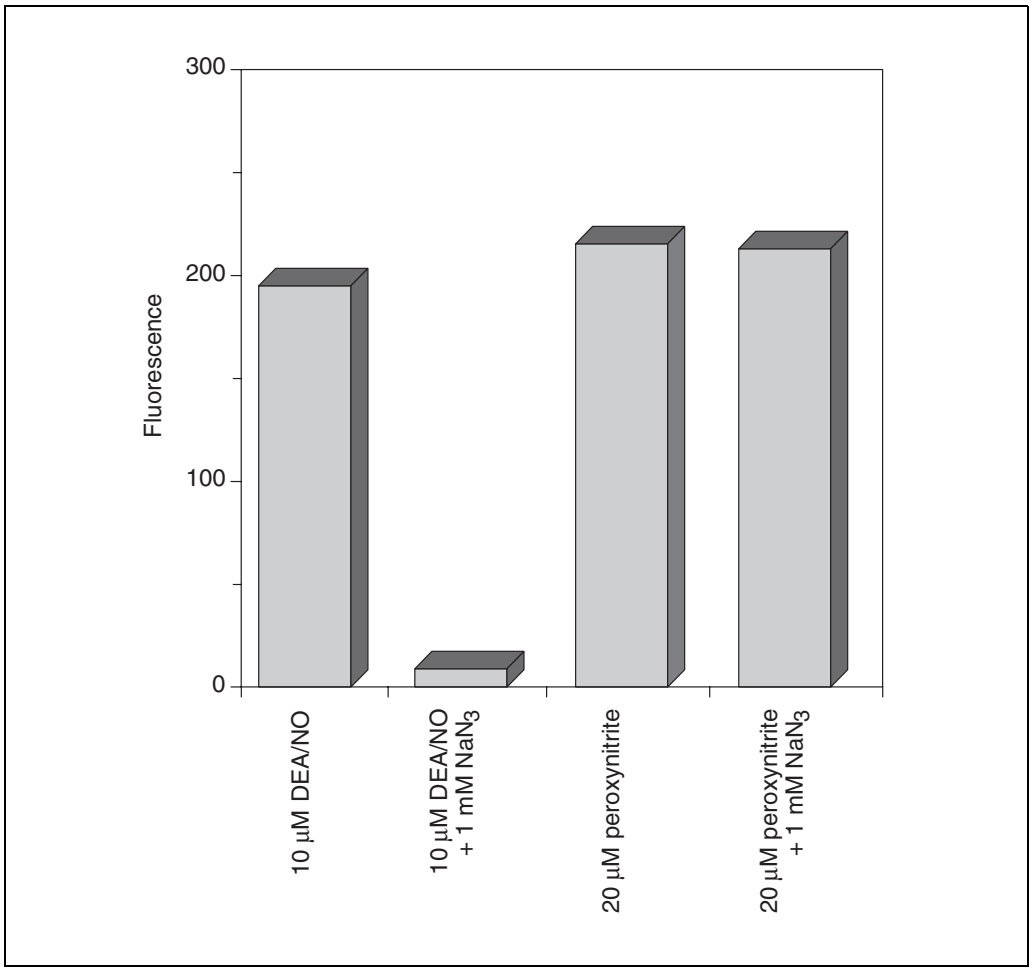

Figure 10.8.5 Comparison of azide between DEA/NO and peroxynitrite. PBS solutions with 10 mM HEPES and 50 μM DETAPAC containing 50 μM DHR were exposed to either 10 μM DEA/NO or 20 μM peroxynitrite with or without 1 mM azide.

(Fig. 10.8.2). From the equation discussed above, this gives a relative reactivity to hydrolysis of 55,000 M^{-1}:1 as defined in Figure 10.8.1. From this information, other substrates such as azide, ascorbate, dithiothreitol (DTT), and glutathione (GSH) can be compared (Table 10.8.1). As seen in Figure 10.8.3 and Table 10.8.1, the $-x_{int}$ shows that relative selectivity to hydrolysis and DAN. This suggests that the order of preference is azide, GSH, ascorbate, and DTT.

Using the method described above, the nitrosative chemistry mediated by the autoxidation reaction in aqueous solution can be compared to that in an acidic nitrite solution, pH 5. DAN nitrosation at pH 5 in the presence of 10 mM sodium nitrite is linear with time. The fluorescence value at 4 min increased with increasing concentrations of DAN. A plot of 1/fluorescence versus 1/[DAN] gives a value of $-1/x$ intercept of 7 μM (Fig. 10.8.2). This suggests a small difference in selectivity for nitrosation reaction with DAN either by the NO/O_2 reaction or by nitrite. However, if the relative selectivity for DTT is compared, there is a marked difference. In Figure 10.8.3, a plot of the concentration of DTT versus 1/fluorescence shows that the x intercept is 68 μM for acidic nitrite solution while the $-x$ intercept is 2.4 mM for the NO/O_2 reaction. This suggests that there is a selectivity difference of 35-fold for DTT between the nitrosation chemistry in acidic nitrite solution and in NO/O_2. Figure 10.8.2 and Figure 10.8.3 illustrate how these methods can be used to distinguish different chemical properties of different agents.

As described above, similar strategies can be used to probe the oxidative chemistry of peroxynitrite and N_2O_3 produced in aqueous solution. The reaction of NO with O_2^- results in the powerful oxidant peroxynitrite:

$$NO + O_2^- \rightarrow ONOO^-$$

It has been shown that when excess NO is present, peroxynitrite can be converted to form nitrosating agents, presumably N_2O_3. DHR has

often been used to quantitate oxidants in biological systems and the presence of $ONOO^-$ (Kooy et al., 1994; Crow, 1997). However, care must be taken. In Figure 10.8.4, 10 μM peroxynitrite is exposed to increasing DHR. A plot of 1/fluorescence versus 1/[DHR] is linear with $-1/x_{int}$ = 19 μM. NO released from the NONOate DEA/NO also oxidizes DHR; however, a plot of 1/DHR versus 1/fluorescence reveals an $-1/x_{int}$ of 97 μM. This suggest that peroxynitrite is a more powerful oxidant than N_2O_3. Azide can be used to distinguish oxidation mediated by peroxynitrite and nitrosating agents such as N_2O_3. 1 mM azide will quench the oxidation mediated by N_2O_3, while oxidation mediated by peroxynitrite is not quenched. As seen in Figure 10.8.5, 10 μM of the NO donor DEA/NO readily oxidizes DHR. However, in the presence of azide (an NO^+ donor scavenger), the oxidation is completely abated. Peroxynitrite-mediated oxidation, on the other hand, shows no quenching by azide. This illustrates how different oxidants can be discerned under various conditions. Under some biological conditions, specific scavengers such as azide can prove useful in deciphering the nature of the intermediates involved.

Critical Parameters and Troubleshooting

These assays are usually straightforward. However, in some media there could be azide, 2-mercaptoethanol, or dithiothreitol (DTT), which will interfere with the measurement. DAN stock solutions can be nitrosated or oxidized readily. These should be made up fresh. Also, the purity of DAN is critical. DHR stock solutions should be stored under argon in a –20°C freezer. The baseline of a measurement should not be any higher than 10% of the lowest reading.

Anticipated Results

The above techniques can provide insights into the type of chemical stress, nitrosative or oxidative, that occurs under the experimental conditions. By formulating different conditions, the RNOS involved can be deciphered. Another advantage is that new agents can be tested for their ability to quench either nitrosative or oxidative damage by different reactive intermediates. The amount of nitrosation or oxidation can be quantitated in specific media (but note vitamins will interfere with these assays).

Time Considerations

Once the equipment is set up and the reagents are ready, these assays require 1 to 2 hr.

Inducible Nitric Oxide Synthase Expression

Nitric oxide synthases (NOSs, EC 1.14.13.39) are a family of isoenzymes that catalyze the production of nitric oxide (NO) from the oxidation of L-arginine in the presence of NADPH (Fig. 10.1.1). Multiple cofactors are required for the enzymatic reaction, including heme, tetrahydrobiopterin (BH4), calmodulin (CaM), and flavins FMN and FAD. The iNOS (Type II NOS), one of the three isoforms of NOS cloned and characterized in mammals, is inducible at the transcriptional level and, in general, is not expressed unless the cells are stimulated. In the presence of stimuli, high levels of iNOS are expressed which then produce large amounts of NO for a long period (up to days), provided L-arginine is available.

Based on the high-output characteristics of iNOS, its expression can be conveniently and specifically detected and measured. This unit describes three basic protocols to determine iNOS expression in the mouse macrophage-like cells, RAW264.7, by measurement of: (1) end-product by measuring the accumulation of nitrite (see Basic Protocol 1), (2) protein detected by immunoblotting (see Basic Protocol 2), and (3) mRNA detected by northern blot analysis (see Basic Protocol 3) using radiolabeled oligonucleotide probes (see Support Protocol). RAW264.7 cells are easily induced to express iNOS in the presence of stimuli like the bacterial product, lipopolysaccharide (LPS), and cytokines (e.g., IFN-γ). LPS alone can stimulate RAW264.7 cells and is therefore chosen to be the stimulus used in these protocols. Expression of iNOS also occurs in many other tissues besides macrophages, such as neurons, astrocytes, microglia, endothelial and smooth muscle cells, in the presence of certain stimuli.

DETECTION OF iNOS EXPRESSION BASED ON NITRITE ACCUMULATION

BASIC PROTOCOL 1

Under appropriate conditions, the NO produced from the NOS pathway undergoes a series of reactions to form stable end-products, nitrite and nitrate, which accumulate in cell culture or in body fluid. In this protocol, only the accumulation of nitrite (i.e., a portion of the NO end-products) is measured to indicate iNOS expression. The culture supernatant is collected and reacted with Griess reagents, a mixture of sulfanilamide (SULF) and *N*-(1-naphthyl)-ethylenediamine (NNED) hydrochloride in 2.5% phosphoric acid solution. Under this condition, the accumulated nitrite taken from the culture is acidified and undergoes diazotization with SULF to form a diazonium salt, which then couples to NNED and forms an azo dye. Since this azo dye has an absorption maximum at 540 nm, the absorbance measured at 530 to 570 nm (depending on the available filter in the microplate reader) is used to indicate iNOS expression.

Materials

RAW264.7 cells (ATCC #TIB 71)
Complete RPMI medium/10% FBS with antibiotics (Life Technologies; see recipe)
100 μg/ml lipopolysaccharide (LPS) working solution (see recipe)
10 mM sodium nitrite (see recipe)
Griess reagent working solution (see recipe)

100-mm-diameter tissue culture dishes
Platform shaker
Ultrasonic bath (Lab-Line Instruments)
96-well microtiter plate
Microplate reader

Contributed by Qiao-wen Xie
Current Protocols in Toxicology (2000) 10.9.1-10.9.16

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Stimulate cells

1. Seed ~10×10^6 RAW264.7 cells in each of two 100-mm-diameter tissue culture dishes (marked as no. 1 and no. 2), with 10 ml of complete RPMI medium/10% FBS per dish.

   Only two culture dishes of cells are used here, because only two conditions are chosen in step 2—without and with LPS stimulation.

   Depending on the needs of the experiment, various numbers of cells and different kinds of culture containers (e.g., 6-well plate, 12-well plate, or others) can be used. If the culture is also to be used to detect iNOS expression by immunoblotting and northern analysis (see Basic Protocols 2 and 3), grow at least 10×10^6 cells/dish. If the culture is to be used only for the measurement of nitrite accumulation, seed 1×10^6 or 0.5×10^6 cells/well in a 12-or 24-well plate, with 1 ml complete RPMI per well.

2. In a tissue culture hood, add 10 µl of 100 µg/ml LPS working solution to dish no.2, making the final concentration of LPS 100 ng/ml. Do not add LPS to dish no.1.

   Different concentrations of LPS or other stimuli can be used, based on the experimental design. If more conditions are being studied, increase the number of culture dishes in step 1, at least one dish for each condition.

3. Incubate at 37°C for a chosen time period.

   Overnight (≥12 hr) is often chosen as a convenient time period. LPS-treated RAW264.7 cells grown overnight normally accumulate micromolar concentrations of nitrite in the culture medium. More than one time point may also be chosen, depending on the experimental design.

Prepare sodium nitrite standard

4. Freshly prepare 200 µM sodium nitrite as the standard solution by diluting the 10 mM stock solution 50-fold with water.

5. In a 96-well microtiter plate, use columns 1 and 2 for the nitrite standard. Place 100 µl of water in each well of columns 1 and 2 of rows A through H. Use wells A1 and A2 as blanks. Add 100 µl of 200 µM sodium nitrite to wells B1 and B2 and mix thoroughly by pipeting up and down. Transfer 100 µl to equivalent wells in row C. Repeat until a series of 2-fold dilution (100, 50, 25, 12.5, 6.25, 3.125, and 0 µM) is prepared in rows B through H. After mixing in row H, remove 100 µl and discard.

Measure nitrite accumulation

6. Remove 100 µl (in triplicate) of culture supernatant from each culture dish and place into corresponding wells of the same 96-well plate as the nitrite standards.

   It is recommended that the culture supernatant be placed into the wells in columns 3 to 5. For example, wells A3, A4, and A5 (row A) can be for the samples from dish 1 (without LPS), and wells B3, B4, and B5 (row B) for the samples from dish 2 (with LPS).

7. Add 100 µl of Griess reagent working solution to each of the wells containing either the water (blanks), nitrite standards, or culture samples. Incubate 5 to 10 min at room temperature after gentle mixing on an orbital platform shaker.

8. Place the 96-well plate in a microplate reader and read the absorbance at 530 to 570 nm, depending on the filter available.
9. Determine the concentration of nitrite accumulated in the culture compared to the sodium nitrite standards.

   Nitrite standards are not necessary for a quick check of nitrite accumulation, when no quantitative analysis is involved.

CONFIRMING iNOS EXPRESSION AT PROTEIN LEVEL BY IMMUNOBLOT

BASIC PROTOCOL 2

Measuring nitrite accumulation in the culture (see Basic Protocol 1) is a simple and rapid method to reveal the expression of iNOS activity. In addition, synthesis of iNOS protein and mRNA can be analyzed to confirm the expression. This protocol describes the detection of iNOS protein in the lysate of RAW264.7 cells after stimulation with LPS, by the use of an antibody specifically against iNOS in an immunoblot.

Materials

10× PBS (see recipe or purchase from Life Technologies)
Lysis buffer (see recipe)
Bradford protein assay reagent kit (Bio-Rad)
NuPAGE Tris-Acetate SDS Buffer Kit (Novex) containing:
  4× sample buffer (also see recipe)
  20× running buffer (also see recipe)
  10× sample reducing agent
Precast NuPAGE 3% to 8% Tris-acetate gel, 1.5-mm-thick, 10 wells (Novex)
Multicolored protein standards (NEN Life Science Products)
20× NuPAGE transfer buffer (Novex; see recipe)
Blocking solution (see recipe)
PVDF or nitrocellulose membrane
PBST (see recipe)
Mouse monoclonal antibody 1E8-B8 (iNOS-specific; R&D Systems)
SuperSignal West Dura Mouse IgG Detection Kit (Pierce) containing:
  Horseradish peroxidase (HRP)-conjugated anti-mouse IgG
  Luminal/enhancer solution
  Stable peroxide solution

Cell scraper (Falcon)
15-ml centrifuge tube
XCell II Mini-Cell (Novex)
XCell II Blot Module (Novex)
Polyvinylidene difluoride (PVDF) or nitrocellulose membrane: pore size, 0.2 μM
Whatman 3MM filter paper or equivalent
Kodak X-Omat AR X-ray film

Additional reagents and equipment for culturing cells and inducing iNOS expression (see Basic Protocol 1), SDS-PAGE (*APPENDIX 3*) and immunoblotting (*UNIT 2.3*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Stimulate cells

1. Grow and stimulate RAW264.7 cells (see Basic Protocol 1. steps 1 to 3). After 12 to 24 hr, measure nitrite accumulation in the cultures (see Basic Protocol 1).

   Nitrite accumulation should be seen within 24 hr after adding LPS. If not, repeat step 1 before preparing cell lysate.

Prepare cell lysate

2. Detach the cells with a cell scraper and transfer the cell suspension to a 15-ml tube.

   The cell scraper can be cleaned and reused, since this step is not performed under sterile conditions.

3. Centrifuge the cells in a benchtop centrifuge 5 min at ~100 × *g*, 4°C, and remove the supernatant.

4. Wash the cell pellet twice, each time by adding 5 ml of ice-cold 1× PBS, centrifuging 5 min at 100 × *g*, 4°C, and removing the supernatant.

5. Resuspend the cells in 1 ml of ice-cold 1× PBS and transfer to a microcentrifuge tube.

6. Microcentrifuge 2 min at 1500 × *g*, 4°C, and discard the supernatant.

   If the pellet is not to be used immediately, store at −70°C.

7. Resuspend the cell pellet in 300 µl of lysis buffer.

   The volume of lysis buffer should be reduced if the concentration of protein is <2 µg/µl (see step 11).

8. Freeze and thaw three times to lyse the cells, each time by placing tubes in liquid nitrogen or in a −70°C freezer for 5 min, then placing tubes in a water bath at room temperature until thawed. Each time, briefly vortex the samples as soon as they thaw.

9. Microcentrifuge 20 min at 12,000 × *g*, 4°C, then transfer the lysate (supernatant) into a fresh microcentrifuge tube on ice.

   Store the lysate at −70°C if not to be used immediately.

10. Measure the protein concentration in the lysate by Bradford assay using the Bio-Rad protein assay reagent kit.

Separate proteins by SDS-PAGE and blot onto membrane

11. Mix 25 µl of lysate containing 50 µg of total protein with 10 µl of 4× NuPAGE sample buffer and 4 µl of 10× reducing agent, boil for 3 to 5 min, and quickly microcentrifuge to collect the sample at the bottom of the tube.

    If the protein concentration of the lysate is >2 µg/µl, dilute it with lysis buffer before mixing.

    IMPORTANT NOTE: *Conditions for steps 11 to 14 are specific for the equipment provided by Novex; conditions for equipment provided by other suppliers may have to be adjusted according to the manufacturer.*

12. Load the sample onto the lane of a pre-cast NuPAGE 3% to 8% Tris-Acetate gel. Also load prestained multicolored protein standards onto the same gel.

13. Separate the proteins on the gel by electrophoresis in a XCell II Mini-Cell using 1× NuPAGE running buffer.

14. Transfer the proteins from the gel to a PVDF (or nitrocellulose) membrane with an XCell II Blot Module, using 1× NuPAGE transfer buffer.

15. Upon completion of the transfer procedure, place the membrane in a container. Briefly rinse with 1× NuPAGE transfer buffer, immerse in blocking solution, and incubate in blocking solution at 4°C overnight with gentle rocking on a platform rocker.

Perform antibody reaction and detection of iNOS protein

16. Wash the membrane three times with PBST for 15 min, 10 min, and 5 min, respectively.
17. Dilute primary antibody 1E8-B8 ≥1:5000 in blocking solution. Immerse the membrane in the diluted primary antibody and gently shake on a platform rocker for 1 hr at room temperature.

    Alternatively, the incubation with primary antibody can be performed overnight at 4°C.

18. Wash the membrane four to six times, each time for 10 min, with PBST.
19. Dilute the secondary antibody (HRP-conjugated anti-mouse IgG) ≥1:100,000 with PBST. Immerse the membrane in the diluted secondary antibody and incubate for 40 min at room temperature with gentle shaking on a platform rocker.
20. Wash the membrane four to six times, each time for 10 min, with PBST.
21. Blot the membrane on 3MM filter paper to remove excess liquid. Measure the area of the membrane.
22. Prepare SuperSignal Western Dura substrate working solution by mixing equal parts Luminal/Enhancer solution and stable peroxide solution in quantities sufficient for the membrane area.

    The volume of substrate required is 0.125 ml/cm^2 of membrane area.

23. Incubate the membrane with substrate working solution 5 min at room temperature. Place the membrane in a plastic bag and expose to X-ray film inside a film cassette (*APPENDIX 3*).
24. Develop the X-ray film after exposure for 20 sec. If not satisfied, reexpose the membrane to additional X-ray film(s) until the optimal time to obtain a clear result is attained.

DETECTION OF iNOS EXPRESSION BY NORTHERN BLOT ANALYSIS

BASIC PROTOCOL 3

Since iNOS is induced at the transcriptional level, its expression should be detected by the synthesis of iNOS mRNA. This protocol describes a northern blot analysis to detect the mRNA synthesis of iNOS in LPS-stimulated RAW264.7 cells using an oligonucleotide probe specific for mouse iNOS.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out experiments and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety office (also see *APPENDIX 1A*).

Materials

TRI Reagent for RNA isolation (Molecular Research Center)
Chloroform
Isopropanol
75% ethanol
DEPC-treated H_2O (see recipe)

1% (w/v) agarose gel with 2% (v/v) formaldehyde (see recipe)
10× MOPS buffer (see recipe)
Loading buffer (see recipe), freshly prepared
Formamide
100% glycerol
RNA Molecular Size Standard (Life Technologies)
20× SSPE, pH 7.4 (Life Technologies; also see recipe)
50× Denhardt solution (see recipe)
10% (w/v) sodium dodecyl sulfate (SDS)
10 mg/ml herring sperm DNA (Promega)
20× SSC: 3.0 M NaCl/0.3 M sodium citrate, pH 7.0 (Life Technologies)

50-ml Oak Ridge centrifuge tubes with caps, polypropylene (Nalge)
Centrifuge (e.g., Sorvall with SS-34 rotor or equivalent)
55° to 60°C and 65° to 70°C water baths
Horizontal electrophoresis apparatus, with circulation (OWL Separation Systems)
UV lightbox
GeneScreenPlus nylon membrane (NEN Life Scientific Products)
Turboblotter Rapid Downward Transfer System (Schleicher & Schuell)
Stratalinker UV cross-linker (Stratagene)
Heat-sealable bags (Kapak)
Impulse sealer (American International Electric)

Additional reagents and equipment for culturing cells and inducing iNOS expression (see Basic Protocol 1), determining RNA concentration by spectrophotometry (*APPENDIX 3*), and preparing oligonucleotide probes specific to mouse iNOS and β-actin (see Support Protocol)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Stimulate cells

1. Grow and stimulate RAW264.7 cells (see Basic Protocol 1, steps 1 to 3).

Isolate total RNA from cells

2. At desired time point(s), remove the medium from the culture dish, add 5 ml of TRI Reagent to the dish, and pipet up and down several times. Transfer the homogenate to a 50-ml centrifuge tube with cap. Incubate at room temperature for 5 min for complete dissociation of the nucleoproteins.

   Due to the presence of phenol in TRI Reagent, polypropylene, but not polystyrene tubes should be used.

3. Add 1 ml of chloroform to the tube, shake vigorously for 15 sec and then incubate 2 to 15 min at room temperature. Centrifuge 15 min at ≤12,000 × *g*, 4°C.

4. Transfer the aqueous (upper) phase to a fresh 50-ml tube, add an equal volume of isopropanol, and mix well. Let stand 5 to 10 min at room temperature. Centrifuge 10 min at ≤12,000 × *g*, 4°C.

5. Discard the supernatant, then wash the RNA pellet by adding 5 ml of 75% ethanol, vortexing briefly, then centrifuging 5 min at 7500 × *g*, 4°C. Remove supernatant.

   If a break is needed, stop the experiment at this step. Keep the RNA pellet in 75% ethanol and store at −70°C to minimize RNA degradation.

6. Briefly dry the RNA pellet (but do not overdry). To dissolve the RNA, add 100 µl of DEPC-treated water to the pellet, passing the solution a few times through a pipet tip. Heat 10 to 15 min at 55° to 60°C. Transfer the RNA solution to a micocentrifuge tube.

7. Determine the RNA concentration according to the absorbance at 260 nm.

   The specific absorbtion coefficient of ssRNA is 0.025 $(\mu g/ml)^{-1}cm^{-1}$. The ratio of A_{260}/A_{280} should be 1.6 to 1.8 if the RNA is free of protein and DNA.

Separate RNA on agarose gel and blot onto membrane

8. Prepare a 1% agarose gel containing 2% formaldehyde for RNA electrophoresis. When the gel is solidified, place in a horizontal electrophoresis apparatus filled with 1× MOPS buffer.

9. Place an aliquot of RNA sample containing 10 µg of total RNA into a microcentrifuge tube and dry in a Speedvac evaporator. At the same time, dry down 5 µl of RNA standard in another tube in the Speedvac evaporator.

10. Add 20 µl of loading buffer to each tube, mix well, and heat at 95°C for 2 min, then cool immediately on ice.

11. Load the RNA standard onto the first lane in the gel. Load samples adjacent to the standard.

12. Run electrophoresis at 5 V/cm until the bromphenol blue dye has migrated at least halfway.

    Circulate the buffer, or change the buffer once, during electrophoresis.

13. Upon completion of electrophoresis, place the gel on the top of an UV light box. Take a picture with a fluorescence ruler beside the lane of RNA standard. On the picture, mark the distance of each RNA standard band from the top of the gel. Estimate the ratio of 28S rRNA (~5 kb)/16S rRNA (~2 kb), which should be ≥1 if no degradation of RNA occurs.

    Other RNA bands may also be seen on the gel: 5S rRNA (0.1 to 0.3 kb) and high-molecular-weight RNA (7 to 15 kb).

14. Soak the gel with DEPC-treated water to remove formaldehyde.

15. Blot RNA onto a GeneScreenPlus nylon membrane using the Turboblotter Rapid Downward Transfer System.

    The transfer can be finished in a few hours or overnight for convenience.

16. Cross-link the RNA to the membrane in a UV cross-linker.

    This step increases hybridization signal compared to oven baking.

Hybridize RNA on the membrane

17. Prepare oligonucleotide probes (see Support Protocol) specific to mouse iNOS and β-actin.

    β-actin is used as an internal control.

18. Place the membrane in a sealable bag with a solution containing:

    6× SSPE, pH 7.4
    5× Denhardt solution
    1% SDS
    100 µg/ml denatured herring sperm DNA.

    Use 1 ml of solution per 5 cm^2 of membrane area. Seal the bag with an impulse sealer.

    The herring sperm DNA from Promega is ready to use.

19. Place the bag into a gently shaking water bath and prehybridize at 65° to 70°C for 2 to 4 hr.

    Hybridization temperature should be ~20°C lower than the T_m of the oligonucleotides.

20. Open the bag and add iNOS-34 and β-actin oligonucleotide probes to a final concentration of 2×10^6 cpm/ml. Reseal the bag, place back in the water bath, and hybridize at 65° to 70°C for 6 to 24 hr.

21. Remove the membrane from the bag and thoroughly wash the membrane with constant agitation as follows:

    a. Three times with 6× SSC/0.1% SDS at 65° to 70°C, 30 min each time
    b. Three times with 2× SSC/0.1% SDS at 65° to 70°C, 15 min each time

    CAUTION: *Carefully handle the isotope waste.*

22. With the RNA face up, blot the membrane on a sheet of 3MM paper to remove excess liquid.

    Do not dry the membrane if rehybridization is planned.

23. Place the membrane into a plastic bag or cover with plastic wrap and expose to X-ray film (within a cassette with intensifying screens) for an optimal time at room temperature or at 70°C depending on the signal. Develop the X-ray film(s).

SUPPORT PROTOCOL

5′-END LABELING OF OLIGONUCLEOTIDE PROBES

This protocol is used to prepare oligonucleotide probes specific to mouse iNOS and β-actin by 5′-end labeling with [γ-^{32}P]ATP. The probe for β-actin is used as a control in the northern blot procedure (see Basic Protocol 3).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out experiments and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety office (also see *APPENDIX 1A*).

Materials

Oligonucleotide iNOS-34: 5′-TCT GTG CTG TCC CAG TGA GGA GCT GCG GGG AGC C-3′
Mouse β-actin oligonucleotide (Clontech)
10× kinase buffer (Promega; also see recipe)
10 mCi/ml [γ-^{32}P]ATP (6000 Ci/mmol; NEN Life Scientific Products)
10 U/µl T4 polynucleotide kinase (Promega)

65°C water bath
Quick-Spin columns (TE) for radiolabeled DNA purification, Sephadex G-25 (Boehringer Mannheim)

1. Dissolve the oligonucleotides in autoclaved distilled water to produce a 500 µM stock solution. Dilute 50-fold to 10 µM as a working solution.

   iNOS-34 is a 34-mer derived from the 5′-end of mouse iNOS cDNA; it is antisense, has 68% G/C content, the T_m is 95°C, and it is synthesized with the help of the Oligo oligonucleotide design software (Molecular Biology Insights). β-actin oligonucleotide is a 30-mer, has 63% G/C content, the T_m is 90°C, and is distributed by Clontech.

2. Add the following to a microcentrifuge tube on ice (total volume 25 µl):

   10.5 µl H_2O
   1.0 µl of 10 µM oligonucleotide (iNOS 34-mer or β-actin 30-mer)
   2.5 µl 10× kinase buffer
   10.0 µl 10 mCi/ml [γ-^{32}P]ATP
   1.0 µl (10 U) polynucleotide kinase.

   Mix well and incubate at 37°C for 30 min.

3. Heat at 65°C to inactivate the kinase.

4. Pass the reaction mixture through a Quick-Spin column (Sephadex G-25) to remove unincorporated [γ-^{32}P]ATP.

5. Count cpm per 0.1 µl of each probe in a scintillation counter.

   The probe should be >10^5 cpm/µl.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agarose gel, 1% (w/v), with 2% (v/v) formaldehyde

For each 50 ml of gel desired, melt 0.5 g of UltraPure agarose in 42.3 ml DEPC-treated water (see recipe). Cool to 60°C, then add 5 ml of 10× MOPS buffer (see recipe), 2.7 ml of 37% formaldehyde, and 25 µl of 10 mg/ml ethidium bromide stock solution (Bio-Rad). Mix well and pour the gel on a tray in a fume hood.

Blocking solution

Dissolve 5 g of nonfat dry milk in 100 ml of PBST (see recipe; 5%, w/v final). Store at 4°C and use within a week.

Complete RPMI medium/10% FBS

To 895 ml of RPMI (with glutamine; Life Technologies), add 100 ml of heat-inactivated FBS and 5 ml of a stock solution (e.g. Life Technologies) of 10,000 U/ml penicillin/10,000 µg/ml streptomycin (10% FBS, 50 U/ml penicillin, 50 µg/ml streptomycin, final). Store up to 6 months at 4°C.

To heat inactivate FBS, thaw a 500-ml bottle of frozen FBS at 37°C and heat in a water bath at 56°C for 1 hr. Divide in aliquots at 50 ml/tube and store at −20°C until use.

Denhardt solution, 50×

Dissolve 5 g Ficoll (Type 400; Sigma), 5 g polyvinylpyrrolidone (Sigma), and 5 g fraction V bovine serum albumin (BSA; Sigma) in water to a final volume of 500 ml. Divide into 50-ml aliquots and store up to 6 months at −20°C.

DEPC-treated water

To each liter of distilled water, add 0.5 ml of diethylpyrocarbonate (DEPC) in the hood (0.5% v/v final). Incubate at 37°C overnight and then autoclave (liquid cycle) for 20 min. Store at room temperature.

Griess reagents

NNED solution: Dissolve 0.1 g *N*-(1-naphthyl)ethylenediamine (NNED) hydrochloride (Sigma) in 100 ml distilled water. Store up to 6 months at 4°C protected from light.

SULF solution: Dissolve 1 g of sulfanilamide (SULF; Sigma) in 5% (v/v) phosphoric acid (Aldrich). Store up to 6 months at 4°C protected from light.

Working reagent: Mix equal volumes of NNED and SULF solutions within 12 hr of use.

Kinase buffer, 10×, pH 7.2

Provided with T4 polynucleotide kinase (Promega)
Composition is as follows:
700 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
100 mM $MgCl_2$
50 mM DTT
Store up to 1 year at −20°C

Lipopolysaccharide (LPS) solution

LPS stock solution (2 mg/ml): Dissolve 2 mg of lipopolysaccharide (LPS; *Escherichia coli* serotype 0111:B4; Sigma) in 1 ml of 1× PBS (see recipe, or purchase from Life Technologies) in a tube. Incubate in an ultrasonic bath (Lab-Line Instruments) for 2 hr at room temperature and then store up to 1 year at −20°C.

LPS working solution (100 μg/ml): Dilute LPS stock solution 20-fold with medium to a final concentration of 100 μg/ml and store up to 6 months at 4°C.

Vortex the LPS working solution every time before use.

Loading buffer

75 μl formamide
15 μl 10× MOPS buffer, pH 7.0 (see recipe)
25 μl 37% formaldehyde
8 μl 100% glycerol
7 μl bromophenol blue (saturated solution in water)
20 μl DEPC-treated water (see recipe)
Store up to 1 year at −70°C

Lysis buffer

Prepare 40 mM Tris·Cl buffer, pH 7.9, by a 25-fold dilution of a stock solution of 1 M Tris·Cl buffer, pH 7.9 (*APPENDIX 2A*). Add 1/1000 volume of each of the protease inhibitor stocks (see recipe).

Final concentration: 40 mM Tris·Cl, pH 7.9, 1 μg/ml each of the protease inhibitors aprotinin, leupeptin, and pepstatin, and 0.1 mM PMSF.

MOPS buffer, pH 7.0, 10×

0.4 M MOPS (pH ~7.0; Sigma)
0.1 M sodium acetate
0.01 M EDTA
DEPC-treated water (see recipe)
Store up to 3 months at room temperature

NuPAGE running buffer, 20×, pH 8.24

Purchase from Novex; composition is as follows:
1 M Tris-Cl, pH 8.24 (*APPENDIX 2A*)
1 M tricine
0.07 M SDS
Store up to at least 6 months at 4°C

NuPAGE sample buffer, 4×, pH 8.5

Purchase from Novex; composition is as follows:
4.4 M glycerol
564 mM Tris base
424 mM Tris·Cl
292 mM LDS (lithium dodecyl sulfate)
2.04 mM EDTA
0.88 mM Serva Blue G-250
0.7 mM phenol red
Store up to at least 6 months at 4°C

NuPAGE transfer buffer, pH 7.2

Purchase from Novex; composition is as follows:
500 mM Bicine
500 mM Bis-Tris
20 mM EDTA
1 mM chlorobutanol
Store up to at least 6 months at 4°C

PBS, 10×

2 g/liter KCl
2 g/liter KH_2PO_4
80 g/liter NaCl
21.6 g/liter $Na_2HPO_4 \cdot 7H_2O$
Store up to 1 year at room temperature

This formulation of 10× PBS may also be purchased from Life Technologies.

PBST

To 895 ml of distilled water, add 100 ml of 10× PBS (see recipe, or purchase from Life Technologies) and 5 ml of polyoxyethylensorbitan monolaurate (final: 1× PBS with polyoxyethylensorbitan monolaurate, 5%, v/v). Store up to 6 months at room temperature.

Protease inhibitor stocks, 1000×

1 mg/ml aprotinin (Sigma) in water, store up to 1 year at −70°C
1 mg/ml leupeptin (Sigma) in water, store up to 1 year at −70°C
1 mg/ml pepstatin (Sigma) in ethanol, store up to 1 year at −70°C
0.1 M PMSF: dissolve 8.7 g phenylmethyl sulfonyl fluoride (Sigma) in 50 ml isopropanol; store up to 1 year at room temperature protected from light

Sodium nitrite solution stock, 10 mM

Dissolve 69.0 mg of sodium nitrite (Sigma) in 100 ml of distilled water. Store at 4°C protected from light. Freshly prepare 200 μM nitrite standard solution from this stock each time it is needed.

SSPE, 20×, pH 7.4

Purchase from Life Technologies; composition is as follows:
1M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
3 M NaCl
0.2 M NaH_2PO_4
0.02 M EDTA
Store up to 1 year at room temperature

COMMENTARY

Background Information

Transcriptional induction of iNOS by LPS has been well documented in mouse macrophages (Xie et al., 1992, 1993; Lorbach et al., 1993). The northern blot analysis described in Basic Protocol 3 is a direct and reliable procedure to detect iNOS expression in the LPS-stimulated RAW264.7 cells at the mRNA synthesis level, but northern analysis involves many steps and is time consuming. Since the iNOS mRNA synthesis induced by LPS leads to a consequent synthesis of iNOS protein, detection of iNOS protein by an immunoblot can also be used to indicate iNOS expression. As described in Basic Protocol 2, immunoblot analysis is a shorter procedure and directly detects iNOS protein in the cell lysate, using an antibody specific to iNOS. The iNOS-specific antibody has also been used in an immunostaining procedure to detect iNOS expression in the whole cell or in tissue samples (Xie et al., 1992; Nicholson et al., 1996; Vodovotz et al., 1996).

The fastest way to reveal iNOS expression, however, is to measure the significant nitrite accumulation in the culture based on the high-output characteristics of iNOS. The assay is conveniently performed as described in Basic Protocol 1. With tightly bound calmodulin, the enzymatic activity of iNOS is independent of elevated calcium level (Cho et al., 1992). In the presence of stimuli, high levels of iNOS are expressed and large amounts of NO are produced for ≥5 days, provided L-arginine is available (Vodovotz et al., 1994). (It is not necessary to replenish the L-arginine because the amount in cell culture medium is usually sufficient.) This characteristic of iNOS is different from that of nNOS or eNOS; the latter are constitutively expressed but at low levels and their activity is dependent on an elevated calcium level for binding of calmodulin. Both nNOS and eNOS produce small amounts of NO over a short period of time, from seconds to minutes (Malinski and Taha, 1992). Under appropriate conditions, NO undergoes a series of reactions to form stable end-products, nitrite and nitrate. Although NO itself is unstable in an aerobic environment and is difficult to measure directly, the measurement of nitrite and nitrate is commonly used as a rapid and simple method to detect NO production. Nitrite accumulation is conveniently measured by reading the absorbance at 530 to 570 nm after reacting the culture supernatant with the Griess reagent (Green et al., 1982).

To make the procedure as simple as possible, Basic Protocol 1 does not include the measurement of nitrate accumulation, which is more complicated and has an extra step to reduce nitrate into nitrite by nitrate reductase or by metallic cadmium. Since the ratio of nitrite to nitrate is frequently the same (usually 3:2 in the culture of stimulated RAW264.7 cells), measurement of nitrite alone is sufficient to serve as an indicator of iNOS expression. Due to the low sensitivity of the Griess reaction, which measures the low micromolar range of nitrite, the assay cannot detect the submicromolar nitrite produced by nNOS or eNOS, even when they are active. In fact, neither nNOS nor eNOS is active in the culture without an increase in intracellular calcium level. Therefore, measurement of nitrite accumulation in the culture is actually a procedure specific for detecting iNOS expression and activity.

All three protocols described in this unit are based on two conditions—with and without LPS treatment—i.e., iNOS is expressed or not expressed. No other conditions are yet included in the protocol. For example, the LPS-induced iNOS expression may be partially inhibited by a certain agent, as detected by a partial reduction in nitrite accumulation. In order to characterize the mechanism of inhibition, or the level of inhibition (transcriptional or posttranscriptional; translational or posttranslational) of inhibition, iNOS protein and mRNA analyses should all be performed in addition to nitrite measurement.

The three protocols described here can also be used to detect iNOS expression in other types of cells, as reported by other investigators (Table 10.9.1). However, the conditions to induce iNOS in these cells may be different from that in RAW264.7 cells, requiring stimulus other than LPS or a mixture of stimuli. Induction of iNOS in rodent cells is usually detected within a day. But it may take more than one day for iNOS to be expressed in human cells. In addition, the level of iNOS expressed in human cells is generally lower than that in rodent cells. When the expression level is very low, it requires other methods with higher sensitivity to detect iNOS induction. Very often, RT-PCR analysis is applied to substitute for northern blot.

Critical Parameters and Troubleshooting

Nitrite accumulation is always detected in RAW264.7 cells after overnight treatment with

Table 10.9.1 Expression of iNOS in Various Cell Types

[a]Abbreviations: IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; TNF, tumor necrosis factor.

100 ng/ml LPS. No significant nitrite should be accumulated in the culture without LPS treatment. If nitrite accumulation is found, the medium should be tested for LPS contamination. Medium with LPS contamination should not be used.

When nitrite accumulation is seen in the culture supernatant of LPS-treated RAW264.7 cells, the lysate from these cells should show a major band at ~130 kDa by immunoblot using an antibody specific to iNOS. If this is not the case, increase the amount of lysate protein and/or use a freshly made lysate. The sensitivity of detection method is also critical. In Basic Protocol 2, a SuperSignal West Dura Extended Duration (HRP) substrate is applied to the chemiluminescent western blot. This provides high sensitivity and long light emission for optimization of the results. Occasionally, some minor bands below 130 kDa may be seen on the blot, due to the degradation of iNOS protein. To reduce degradation, use the lysate as soon as possible and avoid multiple freeze/thaw cycles. Reagents and apparatuses from Novex greatly increase performance in Basic Protocol 2 and are therefore highly recommended.

The most important issue in northern blotting is contamination by RNase. All the containers used should be rinsed with DEPC-treated water, and the experiment should be finished as quickly as possible. A RNA pellet can be obtained from the cell culture using TRI Reagent within 1 hr. With the oligonucleotide probe, the total RNA can be used directly in northern blot analysis without mRNA purification. This shortens the experiment, and, more importantly, reduces the occurrence of contamination. Another advantage to using an oligonucleotide probe is that it can be easily stripped off the membrane, leaving the membrane free to be rehybridized with another probe(s).

Anticipated Results

Basic Protocol 1

Nitrite accumulation is always detected in the LPS-treated RAW264.7 cells, but not in the untreated cells. The 24-hr culture usually accumulates ~50 μM nitrite under the conditions described in the protocol.

Basic Protocol 2

When nitrite accumulation is seen in the culture supernatant of LPS-treated RAW264.7 cells, iNOS protein expression is detected by immunoblot. The lysate from these cells shows a major band at ~130 kDa on the blot after reaction with an antibody specific to iNOS; but the band is not seen in the lysate from the cells not treated with LPS (Fig. 10.9.1). Sometimes, minor bands below 130 kDa may be seen, due to the degradation of iNOS protein during the experimental procedure. With the use of high-sensitivity substrate, SuperSignal West Dura Extended Duration (HRP) substrate, in the chemiluminescent immunoblot, the exposure time is usually <20 sec.

Basic Protocol 3

The iNOS mRNA is synthesized in the RAW264.7 cells stimulated with LPS, but not in the cells without LPS treatment. Figure 10.9.2 is one of the results from northern analysis described in Basic Protocol 3. A band of iNOS mRNA at ~4 kb is seen from the LPS-treated sample but not the untreated sample. However, a band of β-actin mRNA at ~1.8 kb is seen from both samples, since β-actin is a housekeeping gene and should not be affected by the treatment with LPS. Therefore, β-actin is used as an internal control for RNA loading. For a more accurate analysis, the signal ratio of iNOS/β-actin mRNA should be used for an evaluation, not just the total amount of iNOS mRNA.

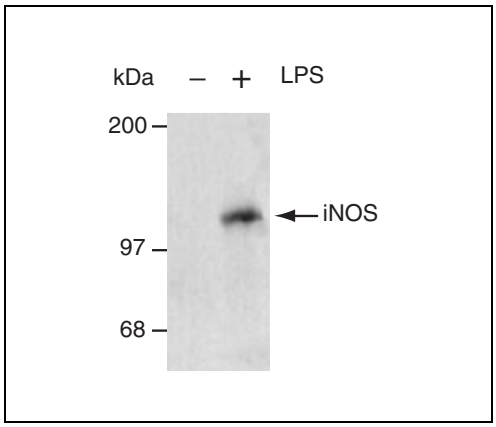

Figure 10.9.1 Immunoblot for iNOS (130 kDa) in the lysate from RAW264.7 cells treated with (+) or without (–) LPS (100 ng/ml) for 18 hr.

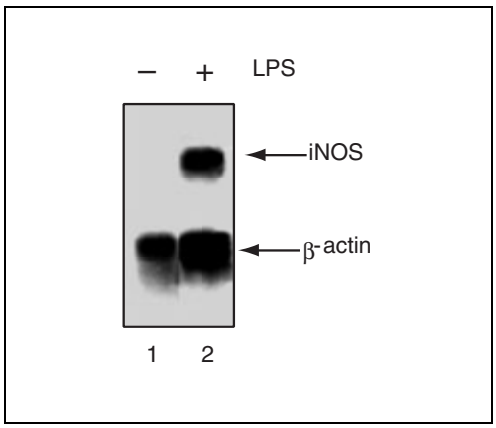

Figure 10.9.2 Northern blot of total RNA from RAW264.7 with (+) and without (–) an 18-hr treatment of LPS (100 ng/ml). The hybridization was performed with two oligonucleotide probes: one is a 34-mer specific for iNOS (4.2 kb) and the other is a 30-mer specific for β-actin (1.9 kb) as an RNA loading control.

Time Considerations

Measurement of nitrite is a rapid assay; the Griess reaction itself only takes 5 to 10 min. To prepare the fresh nitrite standard and the Griess reagent, another 10 to 20 min may be needed. In total, after all the samples are collected, the measurement of nitrite can be finished within 30 min.

With the use of materials from Novex, a lot of time can be saved in immunoblot analysis. The procedure described in Basic Protocol 2 may be finished in 2 days after the cells have been harvested. If the cells are harvested in the morning, cell lysate preparation, protein separation on gel, and blotting onto membrane can be finished on the same day. On the next day, ~5 hr are sufficient to perform the antibody reaction for detection of iNOS protein.

For Basic Protocol 3, depending on the film exposure time, it takes 4 days or more to perform the procedure after the cells are harvested. Day 1 is used to isolate total RNA; only 1 hr is needed. Day 2 is the busiest day; tasks include dissolving the RNA, measuring the RNA concentration, mixing with loading buffer and then running the electrophoresis, followed by overnight blotting to the membrane. On day 3, tasks include labeling the probe(s), prehybridization, and hybridization. Day 4 is used to wash and expose the membrane to X-ray film. If the

signal is strong, the film can be developed on day 4; if the signal is weak, one or two additional days of exposure time may be necessary.

CHAPTER 11
Neurotoxicology

INTRODUCTION

There is continuing concern about environmental neurotoxicity and the potential effects of neurotoxic chemicals on human beings, caused in part by the dearth of information about the overall magnitude of the problem. Indeed, the number of people with neurotoxic disorders, and the extent of neurologic disease and dysfunction that results from exposure to toxic chemicals in the environment, are not known. Until a few years ago, for instance, only a few of the several thousand chemicals in commercial use in the United States had been tested for neurotoxicity, though it can be hoped the recent implementation of new federal guidelines for neurotoxicity and developmental neurotoxicity will lead these gaps in data to be filled.

Exposure to neurotoxic substances either in the workplace or through consumption of contaminated food has led to several outbreaks of neurotoxicity. Examples are the pesticides leptophos and kepone, triorthotolylphosphate, methylmercury, and domoic acid. Occupational and/or environmental exposure to a number of types of chemical such as solvents (e.g., toluene, styrene), metals (e.g., lead, organotins, manganese), and pesticides (e.g., organophosphates) are also associated with neurotoxic effects involving the central and/or peripheral nervous systems. Drugs of abuse, alcohol, and some pharmaceuticals may also cause neurotoxicity, particularly in developing organisms.

This chapter focuses on a variety of approaches that can be used in neurotoxicological research. Setting the stage for the chapter, *UNIT 11.1* defines the principal issues in neurotoxicology. This is followed by three units on behavioral testing of rodents, which together provide an excellent tool to enable investigators to assess the neurotoxic potential of a chemical and its effect on cognitive functions. *UNIT 11.2* describes what is known as the functional observational battery, a first-tier screening test for neurobehavioral effects that has become very important in the regulatory arena. *UNITS 11.3 & 11.4* focus on tests of cognitive functions, which are often affected by neurotoxic chemicals. Tests of spatial memory (radial arm maze, Morris maze, and T maze), which are among the most widely used, are described in detail in *UNIT 11.3*, while advanced behavioral testing procedures for assessing cognition are described in *UNIT 11.4*.

UNIT 11.5 details testing protocols for organophosphate-induced delayed polyneuropathy, including behavioral and postmortem morphological assessment and enzyme assays. These test are a regulatory requirement for all organophosphorus pesticides. A discussion of the issues dealing with risk assessment for neurotoxicity is presented in *UNIT 11.6*, while *UNIT 11.7* provides a description of the behavioral tests (some computerized) available to detect neurotoxicity in humans.

UNITS 11.8 & 11.9 describe several models of global and focal ischemia in the mouse, which leads to neuronal degeneration.

A set of three units discuss electrophysiological approaches to neurotoxicology. *UNIT 11.10* offers a general overview on how electrophysiology can be used in toxicological studies. *UNIT 11.11* describes methods used for intracellular and extracellular recording in slices

Contributed by Lucio G. Costa
Current Protocols in Toxicology (2005) 11.0.1-11.0.2

from different brain areas. *UNIT 11.12* focuses on whole-cell path-clamp electrophysiology in cultured cells for measuring voltage-sensitive calcium channels.

UNIT 11.13 provides protocols for the assessment of sensory neuropathy in rats using thermal and mechanical stimuli. *UNIT 11.14* describes protocols to induce brain hyperthermia in rats.

Lucio G. Costa

Overview of Neurotoxicology

It is widely accepted that the nervous system can be adversely affected by chemicals in the environment (OTA, 1990; NRC, 1992). One well-known example of such a chemical (neurotoxicant) is inorganic lead, which can be found in industrial emissions, lead-based paints, food, beverages, and emissions from the burning of leaded gasolines. Organic lead compounds such as triethyl- and tetraethyllead have also been reported to be neurotoxic in humans and animals. The immature nervous system is particularly sensitive to lead, reflecting the generally accepted rule that exposure to relatively low levels of neurotoxicants during development can cause learning disorders and altered mental development.

Another environmental chemical known to produce neurotoxicity in humans is mercury, which causes sensory, motor, and speech dysfunction (NRC, 1992). One major incidence of human exposure to methylmercury occurred in the mid-1950s when a chemical plant near Minamata Bay, Japan, discharged mercury as part of its waste sludge. An epidemic of mercury poisoning developed when the local inhabitants consumed contaminated fish and shellfish. Children exposed in utero developed a progressive neurological disturbance resembling cerebral palsy. In 1971, a similar epidemic occurred in Iraq resulting from the use of methylmercury as a fungicide to treat grain. Attempts to define the threshold at which mercury produces developmental neurotoxicity remain an active research area.

Repeated exposure to organic solvents has also been reported to produce neurotoxicity in humans. For example, a peripheral nervous system neuropathy has been reported in workers exposed to methyl-*n*-butyl ketone, a dye solvent and cleaning agent. Solvents including diethyl ether, some ketones and alcohols, and various combinations thereof are commonly used in glues, cements, and paints, and can be neurotoxic when inhaled. Repeated exposure to such solvents can lead to permanent neurological effects due to severe and permanent loss of nerve cells.

Pesticides, including insecticides, fungicides, rodenticides, and herbicides, are another class of potentially neurotoxic substances. Pesticides are composed of active ingredients combined with inert substances to make thousands of different formulations. Workers overexposed to pesticides may display overt indications of neurotoxicity, including tremors, weakness, ataxia, visual disturbances, and short-term memory loss. The organophosphorus insecticides, which account for ~40% of registered pesticides, can produce a delayed neurotoxicity that involves an irreversible loss of motor function and an associated neuropathology.

Many naturally occurring chemicals have also been found to be neurotoxic (NRC, 1992). For example, neurotoxicities in humans, domestic livestock, and poultry have been associated with exposure to fungal toxins (mycotoxins) that resemble ergot alkaloids, which have neurotrophic, uterotonic, and vasoconstrictive activities. They can also have direct dopaminergic receptor activity or act as serotonergic and α-adrenoceptor antagonists. Jimson weed (*Datura stramonium*) is known to contain a number of chemicals with anticholinergic activity. An outbreak of toxic encephalopathy caused by eating mussels contaminated with domoic acid, an excitotoxin, was recently reported.

It is not known how many environmental chemicals are neurotoxic to humans. Using a generally broad definition of neurotoxicity, Anger (1990) estimated that of the ~200 chemicals to which one million or more American workers are exposed, more than one-third may have adverse effects on the nervous system at some level of exposure. O'Donoghue (1989), on the other hand, reported that of 488 compounds assessed in his chemical evaluation process, only 2.7% had effects on the nervous system.

DEFINITIONS AND CRITICAL CONCEPTS

Neurotoxicity has been defined as an adverse change in the structure or function of the central and/or peripheral nervous system following chemical exposure (Tilson, 1990). Adverse effects include alterations from baseline that diminish an organism's ability to survive, reproduce, or adapt to the environment. Neurotoxicity is a function of the properties of both the agent and the nervous system itself. Toxicity can occur at any time in the life cycle, from conception through senescence, and its manifestations can change qualitatively and quantitatively with age. The range of responses can vary from short-lived changes following acute exposures to delayed or persistent changes following acute or repeated exposures. Effects

Contributed by Hugh A. Tilson
Current Protocols in Toxicology (1999) 11.1.1-11.1.8

produced by the same neurotoxicant vary in both nature and magnitude at different dose levels. Neurotoxic effects may be progressive, with small deficits occurring soon after exposure and becoming more severe over time. At present, relatively few neurotoxic syndromes have been thoroughly characterized. However, knowledge of exact mechanisms of action is not necessary to conclude that a chemically induced change is a neurotoxic effect.

Effects of chemicals on the nervous system can be assessed using a weight-of-evidence approach that assesses the nature and severity of the response, as well as the dose, the duration, and the persistence of the effect. Neurotoxic effects may be irreversible (i.e., the organism cannot return to the state prior to exposure but is permanently changed) or reversible (i.e., the organism can return to its preexposure condition). Clear or demonstrable irreversible change in either the structure or function of the nervous system is of great concern.

It should be noted that the nervous system is known for its reserve capacity (Tilson and Mitchell, 1983). That is, repeated insult to the nervous system may lead to an adaptation to the neurotoxic insult. There are, however, limits to the capacity for adaptation; when these are exceeded, further exposure may lead to frank manifestations of neurotoxicity at the structural and functional levels. Once damaged, neurons, particularly in the central nervous system, have a limited capacity for regeneration. Reversal of neuronal damage resulting from cell death or from the destruction of cell processes may represent an activation of repair capacity, possibly decreasing future adaptability. Reversible neurotoxic changes must therefore be carefully weighed. Evidence of progressive effects (those that continue to worsen even after the causal agent has been removed), delayed-onset effects (those that occur at a time distant from the last contact with the causal agent), residual effects (those that persist beyond a recovery period), or latent effects (those that become evident only after an environmental challenge or aging) should be weighted heavily. Environmental challenges can include stress, increased physical or cognitive workload, pharmacological manipulations, and nutritional deficiency or excess. Evidence for reversibility may depend on the region of the nervous system affected, the chemical involved, and factors such as the age of the exposed population. Some regions of the nervous system such as peripheral nerve have a high capacity for regeneration, while regions in the brain such as the hippocampus are known for their ability to adapt to neurotoxic insult. For example, adaptation is likely to be seen with solvents (e.g., *n*-hexane) that produce peripheral neuropathy due to the high repair capacity of peripheral nerves. In addition, tolerance to some cholinergic effects of cholinesterase-inhibiting compounds may occur as a result of compensatory down-regulation of muscarinic receptors. It is also generally recognized that younger individuals may have a greater capacity to adapt than older individuals, suggesting that the aged may be at increased risk during neurotoxic exposure. In general, lesser weight is assigned to effects that are rapidly reversible or transient—i.e., measured in minutes, hours, or days—and appear to be associated with the pharmacokinetics (absorption, distribution, metabolism, and excretion) of the chemical and its presence in the body. Reversible changes that occur in the occupational setting or environment, however, should receive a heavy weight if, for example, exposure to a short-acting solvent interferes with operation of heavy equipment in an industrial plant.

Neurotoxic effects can be produced by chemicals that do not require metabolism prior to interacting with their target sites in the nervous system (primary neurotoxic agents) or by those that do (secondary neurotoxic agents). Chemically induced neurotoxic effects can be direct (i.e., due to an agent or its metabolites acting directly on target sites in the nervous system) or indirect (i.e., due to agents or metabolites that produce their effects primarily by interacting with target sites outside the nervous system, which subsequently affect target sites in the nervous system).

NEUROLOGICAL PRINCIPLES FOR NEUROTOXICOLOGY

Structure of the Nervous System

The nervous system is composed of two parts: the central nervous system (CNS) and the peripheral nervous system (PNS; Hammerschlag and Brady, 1989). Within the nervous system, there exist predominantly two general types of cells—neurons and glial cells. Neurons are unique in that they have axons and dendrites, extensions of the neuron along which nerve impulses travel. The structure of the neuron consists of a cell body, which contains a nucleus and organelles for the synthesis of various components necessary for the cell's functioning (e.g., proteins and lipids), dendrites, and axons. Dendrites are numerous

branched processes that emanate from the cell body and increase the neuronal surface area available to receive inputs from other sources. Neurons communicate by releasing neurotransmitters onto specific surface regions (the receptors) of other neurons. Axons are specialized processes that conduct nerve impulses away from the cell toward the terminal synapses and eventually toward other cells (neurons, muscle cells, or gland cells).

Neurons are responsible for the reception, integration, transmission, and storage of information, and certain nerve cells are specialized to respond to particular stimuli. In general, the length of the axon is tens to thousands of times greater than the diameter of the cell body. For example, the cell body whose processes innervate the muscles in the human foot is found in the spinal cord at the level of the middle back. The axons of these cells are more than a meter long. Many, but not all, axons are surrounded by layers of membrane from the cytoplasmic process of glial cells. These layers are called myelin sheaths and are composed mostly of lipid. In the PNS, the myelin sheaths are formed by Schwann cells, while in the CNS the sheaths are formed by the oligodendroglia. The myelin sheath formed by one glial cell covers only a short length of the axon, so the entire length of the axon is ensheathed in myelin composed of numerous glial cells. Between adjacent glial sheaths are very short lengths of bare axon called the nodes of Ranvier. In unmyelinated axons, a nerve impulse must travel in a continuous fashion down the entire length of the nerve. The presence of myelin accelerates the nerve impulse by allowing the impulse to jump from one node to the next.

The nerve cells of the PNS are generally found in aggregates called ganglia. In the CNS (made up of the brain and spinal cord), the neurons are segregated into functionally related aggregates called nuclei. Various nuclei together with the interconnecting bundles of axonal fibers are functionally related to one another to form higher levels of organization called systems—for example, the motor system, the visual system, and the limbic system.

Transport Processes

All types of cells must transport proteins and other molecular components from their site of production near the nucleus to the other sites in the cell. Neurons are unique in that the neuronal cell body must not only maintain the functions normally associated with its own support, but also provide support to its various processes. This support may require transport of material over relatively long distances. The delivery of necessary substances by intracellular transport down the axon (axonal transport) is vulnerable to interruption by toxic chemicals. In addition, the integrity of the function of the neuronal cell body is often dependent on a supply of trophic factors from the cells that it innervates. These factors are continually supplied to the neural cells by the process of retrograde axonal transport, often as a process of normal exchange between two or more cells. Neighboring cells play a significant role in the normal growth and maintenance of the neural cells, and a continual supply of certain trophic factors is necessary for cell functioning.

The majority of axonal transport occurs along longitudinally arranged fiber tracks called neurofilaments. This movement along neurofilaments requires energy in the form of oxidative metabolism. Toxicants that interfere with this metabolism or that disrupt the spatial arrangement or production of neurofilaments may block axonal transport and can produce neuropathy. This can been seen following exposure to many substances, such as *n*-hexane and methyl-*n*-butyl ketone.

Ionic Balance

The axonal membrane is semipermeable to positively and negatively charged ions, such as potassium, sodium, and chloride, both within and outside the axon. The ionic balance that changes following depolarization of the membrane is maintained by continual, active, energy-dependent transport of ions across the membrane. Except in sensory neurons, where it originates at the terminal receptive end of specialized axons, the nerve impulse is a traveling wave of depolarization normally originating from the cell body. This wave is propagated by openings in the membrane that allow ions to enter the cell; the resulting sudden change in the charge across the axon's membrane constitutes the nerve impulse. An amplified depolarization reaches a threshold value and spreads down the axon. The depolarization continues in this fashion until it reaches the synaptic terminal regions. There are a variety of membrane channels (e.g., calcium) that rapidly open and close during impulse generation. Sodium and potassium channels are also very common; they are very small and allow only ions of a certain size to pass. Several classes of neurotoxic agents, especially natural toxins such as tetrodotoxin, inhibit nerve impulse conduction by blocking these channels.

Neurotransmission

The terminal branches of the axon end in small enlargements called synaptic "boutons," from which chemical messengers or neurotransmitters are released to communicate with the synapse of the target cell. When a nerve impulse reaches the terminal branches of the axon, it depolarizes the synaptic boutons. This depolarization causes the release of the chemical messengers—neurotransmitters and neuromodulators—stored in vesicles in the axon terminal. Classical neurotransmitters include serotonin, dopamine, acetylcholine, and norepinephrine, and are typically secreted by one neuron into the synaptic cleft where they act on the postsynaptic membrane. Neuropeptides, another type of neurotransmitter, may travel relatively long distances through the bloodstream to receptors on distant nerve cells or in other tissues. Following depolarization, the amount of secretion is dependent on the number of nerve impulses that reach the synaptic bouton—i.e., the degree of depolarization. The chemical messengers diffuse across the synaptic cleft or into the intraneuronal space and bind to receptors on adjacent nerve cells or effector organs, thus triggering biochemical events that lead to electrical excitation or inhibition.

When information is transmitted from nerves to muscle fibers, the point of interaction is called the neuromuscular junction and the interaction leads to contraction or relaxation of the muscle. When the target is a gland cell, the interaction leads to secretion of hormones. When the target is another neuron, the process (known as synaptic transmission) is slightly more complicated: the binding of the messenger to the receptor of the receiving cell can lead to either the excitation or inhibition of certain activities in the target cell. At an excitatory synapse, the neurotransmitter-receptor interaction leads to the opening of certain ion-specific channels. The charged ions that move through these opened channels carry a current that serves to depolarize the cell membranes. At inhibitory synapses, the interaction leads to the opening of a different type of ion-specific channel that produces an increase in the level of polarization (hyperpolarization). The sum of all the depolarizing and hyperpolarizing currents determines the transmembrane potential, and when a threshold level of depolarization is reached at the axon's initial segment, a nerve impulse is generated and begins to travel down the axon.

The duration of neurotransmitter action is primarily a function of the length of time it remains in the synaptic cleft. This duration is very short due to either rapid degradation of the transmitter by specialized enzymes or by removal of the transmitter by reuptake systems that transport it back into the synaptic bouton. A toxic substance may disrupt this process in several different ways. It is important that the duration of the effect of synaptically released chemical messengers be limited. Some neurotoxicants, such as organophosphorus compounds, carbamate insecticides, and nerve gases, inhibit the enzyme acetylcholinesterase (AChE), which serves to terminate the effect of the neurotransmitter acetylcholine on its target. This results in a buildup of acetylcholine, leading to overstimulation of the target cell, and can cause loss of appetite, anxiety, muscle twitching, and paralysis. Some cholinesterase-inhibiting organophosphates can also cause a delayed neuropathy, which is discussed in greater detail in *UNIT 11.5*. Other substances, particularly biological toxins, are able to interact with the receptor molecule and mimic the action of the neurotransmitter. Some toxic substances, such as neuroactive pharmaceuticals, may interfere with the synthesis of a particular neurotransmitter, while others may block access of the neurotransmitter to its receptor molecule. Neurochemical approaches to neurotoxicology are described in greater detail elsewhere in Chapter 11.

Types of Effects on the Nervous System

The normal activity of the nervous system can be altered by many toxic substances. A variety of adverse health effects can be seen, ranging from impairment of muscular movement to disruption of vision and hearing to memory loss and hallucinations. Toxic substances can alter both the structure and the function of cells in the nervous system. Structural alterations include changes in the morphology of the cell and its subcellular structures, and can be assessed via quantitative morphometric analysis and analytical cytology. In some cases, agents produce neuropathic conditions that resemble naturally occurring neurodegenerative disorders in humans. Cellular alterations can include the accumulation, proliferation, or rearrangement of structural elements (e.g., intermediate filaments, microtubules) or organelles (mitochondria) as well as the breakdown of cells. By affecting the biochemistry and/or physiology of a cell, a toxic substance can alter the internal environment of any neural cell. Intracellular changes

can also result from oxygen deprivation (anoxia), because neurons require relatively large quantities of oxygen due to their high metabolic rate.

At the cellular level, a substance might interfere with processes such as protein synthesis, leading to a reduced production of neurotransmitters and concomitant brain dysfunction. Nicotine and some insecticides mimic the effects of the neurotransmitter acetylcholine. Other substances can alter the synthesis and release of other specific neurotransmitters or activate their receptors in specific neuronal pathways. They may perturb the system by overstimulating receptors, blocking transmitter release, inhibiting transmitter degradation, or blocking reuptake of neurotransmitter precursors. At the cellular level, the flow of ions such as calcium, sodium, and potassium across the cell membrane may also be changed and the transmission of information between nerve cells altered by certain neurotoxicants.

The role of excitatory amino acid (EAA)-mediated synaptic activation is critical for normal function of the CNS. Because endogenous EAA-mediated synaptic transmission is a widespread excitatory system in the brain and is involved in the process of learning and memory, the issue of the effects of endogenous and exogenous EAA-related toxicity has broad implications for both CNS morbidity and mortality in humans. Much of the injury and neuronal death associated with toxicity is mediated by receptors for excitatory amino acids, especially glutamic acid. When applied in sufficient excess from either endogenous or exogenous sources, EAAs have profound neurotoxic effects that can result in the destruction of neurons and, as a consequence, lead to acute phase confusion, seizures, and generalized weakness or to persistent impairments such as memory loss.

One final common path in the activation of many receptor classes appears to be an increase in free cytosolic Ca^{2+}. This increase can result in the release and activation of intracellular enzymes, which can break down the cytoskeleton and in turn cause the release of more glutamate. This has the same effects as other sources of increased EAAs, as discussed above. Some neurotoxicants appear to impair energy metabolism, which can lead to death. It is likely that reduced oxidative metabolism can also result in the partial depolarization of resting membrane potential, in the activation of ionotropic membrane receptor/channels, and in the influx of Ca^{2+} or its release from intracellular stores.

Neurophysiological methods are used to measure chemically induced changes in electrical activity in the nervous system. For example nerve conduction studies measure the speed, amplitude, and refractory period of peripheral sensory or motor nerves, while sensory evoked potentials provide a measure of responses elicited from defined sensory stimuli, such as a tone or light. Although electroencephalogram (EEG) analysis is used in a clinical setting to aid in the diagnosis of neurological diseases, its use in neurotoxicology has not been widely accepted.

Exposure to neurotoxic chemicals can also affect behavior, which is the product of various sensory, motor, and associative functions of the nervous system. Neurotoxic substances can adversely affect sensory or motor functions, disrupt learning and memory processes, or cause detrimental behavioral effects. Although changes may be subtle, the assessment of behavior may serve as a robust means of monitoring the well-being of an organism. Behavioral procedures measure the frequency, pattern, latency, or magnitude of a response, all of which may be differentially affected by neurotoxic chemicals. In the screening of chemicals for potential neurotoxicity, behavioral procedures are frequently used (see *UNITS 11.2, 11.3 & 11.4*). Advanced behavioral testing as described in these units is used to characterize the effects of chemicals on nervous system function.

CRITICAL ISSUES IN DEFINING NEUROTOXIC EFFECTS

Verifying that a chemically induced change is a neurotoxic effect is sometimes difficult. In general, alterations in the structure of the nervous system, such as neuronopathy, myelinopathy, neurodegeneration, axonopathy, and peripheral neuropathy, are neurotoxic effects. Interpretation of structural changes as being neurotoxic is dependent upon a number of methodological issues related to the sampling procedure, the method of sample fixation and preparation, and identification of artifacts.

Chemically induced changes in the function of the nervous system are measured using neurophysiological, neurochemical, and behavioral methods. Irreversible functional changes are typically regarded as neurotoxic. If the effect is reversible, the results should be assessed further using at least one of four additional criteria. For example, some chemicals that produce a reversible effect are known to have a specific neurotoxicological mechanism characterized at a higher level of nervous sys-

tem organization (e.g., cholinesterase-inhibiting insecticides produce clinical signs of cholinergic overstimulation because these compounds inhibit the breakdown of acetylcholine, leading to an overactivation of cholinergic receptors). An increase in our knowledge of neurotoxicity mechanisms will greatly reduce uncertainties in the interpretation of chemically induced changes in the nervous system.

Another criterion by which to evaluate reversible functional effects is to determine if the change covaries with another change that is known to be neurotoxic. For example, it is generally accepted that chemical-induced injury to the nervous system is a toxicological effect. Chemical-induced changes in markers that are associated with injury may therefore be regarded as neurotoxic even though they are short-lived. For example, under some conditions, an increase in the expression of glial fibrillary acidic protein (GFAP) is associated with injury to neurons. A chemical-induced increase in GFAP that is reversible would be of concern since this change is a marker for a generally accepted indicator of neurotoxicity, i.e., neuronal injury.

Reversible functional changes should always be interpreted cautiously because of the well-established ability of the nervous system to adapt to damage. Even when an initial exposure has produced only reversible changes, subsequent exposure to the same or a similar chemical could cause additional damage and result in a decreased ability to respond to further exposures. The nervous system appears to have a functional reserve that, once exhausted, can lead to overt, irreversible neurotoxicity. One method to determine if the functional reserve has been diminished by chemical exposure is to subject the system to a pharmacological or environmental challenge. For example, if an animal is exposed to a neurotoxic chemical and is apparently unaffected, subtle toxicokinetic or toxicodynamic changes may be revealed by shifts in the dose-response curve to a psychostimulant. In cases where reversible functional changes are associated with such adaptive changes, a pharmacological or environmental challenge may unmask subclinical neurological damage.

A fourth criterion that could be used to evaluate reversible changes in nervous system function relates to the occupational or environmental consequences of the effect. For example, exposure to a solvent may produce a relatively short-lived change in motor function. Such an exposure could significantly impair the performance of tasks required in the workplace, leading to a loss of productivity or unsafe performance on the job. Alcohol-induced impairment in the operation of a motor vehicle is another example. In these cases, it is important to be able to estimate the concentration required to produce the neurotoxic effect and to limit exposure to concentrations of the chemical below some defined limit or level.

NEUROTOXICOLOGY RISK ASSESSMENT

Risk assessment is an empirically based process used to estimate the probability that exposure of an individual or population to a chemical, physical, or biological agent will be associated with an adverse effect. The risk assessment process usually involves four steps: hazard identification, dose-response assessment, exposure assessment, and risk characterization (NRC, 1983). Risk management is the process whereby information obtained through the risk assessment process is analyzed to determine whether the assessed risk should be reduced and, if so, to what extent (NRC, 1983).

Hazard identification, the first step of risk assessment, is a process of examining all available experimental and animal data and the associated doses, routes of administration, and durations of exposures to determine qualitatively if an agent causes neurotoxicity in that species and under what conditions. Of particular concern in hazard identification is the use of animal data to identify hazards to humans and to determine the relative sensitivity across species and genders. Overly conservative risk assessments, based on the assumption that humans are always more sensitive than a tested animal species, may result in poor risk management decisions. Conversely, an assumption of equivalent sensitivity in a case where humans actually are more sensitive to a given agent can result in underregulation that might have a negative impact on human health.

A related issue concerns the use of data collected from healthy adult organisms, animal or human, to predict hazards in potentially more sensitive populations such as the very young, the elderly, or the chronically ill. In some cases, assessment of a neurotoxicity hazard is done without including subjects from either end of the human life span or from less-than-healthy subjects; instead, uncertainty factors are used to adjust for more sensitive populations. In addition, single- or multigeneration reproduc-

tive studies in animals may provide a source of information on neurological disorders, behavioral changes, autonomic dysfunction, neuroanatomical anomalies, and other signs of neurotoxicity in the developing animal. For the most part, the basic principles of hazard identification are the same for neurotoxicity as for any adverse effect on health.

The second step in risk assessment is dose-response assessment, which attempts to establish the relationship between the extent of damage or toxicity and the dose of a toxic substance for various conditions of exposure. Because several different kinds of responses may be elicited by a single agent, more than one dose-response relationship may need to be developed (e.g., for neurochemical and morphological parameters). The most frequently used approach for dose-response risk assessment of neurotoxicants and other noncancer endpoints is the uncertainty- or safety-factor approach (Barnes and Dourson, 1988). In general, this approach involves the determination of reference doses (RfDs) by dividing a no-observed-adverse-effect level (NOAEL) by uncertainty factors that presumably account for interspecies differences in sensitivity. Generally, an uncertainty factor of 10 is used to allow for the potentially higher sensitivity in humans than in animals and another uncertainty factor of 10 is used to allow for variability in sensitivity among humans. Hence, the RfD is equal to the NOAEL divided by 100. If the NOAEL cannot be established, it is replaced by the lowest-observed-adverse-effect level (LOAEL) in the RfD calculation and an additional uncertainty factor of 10 is introduced (i.e., the RfD equals the LOAEL divided by 1000). There are several known limitations to the NOAEL/LOAEL approach (Kimmel, 1990) and other quantitative models have been proposed (Gaylor and Slikker, 1990; Glowa and MacPhail, 1995).

The third step in risk assessment is exposure assessment, which determines the source, route, degree, duration, and interval of human exposure to an agent. The results of the dose-response assessment are combined with an estimate of human exposure to obtain a quantitative estimate of risk. As the effect of (or the exposure to) an agent approaches zero, the risk of neurotoxicity approaches zero. It should be recognized that exposure to multiple agents may produce synergistic or additive effects. Sources of exposure may include soil, food, air, water, or intended vehicle (e.g., drug formulation). Exposure can occur via many routes, including ingestion, inhalation, or direct contact with skin. The degree of exposure may be strongly influenced by a number of factors—for example, the occupation of the individual involved. The duration of exposure (i.e., acute or chronic) and interval of exposure (i.e., episodic or continuous) are variables common to all types of risk assessment, including carcinogenicity. Although not routinely used, biological markers (or biomarkers) of exposure could theoretically improve the exposure assessment process and thereby improve the overall risk assessment of neurotoxicants.

The final step in risk assessment combines hazard identification, dose-response assessment, and exposure assessment to yield the characterization of risk. This combined analysis provides an evaluation of the overall quality of the assessment and the degree of confidence in the estimates of risk and conclusions drawn, and describes risk in terms of the nature and extent of harm. The risk characterization summary communicates the results of the risk assessment to the risk manager.

Neurobehavioral Screening in Rodents

Neurobehavioral evaluations are an important component of testing for the neurotoxic potential of chemicals. Observations made during standard toxicity studies or specialized neurotoxicity studies can provide information important for identifying and/or characterizing neurotoxic effects. A protocol that includes a framework for the systematic recording of observations and manipulations, such as a functional observational battery (FOB), is an integral part of neurobehavioral screening. A neurobehavioral test battery can be composed of a variety of endpoints, usually chosen to assess an array of neurological functions, including autonomic, neuromuscular, sensory, and excitability.

The protocols in this unit are divided into (1) observational assessments and (2) manipulative tests. Each protocol is further subdivided into specific tests or endpoints (Table 11.2.1). These various endpoints may be combined into a battery of tests for neurobehavioral screening. Most or all of these protocols/endpoints should be used in the context of a broad neurobehavioral test battery, whereas judicious selection of specific endpoints may be appropriate for more focused neurological testing.

NOTE: In all protocols, the term "rat" is used to describe the test subject. These tests are equally valid in mice; instances where differences exist between mice and rats are listed.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Table 11.2.1 Endpoints in a Neurobehavioral Screening Battery

Observational assessments (Basic Protocols 1 to 5)	Manipulative tests (Basic Protocols 6 to 8)
Activity levels:	*Neurological reflexes/reactions*:
Home-cage observations	Pupil response
Open-field observations	Palpebral reflex
Rearing	Pinna reflex
Reactivity/excitability:	Extensor thrust reflex
Reactivity	*Neuromuscular tests and postural reactions*:
Arousal	Grip strength
Gait and postural characteristics:	Landing food splay
Gait descriptions	Hopping
Postural descriptions	Righting reaction
Involuntary/abnormal motor movements:	*Sensory responses*:
Tremors	Visual test: approach response
Fasciculations	Visual test: visual placing
Clonus	Somatosensory test: touch response
Tonus	Auditory test: click response
Stereotypy	Nociceptive test: tail/toe pinch
Bizarre behaviors	Nociceptive test: flexor reflex
Clinical signs:	Proprioceptive positioning test
Lacrimation	Olfactory test
Salivation	
Hair coat	
Palpebral closure	
Ocular abnormalities	
Muscle tone/mass

Current Protocols in Toxicology (1999) 11.2.1-11.2.16

NOTE: Generally, a sample size of ten to twelve subjects per sex per treatment is sufficient. Control animals must be treated exactly the same as the other groups except that they are administered only vehicle.

OBSERVATIONAL ASSESSMENTS

This section provides observational assessments used to characterize neurological function, a description of the behaviors being observed, and possible ranking scales to be used, where applicable. The observed behaviors are innate, that is, they do not need to be taught or shaped. Thus, observations require little or no interaction between the observer and the subject, with the possible exception of holding the rat. Because the observer makes judgments regarding these behaviors, the assessments are subjective.

The rat may be observed briefly in the home cage, but such observations are quite constrained and therefore limited. The home cage may prevent clear observations due to a variety of factors including available light, position of the cage, and clarity of the cage material. For these reasons, most of these evaluations are made in an open field or arena. The observer should be positioned so as to have a clear, unobstructed view as the rat moves about. Choose an open field that is large enough for the rat to explore, has a nonslippery surface, and has a raised border to prevent the subject from escaping or falling over the edge. Typical open fields include the top of a laboratory cart with a rim, or a benchtop with metal sides enclosing the area. Cover the open field with clean absorbent paper that can be changed after each rat (or clean the area after each rat) to eliminate interfering olfactory cues. Environmental conditions (e.g., lighting and temperature) should be held constant from day to day.

The endpoints described in Basic Protocols 1 to 5 may be evaluated simultaneously by a single observer during the handling phase and open-field observation period. It is suggested that the open-field period be sufficiently long for the observer to score the animal on all the associated endpoints (e.g., 2 or 3 min).

BASIC PROTOCOL 1

Observation of Spontaneous Activity Levels

Spontaneous activity levels of the rat may be evaluated in several circumstances such as in the home cage and while exploring a novel (open-field) environment. Home-cage observations are made while the animal is undisturbed in the cage; open-field observations are made during the time that the animal is exploring the open field or arena. In addition to general activity level, rearing is used as a measure of locomotor activity and exploration and in addition indicates the ability of the animal to lift both forepaws from the surface and place its weight on its haunches. A rear occurs when the front legs of the animal are lifted completely off the surface, when the animal raises up vertically, or when the animal places its front paws or legs on the side or lip of the open-field enclosure. The exact definition of a rear is not as important as consistency across studies. Rats and mice show considerably different levels of activity.

Materials

Subject animals
Home cage
Open field
Silent laboratory counter

Perform home-cage observations

1. Approach the cage quietly so as not to disturb the rat. Do not pull out the cage or move it in any way until the measure has been made.

2. Observe the rat's spontaneous activity. Limit observation to 5 sec or less, as the presence of the observer will influence the rat's activity.
3. Rank the level of spontaneous activity displayed in the cage. Use scoring criteria with a sufficient range of scores to adequately describe the behavior. Possible scoring criteria include:

   1 = No activity (rat may be asleep or sitting motionless)
   2 = Slight (rat may move its head or body, just a very few times)
   3 = Moderate (rat moves about some)
   4 = Active (rat moves more actively around cage)
   5 = High activity (rat moves about rapidly).

Perform open-field observations

4. Place the rat in the center of an open field.
5. Observe the rat for a standard period of time (e.g., 2 or 3 min). Keep the length of open-field observation time consistent across subjects.
6. Rank the amount of activity (locomotion) in the open field, using a scale such as:

   1 = No body movement
   2 = Low (somewhat sluggish, little movement)
   3 = Somewhat low (some exploratory movements)
   4 = Low but active (mostly walking with very little or no running)
   5 = Clearly active (exploratory movements, includes walking and running)
   6 = High (very active, darting or running).

   As an alternative to ranking the level of activity, count the number of times the rat crosses unit areas (e.g., squares that have been marked on the field).

Assess rearing

7. Use a laboratory counter to tabulate rears. Be sure that the counter does not make noise, so that it does not disturb the rat.
8. Count the number of rearing responses within a fixed period of time, typically during the open-field observation time.

   The number of rearing responses observed, and the habituation of such activity, is highly dependent on the strain of rat. Evaluation of this habituation process may provide an additional neurobehavioral endpoint.

Observation of Reactivity and Arousal

BASIC PROTOCOL 2

Measures of reactivity (excitability) assess the animal's level of responsiveness to nonspecific stimuli such as handling or being placed in an open field. Arousal or alertness is inferred from watching the animal in the open field. It can be thought of as the attentiveness or vigilance of the animal. Arousal can be inferred by observing the locomotion, rearing, vibrissa movement (whisking or quick, light sweeping movements of the whiskers), and sniffing behaviors of the animal.

Materials

Subject animals
Home cage
Open field

Assess reactivity/excitability

1. Observe the level of excitability or resistance of a subject animal in response to handling and/or removal from the home cage.

   Handling may precipitate the expression of certain spontaneous neurological abnormalities, and therefore some degree of assessment should be made before handling.

   Always handle rodents gently, and hold the rat or mouse under the shoulders (not by the tail). Rough handling will greatly increase the level of excitability and may compromise subsequent tests.

2. Rank the level of reactivity/excitability using scoring criteria such as:

   1 = Low (no resistance, easy to hold or pick up)
   2 = Moderately low (slight resistance)
   3 = Moderately high (some squirming or moving around)
   4 = High (excited, squirming, twisting)
   5 = Very high (aggressive actions, e.g., biting, tail and throat rattling).

Assess arousal

3. Place the animal in an open field. Observe whisking, rearing, exploration, or responses to sudden noises for 2 or 3 min in order to make an overall ranking of arousal.

4. Rank arousal over the entire observation period, using a scale such as:

   1 = Very low (stupor, coma, or prostrate)
   2 = Low (sluggish, only some movements)
   3 = Somewhat low (slightly sluggish, some exploratory movements)
   4 = Moderate (alert, exploratory behavior)
   5 = Somewhat high (slight excitement, tenseness)
   6 = Very high (very alert, very excited or tense, sudden running or movements).

   With repeated testing, the subject may habituate to the surroundings and arousal scores may subsequently decrease.

BASIC PROTOCOL 3

Observation of Gait and Postural Characteristics

Changes in posture and movements reflect alterations in the central and peripheral nervous systems and as such are sensitive indicators of neurological dysfunction. Gait descriptions refer to movements of the limbs as the rat ambulates; postural descriptions refer to the placement of the body and spinal curvature. Clearly and explicitly describe observations of altered posture or motility, without using slang or nonspecific terms. Ranking the severity of abnormality is also useful for interpreting these changes. Assure a clear view of the rat from the top and sides to make these observations. For these measures, the period of observation is not critical.

Materials

Subject animals
Open field

Observe gait

1. Observe a rat moving about in an open field. Gently prod the animal if it does not move. Look at the movement of all four limbs in relation to one another and to the saggital plane of the body.

   The normal rat moves opposing limbs simultaneously, which allows the body to remain steady.

2. Rank the degree of gait abnormality, using a scale such as:

   1 = No abnormality
   2 = Slight abnormality
   3 = Moderate abnormality
   4 = Severe abnormality.

   Note that even "normal" rats, especially older or heavier ones, may display some gait abnormalities.

3. Describe the gait using either accepted terms (e.g., ataxia) or predefined criteria such as:

   Ataxia (uncoordinated, staggering, wobbly gait)
   Hindlimbs show exaggerated, overcompensated, and/or splayed movements
   Feet (primarily hindfeet) point outward from body
   Forelimbs drag and/or show abnormal positioning
   Walking on toes (the heels of the hind feet are perpendicular to the surface).

Observe posture

4. Observe a rat moving about in an open field. Focus observations on the positions of the back, the belly, and the saggital plane of the body.

   Observation of posture is best made while the subject is moving about. The normal rat walks upright, with the back straight and pelvis off the surface.

5. Rank the degree of postural abnormality, using a scale such as that used for gait characteristics (step 2). Describe postural alterations using criteria such as:

   Completely flattened, pelvis flat on surface
   Pelvis low, dragging somewhat
   Hunched, back raised up.

Observation of Involuntary/Abnormal Motor Movements

BASIC PROTOCOL 4

Involuntary movements include motor acts typically referred to as tremors or convulsions. Tremors indicate rhythmic, repetitive contractions/relaxations of major muscle groups, and may be localized (e.g., head or limbs) or general (whole body). Involuntary movements also include fasciculations, clonus, tonus, and stereotypy. Fasciculations also indicate rhythmic, repetitive movements, but are localized to muscle fibers. When occurring superficially, fasciculations may appear as twitching of the skin. Clonus or myoclonus refers to sudden brief episodes of contraction or relaxation of large muscle groups (muscle jerks). As opposed to tremors, clonic movements are sporadic rather than rhythmic. Tonus refers to a state of prolonged, continuous contraction of large muscle groups. Stereotypy is defined as the pronounced repetition of specific gestures or movements (i.e., excessive or repetitive behaviors that appear purposeless). In addition, the animals should be observed for "bizarre" or unusual behaviors (i.e., behaviors not normally seen in rats). Examples of stereotypic and bizarre behaviors are described below. These behaviors can be observed in the home cage or in an open field. The observation time is not critical.

Materials

Subject animals
Open field or home cage

Examine for involuntary motor movements

1. Rank the magnitude of tremors, fasciculations, and clonic and tonic movements, using a scale such as 1 (none) to 4 (severe) for each behavior.

   Specific terms for tonic movements include opisthotonus (a tetanic spasm in which the spine and extremities are bent backwards) and emprosthotonus (a tetanic contraction of the flexor muscles, curving the back and bending the body forward).

2. Describe the affected area or muscle groups.

Examine for stereotypy

3. Observe for stereotypy and indicate its presence (yes/no).

   Examples include, but are not limited to, circling in tight circles, stereotypic grooming whose duration continues well beyond the normal grooming action, persistent pacing especially in one particular direction, or head weaving back and forth. The behaviors themselves are normal; all rats groom or occasionally walk in a circle. It is rather the frequency and persistence of these behaviors that distinguish them as being stereotypic.

4. Fully describe any stereotypic behavior and indicate its frequency.

   Videotaping is an excellent means of documenting stereotypies.

Examine for bizarre behaviors

5. Observe for any bizarre behaviors and indicate their presence (yes/no).

   Bizarre behaviors should be carefully recorded. Examples include, but are not limited to, self-mutilation (or, for example, evidence of missing digits or bite marks on the tail in singly housed rodents), retropulsion (marked backwards movements), Straub tail (tail is stiff and is held in a vertical position), or writhing (a twisting motion or spasmodic pulling in of the abdominal muscles).

6. Fully describe any unusual behaviors and their magnitude and/or frequency.

   Videotaping is an excellent means of documenting abnormal or bizarre behaviors.

BASIC PROTOCOL 5

Observation of Clinical Signs

Observations of clinical signs should be made while holding the subject animal or observing it in the open field. Subject animals are observed for lacrimation and salivation, hair coat characteristics (color/staining, alopecia, and piloerection), presence and degree of eyelid closure, ocular abnormalities, and muscle tone or mass.

Materials

Subject animal
Open field

Examine for lacrimation

1. Score lacrimation on a two- or three-point scale.

   Lacrimation is evidenced by wetness around the eyes. The normal state is a low basal level of lacrimation, so it is difficult if not impossible to observe decreased lacrimation.

2. Indicate whether tears are clear or tinged red (termed chromodacryorrhea).

   Red porphyrin deposits may be chemically induced or may appear spontaneously in some strains of rats.

Examine for salivation

3. Score salivation on a two- or three-point scale.

   Salivation is evidenced by wetness around the mouth and chin. As with lacrimation, it is difficult to observe decreased salivation.

Examine hair coat

4. Indicate the presence and location of staining or abnormal coloration of the hair.
5. Indicate alopecia (thinning of the hair).
6. Indicate the presence of piloerection (hair standing on end).

   To differentiate piloerection from a scruffy or ungroomed coat, simply stroke the back of the rat in a rostral to caudal direction. Piloerection will still be apparent after stroking.

Examine for palpebral closure

7. Describe the degree of palpebral closure (degree of eyelid closure).

   This will depend on the activity level of the subject. Chemically induced ptosis, or drooping eyelids, is not reversed by handling or otherwise stimulating the rat.

8. Rank palpebral closure or indicate the presence/absence of ptosis.

Examine eyes

9. Indicate corneal opacity or cloudiness for each eye.

   Ocular abnormalities involve changes in the cornea or eyeball.

10. Indicate whether the eyeball appears to bulge (termed exophthalmia) for each eye.

Assess muscle tone/mass

11. Palpate the abdominal muscles and/or large muscle groups.

    Body tone, or resistance of the major abdominal muscles, may be assessed by the feel of the whole body. Muscle tone can also be measured by palpating the large muscle groups (e.g., thigh) and rating its resistance.

12. Indicate any changes in normal muscle tone.

    Terms such as hypotonia (completely flaccid, limp) and hypertonia (body stiff, muscles exert much resistance) can be used where appropriate.

MANIPULATIVE TESTS

A number of tests may be performed to measure specific neurological functions. The tests listed here are manipulative in that they require an interaction between the observer and the subject. As with the observational tests, many of these are subjective measures in that the observer will do the test and rate the subject's response. In addition, a few tests are quantified using simple instruments. Basic Protocols 6 to 8 describe manipulative methods commonly used to characterize neurological function, a description of the behaviors, and possible ranking scales to be used.

Assessment of Neurological Reflexes/Reactions

BASIC PROTOCOL 6

A systematic examination of neurological reflexes or reactions is important to evaluate the integrity of specific nerves or nerve pathways. A reflex is a characteristic response to a specific stimulus and typically involves simple neural circuitry (for example, an eyeblink in response to an air puff). More complex behaviors mediated by several reflex circuits are termed reactions. Because reflexes/reactions are common across many species, these findings can facilitate extrapolation of chemical effects to humans.

Materials

Subject animal
Narrow-beam light source: e.g., pocket-size flashlight (penlight) or otoscope
A fine object such as a thin wire

Test pupil reaction

1. Use a narrow-beam light source and shine the beam in a rat's eye, bringing the beam in from the side of the head.

   The pupil reaction is the response of the pupil to a light stimulus.

2. Watch for the constriction of the pupil, which occurs within seconds. Note whether the reaction is present or absent.

   In brightly lit laboratories, the rat's eyes may have to be covered briefly to dilate the pupils. Even if the pupil is difficult to see, the contraction itself is usually visible.

3. Record any obvious features of the pupil such as miosis (pin-point pupils) or mydriasis (dilated pupils).

Test palpebral reflex

4. Use a fine object such as a thin wire and touch the edge (not the point) of the object to the inside (nasal) point of the eye.

   The palpebral reflex tests the trigeminal and facial nerves in response to a light touch (somatomotor stimulus). The eyelids should quickly close.

5. Indicate the presence/absence of the reflex.

Test pinna reflex

6. Use a fine object such as a thin wire and touch the edge of the object to the skin/hair inside the ear.

   The pinna reflex is another somatomotor test of the cranial nerves. The ear should either shake or flatten against the head.

7. Indicate the presence/absence of the reflex.

Test extensor thrust reflex

8. Hold the rat in one hand. Gently press the fingertips into the plantar surface of the animal's two hindfeet.

   The extensor thrust reflex evaluates the motor/sensory components of the spinal response to pressure in the footpads. The rat will extend the hindlimbs, pushing against the fingertips, and curl the toes around the fingertips. It may be necessary to press against the hindfeet several times to elicit this response.

9. Indicate the presence/absence as well as the strength of the extensor response. Note whether the response is equal in both hindlimbs. If desired, note the number of stimuli required to elicit the response.

BASIC PROTOCOL 7

Neuromuscular Tests and Assessment of Postural Reactions

Postural reactions are necessary for the rat to maintain an upright posture and require intact sensory and motor systems. Neuromuscular tests evaluate muscular coordination and strength. Examination of both functions are necessary to test the motor/muscular systems; however, there is a large sensory component as well (see Basic Protocol 8).

This protocol describes postural and neuromuscular tests that assess grip strength, landing foot splay, hopping, and righting. Tests of grip strength provide a quantitative measure of muscle strength, which reflects the integrity of both peripheral nerves and muscles (Meyer et al., 1979). Grip strength may be measured using commercially available strain gauges with either wire-mesh screens or T bars for the rat to grab. The force at which the rat releases its hold on the screen or T bar is the measure of its grip strength. Alternatively,

an array of wires or screens can be used for the rat to grab, and a subjective assessment can be made regarding the ease with which the grasp can be broken. Landing foot splay is a test of proprioceptive function and muscle tone (Edwards and Parker, 1977). Hopping is a challenging test of postural reaction, which requires adequate balance, proprioception, coordination, and strength. The righting reaction is a test of vestibular function, but coordination and strength are necessary as well for the rat to complete this task.

IMPORTANT NOTE: Do not test landing foot splay or aerial righting if the animal is paralyzed or severely affected by treatment.

Materials

Subject animals
Strain gauge with attached wire-mesh or T bar
Paint or ink
Paper
Measuring stick or ruler

Test grip strength

For forelimb grip strength

1a. Set a rat's forepaws on the screen or T bar attached to a strain gauge. Alternatively, hold the rat until it grabs the screen/bar.

2a. Hold the rat by the base of the tail and pull the rat horizontally, smoothly and quickly, until its grip is broken.

This should be performed in one continuous motion. A slight pause may be necessary before beginning the pulling motion, to assure that the rat's digits are properly curled around the screen or bar and that the paws are not crossed. The observer should place his/her arm under the rat to catch it as soon as it releases the screen or bar.

3a. Read the dial on the gauge and reset it.

4a. Repeat two or three times and use the average of the readings.

Use only those readings that appear to be valid (e.g., rat's paws were placed properly).

For hindlimb grip strength

1b. Hold a rat with its hindfeet close to the screen or T bar attached to a strain gauge.

A platform may be helpful to support the body.

2b. Pull the rat backward, horizontally, until its hind feet grab the screen or bar. Continue to pull until the rat's grip is broken.

This should be performed in one smooth, continuous motion. A slight pause may be necessary before beginning the pulling motion, to assure that the rat's digits are properly curled around the screen or bar and that the paws are not crossed. Stop pulling before the front feet touch the screen or bar.

3b. Read the dial on the gauge and reset it.

4b. Repeat two or three times and use the average of the readings.

Use only those readings that appear to be valid (e.g., rat's paws were placed properly).

Test landing foot splay

5. Dab a small amount of paint or ink on the outer portion of the hindfeet.

Various methods can be used to mark the position of the hindfeet upon landing.

6. Hold rat in a prone position at a standard height, typically 20 to 30 cm above a piece of paper. Use a vertical measure to assure consistency in the height used.
7. Drop the rat.

   A padded surface should be used to cushion the fall and prevent injury in case the rat cannot land properly.
8. Observe where the rat lands on the paper, and immediately circle or otherwise indicate the appropriate marks.

   The rat will often either jump forward upon landing or start walking away, smearing the paint as it moves.
9. Measure the distance between the centers of the marks.
10. Repeat two or three times and use the average of the readings.

Test hopping

11. Hold the rat with three limbs tucked into the body and the body weight supported on one limb.

    Both forelimbs and hindlimbs can be tested, but hindlimb hopping is not as robust. If the rat is given too much support, it will not be compelled to use the single limb to support its weight.
12. Move the rat forward or to the side. The rat should hop the limb as the body is moved to maintain its weight-bearing position.

Test righting reactions

For surface righting

13a. Hold the rat in a supine position on a surface.

14a. Quickly release the rat.

    The rat should immediately flip to resume a normal standing posture. This reaction follows the same pattern in all rodents, with the head turning over first, followed by the forelimbs, and then hindlimbs.

15a. Evaluate the final position of the limbs to evaluate proprioceptive deficits.

    You may try to time the latency to right, but the reaction is often too fast to time with a stopwatch.

For aerial righting

13b. Hold the rat in a supine position, with your hands under the back and shoulders. Position the rat 20 to 30 cm above a surface. Use a vertical measure to assure consistency in the height used.

    Most rats can right from a distance of ≥10 cm.

14b. Quickly release the rat.

    The rat should flip over and land on its feet. A padded surface should be used to cushion the fall and prevent injury in case the rat cannot right itself. Righting follows the same progression described for surface righting (see step 14a).

15b. Score the ease of landing, using a scale ranging from normal righting to slightly uncoordinated to markedly uncoordinated. Evaluate the final position of the limbs to evaluate proprioceptive deficits.

Assessment of Sensory Responses

Sensory reactivity tests measure the responses to stimuli of different sensory modalities. Visual function is difficult to measure in rodents but is nonetheless an important sense to evaluate for potential toxicity. Two visual tests are presented here: a visual approach response and visual placing, which both measure the rat's reaction to an object coming into its field of vision. Somatosensory tests evaluate the sense of touch, pressure, or vibration. A touch response test measures the rat's reaction to a light touch stimulus. For auditory function, a click response test measures the rat's reaction to a sudden sound. For nociception, a tail-pinch or toe-pinch response test measures the rat's perception of brief pain. Additionally, the flexor reflex tests the spinal sensory/motor pathway in response to a brief, painful stimulus. This can be used to measure the sensory response as well as to evaluate muscle strength. Finally, proprioceptive positioning evaluates the awareness of the position of the limbs without visual input, and an olfactory test evaluates orientation to or sniffing of a novel odor.

Most of the stimuli are relatively crude and may not actually be specific for the sensory function being measured. Automated apparatuses, such as acoustic startle chambers, may improve the specificity of some stimuli. Tests for these responses are typically conducted while the animal is moving freely about in an open field. The animal should be positioned properly in order to do certain tests. Because a motor response is the behavior that is observed, there is a large motor component to the tests as well.

Materials

Subject animals
Odorant
Blunt object (e.g., pen or pencil, brush, wire)
Metal clicker or other sound device

Test visual approach response

1. Place a rat in an open field, ensuring that it is properly positioned away from the edge of the field.
2. Approach the rat at nose level with the end of a blunt object, such as a pen or pencil. Be sure that the stimulus is consistent from test to test.
3. Hold the stimulus ~3 cm from the face for ~4 sec to give the rat time to make a response.
4. Rank the magnitude of response to the stimulus using scoring criteria such as:

   1 = No reaction or response
   2 = Slight or sluggish reaction (flinch or startle as evidence of perception)
   3 = Obvious reaction (locomotor orientation as evidence of perception)
   4 = Clear reaction or response (more intense startle or locomotion)
   5 = Exaggerated reaction (may jump, bite, or attack).

Test visual placing

5. Hold the rat by the tail and position it above the edge of a table or cart.
6. Slowly move the rat down toward the surface or edge.

   As it approaches, the rat should extend its head and neck and reach towards the edge with the forelimbs.

7. Indicate the presence/absence of the placing response.

Test somatosensory response

8. Position the rat away from the edge of an open field.
9. Coming in from the side, touch the rump of the rat gently with a blunt object, such as a pen, pencil, brush, or wire. Be sure that the stimulus is consistent from test to test. Use a brief touch (1 to 2 sec) that is deliberate but not too forceful.
10. Score the magnitude of the response using a scale similar to that above (step 4).

Test auditory response

11. Position a sound stimulus ~5 cm above the back of the rat (i.e., outside the field of view).

    Various stimuli may be used, including a metal clicker, finger snap, or hand clap.

12. Make a sudden sound. Be sure that the stimulus is consistent from test to test.

    The rat should react immediately with pinna movement, flinch, or whole-body startle.

13. Score the magnitude of the response using a scale similar to that above (step 4).

Test tail-pinch response

14. Position the rat away from the edge of an open field. Pinch the tail ~2 to 3 cm from the tip, or pinch the toes or foot pad. Pinch hard enough to produce a reliable response in control rats, and be consistent in the intensity of the pinch from test to test.

    The very tip of the tail is relatively insensitive. The rat should react immediately with a flinch, whole-body startle, or an escape response.

    Metal tweezers may be used, or any other device that will make a quick squeeze without damaging tissues.

15. Score the magnitude of the response using a scale similar to that above (step 4).

Test flexor reflex

16. Holding the rat in one hand, use the other hand to grasp the toes on one hindlimb and gently pull the leg.
17. Briefly but sharply pinch the toes. Be consistent in the intensity of the pinch from test to test.

    The rat will immediately retract the leg.

18. Evaluate the presence/absence and the strength of the flexor response.

Test proprioceptive positioning

19. Gently hold the rat on a surface and flex a hindlimb so that the dorsal surface of the paw is down on the surface.
20. Relax the hold on the hindlimb.

    The rat should immediately return the paw to the normal position under the body.

21. Evaluate the presence/absence and the strength of the response. Note whether the response is equal in both hindlimbs.

Test olfactory response

22. Position the rat away from the edge of an open field.
23. Dip a cotton swab in an odorant and approach the rat at nose level with the swab. Be sure that the stimulus is consistent from test to test.

24. Hold the stimulus ~3 cm from the face for ~4 sec to give the rat time to make a response.

25. Indicate the presence/absence of a response, or score the magnitude of the response using a scale similar to that above (step 4).

COMMENTARY

Background Information

Neurobehavioral screening methods such as a functional observational battery (FOB) typically include a series of noninvasive observational and interactive measures that assess the neurobehavioral and functional integrity of the rat. In addition to these measures, automated tests are also often included in neurobehavioral screening. Automated tests are objective, and the observer plays no role in the assessment. The level of instrumentation is higher than the tests that have been described in these protocols. Motor activity is commonly used and is amenable to inclusion in a neurobehavioral screening battery by virtue of its ease of operation as well as its usefulness.

Motor activity is an apical endpoint in that locomotor activity requires intact sensory, motor, and integrative neural function. For that reason, motor activity has been purported to be a very sensitive measure of neuronal function (MacPhail et al., 1989). Motor activity may be measured in many types of devices (reviewed in Reiter and MacPhail, 1979). The systems used to detect activity include, for example, infrared photocells, video tracking, and running wheels. Furthermore, the chambers range from large open fields to small cages to corridors in the shape of a doughnut or a figure eight. Activity can be monitored as horizontal movements (ambulation), vertical displacements (rearing), repetitive movements (stereotypy), or any number of various parameters. Finally, the length of sessions in the chambers can vary, but should be long enough to observe habituation, or a decrease in activity from the initial exploratory phase to a lower, asymptotic level.

Neurotoxicity screening methods are becoming increasingly important in the detection of the neurotoxic potential of new and existing chemicals. In 1985, the U.S. Environmental Protection Agency (EPA) published test guidelines for neurotoxicity test methods that included motor activity and FOB; these have since been revised and their use has become more widespread (Sette, 1989). The EPA originally developed these testing guidelines to provide a more structured framework for neurotoxicity tests. These include guidance on the types of tests, testing conditions, scoring criteria, as well as a requirement for proficiency data or positive-control studies. Several protocols based on these guidelines have been developed for rats and are published (e.g., Gad, 1982; Haggerty, 1989; McDaniel and Moser, 1993; Moser et al., 1988; O'Donoghue, 1989, 1996; reviewed in Tilson and Moser, 1992). Modifications of these screening tests for use in other species have also been published, including those for mice (Tegeris and Balster, 1994), primates (O'Keeffe and Lifshitz, 1989), and dogs (Schaeppi and Fitzgerald, 1989). Note, however, that the field of neurotoxicology is advancing rapidly, and these test methods should be flexible to change as new methodology is introduced.

Numerous studies using these tests have now been conducted to evaluate a variety of chemicals under many different dosing and testing paradigms. The results of these studies document effects of pesticides (e.g., Ehrich et al., 1993; McDaniel and Moser, 1993), solvents (e.g., Daughtrey et al., 1997; Gill et al., 1995), neuropathic chemicals (e.g., Moser et al., 1992), and a variety of other chemicals (e.g., Haggerty and Brown, 1996; LeBel and Foss, 1996), as well as strain- and sex-related differences in the outcomes (e.g., Moser et al., 1991; Moser, 1996). These and other publications should be consulted to obtain information on the types of data generated, characteristic profiles of different chemical classes, and methods for data interpretation. Still, the investigator should develop a standardized protocol that is appropriate for the individual laboratory, and should conduct positive-control studies to assure reproducibility and validity of the methods for the testing situation.

Several types of data are generated using these methods, including continuous (e.g., grip strength), rank-order (e.g., gait score), count (e.g., number of rears), descriptive (e.g., type of gait), and quantal (e.g., presence/absence of piloerection). Nominal data are unordered and can include several outcomes (descriptive data) or only two outcomes (yes/no). This is the crudest form of evaluation and may be especially difficult to interpret without specific ob-

jective criteria (e.g., a definition of "abnormal"). Ordinal, or scalar, data are ranked, and the observations are recorded as a position on a scale, with each rank clearly greater than the preceding one. These data are somewhat more sensitive to small changes in behavior, seen as shifts in the distribution of group scores. The scoring criteria for individual measures should be carefully considered and defined as objectively as possible. The range of possible scores should be sufficient to describe the range of possible differences in the particular behavior, as long as the observer can distinguish these intervals consistently. Interval, or continuous, data are reported on a quantitative scale and assume a normal distribution (sometimes following suitable transformation, e.g., square root). Statistically, these types of data are handled differently and should be analyzed with the appropriate parametric or nonparametric models. When the study design calls for multiple tests on the same subject, the analysis should include a within-subject factor (repeated-measures design). Several approaches for statistical analyses have been suggested (Creason, 1989; Gad, 1989).

These tests produce a large amount of data, as do all batteries of tests. Some investigators prefer to use only expert judgment in data interpretation, whereas others feel that relying on statistically significant effects is a more defensible approach. Because innate behaviors are not under tight experimental control, there is always some variability in the data that could be misinterpreted. Furthermore, simple analyses of all the test measures of the battery could lead to randomly significant results, improper conclusions, and false positives. A possible approach for condensing the multitude of data is to examine the endpoints based on the effects within functional domains, e.g., autonomic, sensory, or neuromuscular function, or levels of general excitability and activity (Moser, 1991). Regardless of the approach used, the investigator must be thoroughly familiar with the tests and data, including the control values, to make scientifically sound conclusions.

Critical Parameters

The observations and manipulations made during these tests are recorded only by the observer. The utility of the tests is dependent on the observer's ability to detect and describe changes in the subject's behavioral or neurological function, and to consistently conduct the tests and accurately record the responses. In addition, some functional changes may be transient, especially during acute toxicity tests. Training is therefore of paramount importance, since there is no other way to calibrate the observer. There is simply no substitute for hands-on experience, particularly during the initial stages of training. Observers should have extensive experience observing and handling untreated rats and then proceed to study rats treated with chemicals known to alter function. To aid in training and recertification of personnel and to improve consistency of the protocols across laboratories, a training video and manual are available from the EPA and the American Industrial Health Council (Moser and Ross, 1996).

A preexposure, or baseline, test is often included to document possible preexisting group or individual differences. Additional testing should be performed at specified times, sufficient to establish a time course of effects. Initial range-finding studies are critical for determining (1) appropriate doses, such that the selection of doses is adequate to define the full range of effectiveness, from no effects to marked changes; and (2) appropriate time of testing to optimize detection of possible neurological effects. The importance of these study parameters cannot be overemphasized.

Observations typically proceed from the least obtrusive to the most manipulative to reduce the influence of handling on subsequent behavior. Always perform the tests in the same order for all rats. The way in which subjects are handled affects their behavior and resulting observations. Personnel involved in performing routine husbandry procedures as well as personnel involved in dosing and testing should handle the rats in a gentle and consistent manner.

These tests are labor intensive. The observer is the instrument and (unlike automated instruments) observers get tired, need lunch breaks, and get sick. To provide consistency within a study, the same observer should conduct all the tests, to the extent possible. To break the monotony of the tests, take care not to exceed reasonable limits on schedules and stagger the tests over days (see Time Considerations, below).

Pay close attention to testing conditions, and ensure that differences are never systematically related to treatment level. Variables that can be controlled include temperature, humidity, lighting, noise, odors, and environmental distractions. The latter factors are more critical than is often realized (i.e., no distractions such as telephones, radios, talking, food). Extrane-

ous noise and/or interruptions during testing must be minimized, as this may alter the behavior of the rats and therefore affect the outcome of the study.

Because most of these tests are subjective, the observer must be "blind" to the treatment conditions of the subject to reduce possible bias or anticipatory results. While this may introduce logistic problems in testing, the importance of this variable cannot be ignored.

Troubleshooting

Because these measures are relatively simple, and there is little or no instrumentation, there is little that can go wrong. All equipment should be properly calibrated. Troubleshooting for commercial equipment should follow manufacturer's instructions. Problems arise when other factors come into play, such as lack of attention by the observer or environmental distractions (see Critical Parameters).

Anticipated Results

As mentioned above, there are numerous publications on these test methods that provide typical control values and examples of chemically induced changes. Another valuable source of information is a recently published report on an international collaborative study, which addressed issues of test validity and interlaboratory reliability of the data. In that study, eight laboratories (four in Europe, four in the U.S.) conducted acute and repeated-dosing studies on seven chemicals. A specific FOB protocol and an automated measure of motor activity were used, but other experimental variables (e.g., type of activity chamber and strain of rat) were not standardized. The results, which show how the screening battery performs in a variety of laboratory settings as well as control data for all endpoints, appear in a special issue of Neurotoxicology (Moser, 1997). Some overall conclusions from this study were that (1) the control data were generally reproducible, but this depended on the individual endpoint, and (2) all participants could detect and characterize the effects of known neurotoxicants using these methods.

Time Considerations

For any FOB and/or motor activity experiment, test times must be established and schedules must be developed to accommodate these test times. An experienced observer can conduct this series of tests in 6 to 8 min, or longer if more time is needed to study the subject's condition. Thus, it may take a full day to test only 35 to 40 rats, and this may be only a half to a third of the number of rats under study. Staggering the dosing and testing is fully acceptable, but it is important to carefully counterbalance the time of testing for each dose group and sex across the days of testing.

Assessment of Spatial Memory

Behavioral tasks must be evaluated in terms of the cognitive functions they require in order to be performed. Each task is a tool that allows the researcher to achieve a specific goal—i.e., to determine the consequences of manipulations of specific brain regions. These manipulations usually fall into one of four categories: stimulation of a single brain region by drugs or small electrical current, impairment of normal function by production of a lesion or administration of appropriate pharmacologic or toxicologic agents, recording of brain activity during the performance of a specific behavioral task, or behavioral phenotyping of transgenic and knockout mice for genes expressed in specific brain regions. All of the tasks described in this unit can be used with each of these four experimental manipulations.

Performance of the radial arm maze task (see Basic Protocol 1 and Alternate Protocol 1) requires intact spatial memory abilities. Normal performance is sensitive to the effects of hippocampal damage, normal aging, and a variety of pharmacologic or toxicologic agents. Performance of the water maze task (see Basic Protocol 2 and Alternate Protocols 2 and 3) also requires intact spatial memory abilities and is particularly sensitive to the effects of aging. The major advantage of the water maze task over the radial arm maze task is that the rats do not need to be water or food deprived; they are quite motivated to escape from the water. The task is also free from errors of omission or abortive choices—i.e., the rat makes an attempt to find the platform on every trial.

This unit also describes the use of the T maze to assess spatial memory, which takes into account the alternating behavior of rats in searching for food (see Background Information). The T maze has been most extensively used to investigate specific aspects of spatial working memory, which is operationally defined as information that is only useful to a rat during the current experience with the task. This is assessed using food-deprived rats in a simple T maze (see Basic Protocol 3). A modification of the T maze allows for the assessment of reference memory, defined as information that is useful across all exposures to the task (i.e., on any day of testing; see Alternate Protocol 4). Finally, in the absence of food-deprivation, a simple T maze can be used to assess spontaneous alternation (see Alternate Protocol 5).

Rats are generally used in research employing these behavioral tasks because a considerable amount is known about their brain anatomy and chemistry. Previous experimental studies have clearly shown that rats can be used to investigate the structure/function relationships between selected brain regions and learning or memory. Eight to ten rats are included in each experimental group, a number that is sufficient for statistical analyses (e.g., an analysis of variance, ANOVA) of the behavioral data and any neurochemical assays or histopathological studies that might be performed for confirmation of the manipulations.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

USE OF RADIAL ARM MAZE TASK TO TEST BASIC WORKING MEMORY

BASIC PROTOCOL 1

The radial arm maze task has been most extensively used to investigate specific aspects of spatial working and reference memory. This task is based upon the premise that animals have evolved an optimal strategy to explore their environment and obtain food with the minimum amount of effort.

A radial arm maze can easily be built by the investigator, so cost for this equipment can be quite low compared to other behavioral testing equipment. Using the maze, however,

Contributed by Gary L. Wenk
Current Protocols in Toxicology (1999) 11.3.1-11.3.18

is quite labor-intensive and requires that a tester be present throughout the task. The maze is typically used for rats, but it can be scaled down in size (by ~75%) for use with mice.

Materials

Rats
Pharmacologic or toxicologic agents (optional)
Food reward: e.g., 1-mg piece of normal chow, flavored (chocolate) or sweetened breakfast cereal, chocolate milk, or water
Radial arm maze (Fig. 11.3.1), handmade or fully automated (Coulbourn Instruments or Columbus Instruments)

Train rats

1. Weigh each rat daily throughout training and testing to monitor health and degree of food deprivation.
2. Restrict food available to rat so that its body weight attains 85% of that prior to training. During testing and training, allow rat to gain ~5 g body weight per week.
3. Allow rat to become comfortable with the experimenter (see Critical Parameters, discussion of rat handling).
4. Give food reward in home cage for a few days prior to training in order to acclimate the rat to the reward in a familiar environment.

   Liquid rewards are preferred if the rat will be given a drug, e.g., scopolamine, that might make swallowing dry food uncomfortable.

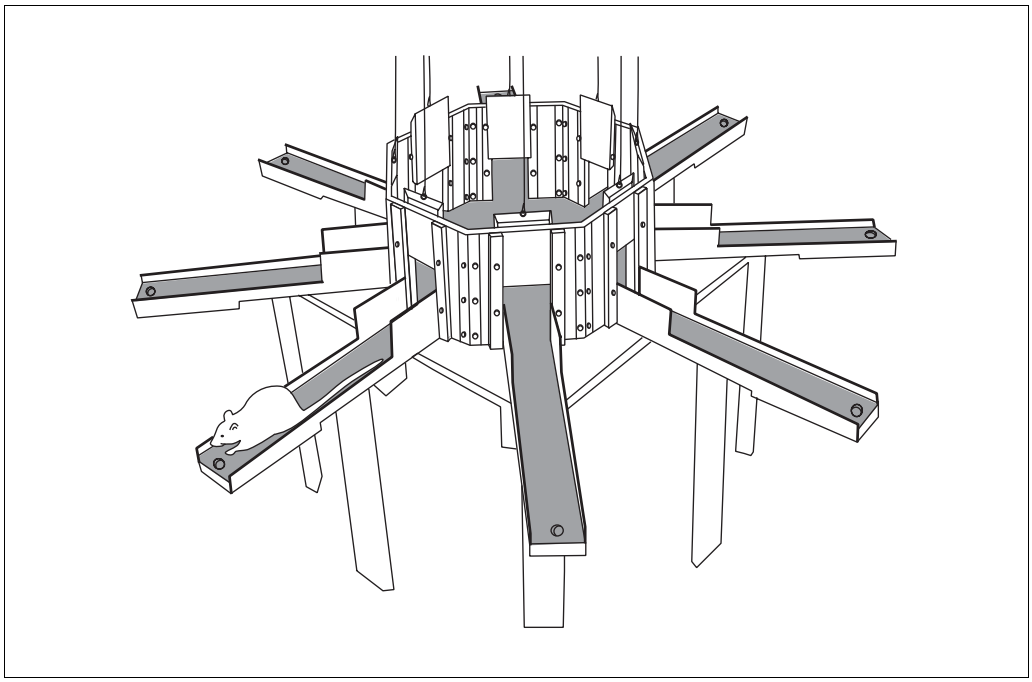

Figure 11.3.1 Eight-arm radial maze. For rats, the central platform should be ≥45 cm in diameter to accommodate the animal and allow it to turn easily between arms. A Plexiglas wall, 25 cm high, surrounds the central platform. The arms are 87 cm long and 10 cm wide, radiating from the central platform at equal angles. For mice, use shorter (35-cm), narrower (5-cm) arms and a smaller (20-cm) central platform. Each arm has a 5-mm-deep hole 1 cm from the end, which is used as a food cup, and each arm is separated from the center platform by a transparent Plexiglas guillotine door that covers a hole in the Plexiglas wall. The guillotine door can be raised or lowered to allow or prevent entry. The guillotine doors are connected by individual strings to a pulley system that allows the experimenter to open any door from one location within the testing room. Short walls (2 cm high) along the edge of the maze arms prevent the animal from falling off the maze.

5. Set up radial arm maze (see Fig. 11.3.1).

   The wooden or Plexiglas maze is set up ~1 m above the floor for easy access to the rat and food cups. It is composed of a central octagonal platform with eight arms extending from it like the spokes of a wheel. Guillotine doors that can be opened and closed individually separate the central platform from the arms. The maze should be placed in a room that contains various external cues that are visible to the rat while it is on the maze—e.g., a doorway, overhead lights, a noisy radio, and large simple designs on the walls. The maze can be handmade or a fully automated setup purchased commercially. The latter, including data analysis software, can be obtained from either Coulbourn Instruments or Columbus Instruments.

6. Place a well-handled pair of rats (preferably cagemates) on the maze at the same time.

   Using two rats reduces the time it takes for each to acclimate to the maze.

7. Spread food rewards around the entire maze to encourage exploration.

   Acclimation should require only 1 or 2 days.

8. On subsequent days, place food only on the arms, then only at the ends of the arms.

9. Finally, place rat alone on maze and food only in the food cup at end of arms. Testing can begin when rat is comfortable being picked up by the experimenter and, when placed alone on the maze, explores without hesitation and without excessive defecation or urination.

   A typical rat will be ready for testing—i.e., food-restricted and acclimated to the maze—within ~7 days. Rats should be run in the maze once a day every day (including weekends, ideally) during training and testing.

Test rats

10. Place food reward at end of each arm before each test session.

11. Place rat on central platform with all guillotine doors closed.

12. Raise all doors simultaneously. Allow rat to enter an arm. Close doors to all other arms.

13. Allow rat time to eat food and to return to central platform.

14. Close door to that arm and confine rat to the central platform area for a set time (from 0 sec to many minutes; 5 sec is ideal to begin).

    Longer waits make the task more difficult to solve—i.e., increase the length of time for which the rat must remember which arms it has entered.

15. Repeat steps 12 to 14 until all food pellets have been retrieved or until a predetermined length of time has elapsed.

16. Record the following data:

    Which arm the rat entered each time and whether it received a food reward
    Time elapsed between the beginning of the test session and the rat's obtaining all eight food rewards
    Number of correct arm choices: i.e., those that are chosen the first time
    Number of incorrect arm choices: i.e., visitations to the same arm more than once during a single test session.

    Time elapsed since the beginning of the session is considered in order to determine how fast the rat is making choices and finding the food rewards. This is also an indirect indication of motivation.

    Visitations to a previously chosen arm is considered a working memory error. Normal healthy young rats will perform this task almost perfectly every time.

    A healthy, happy, and motivated rat should learn this task, such that working memory errors are <15%, within 15 days.

17. Perform data analysis. Performance for all groups is typically expressed as either:
    a. The percentage of correct choices made in each test session in relation to the total number of arms entered,
    b. The absolute number of correct choices made in the first eight to twelve choices of each test session, *or*
    c. The percentage of correct choices made in relation to the number of incorrect choices.

    The data are best presented as a line drawing comparing a performance measure for each group versus daily test sessions. Data from 2 or 4 days of testing can also be averaged into blocks.

18. When performance is stable and choice accuracy is >85%, begin studies with pharmacologic and toxicologic agents or lesions.

    Alternatively, one can study the effects of drugs or lesions upon the acquisition of performance of this task. Drugs can be administered (or lesions produced) either prior to training to assess their effects upon acquisition, or after acquisition in order to assess their effects upon performance.

ALTERNATE PROTOCOL 1

USE OF RADIAL ARM MAZE TASK TO TEST WORKING VERSUS REFERENCE MEMORY

This protocol allows a dissociation to be achieved between working and reference types of memory, whereas the previous protocol is primarily sensitive to impairments in working memory. Working memory is operationally defined as information that is only useful to a rat during the current experience with the task, whereas reference memory is information that is useful across all exposures to the task—i.e., on any day of testing. This protocol should be performed after initial training of rats (Basic Protocol 1) has been completed.

1. Train rats in radial arm maze (see Basic Protocol 1, steps 1 to 9).
2. Place food reward at the end of only four arms of the radial arm maze before each test session.

    The arms chosen to be baited must be the same for a given rat but should vary between rats. For example, bait arms 1, 3, 6, and 8 every time that rat #1 is on the maze, bait arms 1, 4, 5, and 7 every time that rat #2 is on the maze, and so on. This task can be conducted on mazes with more or fewer arms in much the same way.

3. Place rat on maze with all doors raised and allow it to explore the maze completely and retrieve all food rewards.
4. Remove the rat from the maze for a set period of time (1 hr to 1 day).

    Longer delays make the task more difficult for the rat.

5. Bait appropriate four arms of maze for rat.

    In the example discussed above, bait arms 1, 3, 6, and 8 for rat #1.

6. Repeat step 3.
7. Record the following data:

    Number of correct entries into baited arms
    Number of entries into unbaited arms
    Number of reentries into baited arms
    Time elapsed between the beginning of the test session and the rat's obtaining all available food rewards.

    Entries into unbaited arms are reference memory errors; reentries into baited arms are working memory errors.

8. Repeat steps 2 to 7 until performance is stable and choice accuracy is high (>85%).
9. Perform data analysis. Performance for all groups is typically expressed as:
   a. The percentage of correct entries into baited arms in relation to the total number of arms originally baited (working memory performance), *and*
   b. The percentage of entries into arms that are never baited in relation to the number of unbaited arms (reference memory performance).

   The data are best presented as a line drawing comparing working and reference performance for each group versus daily test sessions. Data from 2 or 4 days of testing can be averaged into blocks.
10. Once the rat makes few, or no, reference or working memory errors, begin studies with pharmacologic or toxicologic challenges or lesions.

    Normal healthy young rats will perform this task almost perfectly every time. A healthy, happy, and motivated rat should learn this version of the task, such that working and reference memory errors are <15%, within 10 days.

USE OF MORRIS WATER MAZE TASK TO TEST SPATIAL MEMORY

BASIC PROTOCOL 2

The water maze task has been most extensively used to investigate specific aspects of spatial memory. This task is based upon the premise that animals have evolved an optimal strategy to explore their environment and escape from the water with a minimum amount of effort—i.e., swimming the shortest distance possible. The time it takes a rat to find a hidden platform in a water pool after previous exposure to the setup, using only available external cues, is determined as a measure of spatial memory. Studies with pharmacologic or toxicologic agents or lesions are initiated when performance is stable; the water maze task is particularly sensitive to the effects of aging (Brandeis et al., 1991). Alternatively, one can study the effects of drugs or lesions upon the acquisition of this task. Drugs can be administered (or lesions produced) prior to training to assess their effects upon acquisition, or after acquisition in order to assess their effects upon performance. A water maze (Fig. 11.3.2) can easily be built or purchased by the investigator, so the cost for this equipment can be quite low. Using the maze is quite labor-intensive and requires that a tester be present, or nearby, throughout the task. This maze is typically used for rats, but it can be scaled down in size (by ~50%) for use with mice.

Materials

Rats
Pharmacologic or toxicologic agents (optional)
Water maze apparatus (Fig. 11.3.2)
Tracking system and software (Columbus Instruments, HVS Image, San Diego Instruments, or CPL Systems)

Set up apparatus and begin acquisition testing

1. Set up water maze (see Fig. 11.3.2).

   A water-tight pool, painted white, should be positioned in a room with various external cues that are visible to a rat swimming in the pool, e.g., a doorway, overhead lights and camera (if desired), and large simple designs on the walls. Make water opaque by adding powdered milk or nontoxic white paint to the water. The pool should be designed so that it can be easily drained on a regular basis.
2. Insert platform into one quadrant of the pool.
3. Place rat into water with its head pointed towards the side of pool.

   The starting position should be at a different, and randomized, location each day of testing, e.g., north, south, etc.

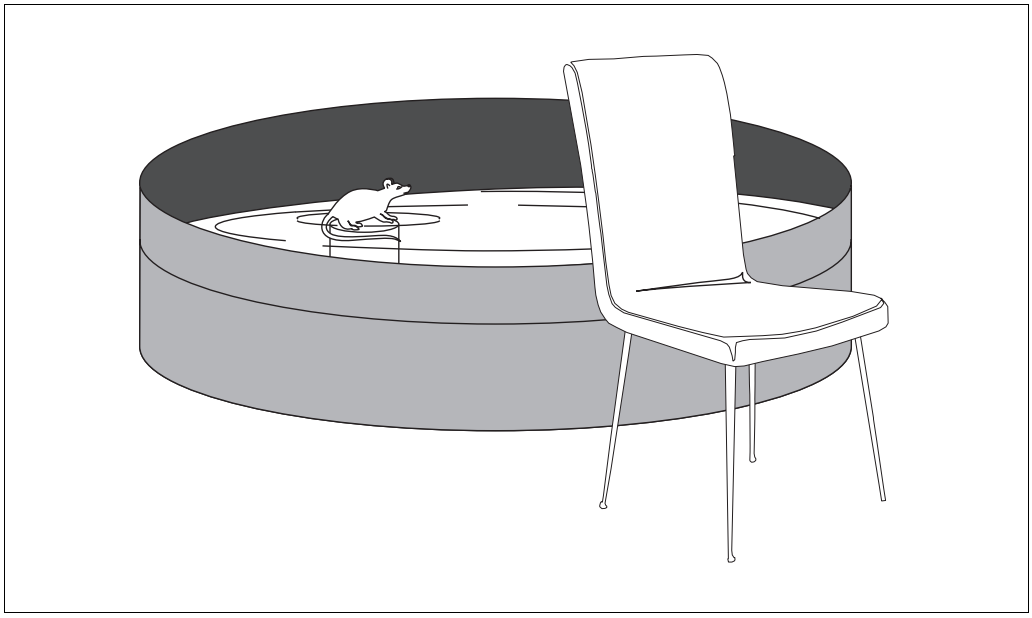

Figure 11.3.2 Morris water maze. The pool should be watertight, 200 cm in diameter and 75 cm deep, and filled with 50 cm water. The actual dimensions of the pool can be varied depending upon the space available to contain it and whether rats or mice are being tested (e.g., for mice, the pool need only be ~100 cm in diameter and 30 cm deep). The water is made opaque by adding nontoxic white paint or powdered milk. A 10-cm circular escape platform should be constructed of a water-resistant material and covered with material (e.g., cloth) that allows the animal to remain on the top when it is submerged. The platform should be made heavy enough to remain upright when submerged or may be attached to the bottom of the pool. The platform should be 48 to 49 cm in height so that it is submerged 1 to 2 cm below the surface. A chair can be positioned near the pool to allow the experimenter easy access and provide an additional cue for the animal. The water temperature should be maintained at ~20°C. It is useful to have an ample supply of towels nearby to dry animals between trials. Also, an incubator can be used to keep them warm between trials.

4. Record time (in seconds) it takes the rat to find the submerged platform. Guide rat to platform on first few trials if it requires >120 sec.

   A tracking camera, positioned ~200 cm above the center of the pool, can be used to quantify the distance swam on each trial and thereby determine swimming speed when combined with latency measurements. The tracking system can also display swim path and distance and provide additional information on search efficiency and exploration patterns during acquisition and probe trials. This equipment and associated computer software can be obtained from several commercial manufacturers.

5. Allow rat to remain on platform for 10 to 15 sec.

   This allows the experimenter time to return to an appropriate place at the side of the water pool in order to be ready for step 6.

6. Remove rat from pool. Wait 5 min.

7. Release rat into pool (from the same location) with platform in same location. Record time for rat to find platform.

8. Give each rat four trials on the first day.

Perform trials

9. On second day, insert platform in same location as on the first day.

10. Release rat with its head pointed towards the side of the water pool.

11. Record time it takes rat to find platform.

12. Give rat eight to ten trials per day with 5-min intertrial intervals for several days until performance is stable and latency to find the platform is low (<5 to 7 sec).
13. Perform data analysis. Performance is expressed as the average time it takes each rat to find the submerged platform. The data are best presented as a line drawing comparing the latency to find the platform for each group versus daily test sessions. Data from 2 or 4 days of testing can be averaged into blocks.
14. Begin studies with pharmacologic or toxicologic agents or lesions.

USE OF WATER MAZE TASK FOR SPATIAL PROBE TRIAL

ALTERNATE PROTOCOL 2

This alternate protocol should be performed after the acquisition phase of testing in Basic Protocol 2 has been completed. It is important that the rats know the location of the hidden platform before beginning this protocol. This knowledge is demonstrated by the rat swimming quickly and directly to the hidden platform. The spatial probe trial is used to test the rat's knowledge of the precise location of the platform. An accurate direction of the swimming behavior provides evidence that the rat has learned the spatial location of the platform relative to the available external cues (Sutherland et al., 1982). Although the spatial probe trial is typically performed only after performance has stabilized, some researchers perform a spatial probe trial at the end of each day of training throughout the acquisition phase, and average performance across trials.

1. Train rats in water maze (see Basic Protocol 2, steps 1 to 12).
2. Set up water pool without platform.
3. Release rat with its head pointed towards the side of the water pool.
4. Remove rat after 90 sec.
5. Record time rat spent in the quadrant that previously contained the platform and calculate as a percentage of total time in pool. If possible (i.e., if using a computer tracking system), also record the percentage of time spent in the other quadrants.
6. Perform data analysis. The data can be expressed as either:
   a. A histogram showing the average amount of time that the rats in each group spent exploring each quadrant of the pool (most typically), *or*
   b. The percentage of time the rat spent exploring the quadrant that had contained the platform in relation to the total time spent exploring the entire pool.

USE OF WATER MAZE TASK TO TEST WORKING MEMORY

ALTERNATE PROTOCOL 3

This alternate protocol can be performed after the acquisition phase of testing in Basic Protocol 2 has been completed. It is important that the rats have demonstrated that they know the location of the hidden platform before this next protocol is begun. This protocol has also been referred to as a "reversal test."

1. Train rats in water maze (see Basic Protocol 2, steps 1 to 12).
2. Release rat with its head pointed towards the side of the water pool.

   Start position should be at same location each day.
3. Record time it takes rat to find submerged platform. Allow rat to remain on platform for 10 sec. Remove rat from pool and place in holding cage for 15 sec.
4. Move submerged platform to new location.
5. Release rat from same location as in step 2.

6. Allow rat to swim for up to 120 sec. Record time it takes for rat to find platform.

   Guide rat to platform if necessary.

7. Allow rat to remain on platform for 10 sec. Remove rat from pool and place in holding cage for 15 sec.

8. Repeat steps 5 to 7 until rat swims directly and quickly to the platform. Record time on each attempt.

9. Repeat steps 4 to 8 once per day for 4 days, with the platform in a different quadrant of the pool each day.

   Latency to find the platform should decrease with each day of testing.

10. Perform data analysis. Performance is expressed as the average time it takes each rat to find the submerged platform at each new location. The data are best presented as multiple line drawings comparing the latency to find the platform for each group and for each location versus daily test sessions. Data from 2 or 4 days of testing can be averaged into blocks.

BASIC PROTOCOL 3

USE OF T MAZE TO TEST SPATIAL MEMORY

This protocol describes the use of the simple T maze (see Fig. 11.3.3) and food deprivation for the assessment of spatial working memory. The maze can easily be built by the investigator, and is much easier to construct than the radial arm maze (Fig. 11.3.1). Similar to the radial arm maze task, this task is quite labor-intensive for the investigator and requires that a tester be present throughout the time the animal is on the maze. This maze is typically used for rats, but it can be scaled down in size (by ~75%) for use with mice.

Materials

Rats
Pharmacologic or toxicologic agents (optional)
Food reward: e.g., 1-mg piece of normal chow, flavored (chocolate) or sweetened breakfast cereal, chocolate milk, or water
Split-stem T maze (Fig. 11.3.3), handmade or commercial (Coulbourn Instruments or Columbus Instruments), without hardware cloth partition, Plexiglas barrier, or curtain

Train rats

1. Weigh each rat daily throughout training and testing to monitor health and degree of food deprivation.

2. Restrict the food available to the rat so that its body weight attains 85% of that prior to training. During testing and training, allow rat to gain ~5 g per week on the restricted diet.

3. Allow rat to become comfortable with the experimenter (see Critical Parameters, discussion of rat handling).

4. Give one food reward in the home cage each day for a few days prior to training in order to acclimate the rat to the reward in a familiar environment.

   Liquid rewards are preferred if the rat will be given a drug (e.g., scopolamine) that might make swallowing dry food uncomfortable.

5. Set up the T maze without the hardware cloth partition, Plexiglas barrier, or curtain on the stem (see Fig. 11.3.3). Spread food rewards around the entire maze to encourage exploration.

   Environmental conditions and materials can be similar to those described for the radial arm maze (Basic Protocol 1).

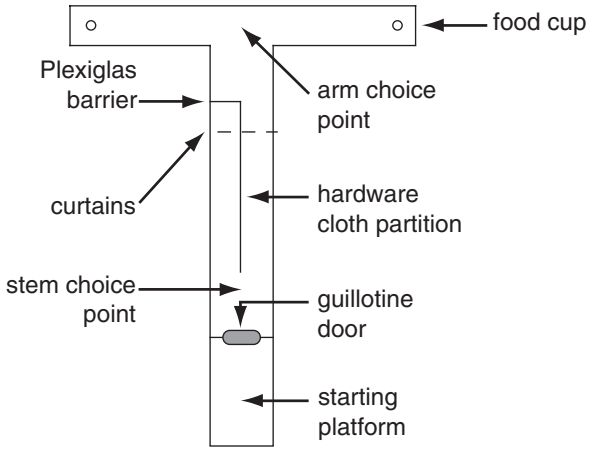

Figure 11.3.3 The split-stem T maze. For rats, the maze consists of a wooden T-shaped platform with a 87 × 20–cm stem and 40 × 10–cm arms at the end. Black Plexiglas can also be used, and is easier to clean. The entire perimeter of the platform has 5-cm walls to discourage the rat from jumping to the floor. Located 1 cm from the distal end of each arm is a food cup (1 cm wide and 1.5 cm deep). The starting platform is 25 cm long and is separated from the stem by a guillotine door (11 cm high and 6 cm wide), mounted in a frame (22 cm high and 18 cm wide). The stem is divided lengthwise into two halves by a hardware cloth partition (i.e., a taut cloth screen or some other opaque partition, 10 cm high and 20 cm long), that starts 20 cm from the guillotine door. Near the end of the partition proximal to the arms, and extending across both sides of the stem, is a white opaque cloth curtain (14 cm high) suspended in a frame that is perpendicular to the stem. A clear Plexiglas barrier (14 cm high and 8 cm wide, suspended in a frame that is perpendicular to the stem) is placed behind one of the curtains to block access to the arms from that side of the stem. A large cache of food reward is suspended under the ends of the arms, under both food cups to prevent the use of olfactory cues. A rich variety of local and distant cues should surround the maze (e.g., large objects that the animal can see from the maze). These can be removed as required by the particular demands of the experiment. The room should not be too bright, as this tends to frighten the animal. To convert this to a standard T maze (see Basic Protocol 3 and Alternate Protocol 5), the hardware cloth partition, Plexiglas barrier, and curtain can be removed from the stem.

6. Place a well-handled pair of rats (particularly cagemates) on the maze at the same time and allow them to explore.

   Having two rats present on the maze will make the rats more comfortable during this initial phase of exploration and will reduce the time it takes for each rat to acclimate to the maze.

   The acclimation period should require only 1 or 2 days. Consumed food rewards should be replaced on the maze during exploration.

7. Repeat once a day for two more days, placing food only on the arms of the maze one day, then only at the ends of the arms on the following day.

8. Place one rat on the maze with food only in the food cup at the end of the arms. Begin testing when the rat is comfortable being picked up by the experimenter and, when placed alone on the maze, explores without hesitation and without excessive defecation or urination.

   A typical rat will be ready for testing (i.e., sufficiently food-restricted and acclimated to the maze) within 7 to 10 days. Each rat should be run alone on the maze once a day every day during training and testing.

Test rats

9. Place a food reward at the end of an open arm.

10. Place a small barrier (i.e., a small block of wood or similar object) on the maze to prevent the rat from entering the other arm.
11. Place the rat on the stem behind the closed guillotine door.
12. Raise the door and allow the rat to enter the stem of the maze. Close the guillotine door quietly (and not on the rat's tail).

    This is called the forced trial. On each day, the open, baited arm for the forced trial should be randomly varied.

13. Allow rat to enter the open arm and eat the food reward. Return the rat to the starting position behind the closed guillotine door. Do not allow the rat to explore the maze.

    At this time the rat must be aware that he has consumed the food at only one location for this trial.

14. Remove the barrier to the arm and place a food reward on the arm not previously rewarded.
15. Confine rat to the starting position for a set time (from 0 sec to many min; 5 sec is ideal to begin). Use the same time for each repetition.

    Longer waiting periods make the task more difficult to solve, i.e., increasing the length of time that the rat must remember which arm it last entered.

16. Raise the guillotine door and allow the rat to enter the stem and either arm of the maze. Close the guillotine door. An arm entry can be defined as the rat either having all four feet on an arm or investigating food cup; this must be determined by the experimenter prior to testing.

    This is called a choice trial.

17. Allow rat to eat the reward and return it to the starting platform. If the rat chooses the unbaited arm, allow it to reach and momentarily explore the empty food cup and then return it to the starting platform.
18. Repeat steps 15 to 17 from one to nine times. For all subsequent choice trials, place food on the side of the maze not entered by the rat on the previous trial. Allow the rat to choose between the two arms. If the rat enters the arm that contains food, record a correct choice. If the rat enters the unbaited arm, record an error and place the rat back at the start position without a food reward.

    The food reward remains in its location until it is found and eaten—i.e., the food pellet should not be moved if it is not found. A rat can receive the maximum amount of reinforcement for choosing correctly on the first choice trial and then alternating its responses between the two arms on subsequent choice trials.

19. Record the following data:

    Number of correct entries into baited arms
    Number of reentries into unbaited arms.

    Repeated visitation to an unbaited arm is considered a working memory error. Normal healthy young rats will perform this task almost perfectly every time. A healthy, happy, and motivated rat should learn this task within 5 days—i.e., working memory errors should be <15%.

20. Begin studies of pharmacologic or toxicologic agents or lesions when performance is stable and choice accuracy is high.

    Alternatively, the effects of drugs or lesions on the acquisition of this task can be studied. Drugs can be administered (or lesions produced) prior to training to assess their effects upon acquisition, or after acquisition in order to assess their effects upon performance.

21. Express performance as the percentage of correct choices made in each test session. Present data as either:

    a. A histogram showing the percent correct choices averaged across a given test period for controls, brain-lesioned, or drug-treated groups, *or*
    b. A line drawing comparing percent correct choices for each group versus daily test sessions.

    Data from daily test sessions can also be averaged into 2-day blocks.

USE OF T MAZE TO TEST WORKING VERSUS REFERENCE MEMORY

ALTERNATE PROTOCOL 4

This protocol, like Alternate Protocol 1, allows the dissociation of working and reference types of memory, and is achieved by changing the external cues (i.e., by moving the maze to a new location), and by using an additional partition and barrier in the T maze stem during the testing phase (Fig. 11.3.3). In this case, the rat is required to associate a specific set of external cues with the memory of which side of the stem is blocked. Otherwise, the test is performed as in Basic Protocol 3.

Additional Materials *(also see Basic Protocol 3)*

Hardware cloth partition, Plexiglas barrier, and curtain for split-stem T maze (Fig. 11.3.3)

1. Train rats in the T maze (see Basic Protocol 3, steps 1 to 8). To vary the demand upon reference memory, move the maze to a different location (or construct an additional maze and place it in a different location).
2. Place the hardware cloth partition, Plexiglas barrier, and curtain on the T maze (Fig. 11.3.3).
3. Begin the forced trial (see Basic Protocol 3, steps 9 to 12). If the rat enters the side of the stem that is blocked by the Plexiglas barrier, allow the rat to make a correction and to enter the open side of the stem.
4. Complete forced trial (see Basic Protocol 3, steps 13 to 14) and perform repeated choice trials (steps 15 to 18).
5. Record the following:

    Number of correct entries into open side of stem
    Number of correct entries into baited arms
    Number of entries into blocked side of stem (reference memory errors)
    Number of reentries into unbaited arms (working memory errors).

    Normal healthy young rats will perform this task almost perfectly every time. A healthy, happy, and motivated rat should learn this version of the task within 10 days—i.e., working and reference memory errors should be <15%.

6. Begin pharmacologic, toxicologic, or lesion analyses (see Basic Protocol 3, step 20).
7. Express performance as the percentage of correct stem and arm choices made in each test session. Present stem- and arm-choice results as separate line drawings comparing percent correct choices for the controls, brain-lesioned, or drug-treated groups, versus each daily test session (for example see Hepler et al., 1985).

    Data from daily test sessions can also be averaged into 2-day blocks.

ALTERNATE PROTOCOL 5

SPONTANEOUS ALTERNATION ON A T MAZE

Sustained performance in this task is based upon the assumption that rats will explore their environment in a repeating and alternating fashion in order to optimize the amount of area investigated, even when exploration is not rewarded by food. Normal alternation performance in this task is consistent with an intact working memory ability. Pharmacologic or toxicologic challenges or discrete lesions are typically made prior to testing a rat on the alternation task.

1. Set up T maze without the hardware cloth partition, Plexiglas barrier, or curtain on the stem (Fig. 11.3.3).
2. Place a well-handled rat on the T maze starting platform.

   Because these rats are only motivated by their desire to explore the maze (i.e., they are not food-deprived), they must be completely comfortable with the experimenter and not fearful of their environment.
3. Raise the guillotine door and allow the rat to walk down the stem and choose an arm.

   A rat has made its choice when it has placed all four of its feet onto one arm. Some rats will tentatively place a foot onto each arm before making a final decision.
4. Return the rat to the starting platform for a set time (from 0 sec to many min; 5 sec is ideal to begin).
5. Repeat steps 3 and 4 nine times.
6. Record the number of entries into each arm.

   Control rats should alternate their arm choices within each test session.
7. Express results as the number of alternations divided by the total number of choices made per session. Present data as either:
   a. A histogram showing the percent correct choices averaged across a given number of tests for controls, brain-lesioned, or drug-treated groups, *or*
   b. A line drawing comparing percent alternations for each group versus each daily test session.

   Data from daily test sessions can also be averaged into 2-day blocks.

COMMENTARY

Background Information

For rats and mice, spatially organized tests are typically learned very quickly and performed very accurately. Consequently, testing these animals in a spatial task—e.g., the radial arm maze or T maze—has become very popular.

Rats can use any of three possible strategies to achieve accurate performance in spatial maze tasks. The first is a place strategy in which the rat uses remote sensory cues to navigate around the maze and obtain a reward. The second is a cue strategy in which local cues are used to help the subject find the reward. The third is a response strategy in which the rat uses a specific sequence of motor acts that are essentially independent of the available sensory cues. These strategies are not necessarily independent of one another: in order to solve the task, the rat may use them in combination. In addition, different components of these strategies may dominate during different stages of training. Therefore, in the T maze task, the rewarded arm can be distinguished from the unbaited arm by its spatial location, by local cues associated with the maze itself, or by the direction in which the rat turns to approach the goal arm.

Good performance on the radial arm maze (see Basic Protocol 1) and T maze (see Basic Protocol 3) requires intact spatial memory abilities. Normal performance is sensitive to the effects of damage to the hippocampus, to the effects of normal aging, and to a variety of pharmacologic or toxicologic agents. Performance of the Morris water maze task (see Basic Protocol 2) also requires intact spatial memory abilities and is particularly sensitive to the effects of aging. The major advantage of the

Morris water task (and of the spontaneous alternation task; see Alternate Protocol 5) over the radial arm and T maze tasks is that the rats do not need to be food- or water-deprived; in the Morris water task the rats are quite motivated to escape from the water. The Morris water task is also free from errors of omission or abortive choices—i.e., the rat makes an attempt to find the platform on every trial.

Each behavioral task must be evaluated in terms of the types of cognitive functions required to perform it. Each task is a tool that allows the researcher to achieve a specific goal, i.e., to determine the consequences of specific manipulations of the brain. These manipulations usually fall into one of four categories: (1) stimulation of a single brain region by drugs or small electrical current, (2) impairment of the normal function of a brain region by production of a lesion or administration of appropriate pharmacologic or toxicologic agents, (3) recording of activity from a brain region while the animal is performing a specific behavioral task, or (4) mutation of a gene expressed in the brain. All the tasks described in this unit can be used in each of these four experimental conditions.

Radial arm maze task

The radial arm maze task was introduced and popularized in its present form by Olton and co-workers (Olton and Samuelson, 1976). The task is a logical extension of the multiple, simultaneous choice tasks originally described by Hamilton (1911) and Tolman et al. (1946); it has been used to measure the effects of various brain manipulations upon specific aspects of memory, such as spatial working and reference memory, and can be adapted for use with rats, mice, and pigeons (Bond et al., 1981; Levy et al., 1983; Wenk et al., 1986). The large number of sequential locations that the rat can visit to obtain a reward makes the task ideal for investigating the effects of drugs or lesions upon serial order memory—i.e., whether locations visited first or last are remembered better (Kesner and Novak, 1982). The task is sensitive to the effects of brain lesions (Becker et al., 1980) and to numerous drugs (for review see Levin, 1988) that either impair or enhance performance, including inebriants such as ethanol (Devenport et al., 1983), endogenous neuropeptides such as vasopressin (Buresova and Skopkova, 1982), amnestic drugs such as scopolamine (Stevens, 1981; Watts et al., 1981; Okaichi and Jarrard, 1982), and neurotoxins such as trimethyltin (Walsh et al., 1982).

Water maze task

The water maze task was designed to address theoretical controversies that arose from using the radial arm maze task (Brandeis et al., 1989): i.e., the concept that memories about spatial information are handled by the brain quite differently than information relating to other forms of learning. The water maze task is not a better or more sensitive task than the radial arm maze task, it simply asks many of the same questions of the animal under different circumstances. Differences between the two tasks include the nature of the locomotion, walking versus swimming; the nature of the motivation, food deprivation versus avoidance of drowning; the location of available cues for finding the reward, local and distant cues versus distant cues only; and the visibility of the location of the reward, a visible food cup on the radial arm maze versus a submerged platform in the water maze task. Sometimes asking the same question in a different way has allowed researchers to discover subtle differences in the contributions of different brain regions or the effects of specific lesions or drugs. The water maze task was introduced by Morris (1981) and colleagues as a spatial localization or navigation task. The task has been extensively used to study the neurobiological mechanisms that underlie spatial learning and memory, age-associated changes in spatial navigation (Gage et al., 1984; Rapp et al., 1987; Pitsikas et al., 1990), and the ability of psychopharmacological agents (Sutherland et al., 1982; Hagan et al., 1983, 1986; McNaughton and Morris, 1987; Brandeis et al., 1991; McNamara and Skelton, 1991), lesions (Morris et al., 1982; Kolb et al., 1983), or gene mutations (Tsien et al., 1996; Crawley et al., 1997) to influence specific cognitive processes.

T maze task

The T maze task has been used to measure the effects of various brain manipulations on specific aspects of spatial memory. It can be adapted for use with rats, mice, gerbils, pigs, sheep, goats, turtles, and pigeons (Schnurr, 1971; Wenk et al., 1987; Avigan and Powers, 1995; Hosoi et al., 1995; Mendl et al., 1997). The task is sensitive to the effects of various brain lesions (Durantou et al., 1989; Aggleton et al., 1995, 1996; Beracochea and Jaffard, 1995; Sanchez-Santed et al., 1997), particularly in the hippocampus (White, 1974), and to numerous drugs or toxins that either enhance or impair spatial memory (Wenk et al., 1989;

Barone et al., 1995; Givens and Olton, 1995; Levin et al., 1996).

Spontaneous alternation behavior is a form of sensory-independent motor behaviors. Tolman (1925) first reported that rats would avoid repeated entry into the arms of a maze. Spontaneous alternation behavior was first defined in a T maze when a rat would go down one arm of a maze first and then go down the other arm on the next trial (Dennis, 1939). It has been proposed that the rat generates a sense of internal inhibition to the first arm after it has explored it and is reluctant to return to that arm on a subsequent choice. Choosing the opposite arm increases the animal's opportunity to find food. Responding in this alternating fashion can, over time and in a complicated environment, substantially increase the amount of food obtained and reduce the amount of time and energy expended (not to mention reducing the time exposed to predators). An alternation strategy would thus confer an adaptive advantage to solving the problem of finding food.

Critical Parameters

Essence of rat handling

Remain relaxed. The rat can sense your nervousness. Be consistent with your treatment and handling. Use the rat's native intelligence and your skills to provide him with the specific knowledge that he needs to perform the task. Take the rat's point of view. Handle the rat the way that you would like King Kong to handle you! Go slowly and be gentle. Do not approach the rat from behind and above; this is how a predator would attack the rat. Do not grab the rat tightly around the abdomen, as its internal organs have very little protection. Support the rat from underneath its body and hold it against yours. Run rats on the maze at the same time every day; rats are like people in that they grow accustomed to a particular schedule. Allow the rat to gain ~5 g each week during testing and training, even though it is food-restricted. Pay attention to how well groomed the animal is; a well-groomed rat is a healthy rat. If the rat is undernourished, it will feel cold to the touch. Sick rats do not provide useful data and may be in danger of dying. Find out why the rat is sick and correct the problem.

Radial arm maze task

Rats will use whatever sensory cues are available to solve the radial arm maze task and obtain a reward. Removing these cues will make performance difficult and impair choice accuracy. Reducing the salience of stimuli around the maze—e.g., completely enclosing the arms or placing the maze in a homogeneous environment—can greatly influence performance. This may force the rat to use other, more egocentric, information to solve the task, such as a sequence of left turns after every arm choice, or to depend upon intramaze cues, such as odor trails.

The guillotine doors are a critical feature of the maze in that they confine the rat to the central platform area between choices. Otherwise, the rat may develop a biased response pattern, which makes interpretation of the performance difficult: i.e., it becomes impossible to determine whether the rat remembered the correct choice or a response habit. For example, without temporary confinement between each arm choice, the rat could successfully solve this task by simply always turning right after each choice and entering the first arm away from the previously chosen one. This simple strategy does not require an accurate knowledge of the spatial environment or memory for a specific location. Unless the experimenter is primarily interested in studying response patterns, it is best to have the rat confined to the central platform prior to making each arm choice.

The number of arms the maze contains can vary depending upon the goals of the experimenter. For example, having fewer arms requires that the animal remember fewer visited places on each trial. Increasing the number of arms increases the mnemonic demands of the task by increasing the list of spatial locations in memory. In addition, an increased number of arms introduces considerably more proactive interference, i.e., interference of previous learning on current memory. Most researchers choose to use eight arms in order to minimize proactive interference (if that is desired) or to shorten the length of time it takes to test each rat. Numerous variations have been introduced in order to automate the task, reduce testing time, or provide alternative interpretations of the psychological processes that underlie normal performance (Bond et al., 1981; Okaichi and Jarrard, 1982).

Most rats are quite fearful of exploring the arms during the initial training periods. Sometimes it is better to have somewhat taller sides (6 to 8 cm) along the edges of the arms to offer more support to the rat. A taller barrier may be attached along the edges of the arms near the central platform. This prevents the rat from jumping from one arm to another and forces the rat into the central platform area between choices. The guillotine doors should be at-

tached by strings to an overhead pulley system that allows all doors, or individual doors, to be raised and lowered by one experimenter from a single location. Alternatively, individual electronic mechanisms could also be installed at a greater cost.

The food reward is typically a small piece (10 mg) of normal chow or a flavored (chocolate is a favorite) or sweetened breakfast cereal. Liquid rewards, such as chocolate milk or water, can also be used. Liquid rewards are preferred if the rat will be given a drug, such as scopolamine, that might make swallowing dry food uncomfortable.

Water maze task

Rats will use whatever sensory cues are available to solve this task and escape from the water. Removing external cues around the pool will make finding the submerged platform more difficult and increase the latency to escape. Reducing the salience of stimuli around the pool may force the rat to use other, more egocentric, information to solve the task. Rats will use a search strategy to find the platform when it is moved. They will swim close to the wall for a few laps, then move further away and continue swimming in concentric circles until they bump into the platform. Latency to find the platform and swimming distance will then decrease quickly thereafter. The greatest advantage of this task over food-motivated tasks is that most rats are more highly motivated to escape from the water. In addition, food restriction is unnecessary, which is a great advantage when testing aged animals, to which such restriction is more stressful.

Performance in the water maze task can be influenced by many factors that should be considered carefully when comparing the results of one study with another. For example, the sex and strain of the rats, the dimensions of the pool and temperature of the water, and the particular training schedule can all affect performance. One should also take into account factors that affect swimming speeds, which include body weight, muscle development, and age. See Brandeis et al. (1989) for a thorough discussion of the role of these factors in performance of the Morris water maze task.

Finally, because older rats or mice are frequently tested in the water maze, it is important to be sure that they can swim adequately and have sufficient visual acuity to use distant cues. To test this, place rat into the pool and allow it to swim to a platform that is supported above the water level. To assist rat, suspend a large visible cue above the platform. If the rat can swim directly to the visible platform without difficulty, it is ready to begin testing using the protocols outlined in this unit.

T maze task

In normal animals, choice accuracy in the T maze task varies with the duration of the delay interval introduced between choices on the maze. Choice accuracy is very good with short intervals (e.g., 5 sec), and approaches random chance performance with extremely long intervals (e.g., >1 hour). Choice accuracy is also influenced by the number of choice trials given within each testing session. When only a single choice trial follows the forced trial, choice accuracy is usually very good. When multiple choice trials are given following the forced trial, performance accuracy worsens as the number of choice trials increases. The memory of choices made earlier in the test session interferes with remembering the most recent choice. This is called proactive interference. The task can also be made more difficult by reducing the number of salient stimuli near the maze (as for the Morris water maze and radial arm maze tasks; see discussion above).

The guillotine door on the stem is a critical feature of the maze, which serves to confine the rat to the starting platform area for a predetermined delay period between choices. The guillotine door also prevents the rat from exploring the maze between choice trials. It is therefore important to quickly return the rat to the starting platform between choice trials so that the rat does not explore the opposite arm of the maze.

Troubleshooting

Radial maze and T maze tasks

The major problems associated with testing rats in open mazes are usually related to two competing factors for the rat: its fear of the maze (or experimenter) versus its motivation to explore and find the food that it knows is on the maze. Excessive fear will prevent the rat from performing. It will usually remain frozen in one place on the maze and not explore. In addition, if it is frightened it will usually defecate and urinate on the maze and squeal when being picked up. If the rat is not making choices on the maze it is impossible to know whether its mnemonic abilities are normal or impaired. Fear can be overcome by considering some of the issues presented in the discussion of rat handling above (see Critical Parameters). The most important thing the experimenter can do

is simply handle the animal more often. Also, higher barriers can be installed along the arms of the maze to provide the rat a better sense of security from falling.

A lack of motivation will produce similar results—i.e., the rat will make little or no attempt to explore the maze and find food. Motivation can be increased by a slightly greater restriction of food intake. The rat's weight and general health must be carefully monitored during food restriction. Usually the rat's weight should not drop below 80% of its free-feeding weight. For most rats, it is only necessary to reduce their weight by 15%. If the rat is aware that a safe food source exists on the maze, it will usually explore the maze to find it.

Water maze task

There are only two problems that are typically associated with this task. First, immersion of the animal into the water may cause significant stress and subsequent endocrinological changes that may interfere with the purpose of the study. These problems are usually resolved with continued exposure to the pool. However, for aged animals this stress can be sufficient to induce cardiovascular system collapse, leading to death or stroke. Second, the method by which the water is made opaque can produce problems. If powdered milk is added to the water, the pool must be drained regularly (e.g., daily) to avoid bacterial contamination and odor. If powdered white paint is used, care must be taken to ensure that it is nontoxic to the animals, which may frequently ingest small quantities of water while performing the task.

Anticipated Results and Time Considerations

Radial arm maze task

A healthy, happy, and motivated rat should learn this task within 15 days: i.e., working and reference memory errors should be <15%. This assumes that the rat is actively making choices and eating the food rewards on the maze. The rat should run quickly down the arms to retrieve the food reward and return to the central platform immediately after eating the reward. During the confinement period the rat will usually wander around the central area and quickly choose an unvisited arm as soon as the guillotine doors are raised. After a control rat has learned the task, a single test session—i.e., eight correct arm choices—should not require more than 5 to 10 min to complete. Rats given drugs or lesions may require two to three times longer to complete the test session. A healthy group of rats, including experimental and control groups, should be able to be trained and tested in Basic Protocol 1 and Alternate Protocol 1 in ~4 weeks. This estimate assumes that all rats are tested once per day.

Water maze task

Control rats may take ~30 to 60 sec to find the platform on the first day of testing. Latency should decrease significantly with subsequent trials to ~5 sec. On the probe test, the rats should spend a greater percentage of time exploring the quadrant that previously contained the platform than in the other quadrants. On both the reversal and working memory tests, the rats should first explore the quadrant that previously contained the platform and then inadvertently find the new location of the platform. On subsequent trials (usually less than five), their latency to find the platform will decrease significantly. All rats should be trained in the Basic Protocol 2 portion of this task within 1 week. The spatial probe trial (Alternate Protocol 2) can be completed in 1 day, and the reversal test (Alternate Protocol 3) within 5 days. Lesioned rats may require a few additional days of training in Basic Protocol 2 in order to reach an asymptotic level of performance. Drugs can be given each day prior to testing in this protocol; however, this will also extend the amount of time required to reach asymptotic performance. Drug administration will also prolong the number of days spent testing in the spatial probe and reversal trials; the number of days depends upon the number of doses to be tested. It is important to have drug-free and saline injection days interspersed between the drug testing days. Obviously, this will prolong the time required to complete this task.

T maze task

A healthy, happy, and motivated rat should perform this task well within 7 days: i.e., the rat should be alternating between arms at least 85% of the time. This assumes that the rat is actively making choices and eating the food rewards on the maze. The rat should run quickly down the arms to retrieve the food reward. After the confinement period, the rat should quickly choose an arm as soon as the guillotine door is raised. Food deprivation and acclimation to the maze take ~10 days. After a control rat has learned the task, a single test session should not require more than 15 min to complete. Rats given drugs or lesions may require up to twice as long to complete a session.

Advanced Behavioral Testing in Rodents: Assessment of Cognitive Function in Animals

In the risk assessment of a neurotoxic chemical, it may be necessary to characterize its effects on cognitive function in rodents. *Cognitive function* refers generally to the information-processing capacity of an animal and subsumes the more discrete processes of learning, memory, attention, and performance. None of these processes is directly observable, and this fact has two important consequences. First, the existence and characteristics of these processes must be inferred from the behavior of a test subject in a specified test environment. Second, other possible sources of behavior change must be ruled out in order to attribute the behavioral effect of a chemical to a particular process. The experimental analysis of behavior provides the tools to quantify behavior; by proper arrangement of the contingencies of response and reinforcement, and by application of appropriate control procedures, the processes of interest can be specifically assessed.

Learning includes the acquisition or utilization of new behavior to solve a new problem, and is quantified by an appropriate change in behavior over time. Because the reinforcement contingencies that govern behavior change frequently in every day life, and because adaptive responses to these changes challenge the information processing capacities of animals, quantifying the behavioral transitions that occur when environmental conditions change can yield powerful techniques for assessing this cognitive function. Protocols for two procedures, acquisition of reference memory for spatial location (Morris water maze) and acquisition of strategy and use of spatial working memory (radial maze) are presented in *UNIT 11.3*. Two others are presented here: autoshaping a lever-press response (see Basic Protocol 1) and repeated acquisition in the radial maze (see Basic Protocol 2).

Memory implies the control of behavior by antecedent events (stimuli no longer present) and has been subdivided into many types in human psychology. A practical dichotomy distinguishes between *reference memory* (memory for information that remains constant across episodes, e.g., what kind of car you drive) and *working memory* (memory for information that changes across episodes, e.g., where you parked your car today). Of the two, working memory is much more labile and more likely to be impaired by intoxication, aging, and disease. Assessment of working memory can thus provide important information regarding the potential cognitive effects of a neurotoxic agent. Many procedures have been devised for assessing memory, including the radial maze (Fig. 11.3.1) and Morris water maze (Fig. 11.3.2), which are used for assessing spatial working and/or reference memory. This unit provides assessments of working memory in the operant environment with delayed matching to position (see Basic Protocol 3) and of reference memory with two-light visual discrimination (see Support Protocol).

Attention refers to a constellation of hypothetical processes by which the nervous system apprehends and organizes sensory input and generates coordinated behavior. As with memory, many varieties of attention have been described in humans, including selective and sustained attention. Although it has been a subject of psychological investigation since William James' seminal work in the late 1800s, the rigorous assessment of attention in animals has begun only recently. Because many deficits in learning and memory may arise from impaired attending to relevant events, it is important to probe for attentional dysfunction as a primary response to chemical intoxication. Visual signal detection (see Basic Protocol 4) is presented here for this purpose.

Performance refers to the pattern(s) of behavior engendered by specific environmental contingencies, usually described in terms of operant *schedules of reinforcement*. The most

Contributed by Philip J. Bushnell
Current Protocols in Toxicology (1999) 11.4.1-11.4.34

common schedules involve ratios (e.g., ten responses yields a food pellet) or intervals (e.g., the first response after 30 sec yields food). These contingencies yield characteristic temporal patterns of behavior that are consistent across a very wide variety of animal species. These schedules may also be combined in various ways: for example, a multiple schedule presents two or more simple schedules sequentially in a test session, with each schedule identified to the subject by a unique stimulus condition. Operant schedules are used primarily to assess performance baselines (i.e., does a chemical interfere with the expression of the behavior pattern engendered by that schedule) without attribution to any particular cognitive process. These schedules also provide powerful tools for the manipulation of behavior for application in other contexts (e.g., the acquisition of a fixed-interval schedule may be used to assess learning). One common performance baseline, the multiple fixed-interval/fixed-ratio (MULT FI/FR) schedule, is presented here (see Basic Protocol 5).

STRATEGIC PLANNING

Assessments of cognitive function are time consuming because they involve training animals to perform complex tasks under carefully controlled conditions. The benefits from this effort include the ability to specify the cognitive process(es) assessed by the procedure, to quantify the effect(s) of a chemical, and to document the time course of onset and recovery from intoxication. Although a good cognitive test will reduce the possibility that differences in test performance result from sensory or motor dysfunction, one should keep in mind that neurotoxic chemicals are more likely than drugs to exert multiple effects on the nervous system, and ancillary tests for noncognitive sources of altered behavior (e.g., sensory dysfunction or motor impairment) may also be necessary.

Generally, tests of cognitive function have not been applied during initial screening of novel compounds with unknown toxicity and mode of action, but are more likely be used to characterize the hazard of a compound in terms of dose-effect or dose-response relationships. In this case, some information about the neural substrate for the toxicity of a chemical should be available, and reasonably specific hypotheses about its potential effects may be generated. These hypotheses should enable one to specify, before training begins, the endpoints (i.e., specific measurements of behavior) that will constitute the critical dependent variables of the experiment. These measurements may be obtained during acquisition of a task, during parametric manipulations after the animals have reached asymptotic performance levels, or during challenges with psychoactive drugs.

This variety of endpoints is available from procedures that yield a trained animal whose behavior can be measured repeatedly. This “baseline approach” allows one to document the time course of onset, duration, and recovery from intoxication by monitoring the performance of the animal in daily tests before and after administration of the toxicant. It also permits the use of powerful within-subject statistical tests, because each animal can serve as its own control, defined by its pretreatment baseline performance.

Alternatively, the stages of training and/or criterion performance can be used to assess the effects of prior treatment from, for example, prenatal exposure to a neurotoxic agent. Tests of differences in cognitive function can then be made across groups of animals trained together identically, as long as criteria for acquisition are defined prior to training, and training is continued until each criterion is reached. Failure to reach criterion by a treated group at any stage of training, or retarded acquisition of the criterion, will indicate a learning deficit.

The number of animals required per group for an experiment will depend upon the consistency with which behavior can be controlled by the procedure, the consistency of the effect of the chemical of interest, and the magnitude of the expected effect. To

demonstrate the properties of a conditioned behavior and the capacity of an animal to perform a task, two or even one animal may be sufficient. For toxicology studies, sample sizes of eight rats per condition are generally sufficient for assessing the effects of chemicals on behaviors that have been conditioned to a baseline, including most of the protocols described here. More animals will be required for autoshaping, which involves acquisition of a new response (pressing a lever) for food. This is because of the weak response-reinforcer relationship that is characteristic of autoshaping and the consequent high variability in the number of trials necessary to elicit the response.

Animals of either sex may be conditioned using the methods described here. When it is possible to do so, including both sexes in an experiment can provide important information regarding sex differences that may emerge from close analysis of the results. For example, compared to males, female rats tend to freeze less in mazes, to acquire autoshaping responses more slowly, and to perform some signal-detection tasks less accurately. In addition, gender-specific effects of chemicals may arise (e.g., with endocrine-disrupting chemicals such as the polychlorinated biphenyls), which cannot be determined without assessment of the behavior of both sexes.

ASSESSMENT OF LEARNING: AUTOSHAPING THE LEVER-PRESS RESPONSE

BASIC PROTOCOL 1

Autoshaping refers to a procedure by which a subject is automatically shaped (i.e., "autoshaped") to a emit a criterion response to a specified manipulandum. This protocol describes a method to train a rat to press a retractable lever for food. It thereby satisfies two needs: providing a systematic, objective means to quantify acquisition of the lever-press as an operant response, and preparing the rat for learning and performing other operant tasks. With this rapid method, useful data regarding learning can be obtained in just a few days of training.

Materials

Subject rats
Precision food pellets: 45 mg for male rats, 37 mg for females (BioServ or PJ Noyes)

Operant conditioning chamber (Fig. 11.4.1; e.g., Coulbourn Instruments, MED Associates, CeNeS, or TSE Systems) including:
- Incandescent house light (~0.1 W)
- Loudspeaker for white noise
- Food cup that can be lighted from within
- Cue light: LED or incandescent bulb behind a clear lens (if using an incandescent bulb, use a glass jewel dome in front of the bulb rather than plastic, as it cannot be gnawed down by the animal)
- Retractable response lever

Pellet dispenser
Computer system and interface to control test environments and stimuli and to collect response data (see Commentary)

Set up equipment

1. Set up one or more standard operant conditioning chambers as shown in Figure 11.4.1.
2. In each chamber, place an incandescent house light (~0.1 W) and a loudspeaker at the top of the panel. Place a food cup in the center of the front wall with the lower edge of its opening positioned 1 to 2 cm above the floor of the chamber.

   Use a food cup that can be lit from within and can detect "nosepokes" (i.e., insertion of the rat's nose or paws into the cup) by means, for example, of a photobeam or a hinged door and microswitch.

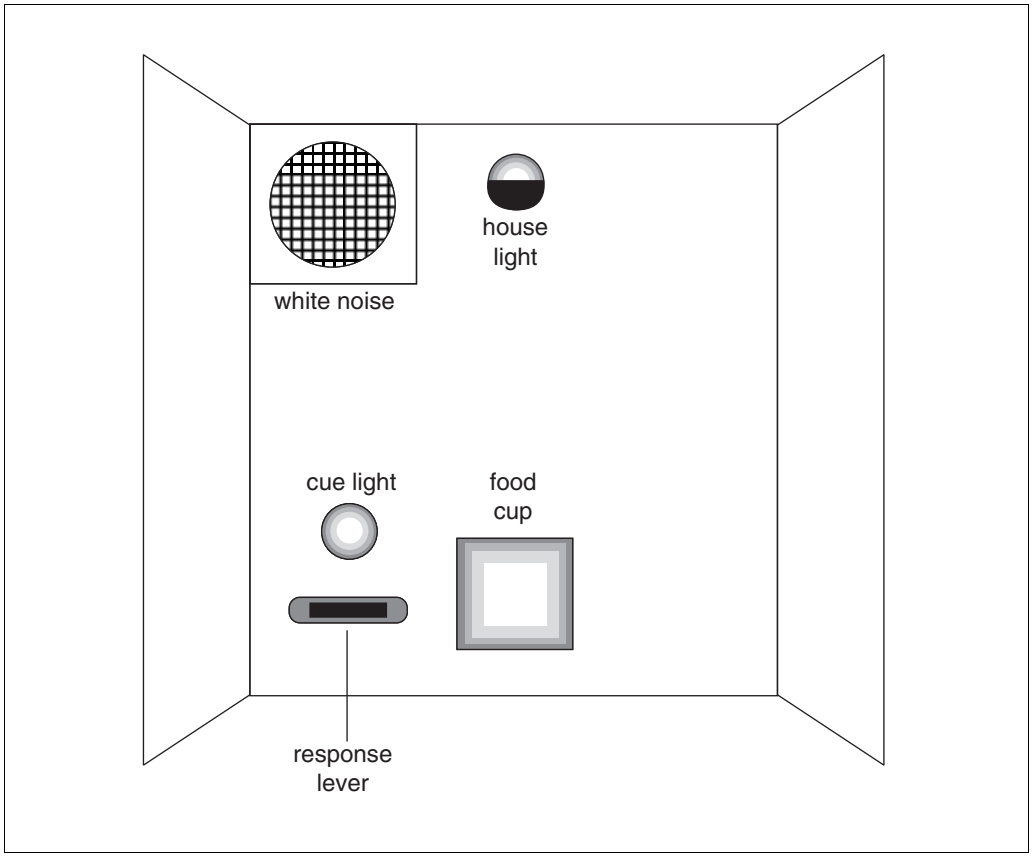

Figure 11.4.1 Configuration of an operant test chamber for autoshaping and multiple fixed-interval/fixed-ratio responding. Only the front panel of the chamber is shown. The response lever must be retractable for autoshaping but need not be for free operant studies. White noise is produced through a loudspeaker. The house light has a shade on its lower side, thus illuminating the chamber by reflecting light from the ceiling. The food cup should be illuminable from within, to indicate the presence of food.

3. Connect a pellet dispenser for delivering precision food pellets (45 mg for male rats, 37 mg for females) to the back of the food cup with clear plastic tubing. Install a retractable response lever to one side of the food cup, and a cue light immediately above the lever.

   If two or more chambers are to be used, it is good practice to set up half the chambers with the cue light and lever on the right side of the food cup and the other half with the cue light and lever on the left side of the food cup.

   In general, it helps to generate a low background level (~65 dB) of white noise through the loudspeaker or with a ventilation fan. In addition, one should provide unique stimulus conditions for the test session (e.g., illumination of the house light), the availability of food (e.g., brief illumination of the food cup or sounding of a quiet but audible tone), and for incorrect responding (e.g., a short period of darkness or an appropriate auditory cue).

Perform preliminary training

4. Establish motivation for appetitive reinforcement by keeping animals hungry on a limited diet. Begin food restriction one week prior to food cup training and continue throughout the entire study (see Critical Parameters, discussion of motivation).

5. Identify each animal uniquely (e.g., by tattoo, ear tag, tail marking, or implanted magnetic tracking device).

   If indelible markers are used to inscribe a number on the animal's tail, these must be refreshed weekly. Marking and remarking the tails can be incorporated into the handling/acclimation procedures.

6. Acclimate animals to handling for one week prior to food cup training (see *UNIT 11.3* for advice on animal handling).
7. Give the animal a few of the food pellets that will be used as reinforcers in its home cage for a few days prior to food cup training.

   This avoids the rats' natural hesitation to accept novel food (bait shyness).
8. Expose animals to test equipment, including any transfer cages that might be used to deliver the animals from their home cages to the test cages. Give the animals a day or two to acclimate to transfer cages and to the location where they will wait while others are being tested.

   The acclimation to food pellets should be done in this venue as well.

Perform food cup training

9. Day 1. Place the animal in the test chamber with a counted number of food pellets (~20) in the food cup. If the food cup has a door, prop it open on the first day. Illuminate the food cup light, and allow 20 min for the animal to consume the food and explore the chamber. Remove the animal and count the pellets remaining in the food cup. Repeat once or twice per day until all pellets are consumed.
10. Day 2. Repeat step 9 with the food cup door closed.

    If the food cup has no door, skip this step.
11. Day 3. Deliver pellets individually at random irregular intervals of ~30 sec (range, 17 to 45 sec). Illuminate the food cup at the time of pellet delivery. Measure the latency between each pellet delivery and the rat's entry into the food cup, and extinguish the light when the rat retrieves the pellet. When the latency is consistently fast (e.g., five consecutive entries with a latency ≤2 sec), food cup training is complete. Administer a maximum of 50 trials per daily session.

    Typically, 1 to 3 sessions will be needed.

Perform tests of autoshaping

12. As soon as food cup training has been completed, either in the same test session (Day 3) or in the next (Day 4), begin inserting the response lever into the chamber during each trial. Extend the response lever into the chamber and illuminate the cue light 15 sec prior to delivering each food pellet, after a variable time interval (starting with delivery of the previous pellet) ranging from 2 to 60 sec and averaging 30 sec.

    If the criterion response occurs (i.e., the rat presses the lever with sufficient force to trip the microswitch) during this 15-sec period, retract the lever, turn off the cue light, and deliver a food pellet immediately. If the criterion response does not occur, deliver a food pellet at the end of the 15-sec period, while simultaneously retracting the lever and extinguishing the cue light. In either case, illuminate the food cup light for 2 sec each time a pellet is delivered. Perform a maximum of 50 trials per daily session.
13. Repeat step 12 for up to four additional daily sessions.

Analyze data

14. Divide each 50-trial test session into five 10-trial blocks. Count the number of trials in each block during which a lever-press response occurs. Measure the response latency (the time between insertion of the lever and detection of the response) if a measure of response speed is desired.

    Acquisition of the response will be seen as an increase in the frequency of responses detected per block and a decrease in response latency across the five blocks of trials in a session.

    During autoshaping, animals will engage in responses to the source of the food (i.e., exploring the food cup, called "goal tracking") and responses to the signal that food

delivery is imminent (i.e., exploring the lever, called "sign tracking"; Schwartz and Gamzu, 1977). Thus, an ancillary measure of goal tracking can be obtained as the frequency of nosepokes (i.e., entries into the food cup) during presentation of the lever in each trial. Typically, rats will engage in goal tracking early during autoshaping and then shift to sign tracking, seen as a shift in responding from the food cup to the lever.

If autoshaping is used to prepare animals for further study, rats that do not press the lever after four sessions may be trained to do so by either of two methods. First, pellet delivery can simply be made contingent upon a response: extend and retract the lever as before, but do not deliver food upon its retraction if the criterion response does not occur. Frequently, the frustration engendered by unexpected nonreinforcement will induce the animals to explore the lever more vigorously and thus obtain food by pressing it. In rare cases, it may be necessary to leave the animal in the chamber overnight with the lever-press-food contingency in effect. (Be sure to provide water.) Failing this, the animal may be shaped by hand by the method of successive approximations (see Troubleshooting).

An alternative to the systematic pairing of the movement of a retractable lever and food delivery during a series of daily tests, as described above, involves placing the animal in an operant chamber with a nonretracting response lever for one or two long sessions (e.g., overnight). This approach relies on the normal exploratory activity of the animal to bring it into contact with the lever and with the contingent delivery of food when the lever is pressed. High success rates have been reported with this method (e.g., Van Haaren et al., 1987). Acquisition of the response can be followed by dividing the session into successive time bins. The advantages of this approach are its simplicity and high success rate. These are balanced by the need to supply water in the chamber and the fact that training a large number of animals will still require either a large number of chambers or several sequential sessions; the overall savings in time and effort may thus not be significant.

BASIC PROTOCOL 2

ASSESSMENT OF LEARNING: REPEATED ACQUISITION IN THE RADIAL MAZE

Repeated acquisition refers to a family of methods for assessing learning in which the subject first learns a rule or strategy to solve a problem and is then given a series of problems that s/he must solve. The rate of increase and asymptotic level of accuracy with which each solution is acquired provide an assessment of learning. This method resembles many situations in daily life; for example, a student in a math class learns rules of calculus and then uses them to solve differential equations. The present method capitalizes upon rats' foraging strategies, in this case quantified in terms of food-seeking behavior in the radial maze. The rat is first trained to seek food efficiently in the maze (*UNIT 11.3*) and then is given a series of daily problems to solve. These problems are defined by the location of food: a different subset of the arms of the maze is baited each day, and the rat is given a series of trials in the maze during which it learns which arms contain food that day.

Materials

Subject rats

Reinforcers for manual system: any cereal- or sugar-based foodstuff that can be delivered in small, reproducible quantities; pieces of breakfast cereal are frequently used (e.g., ¼ of a Froot Loop)

Reinforcers for automated system: precision food pellets, 45 mg for male rats, 37 mg for females (BioServ or PJ Noyes)

Radial arm maze, manual or automated (*UNIT 11.3*; Coulbourn Instruments, MED Associates, or TSE Systems)

Stopwatch (for manual system)

Food pellet dispensers (one at end of each arm for automated system)

Perform preliminary training

1. Train rats in a radial arm maze according to the basic working memory protocol (*UNIT 11.3*).

The materials differ depending upon whether a manually operated maze or an automated maze is to be used. Manual mazes are much cheaper and can be constructed from plywood, sheet metal, and paint, but require labor-intensive operation by a trained observer. Automated mazes rely upon computers to control stimulus conditions, pellet delivery, and recording of the rats' behavior (see Commentary for a fuller discussion of this trade-off). In either case, the experiment requires a radial maze with a minimum of eight identical arms and a set of doors that will confine the rat to the central arena. See UNIT 11.3 and Figure 11.3.1 for further details regarding the dimensions and layout of an appropriate maze.

For manual systems, all data must be recorded on data sheets. For automated systems, programs must be written to control timing of trials, stimulus conditions, and recording of arm-choice sequences. See Commentary for information regarding computer systems and interfaces to control the test environments and stimuli and to collect response data.

2. After the behavior of the rats has stabilized, begin providing multiple trials each day for each rat. Increase the number of trials per session by two each day until the rats perform eight trials in a session.

Perform tests of repeated acquisition

3. Repeat step 2, but instead of baiting all eight arms, select a subset of four arms randomly from the list of all possible subsets. Use this same subset for all trials in a given day, but vary the subset randomly from day to day. Terminate each trial when either all four reinforcers have been obtained or after ten choices have been made with fewer than four reinforcers obtained. Confine the rat to the central arena for an intertrial interval (ITI) of ≥ 10 sec.

   Each day the rat will obtain food only for entering the four baited arms, and not for entering the four unbaited arms. Because a different set is baited each day, the rat has to learn which arms are baited in each session, and its learning ability can be assessed repeatedly (from session to session).

   It is necesssary to run enough trials so that the error frequency for the slowest animal reaches a constant level before the end of the session. Start with about eight trials for each animal each session. The actual number will be determined by the rate at which errors decline to an asymptote of fewer than one error per trial (see Critical Parameters and see Anticipated Results).

4. Record the sequence of arm entries on each trial and whether food was obtained. Count initial entries into baited arms as correct and count entries into unbaited arms as errors.

   Learning each day's problem will be evident as a within-session reduction in error frequency. In other words, on trial 1 of each session, the rat has no information regarding which arms are baited and will be expected to make four errors (i.e., enter all eight arms to find the four with food). The number of errors should decline monotonically across trials in each session, reaching an asymptote of one error or fewer within five trials (see Anticipated Results). A baseline of consistent within-session error reduction should be achieved within 15 daily sessions (3 weeks at 5 sessions per week).

   Note that errors may also include reentries into an arm that was previously baited on that trial as well as reentries into arms that are in the unbaited set for that session. Information regarding these error types may be helpful in interpreting changes in behavior in this task; interpretation of these error types is discussed in Bushnell and Angell (1992).

ASSESSMENT OF WORKING MEMORY: DELAYED MATCHING TO POSITION

BASIC PROTOCOL 3

Working memory refers to the process engaged by remembering information that changes frequently (e.g., where you parked your car today) rather than information that remains constant for long periods of time (what kind of car you drive). Working memory is particularly relevant to toxicology because of its sensitivity to disruption by fatigue, drugs, aging, disease, and intoxication. Delayed matching to position (DMTP) is a type of

delayed-response task that is suitable for testing working memory in rats. In contrast to the radial maze, where spatial aspects of working memory are emphasized, the operant environment emphasizes temporal aspects of the process. Thus, forgetting occurs relatively quickly (e.g., within ~1 min) in operant tests and a complete retention gradient, or "forgetting function," can be generated for each subject in each daily test session. In contrast, forgetting requires hours in the radial maze.

The basic strategy for assessing working memory involves four steps: (1) present the subject with a bit of information to remember (sample); (2) remove it and wait a variable period of time (delay); (3) present that same bit of information with one or more other bits; and (4) reinforce the subject for choosing the bit that had been presented prior to the delay (choice). Choice accuracy can be reduced by increasing the number and similarity of the bits of information, the number of times the choice is repeated (trials), and most importantly the delay between sample and choice. Just two information bits are used in DMTP: the locations of two otherwise identical retractable levers mounted on one wall of an operant chamber. Finally, it is necessary to prevent the rat from simply waiting near the sample lever during the delay, to force it to choose between the two levers when they are inserted after the delay. For this purpose, the rat is trained to emit a specific delay behavior (repetitive responding into the food cup).

DMTP involves four component behaviors that must be trained in sequence: sample response, delay behavior, choice response, and food retrieval. The basic strategy involves training the terminal response (food retrieval) first and building the chain in reverse order. These steps, criteria for advancement, and the expected number of training sessions are outlined in Table 11.4.1.

Materials

Subject rats
Precision food pellets: 45 mg for male rats, 37 mg for females (BioServ or PJ Noyes)
Operant conditioning chamber (Fig. 11.4.2; e.g., Coulbourn Instruments, MED Associates, or CeNeS, or TSE Systems) including:
  Incandescent house light (~0.1 W)
  Loudspeaker for white noise
  Food cup that can be lighted from within
  Cue light: LED or incandescent bulb behind a clear lens (if using an incandescent bulb, use a glass jewel dome in front of the bulb rather than plastic, as it cannot be gnawed down by the animal)
  Two retractable response levers
Pellet dispenser
Computer system and interface to control test environments and stimuli and to collect response data (see Commentary)

Set up equipment

1. Set up equipment as for the lever-press response (see Basic Protocol 1, steps 1 to 3). In addition, mount a second retractable lever on the other side of the front wall of the test chamber (Fig. 11.4.2). Initially, center the food cup between the levers; however, design (or modify) the chamber to permit the food cup and pellet dispenser to be moved to the opposite wall part way through training.

   This latter arrangement physically separates the food cup from the choice levers, thereby reducing the effectiveness of behavioral mediating responses to bridge the delay (see Background Information). Because the animals will be earning a large proportion of their total food intake in the test environment in performing this task, be sure to use nutritionally complete food pellets as reinforcers.

Table 11.4.1 Sequence of Steps for DMTP Training

Protocol, step[a]	Procedure	Parameters	Criterion[b]	Sessions[c]
1, 1-3	Set up equipment			
1, 4-8	Preliminary training			
1, 9	Food cup 1	Food cup door open	Eat all pellets	1
1, 10	Food cup 2	Food cup door closed	Eat all pellets	1
1, 11	Food cup 3	Intermittent pellets	5 consecutive trials with latency[d] <3 sec	1
1, 12-13	Autoshape	Right lever	50 lever presses	4
	Hand shape[e]	Right lever	50 lever presses	1
3, 3	Continuous rft[f]	Right lever	50 right lever presses	1
		Left lever	50 left lever presses	1
3, 4-5	Anti-bias/delay behavior	Food cup front, 1 nosepoke[g]	100 trials	1
3, 6	Anti-bias/delay behavior	Food cup rear, 1 nosepoke	100 trials	5
3, 7	Anti-bias/delay behavior	Food cup rear, 2 nosepokes	100 trials	2
		Food cup rear, nosepoke (VI 2s)[h]	100 trials	5
3, 8	Position match	Max delay[i] 0 sec	≥80% correct	10
3, 9	Position match	Max delay 2 sec	≥80% correct at shortest delay	5
		Max delay 5 sec	≥80% correct at shortest delay	5
		Max delay 10 sec	≥80% correct at shortest delay	5
		Max delay 20 sec	≥80% correct at shortest delay	5

[a]Steps indicated for Basic Protocols 1 and 3.
[b]Criterion for advancing to the next step of training.
[c]Approximate number of sessions to expect for each training step.
[d]Latency to retrieve food pellet from food cup.
[e]If necessary, for rats that do not press the lever at the end of four sessions of autoshaping (see Troubleshooting).
[f]Rft, reinforcement. Continuous rft is equivalent to an FR1 (one response per reinforcer).
[g]Nosepoke refers to opening the food cup door.
[h]VI 2s, variable interval 2-sec. Multiple nosepokes during delay; first nosepoke after 2 sec ends delay and causes levers to insert for choice response.
[i]Maximum time between sample response and end of delay interval. As this value increases, keep shorter delays in the list; use five delay values in final schedule.

Establish food retrieval

2. Perform preliminary and food cup training as described for the lever-press response (see Basic Protocol 1, steps 4 to 12).

Establish sample response

3. Autoshape the lever-press response using one of the levers and its adjacent cue light (see Basic Protocol 1, step 13). Train the animals to press each lever for food, and ensure that they will press either lever when the two are inserted together into the chamber with illumination of their respective cue lights. Set the intertrial interval (ITI) to 10 sec. Use a choice criterion of at least one 100-trial session without a strong preference for either lever.

At this point, either choice is reinforced, as there is no basis for determining which response is "correct." Under these conditions, side preferences (or biases) must be discouraged to prevent their disruptive influence later in the study. One way to accomplish this is to present both levers together on a series of trials and count the number of times each is pressed. If the number of responses on one lever exceeds the number on the other by some criterion ratio (e.g., 60%) after five trials, insert only the other, nonpreferred lever until the ratio of

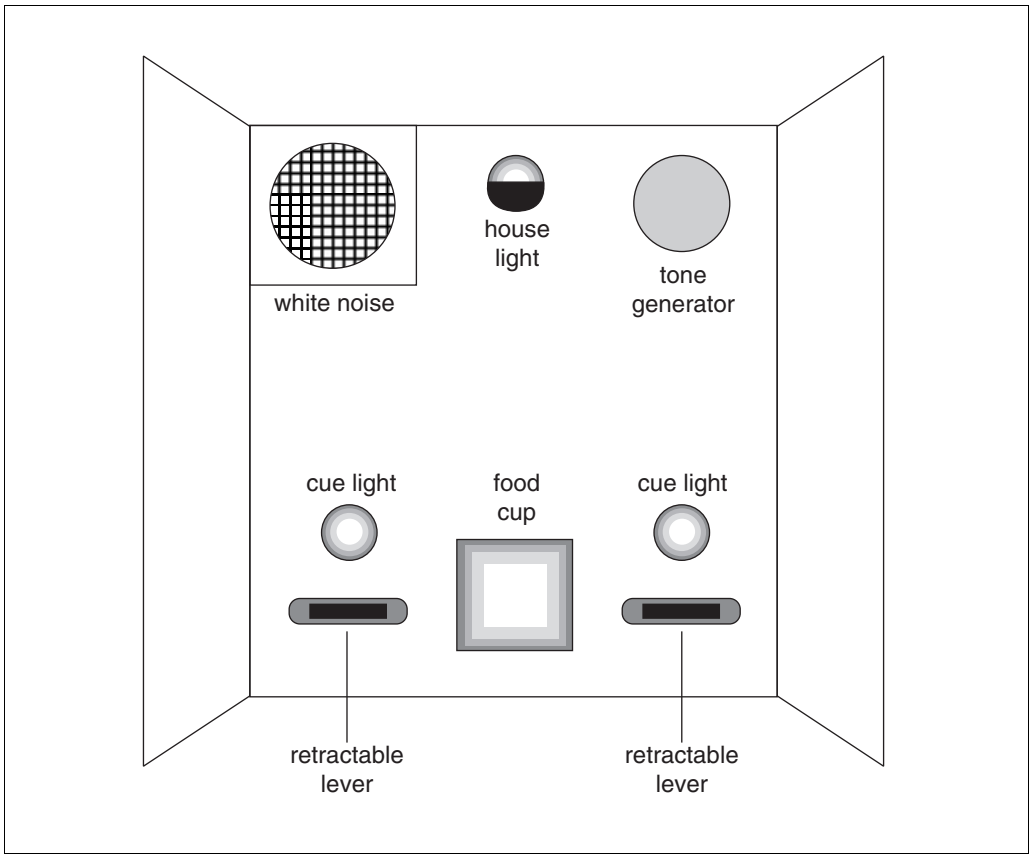

Figure 11.4.2 Configuration of an operant test chamber for delayed matching to position and visual discrimination. Only the front panel of the chamber is shown. In addition to the fixtures in Figure 11.4.1, a second retractable lever and cue light are necessary, and a tone generator is used to provide feedback for each effective nosepoke in the food cup. Early in training, the food cup should be moved to the rear wall of the chamber, to physically remove the rat from the locations of the two possible choice responses.

responses to the two levers falls below the criterion, and then insert both levers on the next trial. The delay behavior (step 4, below) can be introduced while position biases are being minimized.

Establish delay behavior

4. With the food cup between the two levers, begin each trial by turning on the food cup light, and require the rat to initiate each trial with a nosepoke into the food cup.

   Because this light has previously signaled the availability of food, the rat will open the food cup door (if there is one) or poke its nose into the cup looking for food.

5. When a nosepoke occurs, insert both levers into the chamber and reinforce a press on either one. Maintain the anti-bias contingencies of step 3. Use a criterion of at least 100 trials with a bias <60% in one 30-min session.

6. Move the food cup to the center of the rear wall of the chamber and repeat steps 4 and 5.

   Moving the food cup will disrupt performance considerably, as the rat has to relearn the physical relationships among the stimuli and manipulanda. It should be done early in training, before the rat's behavior has become strongly conditioned to the original configuration of the test environment.

7. Repeat steps 4 and 5 but require the rat to emit multiple nosepokes to initiate a trial.

   A fixed-ratio schedule (e.g., n nosepokes per trial initiation) will suffice at this point; however, a variable-interval (VI) schedule will eventually be necessary. A low ratio (e.g., 5) or short interval (e.g., 2 sec) is adequate at this time.

Delay behavior has now been established. During the delay, the rat will be kept busy making nosepokes into the food cup, and cannot simply wait near the sample lever during the delay and make its choice at the end of the delay. Note, however, that behavioral mediating strategies (analogs of rehearsal in humans) cannot be completely eliminated in memory tasks. Some rats will traverse the chamber repeatedly during the delay, returning to the location of the levers and attempting to press them in the retracted position between nosepoke responses in the food cup. If this is a concern, it will be necessary to count these "delay presses" to determine whether their frequency and location are related to the accuracy of choice at the end of the delay. Whereas mediating responses were shown long ago to affect choice accuracy in memory tasks, one study of DMTP suggested that rats do not use them effectively to increase accuracy (Bushnell, 1988).

Establish choice response

8. At the beginning of each trial, randomly select one lever as the sample and insert it into the chamber. When the rat presses it, retract it and turn on the food cup light. When the rat completes its nosepoke response requirement, insert both levers. Retract both levers when one is pressed. Reinforce with food when a matching response is made (i.e., when the rat presses on the same lever that was inserted as the sample at the beginning of that trial). If the rat presses the other lever, turn off the house light for 2 sec and do not deliver food (time out [TO]). Administer correction trials during this phase of training by presenting the same sample after each incorrect response up to a set maximum (usually 3).

   This contingency defines the matching rule as the correct response. The nonmatching rule can also be trained (i.e., reinforce each choice response to the lever not inserted as the sample on that trial). Both rules work for this task, though they differ slightly in rate of acquisition, variability of accuracy at asymptote, and sensitivity to drugs (Dunnett et al., 1989).

   Correction trials facilitate the acquisition of the matching rule by reducing the likelihood that the animal will adopt a position habit, responding only on one choice lever and accepting the 50% reinforcement rate yielded by that strategy. If three correction trials are given sequentially (i.e., the rat has made four consecutive errors), force the correct response on the next trial by withholding the incorrect choice lever. Then begin a new trial by selecting the next sample lever randomly.

   Note that correction trials should not be included in the computations of performance, as they will affect calculations of accuracy. Count correction trials and forced-choice trials separately.

Establish the retention gradient

9. Gradually increase the duration of the delay between sample and choice responses. Intermix several delay values (at least three, preferably five) during each session, ranging from essentially zero (a single nosepoke is required to terminate the delay) to a maximum of 20 or 30 sec. Select, randomly and without replacement, a value for each trial from a list, and repeat selection from the list of values 15 to 20 times during a session (e.g., if five delay values are used, each value will be used 20 times in a 100-trial session).

   For the purpose of programming the contingencies governing delay behavior (nosepoking), it is convenient to think of the list of delay values as a list of intervals in a variable-interval (VI) schedule. Thus, the nosepoke becomes the operant response for this VI schedule, the termination of which results in the opportunity to press a lever for food (rather than in food delivery). A VI schedule will engender a low, steady rate of responding. If the rate is too low, a minimum interresponse time can be imposed (e.g., a trial can be terminated if successive nosepokes are spaced >3 sec apart).

   Accuracy of choice will decline with increasing delay, revealing a retention gradient or forgetting function. The more delay values that are presented in an unpredictable sequence in each test session, the less accurately the subject can anticipate the delay length on a

given trial, increasing the reliability and consistency of the gradient obtained. That is, with just two values, the subject will learn to expect either a short or a long delay and will engage in mediating behavior appropriate to the delay. With a large number of values, the specific delay will be difficult to anticipate and thus engender less effective mediating strategies. Five delays provides a useable compromise between the theoretical optimum of an infinite number of delays and the practical optimum of two delays.

SUPPORT PROTOCOL

ASSESSMENT OF REFERENCE MEMORY: TWO-LIGHT VISUAL DISCRIMINATION

Basic Protocol 3 yields a rigorous test of working memory, yet performance of this task also requires sensory, motor, and motivational competence. A treatment that affects one of these non-mnemonic processes may impair performance of the DMTP task. One way to determine whether this impairment is due to a failure of working memory involves a test that requires all of the components of the DMTP task except working memory. This support protocol describes a test of reference memory that requires the same four component behaviors as DMTP (i.e., sample response, delay behavior, choice response, and food retrieval) trained in the same sequence. However, because the cue light *always* predicts the correct response, accuracy in this task depends upon reference memory for a cue light rather than working memory for the location of the sample lever.

Additional Materials *(also see Basic Protocol 3)*

Tone generator (e.g., Sonalert)

Perform training steps

1. Set up equipment as described for DMTP (see Basic Protocol 3, step 1).
2. Establish food retrieval, choice response, and delay behavior as described (see Basic Protocol 3, steps 2 to 6), but turn on the cue light over the sample lever at the beginning of each trial and again over the correct choice lever after the delay. Continue training until the rat initiates trials with a single nosepoke into the food cup, with the cup at the rear of the test chamber, and presses either lever with equal frequency.

Establish cue discrimination

3. At the beginning of each trial, randomly select one lever as correct and turn on the cue light above it for 2 sec prior to insertion of both levers. Reinforce a press on the lit lever with food and punish a response on the unlit lever with a TO (see Basic Protocol 3, step 8). Use a criterion for advancement of 90% correct responses to the lit lever.

   This 2-sec "cue-light advance" facilitates acquisition of cue discrimination, especially in male rats.

4. To increase the nosepoke requirement, extend the duration of the period during which the rat must make nosepokes from a single response to 5 sec.
5. Shorten the cue-light advance in stages, while maintaining accuracy at 90% or better.

   With female rats, this advance may be reduced to zero, but it may be necessary to keep it at ~1 sec to maintain criterion accuracy in males.

Establish choice response

6. Establish the sample response as for DMTP (see Basic Protocol 3, step 8) with the following exceptions.

   a. Illuminate the cue light over the sample lever while it is extended into the chamber, and extinguish it when the lever is retracted after being pressed.

b. At the end of the delay period, select one of the levers randomly as the correct lever and illuminate the cue light above it.
c. Reinforce a press on the lit lever with food, and punish a response on the unlit lever with a time out. Use a criterion for advancement of 90% correct responses to the lit lever.

The accuracy of this discrimination can be adjusted by varying the duration of the cue-light advance and/or the duration of the cue itself during the choice phase of the trial. Female rats are less sensitive to the cue-light advance, as their response latencies tend to be longer than those of the males, who tend to respond ballistically to the first lever they encounter, regardless of the cue light.

Test sessions can be run with intermixing matching and discrimination trials (e.g., Bushnell et al., 1991) or in separate test sessions or even in different rats.

7. Extend the delay interval (see Basic Protocol 3, step 9).

To make the discrimination task procedurally homologous with the matching task in Basic Protocol 3, the delay interval must be extended on a schedule identical to that used in the matching task. Thus, the only difference between the tasks will be that the discrimination task can be solved using reference memory (the cue light always indicates the correct response), whereas solution of the matching task requires working memory (the lever that is presented as the sample changes on each trial).

ASSESSMENT OF SUSTAINED ATTENTION: VISUAL SIGNAL DETECTION

BASIC PROTOCOL 4

Sustained attention refers to process(es) involved in reporting unpredictable signal events that occur repeatedly over long periods of time. The simplest methods require only that the subject make a response whenever a signal event occurs. However, these methods tend to generate high levels of false-positive responses (false alarms), which seriously complicate interpretation of correct detections (hits). The present method provides control over the rate of false alarms by using a discrete-trial, choice test format in which the rat must report, by pressing one of two levers, whether a signal did or did not occur in a variable, antecedent time interval. The subject must "pay attention" during this time interval to detect the signal reliably. In addition, the strength of the signal is varied within each session to provide a stable response baseline and a control for sensory dysfunction (see below). Finally, the attentional load is increased by making the time interval between signals long and highly variable. A summary of the training steps is outlined in Table 11.4.2.

NOTE: The term signal (as opposed to cue) is used in this protocol to be consistent conceptually with a large literature on signal detection methods and theory. A signal and a cue may be identical physical events; however, these stimuli are typically called cues in the discrimination learning literature and signals in the signal detection literature.

Materials

Subject rats

Precision food pellets: 45 mg for male rats, 37 mg for females (BioServ or PJ Noyes)

Operant conditioning chamber (Fig. 11.4.3; e.g., Coulbourn Instruments, MED Associates, or CeNeS, or TSE Systems) including:
- Incandescent house light (~0.1 W)
- Loudspeaker for white noise
- Food cup that can be lighted from within
- Signal light: LED or incandescent bulb behind a clear lens (if using an incandescent bulb, use a glass jewel dome in front of the bulb rather than plastic, as it cannot be gnawed down by the animal)
- Retractable levers

Pellet dispenser
Clear plastic tubing with inner diameter large enough to accommodate food pellets
Computer system and interface to control test environments and stimuli and to collect response data (see Commentary)

Set up equipment

1. Set up the equipment required for autoshaping (see Basic Protocol 1, steps 1 to 3), but install a second retractable lever in each operant chamber on the same wall as the

Table 11.4.2 Sequence of Steps for Sustained Attention Training

Protocol, step[a]	Procedure	Parameters	Criterion[b]	Sessions[c]
1, 1-3	Set up equipment			
1, 4-8	Preliminary training			
1, 9	Food cup 1	Food cup door open	Eat all pellets	1
1, 10	Food cup 2	Food cup door closed	Eat all pellets	1
1, 11	Food cup 3	Intermittent pellets	5 consecutive trials with latency[d] <3 sec	1
1, 12-13	Autoshape	Right lever	50 lever presses	4
	Hand shape[e]	Right lever	50 lever presses	1
1, 13	Continuous rft[f]	Signal lever	50 signal lever presses	1
4, 3	Continuous rft	Blank lever	50 blank lever presses	1
4, 4	Discrimination training	Correction trials: presignal interval[g] 10 sec, signal light above signal lever, signal duration 2 sec, signal advance[h] 2 sec, trials 100 → 240[i]	≥80% correct	15
4, 5	Discrimination training	Remove correction trials	≥80% correct	1
4, 6	Discrimination training	Signal advance 1 sec, signal duration 1 sec	≥80% correct	3
4, 7	Discrimination training	Turn off signal before lever insertion	≥80% correct	3
4, 8	Discrimination training	Signal above food cup	≥80% correct	6
4, 9	Signal detection	Postsignal interval[j]→ 2, 3, or 4 sec	≥80% correct	6
4, 10	Signal detection	Presignal interval → variable 7 sec	≥80% correct	8
4, 11	Signal detection	Signal intensities → variable	≥80% at highest signal	5
4, 12	Signal detection	Signal duration → 0.3 sec	≥80% at highest signal	10
4, 13	Signal detection	Increase background light level	≥80% at highest signal, ≤20% at lowest signal	5

[a]Steps indicated for Basic Protocols 1 and 4.

[b]Criterion for advancing to the next step of training.

[c]Approximate number of sessions to expect for each training step.

[d]Latency to retrieve food pellet from food cup.

[e]If necessary, for rats that do not press the lever at the end of four sessions of autoshaping (see Troubleshooting).

[f]Rft, reinforcement. Continuous rft is equivalent to an FR1 (one response per reinforcer).

[g]Presignal interval is equivalent to intertrial interval (ITI) at this point. Use a constant value until step 10.

[h]Signal advance is the time between onset of signal and insertion of levers. When signal advance = signal duration, the signal should be turned off when the levers are inserted.

[i]Gradually increase the number of trials from 100 to 240 during this phase.

[j]When the signal advance exceeds signal duration, the signal is turned off before the levers are inserted. Gradually lengthen the signal advance up to 3 sec, then introduce the variable signal advance values.

first and on the other side of the food cup (Fig. 11.4.3A). To facilitate training, keep the signal light immediately above the lever used in autoshaping. Designate the lever that has the signal light above it as the signal lever; designate the other one as the blank lever.

In the final test arrangement, this signal light will be moved to the top center of the panel (Fig. 11.4.3B). In addition, some means will be needed to vary the strength of the signal, which can be defined in terms of either the intensity or duration of the signal. Varying the intensity is preferred, but requires additional hardware. During training, the intensity of the signal light should be ≥10 times that of the background illumination from the house light.

Coulbourn Instruments manufactures a 256-step digital-to-analog converter (DAC) that permits manipulation of the signal intensity. When the DAC is set to 0, it completely attenuates the voltage applied to it and no signal is generated. When it is set to 255, no attenuation is applied to the voltage passed via an amplifier to the light. Intermediate settings yield signals of intermediate brightness.

Several photometric probes are available for measuring the illumination from these light sources; one adequate device is model 450 made by EG&G. It is most appropriate to measure the illuminance (incident light at the photodetector) with a cosine adapter at some location in the chamber where the rat is likely to be during the test (e.g., center of the chamber, floor level). In order to measure this illuminance in a standardized manner in all test chambers, fix the illuminance probe in a template, so the probe will be positioned at the same location each time a measurement is made. For signal durations >100 msec, illumination may be measured with the light continuously on.

Because the animals will be earning a large proportion of their total food intake in the test environment in performing this task, be sure to provide pellets that are nutritionally complete.

Perform initial lever training

2. Autoshape animals for the lever-press response (see Basic Protocol 1, steps 4 to 13) for the signal lever only. Train until each rat presses the lever reliably (50 presses in at least one 50-trial session).

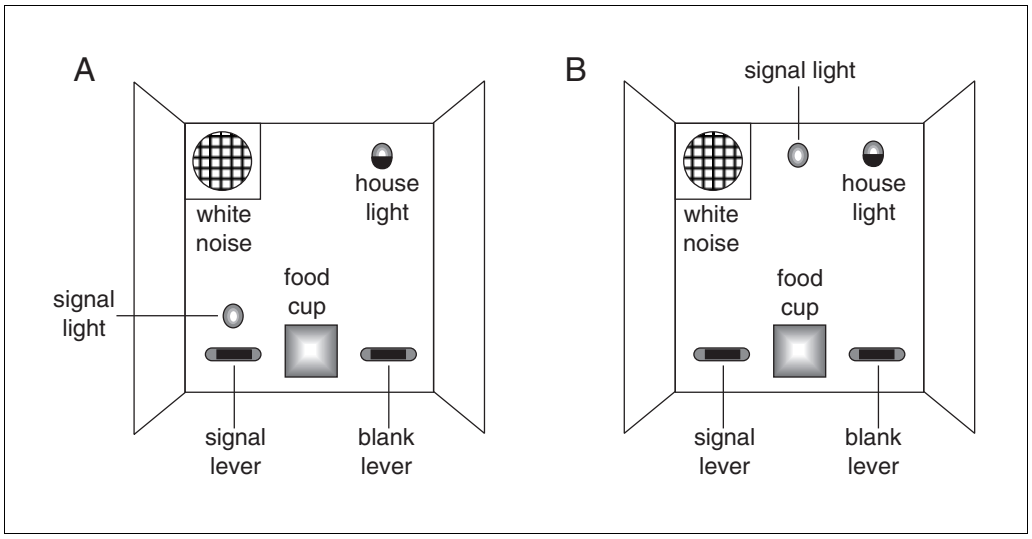

Figure 11.4.3 Configurations of an operant test chamber for testing sustained attention. (**A**) For training, the signal light is located directly above the signal lever (i.e., the lever paired with food on trials when a signal is presented). The blank lever is paired with food on trials lacking a signal. (**B**) Midway through training, after the rats have learned the response rules, the signal light is moved to the top center of the front wall of the chamber for assessment of attention.

3. Perform blank lever training by inserting the blank lever into the box as for autoshaping, but without illuminating the signal light. Train to the same criterion as above (50 presses in at least one 50-trial session).

   All rats should press this lever readily and with little delay. If any rats fail to do so, hand shaping may be required (see Commentary).

Perform tests of discrimination training

4. Present 50 signal and 50 blank trials in random sequence in daily test sessions (30 to 40 min). Separate trials with a 10-sec intertrial interval (ITI), during which the houselight is illuminated.

   a. *For signal trials:* Illuminate the signal lamp for 2 sec and then insert both levers into the chamber, leaving the signal light on. Retract both levers and turn off the signal when either lever is pressed. If the rat presses the signal lever, deliver a food pellet and illuminate the food cup. If the rat presses the blank lever, provide other cues to designate a punishment period or timeout (TO). For a typical TO, extinguish the house light for 2 or 3 sec and/or deliver a brief auditory cue that is unique to this event (a Sonalert, which generates a loud tone of ~4 kHz when supplied with 28 DC volts, is commonly used for this purpose). Follow the reinforcement or TO with the 10-sec ITI.

   b. *For blank trials:* Perform as for signal trials, but do not present a signal, and reverse the contingencies for pressing the two levers (i.e., reinforce a press on the blank lever with food, and follow a press on the signal lever with TO).

   Count the frequencies of correct and incorrect responses in each session. Continue training until each animal reaches a criterion accuracy of 80% or better in at least one 100-trial session.

   Note that there are two types of correct responses and two types of errors in this kind of signal detection task. Correct responses occur on the signal lever on a signal trial (hits) and on the blank lever on a blank trial (correct rejections). Similarly, errors occur when the signal lever is pressed during a blank trial (false alarms) and when the blank lever is pressed during a signal trial (misses).

   Trials in each session may be counted in blocks (e.g., five 20-trial blocks), but the animals will improve more across sessions than across blocks when daily sessions are given. However, session blocks may be useful for detecting equipment failures (see Troubleshooting).

   Use correction trials to facilitate acquisition of the response rules, observing appropriate cautions as described elsewhere (see Basic Protocol 3, step 8, and see Troubleshooting, discussion of poor learning).

   The 2-sec period between onset of the signal and insertion of the levers is called the signal advance, in distinction to the signal duration, which refers to the length of time that the signal is illuminated on each trial. At this point, the signal duration exceeds the signal advance, because the signal remains on after insertion of the levers.

5. Remove correction trials from the training procedure, but be prepared to reinstate them as a remedial measure as needed (i.e., if an animal fails to progress in their absence).

Modify signal parameters

6. Shorten the signal advance and signal duration in 0.5-sec decrements to 1.0 sec. Retrain to criterion (80% correct) after each change.

   Expect the rats to require 1 to 3 sessions at each stage.

7. Turn off the signal light simultaneously with insertion of the levers instead of keeping it lit until the rat makes its response. Retrain to criterion (1 to 5 sessions).

   The signal advance and signal duration are now equal; later, the signal duration will be shortened further, such that the signal terminates several seconds before insertion of the levers.

8. Move the signal light from its position above the signal lever to a position above the food cup at the top of the test chamber (Fig. 11.4.3B), thus placing it in a neutral position with respect to the levers. Retrain to criterion (2 to 10 sessions). Begin increasing the number of trials per session from 100 to the total that will be used in the final procedure, and reduce the presignal interval from 10 to 7 sec.

   Present a minimum of twelve trials (six signal and six blank) per test condition. If both signal strength and testing duration (trial blocks) are important variables, then the total number of trials per test session will equal 12 × number of strengths × number of trial blocks administered (e.g., for three trial blocks and five strengths, 12 × 3 × 5 = 180 trials). At a nominal trial rate of 5/min (ITI ≅ 7 sec), a 180-trial session will require ~40 min to complete. The number of trials should be increased gradually during steps 8 to 10, in 20- to 40-trial increments. For sessions longer than 240 trials, reduce the probability of primary reinforcement (pellet delivery) to maintain the maximum possible number of pellets earned at 240 and to prevent the rats from becoming sated (240 pellets × 45 mg/pellet = 10.8 g of food).

9. Vary the postsignal interval, while keeping the signal duration constant at 1 sec by inserting a variable time between onset of the signal and insertion of the levers. Begin with 1.5 sec and end with 2, 3, or 4 sec, randomly determined on each trial. Retrain as necessary to maintain the criterion of 80% correct accuracy (5 to 7 sessions).

   This change inserts a gap between offset of the signal and insertion of the levers.

10. Vary the duration of the presignal interval by randomly selecting a presignal interval value on each trial, keeping the average duration at 7 sec. Begin with a relatively homogeneous list of values (e.g., 5, 6, 7, 8, and 9 sec) and increase the range of values until very short (≤1 sec) and very long (≥20 sec) values are used. Retrain to criterion after each change in the list (5 to 10 sessions).

    Fleschler and Hoffman (1963) provide an algorithm for calculating constant-probability lists that are appropriate here. These lists of durations maintain a constant probability that the interval will terminate throughout the interval.

    This manipulation will cause a large drop in accuracy when first introduced; accuracy will return toward the previous baseline over about a week of testing, but will not reach the same levels. This decrement appears to be due to the increased attentional demands of the variable presignal interval. The initial decrease in accuracy and the subsequent rate of recovery should provide sensitive measures of sustained attention. Thus, this step should be monitored closely in studies assessing the effects of prior treatment with a test agent.

    Steps 11 to 14 below are designed to increase the difficulty of the task, thus lowering the proportion of hits, P(hit), to an appropriate range. Ideally, the gradient relating P(hit) to signal strength will extend from chance accuracy at the lowest signal strength to near 100% at the highest strength. See Anticipated Results for further explanation. Skip these steps if the task difficulty is appropriate after step 10.

11. *Optional:* Vary the signal strength during each session. Present trials of each signal strength in a completely randomized order or in blocks of 4 to 8.

    If a random order is used, all blank trials in the whole session are equivalent, and false alarms and correct rejections cannot be categorized in terms of signal strength. If trials are blocked, then all four response types can be categorized by intensity for purposes of data analysis.

    Varying the signal strength can be accomplished by varying its intensity, its duration, or both. Conceptually, briefer signals should increase the attentional load of the task (Muir et al., 1993), whereas dimmer signals should provide a sensory challenge rather than an attentional challenge. The degree to which these processes can be selectively challenged by these manipulations remains to be determined. However, it is clear that appropriate manipulation of the signal intensity can be used to establish increment thresholds for the sensory modality of the signal (Bushnell et al., 1997).

12. *Optional:* Vary the signal intensity. Present the brightest two values in one session and include successively dimmer signals each day to facilitate development of a generalization gradient across signal intensity (5 sessions).

13. *Optional:* Increase the background intensity of the signal light from zero (signal light off between signals) to a dim value. In other words, keep the signal light on dimly before each signal and return it to that dim value after each signal. Use a final criterion of ≥80% correct for the most salient signal and ≤20% correct (i.e., guessing) for the least salient signal (5 sessions).

    This increases the difficulty of the task by making the signal an increment in intensity. Psychophysically, increasing the background illumination raises the threshold for detecting the increment in illumination represented by the signal. Skip this step if the task is sufficiently difficult without brighter background illumination.

14. Vary the signal duration within each session, using a range of values of 1 sec to 0.1 sec, using the same strategy as for signal intensity, above.

    This method will produce a gradient of P(hit) across signal durations, as shown by McGaughy and Sarter (1995). Under the assumption that shorter signals involve a greater attentional demand than do longer signals, effects of a treatment specific to attention should reduce accuracy preferentially to short signals.

Analyze data

15. Convert the frequencies of hits, misses, false alarms, and correct rejections (see step 4) at each signal strength to proportions of hits, *P*(hit), and false alarms, *P*(fa). Calculate *P*(hit) as the frequency of hits divided by the sum of the frequencies of hits and misses (i.e., proportion of correct responses on signal trials). Calculate *P*(fa) as the frequency of false alarms divided by the sum of the frequencies of false alarms and correct rejections (i.e., the proportion of errors on blank trials).

    P(hit) and P(fa) can be used to calculate sensitivity and bias indices from signal detection theory, but this approach must be taken with caution, because interpretation of these derived measures depends upon the particular assumptions upon which their calculation is based, and explanation of their meaning invariably requires recourse to the values of P(hit) and P(fa) from which they were derived. In this author's opinion, the advantages of deriving signal detection indices, which involves trading one pair of measures [P(hit) and P(fa)] for another pair of more derived measures (sensitivity and bias), are outweighed by the effort required to calculate and explain these latter measures.

    In addition to these measures of accuracy, response time may be measured as the latency between insertion of the lever and the rat's response. Latency provides an index of motor function akin to a simple reaction time, because rats typically choose which lever to press during the postsignal interval by positioning themselves in front of one of the levers and pressing it as it is inserted into the chamber. Latency typically does not vary with signal intensity (Bushnell et al., 1994).

BASIC PROTOCOL 5

MULTIPLE FIXED-INTERVAL/FIXED-RATIO OPERANT SCHEDULE

Operant schedules are useful for assessing the degree to which one or more contingencies of reinforcement can gain control of the behavior of a subject. In addition, the rate of acquisition of the response rules and control of behavior by reinforcement contingencies can provide evidence regarding the ability of a subject to learn this information and respond accordingly. Because interval and ratio schedules generate different patterns of behavior, it is often useful to observe acquisition and performance of both types, as well as the ability of the subject to switch between schedules within a test session. Thus arises the utility of the multiple schedule, a procedure in which combinations of two or more component schedules are arranged within a test session, each with a unique stimulus associated with the schedule.

This protocol describes training steps for a multiple FR10/FI 1-min schedule for rats. In the FR10 component, every tenth lever press (response) yields a food pellet. In the FI 1-min schedule, the first response after a fixed interval of 1 min (since delivery of the previous pellet) yields a food pellet. FR schedules produce rapid responding until the ratio has been completed, followed by a period with no responding (post-reinforcement pause). In contrast, FI schedules produce a response pattern in which the response rate gradually increases across the time interval, reaching a maximum just prior to the end of the interval. If responses are plotted sequentially and cumulatively across the interval, a positively accelerated curve is revealed; this pattern is called the FI scallop.

Materials

Subject rats
Precision food pellets: 45 mg for male rats, 37 mg for females (BioServ or PJ Noyes)

Operant conditioning chamber (Fig. 11.4.1; e.g., Coulbourn Instruments, MED Associates, or CeNeS, or TSE systems) including:
- Incandescent house light (~0.1 W)
- Loudspeaker for white noise
- Food cup
- Cue light: LED or incandescent bulb behind a clear lens (if using an incandescent bulb, use a glass jewel dome in front of the bulb rather than plastic, as it cannot be gnawed down by the animal)
- Response lever, fixed or retractable
- Tone generator (e.g., Sonalert; optional)

Pellet dispenser
Computer system and interface to control test environments and stimuli and to collect response data (see Commentary)
Computer software for visualizing patterns of response in each component (MED Associates)

Set up equipment

1. Set up equipment as described for autoshaping the lever-press response (see Basic Protocol 1, steps 1 to 3).

   White noise can be provided by a loudspeaker, a ventilation fan, or both.

Perform training steps

2. If retractable levers are used, perform initial training as described for autoshaping (see Basic Protocol 1, steps 4 to 13) until each rat presses the lever reliably (50 presses in at least one 50-trial session). If fixed levers are used, illuminate the cue light prior to delivery of each pellet during the autoshaping phase.

   Hand shaping and/or overnight sessions with a continuous-reinforcement schedule (FR1; each lever press yields a food pellet) in effect are more likely to be needed with fixed levers.

3. Train ratio schedule. Insert the lever into the chamber and illuminate the house light for the duration of the session. After each rat presses the lever reliably for food on the FR1 schedule, gradually increase the number of presses required for delivery of food to a value of 10 (FR10).

   For example, a sequence of ratios with values of 1, 2, 4, 7, and 10 might be used over the course of six to ten sessions. The criterion for advancing to the next ratio is completion of a predetermined number of ratios (e.g., 20) within an allotted time (e.g., 20 min). Stability of the response rate, both within and across sessions, might also be used. See Perone (1991) for a discussion of stability criteria in the design and analysis of free operant studies.

4. Train interval schedule. Insert the lever into the chamber and illuminate the house light and the cue light for the duration of the session. Deliver a pellet immediately following the first lever press that occurs after a short (e.g., 5-sec) time interval. Gradually increase the duration of the interval across six to ten sessions, using interval values of 5, 10, 20, 40, and 60 sec.

   As above, the primary criterion for advancement is completion of a specified number of intervals (e.g., 20) in a session lasting, for example, 30 min.

5. Train multiple schedule. Insert the lever into the chamber and illuminate the house light for the duration of the session. Randomly select a sequence of FR10 and FI 1-min components (e.g., five of each) for each session. Illuminate the cue light at the start of each interval component, and turn it off at the start of each ratio component.

   The number of sessions will depend upon the criteria selected for establishing stability of the behavior in each component; 10 to 20 session are frequently needed.

Analyze data

6. Inspect individual-animal data from cumulative response records or use microanalysis of the distributions of interresponse times (IRTs) and other temporal aspects of responding.

   The traditional approach to data analysis in free operant studies is the individual-animal approach. Other techniques described for quantifying performance (summarized in Perone, 1991) can also provide a wealth of information regarding the patterns of behavior engendered by these schedules.

7. For ratio schedules, quantify performance in terms of overall response rate (ORR), running rate (RR), and post-reinforcement pause (PRP) duration.

   The ORR is the sum of all responses in all FR components divided by the sum of the durations of the FR components. The RR is calculated similarly but excluding the PRP, which is defined as the time between delivery of the pellet and emission of the first response of the next ratio.

8. For interval schedules, quantify ORR as well as the curvature of the FI scallop.

   Curvature of the FI scallop better reflects the control of behavior by time. Two such measures include the index of curvature (IOC), which quantifies the degree to which the response pattern in each interval deviates from linearity (Fry et al., 1960), and the quarter life, which is that portion of the interval required for the animal to emit the first 25% of its total responses in the interval (Herrnstein and Morse, 1957).

COMMENTARY

Background Information

Mazes versus operant chambers

Tests of cognitive function may be carried out in any of a number of devices. Typically, either mazes or operant chambers are used. The same cognitive processes may be assessed in both kinds of apparatus, so neither gains any conceptual advantage over the other. The choice of test environment is generally made instead on the practical issues involved. Mazes are simpler and much cheaper to assemble, but larger and more difficult to automate than operant chambers. A single radial-arm maze or water maze may occupy a test room that could house a dozen operant chambers. In addition, computer control over the operant test environment reduces the intensity of the labor involved in daily testing of the animals, reduces the potential for observer bias in affecting the behavior of the animals, increases the precision with which stimuli and responses can be timed, and facilitates microanalysis of response patterns. These considerations gain significance when viewed in light of the number of animals that must be tested in generating dose-effect information for toxicology studies. A variety of operant chambers are illustrated by Ator (1991). Both mazes and operant chambers are available from commercial suppliers (e.g., Coulbourn Instruments, MED Associates, CeNeS, and TSE Systems).

Motivation and reinforcement

Most often, selected behaviors are reinforced appetitively, using food. Specific techniques for maintaining hunger are detailed below. Alternatively, animals may be induced to work for water by being kept on a limited water supply (e.g., 30 min access to water each day, provided after testing and while food is available in the home cage). The primary advantage of water reinforcement is the ease with which water can be delivered to the animal with a simple water spout and solenoid valve. The primary disadvantage involves the complications associated with maintaining the health of the animal under conditions of chronic thirst. For example, rats will not eat dry lab chow without access to water, so care must be taken to provide both at the same time, and to monitor carefully the weight of the animals during the study.

Escape from aversive stimuli may also be used as motivation. Several traditional tests (e.g., active and passive avoidance) employ termination of electric shock as a negative reinforcer to control behavior. Escape from water has more recently been used, as in the Biel, Cincinnati, and Morris water mazes (the Morris water maze is described in *UNIT 11.3*).

Autoshaping

Originally described in pigeons pressing backlit keys (Brown and Jenkins, 1968), the technique has also been developed for rats (e.g., Davenport, 1974; Poplawsky and Phillips, 1986). Thorough, if dated, reviews of the phenomenon are also available (e.g., Schwartz and Gamzu, 1977). The criterion response may be either a lever press (as described above) or any other response detectable by the computer—e.g., touching the lever or a designated region in the test chamber (Messing and Sparber, 1985) or pressing a backlit pigeon key. The criterion response is elicited by pairing food with a change in the manipulandum (e.g., insertion and retraction of the response lever or illumination of the pigeon key). In essence, pairing the change in the manipulandum with food delivery causes the animal to associate the manipulandum with food and to engage in exploratory ingestive behavior directed at the manipulandum. This exploration can then serve as an operant response if its emission causes immediate delivery of food in a combined autoshaping-operant procedure (Davenport, 1974).

Not all rats will press the response lever under the contingencies described below (expect about seven of eight rats to do so), and the rate of acquisition can vary dramatically across animals within a treatment group (see Fig. 11.4.4). Thus, relatively large sample sizes are typically necessary to detect group differences in autoshaping ($n \geq 12$). A higher percentage of animals will emit touch responses than press responses, and conditioning will proceed correspondingly more quickly (Messing and Sparber, 1985). However, touch responses are more difficult to detect and quantify automatically. In addition, further work with the animals will typically be more conveniently pursued with lever-press responses. The trade-off between the rate and unanimity of acquisition with lever-touch responses and the convenience of lever-press responses should be decided by the long-term goals of the study.

Parametric manipulations, including delay and probability of reinforcement, may be used to slow the rate of acquisition (reviewed by Gleeson, 1991). These manipulations may be useful for teasing out subtle effects of a compound, particularly those that compromise processing of temporal or probabilistic information (Messing and Sparber, 1985).

Repeated acquisition

Repeated acquisition was originally demonstrated in monkeys that learned to press a series of response levers in an operant chamber in a specific sequence each day (Boren and Devine, 1968). Operant response sequence methods have been explored extensively in primates (Thompson, 1974, 1975) and adapted for rats (Cohn et al., 1993; Cohn and Cory-Slechta, 1994). These methods have been ably reviewed both conceptually (Cohn and Paule, 1995) and with respect to neuroactive chemicals (Cohn et al., 1996).

It is rather less time consuming to train rats to perform repeated-acquisition baselines in mazes, either in a three-panel runway (Ohno et al., 1992) or a radial-arm maze (Peele and Baron, 1988; Bushnell and Angell, 1992). Repeated acquisition is more tractable for rats in mazes, probably because of the spatially rich environment and the fact that the problems can be based upon the location of food rather than a specific sequence of responses. In addition, the cognitive processes that support the problem-solving strategy in the maze—i.e., combinations of working and reference memory (Bushnell and Angell, 1992)—are better understood than those involved in acquiring novel sequences of responses.

Delayed matching to position

Delayed matching to position (DMTP) was developed from delayed matching to sample as a means of testing working memory (Honig, 1978) in rodents. The method was developed by Dunnett and colleagues (Dunnett, 1985; Dunnett et al., 1989; Dunnett and Martel, 1990) to assess the neurobiological basis of working memory and the efficacy of cholinergic grafts in the remediation of CNS lesions. It has also been applied to problems in pharmacology and toxicology (Bushnell et al., 1991, 1993; Thomas et al., 1991).

Technically, DMTP is a discrete-trial delayed-response task, with all of the limitations of the delayed-response paradigm (Heise and Milar, 1984; Paule et al., 1998). In contrast to maze procedures, which assess spatial components of working memory, DMTP is one of the few practical means available for assessment of the temporal aspects of working memory in rats. The fact that delays of <30 sec are sufficient to reduce accuracy across delays means that retention gradients can be obtained in test sessions of reasonable duration. For purposes of analysis, this gradient may be approximated by a linear function whose *y* intercept and slope define the probability that the sample information was encoded and the rate at which that information is lost over time, respectively (Bushnell, 1990; Paule et al., 1998). These parameters probably reflect attending to the sample stimulus and rate of forgetting; both are important in determining the accuracy of response when the choice opportunity is provided.

DMTP may also be conducted with a control procedure for assessing reference memory to provide evidence that deficits in accuracy are specific for working memory. For example, the visual-discrimination task described in the Support Protocol requires the same motivation and motor responses demanded by DMTP, but does not require working memory. Thus, a deficit in the DMTP task without a corresponding deficit in visual discrimination strengthens the evidence for impairment of working memory. Note that this case can be made most strongly when baseline accuracy levels on the two tasks are the same (Paule et al., 1998).

Sustained attention

Sustained attention refers to the process(es) by which temporally unpredictable signal events may be detected and reported over prolonged periods of time (reviews by Parasuraman et al., 1987; Craig and Davies, 1991; Nachreiner and Hänecke, 1992). The term vigilance refers to a special type of sustained attention in which the signal events are rare and the test environment is monotonous (Mackworth, 1970; Nachreiner and Hänecke, 1992) and does not apply to the method described here (Bushnell, 1998). The signal-detection method described here for assessing sustained attention provides strong control for changes in the false alarm rate, which can complicate interpretation of studies of sustained attention (see Moore et al., 1992, for a discussion of this problem). The method described here relies upon visual stimuli, but can be implemented in other sensory modalities as well (Bushnell et al., 1994), and can produce very similar psychophysical relationships. The theory of signal detection (Green and Swets, 1974) can be applied to these data to derive indices of sensitivity (reflecting the discriminability of the stimuli) and bias (reflecting the subject's tendency to make a particular choice). However, patterns of effect in this task can be observed as readily and with much less effort by calculating the proportions of hit and false alarm, as described.

Many methods have been devised for assessing attention, both sustained and selective, and have a rich history in pharmacology and neurobiology (Robbins and Everitt, 1995; Bushnell, 1998); however, their application to toxicology is just beginning. Given the importance of attention in learning and memory, and the likelihood that changes in these latter processes may reflect more specific effects on attention, it is likely that this area will expand in the near future. For example, the five-choice serial reaction-time test (Carli et al, 1983; Muir et al., 1994) has become a standard method for studying the neurobiology and pharmacology of attention, but has not yet been used to ask neurotoxicological questions relevant to public health.

Multiple fixed-interval/fixed-ratio schedule

Since Skinner's seminal work on operant conditioning, codified by Ferster and Skinner (1957), schedule-controlled operant behavior has enjoyed a long and rich history in behavioral pharmacology and toxicology. This history has been driven largely by the precise control that can be gained over behavior in a variety of species of test animals, including humans. A great variety of simple and complex schedules have been devised and continue to fascinate students of behavior (Lattal, 1991; any issue of the *Journal of the Experimental Analysis of Behavior*). Operant conditioning focuses on the behavior of the subject per se

and, consistent with the atheoretical approach of Skinner, any association of conditioned behavior to underlying hypothetical processes is eschewed as mentalistic guesswork. Thus, whereas clear evidence of changes in schedule-controlled behavior can often be observed in response to treatment with chemical agents (e.g., Brocco and McMillan, 1983; Moser et al., 1987; Hymowitz et al., 1990), the interpretation of those changes is typically not pursued beyond the observable events themselves. The difficulties with associating schedule-controlled behavior with underlying neurophysiological and neurochemical systems, and with interpreting changes in behavioral baselines in terms of the cognitive processes of concern to public health, have impeded widespread acceptance of these methods as tools in toxicology.

Critical Parameters

Handling animals

See Critical Parameters of *UNIT 11.3* for a discussion of rat handling considerations. In addition, Ator (1991) has provided a thorough description of techniques for handling laboratory animals.

Motivation

Appetitive motivation may be maintained during training and testing by one of several means. Frequently a target body weight is established based upon a percentage (usually 80% or 85%) of the animals' free-feeding weight. Determining the free-feeding weight is not a simple matter, as rats (especially males) continue to gain weight throughout their lifetimes if permitted to do so. Thus, 85% of free-feeding weight may involve a continually increasing weight that must be monitored and adjusted throughout the study.

Alternatively, the rats may be grown to their adult weight and maintained at a constant value thereafter (Ator, 1991). Typical weights are 325 to 375 g for male Long-Evans and Sprague-Dawley rats, and 225 to 275 g for females. Frequent weighing and careful feeding are necessary to maintain weight in a target range. Algorithms for calculating daily feedings to maintain constant body weight are available (e.g., Ali et al., 1992).

Animals should be fed with standard rat chow at the end of each test day, but not immediately after removal from the test chamber (so they don't learn to wait for their food). It will also be necessary to subtract the amount of food earned during daily tests from their total allotment to maintain target body weights when the amount earned in the chambers exceeds 10% of their total daily allocation.

Finally, in preparation for each daily session, it helps to provide a short (~2-min) period in the test chamber or maze before each session to permit the animal to recover from any stress involved in transfer to the test apparatus.

Computer control of testing equipment

Unless a strictly manually operated maze is used, the computer will be an essential aspect of testing cognitive function. Even tracking systems for the Morris water maze use computerized acquisition of speed, heading, and latency data. Thus, selecting the interface and software should be considered carefully.

Many computer software packages may be used for quantifying behavior (Gollub, 1991); in addition, three commercial systems have been designed specifically for testing the behavior of small animals. State Systems wrote an early and successful state-table program called SKED-11, which runs under RSX-11 on Digital PDP-11 minicomputers. Although this computer platform is expensive and outmoded, the software is well developed and relatively flexible. In particular, the multitasking operating system permits such tasks as programming, editing, and file handling to occur while animals are being tested. Up to sixteen stations can be run simultaneously with simple programs, or fewer stations can be run with more complex programs. MED Associates adapted the state-table approach for the PC with their MED-PC system, which runs under DOS or Windows. Because of the limited multitasking availability on these platforms, the system is less flexible than SKED-11, but uses cheaper and more accessible hardware. A third system, L2-T2, was developed by Coulbourn Instruments for the PC. It appears to be suitable for simple operant schedules but handles complex test programs with difficulty. In addition, other custom software may be used, limited only by available time and ingenuity of the researcher and support staff (Gollub, 1991).

Autoshaping

The intertrial interval (ITI) can influence the course of autoshaping. In general, more lever-directed activity and pressing (sign tracking) will be elicited by longer ITIs, and more food-cup-directed activity (goal tracking) will be elicited by shorter ITIs (Van Haaren et al., 1987).

The effects of ITI depend also upon the sex and strain of the rat. Male rats tend to autoshape

faster than female rats, because of more frequent and vigorous exploration of the lever during the pairing of lever retraction with food (van Haaren et al., 1987). Consistent with this gender difference, acquisition of the lever-press response can be facilitated paradoxically by treatments that interfere with the control of fine motor movements. Thus, acute exposure to the organic solvent *p*-xylene increased the rate of acquisition of lever pressing, and this increase in rate was blocked by increasing the force necessary to press the lever (Bushnell, 1989). Because (1) responding begins with exploration of the response lever, (2) the animals were observed to be unsteady and slightly uncoordinated after exposure to xylene, and (3) acquisition of a discrimination reversal was not affected by xylene, the facilitation of autoshaping was interpreted as a reduction in motor control.

The rate of acquisition of an autoshaped response can be slowed by introducing a delay between retraction of the lever and delivery of food (Davenport, 1974; Messing and Sparber, 1985) and, under some conditions, by decreasing the probability with which food is delivered after retraction of the lever (Schwartz and Gamzu, 1977).

Repeated acquisition

Changing the number of arms in the baited set will affect the shape of the acquisition curve. If a lower proportion of arms is baited, more errors will occur on the first trial and fewer on later trials, thus steepening the daily learning curve. Increasing the proportion of baited arms should have the opposite effect (i.e., prolong the acquisition phase, but starting at a lower error level).

The number of trials per session may be adjusted as necessary, with constraints (1) that the animals all reach a low and stable error frequency by the end of the session and (2) that the test session is kept as short as practical. Note that if a treatment is expected to retard learning, then a longer session may be necessary to document the effect.

The subset of arms baited must be varied across the rats tested each day. If the same set of arms is baited each day for all rats, then those rats tested late in the day will find useable odor trails to follow (D.B. Peele, pers. comm.).

Delayed matching to position

Because of the length of the chain of responses necessary for completion of each trial in this task (i.e., sample press, delay responses, choice response, food retrieval), it is advisable to generate a unique stimulus condition or combination of stimuli for each element of the chain. These unique conditions help "pace" the rat through each trial without providing information regarding the choice response. For example, the white noise intensity might be increased after the ITI to mark the beginning of the trial, and then be reduced after collection of the food pellet.

Because a large number of trials are presented in each session in this task, proactive interference (PI) plays an important role in performance. That is, the response made on a given trial is an important factor in determining accuracy on the next trial, and is said to interfere proactively with the subject's choice on the next trial. The influence of proactive interference in working memory tasks has been demonstrated primarily by manipulations of the ITI (Roberts and Kraemer, 1982; Bushnell, 1988; Dunnett and Martel, 1990). These manipulations are based on the assumption that the influence of the previous response will dissipate with time; hence, the strength of the PI will diminish as the ITI is lengthened, and accuracy will increase. Indeed, choice accuracy appears to be closely related to the ratio of the delay interval to the ITI (Roberts and Kraemer, 1982). These considerations gain further importance when the effect of a treatment appears to be mediated through its effects on PI, as has been elegantly documented for nicotine (Dunnett and Martel, 1990).

The DMTP procedure is designed to assess working memory, but obviously requires other processes as well. Thus, in addition to the sensory and motor aspects of performing the task, the contingency governing the response in each component of a trial must be remembered. Because this information remains constant throughout the experiment, it is assumed to require reference memory. An independent assessment of reference memory can be added to this procedure by intercalating discrimination trials randomly among the matching trials (Bushnell et al., 1991). Alternatively, reference memory (e.g., visual discrimination) can be tested independently in the same animals or in others (Bushnell, 1990).

Finally, it should be noted that several variations of this method exist (e.g., White, 1985; Thomas et al., 1991), and other operant methods have been devised for assessing working memory for pharmacological and toxicological investigations—e.g., continuous nonmatch to sample (Spencer et al., 1985) and delayed alternation (Heise and Hudson, 1985).

Sustained attention

Three parameters are particularly efficacious at determining accuracy in the signal-detection task: signal strength, variability of the ITI, and trial rate. First, the intensity of the signal relative to the background illumination strongly influences the probability with which the signal will be detected and reported. This relationship is primarily perceptual, reflecting the fact that the rats are required to detect an increment in illumination. Thus, overall accuracy can be varied by adjusting the ambient illumination as well as the brightness of the signal.

Varying the signal strength (intensity or duration) is important for two reasons. First, it helps to maintain a stable performance baseline, in that the animals are reinforced consistently for detecting strong signals and inconsistently for detecting weaker signals. Second, if the signal strength is varied in terms of its intensity, and if the intensities are chosen appropriately, the shape of the gradient relating *P*(hit) to intensity can distinguish between sensory and attentional dysfunction. That is, an attention deficit is probable if a treatment shifts the gradient downward—seen as a reduced *P*(hit) at all intensities above chance—particularly if *P*(fa) is also elevated. In contrast, if the treatment shifts the *P*(hit) by intensity gradient to the right—i.e., reduced *P*(hit) only at intermediate intensities and no increase in *P*(fa)—then it is more likely that it has caused a deficit in perception of the signal (visual deficit; see Bushnell et al., 1997).

The temporal unpredictability of the signal also affects accuracy, as would be expected of a test of sustained attention. Increasing the variability of the presignal (and postsignal) intervals decreases the temporal predictability of the signal and thus can be presumed to increase the attentional load of the task (Muir et al., 1993). As predicted, increasing the variability of the ITI reduces accuracy in this task (McGaughy and Sarter, 1995); however, accuracy will improve somewhat with practice after a change from a constant to a variable ITI (Bushnell, unpub. observ.).

Accuracy also decreases with increasing trial rate (the rate at which trials are presented; Bushnell and Kelly, 1992). The decrease in accuracy with faster trial presentation rates may be due to fatigue, which develops both in peripheral sensory organs and central processing systems in human subjects in fast-paced tasks (Parasuraman, 1984).

Multiple fixed-interval/fixed-ratio schedule

The particular values of the ratio and interval applied in a multiple schedule will greatly affect the rate and temporal patterning of the behavior obtained (Lattal, 1991; Perone, 1991) and may also interact with the effects of chemicals (Branch, 1991). Thus, comparison across studies must be done carefully, with a keen eye toward differences in both the training history and schedule conditions employed.

Troubleshooting

Hand shaping when autoshaping fails

Some rats will fail to acquire the lever-press response under the conditions described for autoshaping. The behavior of these rats may have to be shaped manually. Shaping refers to a process by which an animal may be induced to emit a specific response by reinforcing behaviors that approximate that response. This method of successive approximations is used extensively in animal training and was formalized for the laboratory by Ferster and Skinner (1957). The process requires a motivated subject (hungry rat), an observer with a means to deliver a reinforcer (food pellet), and a predefined criterion response. Simply put, the observer reinforces behaviors that successively approximate the criterion response until the response is emitted by the animal on its own. A fuller description of this process is given by Gleeson (1991).

In the present context, a hungry rat in an operant chamber may be shaped to press a lever as follows. The rat is shown during the first stages of autoshaping that food will be available periodically in the food cup, accompanied by the sound of a pellet being delivered and illumination of the food cup light. As the experimenter observes the rat moving about the chamber, s/he first causes a food pellet to be delivered into the food cup whenever the rat enters the quadrant of the chamber where the lever is located. Next, food is delivered only when the rat approaches the lever, then only when it sniffs, and then touches the lever. If necessary, the rat may be induced to approach the lever by gently tapping on the panel of the test chamber behind the lever. Finally, only a press vigorous enough to cause the lever to move is reinforced. If the electronic circuitry is set up appropriately, this movement will be detected by the equipment and cause delivery of a pellet. A practiced observer should be able to shape a hungry rat to press a lever in a matter of minutes.

Equipment failures

Many things can go wrong in complex systems like operant conditioning apparatuses: light bulbs burn out, moving parts wear out, microswitches fail, pellet dispensers jam, and retractable levers malfunction. There is no way to eliminate these problems entirely, but their frequency and effects on experiments can be minimized in several ways. First, it is essential to test each piece of equipment each day prior to collecting data from the animals. Test programs need to be written so that any loose bulb or broken wire or stuck response lever results in an easily detectable and traceable fault. Second, it is essential to monitor the progress of each animal during its test session. When, for example, box 2 fails during a data-collection session, it should be obvious from the display that a problem has developed in that box (e.g., the rat has stopped responding, or for the last 5 min it responded only on the left lever, or its accuracy has fallen from 90% to 10%). Third, moving parts must be kept clean to increase their reliability and prolong their lifespan; particular attention should be paid to pellet dispensers, which accumulate dust and a sticky residue, even from "dustless" pellets. However, as discussed below, the olfactory cues in a test chamber become part of the environment, so abrupt changes in these cues from, for example, a sudden, thorough cleaning of the test cage, will seriously disrupt performance. Because of time constraints and the complexity of the equipment, thorough cleaning and sanitization is not feasible between rats, or even daily. However, judicious, regular cleaning of the most failure-prone pieces of equipment is essential; if this is incorporated into the testing routine, it will not interfere with a stable performance baseline.

Most commercially available retractable levers are extended by an electric motor, which tends to produce relatively slow movement. In addition, some older models do not reliably extend and retract repeatedly. These levers may be modified by replacing the motor with a pneumatic cylinder, which greatly increases the speed and reliability of the devices. The rate of motion of the levers under compressed air can be controlled by inserting a small orifice (e.g., a 26- or 27-guage needle) in the air line to the cylinder. Small pneumatic cylinders, solenoid valves, manifolds, and fittings for this purpose are manufactured by Clippard and are available from Carolina Fluid Components. If compressed air is not available or is unreliable in the building, a nearly silent air compressor with adequate capacity and good reliability is manufactured by Jun-Air and is available from the Newport Corporation.

Animals in wrong cages

Each test chamber is unique to a rat, despite our best efforts to make them identical; for example, many of the cues that make the chambers different to the rats are olfactory and too subtle for a human's degenerate sense of smell to discriminate. Thus, rats learn faster and perform more consistently when they are tested in the same test chamber every day. Occasionally, two or more animals may be placed inadvertently in the wrong chambers, which may or may not create obvious differences in performance. Assembling adjacent chambers with mirror-image configurations (e.g., signal lever on the left side in boxes 1, 3, and 5; signal lever on the right in boxes 2, 4, and 6) will increase the likelihood that misplaced animals will be identified quickly, because the reverse contingencies of the chambers will cause a precipitous drop in accuracy or complete response failure due to unexpected nonreinforcement. The best way to minimize these mishaps is to maintain clear identification marks on each animal and to check these marks every time an animal is moved from one cage to another.

Poor (slow) learning

Each animal will learn at its own pace. If the variability in these rates is large, the animals at the slow end of the distribution will be considered slow learners (for options regarding keeping these animals in the study versus eliminating them, see Time Considerations). The particular method used to facilitate learning in these animals will depend upon the specific contingencies in effect at the time and on the animal's training history. For example, correction trials can provide a powerful means to shape the appropriate response and are recommended for the discrimination and matching tests described here. However, some animals will learn a response strategy that depends upon the use of correction trials and avoids the necessity of learning the discrimination planned by the experimenter. This strategy involves pressing one lever on the initial presentation of a trial; if the response is correct, the food is taken. If it is incorrect, the rat simply responds on the other lever on the next presentation (the correction trial). Because the trial conditions are repeated, this strategy guarantees that this second response will be reinforced. Across a session, strict adherence to this strategy will

yield a reinforcement ratio of 66.7%, more than enough to sustain responding. Thus, an animal whose accuracy on a two-choice problem with correction trials plateaus at 60% to 70% should be suspected of having adopted this strategy. The obvious solution is to remove the correction trial contingency to obviate its benefit to the animal.

Response biases may develop in rats that are challenged by a difficult discrimination. A frequent bias involves position: a rat may choose one lever and respond preferentially on it, accepting a reduced rate of reinforcement. An effective strategy to deal with these biases is to alter the proportion of trial types away from the animal's bias. For example, if an animal learning the matching rule develops a left bias, decrease the proportion of trials in which left is the correct matching response, thus reducing the payoff associated with that bias. Similarly, if an animal learning the combined matching and discrimination protocol has high accuracy in one component and low accuracy in the other, then reduce the proportion of trials in the preferred component, thereby selectively reinforcing improvement in the nonpreferred component.

In some cases, animals may have difficulty with a discrimination and not show evidence of a bias or an alternative response strategy. It may be beneficial for these animals to make the discriminative stimulus more salient by, for example, increasing the brightness of a light or reducing the background illumination. Rarely, it may be necessary to cause the light to flash to enhance its effectiveness as a discriminative cue.

Anticipated Results

Autoshaping

Frequencies of lever presses should increase across trial blocks, reaching an asymptote of ten presses per ten-trial block within four to five sessions. As shown in Fig. 11.4.4, acquisition curves for individual rats will vary primarily with respect to the trial block when responding begins; once a rat begins to press the lever, it

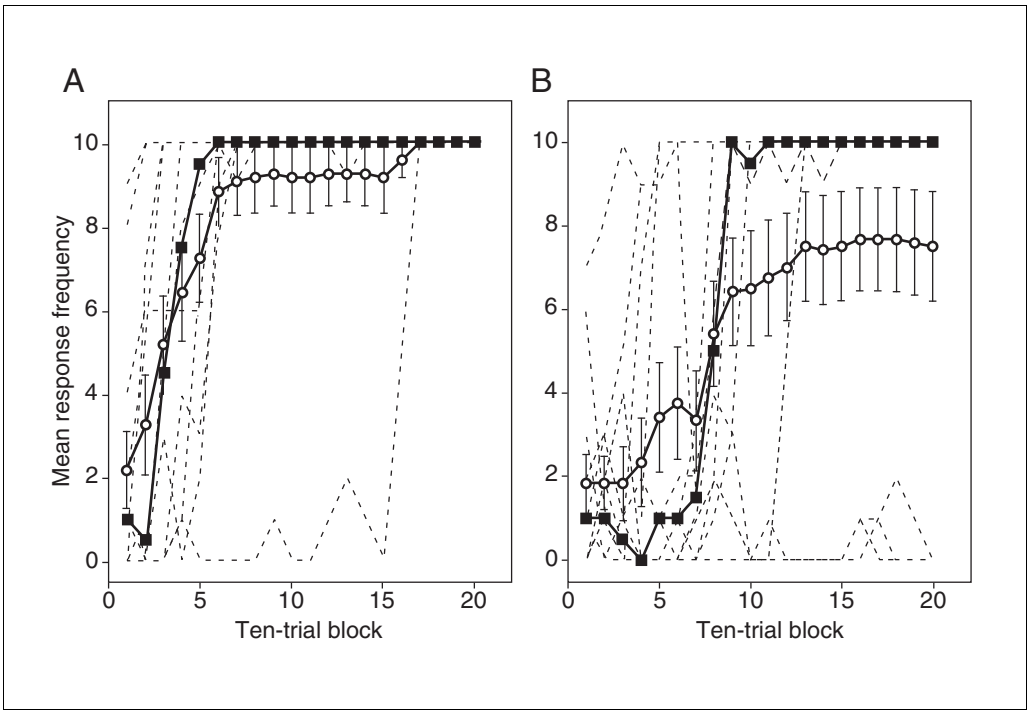

Figure 11.4.4 Representative data from an autoshaping experiment, showing the interanimal variability among male (**A**) and female (**B**) rats. The frequency of lever presses per ten-trial block is plotted as a function of trial block. Individual acquisition curves from each of twelve animals of each sex are shown as dotted lines. The means ± SEM (open circles) and medians (closed squares) are superimposed on the individual animal data (dotted lines). Note that the males tend to reach asymptotic frequencies of pressing sooner than females, that females are more variable in the time at which they begin to press, and that the slopes of the lines for animals that begin to press late are not less steep than for those that begin to press early. In other words, the rate of acquisition of responding does not depend upon the time at which the animal begins to respond.

will generally (but not always) do so quickly and reliably thereafter. Thus, the group average acquisition curve reflects averaging across time (trial block) and can be quite variable. This variability, coupled with the between-subject nature of the experiment and the reticence of 10% to 15% of rats to press the lever at all, increases the number of animals necessary for detecting treatment effects. Because of this variability, the data are often better summarized in terms of medians rather than means (Fig. 11.4.4). In some cases, each subject's acquisition curve can be aligned with respect to the block in which the first lever-press response occurs, and acquisition can be described as the slope with which each rat's response frequency approaches its asymptote.

Note also that some interanimal variability can be eliminated by requiring the rat only to touch the lever, instead of pressing it (Messing and Sparber, 1985), because more animals will touch the levers than will press them under the contingencies described. Two disadvantages of using touches instead of presses are (1) that reliable touch-detecting electric circuitry is needed and (2) that the animals are not necessarily pressing the lever when the study is finished, which reduces their usefulness for future assessments.

Repeated acquisition

Error frequencies should decline from ~4/trial on trial 1 of each session to an asymptote below 1/trial by trial 5 (Fig. 11.4.5). This within-session error reduction shows that learning is occurring and can be repeated in each daily session. Note that because each animal begins each session with about the same error frequency, interanimal variability is much reduced compared to the autoshaping data (Fig. 11.4.4). Interpretation of these data is discussed by Bushnell and Angell (1992).

Delayed matching to position

Choice accuracy should decline from near 100% at the shortest delay to ~60% at the longest (chance performance for this two-choice task is 50%). Typical data are shown in

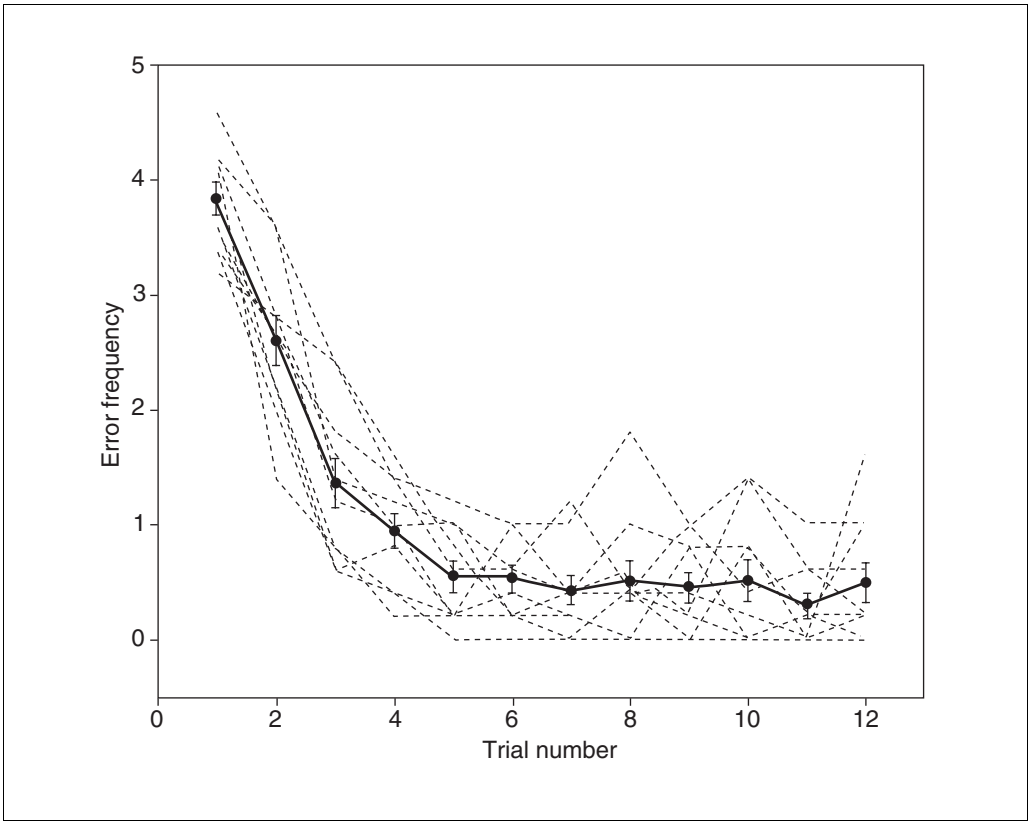

Figure 11.4.5 Representative data from a twelve-trial session of repeated acquisition in the eight-arm radial maze. The number of errors is plotted for each of ten rats (dashed lines) across twelve trials in a single test session. The mean ± SEM is also plotted (filled circles and solid line). The within-session reduction in error frequency indicates that learning is occurring. Note that each animal begins the session with ~4 errors on trial 1, that the error frequencies fall to ≤1 by about trial 5, and that the values are reasonably normally distributed around the mean at each trial.

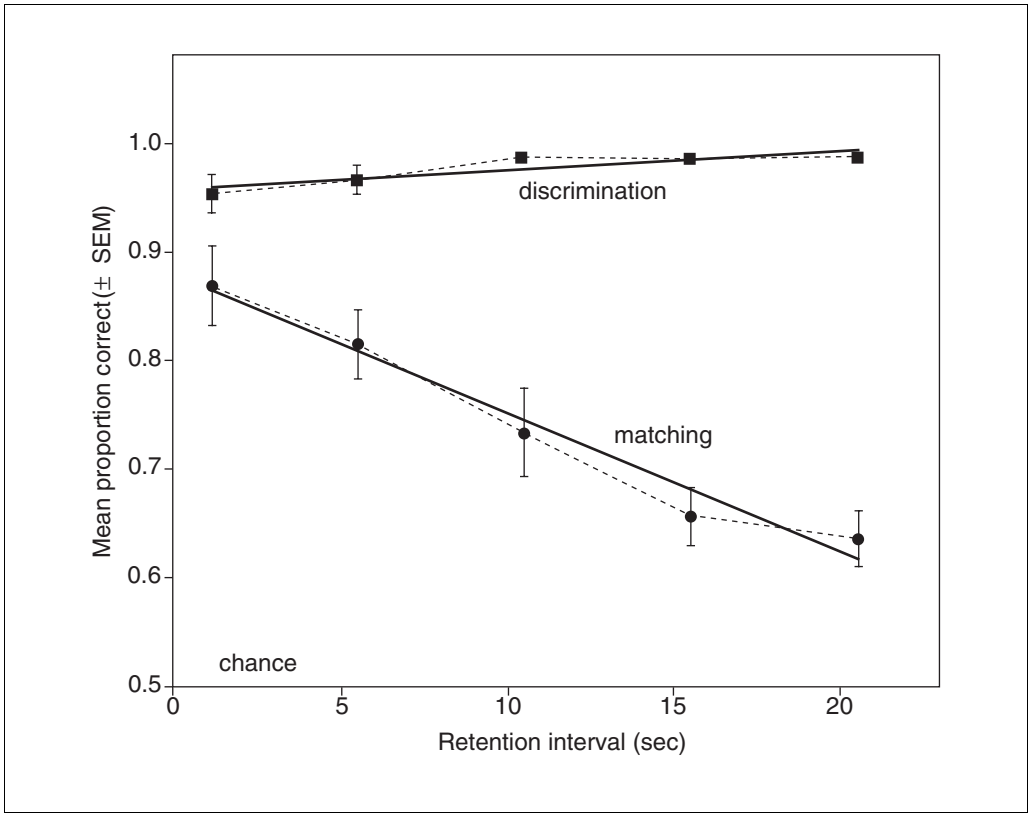

Figure 11.4.6 Representative data from a session of combined delayed matching to position (100 trials) and visual discrimination (100 trials). Points are mean choice accuracy (± SEM) for eight male rats as a function of delay on matching trials (circles), or across delays on discrimination trials (squares). The heavy lines show best-fit linear regressions through the five data points of each trial type. Note that matching accuracy falls across delays, reflecting the fact that the rats forget the trial-dependent sample information across time (working memory). Discrimination accuracy does not fall with increasing delay because the stimulus controlling discrimination accuracy (the cue light) is the same on all trials; thus, accuracy on these trials measures reference memory. Chance accuracy is 0.5 in this two-choice task.

the lower curve in Figure 11.4.6. Delays can be adjusted to establish an appropriate gradient for a given study. If the treatment of interest is expected to reduce accuracy, set the longest delay to produce no less than 70% accuracy; use a longer delay if an increase in accuracy is anticipated. If many sessions are run, expect gradual improvement in accuracy over time.

The theoretical form of the retention gradient is a negatively accelerated exponential. However, with a limited range of delay values, a linear approximation typically fits averaged data well. Linearly spaced delay values tend to produce quasi-linear retention gradients (e.g., Bushnell et al., 1993). Nonlinear gradients have also been modeled (e.g., White, 1985); the theoretical soundness of these gradients must be considered against the simplicity of linear gradients and the ease of their calculation. In any case, both approaches yield similar conclusions regarding the effects of drugs on this task.

Fitting a function to the data points provides the analytic advantage of reducing the number of statistical comparisons that are needed to test for changes in the gradient to two: slope and intercept. In addition, these parameters have interpretive value. The intercept can be considered the probability of encoding the sample stimulus at the beginning of the trial, and the slope the rate at which that information is lost over time (Heise and Milar, 1984; Bushnell, 1990; Paule et al., 1998).

If discrimination trials (see Support Protocol) are also run in this task, the accuracy should be relatively independent of delay (top curves in Fig. 11.4.6). A slight positive slope (increasing accuracy with delay) is not uncommon when matching and discrimination trials are intermixed in the same sessions. This pattern reflects interference with discrimination choice accuracy by the matching response rule, the effect of which decreases across delay, yielding

increased discrimination accuracy with increasing delay.

Sustained attention

When all values of signal strength are included, the gradient of accuracy should range from near chance performance with the weakest signals to near 100% accuracy with strongest signals (Fig. 11.4.7). Chance performance can be defined as the false alarm rate (i.e., the rate of pressing the signal lever during a blank trial), which should range from 5% to 20%, and not vary appreciably across signal intensity. If *P*(hit) at the lowest intensity is too high, increase the background illumination, which should be set during training to a level ≤0.1 times the brightest signal intensity. Interpretation of these data is discussed in Bushnell et al. (1997). *P*(hit) values for each rat at each signal intensity can also be corrected for "guessing" according to the following formula: $P^*(\text{hit}) = [P(\text{hit}) - P(\text{fa})]/[1 - P(\text{fa})]$ (Green and Swets, 1974). This correction assumes that the true proportion of hits, $P^*(\text{hit})$, is elevated by an amount proportional to *P*(fa), and removes that contribution from the observed *P*(hit).

Multiple fixed-interval/fixed-ratio schedule

Typical response patterns on the MULT FI/FR schedule were detailed by Ferster and Skinner (1957), whose data are reproduced by Lattal (1991); examples of drug effects on multiple schedules in rats can be found in Brocco and McMillan (1983). Note that the response rate is high and constant prior to reinforcement in the FR components; by contrast, responding begins slowly and increases with time prior to reinforcement in the FI components (the FI scallop). A clear and thorough analysis of the effects of two pesticides on a MULT FI 5-min/FR10 schedule is provided by Moser et al. (1987).

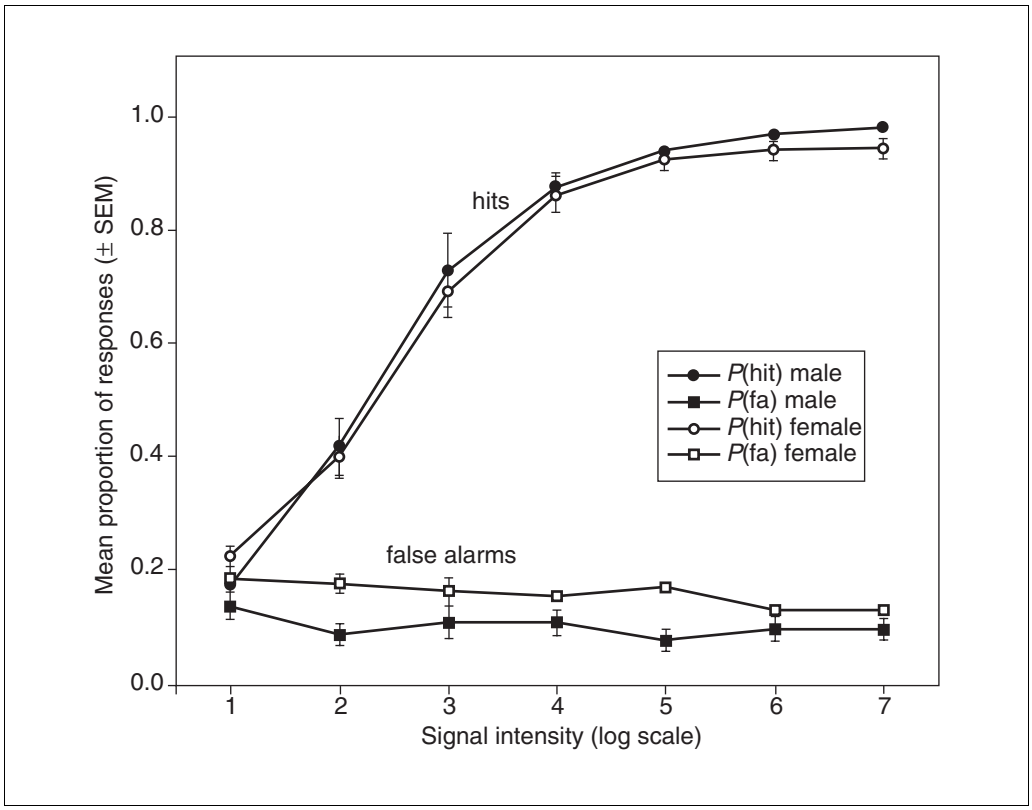

Figure 11.4.7 Representative data from a session of 300 trials of signal detection. These data show that *P*(hit) (the probability of a correct response on a signal trial; open or filled circles) increases with increasing signal intensity (in arbitrary units), whereas *P*(fa) (the probability of an incorrect response on a blank trial; open or filled square) does not vary with signal intensity. *P*(fa) provides an estimate of the probability of guessing (10% to 20%). Values are mean ± SEM for twelve animals per sex. Note that females perform slightly less well than males, primarily because of a higher false alarm rate. A decrease in attention is indicated by a decrease in *P*(hit) across all intensities, or an increase in *P*(fa), or both. A rightward shift in the *P*(hit) function—i.e., reduced *P*(hit) only at intermediate signal intensities—in the absence of an elevated *P*(fa) indicates an increase in threshold for detecting the signal, suggesting sensory impairment.

Time Considerations

Training animals is not a rapid process and achieving the baselines described in this unit requires many sessions. It is important that each animal reach the same criterion of proficiency at each stage of training, and there will necessarily be those animals that reach criterion quickly and those that reach it slowly. This fact has different consequences, depending upon whether untreated animals are being prepared for an experiment after baseline has been achieved, or whether the effects of a previous treatment with a test agent are being assessed.

In training untreated animals, there are two options for dealing with slow animals: (1) they can be retained in the study with additional time allotted for their training, or (2) they can be eliminated to speed up the process. The first option has the obvious disadvantage of taking more time, but preserves the representativeness of the sample of rats selected for the study; in other words, this sample will more accurately represent the population of all rats and will increase the generality of the results of the study. The second option restricts generalization to those rats that learn quickly, introduces a selection bias against those individuals potentially more at risk from the effects of chemical agents, and may require replacing some rats to preserve group sample sizes.

When assessing the effects of a prior treatment, slow learning must be considered as a possible result of that treatment. If some animals are to be segregated on the basis of their performance, criteria for segregation must be developed carefully and applied strictly to all treatment groups.

Autoshaping

After two weeks of acclimation to the animal facility and induction of motivation (hunger) prior to actual testing, an autoshaping study can be completed in two weeks. The first week should be spent handling the animals and acclimating them to transfer cages, test chambers, and the food pellets that will be delivered as reinforcers. The animals should be completely acclimated by the end of 1 week. Autoshaping should be accomplished during the second week, although it would be wise to allow part of a third week in case some animals acquire slowly. Each test session will last ~60 min (depending primarily upon the ITI; see Critical Parameters).

Repeated acquisition

A stable baseline of within-session error reduction should require 20 to 25 training sessions, including those described in *UNIT 11.3*. With 10 trials/session and a 10-sec ITI, each session should last no more than 10 min.

Delayed matching to position

Training to a stable baseline of DMTP performance requires ~40 test sessions (8 weeks at 5 days per week). If the visual discrimination component is also used, an additional 20 sessions (4 weeks) should be allowed to train the discrimination and integrate it into the complete schedule. DMTP test sessions of 100 trials and a maximum delay of 20 sec will require 45 to 50 min per day. To add visual discrimination, the number of trials should be doubled and each session should last 1.75 hr.

Sustained attention

Training to a stable baseline of performance in the sustained-attention task requires ~50 test sessions (10 weeks at 5 days per week). The length of each test session will depend upon the trial rate and the number of trials presented. A 300-trial session at 5 trials/min requires 60 min.

Multiple fixed-interval/fixed-ratio schedule

A simple ratio schedule can be escalated to FR10 in a matter of a week after the rat has learned to press the bar on the FR1 schedule. In contrast to mice, which will eagerly perform high ratios, rats may not perform ratios above 20 to 30 reliably (ratio strain). Performance of interval schedules may stabilize more quickly with respect to measures of patterning (e.g., index of curvature), although large differences between animals in response rate are common. Six to ten weeks (30 to 50 sessions) should be allowed for stability on a typical multiple schedule, although this estimate will depend upon the training history and stability criteria used. Daily sessions should require 30 to 45 min.

Key References

Bushnell, 1998. See above.

This review article describes a large number of approaches to the assessment of attention in experimental animals, primarily rodents. It also discusses general issues regarding the assessment of hypothetical cognitive processes, and the validation of procedures for conducting those assessments.

Cohn and Paule, 1995; Cohn et al., 1996. See above.

This pair of reviews thoroughly covers the realm of repeated acquisition of response sequences, providing a history of the area and background information regarding the approach and implementation of repeated acquisition methods for assessing learning. The first paper reviews the behavioral phenomena and the second the influence of drugs and toxic chemicals on these behaviors.

Heise and Milar, 1984. See above.

This review chapter very nicely lays out the rationale and taxonomy of procedures for assessing learning and memory in animals. The section on memory is particularly useful for understanding and interpreting tests of working memory (e.g., DMTP).

Iversen, I.H. and Lattal, K.A. (eds.) 1991. Experimental Analysis of Behavior, Parts 1 and 2. Elsevier/North-Holland, Amsterdam.

These two volumes discuss clearly and in detail behavioral methods for quantifying and analyzing the behavior of experimental animals. The contributions provide a wealth of information regarding basic techniques for handling and testing animals, and for quantifying patterns of behavior engendered by a wide variety of reinforcement schedules.

Parasuraman, 1984. See above.

This review chapter detailed current knowledge of sustained attention in humans. Much of the development of sustained attention methods in animals is based upon knowledge of human performance of these tasks and the variables that affect it.

Robbins and Everitt, 1995. See above.

This chapter very clearly summarizes current knowledge about the role of the ascending arousal systems in the CNS on attention in animals, as assessed primarily with the 5-choice serial reaction-time test. It is a good general reference for understanding the neurobiological substrates of readiness and directed attention.

Schwartz and Gamzu, 1977. See above.

This chapter reviews various phenomena of autoshaping, primarily in terms of the associative processes (operant and respondent) that support this unique form of conditioning. The chapter provides a readable presentation of many of the variables found to influence acquisition and maintenance of sign-tracking behaviors, the kinds of behaviors that are supported by autoshaping contingencies, generalization to automaintenance schedules, and the theoretical analysis of the phenomenon.

Testing for Organophosphate-Induced Delayed Polyneuropathy

Organophosphorus compounds may cause two distinct types of toxicity: acute cholinergic toxicity and organophosphate-induced delayed polyneuropathy (OPIDP). Evaluating the capability of a compound to cause OPIDP requires treatment of animals (hens) with that compound and measurement of biochemical, clinical, and, when possible, morphological parameters. Generally, hens are administered single doses of organophosphate (OP) and, if necessary, are treated to prevent cholinergic toxicity. Determination of the activity of the putative molecular target for OPIDP—neuropathy target esterase (NTE)—in brain, spinal cord, and peripheral nerve is performed after 1 or 2 days, in association with determination of acetylcholinesterase (AChE) activity. AChE is the target of the acute toxicity, and measurement of its inhibition compared to that of NTE is necessary to assess the potential of a given compound to preferentially cause either toxicity. If high AChE inhibition occurs at doses not causing NTE inhibition, the compound is unlikely to cause OPIPD because animals will not survive the higher doses required. Observation for clinical signs of OPIDP is carried out for up to 3 weeks after treatment, and morphological assessment of selected regions of the central and peripheral nervous system might be performed after 3 weeks (see Basic Protocol 1). Because OPIDP development is associated with >75% NTE inhibition, in the case of negative clinical and morphological findings, measurement of NTE activity (see Basic Protocol 2) gives an indication of the compound's potential to cause OPIDP at higher doses.

Single doses of compounds that might potentially protect from OPIDP (e.g., phosphinates, carbamates, or sulfonyl fluorides) are usually administered to hens 4 to 24 hr before administration of an effective dose of a neuropathic OP. Determination of NTE activity after treatment with these potentially protective compounds is performed at the same time point as that of the administration of the neuropathic OP. More than 30% NTE inhibition is expected to be associated with protection from a subsequent challenging dose of a neuropathic OP. Clinical and morphological observations are carried out as above. When testing a new OP, a control group of hens is pretreated with a known protective compound.

In vitro screening tests might also be useful in identifying NTE inhibitors when the parent compound does not need metabolic activation (see Alternate Protocol). Comparison with their ability to inhibit AChE will also be helpful in assessing the relative potency of the compound to preferentially cause OPIDP or acute cholinergic toxicity.

NOTE: OPs and other esterase inhibitors are generally dangerous compounds (neurotoxicants), and the pure material should be handled with care, using gloves in a chemical fume hood. In case of a spill, clean the area with a 4% to 10% solution of NaOH in 50% water/50% industrial methylated spirits, which should always be available.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

INDUCTION AND EVALUATION OF OPIDP IN HENS

BASIC PROTOCOL 1

This procedure is used to assess the potential of an OP to cause OPIDP in vivo. Neuropathic compounds are usually administered in a single dose, and are expected to cause clinical signs of OPIDP within 8 to 15 days after dosing. Protective compounds (also NTE inhibitors) are administered to a test group of the animals before the neuropa-

Current Protocols in Toxicology (1999) 11.5.1-11.5.14

thic OP. Assessments are made on the basis of a scoring system which classifies the animals according to the severity of the clinical findings. Hens are sacrificed and perfused ~3 weeks after treatment, and assessments are made on the basis of another scoring system,which classifies the animals according to the severity of the morphological lesions.

Materials

Adult domestic laying hens (>6 months of age, preferably 8 to 14 months), standard size, breeds, and strains
Protective compound: e.g. phenylmethylsulfonyl fluoride (PMSF)
Organophosphate to be tested
Saline or glycerol formal (or other vehicles such as dimethylsulfoxide or corn oil)
20 mg/ml atropine sulfate (e.g., Aldrich) in saline
0.1 mg/ml eserine hemisulfate (e.g., Sigma) in saline
200 mg/ml pyridine-2-aldoxime-1-methanesulfonate (e.g., Sigma; or other oxime) in saline
50 mg/ml ketamine in saline
Halothane
Oxygen
Heparin
100 mM sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
4% paraformaldehyde, pH 7.4 (see recipe)
4% formalin: dilute 40% commercial formalin solution to 4% with 100 mM sodium phosphate buffer, pH 7.4

Animal house, equipped to rear adult hens under conditions that permit free mobility
Gavage needles
21/22-G needles for intraperitoneal, subcutaneous, and intramuscular injection
Vaporizer for anesthetic gases
Anesthetizing box (see recipe)
Wooden dissecting board appropriate for hens
Dissecting equipment including:
  Scalpels
  Forceps
  Bone cutter
  Heavy and small scissors
Perfusion apparatus: peristaltic pump (50 to 200 ml/min) with connecting tubes and a cannula (a gavage needle can be used)
Large (>5 liter) container for the perfusion solution, with faucet on bottom
5- to 50-ml plastic containers with leak-proof caps to store tissues sampled for histology

Treat animals with compounds to be tested

1. Fast hens overnight if the oral route of administration is to be used.

2. Dissolve compounds (protective compound and organophosphate) in the appropriate vehicle (saline if water-soluble; otherwise dissolve in appropriate solvent e.g., glycerol formal, corn oil, or DMSO). Prepare solution to have the desired dose administered in the following volumes of administration.

   Gavage: 1 ml/kg
   Subcutaneous injection: 0.2 ml/kg (if the test compound is poorly soluble, use up to 1 ml/kg and two sites of injection, preferably in the anterot-horacic region)

The choice of the dose of the compound under test can be based on preliminary experiments where NTE has been measured (see Basic Protocol 2). The dose should cause >70% NTE inhibition or the maximum attainable inhibition. If there is significant acute cholinergic toxicity (whose signs include mitosis, hypersalivation, diarrhea, muscle fasciculation or, if severe, paralysis), adequate treatment (step 5) will significantly increase the LD_{50}.

3. Assign animals to experimental groups including at least the following:

   a. Control (vehicle-treated) group.
   b. A group to be treated with one dose level of the compound under study.
   c. A group be pretreated with a protective compound (e.g., 30 mg/kg PMSF, subcutaneously, 24 hr before dosing, as in group "b").

   Three animals per group are generally sufficient for a yes/no evaluation. Five or more are required to estimate a dose-response relationship.

4. Pretreat group "c" with the protective compound at the appropriate time interval before administration of the test compound, with the desired doses administered in the volumes listed in step 2. Pretreat groups "a" and "b" with vehicle.

5. If treatment against cholinergic toxicity is required, inject the hens intraperitoneally, 10 min before administration of the test compound, with 1 ml/kg of a 20 mg/ml solution of atropine (20 mg/kg) and 1 ml/kg of a 0.1 mg/ml solution of eserine (0.1 mg/kg).

6. Treat groups "b" and "c" with the organophosphate, with the desired doses administered in the volumes listed in step 2. Treat group "a" with vehicle only.

7. Depending on severity of cholinergic toxicity, inject again with atropine (after dosing with the test compound) intraperitoneally, at the same dose as in step 5, as needed, and with 0.5 ml/kg of a 200 mg/ml solution of pyridine-2-aldoxime-1-methanesulfonate (100 mg/kg), every 8 to 12 hr, intramuscularly, either in the anterothoracic muscles (preferably) or in the muscles of the thigh.

   Duration of treatment with atropine and pyridine-2-aldoxime-1-methanesulfonate will depend on duration of cholinergic signs. These can be estimated in a pilot experiment which includes a prolonged (2- to 4-day) observation of the animals and/or measurement of the time course of AChE inhibition. More than 60% inhibition is associated with signs of toxicity; death occurs at >95% AChE inhibition.

Observe animals for clinical symptoms

8. Observe the hens in an open space, not in the cage, every other day for up to 21 days after treatment. After 2 to 3 min of free walking, evaluate the animals according to the following 0- to 8-point scoring system:

   0: No defects in posture, standing ability, or walking performance
   1: Minor changes in walking performance
   2: Clear changes in walking performance with some falling of the hind end
   3: Walking limited to short steps with frequent falling of the hind end
   4: Still able to walk, but often remain sitting on metatarsus
   5: Unable to walk, sitting on metatarsus, but able to stand when lifted
   6: Unable to stand when lifted
   7: Unable to stand, wings drop
   8: Unable to stand, extended legs and wings.

   Onset is usually between days 8 and 14 and peak score is reached by days 15 to 18.

   It might be necessary to sacrifice the hens for humane reasons when OPIDP is severe (grades 6 to 8) because they cannot feed or drink.

9. *Optional:* Evaluate the leg-retraction reflex by placing a hand under the breast and lifting the hen, observing whether the animal retracts its leg from the dangling position.

   A normal animal retracts its leg from the dangling position. If peripheral nerve lesions are present, the leg will remain extended and flaccid. Assess this reflex before dosing, since a few hens may have spontaneously lost it and therefore should not be used in the test.

Perform morphological assessment

10. At the end of the observation period, ~21 days, deeply anesthetize hens with an injection of 1 ml/kg ketamine (50 mg/kg intraperitoneally) followed by inhalation of 3% to 4% halothane with 1.5 liters/min oxygen in an anesthetizing box.

    CAUTION: *Perform the procedure in a chemical fume hood, and use gloves, goggles, and a mask.*

11. Remove the hen from the anesthetizing box and secure it on its back on a wooden board by tying the spread legs to the corners of the board with ropes, and pinning the head and the spread wings with needles.

12. Carefully open the abdomen with a scalpel just below the rib cage. Make and incision in the middle, below the sternum and along the rib cage, of ~10 cm, taking care not to cut the liver, which is just below the surface.

13. Cut the rib cage laterally with scissors and reflect the sternum backwards (the bone is very hard) with the attached distal part of the ribs.

14. Expose the heart and inject 1500 to 2000 U heparin into the heart. Cut the pericardium, then the wall of the right atrium, and finally the apex of the left ventricle.

15. Start the pump (100 to 150 ml/min) and insert the cannula in the left ventricle. Clamp the cannula.

    The tip of the cannula must be within the heart to obtain optimal perfusion.

16. Perfuse for ~1 min with 100 mM sodium phosphate buffer, pH 7.4, then switch to paraformaldehyde solution until the animal is stiffened, or until ~4 liters of perfusion solution (15 to 20 min in total) have been perfused.

17. Dissect the sciatic nerve (n. ischiadicum) and its main branches, the peroneal (n. peronaeus) and the tibial (n. tibialis) nerves to the ankle, the lumbo-sacral (easily recognizable by the presence of the glycogen body), the mid-thoracic and the upper cervical spinal cord, and the brain.

    Avoid tissue drying during dissection by bathing exposed tissues with 4% paraformaldehyde fixative. Manipulate tissues as little as possible with forceps. See Koch (1973) for anatomical details.

18. Keep the samples in 4% formalin, in plastic containers with leak-proof caps until processed.

19. Score axonal lesions in peripheral nerves, spinal cord tracts, cerebellum, and medulla oblongata (other areas of the brain are optional) according to the following semi-quantitative scoring system:

    0: No abnormality
    1: Occasional disruption of axons (one to four disruptions in any spinal cord slide, one or two disruptions in any peripheral nerve slide) with rare myelin abnormalities (these might be found in control animals)

2: Fragmentation/disruption of few axons (five or more in any spinal cord slide, three or more in any peripheral nerve slide) with minimal myelin changes (spheroids)
3: Extent of damage greater than in 2; changes as described in 4, but not as widespread
4: Widespread fragmentation/disruption of many axons, with variation in thickness; distortion/fragmentation of myelin sheaths; glial/Schwann cell response.

See Bickford and Sprague (1983) and Prentice and Roberts (1983) for details of scoring procedure, and Sprague et al. (1980) for description of lesions.

DETERMINATION OF NEUROPATHY TARGET ESTERASE ACTIVITY

BASIC PROTOCOL 2

This protocol describes a spectrophotometric assay to determine the activity of neuropathy target esterase (NTE) in nervous tissues. NTE activity is determined as the phenyl valerate (PV) esterase activity that is resistant to inhibition by paraoxon (a non-neuropathic organophosphate) and sensitive to inhibition by mipafox (a neuropathic organophosphate). Tissue homogenates are preincubated with these inhibitors prior to PV addition. Hydrolysis is stopped by protein denaturation (and sometimes precipitation) followed by colorimetric measurement of the phenol content of the sample.

Materials

Adult domestic laying hens (>6 months of age, preferably 8 to 14 months), standard size, breeds, and strains
Organophosphate (OP) to be tested, in appropriate solvent (see Basic Protocol 1)
Tris/EDTA buffer (see recipe), ice-cold
10 mM mipafox stock solution (see recipe)
10 mM paraoxon stock solution (see recipe)
15 and 30 mg/ml phenyl valerate (PV) stock solutions (see recipe)
0.03% (v/v) Triton X-100 in double-distilled water
SDS/AAP solution (see recipe)
0.4% (w/v) $K_3Fe(CN)_6$ in double-distilled water (stable for months at room temperature)
Modified Koenig buffer: 0.7 M glycine/0.05 M triethylamine·HCl, pH 6.0 (store up to 2 months at 4°C)
0.35 M perchloric acid/0.36 M sodium acetate
Tris/AAP buffer (see recipe)

Guillotine
Forceps
Scalpel
Polytron homogenizer (Brinkmann) with PTA 10S and 7S sondes (for brain and spinal cord, a glass-Teflon Potter-Elvehjem homogenizer can be used; for the peripheral nerve this might pose some problems and require more time)

NOTE: All procedures performed at room temperature unless otherwise specified.

Dose, sacrifice, and dissect hens

1. Administer OP to the hens (see Basic Protocol 1)

   Give the compound used to protect from OPIDP (e.g., PMSF) alone if its (protective) effect on NTE is to be tested.

2. Sacrifice hens with a guillotine, generally 24 hr after dosing.

   Three animals per group are generally sufficient to determine a dose-response relationship. Timing of sacrifice may change depending on the toxicokinetics of the compound under study.

3. Remove brain, spinal cord (lumbo-sacral), and sciatic nerves with their two major branches, down to the ankle (see Basic Protocol 1, step 17). Put tissues in ice-cold Tris/EDTA buffer.

Determine NTE

For brain and spinal cord

4a. Remove fat, meninges, and vessels. Weigh the tissues. Prepare a 10% (w/v) homogenate in Tris/EDTA buffer using a Polytron (with PTA 10S sonde, at speed 7, for 10 sec). Dilute the homogenate (for brain 1:15; for spinal cord 1:10) with Tris/EDTA buffer.

5a. Prepare paraoxon and mipafox working solutions as follows.

Paraoxon: mix 0.1 ml of 10 mM stock solution with 6.15 ml Tris/EDTA buffer.
Mipafox: mix 0.1 ml of 10 mM stock solution with 4.9 ml Tris/EDTA buffer.

6a. Assemble reaction mixtures as described in Table 11.5.1 and incubate 20 min at 37°C.

7a. Prepare working suspension of PV by adding 1 vol of 15 mg/ml PV stock solution to 30 vol of 0.03% Triton X-100. Add 1 ml of the suspension to each tube and incubate brain 15 min or spinal cord 25 min at 37°C.

The substrate that will be added to the tubes is actually a white, cloudy dispersion rather than a solution.

8a. Terminate reactions by adding 1 ml of SDS/AAP solution to each tube, then add 0.5 ml of homogenate to tube 3. Mix thoroughly and add 0.5 ml of 0.4% $K_3Fe(CN)_6$ solution to each tube. Wait at least 3 min, then measure absorbance at 510 nm.

The color is stable for at least 30 min. Under these conditions, the molar extinction coefficient (ε_{510}) for phenol (the hydrolysis product of PV) is ~13,900 M^{-1} cm^{-1}.

9a. Calculate activity in each tube according to the following equations.

Brain:

$$\frac{OD_{510}}{13{,}900}\times\left(3.5\times10^{-3}\right)\times\frac{1}{15}\times\frac{1}{0.0033}\times10^{6}$$

$$=(\mu\text{mol PV hydrolyzed})\cdot\text{min}^{-1}\cdot(\text{g tissue})^{-1}$$

Spinal cord:

$$\frac{OD_{510}}{13{,}900}\times\left(3.5\times10^{-3}\right)\times\frac{1}{15}\times\frac{1}{0.0033}\times10^{6}$$

$$=(\mu\text{mol PV hydrolyzed})\cdot\text{min}^{-1}\cdot(\text{g tissue})^{-1}$$

where 3.5×10^{-3} is the total reaction volume in liters, 15 and 25 min are the incubation times respectively, for brain and spinal cord, and 0.0033 and 0.005 g are the weights, respectively, of brain and spinal cord tissue added to the reactions on the basis of the dilutions made in step 4a and the aliquots of homogenate added to the reactions.

10a. Calculate NTE activity as the activity measured in tube 1 minus that in tube 2.

The blank (tube 3) is not used in the calculations, but it is added for control of activity in tube 2 and development of color.

Table 11.5.1 Preparation of NTE Reaction Mix for Brain and Spinal Cord

Tube	Paraoxon working solution[a]	Tris/EDTA buffer	Mipafox working solution[b]	Homogenate
1	0.25 ml	0.25 ml	—	0.5 ml
2	0.25 ml	—	0.25 ml	0.5 ml
3 (blank)	0.25 ml	—	0.25 ml	—[c]

[a]Refers to working solution prepared in step 5a; final concentration in each tube will be 40 µM.

[b]Refers to working solution prepared in step 5a; final concentration in each tube will be 50 µM.

[c]Add 0.5 ml of homogenate at step 8a, after the PV solution.

Table 11.5.2 Preparation of NTE Reaction Mix for Peripheral Nerve

Tube	Paraoxon working solution[a]	Tris/EDTA buffer	Mipafox working solution[b]	Supernatant
1	0.05 ml	0.05 ml	—	1.0 ml
2	0.05 ml	—	0.05 ml	1.0 ml
3	0.05 ml	—	0.05 ml	—[c]

[a]Refers to working solution prepared in step 5b; final concentration in each tube will be 40 µM.

[b] Refers to working solution prepared in step 5b; final concentration in each tube will be 50 µM.

[c]Add 1 ml of supernatant at step 8b, after the PV solution.

For peripheral nerve

4b. Cut the nerve into 1 to 1.5-cm segments and immerse in modified Koenig buffer at 0°C for ~2 hr. Remove the fat and collagen and desheath the nerve with fine forceps and a scalpel. Rinse the tissue in water to remove excess glycine, gently dry on filter paper, and weigh. Using a Polytron (PTA 7S sonde, at speed 7, three times for 10 sec), prepare a 40 mg/ml homogenate in Tris/EDTA buffer. Centrifuge for 10 min at 1000 × *g*, 4°C, and use the supernatant for the assay.

Tissues can be frozen after weighing (the enzymatic activity is stable for months at –80°C if tissues are frozen within hours of sampling). Loss of activity is expected if homogenates are frozen.

5b. Prepare paraoxon and mipafox working solutions as follows.

Paraoxon: mix 0.1 ml 10 mM stock solution with 1.04 ml Tris/EDTA buffer
Mipafox: mix 0.1 ml of 10 mM stock solution with 0.81 ml Tris/EDTA buffer

6b. Assemble reaction mixtures as described in Table 11.5.2 and incubate 20 min at 37°C.

7b. Prepare a working suspension of PV by adding 1 vol of 30 mg/ml PV stock solution to 30 vol of 0.03% Triton X-100. Add 1 ml of this suspension to each tube and incubate 35 min at 37°C.

8b. Terminate the reaction by adding 1 ml ice-cold perchloric acid/sodium acetate solution, then add 1 ml of the supernatant obtained in step 4b to tube 3. Mix thoroughly, keep in ice-cold bath for 5 to 10 min, then centrifuge ~5 min at 1000 × *g*, 4°C.

9b. Place 2 ml of the supernatant in a fresh tube, then add 1 ml of Tris/AAP buffer and 0.5 ml of 0.4% $K_3Fe(CN)_6$ solution. Measure absorbance at 510 nm.

Under these conditions, the ε_{510} for phenol (the hydrolysis product of PV) is ~13,900 M^{-1} cm^{-1}.

10b. Calculate activity in each tube according to the following equation:

$$\frac{OD_{510}}{13{,}900} \times \left(3.5 \times 10^{-3}\right) \times \frac{3.1}{2} \times \frac{1}{35} \times \frac{1}{0.04}$$

$$= (\mu\text{mol PV hydrolyzed}) \cdot \text{min}^{-1} \cdot (\text{g tissue})^{-1}$$

where 3.5×10^{-3} is the total reaction volume in liters, 3.1/2 is the dilution factor, 35 min is the incubation time, and 0.04 is the weight of tissue added.

11b. Calculate NTE activity as the activity measured in tube 1 minus that in tube 2.

The blank (tube 3) is not used in the calculations, but it is added for control of activity in tube 2 and development of color.

ALTERNATE PROTOCOL

DETERMINATION OF THE IN VITRO INHIBITORY POWER OF A COMPOUND ON NTE

This protocol can be applied to compounds that do not need metabolic activation. It provides information on the inhibitory power of the compound on NTE which, in combination with the inhibitory power on AChE, gives an indication of the potency to cause OPIDP relative to acute toxicity. Data might also be helpful for interspecies comparisons (including human).

Additional Materials *(also see Basic Protocol 2)*

Test compound (putative inhibitor)
Acetone

1. Prepare a 10 mM stock solution in acetone of the compound under study. Prepare working solutions in acetone at 100× the desired final assay concentration.
2. Perform steps 1 to 5a or 5b of Basic Protocol 2 (depending on the target tissue).

3a. *For fixed-time incubations:* Assemble the reaction mixtures according to Table 11.5.1 or 11.5.2 (see Basic Protocol 2, step 6a or 6b), but add 10 µl of the 100× test compound to each incubation tube (including blank) in addition to the paraoxon, buffer, and mipafox. Add homogenates and proceed as described in the remaining steps of Basic Protocol 2.

Control samples (not containing the inhibitor) should contain 10 µl acetone, although 1% acetone has no or minimal effect on NTE activity.

3b. *For a time course of inhibition:* Assemble the reaction mixtures according to Table 11.5.1 or 11.5.2 (see Basic Protocol 2, step 6a or 6b). Add 10 µl of the chosen concentration(s) of test compound at various times (0 to 20 min) after addition of homogenates to the tubes containing paraoxon, buffer, and mipafox. For each time point, proceed as described in the remaining steps of Basic Protocol 2. Calculate the percentage of activity/inhibition as compared to a control sample (10 µl of acetone alone).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

4-Aminoantipyrine, 0.5%

Prepare a 0.5% (w/v) solution of 4-aminoantipyrine (4-AAP; also called 4-aminophenazone; e.g., Sigma) in 50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*).

This solution is stable for a few months if kept in the dark at room temperature.

Anesthetizing box

Custom-prepare a 20 × 15 × 10–cm Plexiglas box with a 1-cm-diameter inlet and outlet for the anesthetic gas. Have one of the walls divided into two halves—one fixed, the other capable of being opened. Make a hole ~5 cm in diameter in the center of this wall (so that it is equally divided between the two halves and will close, stock-like, around the neck of the hen). Put a ring made of soft rubber around the hole.

To put the head of the hen into the box, open the half-wall, lay the neck on the hole and close the wall.

Mipafox stock solution, 10 mM

Dissolve 1.82 mg/ml of solid mipafox (Oryza Laboratories; 10 mM final) in Tris/citrate buffer (see recipe). This solution is stable for ~3 weeks at room temperature. Prepare the working solutions on day of use (see Basic Protocol 2, step 5a or 5b).

CAUTION: *Mipafox is a dangerous neurotoxicant. Handle solid mipafox with care using gloves under a chemical fume hood. In case of spill, clean with a 4% to 10% solution of NaOH in water/industrial methylated spirits which should always on hand. There is no significant hazard in handling small volumes of the solution.*

Paraformaldehyde solution, 4%

Dissolve paraformaldehyde to 4% (w/v) in warm 100 mM sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*). Store up to a few days at 4°C.

CAUTION: *Paraformaldehyde is a strong irritant. The operation should be performed under a chemical fume hood. Use gloves, goggles and a mask.*

Paraoxon stock solution, 10 mM

Dissolve 2.75 mg/ml paraoxon (Sigma) in dry acetone (obtained by placing a layer of anhydrous Na_2SO_4 at the bottom of the container). Close vial tightly to avoid evaporation of acetone. Store up to several months in a desiccator at room temperature.

When using small volumes of acetone it is advisable to cool the solution on ice to reduce evaporation.

In the past, certain paraoxon batches contained small amounts of an impurity [ethyl bis-(4-nitrophenyl) phosphate] that inhibits NTE; therefore, purification of paraoxon was necessary. The authors now use paraoxon from Sigma, which does not require purification.

CAUTION: *Paraoxon is a dangerous neurotoxicant. Handle pure paraoxon with care using gloves under a chemical fume hood. In case of a spill, clean with a 4% to 10% solution of NaOH in 50% water/50% industrial methylated spirits, which should always be kept on hand. There is no significant hazard in handling small volumes of the solution.*

Phenyl valerate (PV) stock solutions, 15 and 30 mg/ml

Dissolve phenyl valerate (PV; Oryza Laboratories) in redistilled dimethylformamide to concentrations of 15 or 30 mg/ml (depending on the tissue under study; see Basic Protocol 2). Store stock solutions up to 3 weeks (or longer) in the dark at room temperature. Prepare working suspension (see Basic Protocol 2, steps 7a and 7b) on day of use.

If PV contains an excessive amount of phenol (giving a blank absorbance of >0.150), remove it by washing PV in a separatory funnel in petroleum ether 60–80° with ice-cold 2 N NaOH followed by washing with water, drying over anhydrous sodium sulfate, and removal of solvent.

SDS/AAP solution

Prepare a 1% (w/v) solution of sodium dodecyl sulfate (SDS) in 50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*). Mix 950 ml of the SDS solution with 50 ml of 0.5% 4-aminoantipyrine (see recipe). Store up to several weeks in a dark glass bottle at room temperature.

SDS dissolves rather slowly; dissolution can be accelerated by warming in a 35° to 40°C water bath.

Tris/AAP buffer

Mix 95 ml of 0.5 M Tris·Cl, (pH 9.0 at 25°C; *APPENDIX 2A*) and 5 ml of 0.5% 4-aminoantipyrine (see recipe). Prepare fresh daily.

Tris/citrate buffer

Prepare 50 mM Tris base in water and 50 mM citric acid in water. Titrate the Tris solution with the citric acid to reach a pH of 6.0 at 25°C. Store up to 1 month at 4°C.

Tris/EDTA buffer

Add 4 ml of 0.5 M EDTA (ethylenediaminetetraacetic acid disodium salt, dihydrate; *APPENDIX 2A*) to 996 ml of 50 mM Tris·Cl, pH 8.0 at 25°C (*APPENDIX 2A*). Store up to 1 month at 4°C.

COMMENTARY

Background Information

This unit describes procedures for the assessment of the neuropathic potential of an organophosphate (OP) compound [(thio)phosphate, (thio)phosphonate, phosphoro(thio)amidate] or the ability of other esterase inhibitors (carbamates, phosphinates, and sulfonyl fluorides) to provide protection from induced delayed polyneuropathy (OPIDP) caused by OPs.

Single doses of certain OP compounds cause a peripheral neuropathy (OPIDP). This effect is independent of their ability to cause the cholinergic syndrome by inhibiting neural AChE (Lotti, 1992). OPIDP is a central-peripheral polyneuropathy characterized by degeneration (with secondary demyelination) of distal parts of long and large-diameter axons (Bouldin and Cavanagh, 1979a,b). The animal of choice for OPIDP studies is the hen (Johnson, 1982); chicks are resistant to OPIDP (Johnson and Barnes, 1970; Peraica et al., 1993). Rodents were initially believed to be resistant to OPIDP; however later experiments showed that morphological lesions resembling those of OPIDP could be demonstrated in rodents (Padilla and Veronesi, 1988), and clinical OPIDP could also be elicited in older rats (6 months of age or older; Moretto et al., 1992). Therefore, the apparent resistance was due to the young age of the commonly used animals.

The molecular target of OPIDP is believed to be a neural protein with an esterasic activity, called neuropathy target esterase (NTE, formerly known as neurotoxic esterase; Johnson, 1982; Lotti, 1992). This protein, whose physiological function or functions are unknown, was initially identified as a phosphorylation site that could be blocked by the neuropathic OP mipafox, but not by the non-neuropathic OP paraoxon. Subsequently, it was shown that esters such as phenyl valerate (PV) blocked the phosphorylation. PV is now used as substrate to detect NTE activity, which is the PV esterase activity resistant to inhibition by paraoxon and sensitive to inhibition by mipafox (Johnson, 1969, 1977, 1982). NTE inhibitors are divided into two groups: (1) neuropathic inhibitors—i.e., (thio)phosphates, (thio)phosphonates, and phosphoro(thio)amidates (group 1 compounds); and (2) non-neuropathic, protective inhibitors—i.e., phosphinates, carbamates, and sulfonyl fluorides (group 2 compounds). The latter (group 2) compounds not only do not cause OPIDP, but also protect from OPIDP when given prior to administration of group 1 compounds because they block NTE, which cannot therefore be phosphorylated. This is the best evidence that NTE is in fact the target of OPIDP. The threshold to trigger the mechanism of OPIDP is ~75% NTE inhibition—soon after dosing, the peak is reached at different times according to the toxicokinetics of the compound. Consequently, if >30% of NTE is inhibited by a group 2 compound, the animal is protected from a subsequent neuropathic com-

pound because <75% of the target remained available for phosphorylation. Therefore, a group of hens pretreated with a known protective compound should always be added as a control when testing an OP compound for OPIDP. The dose of PMSF (30 mg/kg subcutaneously) suggested in the above protocols will cause ~50% NTE inhibition, and protect hens from at least 5 times the minimum neuropathic OP dose (Lotti et al., 1995). The relevant interaction between NTE and inhibitors occurs in the axon rather than in the cell body (i.e., in peripheral nerve and in spinal cord, not in the brain; Lotti et al., 1987).

It should be noted that a few years ago, a phenomenon called promotion of OPIDP was described by two independent groups (Pope and Padilla, 1990; Lotti et al., 1991), whereby protective doses of group 2 compounds, when administered after (rather than before) a neuropathic OP, caused an exacerbation of the effects of the OP. It was later shown that some other inhibitors caused promotion at doses not inhibitory, or only marginally inhibitory, to NTE (Moretto et al., 1994; Lotti et al., 1995). It was concluded that NTE is unlikely to be the target of promotion. It was also shown that promotion is a more general phenomenon, also involving axonopathies other than OPIDP (Moretto and Lotti, 1993, Moretto et al., 1994). All protective compounds tested thus far do cause promotion when given after the neuropathic OP. A promoter (e.g., PMSF, 120 mg/kg subcutaneously) might be administered after the compound under study when a sufficiently high dose cannot be given because of acute toxicity. In this way, the neuropathic potential that might be suspected because of some NTE inhibition can be demonstrated.

The procedures for clinical observation and determination of NTE activity as described in this unit provide essential information for assessing the ability of a compound to cause OPIDP. Morphological data, though useful, are not likely to modify or add qualitatively relevant information. Moreover, it has been reported that there is a poor correlation between clinical scores and morphological scores, especially in peripheral nerves (Prentice and Roberts, 1983). Other scoring systems have been proposed (Abou-Donia and Graham, 1979; Prentice and Majeed, 1983; Roberts et al., 1983; Jortner and Ehrich, 1987) for both clinical and morphological analysis. Those presented in this unit have been used for many years and have proved to be reliable and quick to perform.

Guidelines for testing for OPIDP have been introduced for regulatory purposes (OECD, 1995a,b; also see United States Environmental Protection Agency document OPPTS 810.6100: "Delayed neurotoxicity of organophosphorus substances following acute and 28-day exposure"). These guidelines require a single oral dose and (on occasion) 28-day repeated dosing studies. In the single-dose study, one dose level at about the oral LD_{50} and a concurrent positive control (e.g., tri-*o*-cresyl phosphate) should be used. Protection or promotion experiments are not required. The repeated 28-day rat study is required if the single oral dose produces a positive response (biochemical, clinical, or morphological). However, OPIDP is not induced, it should be noted, even if some NTE inhibition is maintained for several weeks but the threshold is not reached (Lotti and Johnson, 1980). This repeated dosing experiment will not add information on the neuropathic potential of a given compound other than a comparison between the possible cumulative effect on NTE and that on AChE. For instance, spontaneous reactivation might occur for AChE, but not NTE, inhibited by dimethylphosphates, and this will result in a higher cumulative effect on the latter.

The NTE assay was first introduced by Johnson (1977) for determination in hen brain and spinal cord. It was subsequently modified to allow determination in peripheral nerves (Caroldi and Lotti, 1982; slightly modified by Moretto et al., 1989). For peripheral nerves, there are methods that differ slightly from the one presented in this unit. The authors of Barril et al. (1988) do not put nerves in modified Koenig buffer, do not desheath nerves, and add 0.32 M sucrose to the Tris/EDTA buffer. This method will result, in a greater amount of debris, in a slightly lower activity when expressed on a tissue weight basis, and in a possibly larger interindividual variability if activity is expressed per gram of tissue and not per milligram of protein, (the latter being the suggested form of expression). This quicker method of preparing the tissue might be used for in vitro inhibition studies when the precise determination of absolute activity is not required. Kayyali et al. (1991) reported that SDS induces a shift in the phenol/4-AAP chromophore spectrum with peak absorbance at 490 nm and not at 510 nm. However, since the change in ε is not very great and all data have so far been obtained at 510 nm, the method presented here uses 510 nm. Automated microassays have been proposed for NTE and other PV esterases (Correll and

Ehrich, 1991; Escudero et al., 1996). These methods do not introduce relevant qualitative modifications and require more expensive instruments, but they are useful for assessing hundreds of samples, especially when small amounts of tissues are available.

Critical Parameters and Troubleshooting

Animals. Hens used for OPIDP studies usually come from commercial egg production farms; these animals live in an environment where exposure to infectious agents, variable feed and water quality, and even exposure to chemicals (e.g., pesticides) are possible. All these factors might lead to wrong and uninterpretable results. Moreover, hens are sometimes handled by their legs, which might cause trauma and consequently cause clinical observation to be biased. Even specific-pathogen-free hens present background morphological lesions which should be taken into account when evaluating slides from treated hens. Sometimes these lesions are qualitatively similar to those associated with OPIDP (e.g., axonal swelling or degeneration), but most frequently the involved sites (e.g., brain) and types of lesion (e.g., focal gliosis, perivascular cuffing) are not typical of OPIDP (Bickford and Sprague, 1983).

Perfusion. Good hen perfusion is not easy to obtain. Better results are obtained if the tip of the cannula rests inside the heart and is not pushed too far into the aorta.

Test compounds. Stability of compounds in different solvents is generally not known. It is therefore advisable to dissolve them immediately before use (unless otherwise indicated). It should also be remembered that impurities might be present which can be much more active than the compound itself. Protection by PMSF (or other compounds) might not be complete for toxicokinetic reasons. It is possible that peak NTE inhibition by some OPs is reached a few days after dosing, when the protective effect of PMSF is reduced due to reappearance of NTE.

NTE assay. The NTE assay is relatively easy to perform and major difficulties are not expected. The pH of the reaction is not critical because NTE activity is rather stable over a wide pH range (i.e., pH 6 to 9; Johnson, 1982). However, basic pH is needed for color development. NTE is very sensitive to detergents. If using recyclable glassware, plasticware, or tubes, be sure that they are washed with little detergent and rinsed thoroughly. If the blank is too high, it is possible that the phenyl valerate spontaneously hydrolyzed, most likely in the stock solution. This decomposition might be due to light, temperature, length of storage, or to the presence of water in the dimethylformamide. In the latter case, the dimethylformamide should be redistilled. Purify phenyl valerate if the batch contains too much phenol (Johnson, 1977). The concentrations of paraoxon and mipafox are such that either small decreases or increases will not substantially change the results of the assay. However, paraoxon (at high concentrations) is a very weak, reversible NTE inhibitor, and some PV esterase activity (especially in the peripheral nerve) is sensitive to high mipafox concentrations (Vilanova et al., 1990).

Anticipated Results

Group 1 compounds are expected to cause OPIDP when inhibiting NTE by more than 75% in spinal cord and/or peripheral nerve. Clinical signs will appear between days 9 and 14 after treatment, and peak between days 15 and 18. This will depend on the severity of OPIDP, and on the toxicokinetics of the compound. It might be necessary to sacrifice the hens for humane reasons when OPIDP is severe (grades 6 to 8) because they cannot feed or drink. Clinical signs are expected to be associated with typical lesions in spinal cord and peripheral nerves. Group 2 compounds should not cause OPIDP. Group 2 compounds that cause more than 30% NTE inhibition in spinal cord and peripheral nerve should protect from OPIDP when administered prior to administration of a group 1 compound. Exceptions are represented by neuropathic compounds with slow toxicokinetics, which cause peak NTE inhibition several days after dosing, when the protective effect has either vanished or become reduced due to concomitant reappearance of NTE.

Atypical clinical signs, characterized by spasticity rather than flaccidity and accompanied by morphological lesions limited to spinal cord and medulla oblongata, may appear, which are associated with preferential inhibition of spinal cord NTE rather than peripheral nerve NTE. This may happen for toxicokinetic reasons, or because of different sensitivity to inhibition of NTE from the two tissues (Moretto et al., 1989).

Control NTE activity is expected to yield the following absorbance values at 510 nm in a typical assay.

Brain: paraoxon-resistant activity (B-activity; tube 1): 0.80 to 0.95; paraoxon-resistant,

mipafox-sensitive activity (C-activity; tube 2): 0.350 to 0.450; NTE activity (B – C): 0.40 to 0.50; blank (tube 3): ~0.10. These will correspond to an activity of 2.2 to 2.5 μmol of PV hydrolyzed·min^{-1}·g of $tissue^{-1}$.

Spinal cord: B-activity: 0.675 to 0.80; C-activity: 0.40 to 0.50; NTE activity (B – C): 0.275 to 0.35; blank: ~0.120. These will correspond to an activity of 0.6 to 0.7 μmol of PV hydrolyzed·min^{-1}·g of $tissue^{-1}$.

Peripheral nerve: B-activity: 1.10 to 1.30; C-activity: 0.75 to 1.00; NTE activity (B – C): 0.35 to 0.50; blank: ~0.15. These will correspond to an activity of. 0.09 to 0.12 μmol of PV hydrolyzed·min^{-1} g of $tissue^{-1}$.

Time Considerations

The experiments that include clinical observation last ~3 weeks. Administration of compounds and treatment against cholinergic toxicity might require the presence of a worker for several hours on the first day and every 6 to 12 hr during the following days. Clinical observation of each animal requires 3 to 5 min.

In one working day, 7 to 10 hens can be perfused and dissected by two workers. Also in one working day, brain, spinal cord, and sciatic nerves from 15 to 20 hens can be dissected, cleaned, weighed, and stored at −80°C. Approximately 50 tissue samples (30 to 40 if from peripheral nerves) can be assayed for NTE activity (assuming analysis in duplicate) in a single day. Determination of brain AChE (if deemed necessary or useful) in 50 samples requires ~2 hr with a multicell spectrophotometer, assuming that the same initial homogenate (prepared for NTE assay) is used.

Risk Assessment and Neurotoxicology

AIMS AND OBJECTIVES

Risk assessment refers to the use of toxicological data to define the relationship between exposure to an agent and an adverse health outcome. The goal is to develop a quantitative estimate of the probability that a given health outcome results from a specific exposure to an agent for a particular length of time by a particular route. Neurotoxicity may be defined as any adverse effect on the structure or function of the central and/or peripheral nervous system by a biological, chemical, or physical agent. Neurotoxic effects may be permanent or reversible, produced by neuropharmacological or neurodegenerative properties of a neurotoxicant, or resulting from direct or indirect actions on the nervous system. Adverse effects can include both unwanted effects and any alteration from baseline that diminishes the ability of an organism to survive, reproduce, or adapt to its environment. Putting this together, neurotoxicity risk assessment seeks to define the relationship between an adverse health outcome and exposure to an agent that affects the structure or function of the nervous system.

RISK ASSESSMENT

The risk assessment process has been described by the National Research Council (NRC) as including four components: (1) hazard identification, (2) dose-response assessment, (3) exposure assessment, and (4) risk characterization (NRC, 1983). The first two components focus on characterizing the sufficiency and strength of the toxicological data. Knowledge of the dose relatedness of the data is critical to dose-response modeling and further quantitative assessment. The third component, exposure assessment, provides human exposure estimates based on therapeutic, accidental, environmental, and/or occupational exposure possibilities. The final step in the risk assessment process is to integrate all the data and determine human risk. This risk assessment process is usually conducted by a risk assessor, whereas the influence of other factors—including economic, social, and health benefits—on risk characterization is determined by a risk manager. The logic of conducting risk assessment and risk management separately is to allow the scientific toxicological data to be evaluated fully without influences from unscientific factors (NRC, 1983).

Although many government agencies provide the framework for risk assessment as a focus of their missions, the United States Environmental Protection Agency (EPA) and United States Food and Drug Administration (FDA) have the responsibility for regulation of many agents to which the U.S. public may come into contact. Because of the widespread use of risk assessment procedures by the EPA and FDA, and the potential for agents under their responsibility to produce neurotoxicity, the EPA- and FDA-recommended procedures for neurotoxicity risk assessment will be the primary focus of this review.

Neurotoxicity Risk Assessment Within the FDA

The FDA has responsibility for the safety and efficacy of drugs, biologics, and medical devices, as well as ensuring the safety of food and food-related chemicals, cosmetics, electronic products that emit radiation, and veterinary drugs. Under the food, drug, and cosmetics laws, the FDA is charged with the responsibility of regulating products that account for 25 cents out of every dollar spent by U.S. consumers (Slikker and Sobotka, 1997). Although the FDA generally follows a rather structured review and approval process in making its regulatory decisions about these products, there are few formally written guidelines. The most detailed account of the agency's approach for assessing risk of adverse health effects is described in the FDA's Redbook I (U.S. FDA, 1982). This publication described the nature and extent of toxicological testing that was considered necessary for the agency to assure the safety of foods and color additives intended for use in human foods.

Recently, a proposed set of guidelines, referred to as Redbook II, has been drafted and disseminated for public comment and revision (Sobotka et al., 1996; Slikker and Sobotka, 1997). These proposed guidelines include specific attention to neurotoxicity and describe the nature and extent of information deemed necessary for the assessment of neurotoxic potential. The Redbook II guidelines suggest a structured process of tiered testing. Each tier or stage of testing focuses on different aspects of assessment: (1) screening, (2) characterization of effects, and (3) dose-response assessment. In the first stage, chemicals are initially screened across a range of dose levels for any clinical or

Current Protocols in Toxicology (1999) 11.6.1-11.6.7

pathological signs of toxicity, including those involving the nervous system. Those chemicals showing evidence of adverse effects on the nervous system may be presumptively identified as candidates for subsequent specific neurotoxicity testing to confirm and further characterize the scope of nervous system involvement and to determine dose-response relationships, including a determination of the no-observed-adverse-effect level (NOAEL). A tiered approach to neurotoxicity testing and evaluation allows for multiple decision points at which scientifically based decisions can be made about the adequacy of available information and the need for additional testing (Sobotka et al., 1996).

The FDA has used the NOAEL from bioassay data for noncancer effects as the starting point for safety assessment of chemicals. The NOAEL was defined to be the largest dose that did not appear to result in an increase in adverse biological effects above the level measured in unexposed control animals. In determining safe intake for humans, the NOAEL was divided by a safety factor of 10 to account for possible increased sensitivity of humans compared to test animals, and another safety factor of 10 to account for sensitive individuals (Gaylor et al., 1997). Additional safety factors were often employed to account for long-term effects based on short-term experiments or other inadequacies of the experimental data. The acceptable daily intake (ADI) was simply defined as ADI = NOAEL/($F_1 \times F_2 \times$...), where F_i are safety factors (Gaylor et al., 1997). In a case where all doses showed an adverse effect greater than that seen in the controls, the lowest observed adverse effect level (LOAEL) was divided by 10 to estimate the NOAEL. Some investigations have indicated that the NOAEL can be estimated from the LOAEL by dividing by a factor of three to five (Weil and McCollister, 1963; Abdel-Rahman and Kadry, 1995; Kadry et al., 1995). The above procedure is described in detail by Barnes and Dourson (1988). They state that the ADI is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure in the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime.

Neurotoxicity Risk Assessment Within the EPA

The EPA risk assessment guidelines for Neurotoxicity Risk Assessment were finalized quite recently (EPA, 1998). They are firmly based on an earlier document, Final report: Principles of neurotoxicity risk assessment (Reiter et al., 1994). Neurotoxicity risk assessment in the EPA frequently relies on animal data and the necessity to extrapolate the outcome of the animal studies to predict human risk. Therefore, a number of default assumptions are necessary but applied with informed discretion. These assumptions are plausibly conservative in nature because they are designed to protect public health, and they are well supported by current scientific knowledge (NRC, 1994). These assumptions include: (1) neurophysiological, neurochemical, behavioral, and neuroanatomical manifestations of toxicity are of concern as a basis for risk assessment; (2) agents that elicit adverse neurotoxic effects in experimental animal studies will produce hazard in humans; (3) neurotoxic effects seen in animal studies may not always reflect those seen in humans; and (4) unless there are data to suggest otherwise, the most sensitive species will be used as a basis for human risk assessment.

BIOLOGICAL MARKERS

The appropriate selection and use of biological markers or biomarkers is fundamental for the conduct of risk assessments for neurotoxicants, and biomarkers can be used to reduce knowledge gaps and minimize assumptions. Biomarkers may be defined as indicators signaling events in a biological system and are classified into three categories: indicators of exposure, effect, and susceptibility (NRC, 1987). Exposure biomarkers involve the quantitation of exogenous agents or of the complex of endogenous substances with exogenous agents within the system. Biomarkers of effect or endpoints are measures of an endogenous component of the biological system that is recognized as an alteration of disease or pathogenesis. A biomarker of susceptibility is an indicator that demonstrates that a particular biological system is especially vulnerable to toxic insult by an exogenous agent (NRC, 1987; Slikker, 1991).

ASSESSING HUMAN NEUROTOXICITY

Because of technical and ethical considerations, neurotoxicity in humans is primarily measured by noninvasive neurophysiological and neurobehavioral methods. Clinical neurological and neuropsychological approaches have been used extensively to evaluate neurological diseases, and these same methods have been used to assess patients suspected of having

Table 11.6.1 Some Human Neurobehavioral Methods

	Wechsler Memory Scale
	Complex brain function tasks
Affect	Profile of Mood States (POMS)

neurotoxic insults (Reiter et al., 1994). In addition, many neurobehavioral methods have been proposed or used to assess neurobehavioral function in humans (Table 11.6.1). In recent years, imaging techniques—including magnetic resonance imaging (MRI) and computerized tomography (CT)—and computerized brain electrical activity mapping, as well as operant behavioral assessments, have provided noninvasive and quantitative methods for human neurotoxicity assessment (Slikker and Chang, 1998). Epidemiological approaches—including retrospective and prospective studies—provide the means for evaluating the effects of neurotoxic substances in human populations (Reiter et al., 1994; Chang and Slikker, 1995).

ANIMAL MODELS

Whereas human data are available from clinical trials for therapeutics such as drugs and biologics, initial preclinical studies to determine dose, pharmacokinetic, and safety parameters are usually performed in animal models. Use of in vivo animal studies currently serves as the principal approach for detecting and characterizing neurotoxic hazards and helping to identify factors affecting susceptibility to neurotoxicity. In vitro tests have been proposed as a means of complementing whole-animal tests and, when properly developed, may be less time consuming and more cost effective than in vivo assessments (Reiter et al., 1994). The currently used in vitro tests have certain limitations, however, including the inability to model neurobehavioral effects (e.g., memory, learning, or sensory dysfunction).

Validation of animal models, whether in vivo or in vitro, is of paramount importance and may include measures of construct, criterion, and predictive validity. Despite the biological similarity of humans and many animal models, differential susceptibility to toxicants is well documented between species. Predictive capability or concordance between human and animal models after exposure to human neurotoxicants, however, has frequently been reported (Slikker, 1994a,b; Reiter et al., 1994; Slikker and Chang, 1998). These comparable outcomes provide a firm foundation for the use of animal models in neurotoxicity risk assessment. Examples of neurotoxicity endpoints or biomarkers of effect (Reiter et al., 1994; Slikker and Gaylor, 1995b; EPA, 1998) for each of the four major disciplines of neurotoxicology (neuropathological, neurochemical, neurophysiological, and behavioral) are shown in Table 11.6.2.

Generally, the most sensitive endpoint is used to determine toxicological risk. Regardless of the endpoint category (e.g., neurochemical, histological, physiological, or behavioral), the most sensitive one is used as the basis for risk

assessment. Even relatively complex indices such as behavior can be quantified in terms of, for example, rate of responding, percent task completed, or time to complete task, and can be used to determine NOAEL or LOAEL. However, long-latency effects, regardless of the endpoint category, are more problematic. It is generally assumed that average dose or total dose is a reasonable measure of exposure when doses are not equivalent in time, rate, or route of administration and the average (or total) dose is proportional to adverse effect. This major assumption is most prudently applied if it can be supported by empirical or mechanistic data. Animals exposed pre- or postnatally to test agent may be assessed as juveniles and later in life as adults and during senescence. Multi–time point approaches in different groups of animals, or longitudinal study designs with the use of the same animals, can provide for the assessment of long-latency effects (Reiter et al., 1994; Chang and Slikker, 1995; Sobotka et al., 1996; EPA, 1998).

TRADITIONAL RISK ASSESSMENT PROCEDURES FOR NEUROTOXICANTS

The regulation of neurotoxicants has generally been based upon setting reference doses (RfDs) by dividing the NOAEL by uncertainty

Table 11.6.2 Neurotoxicological Biomarkers of Effect

Neuropathological or structural endpoints	Gross changes in morphology, including brain weight
	Histologic changes in neurons or glia (neuronopathy, axonopathy, myelinopathy)
Neurochemical endpoints	Alterations in synthesis, release, uptake, or degradation of neurotransmitters
	Alterations in second messenger–associated signal transduction
	Alterations in membrane-bound enzymes regulating neuronal activity
	Alteration of neurotoxic esterase
	Alterations in developmental patterns of neurochemical systems
	Increases in glial fibrillary acidic protein in adults
Neurophysiological endpoints	Change in velocity, amplitude, or refractory period of nerve conduction
	Change in latency or amplitude of sensory-evoked potentials
	Change in electroencephalographic pattern or power spectrum
Behavioral endpoints	Absence or altered occurrence, magnitude or latency of sensorimotor reflex
	Altered magnitude of neurological measurements, such as grip strength or hindlimb splay
	Increases or decreases in motor activity
	Changes in rate, temporal patterning, or accuracy of schedule-controlled behavior
	Changes in motor coordination, weakness, paralysis, abnormal movement or posture, tremor, ongoing performance
	Changes in touch, sight, sound, taste, or smell sensations
	Changes in learning, memory, and attention
	Occurrences of seizures
	Altered temporal development of behaviors or reflex responses
	Autonomic signs

factors that hopefully account for interspecies and intraspecies extrapolation of experimental results in animals to humans (Barnes and Dourson, 1988; Kimmel, 1990). Generally, an uncertainty factor of 10 is used to allow for potentially higher sensitivity in humans than animals and another uncertainty factor of 10 is used to allow for variability in sensitivity among humans. Hence, the RfD = NOAEL/100. If NOAEL cannot be established, it is replaced by LOAEL in the calculation of the RfD and an additional uncertainty factor of 10 is often introduced, so that RfD = LOAEL/1000. It is assumed that this approach produces a dose with no significant neurotoxic risk, but this procedure makes no attempt to estimate the potential risk as a function of dose or to even consider the potential risk at the NOAEL.

Risk assessment procedures for developmental neurotoxicity have generally followed those for adult neurotoxicity. Several aspects of development require special consideration, however, and these include agent delivery (e.g., transplacental, lactational), susceptible periods of development (e.g., organogenesis, histogenesis), and latent presentation of effects (e.g., postnatal, senescent). Although quantitative risk assessment approaches have been applied, the limited number of developmental neurotoxicity risk assessments conducted have generally followed the RfD approach (Slikker, 1994a,b; Slikker and Chang, 1998).

LIMITATIONS AND ASSUMPTIONS

There are several features of the RfD or safety factor approach that deserve consideration. First, the method assumes a theoretical threshold dose below which no biological effects of any type are observed in a heterogeneous population. Not only is the determination of a threshold dose influenced by the sensitivity of the analytical methods employed, but the theoretical bases of a threshold dose may be questioned. Unfortunately, less sensitive experiments can result in higher RfDs. If, due to normal variation in cellular function, an adverse effect can occur in untreated control subjects, then endogenous or exogenous factors may already be supplying a stimulus that is equivalent to a dose above threshold. If exposure to an agent augments this stimulus in a strictly monotone manner as dose increases, then an additional risk is expected and no threshold dose exists for that agent (Gaylor and Slikker, 1990). Secondly, the magnitudes of the safety factors used to determine RfDs—interspecies extrapolation (10) and intraspecies extrapolation (10)—are based more on best estimates than actual data (Reiter et al., 1994; Slikker and Gaylor, 1995a).

The RfD approach relies on a single experimental observation (NOAEL or LOAEL) instead of using complete dose-response data in the calculation of risk estimates. Because chemical interactions with biological systems are often specific, stereoselective, and/or saturable, a chemical's dose-response curve may not be linear. Examples include enzyme-substrate binding leading to substrate metabolism, transport, and receptor-binding, any or all of which may be a requirement for an agent's effect or toxicity. The certainty of low-dose extrapolation is markedly affected by the shape of the dose-response curve (U.S. FDA, 1971). Therefore, the use of dose-response data should enhance the certainty of risk estimations when thresholds are not assumed or determined.

QUANTITATIVE DOSE-RESPONSE-BASED RISK ASSESSMENT APPROACHES

Dose-response models have generated considerable interest and are seen by many to be more appropriate (and quantitative) than the safety-factor approach to risk assessment. Rather than routinely applying a fixed safety factor to the NOAEL (which is based on a single dose) to estimate a safe dose, these approaches use data from the entire dose-response curve (Reiter et al., 1994).

Two fundamentally different approaches in the use of dose-response data have been developed to estimate risk. Dews and coworkers (Glowa et al., 1983; Dews, 1986; Glowa and Dews, 1987) and Crump (1984) demonstrated an approach in which information on the shape of the dose-response curve was used to estimate levels of exposure associated with relatively small effects (i.e., a 1%, 5%, or 10% change in a biological endpoint). Both Dews and Crump fit a mathematical function to the data and provided an estimate of the variability in exposure levels associated with a relatively small effect. Crump (1984) proposed the benchmark dose (BMD) as a replacement for the NOAEL in setting an ADI. The BMD was defined as a dose corresponding to an excess risk of 1% to 10% above background. A lower confidence (LBMD) was placed on the BMD to account for the variability in the experimental data. It was proposed that the ADI could be estimated as the LBMD divided by appropriate safety factors. For risk levels of 1% to 5%, the LBMD could be treated as the NOAEL; at the 10% risk level,

LBMD could be LOAEL. Kodell and West (1993) provide a procedure for estimating confidence limits on the BMD for continuous data following the modeling approach of Gaylor and Slikker (1990).

In another approach developed by Gaylor and Slikker (1990, 1992) for use with continuous data, a mathematical relationship is first established between the average biological effect and the dose of a given chemical. A second step determines the distribution (variability) of individual measurements of biological effects about the dose-response curve. The third step statistically defines an adverse or "abnormal" level of a biological effect in an untreated population. The fourth step estimates the probability of an adverse or abnormal level as a function of dose utilizing the information from the first three steps. The advantages of these dose-response models are that they encourage the generation and use of data needed to define a complete dose-response curve and provide an estimate of risk and/or changes in the average response as a function of dose.

BIOLOGICALLY BASED RISK ASSESSMENT

The development of quantitative risk assessment approaches depends, in part, on the availability of information on the mechanism of action and the pharmacokinetics of the agent in question. The development and use of physiologically based pharmacokinetic models to define target tissue concentrations of neurotoxicants is an important advancement for neurotoxicity risk assessment (Kim et al., 1995; Slikker et al., 1996; Slikker and Chang, 1998). In the development of a biologically based dose-response model for the psychoactive agent methylenedioxymethamphetamine (MDMA), Slikker and Gaylor (1990) considered several factors, including the pharmacokinetics of the parent chemical, the target tissue concentrations of the parent chemical or its bioactivated proximate toxicant, the uptake kinetics of the parent chemical or metabolite into the target cell, and the interaction of the chemical or metabolite with the membrane or with presumed receptor site(s). Because these theoretical factors contain a saturable step due to limited amounts of required enzyme, reuptake, or receptor site(s), a nonlinear, saturable dose-response curve was predicted. In the case of neurochemical effects of MDMA in the rodent, saturation mechanisms were hypothesized and, indeed, saturation curves provided relatively good fits to the experimental results. Some of the advantages of the biologically based quantitative approaches over the currently used RfD risk assessment procedures include the ability to (1) utilize continuous data, (2) utilize all of the dose-response data, (3) incorporate biological information into the dose-response model, and (4) provide an actual risk of exposure to a given dose. The conclusion was that use of dose-response models based on plausible biological mechanisms provides more validity to predication than purely empirical models.

CONCLUSION

Decisions concerning the production and use of chemicals and other agents are now generally considered in terms of not just risk, but of a balance between risk, health, and economic or environmental benefit. These risk/benefit decisions, usually made by risk managers, require quantitative risk assessments. In order for the risk manager to make a decision where the benefit is estimated in quantitative terms, the risk assessment side of the equation must also be quantitative. Therefore, there is a need for risk assessment procedures for neurotoxicants that are quantitative. A single risk assessment model may not be adequate for all conditions of exposure, for all endpoints, or for all agents. Risk assessment models of the future may well include biomarkers of both effect and exposure as well as biologically based mechanistic and pharmacokinetic considerations derived from both epidemiologic and experimental test system data.

Neurobehavioral Testing in Humans

Evaluation of the effects of chemical exposure in humans is a worldwide concern. Each year more than 1000 new chemical compounds are developed for use in industry, most of which have never been evaluated for possible neurotoxic effects on humans (Anger, 1990). Human neurobehavioral research or clinical evaluations of populations exposed to chemicals must be carefully planned, and research must additionally be carefully structured.

The distinction between clinical examinations administered for the purpose of diagnosing clinical abnormalities and research designed to detect group differences is an important one. Clinical neuropsychological evaluations require highly trained professional clinical psychologists or neuropsychologists who use a semi-structured test series based on current information and guided by clinical judgment and neuropsychological constructs that structure the assessment (Lezak, 1995; White, 1995). The clinical study has much to recommend it, as it is very sensitive to adverse effects in many neurobehavioral and psychological domains. It is, however, also very time consuming, requires a highly trained and experienced professional, and is therefore very expensive relative to experimental studies, which typically employ technicians to administer preplanned tests.

Clinical diagnostic examinations are most efficient and productive when following a diagnostic path dictated by training, clinical judgment, and experience. However, experimental research takes the exact opposite tack. Testing procedures are rigorously standardized across participants (although clinical studies use standard procedures, the specific tests selected may vary across participants) with the goal of making administration procedures invariant. Variance from standardized procedures leads to variability in the data that compromises the reliability, validity, and sensitivity of the tests.

Be it clinical assessment or experimental research, it is not possible to define a single protocol that will be appropriate in all cases; the protocol will depend on the goals of the study and the chemical exposure(s) that constitute the study's independent variable. In what follows, the necessary steps to develop a protocol are described, using a clinical evaluation and health promotion project involving experimental research procedures to illustrate the process. However, this unit is focused primarily on experimental research.

Experimental or clinical studies can be conducted in the laboratory or in the field. Testing at a site remote from the clinic or laboratory requires increased planning and rigorous procedural control because the controls routinely used in laboratory research (e.g., noise control, since extraneous sounds can invalidate a test of attention) are less available and some equipment is not portable. Otherwise, laboratory and field testing should be identical in planning and execution. This discussion centers on the more logistically complex field research that has dominated neurotoxicology publications in the 1990s.

STUDY DESIGN: DEFINING THE GOAL OF THE RESEARCH

Planning begins with the question the investigator wishes to answer, cast as a hypothesis to be tested. For example, (a) xylene exposure reversibly affects attention at 50 ppm, or (b) occupational exposures to xylene are associated with deficits in attention. Hypothesis (a) is readily studied in a laboratory equipped with inhalation exposure capabilities, and hypothesis (b) is typically pursued in a location near the workplace where the exposures are occurring in order to stimulate a high recruitment rate and minimize expenses. Even if the effects of the agent under study are unknown, it is best to structure the study or assessment around a limited range of hypothesized effects based on symptom reports, results in the scientific literature, or whatever served to trigger the study. It is also best to pursue at least two exposure levels in addition to a control or zero-level exposure, although this is admittedly rarely done in human behavioral neurotoxicology (Anger, 1990; Anger et al., 1998). Doing so allows the identification of a dose-response effect, which greatly increases confidence that the chemical exposure (the independent variable) is indeed responsible for the neurobehavioral test deficits (the effect) measured.

Identifying Performance Deficits

A critical issue in the design of a study is the availability of a baseline condition. If acute exposure effects are of interest, then baseline testing adds a huge degree of sensitivity by providing the basis for within-subject compari-

Contributed by W. Kent Anger, Diane S. Rohlman, and Daniel Storzbach
Current Protocols in Toxicology (1999) 11.7.1-11.7.17

sons (i.e., before versus during or after). In the absence of baseline data, norms developed for a neurobehavioral test have occasionally been used to detect performance deficits. The use of historical or clinical norms as a means for comparison may now appear possible with the publication of large-*n* studies (e.g., Anger et al., 1997). However, this is fraught with pitfalls unless the investigator is thoroughly familiar with the tests in numerous applications including large-*n* studies. The neurobehavioral tests used in behavioral neurotoxicology research do not have norms for all ages, cultural groups, educational backgrounds, or gender, and test performance may vary between different areas of a country with the population diversity of the United States (Anger et al., 1997). The results of large-*n* studies may not be representative of specific worker populations and may include ethnic, cultural, or gender bias that is not explicit in the publication. Different equipment or test procedures or parameters could produce highly variant results that would never be recognized without a control group. These points argue powerfully for always employing a control group for any research study or clinical assessment unless there is very strong evidence that norms from a population representative of the exposed group are available.

Example

An example of a clinical evaluation and health promotion project that was evaluated both as an experimental study and an individual clinical assessment illustrates this approach in a field (i.e., nonlaboratory) milieu. Youths in Texarkana (on the border of Arkansas and Texas) obtained mercury from an abandoned neon lamp factory and then became exposed to the mercury in various ways. It was reported that some dipped quarters in the mercury to see the shiny result, thus receiving exposure through their skin. At least one person dipped a cigarette in the mercury and smoked it, providing extremely rapid high-concentration exposure to mercury fumes by inhalation.

Because only a small number of exposed individuals were available or willing to be tested, the main goal was a clinical evaluation using norms and a "control" group drawn from willing community members (unexposed classmates). Urine samples were collected from the exposed students whose primary history of mercury exposure had occurred in the prior few months; the ability to measure urine mercury, which would serve as a good biomarker of current and historical exposure, was a useful feature of this study (again, a relatively rare one). This ability to correlate neurobehavioral performance with a good exposure biomarker offered the potential for an experimental study, although the viability of the result as publishable research depended on a reasonable sample size with a range of urine mercury exposures. The inability to select the controls in a random manner from the unexposed population virtually precluded a credible cross-sectional comparison (although events would add even greater barriers). At a minimum, the results were expected to provide the basis for a clinical assessment on an individual basis. The small number of tests given by technical staff limited the depth and scope of the judgments but allowed cost-efficient evaluation (the more participants, the less expensive it would be per participant).

TEST SELECTION: BUILDING A BATTERY

Once the study design has been developed it is necessary to select a battery of tests to administer to the study participants. The initial step in building a battery is to identify the functions to be measured. This may be based on the known effects of the chemical under study, or—if the neurotoxic endpoints of the chemical are only suspected—based on the symptoms expressed by exposed individuals. It is necessary to include some established tests of neurotoxicity. A functional assessment (i.e., measurement of all neurobehavioral and cognitive functions) might be attempted, but a complete assessment would be prohibitively expensive and is not a serious option. If, as is usually the case, it is believed that the effects are only partially understood, then a consensus test battery, described below, is the safest basis for test selection. The necessary steps are first to identify primary tests and desirable secondary tests, and then to consider statistical power, the available participant pool, and the time and budget limitations that constrain the selection of a large number of tests.

Primary tests are those that essentially define the critical effects that must be measured—it is around these tests that the hypothesis is framed, and it is for these measures that there must be sufficient statistical power to detect an effect of expected size (e.g., a 10% difference from control performance). Secondary measures are potentially useful additions that are not critical but may add valuable supplementary findings for future consideration. However, a single study realistically can only answer one

or two questions unless the participant pool is unusually large (see discussion of statistical power, below).

Behavioral tests that are proven to be sensitive to neurotoxicity in human neurobehavioral research should be included in any study. The risk of using unproven tests exclusively lies in not finding an effect. In this case, it is uncertain if (1) a neurotoxic effect was present but the test was insensitive, or (2) there was no neurotoxic effect. Thus, established tests should always be used, and it is recommended that a core of standardized tests known to be sensitive to neurotoxicants be employed. This strategy has been recommended by the expert groups drawn together to develop the consensus test batteries to assess neurotoxicity (Johnson et al., 1987; Anger et al., 1994). However, inclusion of new tests that assess functions not previously studied or that might more effectively test a function known to be affected by the neurotoxic chemicals is a positive contribution to the field.

Established Tests

There is a wide assortment of established tests of functions known to be affected by neurotoxic chemicals (Anger, 1990). For a principal investigator (PI) who has not previously used neurobehavioral tests, consensus test batteries are recommended because they have established sensitivity, proven training materials, established parameters for the tests (e.g., number of trials, test difficulty), and they allow the PI to evaluate the effectiveness of the testing by examining the outcome in the control group. The two consensus test batteries developed to study neurotoxic endpoints in humans are described below.

Neurobehavioral tests typically assess performance, although questionnaire-type psychological tests (Lezak, 1995) are increasingly used because of the growing recognition that psychological factors can contribute to performance deficits and concern that some exposed people may be motivated to perform below their potential. Psychological tests that measure factors such as anxiety, depression, perceived mental or physical health status, and tendency to abuse substances are recommended to reveal situational variables that may affect performance (e.g., fear or anxiety over one's health if one is exposed to a chemical that might be harmful).

Another factor that should be measured is motivation. Companies are often concerned that a few individuals hostile to the intent of a neurobehavioral study could skew the results and produce an apparent, but false, effect. However, such individuals would more likely add substantially to the variability, which reduces the likelihood that any effect will be detected—that is, their presence is more likely to lead to a false negative than a false positive. Moreover, in the authors' experience such individuals are rarely encountered. Nonetheless, detection of these individuals allows the investigator to eliminate their data, and thus the variability they bring to the analysis. To assess motivation (e.g., Pankratz and Binder, 1997), the authors developed the Oregon Dual Task Procedure (ODTP; Anger et al., 1999), a computerized variant of the Portland Digit Recognition Task (PDRT; Binder, 1993), in which the number of errors (not the response speed or latency measure) is the measure of motivation. This measure of motivation has been validated for the PDRT (Binder, 1993) but not the ODTP.

Consensus Batteries to Detect Neurotoxicity

The first consensus test battery designed to detect deficits suggestive of neurotoxic exposures was the Neurobehavioral Core Test Battery (NCTB), developed by an expert panel convened by the World Health Organization (WHO) with leadership from the National Institute for Occupational Safety and Health (NIOSH). The NCTB was selected to provide an instrument for population screening and research, and to foster the development of a database of common tests shown to be sensitive to neurotoxic disorders (Johnson et al., 1987). The NCTB comprises seven tests (Table 11.7.1) that met three criteria: (1) they had detected statistically significant differences between exposed and control groups in workplace research; (2) technicians could, following minimal training, reliably administer them; and (3) the materials and equipment they required were inexpensive and could be administered in remote settings (Johnson et al., 1987).

In a 10-country cross-cultural study of the NCTB in unexposed control populations administered in nine different languages, mean test performance among the nine countries with similar education levels was within ~1 standard deviation (SD) between the high and low scores. Test performance from the tenth country was substantially inferior on all but the Santa Ana test. Participants from the tenth country had a mean education level of 3 years, compared to a mean education level in the remaining countries exceeding 9 years (Anger et al., 1993). This suggests that the NCTB can be

administered to a broad range of populations with >10 years of education. There is an NCTB Operational Guide (obtainable from the authors) which allows use of this battery following a standardized method. The NCTB tests are widely used in neurotoxicology research (Anger, 1990), and the NCTB has been used in several studies (e.g., Liang et al., 1990).

The other consensus behavioral neurotoxicology test battery was developed by an expert committee (Anger et al., 1994) convened by the Agency for Toxic Substances and Disease Registry (ATSDR). The Adult Environmental Neurobehavioral Test Battery (AENTB) was designed to detect the effects of low-concentration exposures from hazardous waste sites. The same criteria used by the WHO expert group were applied. This expert group proposed a larger number of sensory, motor, and cognitive tests than were found in the NCTB. ATSDR has employed the AENTB to study hazardous waste exposures in three populations (Amler et al., 1994, 1995).

ATSDR has also developed the Pediatric Environmental Neurobehavioral Test Battery (PENTB), which employs observational methods to assess neurotoxicity in very young children, adding performance measures to test older children (Amler et al., 1996). This is not, strictly speaking, a consensus battery in that an open panel was not assembled with opportunity for comment from a broad array of scientists, although an expert group did develop the recommendation, and this was followed by extensive piloting and comment solicited from outside experts.

Computerized Test Batteries

Computerized tests have the potential to standardize neurotoxicity testing, and they may lead to the development of a large and consistent database, just as they have already caused an increased use of established tests. Computer-implemented tests have begun to dominate neurotoxicity testing as demonstrated in Portland, Ore., USA, during 1995 at the first symposium to examine this subject (e.g., Anger et al., 1996a). Topics of test validation (e.g., Krengel et al., 1996; White et al., 1996) and analysis (Heyer et al., 1996) were discussed, as were many new developments in this active field. The developers of the computer-based batteries, primarily university-based research scientists, can be contacted to purchase or obtain access to the batteries.

There are several computerized batteries comprised of standardized neurobehavioral tests. The first significant battery to be developed was the Neurobehavioral Evaluation System (NES and NES2; Letz, 1990); this battery is currently the most widely used. The NES2 has been used internationally, and on-screen

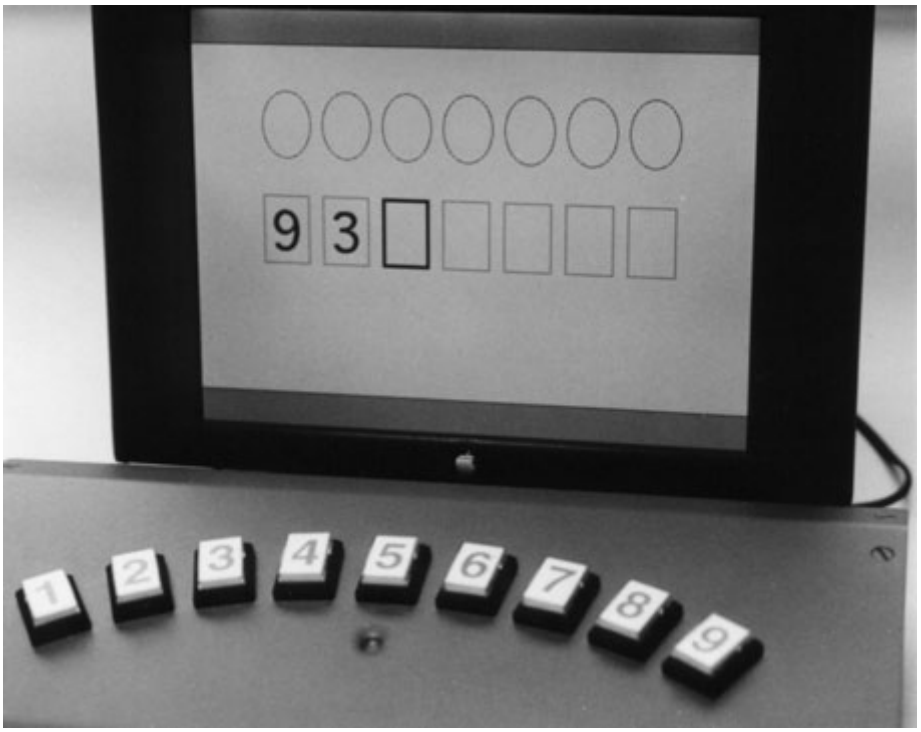

Figure 11.7.1 The 9-button DataSled response input unit is pictured set over the keyboard of a laptop computer (used for field studies due to the compact size and ease of transport). The laptop screen pictures the stimulus (dark line around the empty rectangle), indicating to participants to make their third response in the 7-digit step of the Digit Span test.

instructions are available in several languages, including English, Chinese, Japanese, Finnish, French, and Spanish (e.g., Letz, 1990). It has modifiable test parameters (e.g., number of trials), which allows researchers to adjust the test to answer specific hypotheses (e.g., does a longer test of attention reveal effects that only appear when attention is sustained over a long period of time). Because the default parameter settings vary in different versions of NES2, investigators must be careful to set the test parameters to appropriate settings to ensure that their data will be relevant to the existing database. Unfortunately, few investigators publish the parameters they have used. The NES2 (i.e., version 2 of the NES) is now evolving into the light pen–based NES3, which will debut as a screening battery with fixed parameters (Letz et al., 1996).

Sharing many properties with the NES2 is the Swedish Performance Evaluation System (SPES), available with instructions in Swedish and English. The SPES has preset, unmodifiable parameters (although of course the developer can reprogram these), saving the PI from the need to determine and set the parameters (Iregren et al., 1996). SPES consists of fourteen performance tests as well as four self-rating scales for mood, performance, and symptoms. Both the SPES and NES2 use the keyboard for input, plus a joystick for tests requiring a rapid single response (e.g., simple reaction time).

The authors have developed two computerized test batteries that are designed for the field or the laboratory. They feature the same computer system and simple and thoroughly tested instructions (Anger et al., 1996b; Kovera et al., 1996). The performance test battery, the Behavioral Assessment and Research System (BARS), was developed for presentation on a laptop computer for convenient application in the field, and a simple unintimidating response input unit, the DataSled (Fig. 11.7.1) is employed to avoid multiple problems with keyboard input (e.g., poor ergonomics for testing). The test stimuli are integrated with the instructions, which are presented in a stepped fashion (Rohlman et al., 1996), so that participants demonstrate their understanding of each test concept before moving to the next instructional stage, followed by practice on the complete test. The parameters are extensively and readily modifiable (see *http://home.att.net/~angerk*), and they have a recommended default setting.

BARS tests have now been successfully used with children as young as 5 years (Anger et al., 1996b), adults as old as 91 (Anger et al., unpub. observ.), and in people with limited education (Rohlman et al., 1996). Instructions are available in written or spoken format, in English, Spanish, and other languages. A growing database is available for review (e.g., Anger et al., 1999; Binder et al., 1999; Campbell et al., 1999).

The companion battery is the Health Screening System (HSS). This is a questionnaire-administration system, initially with twelve standard tests of physical and psychological health symptoms, personality, mood, life, and (for military veterans) combat experience. Other tests with comparable multiple-choice answers are readily added. Instructions, test items, and choices can be presented in onscreen written format, or they can be spoken via a user option selectable at any time during testing (Kovera et al., 1996). Psychological factors, not often employed in neurotoxicity assessments, are of increasing importance as subtle factors are considered (e.g., Anger et al., 1998).

Both BARS and HSS can be simultaneously administered to up to ten people by a single technician, and few questions are generated because of the intuitive nature of the instructions and tests. This is significantly more efficient than existing neurobehavioral test batteries. Other batteries such as Stollery's Automated Computerized Testing (ACT) system (Stollery, 1996) and the Automated Performance Testing System (APTS; Kennedy et al., 1987) are also available and worth consideration, as are the very popular NES2 and the SPES.

Recommendations for a minimum computerized test battery

Although the test situation, type of exposure, and time constraints dictate some of the tests to be used, it is recommended that a common core set of tests should be administered in all studies (Iregren and Letz, 1992). Data from these common tests will allow a comparison of effects across studies and can help build a general knowledge base. Iregren and Letz (1992) recommend a "Minimum Common Core Computerized Battery (MCCCB)" that consists of three tests, Simple Reaction Time, Symbol-Digit substitution, and Finger Tapping. These tests have demonstrated sensitivity to a variety of neurotoxic chemicals. To further aid comparisons, a standard set of parameters for these tests should also be used. The parameters from the NES2 version of the Symbol-Digit test and the SPES parameters for Simple Reaction Time and Finger Tapping are recommended (Iregren and Letz, 1992).

Cautions with computerized test batteries

There are many computerized test systems currently available, which vary in terms of hardware, stimulus presentation, accuracy of data collection, and ease of use. Although many of these systems include common tests (e.g., Reaction Time, Symbol-Digit, Finger Tapping) different parameter settings and screen images are used, and caution must be used when making comparisons of data across test systems. Unfortunately a description of the physical appearance of a test (available at <*http://home.att.net/~angerk*> for BARS and HSS tests) and the parameter values used is often missing from published reports. This is an even greater problem when new test systems are developed. The ease with which new test batteries can be developed is an important advance, but at the same time cause for concern: the development of new computerized tests or test batteries is not a task for the inexperienced. Caution should be used to guard against systems with unproven reliability.

Biomarkers: Exposure History

It is essential to collect information on exposure history, along with a biomarker of personal exposure, if possible. The investigator should recognize that the biomarker measure is linked to the time at which the sample is collected and may not reflect the history of exposures if they varied over time. Damage may have been accumulating over time, as well. In some cases, a history of exposures may exist if industrial hygiene and/or biological marker samples have been taken over the years in a company; this is certainly worth an inquiry if the chemical in question is a known toxicant such as mercury or lead. A specialist in biomarkers is required for an adequate treatment of this specialized subject (e.g., Travis, 1993).

Ancillary Measures

There are additional measures that are not direct tests of neurotoxicity which are recommended. It is also important to include at least one negative control test; this is a test that should not be affected by the chemical under study. Inclusion of a negative control test will calm the fears of those who believe that neurobehavioral tests are supersensitive to any

change in environment and therefore likely to give spurious results. It is also a good experimental design strategy. Furthermore, obtaining a history of occupations and jobs, as well as hobbies, is important as neurotoxic effects may be permanent and could result from previous exposure(s). These questionnaires need to be structured to fit the situation under study; standard questionnaires are printed in the initial publication describing the NCTB (Johnson et al., 1987). Although comprehensiveness of the information is important, a lengthy testing time runs the risk of tiring the participants and affecting data at the end of testing. Fifty minutes is probably the ideal session test time, although the authors regularly exceed that time without apparent adverse impact, using 7-min session breaks to refresh participants.

Example

Returning to the example of the Texarkana mercury-exposed group, the assessment was cast in terms of a research hypothesis: mercury exposure would produce increased tremor and deficits in short-term memory, possibly in a dose-response pattern. Given the short exposure period, such effects seemed unlikely, but that was the hypothesis to be tested. Thus, the hypothesis does not have to represent one's expectation, only what one wants to evaluate. The extensive history of mercury research (e.g., Anger, 1990; Echeverria et al., 1995) reduced the need to use a consensus battery, and time constraints and the desire to include a test of motivation (there was concern that the youths might be resistant to the testing) dictated the use of selected core tests rather than a complete consensus battery. Based on the demonstrated effects of metallic or inorganic mercury identified in the hypothesis, the primary tests selected were: (1) a measure of hand steadiness, and (2) the ODTP, which requires the participant to recognize a 5-digit number (from two options) after up to 25 sec of performing a distracter task. In addition to short-term recognition memory (response latency on correct trials), this test was also selected to assess motivation (the number of errors, as noted above).

The Symbol-Digit, Simple Reaction Time, and Tapping tests were also included in the battery. These tests have been widely used in neurotoxicology research, have revealed differences between groups with mercury exposure and controls, and are recommended as part of the MCCCB. For a negative control test, a subtest of the Wide Range Achievement Test III (WRAT-III), which measures reading level and has age-adjusted norms (Johnstone et al., 1996), was selected. Reading proficiency is believed (though admittedly without much direct evidence) to be insensitive to exposure to neurotoxic chemicals and is correlated with preexposure cognitive ability. Lower levels of education are associated with reduced performance on some of the neurobehavioral tests (Anger et al., 1997). Finally, the Beck Depression and Anxiety inventories (BDI and BAI) were added to the battery of tests to assess mood and psychological factors, and the SF-36 symptom checklist was included to measure perceived mental and physical health.

All of the performance tests were administered using the BARS test battery, except for the Hand Steadiness Test and the WRAT-III, which were administered individually. The psychological tests (BDI, BAI, and SF-36) were administered with the HSS. An example of a typical SF-36 "screen" is shown in Figure 11.7.2. The BARS and HSS were selected because they use a common platform and are easy to administer.

Urine mercury was selected as the biomarker. In this case, it was reasonable to expect that urine mercury would reflect the entire history of exposures of the people tested, since those exposures had begun only 3 months prior to testing.

PRELIMINARY DATA ANALYSIS PLAN AND POWER ANALYSIS

The preliminary data analysis plan should be developed at the same time as the study design and during the selection of tests and measures. It is dependent on the experimental design (e.g., comparison of an exposed to an unexposed control group, which would involve a *t*-test comparison between the groups), the levels of the independent variable (e.g., one level would be one exposed group, and two levels would be high and low exposure groups), and the number of participants available to study. It also serves to provide the basics for making a power analysis. A power analysis is unfortunately often ignored in experimental field research, especially when the need to initiate testing is urgent. However, it can be done very quickly and is necessary for understanding the outcome of any statistical analysis of neurotoxicity assessments. In most situations, a simple hypothesis is being tested and the experimental design is a comparison between an exposed and a control group. An approximate calculation can be based on the mean and standard deviation of the primary test

from published data, and the percent difference the investigator considers to be evidence of an adverse effect (e.g., 10% poorer performance by the exposed than the control group).

The power analysis allows the investigator to determine the number of participants that must provide test data to produce a credible research study (or confidence in statistical analyses of clinical field studies for which there is no control over the sample size). The number of participants needed is proportional to the ratio of the mean to the standard deviation (SD) of the primary test measure(s). Table 11.7.2 presents means and standard deviations that can provide a general guide. Obviously, the larger the standard deviation relative to the mean, the more participants are needed (put differently, the less sensitive the test is due to the high degree of variability). If the SD of the primary measure is ~20% of the mean, ~49 participants (24 in one group and 25 in the other) would be sufficient to detect a 10% deficit in the exposed versus control group. These numbers are based on three assumptions: (1) an alpha or significance level of 0.05 (often termed the 5% level); (2) a beta or undetected impairment probability

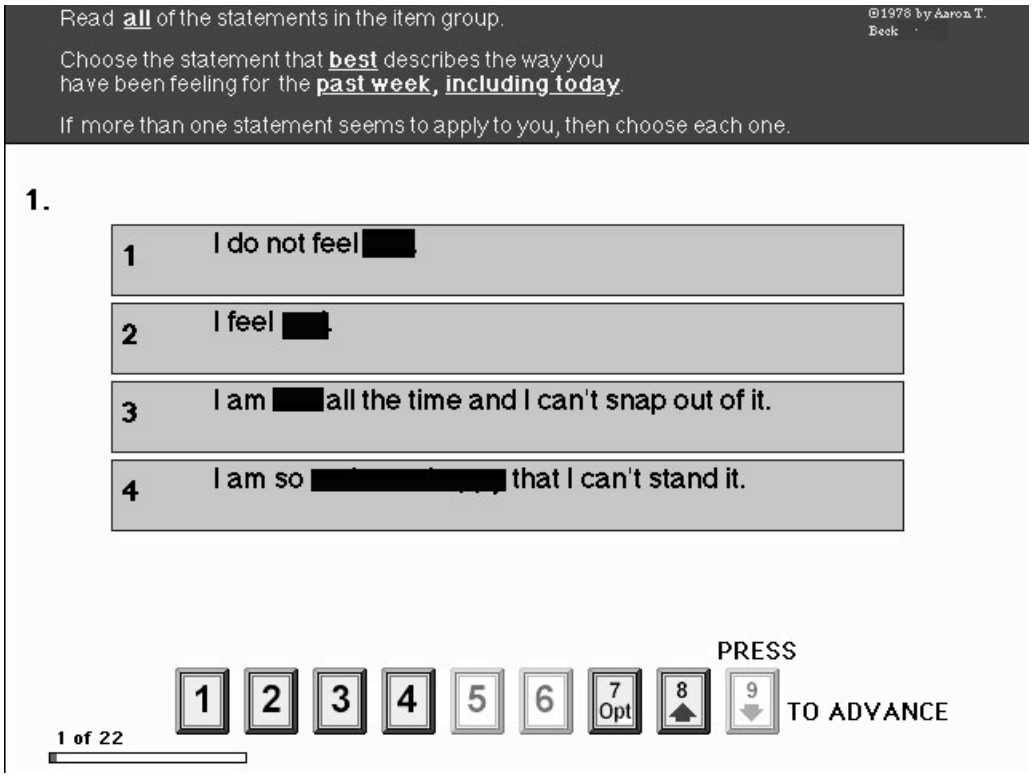

Figure 11.7.2 A typical screen from the Health Screening System (HSS) implementation of the Beck Depression Inventory. The rectangles numbered 1 to 9 at the bottom of the figure represent the physical DataSled response input unit used by participants to choose responses during the test.

Table 11.7.2 Means and Standard Deviations Required to Detect Statistically Significant Differences[a]

Mean	SD	Mean/SD ratio	*N* for difference of:[b]		
			10%	15%	20%
100	10	10%	12	5	3
100	15	15%	28	12	7
100	20	20%	49	22	12

[a]Hypothetical test mean of 100, SD, and ratio of mean to SD expressed as a percentage, and the *N* required per group to detect a 10%, 15% or 20% difference between the groups.

[b]Assumes alpha of 0.05, beta of 0.20, and a directional hypothesis (e.g., exposed individuals will have performance deficits).

of 0.20 (yielding 80% "power" to detect a true effect); and (3) one can predict the direction of an adverse effect (e.g., response speed slows down), to produce what is generally termed a directional or 1-tail test (Pagano and Evereau, 1993).

The reader should realize that these sample size numbers provide only an estimate and would differ if the PI chose alternative assumptions. For example, this power analysis is only relevant for a small number of test measures, the primary measures. If several measures are to be treated as "primary," the number must be adjusted for the number of tests used, because the more tests administered the more likely a difference between the groups will be discovered purely by chance (just as the more you flip a coin the more likely it is that you will get at least one head and at least one tail). Thus, a statistician should be consulted to discuss the many underlying factors. However, entering that discussion with the information identified in the preceding paragraph in hand (that is, with casting of the hypothesis to be tested, selection of primary measures, mean and standard deviation of those measures, and determination of how much of a deficit constitutes an adverse effect or must be detected, all completed) will allow this to be a fairly brief consultation to add some precision to the number of participants that need to be tested.

The power analysis will reveal which tests can be rationally employed in a study—since the mean/SD ratio varies considerably between tests—as well as how many tests can serve as primary measures. Further, if the number of participants is fluid or expandable, this will assist in limiting the number to an appropriate minimum. Of course, one can employ any number of secondary measures on which the outcome is reported but the results are not a basis on which the hypothesis is tested (i.e., the basis on which one concludes that the chemical did have an effect or that the exposed have a significant deficit compared to the controls). This may seem curious or even mystical, but it is simply based on the issue of chance: the more tests you administer, the more likely you are to chance upon one on which people differ.

Example

In the Texarkana example, the primary endpoints were measures of tremor and short-term memory. These were selected in part based on evidence in the literature and in part because of the authors' experience with this memory measure. Data were collected on several hundred people, and with this information a straightforward power analysis was undertaken. The ODTP served as the primary test. In data on young adults taking the ODTP (Anger et al., 1999), the mean latency is ~2000 msec (to make a choice between two options and press a button to indicate which choice) with an SD of ~400 msec; thus, the SD is ~20% of the mean. This would require an estimated 22 people in the exposed and 22 people in the control group to detect a 15% difference between the exposed and control groups, and ~12 people in each group to detect a 20% difference (see Table 11.7.2). A similar procedure can be employed when there is a body burden measure—as in Texarkana, where the relationship between the test measures can be correlated with urine mercury (which was to be the main analytic strategy). The ability to detect a 10% to 15% difference is a reasonable power level, and it reflects "deficits" that would probably be undetectable in a standard medical exam (which of course would not employ such structured neurobehavioral tests). With this preparation, the research team arrived in Texarkana prepared to test 50 people in the one day available for testing (although this number would elude the team).

IMPLICATIONS OF DEMOGRAPHIC FACTORS

A critical aspect of test selection is recognition of the key demographic factors in the test population that could affect performance on neurobehavioral tests. These factors are (1) gender (e.g., the dynamometer strength test); (2) age (e.g., people past retirement age will take much longer to complete the tests and will be slower on tests employing latency measures such as the Symbol Digit or ODTP); (3) education (e.g., performance on cognitive and motor tests will be slower in persons with <10 years of education, and tests with simple and clear instructions are highly preferred for such persons); and (4) ethnicity (e.g., tests that involve memory of Asian letters would be difficult for people whose cultural background does not include exposure to such figures). These factors may guide test selection and argue powerfully for performing pilot assessments of the tests in the population of interest and for selection of a comparable control group in cross-sectional studies (Anger et al., 1997).

Demographic data should be collected for each test participant. This should include age (obtain the date of birth and subtract that from the date of testing to get the actual age at time

of testing), years of education (discriminate between GED and 12 years; 16 is typically a BA, 17 an MA), gender, and ethnicity. If the project is funded by a federal grant, this information must be reported annually to that agency by the recipient institution.

Example

In the Texarkana example, the WRAT-III test of reading ability, which is normed on a national sample (Johnstone et al., 1996), provided an estimate of general intellectual attainment. This factor affects performance on all the planned tests. If the exposed and control participants were of comparable educational attainment, then a cross-sectional comparison might be possible, although the nonrandom nature of the sample would limit the generality of those comparisons. This was a primary concern, as the participants were expected to be of the same age and from the US majority ethnic background. Gender is a relatively minor factor on the selected tests, although it was expected to play enough of a role that it was hoped that an equal number of males and females would be tested in each group.

TEST DETAILS: THE PARAMETERS

Selection of the tests does not complete the process. The parameters (e.g., number of trials, test difficulty) for a test should be selected with care, keeping in mind the study's goals and limitations. Parameters that replicate previous administrations of a test are a good starting point because they provide a basis for comparing the data from the current study to data collected previously. However, caution should be used when comparing data from different studies, because many factors that may affect performance (e.g., size of stimuli or number of trials) can vary. The goal of testing is to select test parameters that provide a reliable and valid sample of behavior.

Test duration is a critical parameter that is often manipulated to meet time limitations. Due to the limited time available for testing and the need and desire to use a variety of tests, the duration of a test may be shortened. Test duration can be manipulated by changing the number of trials in a test or the length of a trial. Varying the duration of a test can have two effects on the performance measured. A duration that is too brief may not allow performance to stabilize. Conversely, a duration that is too long may cause fatigue to impact performance. Stable performance may develop in a single test session, but it may develop at different points in different people. Tests with a steep learning curve (such as the Symbol Digit test, in which the first trial is often discarded or only the data from the fastest trial is selected) can have a high degree of variance across participants in early trials, so the data after those trials should be chosen for analysis.

In some situations the study may be structured such that people are tested multiple times. One concern in such cases is that repeat testing may cause practice and learning effects. This may make performance from the first testing session appear lower than performance from subsequent sessions. A solution to this problem is to discard the data from the first testing session as training data. Another solution is to have multiple sets of stimuli for a test. For example, the Digit Span test presents a series of numbers and the task is to recall the numbers. If the same set of numbers are used in several sessions, over time the test participant will learn the numbers and his or her performance will improve. A solution to this problem is to have multiple sets of numbers. This idea of alternate forms is common in other testing situations. All sets of stimuli should be pilot tested ahead of time to ensure that one set is not more easy or difficult than another.

The type of stimulus that is chosen in a test can also affect performance. Changing the stimulus in a Simple Reaction Time test from a screen image ("Press 5 when the square appears") to a lighted key ("Press 5 when the 5 key lights up") increased the mean response latency significantly, from 331 msec to 371 msec in a small sample studied by the authors. The type of stimulus, as well as the size and shape of the stimulus, can affect performance. Using letters or English words can put less-educated people or non–English speakers at a disadvantage. Some tests minimize this bias by using stimuli that do not rely on words, letters, or common shapes (i.e., by using random patterns).

Variations in the presentation of the stimuli can also affect performance. The Symbol Digit test is a coding test in which numbers are paired with nine symbols and the participant must enter the numbers in a matrix that includes only the symbols but not the numbers (Figure 11.7.3 depicts the BARS implementation of this test). The test can employ fixed or random symbol-digit pairings on succeeding trials. In the fixed condition, the same symbols are paired with the same numbers on every trial. In the random condition, the same symbols are used but the

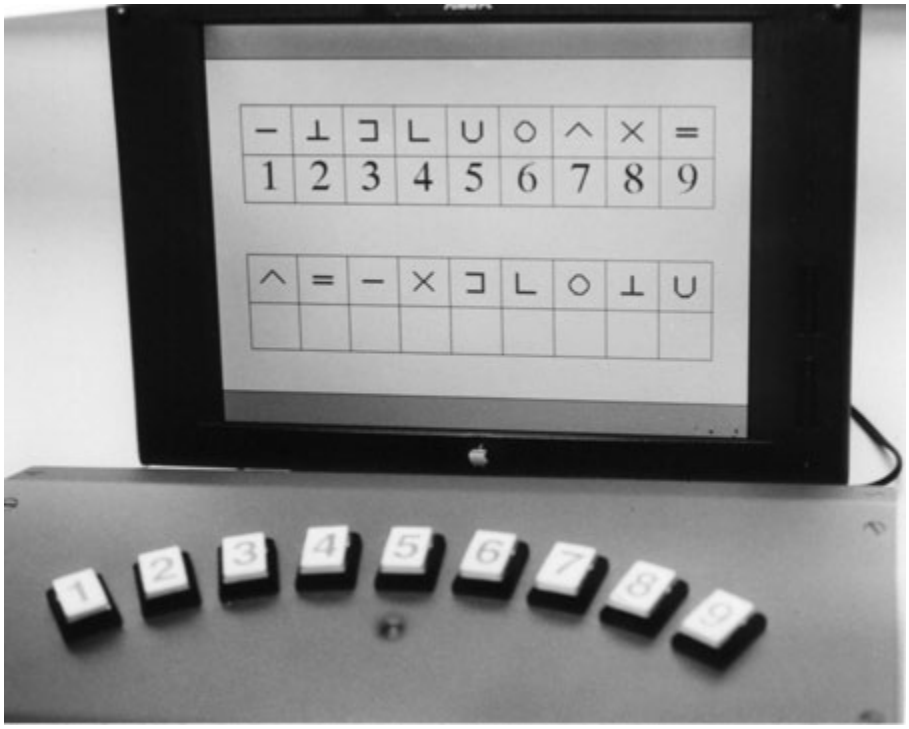

Figure 11.7.3 Test "screen" from the Behavioral Assessment and Research System (BARS) Symbol Digit coding test. At the bottom of the picture is the 9-button DataSled response input unit for participants.

numbers are rotated among the symbols on each new trial. Performance in the fixed condition tends to be significantly faster than in the random condition because people start to learn the symbol-digit pairings, which is impossible in the random condition.

Parameter settings can also be adjusted to control for the difficulty level of a test. Increasing the number of stimuli in a test requiring the participant to remember a stimulus pattern can make the test more difficult. Having a large number of stimuli or a fast presentation rate of stimuli can also add to the difficulty of a test requiring a differential response. Because of individual differences in test performance, selecting the optimal difficulty level of a test for a group may be complex. One solution is to develop a test so that the optimal parameter settings are determined by the test participant. Titrating the time between the stimulus presentations based on participant performance is one example of such an approach. When a person responds correctly to a stimulus, the intervals between the stimuli becomes shorter, so they appear more frequently. When a person responds incorrectly to a stimulus, the duration between the stimuli becomes longer. This allows each individual's performance to determine the difficulty level of the test. This strategy is employed in the BARS Selective Attention Test (SAT) for measuring attention. The SAT is a simple task in which dots appear on the screen and the participant responds on different buttons when the dots are inside but not outside two squares. Figure 11.7.4 is an example from an SAT "instruction" screen used during the training period, demonstrating the integration of the instructions with the test stimuli (Rohlman et al., 1996).

A final area of concern is the presentation order of the tests in a battery. Ideally, test order should have no effect on performance. However, if there is a concern about the order of the tests (e.g., it may be desirable that a tapping test not be followed immediately by a test of reaction time, to prevent fatigue from affecting the second test), techniques such as counterbalancing the order of the tests in the battery should be used to reduce this effect. Time constraints and equipment needs may also influence the test order.

Example

Because of the small number of participants to be tested in the Texarkana example and the desire to provide a clinical evaluation, certain test parameters were selected. The authors' laboratory maintains a large database of results from testing US veterans of the Persian Gulf (Anger et al., 1999), and it was anticipated that

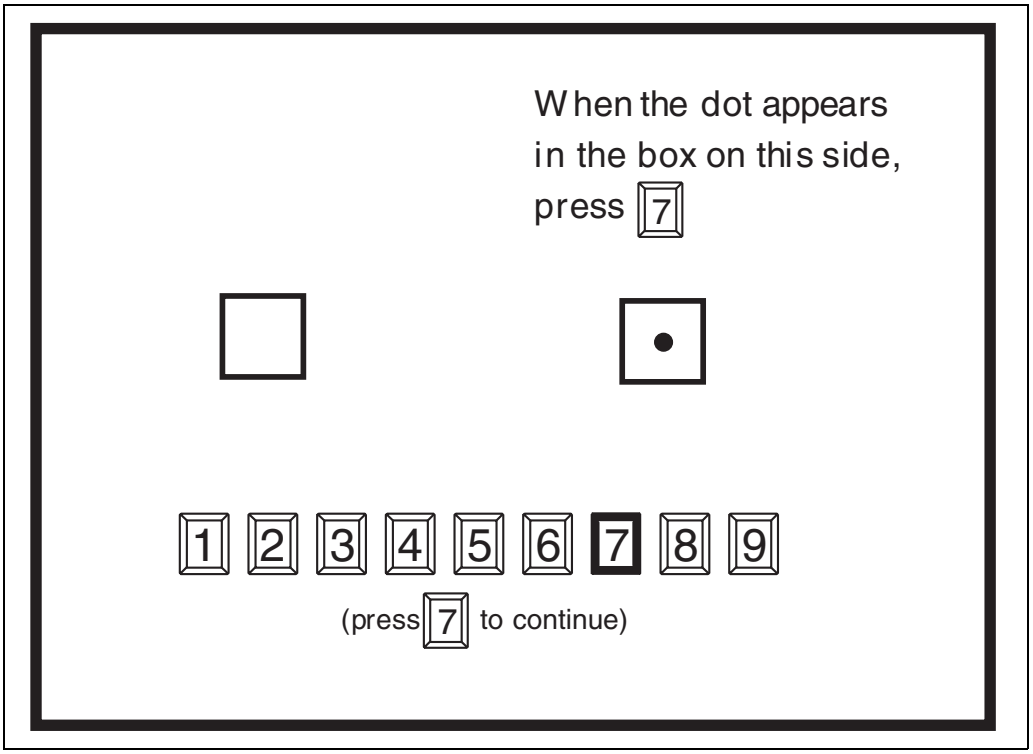

Figure 11.7.4 Instruction "screen" from the Behavioral Assessment and Research System (BARS) Selective Attention Test (SAT). The various instruction screens teach the participant which buttons to press for the various stimulus events (dots inside and outside the two boxes on the screen). The dot is enlarged during the training period which follows a series of steps that integrate the instructions with the test stimuli.

the data from the healthy control participants would serve as one basis for comparison. The same test parameters and test order that were used with the veterans were therefore selected for the Texarkana study, with a few modifications. One consideration was that the administration time recorded for the large number of tests selected was lengthy, and the amount of time participants would have for testing was unknown. Another concern was the motivation or attitude of the test participants: since the test was lengthy, early "burnout" was a possibility. For these reasons the number of trials in the Simple Reaction Time test was reduced and the test order was changed by putting the longest test at the end of the battery. This ensured that as many tests as possible could be completed in the event that the battery had to be shortened at the outset of testing (normally an unacceptable contingency, but for this unique project outside the investigators' control). These are only examples of the many considerations that affected the selection of test parameters.

TEST SETTING

The selection of an appropriate test setting depends on a variety of factors; the guidance that follows is based on the standard procedures in the authors' research. In some studies it is beneficial to divide the testing environment into several testing stations. No matter how many test stations are planned, there are certain common characteristics. The test room should be quiet. Telephones and loudspeakers must be turned off so they do not interrupt testing. The temperature in the room should be set at a comfortable level (e.g., 72°F). There should be adequate lighting, and curtains or blinds may be needed to block excessive sunshine. Sufficient table space should be provided for all of the equipment and for a writing surface, if necessary (often by purchasing folding tables at the site and then selling or donating them to local concerns after testing is finished, since shipping these in two directions often costs more than purchasing them). Electrical outlets and power strips must be provided for all equipment. The test order may influence the specific layout of the test stations.

During testing with BARS computerized tests, up to ten people are tested at one time by one research technician. The ten stations are typically located in one large room. Standard tables are placed end to end, and 1-meter-tall

panels are used to divide the tables into individual work stations that screen participants from distracters (e.g., participants who know each other tend to try to talk during testing, which will affect their data). Each station has a PowerBook laptop computer, DataSled response input unit, headphones for spoken instructions (to avoid distracting others), and a comfortable nontilting chair. There are a separate table and chair for the examiner. Food and drink are not allowed at the testing stations.

If participants are being tested as a group, as suggested above, a reception or waiting area is necessary to greet them. This area is also used to obtain informed consent and give basic instructions to the participants. It is important to have a separate waiting area during group testing because participants will arrive at different times and finish at different times.

When there are multiple testing stations, a schedule and plan of movement should be developed before testing begins. For example, the first participant to arrive may begin at Station 1, the second at Station 2, and so on. The time at each station should be set to be approximately equal in order to minimize waiting time for the participants, although arrival times often negate this plan. It should also be recognized that test completion time varies like other variables, so that almost 50% of the participants will take longer than the mean testing time.

Prior to the start of the study, it is essential to conduct a pilot study to evaluate the procedures. This includes factors such as the maximum number of participants expected at any one time, to determine if there are problems with the room layout or participant flow. Pilot participants should be as similar to the expected participants as possible, to increase the probability that any likely problems (e.g., poor test procedures or unclear instructions) will be encountered in that phase.

STUDY DETAILS: PROTOCOLS

Protocol Book

A protocol book should be assembled for each study, most conveniently in a looseleaf binder. It should contain the protocols used to administer each test in the battery as well as equipment lists, troubleshooting guidelines, copies of any data forms used in the study, a list of regular and emergency phone numbers, a picture of the testing layout, and instructions on how to record information in the log.

Instructions should be separated into "stations" if more than one test area is planned, and each page placed in a protective plastic sheet to prevent loss or damage. The protocol for each test should begin on a separate page. This allows modifications to be made easily during the development of the protocol and provides clarity for the examiner. The test protocols are developed and then pilot tested to ensure they work effectively. Any revisions should be made before the start of testing, and the protocol is not changed during the study.

The protocol for a test includes a list of the equipment and a description of the setup procedures, comprising instructions for assembling the equipment as well as the steps required to start the testing software and any calibration procedures. For noncomputerized equipment this includes the physical layout of the equipment and the procedures required. Following the setup procedures are the instructions that will be read to the test participant. They are to be read exactly as on the page. These instructions are placed in boldface or within a box to make them stand out from the procedures required to administer a test, so the examiner can locate them quickly. The procedures required to administer the test follow the instructions, and information about scoring, backing up, and/or downloading the data are presented last.

The protocol book should also contain information on how to troubleshoot problems. Problems during testing are unwelcome but likely to arise. The troubleshooting guidelines should contain information on potential participant problems, possible steps to solve them, and instructions on how to record the problem in a log book, which should be available at every test station.

Examiners

Health professionals with a BA/BS/RN in any discipline and competent health technicians can administer neurobehavioral tests reliably and effectively after 5 to 10 hr of training, at least half of which should be spent practicing with representative participants under observation by the trainer. The main requirements are that the examiner remain alert and be committed to testing in a careful and conscientious manner. Examiners must be capable of reading the instructions and following the procedural aspects of the protocol exactly.

A "professional" appearance is required—something that is difficult to define, although certain basic requirements are obvious. An examiner must be clean, wear only limited makeup, avoid jewelry, have neat hair, and use

no perfume. Examiners should begin testing each day with clean clothes that are appropriate for the test setting and population.

Examiners should be blind to whether the participants are identified as exposed or controls. Even with computerized testing, the potential for bias is to be avoided. It is important to "certify" new examiners for each study before testing begins, by requiring them to meet the standards in this section. The certification involves observing the examiner administer all the tests in the battery and grading their performance on each test. A no-errors criterion is used.

STUDY DETAILS: PROCEDURES

Recruiting

The plan for recruiting test participants generally involves both control (unexposed) as well as exposed individuals. The demographics of the two groups should be kept as equal as possible. One method of recruiting participants is to advertise in a local newspaper. The advertisement should give a brief description of the study, list any requirements, and give a phone number to call to schedule an appointment. A script should be prepared for the scheduler to read when potential recruits call. The script includes any screening questions, which must be phrased so that the potential recruit cannot glean the criterion they need to meet. For example, if the criteria require that the participants be over 25 years of age, the age of the caller is queried rather than if they are over 25. The script also includes clear directions to the testing site. Participants should be asked to bring a photo ID on the day of testing to confirm necessary demographic factors and assure the name is correct. If scheduling occurs more than a day in advance of testing, a reminder phone call is helpful to decrease the "no show" rate.

Prior to testing a packet should be prepared for each test participant that includes the consent form, a demographic data sheet, paper data forms, and the form they sign when they are paid at the end of the experiment (e.g., on the bottom of the consent form). One approach is to generate a page of labels with each participant identifier ID number to attach to all of the forms (front and back). A unique ID should be assigned to each test participant when they arrive. Participants should be assigned numbers sequentially, whether they are in the exposed or control group, to ensure blinding of the examiners and those who will score and enter data. With multiple stations, a station or test checklist may be used for tracking, and name tags with their names and IDs are useful for identifying the test participants. With multiple stations, the examiners maintain control of all data forms at their individual stations; only the station checklist (with examiner initials for each completed station) travels with the participants and their packets.

Quality Assurance

Examiner training is typically certified at the beginning of the study, but to prevent examiner drift the effectiveness of the training must be verified if the study continues for any length of time. Mid-study checks every 2 to 3 weeks, or every 20 to 30 participant test hours by an examiner, are desirable.

DATA MANAGEMENT

Data from computer files should be labeled and stored on two diskettes immediately following each test session. During the study the completed data forms should be placed in locked safes or file cabinets. The data should be kept in two physically separate and secure sites. This redundancy minimizes the possibility of irretrievable loss of data through accident or error.

The data from the paper forms are entered into a spreadsheet. To minimize entry errors, the order of entry into the spreadsheet should follow the order of the data on the paper forms. All scoring and calculations should be recorded and entered into the spreadsheet. Paper data should be entered twice by different people. When both entries are completed, the data must be compared and checked for inconsistencies—easily done in spreadsheets using an "if" statement. Any inconsistencies will be flagged, and the paper data forms can then be reviewed to determine which entry is correct. One of the spreadsheets is then modified to develop a final data file. Multiple backup copies (dated) of the data should be made frequently, and routinely at the end of every day.

DATA ANALYSIS

The analysis should begin with an inspection of the basic descriptive data—means and standard deviations. The study logs are reviewed for examiner notes that would explain data outliers or reveal data that should be excluded from the analysis. The key variables that affect neurobehavioral performance—age, education, gender, and ethnicity—are examined to identify possible differences between the exposed and control groups, taking care to

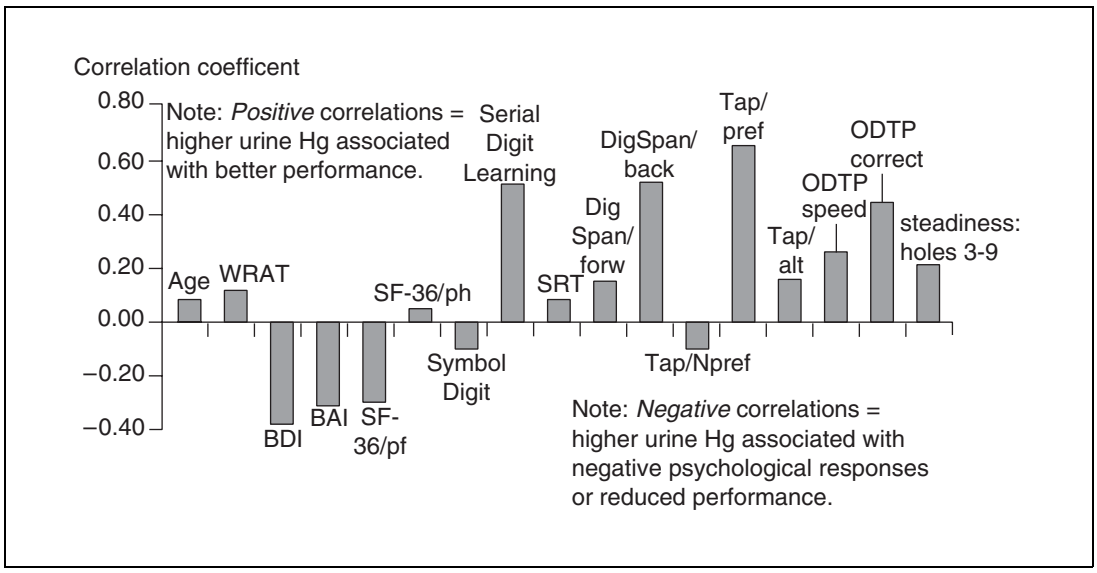

Figure 11.7.5 Urine mercury correlations with age, Wide Range Achievement Test (WRAT), psychological, and neurobehavioral test performance in eight Texarkana participants exposed to mercury. The Symbol Digit, Simple Reaction Time (SRT), and Oregon Dual Task Procedure (ODTP) scores normally presented as latencies are represented in the figure as speed for coherence of presentation (i.e., so negative or poorer performance is always represented as negative correlations); BDI (Beck Depression Inventory), BAI (Beck Anxiety Inventory), and SF-36 symptom checklist—physical functioning (SF-36/pf) and physical health (SF-36/ph)—correlations are reversed in the figure to present increased urine mercury concentrations as associated with greater distress (i.e., the adverse outcome). Three measures of fingertapping are also shown: preferred hand (Tap/pref), non-preferred hand (Tap/Npref), and alternating hands (Tap/alt). Other abbreviations: DigSpan, Digit Span.

focus on the primary measures. Simple analyses such as *t*-tests will reveal large group differences. (As a word of caution, avoid elevating a secondary measure to primary status because the groups happen to differ on that measure.) If nothing emerges, pursue more powerful analyses to identify small effects, in consultation with an experienced statistician (a powerful ally to be enlisted during the power analyses and certainly before the data are collected).

Example

The Texarkana project proved challenging from an analytic perspective. Only eight mercury-exposed participants and four controls were available for testing. Initial inspection of the results revealed that one mercury-exposed participant had clinically significant scores on the Beck Depression and Anxiety Inventories. This participant was excluded from the data analysis because depression affects test performance and was judged unlikely to be a result of the exposures (more likely a result of the situational events surrounding the mercury incidents). A second mercury-exposed participant was excluded from the analysis because of a performance on the test of motivation suggesting a lack of motivation to perform the tests, which rendered the test results suspect. This left six mercury-exposed and four control participants.

The WRAT-III reading test revealed that the mercury-exposed participants had a decidedly lower educational attainment than was expected for their current grade in school or for their age, while the controls achieved expected scores for their age and grade in school. Clearly, cross-sectional comparisons were impossible due to the small numbers and the reading-test differences, in addition to the lack of random selection noted above. While individual clinical assessments were valuable, they failed to reveal response patterns indicative of neurotoxic effect. Even more telling were the correlations between urine mercury and test results (Fig. 11.7.5). There were positive correlations between urine mercury and most performance measures, although none were significant due to the small sample size. If these differences had been associated with the mercury exposures, the expected correlation would have been negative—with higher mercury associated with lower performance scores. The trend of the psychological tests was in the expected direction, though again not significantly: higher urine mercury was minimally associated with

more symptoms of depression, anxiety, and adverse health function as perceived by the individual. Since the publicity, suggestion of adverse long-term consequences of mercury exposure, and events surrounding the mercury exposure (e.g., house evacuation during the cleanup) had a decidedly negative tenor, it is much more likely that situational events played a larger role in the psychological test results than did the mercury exposure, but there was insufficient information to draw firm conclusions on this score.

COMMENTARY

Neurobehavioral and psychological tests are frequently used to evaluate exposures to neurotoxic chemicals. A single protocol to study neurotoxic effects in humans would be desirable but dangerous. If there is little time to review the literature or consider the symptoms of the exposed population, then the NCTB (Johnson et al., 1987; Anger et al., 1993) or AENTB (Amler et al., 1994; Anger et al., 1994) consensus batteries are recommended. Manuals describing the administration of these two tests in complete detail are available. The NCTB manual is not published but may be obtained in English and Spanish versions from the authors (Anger). The AENTB manual is published (Amler et al., 1995) and is available from ATSDR (1600 Clifton Rd., Atlanta, Ga. 30333 USA).

This unit details the steps to take in developing a research study and implementing it in a laboratory or field setting. The effort is best mounted by a multidisciplinary team, including experimental psychologists for methodology, clinical psychologists to assess possible psychological implications of the exposures and to represent the interests of the exposed individual, industrial hygienists to measure the chemical in various media, neuroscientists who can propose biomarkers and suggest the possible mechanism(s) of effect(s), and statisticians who can assist with experimental design, statistical power analyses, and statistical analyses of the data.

Mouse Models of Global Cerebral Ischemia

Hippocampal neurodegeneration (HN) occurs as a result of global ischemia when blood flow to the brain is temporarily interrupted and then restarted. It can be observed in clinical cases of cardiac arrest, drowning, electrocution, and anesthesia-related accidents that are followed by successful, but somewhat delayed, resuscitation. HN can also result as a consequence of carbon monoxide inhalation (Nabeshima et al., 1991), certain hypoxemic-ischemic conditions (MacMillan et al., 1993), and as a result of measles infection (Andersson et al., 1993). HN leads to memory impairment and behavioral deficits in both humans (Beuret et al., 1993) and laboratory animals. For better understanding of the pathophysiology of this condition and molecular mechanisms involved, use of rodent replicas of HN has been recommended.

This unit describes basic surgical protocols for three models of global cerebral ischemia. These models are carried out by means of transient occlusion of both common carotid arteries (hence the name two-vessel occlusion model; see Basic Protocol 3), or in conjunction with either transient basilar artery occlusion (three-vessel occlusion model; see Basic Protocol 1) or permanent bilateral vertebral artery occlusion (four-vessel occlusion model; see Basic Protocol 2). Both controlled hypotension and ligation of the muscles on the neck can be used as adjunct procedures in all of these models to further diminish collateral blood flow to the ischemic hippocampus. These models were adapted from the laboratory rat and extensively validated in mice. The unit also describes basic histological techniques of brain tissue preparation (see Support Protocols 1 and 2) and methods for evaluation of hippocampal injury (see Support Protocols 3 to 6).

NOTE: All protocols using live animals must first be reviewed by the Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Surgical instruments should be sterilized in a hot-glass-bead, dry surgical instrument sterilizer (Stoelting) and should be kept on a silicon mat for safeguarding. Instruments for perfusion should not be pooled together with instruments intended for in vivo surgeries, but should be kept separately. Microscissors (Moria) are especially valuable items for in vivo microsurgical manipulations. Several different kinds should be purchased. Instruments made of titanium are very robust and are 30% to 40% lighter than similar instruments made of Dumostar, Dumoxel, or Inox stainless steel. They are also corrosion and heat resistant and nonmagnetic, but they are hard to resharpen or recondition.

NOTE: It is recommended that the reader search *Linscott's Directory of Immunological and Biological Reagents* (2000) to find competitive pricing prior to purchase of any antibodies, histostain kits, and other reagents.

THREE-VESSEL OCCLUSION MODEL OF GLOBAL CEREBRAL ISCHEMIA

BASIC PROTOCOL 1

The purpose of this protocol is to induce a transient global ischemic episode by means of either permanent or transient occlusion of the basilar artery and simultaneous occlusion of both common carotid arteries. Throughout the procedure, the ischemic episode and the postischemic reperfusion period are thoroughly controlled by evaluation of either cortical or hippocampal regional cerebral blood flow and cortical electrical activity. Delayed neuronal death to the CA1 subregion of the hippocampus develops by the end of 72 hr and is presumed to be of apoptotic origin. The borders of the CA1 subregion can be defined by a perpendicular line connecting both dentate gyrus blades with CA1-CA2 pyramidal cell layer laterally.

Contributed by Nariman Panahian

Current Protocols in Toxicology (2000) 11.8.1-11.8.24

The three-vessel occlusion global ischemia model is recommended for investigators studying the mechanisms of delayed neuronal death and apoptotic injury. This model can be used for assessment of neuroprotective potential of novel pharmacological agents administered either systemically, intracerebroventricularly, or locally (via iontophoretic applications).

Materials

Adult mice, 20 to 28 g (e.g., Harlan Bioproducts for Science, Jackson Laboratory, Taconic Farms)
3% and 1.5% (v/v) halothane in 70% N_2O/30% O_2
Acrylic dental cement (Stoelting)
Surgical glue
Xylocaine solution: 2.5% (v/v) lidocaine solution
1000 U/ml heparin
Heparinized saline: 100 µl heparin in 100 ml saline, use immediately

Fluotec 3 halothane vaporizer equipped with air, N_2O, and O_2 flowmeter assembly (Colonial Medical Supply)
Plexiglas halothane induction chamber for rodents (Stoelting)
Homeothermic blanket for rodents with feedback-regulated maintenance of body temperature (Stoelting)
YSI thermocouple equipped with a microprobe (model 511, S.N. K076, Harvard Apparatus)
SEP/EEG gold screws: gold-wire electrophysiology contacts for EEG and/or SEP monitoring (Fine Science Tools #19003-02)
Stereotaxic frame: dual-manipulator model with swivel mouse nose adaptor (David Kopf Instruments; optional)
Periflux PF-3 laser Doppler flowmeter equipped with PF318 master probe and MTB 500-0 straight fiberoptic microtips (Perimed)
Cotton swabs
8-0, 10-0, and 11-0 black monofilament nylon atraumatic sutures (Ethicon)
Absorbtion spears, 1 box
PE-10 intramedic polyethylene tubing (Clay Adams)
Lucr-Lok stopcock (Becton Dickinson)
27.5-G needle (Becton Dickinson)
1-ml tuberculin syringes (Becton Dickinson)
20-G, 17-mm-long angiocatheter (Angiocath, Deseret Medical) and curved stilette
SAR-830/P small animal ventilator, volume and pressure cycled, with built-in pump, flowmeter, and internal valves (CWE)
Microcapnometer (Columbus Instruments)
Blood gas analyzer (800 series; Ciba-Corning)
Heparinized microhematocrit capillary tubes (Fisher Scientific)
Overhead infrared reflector lamp (120 V, 250 W, GE; Harvard Apparatus)
6-0 silk black braided monofilament suture on a cutting G-7 needle (Ethicon)
Transpore surgical adhesive tape (Baxter Medical Supply)
Rodent intensive care and temperature control unit (DW-1, ThermoCare)
Stereomicroscope consisting of:
  MZ-8 Leica stereomicroscope on a three-dimensional SMS-20 ball-bearing boom stand, WF 10×/21M HP eyepieces, and 0.8× achromatic main objective lens, FWD = 112 mm (Kramer Scientific)
  Optical carrier equipped with a double-barrel coaxial surgical illuminator integrated with EKE rheostat light source

MacLab 8/e data acquisition system equipped with ETH-400 and Bridge preamplifiers running Chart and Scope software, with blood pressure transducers, EEG, EKG electrodes, BNC cables, thermocouple (AD Instruments)

Macintosh Power PC Laptop computer

Statview v. 5 statistical package for the Macintosh (SAS Institute, Inc.)

Statistical software for power analysis: Primer of Biostatistics (McGraw-Hill)

Viking, Nicolet Pathfinder four-channel evoked potential unit (Nicolet Biomedical)

440-E animal laboratory bipolar coagulator with McPherson bipolar miniature forceps and cords (Medifor)

Software packages for image analysis: Image ProPlus v. 3.0 (Media Cybernetics)

XLC-140 caposil or calcium-filled liquid nitrogen (vapor releasing) freezing chamber (LabRepco)

Timer (VWR)

Microsurgical instruments (Fine Science Tools):

Vibration-free microdrill (11,000 rpm) with 400-μm drill bits (#18000-17)

Moria miniature scalpel (#10315-12)

Straight titanium forceps (#11602-16) or suture-tying forceps (#18025-10)

Angled fine forceps (#11063-07)

Biologie no. 5 titanium forceps, 0.05 × 0.02–mm tip (#11252-40)

Dumont no. 4 forceps (#11241-30)

Dumont microsurgery forceps with atraumatic 0.1 × 0.06–mm tips (no. 55; #11253-20)

Dumont straight-tip forceps, 0.2 × 0.12–mm tip (#11203-23)

Dumont straight ultrafine forceps, 0.05 × 0.01–mm tip (#11254-20)

Epoxy-covered forceps (#11220-21)

Moria MC40 ultrafine forceps (#11370-40)

Vessel cannulation forceps S&T (#00571-13)

Vannas-Tubingen straight titanium scissors (#150007-08)

Small-blade scissors (#15000-08) or extra-delicate mini-Vannas scissors (#15000-00)

Student Vannas spring scissors, straight (#15100-09)

Mini-Goldstein retractor (#17002-02)

Yasargil vascular clip (Aesculap FD722), closing force = 0.98 N

Battery-operated small vessel cauterizer with angled and straight 0.2-mm-diameter tips made of platinum-iridium alloy (#18000-00)

Zen temporary clips (13 × 0.4–mm, 15-g closing force; Ohwa Tsusho)

Additional reagents and equipment for assessment of hippocampal injury (Support Protocols 1 to 6)

Prepare animals for physiological monitoring

1. Provide adult mice access to food and water ad libitum and keep animals under diurnal light conditions. Weigh animals prior to surgery.

2. Induce surgical-level anesthesia with 3% halothane in 70% N_2O/30% O_2 using a Fluotec 3 halothane vaporizer in a Plexiglas halothane induction chamber. Maintain further anesthesia using 1.5% halothane in 70% N_2O/30% O_2.

   Anesthesia will be discontinued ~2 min before vascular occlusions.

3. Place the mouse supine on a homeothermic blanket for regulated maintenance of body temperature with a YSI thermocouple. Insert a rectal probe.

   Surgical procedures may be performed without temperature adjustment until step 21.

4. Turn the mouse on its belly, expose the surface of the skull, and drill two burr holes (bregma = 0; 2 mm lateral of midline) with a vibration-free microdrill using surgical stereotoxic coordinates from the Franklin-Paxinos brain atlas (1997). Perform all surgical procedures on mice using a Leica MZ-8 stereomicroscope equipped with coaxial illuminator and EKE light source.

5. Hold two SEP/EEG gold screws in place using epoxy-covered forceps and bond them permanently to the surface of the skull using acrylic dental cement. Attach wire contacts to Viking-Nicolet Pathfinder evoked-potential unit.

   If desired and for greater precision, this procedure may be done with the mouse positioned in a stereotaxic frame.

6. Attach a fiberoptic microtip (for a Doppler flowmeter) to the surface of the drilled skull (2 mm posterior of bregma; 3.5 mm lateral of midline) using surgical glue.

7. Insert an Omega thermocouple 33-G needle probe into the cerebellum for direct brain temperature measurements, and fix in place using surgical glue.

Catheterize femoral artery

8. Begin femoral arterial cutdown by cutting cutaneous tissues and fascia propria using straight student Vannas scissors and Dumont no. 4 forceps. Identify the femoral artery in a common sheath together with the femoral vein and saphenous nerve.

9. Using two cotton swabs, dissect the bundle upwards bluntly to the level of the inguinal ligament and as much upwards as possible. Carefully examine all components of the bundle and then dissect them using Dumont straight ultrafine forceps, Biologie no. 5 titanium forceps, and Dumont microsurgery forceps with atraumatic tips (no. 55). Separate the nerve, the most lateral in location, from the surface of the femoral artery.

   The surface of the femoral vein must never be touched or pulled in any way, as this will rip open its wall and result in immediate bleeding.

10. Insert Dumont straight ultrafine forceps between the femoral artery and the vein below artery profunda femoris.

    If this is not done, the animal will loose all functions of that lower extremity when the catheter is extracted, with subsequent gangrenous transformation.

11. Peel the common vascular sheath off and upwards, toward the inguinal ligament, thus skeletonizing (freeing) necessary surgical space on the vessel.

12. Use angled fine forceps to pass a 10-0 monofilament nylon atraumatic suture behind the distal portions of femoral artery and vein, and ligate them separately.

13. Position a single Yasargil vascular clip proximally on the surface of both femoral artery and vein to achieve total cessation of blood flow. Then use a pair of Dumont straight-tip forceps to tie up the knots.

14. Stretch the femoral artery out by holding its entire width with Moria MC40 ultrafine forceps at the level of the placed knot and make a small cutdown at an angle of 30° to 35° through its wall using small-blade scissors or extra-delicate, mini-Vannas scissors.

    As a rule, some blood leaks back, originating from perforant muscular branches and artery profunda itself. In this case, absorption spears should be used for hemostasis. If the mouse is <25 g in weight, a drop of xylocaine solution may be applied to the surface of the femoral artery for maximum vasodilation and visibility.

15. Mount a PE-10 intramedic polyethylene tubing to a filed-down 27.5-G needle attached to a Luer-Lok stopcock and attach it to a 1-ml tuberculin syringe filled with heparinized saline. Flush the tubing to remove any air bubbles.

    The front tip of the tubing is slightly beveled, using student Vannas scissors, for ease of intraarterial introduction.

16. Hold the tip of the catheter (27.5-G needle) with either straight titanium forceps or suture-tying forceps (depending on the surgeon's hand size), and hold the arterial wall at the cutdown site with Biologie no. 5 or Dumont no. 55 forceps. Gradually pull the artery over the PE-10 tubing (as stockings onto a foot), advancing the tubing forward until it reaches the level of the external iliac artery.

17. After cannulation, fix the PE-10 tubing in place with a 10-0 monofilament nylon suture. Close the wound with surgical glue. Attach needle-stopcock-syringe assembly to MacLab 8/e pressure transducer.

    The wound is closed permanently to make sure that the in-dwelling tubing does not get dislodged when the animal is turned over or connected to the monitoring equipment.

Intubate mouse

18. Hyperextend the neck. Using straight student Vannas scissors, make an anterior midline incision through platysma and fascia propria to expose the trachea and thus facilitate intubation under direct visual control. Cut both sternohyoid and sternothyroid muscles.

    No hemostasis is necessary and, as a rule of thumb, very little or no bleeding at all will result. If bleeding results, use a small-vessel cauterizer to stop the bleeding. If branches of the external carotid artery are accidentally severed, use the McPherson bipolar coagulator and miniature forceps to close.

19. Intubate the mouse using a 20-G, 17-mm-long angiocatheter on a curved stilette. Achieve controlled ventilation using an SAR-830/P small-animal ventilator with the following settings:

    inspiratory stroke volume ≤ 0.5 ml
    inspiratory time = 0.1 sec
    respiratory rate = 110 to 120 breaths per min.

    The microcapnometer tubing must be positioned into the lateral outlet of the intubation angiocatheter to minimize dead space and to get an accurate $EtCO_2$ reading.

Monitor respiration, body temperature, cerebral flow, blood pressure, and heart rate

20. Adjust effective ventilation flow rates by respiratory end-tidal values using microcapnometer and arterial blood gas (pCO_2, pO_2) readings (Dalkara et al., 1995). To monitor, use heparinized microhematocrit capillary tubes and sample 50 µl arterial blood directly from the 27.5-G needle firmly attached to the in-dwelling PE-10 tubing placed in the femoral artery.

    Normal readings are:

    $pC0_2$ = 35 ± 3 mm Hg
    pH^2 = 7.27 ± 0.2
    $p0_2$ = 100–150 mm Hg
    Blood pressure (BP) = 95 ± 9 mm Hg
    Heart rate = 545 ± 78 beats/min

    After blood withdrawals, the intra-arterial lines must always be flushed with heparinized saline to prevent blood clots from forming in the catheter which could disrupt blood pressure recording.

21. Maintain rectal temperature (37° to 37.5°C) by means of the homeothermic blanket coupled to the YSI thermocouple and microprobe.

22. Maintain brain temperature between 36.5° and 37.5°C by means of an overhead infrared reflector lamp.
23. Determine regional cerebral blood flow (rCBF) by laser Doppler flowmetry using a flexible fiberoptic extension of the master probe, which was previously affixed to the surface of the skull (step 6).

    Initial rCBF values are taken as 100%.

Perform three-vessel occlusion

24. Establish physiological baselines. Start continuous-recording MacLab software (Chart) and hardware connected to a Macintosh laptop computer.
25. Pass a 6-0 braided monofilament suture underneath the mouse's front incisors and tape to the operating table using Transpore surgical tape.
26. Hyperextend the mouse by applying simultaneous downward traction to the tip of the tail and upward traction to the surgical suture behind the front incisors.

    Failure to perform this maneuver will make it difficult to expose the basilar artery.

27. Further hyperextend the neck by placing two or three cotton swabs underneath it.
28. Expose the left and right carotid bundles behind the sternocleidomastoid muscles. Retract the left carotid bundle laterally and the trachea-esophagus medially with a spatula.
29. Position a mini-Goldstein retractor at the level of the hypoglossal nerve and the hyoid bone on the left side. Identify the body of the first cervical vertebra and reveal the atlanto-occipital membrane along with the basal surface of the occipital and sphenoid bones.

    Only by overextention of the neck and slight traction in the opposite direction applied to the tail and front incisors can the atlanto-occipatal membrane be stretched and the vertebro-basilar junction revealed.

    For this step experienced users may use a spatula to expand the wound.

30. Transect the dura mater with a Moria miniature scalpel and Vannas-Tubingen straight titanium scissors. Absorb the drops of cerebrospinal fluid that are released using absorption spears.

    Using the Moria miniature scalpel helps to abolish blade drag and tissue distortion. Absorption spears are synthetic sponges capable of absorbing fluids faster and retaining them three times longer than analogous cotton sponges or pieces of gauze.

31. Identify the basilar artery, both vertebral arteries, and anterior spinal artery on the surface of the brainstem. Dissect the basilar artery free of the arachnoid membrane using Dumont straight ultrafine forceps.

    Without this maneuver, it will not be possible to achieve complete clipping of the basilar artery using Zen temporary clips. The arms of the clip (not just the tip) must embrace the basilar artery in order to completely arrest blood flow. Alternatively, the basilar artery may be tied off permanently using an 11-0 Ethicon monofilament nylon suture.

32. Position Zen temporary clips on the basilar artery and the two carotid arteries using vessel cannulation forceps and immediately start the timer. Occlude the arteries for 10 to 15 min. Discontinue anesthesia 1 to 2 min before vascular occulsions.

    A clip applier for the Zen temporary clips is currently unavailable. However, the size of the grooves present on the vessel cannulation forceps matches the clip size with precise tolerances, and can be purchased at 10% of the cost of all clip appliers available on the market today.

33. Control brain temperature as needed by bringing the overhead infrared reflector lamp closer to the animal as the brain temperature drops throughout the ischemic episode.

    These conditions produce satisfactory ischemia with cortical rCBF measurements consistently reduced to ≤10% of the initial baseline values and prominent suppression of cortical electrical activity.

34. Remove clips to induce reperfusion (≥72 hr). Remove laser Doppler flowmeter and skull temperature probes.

35. Close wound with 6-0 Ethicon nylon sutures and extubate. Leave the femoral arterial catheter in place for the first 24 hr. Use Transpore surgical adhesive tape to affix catheter and Luer-Lok stopcock containing heparinized saline solution to the back of the animal.

    The catheter may be used for infusion of supplemental nutrition, crystalloid solutions (Ringer's lactate), and balanced amino acid mixture-Novamine (Kabi Pharmacia), depending on the condition of the animal.

36. Transport the mouse to a rodent intensive care and temperature control unit and keep at 28° to 31°C for 72 hr to maintain normothermia.

Assess results

37. Perform behavioral assessment during the first 2 and 6 hr after induction of global ischemia and every 24 hr thereafter. Check for the following clinical signs: impaired grasping, akinesis, locomotor hyperactivity in response to a loud finger snap, impaired ability to recognize water and laboratory chow, and loss in body weight.

38. After 3 to 7 days past reperfusion, sacrifice mice for assessment of hippocampal injury (see Support Protocols 1 to 6).

FOUR-VESSEL OCCLUSION MODEL OF GLOBAL CEREBRAL ISCHEMIA

BASIC PROTOCOL 2

The four-vessel occlusion model may not require intubation and intraischemic ventilation of animals. The model is not as laborious as the three-vessel occlusion model and can be used by investigators not adept in microsurgical techniques. In brief, the purpose of the model is to induce delayed hippocampal injury by occlusion of both vertebral and both common carotid arteries with an interval of 24 hr. Vertebral arteries are occluded permanently, while both common carotids are occluded transiently. In this model, vital brain stem structures are less likely to become ischemic, since portions of the basilar artery as well as posterior inferior cerebellar arteries (responsible for collateral circulation) are preserved, because the level of interruption of blood supply to the posterior circulation is much lower than in the three-vessel occlusion model. The possibility of ischemic preconditioning may be the only drawback related to this model—in this model, both vertebral arteries are occluded 24 hr prior to the ischemic insult to the hippocampus.

Materials

Adult mice, 20 to 28 g (e.g., Harlan Bioproducts for Science, Jackson Laboratory, Taconic Farms)

2.0% (v/v) halothane in 70% N_2O/30% O_2

Surgical glue

Standard stereotaxic frame (Stoelting or David Kopf Instruments) equipped with mouse ear bars, micromanipulators, and a specially designed Narashigi head holder, and inhalation anesthesia nose cone

Transpore surgical adhesive tape (Baxter Medical Supply)

6-0 silk black monofilament nylon atraumatic sutures (Ethicon)

Cotton swabs
1-ml syringes (Becton Dickinson)
6-0 silk black braided suture on a cutting G-7 needle (Ethicon)
Surgical gauze
Stereomicroscope consisting of:
MZ-8 Leica stereomicroscope on a three-dimensional SMS-20 ball-bearing boom stand, WF 10×/21M HP eyepieces, and 0.8× achromatic main objective lens, FWD = 112 mm (Kramer Scientific)
Optical carrier equipped with a double-barrel coaxial surgical illuminator integrated with EKE rheostat light source
Fluotec 3 halothane vaporizer equipped with air, N_2O, and O_2 flowmeter assembly (Colonial Medical Supply)
Plexiglass halothane induction chamber for rodents (Stoelting)
440-E animal laboratory bipolar coagulator with McPherson bipolar miniature forceps and cords (Medifor)
YSI thermocouple equipped with a microprobe (model 511, S.N. K076; Harvard Apparatus)
Overhead infrared reflector lamp (120 V, 250 W, GE; Harvard Apparatus)
Rodent intensive care and temperature control unit (DW-1, ThermoCare)
Hot glass bead dry surgical instrument sterilizer (Stoelting)
Timer (VWR)
Homeothermic blanket for rodents with feedback regulated maintenance of body temperature (Stoelting)
Microsurgical instruments (Fine Science Tools):
Vibration-free microdrill (11,000 rpm) with 400-μm drill bits (#18000-17)
Scalpel blade
Biologie no. 5 titanium forceps, , 0.05 × 0.02–mm tip (#11252-40)
Dumont no. 4 forceps (#11241-30)
Student Vannas spring scissors, straight (#15100-09)
Mini-Goldstein retractor (#17002-02)
Battery-operated small-vessel cauterizer with angled and straight 0.2-mm-diameter platinum/iridium alloy tips (#18000-00)
Suture-tying forceps (#18025-10)
Vessel cannulation forceps S&T (#00571-13)
Zen temporary clips (13 × 0.4–mm, 15-g closing force; Ohwa Tsusho) and clip applier
Absorbtion spears, 1 box

Additional reagents and equipment for assessment of hippocampal injury (Support Protocols 1 to 6)

Occlude vertebral arteries

1. Place the animal on a homeothermic blanket and insert rectal temperature probe.
2. Position the adult mouse with its head in a stereotaxic frame and continuously deliver 2.0% halothane in 70% N_2O/30% O_2 to the animal using a Fluotec-3 halothane vaporizer via a nose cone. Maintain halothane anesthesia throughout occlusion of the vertebral arteries.
3. Position the animal's head in the stereotaxic frame with a downward flexion of ~30°.

   This angle is optimal for alignment of alar foramina with vertebral arteries passing underneath them. It was found emperically based on analysis of many animals perfused with carbon black ink (for vascular labeling) in which the alar foramina were drilled for visual evidence of exposure of these vessels.

4. Apply downward traction to the animal's tail throughout the surgical procedure, fixing the tail in place with Transpore surgical adhesive tape.

   This maneuver helps stretch out neck muscles and facilities exposure of the alar foramina and the vertebral arteries beneath them.

5. Using a Leica MZ-8 stereomicroscope to view the field, make a surgical incision through the superficial layers of the dorsal surface of the neck using a sharp scalpel.

6. Using a scalpel blade, student Vannas scissors, and an electrocauterizer, cut the muscles longitudinally and separate them from the body of the first cervical vertebra, exposing alar foramina and the vascular arterial branches passing through them.

7. Position a mini-Goldstein retractor at the midline between the surfaces of the cut muscles, taking care not to dissect neck muscles from the occipital region of the skull. Dissect neck muscles laterally in both left and right directions to expose alar foramina of the first cervical vertebra. Use the electrocauterizer and Dumont No. 4 and Biologie No. 5 forceps as needed during the dissection.

   Dissecting neck muscles from this region of the skull hinders the animal's natural feeding and drinking activity throughout the postoperative period.

8. To ensure complete occlusion of the vertebral arteries, drill the alar foramina using a vibration-free microdrill.

   This step should always be performed, as partial or complete ossification and tortuosity are common (Panahian et al., 1996).

9. Cauterize the vertebral arteries through the alar foramina using a battery-operated small-vessel cauterizer equipped with a straight 0.2-mm-diameter platinum/iridium alloy tip.

   Hemostasis is usually easy to achieve using absorption spears and/or surgical gauze.

10. Suture the wound (skin and muscles) using 6-0 nylon atraumatic sutures and suture-tying forceps. Allow the mouse to recover for 24 hr.

    It is not necessary to maintain body temperature during occlusion of the vertebral arteries or the recovery period.

Occlude carotid arteries

11. Induce anesthesia with 2.0% halothane as above.

12. Hyperextend the neck by placing two or three cotton swabs underneath it, and gently expose both common carotid arteries, without using traction, behind the sternocleidomastoid muscles.

13. Terminate anesthesia for ~1 min, and then occlude the carotid arteries for 10 to 15 min using Zen temporary clips with the aid of a vessel cannulation forceps. Control rectal temperature with YSI thermocouple and infrared reflector lamp.

Assess results

14. During the next 10 to 15 min, assess the mouse for the presence of behavioral signs of global ischemia:

    a. Mouse becomes unconscious but responds to a tail pinch throughout the ischemic procedure and a short while after induction of reperfusion (step 15).
    b. Mouse develops mydriasis (pupil dilation) and ocular anemia (exceptionally clear to observe in albino mice; Swiss-Webster, SV-129) during ischemic episode.

c. Mouse shows behavioral signs of recovery from a global ischemic episode: impaired grasping, akinesis, locomotor hyperactivity in response to a loud finger snap, and impaired ability to recognize water and laboratory chow.

15. Remove clips and reperfuse the animal following 10 to 15 min of ischemia (as assessed by the timer). Close the wound on the front of the neck with 6-0 nylon sutures and suture-tying forceps.

16. Keep the animals in a rodent intensive care and temperature control unit for 72 hr.

17. Sacrifice the animal anytime after 72 hr for assessment of hippocampal injury (see Support Protocols 1 to 6).

BASIC PROTOCOL 3

TWO-VESSEL OCCLUSION MODEL OF GLOBAL CEREBRAL ISCHEMIA

The Smith model is performed with minor modifications to the existing protocol (Smith et al., 1984; Fujii et al., 1997). It is a model of bilateral common carotid artery occlusion supplemented with exsanguination in order to achieve intraischemic hypotension. It is also the model that requires the greatest monitoring skills. Mice must be continuously anesthetized and preferably ventilated throughout the entire procedure. This model is recommended for acute in vivo (nonsurvival) studies involving extensive monitoring (e.g., single-cell hippocampal electrophysiology). Because the animals are well anesthetized while in the stereotaxic frame, a variety of electrodes and monitoring devices can be easily incorporated into the stereotaxic setup. The author recommends inflatable vascular occluders (In Vivo Metric) for occlusion of both common carotid arteries to avoid the need to swivel animal 90° for clipping of carotid arteries. This way, the global ischemic episode will also be induced with the animal in a more natural physiological position. Vibration from such swiveling manipulations may interfere with the quality of on-line continuous physiological monitoring. The In Vivo Metric cuffs are circumferentially attached around both common carotid arteries using 8-0 Ethicon monofilament nylon sutures and their tubing is inflated with saline or air using a 10-ml syringe.

Materials

Adult mice, 20 to 28 g (e.g., Harlan Bioproducts for Science, Jackson Laboratory, Taconic Farms)

3% and 1.5% (v/v) halothane in 70% N_2O/30% O_2

Xylocaine solution

Heparinized saline: 100 µl heparin in 100 ml saline, use immediately

Surgical glue

Acrylic dental cement (Stoelting)

Fluotec 3 halothane vaporizer equipped with air, N_2O, and O_2 flowmeter assembly (Colonial Medical Supply)

Plexiglass halothane induction chamber for rodents (Stoelting)

Homeothermic blanket for rodents with feedback-regulated maintenance body temperature (Stoelting)

YSI thermocouple equipped with a microphone (model 511, S.N. Ko76; Harvard Apparatus)

Omega thermocouple with 33-G needle probe for direct brain temperature measurements (Harvard Apparatus)

Cotton swabs

8-0, 10-0, and 11-0 black monofilament nylon atraumatic sutures (Ethicon)

Absorption spears

PE-10 intramedic polyethylene tubing (Clay Adams)

27.5-G needle (Becton Dickinson)

1- and 10-ml syringes (Becton Dickinson)
Periflux PF-3 laser Doppler flowmeter equipped with PF318 master probe and MTB 500-0 straight fiberoptic microtips (Perimed)
SEP/EEG gold screws: gold-wire electrophysiology contacts for EEG and/or SEP monitoring (Fine Science Tools #19003-02)
Stereotaxic frame: dual-manipulator model with swivel mouse nose adaptor (David Kopf Instruments)
20-G and 26-G, 17-mm-long angiocatheters (Angiocath, Deseret Medical) and curved stilette
SAR-830/P small-animal ventilator, volume and pressure cycled, with built-in pump, flowmeter, and internal valves (CWE)
6-0 silk black braided suture on a cutting G-7 needle (Ethicon)
500-µl gas-tight Hamilton syringe, heparinized
Vascular occluders, 2-mm diameter (OC2A; In Vivo Metric; optional)
Transpore surgical adhesive tape (Baxter Medical Supply)
Heparinized microhematocrit capillary tubes (Fisher Scientific)
Surgical gauze
Stereomicroscope consisting of:
  MZ-8 Leica stereomicroscope on a three-dimensional SMS-20 ball-bearing boom stand, WF 10×/21M HP eyepieces, and 0.8× achromatic main objective lens, FWD = 112 mm (Kramer Scientific)
  Optical carrier equipped with a double-barrel coaxial surgical illuminator integrated with EKE rheostat light source
Microcapnometer (Columbus Instruments)
MacLab 8/e data acquisition system equipped with ETH-400 and Bridge preamplifiers running Chart and Scope software, with blood pressure transducers, EEG, EKG electrodes, BNC cables, thermocouple (AD Instruments)
Macintosh Power PC Laptop computer
Viking, Nicolet Pathfinder four-channel evoked potential unit (Nicolet Biomedical)
800 series blood gas analyzer (Ciba-Corning)
440-E animal laboratory bipolar coagulator with McPherson bipolar miniature forceps and cords (Medifor)
YSI thermocouple equipped with a microprobe (model 511, S.N. K076, Harvard Apparatus)
Omega thermocouple with 33-G needle probe for direct brain temperature measurements (Harvard Apparatus)
Overhead infrared reflector lamp (120 V, 250 W, GE; Harvard Apparatus)
Rodent intensive care and temperature control unit (DW-1, ThermoCare)
Hot glass bead dry surgical instrument sterilizer (Stoelting)
Timer (VWR)
Homeothermic blanket for rodents with feedback regulated maintenance of body temperature (Stoelting)
Laboratory scale for weighing mice
Micro-surgical instruments (Fine Science Tools):
  Vibration-free microdrill (11,000 rpm) with 400-µm drill bits (#18000-17)
  Biologie no. 5 titanium forceps, 0.05 × 0.02–mm tip (#11252-40)
  Dumont no. 4 forceps (#11241-30)
  Dumont microsurgery forceps with atraumatic 0.1 × 0.06–mm tips (no. 55; #11253-20)
  Dumont straight-tip forceps, 0.2 × 0.12–mm tip (#11203-23)
  Dumont straight ultrafine forceps, 0.05 × 0.01–mm tip (#11254-20)
  Moria MC40 ultrafine forceps (#11370-40)

Small-blade scissors (#15000-08) or extra-delicate mini-Vannas scissors (#15000-00)
Student Vannas spring scissors, straight (#15100-09)
Mini-Goldstein retractor (#17002-02)
Micro-clip applicator with 18055 series micro-serrefines (#18056-14)
Battery-operated small-vessel cauterizer with angled and straight 0.2-mm-diameter platinum/iridium alloy tips (#18000-00)
Vessel cannulation forceps S&T (#00571-13)
Yasargil vascular clip (Aesculap FD722), closing force = 0.98 N
Zen temporary clips (13 × 0.4 mm, 15-g closing force; Ohwa Tsusho)

Additional reagents and equipment for assessment of hippocampal injury (Support Protocols 1 to 6)

Catheterize femoral arteries

1. Anesthetize an adult mouse with 3% halothane in 70% N_2O/30% O_2 using a Fluotec 3 halothane vaporizer in a Plexiglas halothane induction chamber. Maintain further anesthesia using 1.5% halothane in 70% N_2O/30% O_2. Place the animal on a homeothermic blanket and insert the rectal temperature probe.

2. Position an arterial catheter (PE-10 tubing affixed to 27.5-G needle) in the femoral artery and fix in place with surgical glue (see Basic Protocol 1, steps 8 to 17). Place a second arterial catheter in the other femoral artery.

   Small-blade scissors and Moria MC40 ultrafine forceps can expedite placement of the second arterial catheter. Dumont microsurgery forceps with atraumatic tips, Dumont straight-tip forceps, and Dumont straight ultrafine forceps are helpful in dissecting, the artery from the fermoral vein.

   Placement of the second arterial line is required for adequate control of intraischemic systemic arterial blood pressure, while the first arterial line is used solely for withdrawal of blood.

Set up monitoring devices

3. Affix the probe of a laser Doppler flowmeter over an avascular region of the cerebral cortex (see Basic Protocol 1, step 6).

4. Insert a miniature Omega temperature needle probe into the cerebellum (see Basic Protocol 1, step 7).

   Both probes are either positioned and held in place using micromanipulators or simply glued to the surface of the skull using surgical glue. Positioning the animal in a stereotaxic frame will simplify these tasks.

5. *Optional:* Place EEG/SEP electrodes for complete monitoring (see Basic Protocol 1, steps 4 and 5) and connect to the Viking, Nicolet Pathfinder evoked potential unit.

6. Intubate the mouse (see Basic Protocol 1, steps 18 and 19) and ventilate under control of end tidal CO_2 ($EtCO_2$) microcapnometer and arterial blood gases, assessed using microhematocrit capillary tubes and blood gas analyzer, to prevent intraischemic respiratory arrest, hypoxia, or postischemic hyperventilation.

7. Monitor respiration, body temperature, cerebral blood flow pressure, and heart rate (see Basic Protocol 1, steps 20 and 24).

Occlude carotid arteries

8. Expose both common carotid arteries and place 6-0 braided guiding sutures underneath them for rapid guidance to their location when the mouse is swiveled.

9. Expose right and left carotid bundles (see Basic Protocol 1, steps 25 to 28).
10. Rapidly withdraw 200 to 300 µl of arterial blood into a heparinized 500-µl Hamilton gas-tight syringe, sealed from atmospheric air and kept warm on a homeothermic blanket.
11. Swivel the animal 90° (to facilitate clipping) in a dual-maniputator model stereotaxic frame and quickly place Zen temporary clips on the common carotid arteries using guiding sutures and vessel cannulation forcep.

    Guiding sutures are needed to identify common carotid arteries (CCAs) and clip them. Do not stretch CCAs excessively as this may cause irritation to the carotid glomus and the superior cervical ganglion, and this may cause lung edema after reprefusion.

    Alternatively, a pair of In Vivo Metric vascular occluders can be placed on the carotids and inflated with air or saline to induce occlusions.
12. Monitor cortical blood flow and mean arterial blood pressure using MacLab 8/e system and Macintosh laptop computer. Withdraw additional blood as necessary to achieve relative cerebral blood flow reductions of 90% (corresponding to mean arterial blood pressure of 50 to 60 mmHg).

    Mice may become physiologically unstable and even go into cardiac arrest if systemic blood pressure drops to 35 mmHg or below.

    Blood withdrawal is an efficient procedure that momentarily suppresses compensatory increases in mean arterial blood pressure caused by a surge in catecholamine release.
13. Induce reperfusion and then swivel the animal back to its original position.

    If this maneuver is performed immediately after clip occlusion, vibration may interfere with the quality of on-line physiological recordings.
14. Reinfuse the withdrawn blood slowly.

    Rapid administration of blood after unclipping results in a sustained hyperemic episode. Do not increase halothane levels in order to prevent transient intraischemic increases in mean arterial pressure, as this may result in hypothermia and higher levels of halothane may be neuroprotective in this model.

Assess results

15. Weight mice daily. Perform behaviorial assessment (see Basic Protocol 1, step 37). Sacrifice mice after 2 to 3 days for assessment of hippocampal injury (see Support Protocols 1 to 6).

PREPARATION AND STAINING OF FROZEN SECTIONS

SUPPORT PROTOCOL 1

The brains are rapidly frozen, sectioned, and stained for visualizing ischemic neuronal damage. Both thionin and hematoxylin are good nuclear stains, while eosin labels the cytoplasm of neurons.

Materials

Mice from ischemia experiments (see Basic Protocols 1 to 3)
Isopentane (2-methylbutane), −15° to −20°C
Fixative solution: 1:1:1:1 (v/v/v/v) glacial acetic acid/acetone/absolute ethanol/water
Harris hematoxylin solution, ready-made (Polyscientific)
Thionin solution (see recipe)
1% (v/v) acid alcohol (Polyscientific)
0.05% (w/v) lithium carbonate (Polyscientific)

Eosin Y alcoholic working solution (Polyscientific)
95% and 100% (v/v) ethanol
Cytoseal 60 (low-viscosity mounting medium; VWR or Stephens Scientific) or Permount (Fisher Scientific)
Xylene

Dissection tools (e.g., see Basic Protocols 1 to 3 and Support Protocol 2)
Dual-compressor cryomicrotome (Jung CM 3000; Kramer Scientific)
1600-W hair dryer
Superfrost Plus glass slides (Fisher Scientific)
25-slide containers, sealed and dessicated (VWR)
Coplin jars
24 × 50–mm coverslips (VWR)
Aluminum foil
15-ml plastic centrifuge tubes
Light microscope (e.g. Olympus AX-70)

Prepare slides

1. Rapidly dissect the brains of mice from the skull.
2. Place them in isopentane at −15° to −20°C for ~2 min.
3. Store cryoprotected brains, wrapped in foil, indefinitely at −70°C in sealed plastic 15-ml centrifuge tubes.

   IMPORTANT NOTE: *Brains submerged in isopentane cooled to low temperatures (−40°C and below) may develop freezing artifacts manifesting as "swiss cheese syndrome," which is visible after hematoxylin and eosin staining. Such artifacts are less likely to be detected if thionin staining is used instead. Thionin staining is also less likely to detect episodes of immune response/cytotoxicity after gene therapy.*

   Brains can also be frozen artifact-free with liquid nitrogen vapor in a Caposil-filled XLC-140 freezing chamber (Vonsattel et al., 1995). One advantage of this approach is that both control and treated brains can be frozen simultaneously under identical conditions. Better antigen preservation has also been reported when this method of preservation is used for such techniques as immunocytochemistry and in situ hybridization. This method is less laborious compared to isopentane or hexane cryopreservation and is a definite time saver for those routinely processing large numbers of animal tissues.
4. Cut serial 10-µm thick coronal sections of the entire hippocampus using a dual-compressor cryomicrotome according to the manufacturer's instructions.
5. Mount sections on Superfrost Plus slides.
6. Store slides in sealed and dessicated 25-slide containers indefinitely at −70° to −80°C.

   It is recommended to cut and handle all brains under RNase-free conditions and to create a "bank" of specimens for future use for experiments involving in situ hybridization, immunocytochemistry, or histochemistry (Lu and Haber, 1992).

Stain slides

7. Thaw slides briefly with a hair dryer (~30 sec).

For hematoxylin/eosin staining

8a. Fix specimens 2 min in fixative solution in a Coplin jar.

9a. Wash sections 1 min in running tap water.

10a. Incubate slides 2 to 2.5 min in Harris hematoxylin solution and wash 4 min.

11a. Dip slides into 1% acid alcohol for 1 sec and wash 4 min in running water.

12a. Transfer slides into 0.05% lithium carbonate and wash 1 min in running water.

No running water is used after this step.

13a. Incubate 1 min in Eosin Y alcoholic working solution.

14a. Dehydrate sections in two changes each of 95% and 100% ethanol (15 dips in each).

15a. Transfer slides to xylene for 5 min (or store overnight in xylene).

16a. Mount in Cytoseal 60 or Permount and cover with a 24 × 50–mm coverslip.

17a. View using a conventional light microscope.

For thionin staining alone

8b. Stain 10-µm-thick frozen sections in thionin solution for 1 to 2 min in Coplin jars.

Staining duration depends on section thickness.

9b. Wash thoroughly for 10 min in running water.

10b. Dehydrate specimens in two changes each of 95% and 100% ethanol (15 dips each).

11b. Incubate 5 min in xylene.

12b. Mount using Cytoseal 60 or Permount and add a 24 × 50–mm coverslip.

13b. View using a conventional ligh microscope.

PERFUSION FIXATION OF BRAINS FOR IMMUNOCYTOCHEMICAL EXPERIMENTS

SUPPORT PROTOCOL 2

For immunocytochemical experiments, the author recommends the use of free-floating sections cut at a thickness of 40 µm or less. For this purpose, mice are perfusion fixed with 4% paraformaldehyde in phosphate buffer (pH = 7.4).

Materials

Mice from ischemic experiment (see Basic Protocols 1 to 3)
Heparinized saline: 100 µl heparin in 100 ml saline, 4°C
4% (w/v) paraformaldehyde, chilled to 4°C (see recipe)
Cryoprotectant solution (see recipe)
Powdered dry ice
Cytoseal

Mayo Toughcut tungsten-carbide scissors (Fine Science Tools #14512-15)
Adson Graefe tissue forceps (Fine Science Tools #11030-12)
Fine straight serrated scissors (Fine Science Tools #14070-12)
Moria fine forceps with microserrations (Fine Science Tools, Moria MC31#11370-31
Straight student Vannas scissors (Fine Science Tools #15000-09)
26-G, 17-mm-long angiocatheter (Angiocath, Deseret Medical) and curved stilette
Friedman-Pearson microrongeurs (Fine Science Tools #16020-14)
20-ml scintillation vials
Sliding microtome (HM 400 R from MICROM Laborgeräte GmbH; distributed by Carl Zeiss)

Additional reagents and equipment for halothane anesthesia (see Basic Protocol 1)

1. Place mouse under 3% halothane anesthesia (see Basic Protocol 1, step 2), and expose the chest cavity. Use Mayo toughcut scissors, Adson-Graefe forceps, and fine straight serrated scissors to cut the diaphragm. Hold the beating heart with Moria fine forceps.
2. Nick the heart with straight student Vannas scissors just enough to facilitate introduction of the tip of a 26-G perfusion catheter first into the left ventricle and then into the ascending arch of the aorta. Begin perfusion with 40 to 50 ml heparinized saline.

   No longer than ~30 to 45 sec should elapse from the time the chest cavity is opened to the time a successful perfusion is initiated.
3. When the effluent is clear of blood, administer 40 to 50 ml chilled 4% paraformaldehyde solution (4° to 6°C).

   Muscle twitching starts immediately thereafter and the animal should appear very stiff. The following are signs of an unsuccessful perfusion: (1) animal fails to develop rigor mortis (does not appear stiff); (2) no muscular twitching is present during infusion of 4% paraformaldehyde; (3) blood is present in the liver, which appears to be reddish or patchily perfused (after a successful perfusion the color of the liver is yellow, with no blood present); and (4) lungs are "inflated" with saline and perfusate is coming out of the mouse's upper respiratory tract (due to accidental perforation of the intraventricular septum by the tip of the 26-G perfusion catheter and administration of the perfusion solution into the pulmonary vascular system).
4. Extract the brain from the skull using Friedman-Pearson microrongeurs. Postfix in 4% paraformaldehyde for 4 to 6 hr at 4°C. Place brain into a 20-ml scintillation vial filled with cryoprotectant solution and allow the brain to sink to the bottom (2 to 3 days at 4°C).

   Brains may be stored indefinitely in this solution.
5. Process brain for preparation of free-floating sections using powdered dry ice and a sliding microtome according to manufacturer's instructions. Cut sections that are 35 to 40 μm thick.
6. Process free-floating sections for immunocytochemistry (Panahian et al., 1999).

   Alternatively, free-floating sections may be stored in 0.1 M phosphate buffer without azide, 4°C, up to 6 months.

SUPPORT PROTOCOL 3

QUANTITATIVE AND QUALITATIVE METHODS OF EVALUATING HIPPOCAMPAL INJURY

The number of viable pyramidal neurons in the CA1 subregion is counted in a coronally cut section of the brain using 200× magnification and a microscope equipped with a reticle. Sections 6- to 10-μm thick are used for hematoxylin and eosin staining and quantitative analysis; sections 35- to 40-μm thick are used for immunocytochemistry. Damaged neurons, when stained with hematoxylin and eosin (see Support Protocol 1), appear as shrunken, eosinophilic structures with scalloped cytoplasmic membrane and pyknotic nuclei. They are concentrated in CA1 and hilar regions of the hippocampus. Pyramidal neurons are counted in a 1-mm segment of the CA1 subregion on both the right and left sides and their values are averaged to derive a quantitative score for each mouse (Clifton et al., 1989; Nabeshima et al., 1991; Ishimaru et al., 1992). The average number of pyramidal neurons in the selected 1-mm stretch of the CA1 may vary between 220 to 300 and may be dependent on the technique of histological preparation of specimens. Paraformaldehyde fixation and paraffin embedding are known to result in tissue shrinkage; however, this phenomenon is not observed in unfixed, cryoprotected specimens used for preparation of frozen sections.

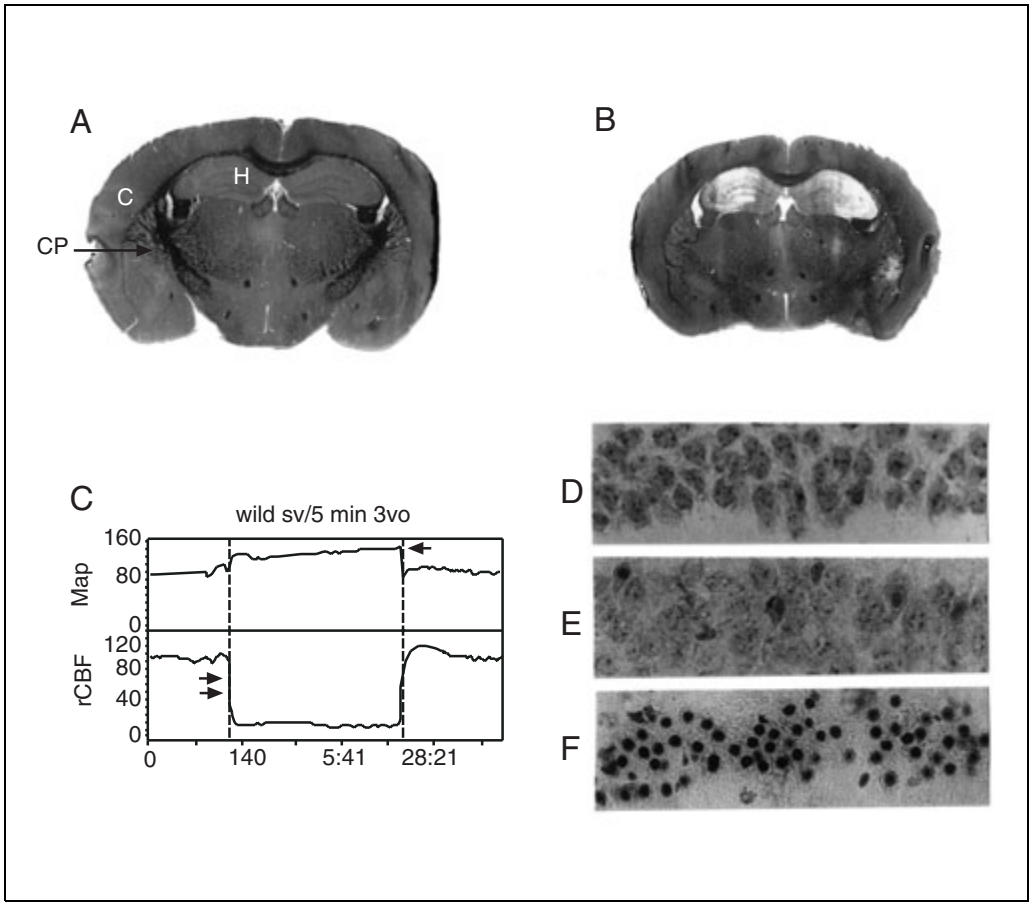

Figure 11.8.1 Three-vessel occlusion model of global cerebral ischemia in the laboratory mouse. (**A**) A hematoxylin and eosin–stained coronal section from a sham operated animal (C, cortex; H, hippocampus; CP, caudoputamen). (**B**) An ischemic episode of 15 min three-vessel occlusion followed by 72 hr reperfusion results in symmetrical injury to both hippocampi. Note that the overlying cerebral cortex is not affected. (**C**) A 5-min global ischemic episode is recorded using MacLab data acquisition system. Note a profound drop in the levels of cortical cerebral blood flow (rCBF; double arrowheads) and a compensatory increase in mean arterial blood pressure (MAP; single arrowhead). "wild sv/5 min 3vo" identifies this as an experiment in a SV129 wild-type mouse after 5 min of a 3-vessel-occulsion ischemic episode. Sham operations (**D**) and 5 min of global ischemia (**E**) result in minor injury to the CA1 hippocampal neurons. However, 15 min of global ischemia leads to complete CA1 wipeout (**F**). Magnification: A and C, 10×; D-F, 400×.

It should not be surprising to observe uneven "wipe out" of pyramidal neurons across the entire stretch of the CA1 subregion (i.e., more neurons present in the medial 1-mm stretch than in the lateral one bordering the CA2 subregion). Bilateral symmetry of hippocampal injury is the hallmark of a technically well-established model (Fig. 11.8.1). However, this may not be the case if selected ischemic intervals are shorter than 10 min. In such a case, injury to the CA1 subregion may be asymmetrical and even patchy. Thus, in order to make a meaningful interpretation of the data, pyramidal cell counts obtained from both sides of each hippocampal CA1 subregion need to be averaged. In order to detect subtle morphological differences between studied strains of mice, the author recommends that cell counts be performed throughout the entire CA1 subregion using four or five representative hippocampal coronal sections (with known distances between them) with the aid of an image analysis system (Image ProPlus; Media Cybernetics). The number of viable neurons (basophilic) is then analyzed using analysis of variance (ANOVA) followed by a recommended posthoc analysis (Statview v.5; SAS Institute). Sample size is determined by power analysis calculations (Primer of Biostatistics; also see *UNIT 1.2*).

An alternative approach is to evaluate specimens by a modified qualitative scoring method as suggested by Mòller et al. (1994):

Grade 0: No damage to any hippocampal subregions;

Grade 1: Scattered ischemic neurons in CA1 and/or hilus subregions;

Grade 2: Moderate ischemic neuronal loss in CA1 subregion (minor neuronal loss and/or edema may be present in CA2 and CA3 subregions);

Grade 3: Severe pyramidal cell loss within CA1 subregion;

Grade 4: Extensive cell loss in all hippocampal subregions.

SUPPORT PROTOCOL 4

MORPHOLOGICAL ANALYSIS OF HIPPOCAMPAL INJURY

Stratum oriens and radiale of the CA1 subregion appear more dense and eosinophylic by comparison to the dentate gyrus. Nuclear pyknosis, vacuolization, eosinophilia, cytoplasmic shrinkage, and triangulation should be considered typical features of injury during histological evaluation of the data. The number of glial cells in both of the stratum oriens and radiale of the CA1 subregion will dramatically increase after 72 hr of animal survival and can easily be detected using routine histostains (e.g., hematoxylin and eosin; see Support Protocol 1). Scattered, single, eosinophylic, triangulated (Nissl-type) neurons are frequently observed in layers 3 and 4 of the cortex bilaterally in most animals studied. Lesions typical for laminar necrosis involve cortical layers 5 and 6 and portions of the corpus callosum, as well as damage to the chorioid plexus and the wall of the lateral ventricle, and can be observed if clip occlusion intervals exceed 20 min.

SUPPORT PROTOCOL 5

PHYSIOLOGICAL PARAMETERS CONFIRMING HIPPOCAMPAL INJURY

Successful ischemic episode is evidenced by rapid decrease in both cortical and hippocampal regional cerebral blood flow values as well as flattening of the EEG and/or suppression of the SEP peaks to a flat line (Fig 11.8.1C). These changes should take place in the absence of a significant elevation in arterial blood pressure.

SUPPORT PROTOCOL 6

CLINICAL CRITERIA OF HIPPOCAMPAL INJURY

The following five clinical signs are important as predictors of the successful outcome of global ischemia models:

1. Immediate maximal dilation of both pupils and signs of ocular anemia (color changes from bright red-pink to extremely pale due to lack of filling of blood vessels) lasting throughout the global ischemic episode.
2. Absence of retrograde filling of the carotid arteries after placement of the clips during the ischemic episode.
3. A period of unconsciousness lasting up to 30 min after restoration of blood flow.
4. Traveling of longer distances in the cage by an otherwise akinetic mouse in response to loud finger snaps during the first 24 hr after induction of global cerebral ischemia.
5. Prominent weight loss by 72 hr.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cryoprotectant solution

300 ml ethylene glycol
200 g sucrose
600 ml 0.1 M phosphate buffer, pH 7.4
Store indefinitely at 4°C

Paraformaldehyde, 4% (w/v)

Dissolve 40 g paraformaldehyde (Mallinckrodt) in 1 liter of 0.1 M phosphate buffer, pH 7.4. Heat to 60°C with constant stirring to dissolve the paraformaldehyde. Then chill for 4 hr on ice in the refrigerator (4°C) before use.

Boiling inactivates paraformaldehyde.

Thionin solution

500 mg thionin (Sigma)
37 g sodium acetate
940 ml H_2O
Mix thoroughly
Add ~30 to 35 ml glacial acidic acid to adjust the final pH to 4.2
Store up to 1 year at room temperature

COMMENTARY

Background Information

This unit describes models that cause symmetrical, reproducible, and graded injury to the hippocampus. Their purpose is to induce time-dependent delayed neuronal injury to the CA1 and hilar subregions of the hippocampus by means of transient interruption of blood supply to the hippocampus and forebrain structures. This results in intraischemic global energy failure and drops in cortical and hippocampal electrical activity. An episode of global ischemia is usually followed by postischemic hyperemia during the reperfusion period. Decrease in protein synthesis, increase/decrease in cerebral metabolic rate of glucose utilization, and induction of immediate early genes have previously been reported for this condition (Geddes et al., 1996).

Basilar artery occlusion can also be performed as a two-stage procedure. This strategy is especially useful if several groups of mice need to be processed in one day under identical experimental conditions with insufficient time for detailed physiological monitoring. In this case, the basilar artery is not dissected free of the arachnoid, but is instead ligated (through the arachnoid membrane) using atraumatic 10-0 or 11-0 Ethicon suture material. (A microneedle holder will greatly facilitate insertion of the needle underneath the basilar artery without inflicting trauma to the brainstem.) Three to four knots should be tied over the artery using two no. 55 forceps. Twenty-four hours after permanent occlusion of the basilar artery, two Zen clips are positioned on the carotid bifurcation, resulting in clip occlusion of both external and internal carotid arteries. If basilar artery and carotids are to be occluded simultaneously, there is no need to occlude both carotid arteries (external and internal).

Patent and well-established posterior collateral supply (from the circle of Willis) to the vital areas of the brainstem is an absolute prerequisite for the successful accomplishment of the hippocampal neurodegeneration model (Murakami et al., 1998). It guarantees uneventful postoperative recovery of animals and long-term survival. Surgical models of global ischemia are technically demanding procedures, requiring the use of an operating microscope, microsurgical finesse, and patience in care for operated animals.

Pilot studies examining the phenomena of selective neuronal vulnerability, delayed neuronal death, and apoptosis-related hippocampal injury were first carried out in the gerbil, because the circle of Willis in this animal is functionally incomplete (Yamada et al., 1984). These studies led to development of various techniques presently used in quantitative assessment of hippocampal injury. Different time intervals of ischemic injury ranging from 2 to 10 min have

been tested (Matsuyama et al., 1993). The outcome of the gerbil model resulted in delayed neuronal death of selectively vulnerable neurons of the CA1 hippocampal subregion. Pathophysiology of repeated ischemic occlusions as well as hippocampal preconditioning (ischemic, hypotensive, hyperthermic, pharmacological, or mechanical by means of a direct intrahippocampal injection) were extensively examined (Kato and Kogure, 1990; Yamauchi et al., 1991). Because of the high incidence of epileptic seizures, the gerbil model of hippocampal neurodegeneration remains of limited applicability. Due to advances in transgenic technology, interest in investigation of the molecular mechanisms of ischemic injury shifted largely towards the laboratory mouse.

Based on the author's experience, mice are difficult to resuscitate. Cardiac arrest may occur if the mean arterial blood pressure of the mouse drops to 35 mmHg or below. This may occur if an investigator inadvertently withdraws blood in excess of volumes required to induce hypotention in the two-vessel occlusion model. In the author's hands, the cardiac arrest model (de Garavilla et al., 1984) resulted in very high mortality and seizures. The de la Torre model, which was first developed in the rat (de la Torre and Fortin, 1991), is one of the most technically complex models. It requires direct transthoracic access to the aortic arch and ligation of both subclavian arteries to arrest flow in the vertebral arteries, followed by timed occlusion of both common carotids. The model may lead to postoperative pneumothorax and atelectasis, and may require prolonged postoperative ventilation. Detailed knowledge of vascular anatomy and rodent resuscitation techniques is an absolute requirement for any investigator attempting to successfully replicate the de la Torre model. The other major concern is the fact that the model is time consuming, making it difficult to complete experiments on a group(s) of mice in one day under similar conditions.

A model of the "new genre" is that of measles virus–mediated hippocampal neurodegeneration (Andersson et al., 1993). It has been reported in BALB/c mice after intracerebral inoculation of its hamster neurotrophic strain. The model was reported to be sensitive and successfully ameliorated by the noncompetitive *N*-methyl-D-aspartate (NMDA) antagonist MK-801, something that has long been disputed by others using a four-vessel occlusion model of hippocampal neurodegeneration in the laboratory rat (Buchan and Pusinelli, 1990).

Critical Parameters

The following parameters are crucial for establishing a successful model of hippocampal neurodegeneration. (1) There must be immediate maximal dilation of both pupils and signs of ocular anemia lasting throughout the global ischemic episode. (2) There should be absence of retrograde filling of the carotids. (3) The animal should experience a period of unconsciousness lasting for up to 15 to 30 min after restoration of blood flow. (Restoration of blood flow during reperfusion is confirmed by inspecting for filling of all three arteries. Mydriasis should resolve immediately). (4) The animal, which is otherwise akinetic, should travel longer distances in the cage in response to loud finger snap during the first 24 hr after induction of global cerebral ischemia (increased locomotor activity). (5) The animal should display a prominent weight loss by 72 hr. (6) There should be impaired forepaw grasping. (7) The animal should display transient inability to recognize water and laboratory chow. (It is recommended that mice subjected to hippocampal neurodegeneration be fed with laboratory chow soaked in water and that the animal be kept under constant observation. Solutions of Novamine and Ringers lactate may be administered to sustain these animals hemodynamically and physiologically.)

Rectal and direct brain temperatures should be monitored before, during, and after the ischemic episode. Failure to monitor and control brain temperature throughout the global ischemic episode may result in the absence of hippocampal injury. Dramatic decrease in brain temperature values will be observed after clip occlusion (rectal temperature will stay normal as the animal lies on the homeothermic blanket) and slight increase in temperature may take place after induction of postischemic reperfusion.

Every animal should be checked for the absence of retrograde filling of the carotids above positioned clips (Kuroiwa et al., 1990) and rapid dilation of both pupils (mydriasis; Panahian et al., 1996). If rapid mydriasis is not observed, partial clip occlusion and/or faulty clip mechanism should be suspected. In this case, the animal should be euthanized.

Reduction in cortical regional cerebral blood flow to ≤10% of baseline was reported to be highly correlated with significant morphological damage to the CA1 hippocampal subregion (Dirnagl et al., 1993). The same also applies for flattening of the EEG and evoked potentials. Direct hippocampal blood flow (Kuroiwa et al., 1992) can be measured as an alternative to

measuring cortical regional cerebral blood flow in this mouse model. As a means of improving the model and making it more consistent, ligation of neck muscles is recommended to arrest possible collateral circulation (Kameyama et al., 1985). Clipping both external and internal carotid arteries make CA1 lesions more consistent, symmetrical, and reproducible. Hippocampal damage after the two-vessel occlusion model is less predictable than it is in other models and is usually asymmetrical, with considerable cortical injury, pericallosal laminar necrosis, and bilateral wipe-out of the chorioid plexus, including damage to the caudate. The time course of the injury to chorioid plexa may not necessarily be delayed, but rather immediate, in parallel with the time course of laminar necrosis and ischemic damage to the caudate (first 24 hr). There is animal-to-animal variation in the volumes of blood that must be withdrawn upon clip occlusion of the common carotid arteries to achieve controlled hypotention. The most important parameters for this model are the values of mean arterial pressure, regional cerebral blood flow (which must remain well below 10%), and brain temperature. In some mice, a drop in mean arterial pressure towards the end of the experiment necessitates partial reinfusion of shed blood. Cardiac arrest may result if mean arterial pressure levels are allowed to fall to 35 mmHg or below. On an average, it requires ~1 min of close monitoring after placement of the clips to suppress possible fluctuations in mean arterial pressure and regional cerebral blood flow. Thus, it is recommended that the time of ischemic occlusion for this model be longer compared to the other models (~15 to 20 min).

The levels of end tidal CO_2 ($EtCO_2$) decline considerably from 36 ± 4 mmHg at baseline to 23 ± 6 mmHg during ischemia. Upon unclipping and reinfusion of shed blood, a dramatic rise in $EtCO_2$ is observed during the first 1 to 2 min (to 68 ± 10 mmHg); this equilibrates by the end of the second min after reperfusion. Shortly after reinfusion of shed blood, a pronounced hyperemic episode usually results (up to three to four times baseline values), lasting for up to 7 min. This rise in regional cerebral blood flow may be triggered by rapid reinfusion of shed blood. It can be avoided or significantly decreased if the shed portion of the blood is administered very slowly into the animal's circulatory system after removal of the clips. Smith et al. (1984) were one of the first groups to use flow autoradiography for confirmation of successful ischemia. The authors also made a significant contribution by demonstrating that lactate production, ATP depletion, and high levels of catecholamine release occur during the ischemic period.

The author does not withdraw blood from the superior or inferior caval veins, but rather insert two arterial femoral catheters: the first for withdrawal of arterial blood and the second for monitoring mean arterial pressure. Arterial blood is quicker to withdraw in the mouse than venous blood, especially during the clip occlusion episode when every second counts.

Disadvantages of the two-vessel occlusion model are the use of an anesthetic during the ischemic episode as well as more extensive brain damage (not limited to the hippocampus). This model is also known to alter systemic pH and cardiac function, and to cause pulmonary complications. Respiratory complications (wheezing, edema) after the Smith procedure considerably decrease upon administration of the ganglionic blocker Arfonad or intra-arterial infusion of trimethaphan camsylate (Sheng et al., 1999). Pharmacological agents (sodium bicarbonate, ganglionic blockers, α-adrenoreceptor blockers) can be successfully used to influence the outcome of this model (Smith et al., 1984). Mice that survive the procedure rarely develop "hunchback" postures, as described for this model in the rat (Smith et al., 1984).

Care should be taken to avoid severe traction on the carotids and superior sympathetic cervical ganglion, touching the brainstem, or applying pressure on the vagal nerve even with fine forceps. Such manipulations may result in instantaneous drop of arterial blood pressure. The hypoglossal nerve in the mouse intersects with both external (located medially) and internal (located laterally) carotid arteries. Experienced investigators may thus refrain from using any retractors. Special care should be taken to avoid compression of the carotid glomus and superior cervical sympathetic ganglion located underneath the carotid bifurcation. Compression of the trachea may take place if the mini-Goldstein retractor is improperly positioned. This usually leads to respiratory distress syndrome, culminating in postoperative wheezing and lung edema. Traction to the vagal nerve, superior cervical ganglion, and accidental stretching of the common carotids during application of the clips may result in increased postoperative mortality due to pulmonary edema and shock.

Troubleshooting

After lengthy ischemic episodes (15 to 20 min), some mice may not regain spontaneous respiratory activity during the reperfusion pe-

riod. This observation indicates that during the ischemic episode, significant damage has resulted to the vital respiratory and/or cardiovascular centers of the brainstem due to poor vascular collaterals. This phenomenon is largely strain dependent (Ward et al., 1990; Barone et al., 1993; Panahian et al., 1996; Fujii et al., 1997). Most of the operated mice, if taken off the ventilator (not extubated) synchronously with removal of the clips, will exhibit a brief hyperventilation episode with dramatically increased respiratory rates. They should be kept intubated and ventilated until this condition resolves and they regain full consciousness. Thus, the time of extubation may vary (15 min to 1 hr) and will depend upon reestablishment of normal respiratory activity, $EtCO_2$, and actual blood gas (ABG) values, and upon the time when the animals fully regain consciousness. It is also noteworthy to mention that ABG values are strain dependent (Dalkara et al., 1995).

Time-dependent mortality usually results from respiratory distress syndrome culminating in lung edema during the first 12 hr, or epiliptic seizures thereafter. An overall mortality of at least 30% should be expected.

Asymmetric hippocampal damage has been observed in 20% of studied mice. These observations were previously reported in the gerbil model (Clifton et al., 1989) and in two commonly used rat models: two- and four-vessel occlusion. Ligating the paravertebral neck muscles or reducing intraischemic blood pressure to 70, 60, or even 50 mmHg circumvents the problem of asymmetric hippocampal lesions. The author also recommends clipping both external (to decrease collateral flow) and internal carotid arteries on left and right sides of the neck.

In the event that no lesion results from the treatment, check the closing force of microvascular clips as their compression mechanism may deteriorate with repeated use. Purchase additional clips as back up. Carefully monitor the intracerebral temperature during the ischemic period and use the infrared lamp to bring it to normal values. Use caution when adjusting the infrared lamp, because the infrared lamp may offset the readings of the laser Doppler flowmeter probe. When blood flow to the brain of the mouse is transiently interrupted, intracerebral temperature will decline over time, whereas body temperature will stay normal. Make sure the animal spends 72 hr in the temperature-controlled unit. Occlude both external and internal carotid arteries with one clip simultaneously on both sides of the neck. Suppress the intraischemic elevation of blood pressure at any cost; use exsanguination, ganglionic blockers, or any other method to keep it below 80 mmHg. Shed blood must be reinfused very slowly intrarterially or simply discarded. Rapid administration of shed blood may cause loss of cerebral autoregulation and profound hyperemic episode. After administration of shed blood, mice may develop metabolic acidosis. Do not attempt to permanently tie off one of the carotids as recommended in the Levine-type models of hypoxia-ischemia (MacMillan et al., 1993), as this will inevitably lead to asymmetric hippocampal injury. Make sure that the basilar artery is permanently ligated or cauterized using McPherson forceps or an electrocautery device (Fine Science Tools). Twenty-four hours later, proceed with bilateral temporary occlusions of both common carotids. During the occlusion episode, confirm that mice develop mydriasis within the first 10 to 15 sec postocclusion. As another indicator, suppression of retinal blood flow can be effectively monitored using a laser Doppler flowmeter probe placed on the surface of the eye. No retrograde filling of carotids should be present. Mice must be disconnected from halothane 1 min prior to placement of clips and remain unconscious throughout the ischemic procedure and for an additional 10 to 30 min after carotid clips are removed for induction of reperfusion. If mice regain consciousness shortly after the end of the procedure, much of their CA1 subregion will remain preserved. Perform carbon black studies (Panahian et al., 1999) for confirmation of cerebrovascular anatomical anomalies.

If mice develop convulsions during the first 24 hr postocclusion, they must be immediately euthanized, since they will not last 72 hr. However, isolated convulsion episodes are common and must not be confused with rolling seizures. It is important to determine the frequency of these convulsion episodes. Convulsions may be ameliorated by briefly anesthetizing animals with 1.5% halothane and restraining them until sacrifice.

Anticipated Results

Contrary to focal ischemia, global ischemia is a replica of a state of global energy failure. Albeit transient by nature, it leads to delayed neuronal death of selectively vulnerable pyramidal neurons of the CA1 subregion as well as neurons located in the hilar region of the dentate gyrus. Damage to the hippocampus is symmetrical, without involvement of the overlying cortex and with presence of minor injury to the caudoputamen (Fig 11.8.1A-F). Damage

to the dentate gyrus is not typical for this model, but it has been noted when ischemic intervals exceed 10 min, and it is resistant to hypothermic treatment (Agardh et al., 1992).

After three-vessel occlusion, hippocampal neurodegeneration will take place between 48 to 72 hr. From 72 hr to 7 days, the stratum oriens and radiale of the CA1 subregion will be invaded by glial cells. This infiltration will be more prominent within the medial portions of the CA1 subregion. Instantaneous rise in mean arterial blood pressure (Fig. 11.8.1C) upon clip occlusion of both common carotid arteries results in increased collateral flow to the hippocampus. This hypertensive episode must be dealt with decisively, and both hemorrhagic hypotention and treatment with ganglionic blockers (Arfonad) have been suggested. Out of 250 to 300 neurons in a 1-mm region of CA1, few are injured after 5 min of global ischemia compared to sham operated mice (Fig. 11.8.1, compare panels D and E), and only 40 to 60 live neurons are left after a 10-min ischemic episode followed by 72 hr reperfusion. After 15 min of global ischemia, there is a complete wipeout of all neurons within the ischemic CA1 subregion (grade IV injury; see Support Protocol 3 and Fig. 11.8.1F).

The role of ischemic preconditioning has not been extensively studied in the mouse four-vessel occlusion model. Because it is a two-step surgical procedure, investigators should always include control animals in which both vertebral arteries have been occluded but the main ischemic episode (bilateral common carotid artery occlusion) has not been carried out. Power analysis should be performed to assess the number of mice needed for the study, based on preliminary results and values of standard deviations, using statistical software (Primer of Biostatistics). The highest mortality should be expected after two-vessel occlusion with hemorrhagic hypotension due to profound blood-brain barrier (BBB) injury in this model (Preston et al., 1993). Nevertheless, it remains a reliable model for physiological monitoring in settings of an acute experiment.

Time Considerations

The model of three-vessel occlusion is reliable and does not require the use of a stereotactic frame. In experienced hands, the surgery can be completed within 30 min (as a one-stage procedure), if the animal is not prepared for physiological monitoring. If monitoring is included, the time required is: (1) no more than 20 to 25 min for placement of SEP/EEG electrodes, fiberoptic tip of the flowprobe, and needle probe of the Omega thermocouple; (2) 7 to 10 min for femoral cutdown; (3) 3 to 5 min for intubation; and (4) 15 to 20 min for surgery.

A total of 1 hr preparation for performance of complete monitoring of the global ischemic episode is required. This is followed by 10 to 15 min of global ischemic episode itself and ≥15 to 20 min monitoring of the recovery period after induction of postischemic reperfusion. With physiological monitoring, the experiment can be performed on approximately four to six mice in 1 day. Without monitoring, that number increases to twelve to fourteen mice per day. The author recommends that all mice be intubated and ventilated, and that brain temperature be measured in every mouse throughout the entire procedure. After the model is established in the lab, monitoring may be performed on only selected animals (Panahian et al., 1996).

Mouse Models of Focal Cerebral Ischemia

Stroke has been defined as a group of neurological disorders encompassing ischemic stroke, intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH) (Garcia et al., 1997). More than 500,000 new patients per year in the United States are affected by stroke (Fisher et al., 1999). Reproducible animal models of stroke are indispensable for investigation of pathogenesis and treatment of ischemic brain injury. Predictable location and size of infarction, as well as consistent production of neurological deficits and changes in blood flow, make it possible to evaluate the potential of novel therapeutic agents. With the advances in genetic engineering, different mouse strains with various man-made gene deletions or overexpressions (e.g., increases in the number of gene copies) are becoming available for ischemia research. Introduction of the laboratory mouse into stroke research has appropriately raised the standards of conventional physiology monitoring equipment. Throughout the past decade pioneering experiments were performed with great success using mouse species for screening of neuroprotective agents (Gotti et al., 1990; Backhauss et al., 1992). Ischemic stroke in mice can be induced using models adapted from the laboratory rat; these experiments involve craniectomy and direct exposure of the middle cerebral artery (Tamura et al., 1981; see Basic Protocol 1). Alternatively, ischemic stroke may be replicated using a coated filament obturator (Hara et al., 1996; Hata et al., 1998), which, after its endovascular introduction, is left in the intracranial portion of the internal carotid artery (ICA) to occlude the middle carotid artery (MCA) for controlled intervals of time. The general purpose of these two models is to replicate the human condition of ischemic stroke and transient ischemic attacks. Both models provide an opportunity to study novel mechanisms of neuroprotection in genetically altered mice, as well as to test pharmacologic agents for neuroprotection in both short- and long-term experiments. The filament model is used primarily to elucidate novel mechanisms of programmed cell death and brain reperfusion injury (Ma et al., 1998; Wang et al., 1998) as well as during trials for pharmacological amelioration of ischemic stroke. The Tamura-type model of permanent MCA occlusion (MCAo) is known to be statistically robust and produces minimal data scatter. It is widely used for assessing the impact of overexpression of neuroprotective genes on the course of ischemic neuronal injury in vivo (Martinou et al., 1994) as well as for the identification of genes playing major roles in neurodegeneration using knockout technology (Huang et al., 1994).

This unit describes two methods for inducing focal ischemia: one by proximal middle cerebral artery occlusion (see Basic Protocol 1) and one by permanent endovascular occlusion (see Basic Protocol 2). Alternatives of transient endovascular occlusion (see Alternate Protocol 1) and subarachnoid hemorrhage (Alternate Protocol 2) are also given. A number of protocols are described for determining the effects of ischemia induction: assessing physiological features (see Support Protocol 1), mapping of the circulation by perfusing the blood vessels with carbon black (see Support Protocol 2), determining stroke volume by staining with 2,3,5-triphenyltetrazolium chloride (see Support Protocol 3), evaluating post-treatment behavior (see Support Protocol 4), assessing stroke volume and cerebral edema (see Support Protocol 5), assessing the size of ischemic penumbra (see Support Protocol 6), and analyzing the statistics and presenting the data (see Support Protocol 7).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

BASIC PROTOCOL 1

SUBTEMPORAL CRANIECTOMY: PROXIMAL MCA OCCLUSION

The purpose of this model is to serve as a replica of human ischemic stroke. The model is widely used for screening neuroprotective agents, assessing the therapeutic potential of overexpression of therapeutic genes, and analyzing the impact of gene knockout technology on the outcome of ischemic stroke. Occlusion of the MCA near its origin (below the level of the olfactory tract) is sufficient to induce a reproducible ischemic lesion in the cortex and caudoputamen of mice with a coefficient of variation ≤10%. The model is primarily used for permanent occlusions, but may also be used to induce transient ischemia. For this purpose, the main trunk of the MCA must be transiently occluded with a fine microclip; however, the animal will need to be re-anesthetized for clip removal and induction of reperfusion. If selected intervals of ischemia are short (30 to 90 min), it may not be necessary to disconnect the animal from anesthesia. Regional cerebral blood flow (rCBF) may be monitored to confirm intraischemic reductions in cortical cerebral blood flow as well as its re-establishment upon reperfusion, but monitoring is not mandatory. Successful MCAo is confirmed upon the awakening of the mice using a behavioral assessment (see Support Protocol 4).

Materials

Mice
2% and 3% (v/v) halothane vaporized with 30% O_2/70% N_2 (Halocarbon Laboratories)
Halothane vaporizer (e.g., Fluotec model 3; Colonial Medical Supply)
Plexiglas anesthesia induction chamber for rodents (Stoelting)
Homeothermic blanket with feedback-regulated maintenance of body temperature (Stoelting)
YSI thermocouple equipped with a rectal temperature probe (Harvard Apparatus)
Nose cone: plastic housing of 20-G angiocatheter (Angiocath, Deseret Medical)
Surgical gauze
Surgical and microsurgical instruments (*UNIT 11.8*; Fine Science Tools):
  Student Vannas scissors
  Electrocautery device
  Friedman-Pearson micro-rongeurs
  Mini-Goldstein retractor
  No. 5 forceps
  No. 55 microforceps
Stereomicroscope with 10× objective (e.g., Leica MZ-8; Leica USA)
Microdrill and 0.35- to 0.42-mm diameter ultrafine burrs (Fine Science Tools)
27.5-G blunted needle with tip bent 90° (Becton Dickinson)
30-G needle, bent (Becton Dickinson)
Gelfoam (Upjohn, Becton Dickinson)
6-0 monofilament nylon atraumatic sutures (Ethicon)
Rodent intensive care and temperature-control unit (Thermocare)

Anesthetize the mouse

1. Anesthetize mouse with 3% (v/v) halothane vaporized with 30% O_2/70% N_2 using a halothane vaporizer and a Plexiglas anesthesia induction chamber for rodents. Place the mouse on a homeothermic blanket and insert a rectal temperature probe.
2. Switch the animal to 2% halothane (v/v) vaporized with 30% O_2/70% N_2 administered by means of a nose cone.

Alternatively the animal can be intubated and artificially ventilated (see UNIT 11.8).

3. Position the mouse's head on several pieces of gauze to level it with the body.

   No restraining devices are necessary.

Dissect the MCA

4. Make a vertical skin incision half the distance between the external auditory canal and the right orbit using student Vannas scissors. Make the incision long enough to gain access to the zygomatic arch and to the coronoid and condylar processes of the mandible. Cauterize superficial facial veins in the area of the zygomatic arch with an electrocautery device to prevent bleeding. Expose the body of the zygomatic arch widely by cutting away muscle from the bone with the electrocautery device and rongeur it away using Friedman-Pearson micro-rongeurs.

   IMPORTANT NOTE: *It is desirable to avoid rongeuring in the vicinity of the orbit as severe bleeding from the retro-orbital vessels may result.*

5. Carefully position a mini-Goldstein retractor to expose the opening.

   If the mouse develops arterial or venous bleeding as a result of surgical manipulations, the experiment for that animal should be aborted.

6. After the zygomatic arch has been rongeured away, identify the mandibular nerve (a branch of the trigeminal nerve). Bluntly dissect fibers of the temporal muscle (at approximately mid-distance between auditory canal and orbit) using no. 55 microforceps in order to expose the mandibular nerve. Identify the shiny tendon of the temporal muscle. Using a stereomicroscope at 10× magnification, locate the mandibular nerve in the vicinity of its posterior side, eventually crossing it from behind, and heading underneath.

   The nerve has a thickness of ~300 to 400 μm and is easily recognizable under 10× magnification of the microscope.

7. Carefully dissect the nerve using no. 5 and no. 55 microforceps and trace it to the foramen ovale. Insert no. 5 forceps in between the mandible and the retromandibular surface of the skull (infratemporal fossa) to gain access to the foramen ovale.

8. Once the foramen ovale has been found, identify the olfactory tract (a thick white band underneath the thin skull bones), which passes above the oval foramen and upwards (heading towards 1 o'clock), making a bend and heading towards the 3 o'clock direction.

   The juncture of the mandibular nerve and olfactory tract forms an angle opening towards the nose of the animal where the bottom leg is the mandibular nerve going into the oval foramen and the top leg is the olfactory tract underneath the skull bones, forming a bend (genu olfactorii). The MCA extends upwards eventually intersecting with both legs to form a triangle. Below the intersection with the olfactory tract, the MCA gives off one or several small branches of the lenticulostriatal artery, which provides a vascular supply to the caudate nucleus. The second intersection that the MCA makes is with the inferior cerebral vein before it divides into numerous branches supplying the cerebral cortex.

Occlude the MCA

9. Perform a craniectomy using a microdrill and 0.35- to 0.42-mm diameter ultrafine burrs to drill one hole. Make craniectomy anterior and above from the oval foramen over the trunk of the MCA, which can be identified through the thin skull bones of the mouse.

   Saline cooling of the drill helps to prevent local damage to the cortex from generated heat and also helps to disperse vibration.

10. Thin the bones of the skull overlying the trunk of the MCA by drilling and peeling the bone off using a blunted, 27.5-G needle with tip bent 90°.
11. Cut open the dura mater by means of the sharp end of a bent 30-G needle.
12. Further dissect the arachnoid membrane to free the artery so that it can be slightly elevated above the surface of the cortex and then cauterized.

    IMPORTANT NOTE: *Do not apply pressure to the underlying brain tissue with instruments during surgical dissections.*

    For permanent occlusions, the MCA can be tied off using an Ethicon 11-0 monofilament nylon suture; however, such procedures require surgical finesse (Welsh et al., 1987) and may be difficult for beginners.

    The MCA can also be occluded transiently for various periods of time (this interval is usually chosen not to exceed the duration of the therapeutic window or 0 to 4 hr) using a 10-B Zen microclip (Ohwa Tsusho) and an S&T clip applier (Fine Science Tools). Five minutes prior to reperfusion, the animal is re-anesthetized with halothane, sutures are taken off and the vascular clip is removed. The wound is closed again using Ethicon 6-0 monofilament nylon sutures.

Close the wound

13. Cover the site of the craniectomy with a small piece of Gelfoam. Close the wound using Ethicon 6-0 monofilament nylon sutures.
14. Take the animal off anesthesia and allow it to recover in a rodent intensive care and temperature-controlled unit.
15. Evaluate the ischemic injury (Support Protocols 1 to 6).

BASIC PROTOCOL 2

PERMANENT ENDOVASCULAR OCCLUSION MODEL OF FOCAL ISCHEMIA

The filament model is important for those investigators interested in studying the consequences of reperfusion injury in ischemic stroke. An advantage of this model is the use of endovascular techniques for MCA occlusions without the necessity of performing a craniectomy. A disadvantage of the model is a higher incidence of brain edema (if compared to the Tamura model; see Basic Protocol 1), as well as a higher rate of technical complications and mortality. The filament model is primarily used to elucidate novel mechanisms of programmed cell death and reperfusion injury (Wang et al., 1998), as well as their possible pharmacological amelioration (Ma et al., 1998).

Two other MCA endovascular occlusion models have recently been described: an embolic model (Z. Zhang et al., 1997) and a thromboembolic model (Kilic et al., 1998). Both models involve clot preparation from donor mice and infusion into the circle of Willis to block the MCA. Both models may be transformed from permanent to transient ischemia by the administration of tissue plasminogen activator (tPA) or other "clot-busting" agents. Variability in the development of cerebral infarction as well as hemorrhagic complications should be expected if tPA is used (Wang et al., 1998).

A tight strain-dependent relationship exists between the age and weight of the animals, and the diameter of arteries of the circle of Willis (see Critical Parameters). As part of the replication of the model in the laboratory, it is important to match the diameter of the arterial vessels of the mouse against those of the filaments precoated with different thicknesses of coating material (Table 11.9.1). Based on these preliminary findings, an optimum weight range of mice that best matches specific sizes of the coated filament may be selected. It is recommended that several trial runs of filament occlusions be made

Table 11.9.1 Filament Obturator Coatings

Coating medium (supplier)	Description
Reprosil (Dental Supply International)	Hydrophilic vinyl polysiloxane dental impression material.[a] Recommended for coating of filaments made from 8-0 Ethicon monofilament nylon; this coating material is easier to shape than Cuttersil.
Xantopren (Bayer Dental) or Cuttersil (Miles Dental Products)	Silicone resins that come with elastomer activator. Recommended for coating of filaments made from 8-0 Ethicon monofilament nylon.[b]
Poly-L-lysine (Sigma)	Recommended for coating of filaments made from 7-0 Ethicon monofilament nylon (recommend using a 5-0 nylon filament).[c]
Endothelin-1 (Calbiochem-Novabiochem)	Recommended for coating filaments made from 7-0 Ethicon monofilament nylon or otherwise administered directly onto the MCA from the outside via a stereotaxic approach.[d]

[a]Fouad and Bennett (1998)

[b]Hara et al. (1996); Hata et al. (1998)

[c]Belayev et al. (1999)

[d]Sharkey et al. (1994)

ex-vivo. Such occlusions should be performed on unfixed mouse brains, as well as in mice subjected to carbon black mapping (see Support Protocol 2) of their respective arteries of the circle of Willis to confirm proper filament placement. Before endovascular insertion of the filament, the vessels of the circle of Willis should be exposed, preferably from the base of the skull, to facilitate training in mastering the surgical technique.

All transient ischemia experiments should be done in conjunction with monitoring of cortical rCBF using a laser Doppler flowmeter for confirmation of the intra-ischemic drop in rCBF values as well as confirmation of re-establishment of postischemic flow within the MCA territory.

NOTE: This model may not be advisable for stroke research on genetically altered mice with known vascular or hematological disorders.

NOTE: All surgeries should be performed on only one hemisphere of the brain (Robinson, 1979) and one gender of mouse (Fisher et al., 1999).

Materials

Coating material (Table 11.9.1)
Mice to be tested
2% and 3% (v/v) halothane in 30% O_2/70% N_2 (Halocarbon Laboratories)

6-0, 7-0, 8-0, and 10-0 monofilament nylon atraumatic sutures (Ethicon)
27.5-G needle (Becton Dickinson)
Halothane vaporizer (e.g., Fluotec Model 3; Colonial Medical Supply)
Plexiglas induction anesthesia chamber (Stoelting)
Homeothermic blanket for rodents with feedback-regulated maintenance of body temperature (Stoelting)
YSI thermocouple equipped with a rectal temperature probe (Harvard Apparatus)
SAR-830/P small animal ventilator, volume and pressure cycled, with built in pump, flowmeter, and internal valves (CWE)

Endotracheal tube: 20-G, 17-mm-long angiocatheter on a curved stilette (Angiocath, Deseret Medical)
Catheter (i.e., PE-10 polyethylene tubing; Intramedic)
Microcapnometer (Columbus Instruments)
PF-3 laser Doppler flowmeter with masterprobe (Periflux, Perimed)
Cotton swabs
Microdrill and 0.35- to 0.42-mm diameter, ultrafine burrs (Fine Science Tools)
Surgical instruments (Fine Science Tools):
Student Vannas microscissors
No. 5 and no. 55 forceps
Curved Moria forceps
Stereotaxic frame, non-ferromagnetic (Massachusetts General Hospital machine shop; optional)
Surgical glue (optional)
16-G tubing (optional)
Silicone lubricant (optional)
Gelfoam (Upjohn, Becton Dickinson; optional)
Macintosh Power PC laptop computer
MacLab/8e data acquisition system equipped with ETH-400 and bridge preamplifiers running Scope and Chart software, with blood pressure transducers, EEG and EKG electrodes, BNC cables, and thermocouple (AD Instruments)
Blood gas analyzer (800 series, Ciba-Corning)
Zen temporary clips (13 × 0.4–mm, 15 g closing force; Ohwa Tsusho)
Vessel cannulation forceps S&T (Fine Science Tools)

Additional reagents and equipment for inserting arterial catheters, positioning laser Doppler flowmeter probes for rCBF monitoring, and artificial ventilation (*UNIT 11.8*).

Prepare the coated filaments

1. Select the compound with which to coat the body and the tip of the nylon filament (Table 11.9.1).

   Selection of coating material for the filament obturator is extremely important for the successful outcome of the model.

2. Submerge the filament in coating medium for 5 to 10 sec. Afterwards, gently shape the filament (with the yet unhardened coating medium) using the left index finger and thumb in one continuous motion (see Critical Parameters). Let the coated filaments dry for 2 hr in an upward position by placing in tiny wells carved into a styrofoam container with a 27.5-G needle.

Prepare the mouse

3. Purchase adult mice weighing 22 to 24 g from any reputable vendor. Provide access to water and laboratory chow ad libitum. Weigh the mice prior to surgeries and at the time of sacrifice.

4. Induce surgical-level anesthesia with 3% (v/v) halothane vaporized in 30% O_2/70% N_2 using a halothane vaporizer and a Plexiglas anesthesia induction chamber for rodents. Maintain the mouse under 2% (v/v) halothane vaporized in 30% O_2/70% N_2 throughout surgery and insertion of the filament.

   After insertion of the filament, animals are either awakened and behaviorally tested for confirmation of successful MCA occlusion (see Support Protocol 4) or maintained under 1% (v/v) halothane vaporized in 30% O_2/70% N_2 until withdrawal of the filament and initiation of reperfusion.

5. For insertion of the filament, position the mouse on a homeothermic blanket for regulated maintenance of body temperature. Insert a rectal probe to monitor temperature.

6. Intubate with a 20-G endotracheal tube and artificially ventilate the mouse for complete monitoring of physiological parameters (*UNIT 11.8*). Monitor respiratory status ($EtCO_2$) using a microcapnometer.

   Parameters of blood pressure, heart rate, body temperature are acquired on-line and analyzed directly using MacLab sensors connected to the ETH-400 preamplifier. End-tidal CO_2 ($EtCO_2$) is determined by the microcapnometer. Regional cerebral blood flow is determined by the Perimed Periflux PF-3 laser Doppler flowmeter. Cerebrovascular resistance is calculated on-line from parameters of rCBF (%) and mean arterial blood pressure (mmHg) using the calculated values option of Chart software.

   The microcapnometer, laser Doppler flowmeter, and ventilator are connected to MacLab/8e via BNC cables for analog output.

   IMPORTANT NOTE: *In all experiments involving MRI, mice should be ventilated. The ventilator can be effectively shielded from strong magnetic fields or placed a safe distance away at the expense of an increase in the overall length of the tubing. The length of the inflow and outflow tubes does not really matter as long as the length of the Y connector (the level at which both tubes converge on the way to the intubation tube) is short enough that it does not increase the dead space, which otherwise may suffocate the mouse (Dalkara et al., 1995). The intubation tube is usually sutured to the upper lip of the mouse with 6-0 monofilament nylon sutures so as to prevent it from slipping out.*

7. Place a femoral arterial catheter for monitoring of mean arterial blood pressure and assessment of arterial blood gas status using a blood gas analyzer with a MacLab/8e pressure transducer.

8. Attach a fiberoptic PF-3 laser Doppler flowmeter masterprobe to the skull thinned by drilling in the area of distribution of the middle cerebral artery at bregma-0, and ~1 mm below the junction of the sphenoid, temporal, and parietal bones.

   For this purpose, upper portions of the temporal muscle need to be carefully detached using student Vannas scissors and fiberoptic probe fixed to the surface of the skull using surgical glue.

   For detailed procedures of arterial catheter insertion techniques, positioning of the laser Doppler flowmeter probe for rCBF monitoring, and artificial ventilation see UNIT 11.8.

9. Once the mouse is placed on the homeothermic blanket, position the mouse with the neck slightly hyperextended.

   Placement of two cotton swabs underneath the neck region is usually sufficient to hyperextend the neck.

Dissect the vessels

10. Make an anterior midline incision through the platysma and fascia propria using student Vannas microscissors.

11. Expose the carotid bundle anterior and underneath the sternocleidomastoid muscle. Bluntly dissect the common carotid artery using no. 5 and no. 55 forceps.

    Take care not to exert any traction or traumatize the vagal nerve during dissection of the common carotid artery (CCA).

12. Dissect the CCA upwards to the level of its division into the external (ECA) and internal (ICA) carotids.

The superior cervical ganglion of the cervical sympathetic tract can be easily spotted in the carotid triangle, directly underneath the carotid bifurcation (for details of rodent sympathetic tract anatomy, see Hedger and Webber, 1976). External and internal carotid arteries form a triangle with the hypoglossal nerve at the level of the hyoid bone. The external carotid artery is located medially, while the internal carotid artery is located laterally and the hypoglossal nerve horizontally, at the top of the triangle. The hypoglossal nerve appears as a prominent thick white band about the same diameter as the common carotid artery.

13. After the dissection is completed, rotate the animal's head ~60° degrees to the contralateral side in order to expose the pterygopalatine artery (PPA).

14. Apply downward traction on the ICA at its intersection with the hypoglossal nerve with no. 5 forceps to reveal the PPA, which branches off the ICA above the level of the hypoglossal nerve.

    The Pterygopalatine (PPA) artery is the only artery that branches off the ICA. It runs horizontally, while the suprahypoglossal portion of the ICA ascends vertically at a sharp angle. Traction on the ICA brings the PPA forward towards the operator.

15. After this surgical maneuver, bring the delicate curved Moria forceps underneath the PPA. Discontinue traction. Use no. 55 forceps to bring forward the end of the 10-0 monofilament nylon thread towards the Moria forceps. During this maneuver, advance the 10-0 monofilament nylon suture further around the PPA with curved Moria forceps until it is tied off.

    IMPORTANT NOTE: *Failure to perform this step will result in the filament entering the PPA during the insertion procedure.*

16. For permanent occlusion of the MCA, tie off the ECA with 10-0 monofilament nylon (as proximally as possible to prevent the filament from entering its lumen) and tie off the CCA mid-distance between the level of the clavicle and carotid bifurcation.

17. Position a second 10-0 ligature loosely underneath the carotid bifurcation.

18. Place a Zen temporary microclip on the ICA above the level of the hypoglossal nerve as far upward as possible using a clip applier (S&T vessel cannulation forceps).

    Clipping the ICA prevents arterial backflow from the vessels of the circle of Willis.

Insert the filament

19. Make a small nick in the wall of the CCA using vascular scissors at mid-distance between the first (proximal) knot and the loosely positioned ligature at the level of the CCA bifurcation.

20. Confirm that no backflow bleeding is present. Insert the coated filament until its tip reaches the level of Zen temporary microclip and tighten the 10-0 Ethicon suture around the CCA.

21. Release Zen temporary microclip with the right hand using a clip applier. In order to prevent filament "wash out" and fatal bleeding from the carotid artery (see Critical Parameters and Troubleshooting), always hold on to the rear end of the filament with no. 5 forceps positioned in the left hand.

22. Before insertion of the filament into the intercranial portion of the circle of Willis, remove all cotton swabs from underneath the neck and return the head to its normal position. Insert a coated 8-0 Ethicon nylon filament to a distance of ~12 mm (from the carotid bifurcation) until it is safely lodged in the anterior cerebral artery.

Insertion of the coated filament should be performed very gradually, avoiding any possible resistance.

23. After the filament is advanced, secure it in place to the CCA with a 10-0 Ethicon nylon ligature. Close the surgical skin incision atraumatically with 6-0 Ethicon monofilament nylon sutures. Disconnect from anesthesia and allow to recover under normothermic conditions.

Perform MRI studies to determine lesion progression (optional)

NOTE: Reperfusion can be induced anytime by withdrawal of the filament from outside of the magnet. The body temperature of the mouse positioned in the magnet is monitored by a rectal probe and maintained at 37°C by means of a water blanket or warm air current. In a pilot study, no differences in systemic arterial blood pressure, heart rate, or cortical rCBF were detected in mice monitored for 2 hr in a vertical position simulating the environment of the vertical bore 9.1 Tesla magnet (N. Panahian and S. Kennedy, unpub. observ.).

24. After insertion of the filament and confirmation of rCBF drop to ~20%, transfer the mouse to a specially made stereotaxic frame of non-ferromagnetic material.

    This frame is usually constructed to be within the bird-cage MRI coil, to effectively suppress any motion artifact (Schulz et al., 1997; van Dorstein et al., 1999).

    Later, the coil will be inserted into the bore of a vertical or a horizontal magnet.

25. Glue a 6-0 nylon thread (heavily lubricated with silicone), a meter or more in length, to the lower end of the filament and pass it through a 16-G tubing (acting as its sheath) securely attached to the animal's belly with surgical glue on its way out of the magnet.

26. Place a large piece of Gelfoam at the site of the ECA to prevent possible postreperfusion bleeding. Also tightly suture the skin with 6-0 nylon sutures to prevent external hemorrhage.

    If reperfusion is attempted during MRI, vascular clips cannot be used even if they are made of non-ferromagnetic material, as removing the clips will cause interference with magnetic gradients and negatively impact the quality of the obtained image. It is not safe to reperfuse the mouse in the magnet with the common carotid artery not clipped or not permanently tied off. This may result in profuse bleeding from the site of incision in the ECA after withdrawal of the filament during initiation of reperfusion. The filament is usually introduced into the intracranial portion of the ICA and the circle of Willis via the external carotid artery. The pterygopalatine artery (PPA) is usually left intact or electrocauterized using McPherson-type bipolars (Radionics). In cases like this, the author recommends that only 8 to 10 mm of the proximal portion of the filament are coated, and that the external carotid artery is skeletonized to the greatest possible length and tied off as far distally (away from the CCA) as possible. Thus, in order to initiate postischemic reperfusion, the surgeon pulls the coated portion of the filament into this man-made vascular "pouch" created from the remnant of the ECA and does not attempt to retrieve the filament until the animal is sacrificed to avoid the possibility of profuse arterial bleeding.

TRANSIENT ENDOVASCULAR OCCLUSION FOCAL ISCHEMIA

ALTERNATE PROTOCOL 1

If the filament is left in place (permanently) within arteries of the circle of Willis, it becomes a model of "permanent" ischemia. An alternative technique should be used for filament models involving transient occlusions. The filament in these cases should be introduced into the circle of Willis through the external carotid artery (see Basic Protocol 2) with the following variations. During MCA occlusion, do not tie off the distal portion of the CCA, but occlude it with a 10-B Zen microclip using S&T vessel cannulation forceps (Fine Science Tools) as a clip applier. Upon induction of reperfusion, withdraw

the filament, tie off the ECA, and only then, release the 10-B Zen microclip from the CCA. Suture the skin with 6-0 monofilament nylon (Ethicon), and allow the animal to recover under normothermic conditions.

ALTERNATE PROTOCOL 2

INDUCING THE FILAMENT MODEL OF SUBARACHNOID HEMORRHAGE

In order to introduce the filament model of subarachnoid hemorrhage (SAH), either a 5-0 or 6-0 nylon filament is introduced into the circle of Willis (see Basic Protocol 2) and advanced into the anterior cerebral artery (ACA). When there is resistance to further forward movement of the filament, an additional 3 to 4 mm of filament is advanced to ensure perforation of the artery. The tip of the filament is immediately withdrawn to allow reperfusion to take place. Animals are sacrificed at 30 min, 24 hr, 3 days, and 7 days and perfused transcardially with a solution of carbon black in 10% gelatin (Kamii et al., 1999). Vasospasm is evaluated ex-vivo by the diameter of the proximal portion of the MCA using the magnification of a stereomicroscope directly connected to an image analysis system or three dimensionally using the corrosion cast technique (Ono et al., 1997).

ALTERNATE PROTOCOL 3

INDUCING HEMORRHAGIC STROKE MODEL BY COLLAGENASE INJECTION

Intracerebral hemorrhage (ICH) in mice is modeled by injection of bacterial collagenase into the caudate nucleus as described by Clark et al. (1998). Hemorrhagic transformation of the ischemic stroke as well as ICH, due to their serious prognosis, are considered exclusion criteria in most preclinical and clinical studies, including treatment with "clot busting agents" like tPA. There may be different levels of susceptibility of arterial vascular elements (e.g., basal laminae) to collagenase injection in genetically altered mice, and hence a different size of hematoma formation.

Materials

Mice
2% (v/v) halothane in 30% O_2/70% N_2 (Halocarbon Laboratories)
0.150 U/µl *Clostridium histolyticum* collagenase (Sigma)
Normal saline: 0.9% (w/v) NaCl
TTC staining solution (see recipe) or H&E stain (optional)

Homeothermic blanket for rodents with feedback-regulated maintenance of body temperature (Stoelting)
YSI thermocouple equipped with a rectal temperature probe (Harvard Apparatus)
Ultraprecise stereotaxic apparatus with gas anesthesia nose cone (Kopf Instruments)
Stereotaxic drill
Microdrill with ultrafine drill bits slightly larger than 32-G needle (Fine Science Tools)
Gas-tight microsyringes (Hamilton) with 32-G stainless steel needles without bevels
Rodent intensive care and temperature-control unit (Thermocare)
Surgical wax (Ethicon)
6-0 monofilament nylon sutures (Ethicon)

Prepare mouse

1. Administer 2% halothane to anesthetize mouse. Use a homeothermic blanket and YSI thermocouple with rectal temperature probe to establish and maintain normothermia.
2. Position and align the head of the mouse in the head holder of the ultraprecise stereotaxic apparatus equipped with a gas anesthesia nose cone. Tighten the earbars

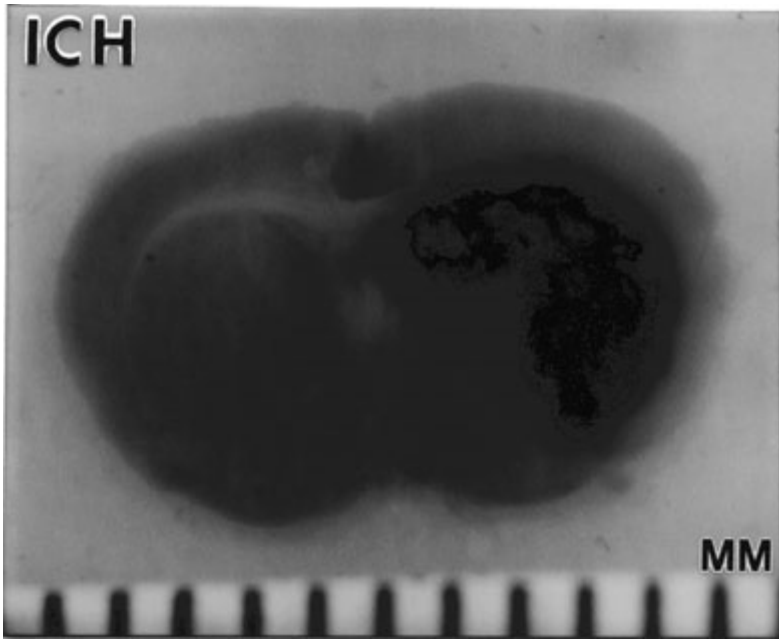

Figure 11.9.1 Hemorrhagic stroke 24 hr after stereotaxic administration of collagenase (0.075 U in 0.5 μl) into the caudate nucleus according to Clark et al. (1998). Hemorrhagic transformation and edema within this 2-mm-thick, TTC-stained coronal specimen of the mouse brain. Scale: 1 mm; magnification: 10×.

slightly, enough to prevent shifting of the stereotaxic zero point established at the intersection of Bregma and the sagittal suture.

3. Set the stereotaxic drill set-up manually to the following coordinates: anterior-posterior-(+0.7); medio-lateral-(2.0).

4. Drill the skull with the microdrill under constant saline irrigation to dissipate vibration and temperature effect on to the underlying brain.

   The diameter of the drilled burr hole only slightly exceeds that of the 32 GA needle to achieve a snug fit and prevent backflow.

Inject the mouse

5. Perform all stereotaxic injections using a gas-tight microsyringe coupled to a 32-G stainless steel needle without bevel. Gradually introduce the needle over 2 min into the brain to the depth of 3 mm.

   Bacterial collagenase can cause higher inflammatory response compared to blood infusion models of ICH. Also, the collagenase ICH model causes diffuse blood brain barrier breakdown.

6. Leave the needle in place for 20 min during the injection. Inject 0.5 μl suspension of bacterial collagenase from *Clostridium histolyticum* (0.075 U) gradually into the caudate nucleus of the mouse. Then gradually remove the needle over 2 min.

   Control animals receive 0.5 μl of normal saline instead.

7. Seal the site of the burr hole with surgical wax and suture soft tissues using 6-0 monofilament nylon sutures.

8. Transfer mouse to the rodent intensive care and temperature-control unit.

Assess results

9. Monitor animal weights and neurological status prior to surgery and every 24 hr after ICH induction until sacrifice.

10. Stain specimens with TTC staining solution (Support Protocol 3) or H&E as shown in Figure 11.9.1.

SUPPORT PROTOCOL 1

ASSESSMENT OF SYSTEMIC PHYSIOLOGICAL PARAMETERS

Systemic physiological characterization should be performed on both male and female animals of genetically engineered mice separately and matched against a hybrid strain colony. It is also important to perform these experiments on animals of uniform weight. Pelt color may differ among strains because mice are genetically inbred; however, it is important that within the same studied strain all mice have the same pelt color. Mice should always be kept in conditions of diurnal light cycle and given unrestricted access to water and laboratory chow.

Materials *(also see Basic Protocol 1 and 2)*

Mice treated to induce focal ischemia (see Basic Protocol 1 and 2) and control mice
2.5% and 1.0% to 1.5% (v/v) halothane vaporized with 30% O_2/70% N_2O (Halocarbon Laboratories)
α-Chloralose (Rochester Hospital Supply)

Homeothermic blanket (Stoelting)
Overhead infrared lamp, YSI thermocouple with rectal temperature probe (Harvard Apparatus)
Macintosh Powerbook, MacLab/8e data acquisition system with four-channel ETH-400 transducer-amplifier (AD Instruments), and appropriate software (e.g., Scope and Chart; AD Instruments)

1. For physiological monitoring, anesthetize either mice treated to induce focal ischemia (see Basic Protocol 1 and 2) or controls with 2.5% (v/v) halothane vaporized with 30% O_2/70% N_2O using a halothane vaporizer and Plexiglas anesthesia induction chamber for rodents.

2. Place the mouse supine on a homeothermic blanket and intubate with a 20-G endotracheal tube.

3. Switch the anesthesia to between 1.0% and 1.5% halothane.

4. Control the rectal temperature thoroughly by means of an overhead infrared lamp, homeothermic blanket, YSI thermocouple with rectal probe maintaining the rectal temperature at 37°C throughout the entire period of physiological monitoring.

   The overhead infrared lamp is used to quickly raise the body temperature by several degrees in a hypothermic animal. This saves time while establishing physiological baselines.

   The laser Doppler flowmeter will show erratic (artifactual) readings when the overhead infrared lamp is on.

5. Cannulate the femoral artery with PE-10 tubing for systemic arterial blood pressure measurements and sampling for confirmation of arterial blood gas status (i.e., pH, pO_2, and pCO_2) using a blood gas analyzer.

6. Change the anesthesia to 80 mg/kg α-chloralose administered intravenously upon initiation of artificial ventilation. Give the drug subsequently every hour at a dose of 40 mg/kg after the femoral vein is catheterized.

CAUTION: *Halothane anesthesia exerts negative chronotropic and inotropic effects on the hearts of mice, manifesting in decreased mean arterial blood pressure and heart rate. For baseline comparison of mean values of arterial blood pressure and heart rate, α-chloralose should be used as described (Hara et al., 1996).*

7. Connect the mouse to a CWE SAR830P ventilator and adjust effective flow rates based on the measurements of the microcapnometer.

   Inspiratory time should be set between 0.07 and 0.1 sec. The stroke volume of the ventilator must not exceed 0.5 to 0.6 ml and the respiratory rate 120 to 170 breaths/min.

8. Monitor regional cerebral blood flow (rCBF) using a Periflux PF2B laser Doppler flowmeter equipped with a flexible microprobe (Perimed), affixed directly to the surface of the skull (previously thinned by drilling; see Basic Protocol 2, step 8) overlying the MCA territory. Perform on-line data acquisition and analysis using a Macintosh Powerbook with a MacLab/8e recording unit with four-channel ETH-400 transducer-amplifier and appropriate software (e.g., Scope and Chart).

CARBON BLACK PERFUSIONS

SUPPORT PROTOCOL 2

Carbon Black perfusion of the brain arteries allows detection of vascular anomalies within the circle of Willis, detection of the borders of avascular territory after stroke, determination of the pattern of branching and topography of cortical arterial anastomoses (e.g., between branches of MCA and pericallosal artery), and determination of vascular diameter after subarachnoid hemorrhage.

Materials

Mice treated to induce focal ischemia (see Basic Protocol 1 or 2) and control mice
Heparinized saline: 100 µl heparin in 100 ml saline (0.9% w/v NaCl; use immediately)
1.6% to 1.8% (v/v) Higgins Black Magic waterproof drawing ink (Eberhard Faber)
4% (w/v) paraformaldehyde (*UNIT 11.8*)

MZ-8 Leica stereomicroscope
Styrofoam board and pins or tacks
26-G plastic catheter mounted on a 10-ml syringe
Camera (e.g., MicroCam; Polaroid)

1. Anesthetize either a mouse treated to induce focal ischemia or a control mouse with 3% (v/v) halothane vaporized with 30% (v/v) O_2/70% N_2 using a halothane vaporizer and Plexiglas anesthesia induction chamber for rodents.

2. Place the mouse belly up with extremities spread out as far as possible. Pin down the upper and lower paws to a styrofoam board (a piece of commercially available styrofoam) using pins or thumbtacks. Continue halothane anesthesia using a nose cone (see Basic Protocol 1). Introduce a 26-G plastic catheter mounted on a 10-ml syringe into the left ventricle and initiate transcardiac perfusion with 20 ml of heparinized saline.

   For details of the mouse perfusion fixation protocol see UNIT 11.8.

3. Cut open the right atrium to release the effluent. Advance the catheter into the ascending aorta and inject ~1 ml of a 1.6% to 1.8% (hypertonic) solution of Higgins Black Magic waterproof drawing ink, until the animal's tongue, lips, and paws turn black.

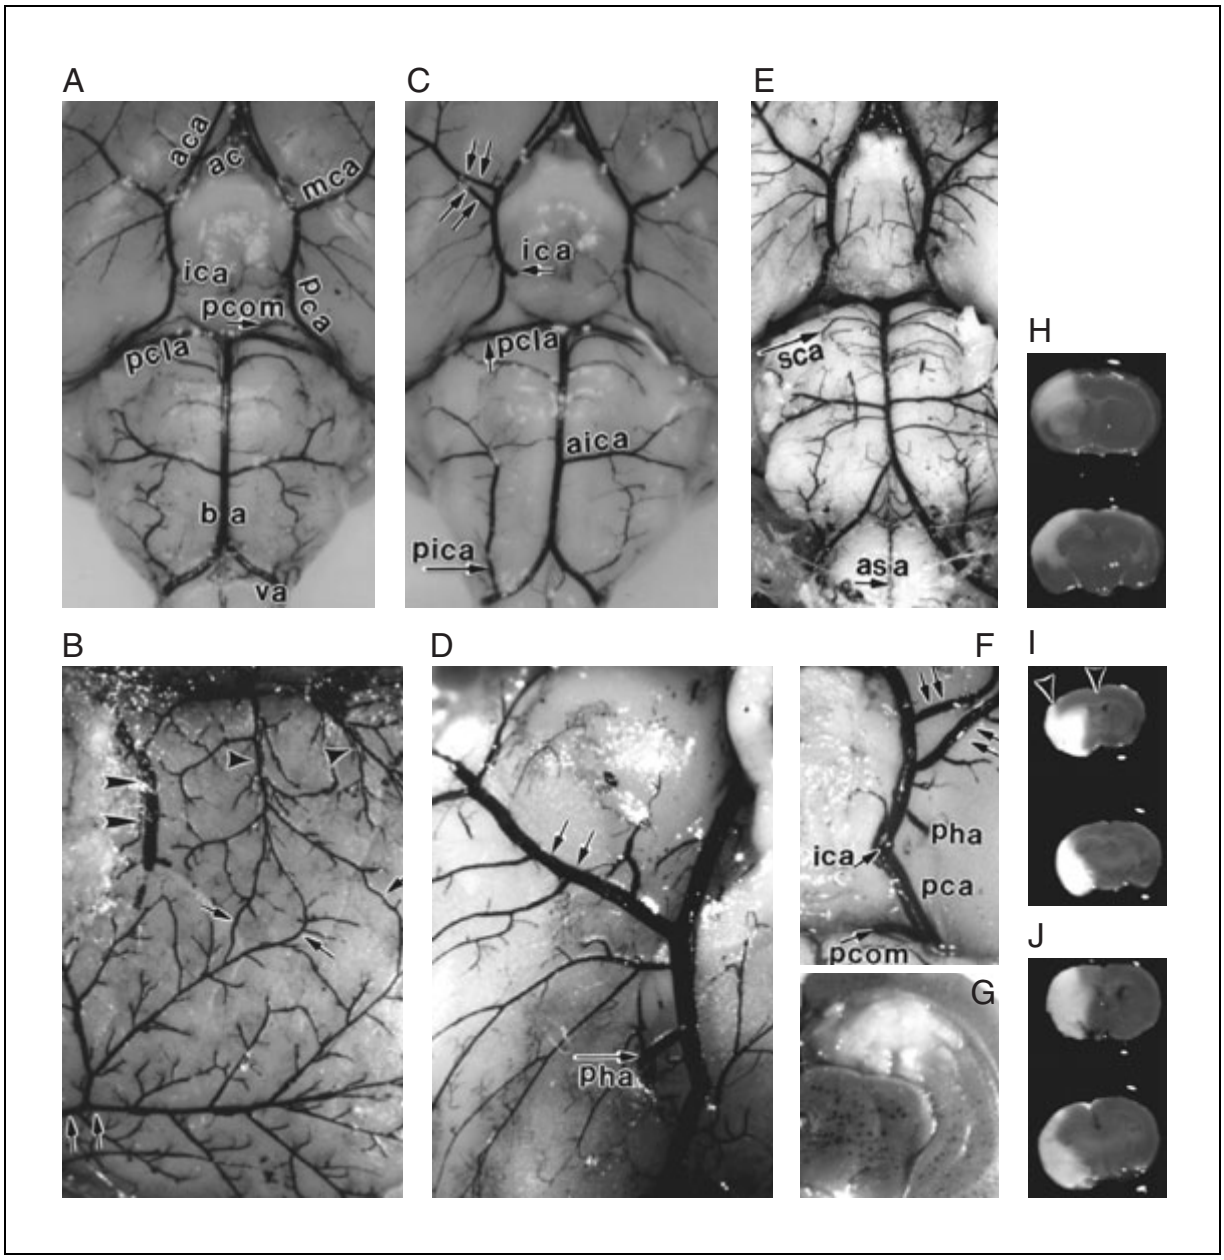

Figure 11.9.2 Carbon black vascular mapping of the brains of intact mice for demonstration of vascular anomalies (**A, C, D, E, F**) and mapping of arterial cortical collaterals (**B**, marked as small single arrows) between branches of pericallosal artery (marked with single arrow-heads) and middle cerebral artery (mca; marked with small double arrows). The level of the bregma is marked with big double arrows. Note duplications of MCA marked by small double arrows (**C** and **F**); absence of one (or both) of the posterior communicating arteries (pcom; C versus A); presence of increased posterior vascular arborizations of the MCA (D and E); absence of right anterior inferior cerebellar artery (aica , C). (**G, H, I, J**) TTC staining of mouse brains after 24 hr MCAo using either filament (G and J), Brint (H) or Tamura-type models (I). Note decreased cerebral edema in the Tamura (I) versus the filament model (J). Upper cortical regions overlying the caudate nucleus and corresponding to watershed areas (marked with arrowheads) are preserved in the Brint and Tamura models (H and I), but are compromised in the filament model (J). SV-129 mice were used in these experiments. As a result of partial filament insertion due to excessive coating material, occlusion of the posterior hippocampal artery (pha) resulted in a lesion in the upper posterior portions of the hippocampus in a C57Bl/6 mouse (G). Abbreviations: ac, anterior communicating artery; aca, anterior cerebral artery; aica, anterior inferior cerebellar artery; asa, anterior spinal artery; ba, basilar artery; ica, internal carotid artery; mca, middle cerebral artery; pca, posterior cerebral artery; pcla, posterior cerebellar artery; pcom, posterior communicating artery; pha, posterior hippocampal artery; pica, posterior inferior cerebellar artery; sca, superior cerebellar artery; va, vertebral artery.

IMPORTANT NOTE: *If the osmolarity of the final solution is lower than 1.6%, extravasation of the dye will take place resulting in the presence of dark background as well as both arterial and venous labeling.*

For labeling of fine cortical capillaries and microvessels, crystals of NaCl should be added directly to aliquots of ink, for a final hypertonic solution of 1.6% to 1.8%, without addition of particles of activated carbon. Alternatively, the carbon black perfusion solution may be prepared by adding the dye into a 10% (w/v) gelatin perfusion solution (Kamii et al., 1999).

Alternatively, ~1 ml Higgins Black Magic ink may be added to a 15% (w/v) polyacrylamide separating gel (5 ml), immediately after Temed and ammonium persulfate. This solution is used to transcardially perfuse the mouse. The gel will polymerize in arterial vessels of the brain and form a cast. Color intensity is determined by the amount of ink (B.A. Brown and N. Panahian, unpub. observ.).

Mapping of the large arterial blood vessels of the circle of Willis may be performed by directly mixing particles of activated carbon (G-60, 100 mesh; Aldrich) with Higgins Black Magic waterproof drawing ink. The final concentration of carbon particles is chosen arbitrarily and depends on the viscosity of the final solution and its ability to pass through a 22- to 26-G plastic catheter placed into the ascending aorta of mice.

4. Upon completion of perfusion, perform a small craniectomy to allow better access of fixative to the brain. Fix the brains 3 to 4 days in 4% PFA.

5. After fixation, extract the brains carefully from the skull using extra fine Friedman-Pearson microrongeurs. First separate the lower jaw and soft tissues from the skull using Friedman-Pearson rongeurs.

   IMPORTANT NOTE: *No twisting motion should be used when performing dissections with extra-fine Friedman-Pearson micro-rongeurs, as this may damage the instrument beyond repair.*

   Such dissections should be started from the base of the skull so that all major arterial branches of the brain as well as the brainstem and upper portions of the spinal cord will be preserved (Fig. 11.9.2A to F). Using the same dissection approach, the branches of the middle cerebral artery and their collaterals with pericallosal artery (in the "watershed areas") will always remain intact (Fig. 11.9.2B). Similar tactics of anatomical dissection can be used to detect the presence of vascular arterial anomalies like duplication of MCA (Fig. 11.9.2C and F), absence of one (or both) of the posterior communicating arteries (Fig. 11.9.2C), presence of increased posterior vascular arborizations of the MCA (Fig. 11.9.2D and E), absence of anterior inferior cerebellar artery (aica; Fig. 11.9.2C), as well as the presence of connections between branches of external and internal carotid arteries which may form Rete Mirabile (Fuwa, 1994).

6. Examine the vessels of the circle of Willis and their branches at 10 to 20× magnification using a Leica MZ-8 stereomicroscope equipped with a 0.8× apochromatic objective and 10× wide-angle eyepieces. Photograph anatomical specimens using a Polaroid camera (e.g., MicroCam).

TTC STAINING TO DETERMINE STROKE VOLUME

SUPPORT PROTOCOL 3

It is customary to perform analysis of stroke volume using triphenyltetrazolium chloride (TTC) staining (Bose et al., 1984; Isayama et al., 1991). Areas of the brain with active mitochondrial enzymes will stain bright red, while areas of infarcted tissue will remain white. This method cannot be used to accurately assess the area of ischemic neuronal injury during early (6 to 12 hr) and late (2 to 3 days or longer) periods of stroke, but it is widely used for detection of stroke volume at 24 hr (Fig. 11.9.2H to J and Fig. 11.9.3). Tissue stained with TTC and stored in 4% paraformaldehyde may be processed for hematoxylin and eosin (H&E) staining and immunocytochemistry.

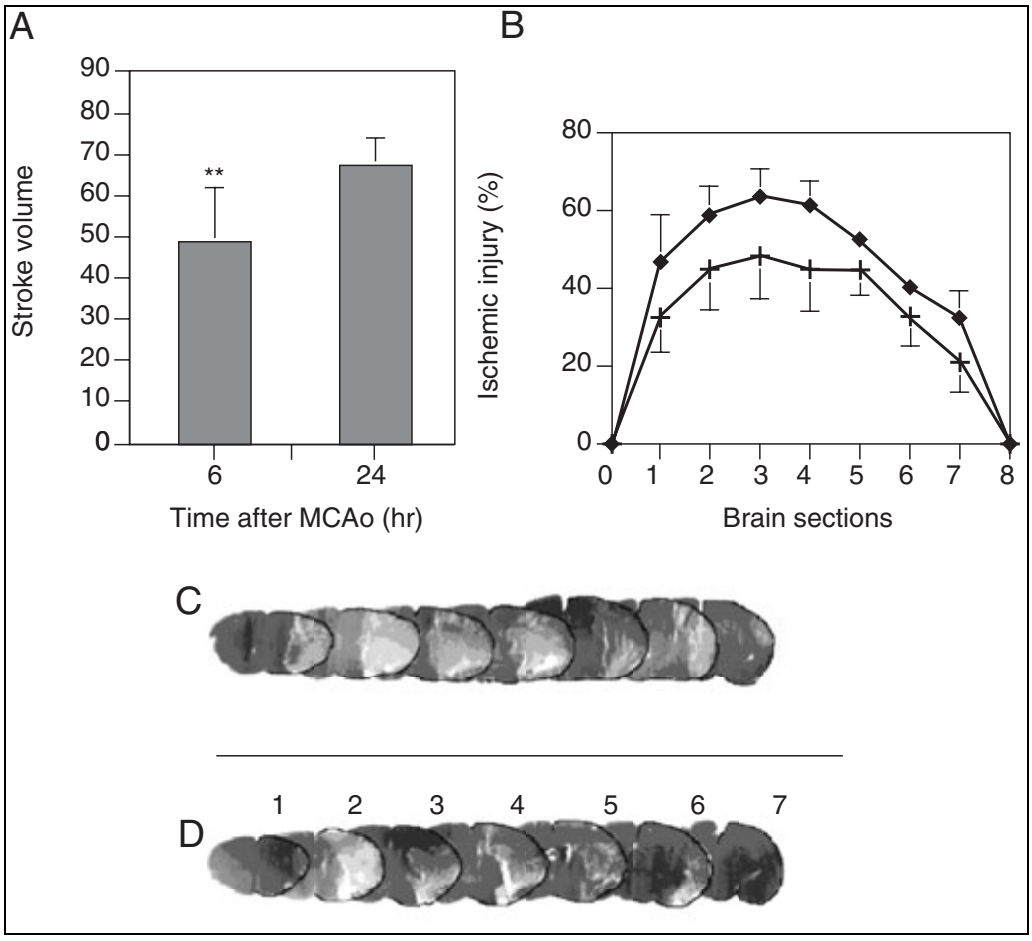

Figure 11.9.3 Analysis of stroke volume. (**A**) Cumulative stroke volume in DNX mice derived from seven representative coronal brain sections, multiplied by the distance between them. Animals were subjected to permanent MCA occlusion (pMCAo) using the subtemporal approach. (**B)** Anterior-posterior distribution of injury at 6 hr (crosses) and at 24 hr (diamonds) in DNX mice. The volume of stroke and anterior-posterior distribution was reconstructed based on hematoxylin and eosin–stained specimens. (**C**) H&E–stained coronal sections 1 to 7 were used to plot anterior-posterior distribution of the ischemic lesion at 6 hr after MCAo in DNX mice. The lesion appears to be much smaller in heme oxygenase-1 overexpressing mice (**D**).

NOTE: Due to the consequences of breakage of the blood-brain barrier and migration of inflammatory cells after 24 hr, the method subsequently becomes only marginally reliable.

Materials

Brains of control mice and mice treated to induce focal ischemia (see Basic Protocols 1 and 2)
PBS (*APPENDIX 2A*), 4°C
2% (w/v) 2,3,5-triphenyltetrazolium chloride staining solution (TTC; see recipe), prewarmed to 35° to 36°C
Brainslicer (EM Corp.) and razor blades, 4°C (stainless steel)
Spatula
Weigh boats or Petri dishes

1. Chill the brains of control mice or mice treated to induce focal ischemia in 4°C PBS for 5 min on ice.

2. Using a brainslicer and razor blades chilled to 4°C, cut the brains coronally at 1- or 2-mm regular intervals to give eight or four coronal sections, respectively.

   Both the brainslicer and razor blades must be of stainless steel and cooled to 4°C beforehand to facilitate cutting. Cooled brains also become firmer in consistency and do not stick to the surfaces of razor blades during cutting.

   It is almost impossible to consistently sample the brain tissue throughout the same anatomical areas from animal to animal using the brain matrix. Tangential distortion of brain slices due to edema and presence of midline shifting is common. Avoiding tangential distortion is difficult, as most manufacturers design brain matrixes for cutting normal rodent brains. Brain slices obtained using the matrix technique, in their anterior-posterior distribution, will not consistently correspond to exact same anatomical coordinates (locations) from animal to animal.

3. Transfer the four coronal 2-mm-thick sections per brain to a solution of 2% (w/v) 2,3,5-triphenyltetrazolium chloride (TTC) prewarmed to 35°C. Incubate for 30 min in a weigh boat or Petri dish at 35°C in a dark environment.

   TTC-stained sections may be stored up to 6 months without fading at 4° to 8°C in 10% buffered formalin (or 4% paraformaldehyde; PFA) in 20-ml scintillation vials wrapped in aluminum foil (TTC-stained material is light sensitive).

4. Estimate stroke volume and store images electronically for future reference.

BEHAVIORAL ASSESSMENT OF FOCAL ISCHEMIA

SUPPORT PROTOCOL 4

Behavioral assessment of mice after stroke is based on the criteria listed in Table 11.9.2. A cumulative behavioral score is obtained that is included in the statistical interpretation of the data (see Support Protocol 7). Behavioral functions after stroke recover faster in the mouse than in nonhuman primates because mice have a higher potential for cerebral plasticity.

IMPORTANT NOTE: Mice with grade 3 behavioral deficits are prone to severe hypothermia, thus normothermic conditions need to be continuously maintained. Hypothermia is more likely to impact transient rather than permanent focal ischemia (Ridenour et al., 1992). Contrary to rats, forearm flexion is not a reliable behavioral sign in mice and thus may not be included in statistical data analysis.

Table 11.9.2 Behavioral Score Criteria

Score	Criteria
Grade 0	No observable behavioral deficit.
Grade 1	Decreased resistance to lateral push and long radius circling.
Grade 2	Decreased resistance to lateral push, decreased grasping, weight loss (<15%), short radius circling, but normal posture at rest.
Grade 3	Leaning to the contralateral side at rest with prominent short radius circling activity, weight loss >15% by 24 hr.

ASSESSMENT OF HEMISPHERIC VOLUME OF STROKE AND CEREBRAL EDEMA

Stroke volume (V_s), measured in cubic millimeters, is derived by numerical integration of consecutive hematoxylin and eosin [or thionin (*UNIT 11.8*) or TTC (Support Protocol 3)] stained coronal sections sampled at known intervals using the following formula: V_s (mm^3) = Σ areas of hemispheric lesions (mm^2) × distance between sampled histological sections (mm).

Alternatively, percent of hemispheric injury (HS) may be calculated using the following formula: HS (%) = [Σ (areas of hemispheric lesions)/Σ (areas of ipsilateral sections)] × 100.

Seven representative coronal sections sampled at known intervals are sufficient to estimate the volume of stroke in the laboratory mouse (Fig. 11.9.3A to D). For mapping of the areas of anterior-posterior distribution of ischemic neuronal injury, the following anatomical coronal coordinates, relative to the bregma, are the most representative (taken from the mouse brain atlas; Franklin and Paxinos, 1997):

0. Bregma 2.96 mm
1. Bregma 1.98 mm
2. Bregma 1.42 mm
3. Bregma 0.98 mm
4. Bregma 0.0 mm
5. Bregma (–)1.06 mm
6. Bregma (–)2.06 mm
7. and Bregma (–)3.08 mm.

A chart of the anterior-posterior distribution of the ischemic lesion helps to identify specific anatomical areas affected by ischemia (Fig. 11.9.2B) and is also helpful in mapping out and analyzing the mechanisms of time-dependent maturation of the ischemic lesion (Du et al., 1996). It also helps to define the spread of the lesion and postischemic brain edema which may occur anterior of the bregma, posterior of the bregma, or both ways (Fig. 11.9.2C).

IMPORTANT NOTE: The distance between coronal anterior-posterior sampled areas of interest (based on frozen sections or TTC-stained sections) will appear larger if compared to the corresponding areas from the mouse brain atlas of Franklin and Paxinos (1997) in which data is reported based on formalin-fixed and paraffin-embedded specimens (brains may shrink up to 30% based on the selection of fixative and embedding medium).

It is extremely important to dissect individual components contributing to the overall size of the ischemic lesion in mice and ask the following questions: (1) What is the pattern of lesion progression (anterior, posterior, or both ways)? (2) Does the lesion progress over the course of 24 hr, 3 days, 7 days? (3) Does the lesion involve cortex, caudate-putamen, or both? (4) Does the lesion spread into areas outside of the distribution of the MCA (e.g., hippocampus, substantia nigra, and other thalamic, subthalamic, and brainstem structures)?

MCA occlusion may sometimes cause ischemic damage to the hippocampus in certain strains of mice (e.g., C57Bl/6). Ischemic damage to thalamic and subthalamic structures may result as well (partially due to the presence of vascular anomalies), and when present, usually manifests in a pronounced drop in body temperature (both after permanent and transient occlusions) and grade 3 cumulative behavioral scores (Table 11.9.2).

The Swanson correction technique of adjustment for hemispheric edema (Hara et al., 1996) should be used according to the formula:

$$V_{\text{adjusted}} = V_{\text{left hemisphere}} - (V_{\text{right hemisphere}} - \text{measured infarct volume})$$

where all volumes are measured in cubic millimeters.

The purpose of this approach is to adjust for brain swelling by correcting for infarct volume. Hemispheric edema can also be accurately measured ex vivo (applying the same principle) using MRI (Steinberg et al., 1995). Brain edema in models involving postischemic reperfusion is usually considerably higher in filament models than in Tamura craniectomies due to the fact that the site of craniectomy acts as a vent, contributes to postischemic (Cushing-type) decompression, and thus decreases brain swelling.

ASSESSMENT OF THE SIZE OF THE ISCHEMIC PENUMBRA

SUPPORT PROTOCOL 6

The dimensions of the ischemic penumbra in genetically altered mice, or those subjected to treatment with pharmacological agents, may vary. Systemic physiological parameters must be monitored in all studied animals. Critical parameters describing ischemic penumbra and its thresholds have been previously reported (Hakim, 1987; Ginsberg et al., 1996). Assessment of the size of the ischemic penumbra can be performed noninvasively in vivo using laser Doppler flowmetry and electrophysiology (Dalkara et al., 1994), or CT scanning (Lo et al., 1996) and magnetic resonance imaging (van Dorstein et al., 1999). The stretch of the ischemic penumbra can also be determined ex-vivo using a combination of techniques. It may be determined histochemically based on morphological characteristics of hematoxylin and eosin and NADPH diaphorase staining (Panahian et al., 1999), assessment of ATP synthesis, tissue pH, and cerebral protein synthesis (Hata et al., 1998), analysis of biliverdin reductase antioxidant potential (Panahian and Maines, 2000) and overexpression of heat shock proteins (Sharp et al., 2000).

STATISTICAL ANALYSIS AND DATA PRESENTATION

SUPPORT PROTOCOL 7

Statistical evaluation of neuroprotection data is performed using unpaired two-tail t-test (for two group comparisons) or analysis of variance (ANOVA) followed by posthoc analysis (in case of three or more studied groups) as recommended in Statview v. 5.0 (SAS Institute; also see *UNIT 1.2*). Physiological parameters are best compared using repeated measures ANOVA. Behavioral data are analyzed using nonparametric statistics: Mann-Whitney for two-group comparisons or Kruskal-Wallis for three or more groups of animals (Huang et al., 1994). Somatosensory evoked potentials (SEPs) and electroencephalographic (EEG) values (if monitored) may further be analyzed using software such as Igor (WaveMetrics) as well as Scope and Chart (AD Instruments). SEPs are analyzed by derived values of wave amplitude using ANOVA. Changes over time in SEP amplitude are analyzed using repeated measures ANOVA. Electroencephalographic values are analyzed using Fast Fourrier Transformation Analysis (FFT) (Dalkara et al., 1994). The minimal number of animals is determined based on the values of the coefficient of variation (ratio of the standard deviation to the mean multiplied by 100) and power analysis calculations using Primer of Biostatistics (v.3.01, McGraw Hill). Power calculations are carried out with $\alpha = 0.05$, $\beta = 0.05$, $p < 0.05$ and estimated to the power of 0.9. Meta-analysis should be carried out to minimize the number of animals essential to reject the null hypothesis and prove statistical significance. Brain specimens are always compared to control and sham-operated animals. Anterior-posterior distribution of the ischemic lesion is mapped using Cricket Graph III (Computer Associates International), and final data is presented using Canvas v. 7.0 or higher (Deneba Software).

Meta-analysis is extremely important for both preclinical and clinical trials (K.I. Maynard, unpub. observ.). Meta-analysis involves statistical analysis of summary information derived from similar but independent studies. Meta-analysis approach allows investigators to increase statistical power in order to detect an overall effect of significance, as well as to estimate the degree of benefit, assess amount of variability, and identify specific characteristics for these previously reported and analyzed studies (Normand, 1999).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

TTC staining solution

Dissolve 2 g of 2,3,5-triphenyltetrazolium chloride (TTC) in 100 ml of 0.1 M phosphate buffered saline, pH 7.4, prewarmed to 35° to 36°C. Prepare final solution in any glass or plastic container wrapped in aluminum foil because TTC solution is light sensitive. Use immediately.

COMMENTARY

Background Information

Why choose the mouse model after all?

Stroke models have been successfully reproduced in a variety of animal species: squirrel monkey (Hudgins and Garcia, 1970), gerbils (Berry et al., 1975), rabbit (Steinberg et al., 1995), cat (O'Brien and Waltz, 1973; Bose et al., 1984; Berkelbach et al., 1988), and dog (Suzuki et al., 1980). As a rule of thumb, the larger the animal species, the higher the variability in the size and location of the ischemic lesion. If compared to the cat, rabbit, or dog, the origin of the middle cerebral artery (MCA) in rodents lies further from the optic foramen; therefore, transorbital (Sundt-type) approaches to the MCA in both mice and rats are unsuitable and a subtemporal approach must be carried out instead. Extensive collateral cerebral circulation in the dog renders this species hardly fit for stroke research and requires clipping of many arterial branches for induction of a reproducible ischemic lesion (Suzuki et al., 1980). On the other hand, gerbils are not recommended for stroke research because of high mortality and higher incidence of postoperative seizures after MCAo. The arterial wall of the MCA of the cat contains a significant number of elastic elements, thus during transient MCA occlusion, the artery itself can be stretched out of the orbit using a vascular hook. Conversely, the vascular wall of the MCA in the rabbit is extremely fragile. The shape of the intracranial portion of the internal carotid artery within the cavernous sinus region of higher animal species is curved (van Loveren et al., 1991) in comparison to rodents, in which it is almost a straight line. Thus, performing endovascular filament occlusion models in dogs, cats, or rabbits may not be worthwhile to attempt due to obvious technical complexities and low chances for success. Smaller animals like mice and rats, on the other hand, are easier to handle, inexpensive, and readily available.

This unit describes basic protocols for the two most reproducible models of middle cerebral artery (MCA) occlusion in the laboratory mouse: the Tamura model (see Basic Protocol 1), which is carried out by means of a craniectomy, exposure, and direct coagulation of the MCA (adapted from the rat) and the filament endovascular occlusion model (see Basic Protocol 2), during which the calvarium is left intact, but the MCA is occluded "blindly" using a filament-obturator. Two other modifications of the subtemporal (Tamura-type) protocol are known to exist: distal MCAo at the upper level of the olfactory tract (Fig. 11.9.2A to C) and tandem MCA and ipsilateral CCA occlusion, during which the MCA is occluded more distally, at the level of the inferior cerebral vein (Brint et al., 1988).

Tamura-type models

The subtemporal approach provides clear anatomical visualization of the MCA and its branches. The trunk of the MCA is cauterized in one spot and, unlike similar models in the rat, segmental occlusion of the MCA and its branches within the stretch of MCA from the olfactory tract to the inferior cerebral vein (in order to achieve uniform size cortical lesions)

is not necessary (Menzies et al., 1992; F. Zhang et al., 1997). The whole surgical procedure is relatively quick and can be accomplished in under 10 to 15 min from the time the animal is anesthetized.

In the model of distal MCAo (at the level of inferior cerebral vein or Brint model), lenticulostriatal arteries are left intact and lesions in the caudate nucleus are considerably smaller, with minor damage to the cortical areas overlying the hippocampal region (Fig. 11.9.2H) versus those after proximal MCAo (Fig. 11.9.2I), which manifest in complete ischemic wipe-out of the caudate nucleus and extensive cortical damage in posterior hemispheric areas overlying the hippocampus. The author found that tandem occlusion of MCA (immediately above the level of the olfactory tract) and ipsilateral common carotid artery as reported by Brint et al. (1988) for the laboratory rat is not necessary to perform in the mouse as it does not affect the overall results. In a model of transient ischemia carried out using clip occlusion, ligation of the common carotid artery may unnecessarily delay postischemic recovery of cortical blood flow during the reperfusion phase of the experiment.

The Brint-type model of tandem occlusion of MCA and ipsilateral CCA may be supplemented by 1-hr clip occlusion of the contralateral CCA as previously reported for the laboratory rat (Chen et al., 1986). The site of MCA occlusion in this particular model is even more distal: at the level of or directly above the intersection of MCA with the inferior cerebral vein. Tandem models can be successfully used by investigators performing electrophysiological and iontophoretic studies or by anyone interested in performing continuous flowmetric monitoring of ischemic penumbra in nonsurvival experiments. To fit such experimental needs, the model can be easily induced with the animal positioned in a stereotaxic frame. In this case, distal clipping of the MCA may be supplemented with tandem ipsilateral/contralateral CCA occlusion using inflatable vascular occluders (In Vivo Metric). The occluder cuffs are circumferentially attached around the common carotid arteries of mice using 8-0 monofilament nylon under halothane anesthesia. Injection of saline into the tubing inflates the cuffs and compresses the vessels. Transient carotid occlusions, using the cuffs, can also be performed on unanesthetized mice to screen for the presence of vascular anomalies (e.g., absence of Pcom).

At any time, the Brint model can be transformed into the Chen-Hsu model by placing an extra clip on the contralateral carotid artery. Codman or Biemer microclips or Zen temporary clips are good choices for this purpose. The Chen-Hsu model in the mouse, unlike that in the rat, may result in ischemic damage to the caudate nucleus. Ischemic wipe-out of the putamen is uncommon. In rats, this model was proven reliable to study effects of growth factors on therapeutic neuroprotection in stroke (Speliotes et al., 1996); however, the model has also been reported to cause very delayed maturation of the ischemic lesion (Du et al., 1996).

Among some of the advantages of the Tamura-type approach to the MCA is the fact that vascular anomalies within the MCA region can be detected through the site of craniectomy, which will also decompress the brain during the postischemic period. Thus, the volume of intracerebral edema in this model is lower than it is in the filament model in which the calvarium remains intact (Fig. 11.9.2A, compare I and J). Cerebral edema (both cytotoxic and vasogenic) contributes to elevations in intracerebral pressure (ICP) and results in decreased intracerebral capillary perfusion, further increasing the size of the ischemic lesion over time. The Tamura model in the mouse can be characterized overall as a model of very low postoperative mortality (0% to 1%) and high reproducibility. The author does not have sufficient data relating to long-term behavioral, physiological, and/or biochemical differences between left-sided and right-sided lesions induced by MCAo as was reported for the laboratory rat (Robinson, 1979).

Filament occlusion models

It is a common consensus that therapeutic neuroprotection is somewhat easier to demonstrate in models of transient ischemia (provided the MCAo protocol does not exceed 2 hr). These models of transient ischemic injury were also reported to be "temperature sensitive" (Ridenour et al., 1992) and prone to postischemic cerebral edema and elevations in ICP. All of these factors contribute to statistical variability requiring greater number of animals to complete a study (Huang et al., 1994). Hemispheric lesions induced by transient filament MCAo of short duration (30 to 90 min) may lead to delayed maturation of lesions over the course of 7 to 14 days (Du et al., 1996; Endres et al., 1998). These slowly maturing lesions are apoptosis prone. The filament MCAo model in the

mouse (either permanent or transient) is by no means a "selective" procedure, as not just the MCA is occluded, but also the anterior cerebral, posterior communicating, and internal carotid arteries. This contributes to a significant decrease in collateral circulation within the region of distribution of the MCA and cortical "watershed" territories (shown in Fig. 11.9.2B and I), causing an increase in the size of the ischemic lesion accordingly. The lesion may further increase in size if a 3-hr occlusion/21-hr reperfusion paradigm is used (Fig. 11.9.2J). If only partial reduction in cortical rCBF takes place after insertion of the filament, the Chen-Hsu-type procedure (1-hr contralateral CCA clipping) to further reduce the values of cortical rCBF in the filament model must never be considered as an option because it will kill the mouse. Damage to vital brain stem structures is the likely explanation. In acute MRI experiments, it may be possible to supplement MCA filament occlusion with either bilateral or unilateral vertebral artery occlusions as described for the laboratory rat (see *UNIT 11.8*).

Critical Parameters and Troubleshooting

A very strong correlation exists between the loss of body weight and the size of the ischemic lesion. Mice developing large ischemic hemispheric lesions will exhibit short radius circling activity. Unlike rats, forearm flexion is not a reliable sign for behavioral assessment in mice (Menzies et al., 1992) and could be absent in mice that will otherwise develop severe hemispheric lesions. Mice also have low volumes of circulating blood (1 to 1.5 ml), and as a result of intraoperative bleeding, usually develop profound hypotension, which contributes to an increase in the size of the ischemic lesions. Other variables that may affect the size of the ischemic lesion include the following. (1) The strain of mice used in the study: certain strains of mice (e.g., SV-129) are less sensitive to ischemic injury than others (e.g., C57Bl/6). Ipsilateral hippocampal, thalamic, and subthalamic ischemic injuries have been noted as a result of permanent MCA occlusions at 24 hr in C57Bl/6 mice. (2) Sex differences: these have been shown to affect the outcome of MCAo, thus neuroprotection should be examined in male and female animals separately. (3) The presence of vascular anomalies. (4) Brain temperature, which primarily affects outcomes of the transient filament model. (5) Perturbations in physiological and hemodynamic parameters: these may be due to abnormal blood glucose levels, hemodilution, and volume-expansion due to constant flushing of arterial and venous catheters (e.g., due to systemic heparinization, decrease in mean arterial pressure due to frequent blood sampling for arterial blood glucose, or other tests). (6) Air emboli: this condition will manifest in decreased respiratory end tidal CO_2 ($EtCO_2$), but high arterial pCO_2 values. It may mislead investigators into lowering the respiratory rate accordingly during artificial ventilation (if arterial blood gases are not monitored). (7) Hypoxic conditions: these are encountered as a consequence of a prolonged period of halothane anesthesia (>2%) or flaws in $EtCO_2$ monitoring during artificial ventilation; if the animal remains in this condition with pCO_2 values above 55 Torr for periods exceeding 30 min, dramatic exacerbation of the ischemic lesions will result.

Filament shape and coating

The tip of the coated filament must never resemble a "club" and must have equal thickness of coating material on its body. The filament will eventually be lodged in the distal portions of the anterior cerebral artery (ACA), the diameter of which is smaller than that of the intracranial portion of the internal carotid artery (ICA). Clubbing of the tip of the filament will not facilitate its advance into these vessels and is absolutely unnecessary. Usually, a 12-mm advance from the carotid bifurcation is considered adequate for occlusion of the ICA, MCA, ACA, and posterior communicating artery (Pcom). Should there be any vascular anomalies (e.g., duplications of MCA), extra branches will get occluded by the coated side of the filament as well. The author recommends using 20-mm-long coated filaments for this purpose, marked at the 12-mm interval with red nail polish.

Poly-L-lysine does not affect the overall diameter of the suture. It only increases adhesive forces around the suture (Belayev et al., 1999), thus forcibly constricting vessels on the filament. Endothelin coating (a potent vascular constrictor) may also be used as an alternative option (Sharkey et al., 1994). In contrast, soft Reprosil and Xantopren coatings mechanically dilate the vessels as the filament is advanced forward. The author does not perform flame-heating of the filament tips due to their small size. Reprosil coating will stay well attached, allowing coated filaments to be reused a number of times, from animal to animal, contributing to the statistical consistency of the study. Both Xantopren and Cuttersil coated filaments

cannot be reused and should be made 2 to 6 hr before MCA occlusion (see Table 11.9.1).

The author prefers to use coated filaments made of 8-0 Ethicon monofilament nylon in a highly defined weight range of mice (22 to 24 g). If the intracranial vessels are too small for the inserted filament (thus preventing its advance), it is swapped for the one with slightly thinner coating; however, in heavier animals (28 to 30 g), cerebral ischemic lesions may be of inconsistent size due to lack of the "snug fit" between the wall of the vessel and that of the coated filament. For animals of this weight range, the author recommends the use of 7-0 coated nylon or prolene filaments. Neither 8-0 or 7-0 coated monofilament nylon sutures are rigid enough to cause arterial perforations. Anyone using uncoated 5-0 or 6-0 nylon sutures is at great risk of causing inadvertent arterial perforation. Interestingly, these perforations in some cases may result in hematoma formation and subarachnoid hemorrhage, leading to spasm of the MCA and its branches and formation of an ischemic lesion, leading to false-positive results and possible misinterpretation of data. Alternatively, in mice with arterial perforations, no hemispheric lesion may be noted if the filament is not removed from the ICA. Such extreme cases are strong indicators of serious technical flaws.

Filament does not advance into the intracranial portion of ICA or stops short of MCA

It is important to note the length of the filament (mm) that is introduced into the vessels. Twelve millimeters of the filament length needs to be manually advanced into the cranium from the carotid bifurcation in order to successfully block the MCA. The tip of the filament may be lodged against the stump of the PPA (~3 to 5 mm from carotid bifurcation). Thus, it is important to tie off the pterygopalatine artery (PPA) as proximally as possible to the ICA using 10-0 monofilament nylon, so as not to create an endovascular pouch. Alternatively, the filament may have excessive layers of coating material preventing it from entering the intracranial portion of the ICA or moving past the posterior hippocampal artery (~8 to 9 mm). In this case, a lesion in the upper posterior hippocampal area may result if the filament is left in place for 24 hr (Fig. 11.9.2G). If the filament cannot be advanced 12 mm, it should be partially withdrawn and inserted again. If this does not help, a filament with thinner coating should be used.

Filament is "washed out" from the ICA after removal of the upper clip

When the upper clip is released, but the filament is not secured in place with no. 5 forceps and/or a 10-0 monofilament nylon suture tied around the vessel at the level of CCA bifurcation, the filament will be washed out by the blood stream due to backflow from the circle of Willis. In this case, due to extensive blood loss, the experiment should be aborted.

Portions of filament coating material remain in the vessels

This is confirmed by examining the withdrawn filament for missing fragments of the coating material. Loss of material may lead to failure or just partial reperfusion of the ischemic hemisphere. It is recommended that after the animal is sacrificed ICA, MCA, and other arterial vessels of the circle of Willis be examined for the presence of fragmented coating material. If found, the animal should be excluded from the study.

Detecting an arterial perforation by the filament

8-0 filaments coated with Reprosil or Xantopren lack sufficient stiffness to perforate major arterial branches (Table 11.9.1). The operator will encounter mounting resistance and the filament will stop advancing if its coating is excessive or the diameter of the vessels is smaller than projected. If the filament has perforated the wall of the ICA, an alarming sign to the investigator is an absence of arterial backflow upon extraction of the filament during the reperfusion phase of the experiment. As a result of arterial perforation and subsequent subdural hematoma formation, mice may develop erroneous circling behavior to the ipsilateral side of the filament insertion (wrong direction circling). Mice usually do not die as a result of arterial perforation by the filament if it is a model of permanent MCAo; death primarily occurs in transient models, in which the physical presence of the filament is no longer there to plug the laceration. Animals may even develop a lesion due to vasospasm, triggered by blood released into the subdural and subarachnoid space. Based on these observations, a filament model of subarachnoid hemorrhage in the mouse has recently been described (Kamii et al., 1999). The condition of the animals will notably deteriorate due to the mass effect of hematoma formation, ensuing brain edema, midline shifting, and brainstem herniation. Intracerebral pressure (ICP) will noticeably rise causing further con-

striction of brain capillaries and decrease in microcirculation.

Mice develop rolling seizures during postischemic reperfusion

All animals developing seizure-related hyperactivity must be excluded from the study.

Mice demonstrate abnormal circling behavior after withdrawal of the filament

Anatomical pathways within the brain cross over to the other side. Thus, if a lesion is induced within the right cortex and caudate nucleus, the left upper and lower limbs of the mouse will become weak. Upon a light tail pinch, such animals will attempt to escape, and because the limbs on the right are stronger, mice will circle counterclockwise (away from the lesion). If an animal, upon awakening from anesthesia, attempts to circle clockwise and the surgical manipulations were performed on the right side, or in other words if the animal circles towards the lesion, hematoma formation should be suspected. This observation together with lack of signs of postischemic reperfusion based on readings of rCBF, should suggest in favor of aborting the experiment.

Possible problems during Tamura-type craniectomy

It is not recommended to drill in one spot longer than 2 to 3 sec. This may cause damage to the underlying brain tissue and edema and hemorrhagic transformation. Drilling over the surface of the MCA trunk may result in its constriction and extravasation of blood elements and plasma. The author recommends that investigators, for perfection of their microsurgical techniques, perfuse one or two mice with a saline solution of 2% Evans Blue to detect possible damage to the blood-brain barrier after drilling (Hudgins and Garcia, 1970).

Possible problems after Tamura-type craniectomies

Mice may demonstrate feeding difficulties. Excessive damage to the temporalis muscle and inadvertent damage to the bone of the lower jaw during craniectomy may cause feeding difficulties manifesting in postoperative weight loss.

Anticipated Results

Volumes of stroke after Tamura-type permanent proximal MCA occlusion (below the level of olfactory tract) should be in the range of 90 to 110 mm^3 (with incorporation of the Swanson correction for cerebral edema) and are dependent on the strain of mice used in the study and the time of sacrifice of animals. If the MCAo is performed immediately above the level of the olfactory tract, lenticulostriatal arteries are usually spared and the final lesion will be in the range of 65 to 75 mm^3. If the MCA is occluded at the level of inferior cerebral vein (Brint model) the lesions will hardly exceed 40 mm^3, but may increase to 70 mm^3 if the ipsilateral carotid artery is occluded permanently and the contralateral carotid artery is clipped transiently for 1 hr (Chen-Hsu model).

After 3 hr of transient cerebral ischemia, SV-129 mice develop smaller lesions than C57Bl/6 mice (67 ± 13 mm^3 versus 96 ± 29 mm^3; Hara et al., 1996). The size of lesions after transient filament model may vary and are entirely dependent on the duration of ischemic occlusion, duration of postischemic reperfusion, and strain of animals used in the study. This model may require a greater number of animals to reach a sufficient statistical power to yield meaningful results. The coefficient of variation must be calculated for each individual strain of mice. Placement of arterial and venous catheters, intubation of the animal, placement of laser Doppler flowmeter probes and SEP electrodes is time consuming and may not allow the investigator to screen three to four different groups of mice (4 to 5 mice per group) in one day. Collection of samples for assessment of arterial blood gas status (pO_2, pCO_2, pH, etc.) is informative; however, frequent flushing of arterial and venous lines will result in inadvertent heparinization of the animal and increased probability of intraoperative and/or postoperative bleeding. Furthermore, since the volume of circulating blood in the mouse is 1 to 1.5 ml, hemodilution and volume expansion may alter the natural course of pathophysiology of the stroke, making acquired data difficult to interpret.

Time Considerations

Tamura model

The complete surgical procedure should not take longer than 10 to 15 min per mouse to accomplish. Since there is no blood loss, and surgeries are quick, monitoring systemic parameters may be carried out in selected animals. Operation on 10 to 20 mice may be performed in one day under identical conditions.

Filament model

The exact time required for completion of the model depends on the time of establishment of reperfusion which may vary from 30 min to 3 hr.

Principles of Electrophysiology: An Overview

NEURORECEPTORS AND ION CHANNELS

Neuroreceptors and ion channels are the fundamental sites of nerve function. In nerve fibers, opening and closing of voltage-gated ion channels such as sodium, potassium, and calcium channels generate action potentials. At nerve terminals that make synaptic contact with postsynaptic neurons or effector organs such as muscle, membrane depolarizations caused by action potentials open calcium channels. This results in Ca^{2+} influx, which in turn causes release of neurotransmitters by exocytosis. The released neurotransmitters bind to specific ligand-gated receptors on the postsynaptic membrane. The receptors are thus activated, resulting in the opening of the channel associated with them. Influx or efflux of specific ions through the open channels occurs to complete synaptic or neuromuscular transmission.

The generation and propagation of action potentials along the nerve fibers and synaptic and neuromuscular transmission form the basis for motor function, sensory function, and cognition/learning/memory in the peripheral and central nervous systems. Thus, any behaviors of animals and humans should ultimately be explained on the basis of receptor/channel functions. Neurotoxic actions of environmental toxicants, natural toxins, and therapeutic drugs at high doses are in many cases due to their interactions with various neuroreceptors and ion channels.

Neuroreceptors and ion channels may be classified into two large categories, voltage-gated ion channels and ligand-gated ion channels. Voltage-gated ion channels comprise sodium channels, potassium channels, and calcium channels, and each type of channel contains several subtypes. Neuroreceptors comprise multisubunit proteins, which form an ion channel. Many types of neuroreceptors are known, including, but not limited to, acetylcholine (ACh) receptors, glutamate receptors, γ-aminobutyric acid (GABA) receptors, glycine receptors, adrenergic receptors, and serotonin receptors. Furthermore, each of these neuroreceptors comprises several subtypes.

Simplified kinetic schemes of receptor channel activity are illustrated in Figure 11.10.1. Closed voltage-gated channels (C_c) open upon depolarizing stimulation (C_o), and eventually inactivate (C_i), as shown in scheme I of Figure 11.10.1. Neuroreceptors at resting state (R) are activated (R^*A_2) when bound by two molecules of agonist (A), a ligand, but may be desensitized ($R^*A_2{}^D$) with prolonged stimulation, as shown in scheme II of Figure 11.10.1.

Methods of Measuring Receptor/Channel Activity

The activity of receptors/channels is represented by ionic currents that result from ionic fluxes through the open channels. A large amount of ions flows through an open channel in a short period of time. For example, in an ion channel associated with the nicotinic ACh receptor, as many as 4.1×10^7 ions flow per second through a channel yielding a current of 6.6 pA (Hille, 2001). Upon stimulation either by membrane depolarizations (for voltage-gated channels) or by transmitters (for ligand-gated channels), the channel opens and closes quickly with an open time of only several milliseconds. Therefore, only electrophysiological methods can accurately follow the time course of channel activity and the resultant potential changes, e.g., action potentials.

However, other methods are also available, depending on the purpose of measurement and study. Ligand binding assays are often used, although this method is limited to the binding process, without allowing measurement of physiological functions that follow ligand

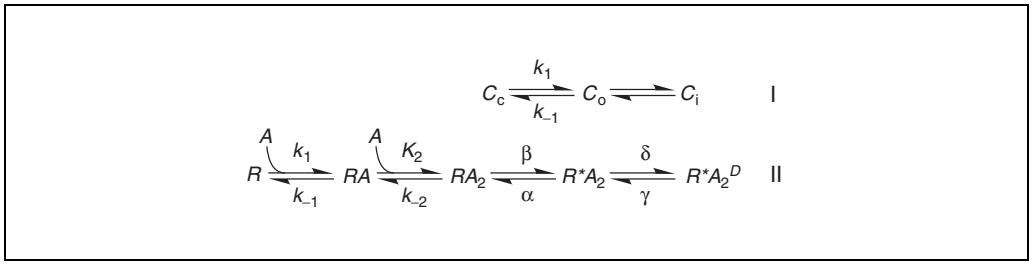

Figure 11.10.1 Simplified kinetic schemes of receptor channel activity. See text for further explanation.

binding. The advantage of this method is that it is simple, quick, and easy. The drawbacks are that the data could be misleading, as the method does not allow one to see functional changes, and that there is often more than one binding site for a ligand on a neuroreceptor/channel. For example, at least six binding sites are known to exist in the sodium channel (Catterall, 1992, 1995; Narahashi, 1998), and specific binding of [^{3}H]batrachotoxin A 20 α-benzoate to site 2 (Catterall et al., 1981) has been used often as a measure of the action of a test chemical on the sodium channel. However, this method is not sufficient, especially for screening of compounds, because there are other binding sites in the sodium channel. Similar precautions in binding experiments are applicable to other receptors and ion channels. Ion flux measurements using labeled ions have also been used often, but this method fails to follow rapid movements of permeating ions through open channels. Imaging techniques have been well developed and are being used extensively as a measure of receptor/channel activity. For example, Fura-2 can be used for the measurement of increases in the intracellular ionized Ca^{2+} concentration associated with openings of calcium channels or activation of NMDA receptors. One advantage of this method is that it is applicable to the case where routine electrophysiological techniques cannot be used. However, time resolution is not as fast as that of electrophysiological methods.

Applications of Electrophysiological Techniques

Since electrophysiological techniques allow us to measure the activity of the nervous system most accurately, they have a broad application to various types of research. These include, but are not limited to, mechanistic studies, clinical examinations, and high-throughput screenings. For clinical examinations of toxic effects of a chemical, conduction velocity of nerve action potentials is often measured and an electroencephalogram (EEG) is often performed. For high-throughput screenings of test chemicals, the two-microelectrode voltage clamp method, as applied to *Xenopus* oocytes expressing sodium channels, is being used, sometimes with the aid of a robot. Imaging techniques are also being used for high-throughput screenings. However, the most important application of electrophysiological techniques is for the study of the mechanism of action of test chemicals on neuroreceptors and ion channels.

Mechanistic Studies

While some useful information can be obtained by recording resting potential and action potential from neurons or nerve fibers, this method is far from satisfactory for elucidating the mechanism of action of test chemicals on the nervous system. Since the basis for nerve excitation and synaptic transmission resides in the activity of neuroreceptors and ion channels, it is imperative to record ionic currents associated with receptor/channel function.

The most accurate and straightforward method for recording ionic currents is the voltage clamp. This technique was originally developed by Cole (1949) for squid giant axons with 400- to 500-μm diameter and was extensively used by Hodgkin, Huxley and Katz (Hodgkin et al., 1952; Hodgkin and Huxley, 1952a,b,c,d) for the purpose of elucidating the ionic mechanism of nerve excitation. It was later adapted to muscle end-plates (Takeuchi and Takeuchi, 1959), large neurons (Hagiwara and Saito, 1959), nodes of Ranvier (Dodge and Frankenhaeuser, 1959), and smaller giant axons of lobster (80 μm in diameter; Julian et al., 1962a,b). These voltage clamp techniques were used extensively, but they could not be used for small cells such as brain neurons and smooth muscle cells. Nowadays, the two-microelectrode voltage clamp technique, originally used for large neurons (Hagiwara and Saito, 1959), is being used extensively for recording of currents from *Xenopus* oocytes expressing various receptors/channels.

A breakthrough was achieved by Neher and Sakmann (1976), who successfully recorded single-channel currents from nicotinic acetylcholine (nACh) receptors of denervated muscle fibers. This technique, called patch clamp, was later improved to record currents from an entire cell membrane (whole-cell currents) and single-channel currents from either a patch of the cell membrane (cell-attached patch clamp) or an outside-out or inside-out membrane patch (Hamill et al., 1981). The patch-clamp techniques have proven extremely versatile and useful, as they are applicable to almost any type of cells—such as brain neurons, myocytes, lymphocytes, and red blood cells—to record single-channel currents. It should be emphasized that the patch clamp is a variation of the voltage clamp, and therefore the space clamp condition, which will be described below, must be satisfied to perform patch-clamp measurements of ionic currents.

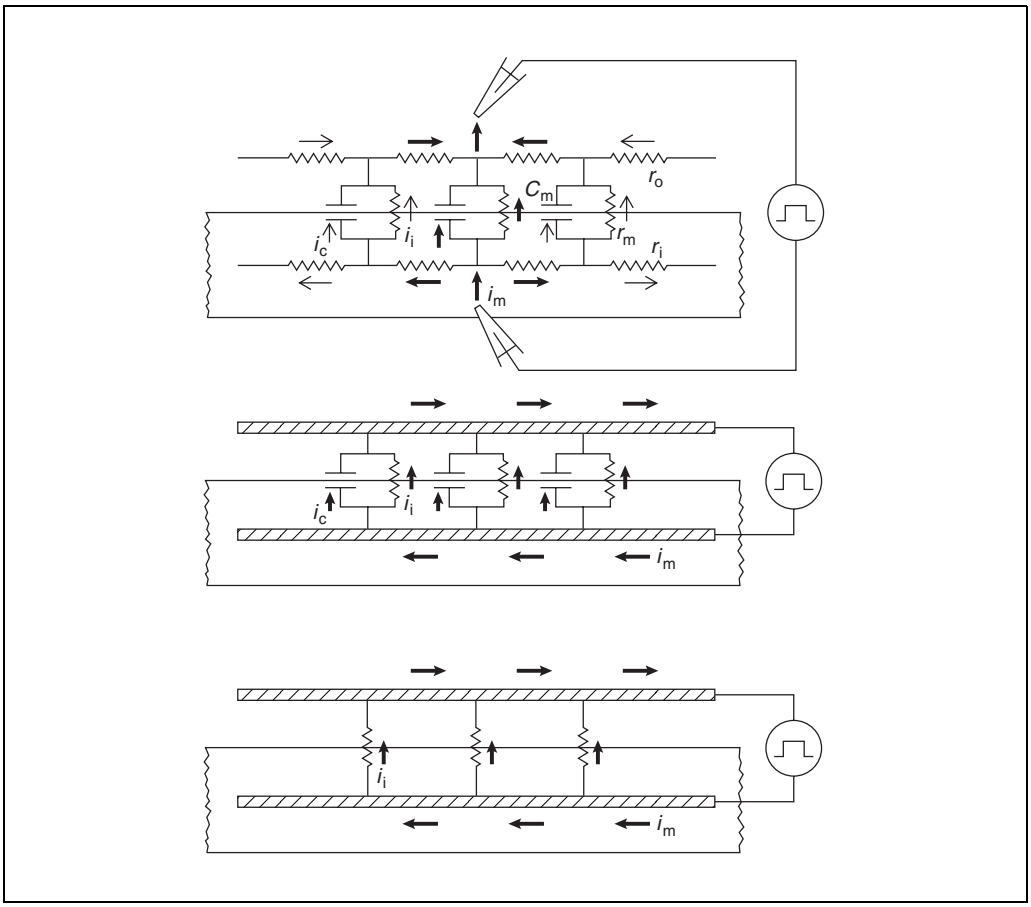

Figure 11.10.2 Current flow in an axon preparation. In the top diagram, current is applied to the axon through internal and external microelectrodes. The membrane current and longitudinal current are not uniform along the axon. In the middle diagram, current is applied through internal and external wire electrodes. The membrane current and longitudinal current are uniform along the axon (space clamp). In the bottom diagram, which illustrates the case when the axon in space clamp condition is voltage clamped, no capacitive current (i_c) flows while the membrane potential is maintained at a constant level, making it possible to measure the ionic current (i_i). Definitions: i_m, total membrane current; r_o, external resistance; r_i, internal resistance; r_m, membrane resistance; and c_m, membrane capacity. From Narahashi (1971) and used with permission of Academic Press.

BASIC PRINCIPLE OF RECEPTOR/CHANNEL FUNCTION

Electrophysiological experiments such as those by patch clamp are considerably different from other types of biomedical experiments—e.g., in biochemistry, molecular biology, immunology, and genetics—in that it is mandatory for the investigators to understand the basic principle of nerve excitation and synaptic transmission. The reasons for this lie in the fact that one must be able not only to understand the signals being recorded but also to evaluate whether the signals are of the proper shape without being contaminated by artifacts. This must be done quickly in live experiments. If patch-clamp experiments are not properly performed, the recorded signals often contain artifacts distorting the current shape and possibly leading to the wrong conclusions. Equally important is the ability of the investigators to understand and interpret any changes in electrical signals that may be caused by application of test chemicals. Contrary to many other types of in vitro experiments, electrophysiological experiments such as those by patch clamp must deal with live cells, which are often short-lived under the in vitro experimental conditions. Thus, any decisions, such as planning the next protocol, must be made quickly. This is the reason why in most cases technicians cannot properly perform patch-clamp experiments unless they have been well trained in the basic principles at the graduate school level.

Cable Properties and Voltage Clamp Principle

The principle of voltage clamp is based on the measurement of channel conductance

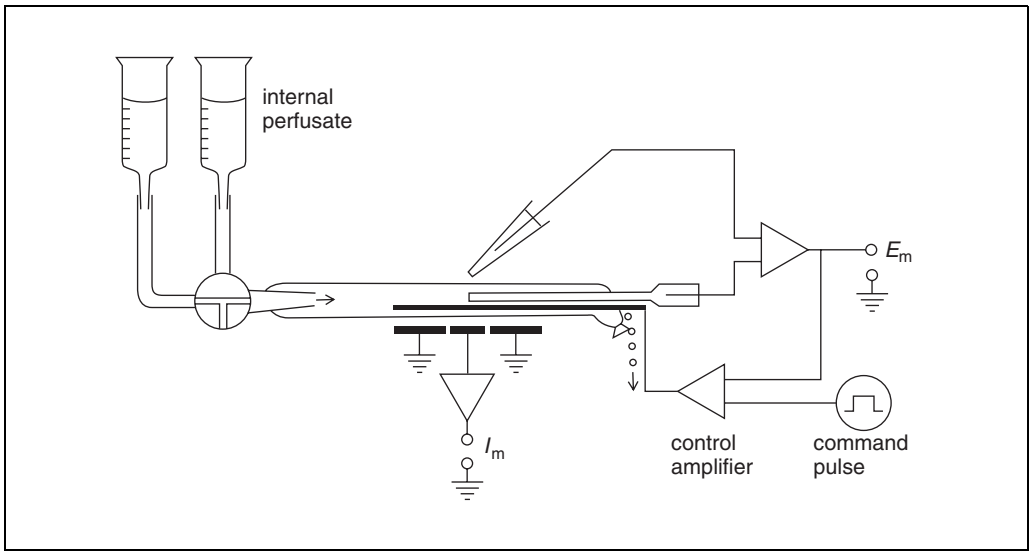

Figure 11.10.3 Voltage clamp of an internally perfused squid giant axon. See text for further explanation. Definitions: E_m, membrane potential; I_m, membrane current. From Narahashi (1984) and used with permission of John Wiley & Sons, Inc.

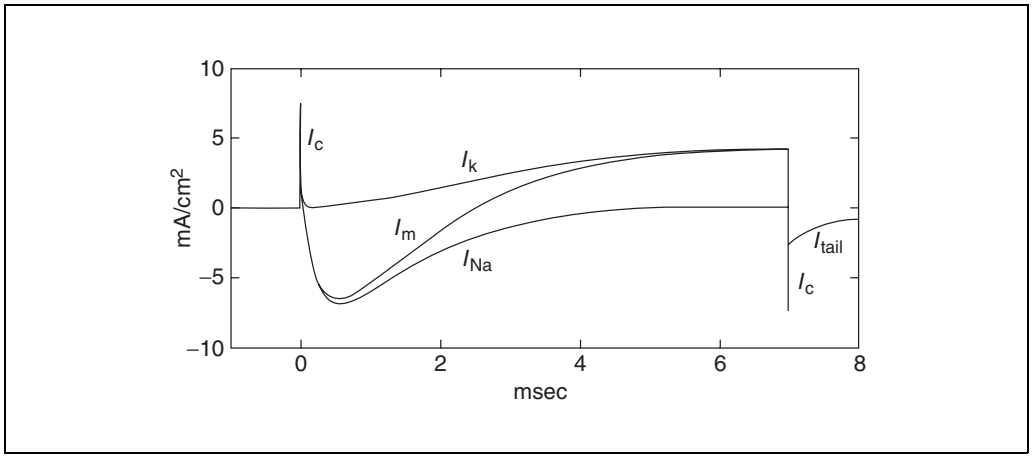

Figure 11.10.4 Membrane current (I_m) and its sodium (I_{Na}), potassium (I_K), and capacitive (I_c) current components associated with a step depolarization of the nerve membrane under voltage clamp condition. From Narahashi (1981) and used with permission of Pergamon Press.

through simultaneous recordings of both membrane potential and membrane ionic current. According to Ohm's law, the sodium conductance (g_{Na}) and the potassium conductance (g_K) are given by Equations 11.10.1 and 11.10.2:

$$g_{Na} = \frac{I_{Na}}{E - E_{Na}}$$

Equation 11.10.1

$$g_K = \frac{I_K}{E - E_K}$$

Equation 11.10.2

where I_{Na} and I_K are sodium and potassium currents, respectively, E is the membrane potential, and E_{Na} and K_K are the equilibrium potentials for sodium and potassium, respectively, as defined by the Nernst equation.

In order to clearly understand the voltage clamp principle, it is imperative to become familiar with the cable properties of a cell. Detailed analysis of cable properties is beyond the scope of this unit, and only the information that is absolutely essential for voltage clamp is described here, using the classical prototype technique as applied to the squid giant axon. This prototype is the easiest for understanding the principle of voltage clamp. The electrical equivalent circuit of a portion of an axon is shown in Figure 11.10.2. The external and internal phases of the axon are represented by

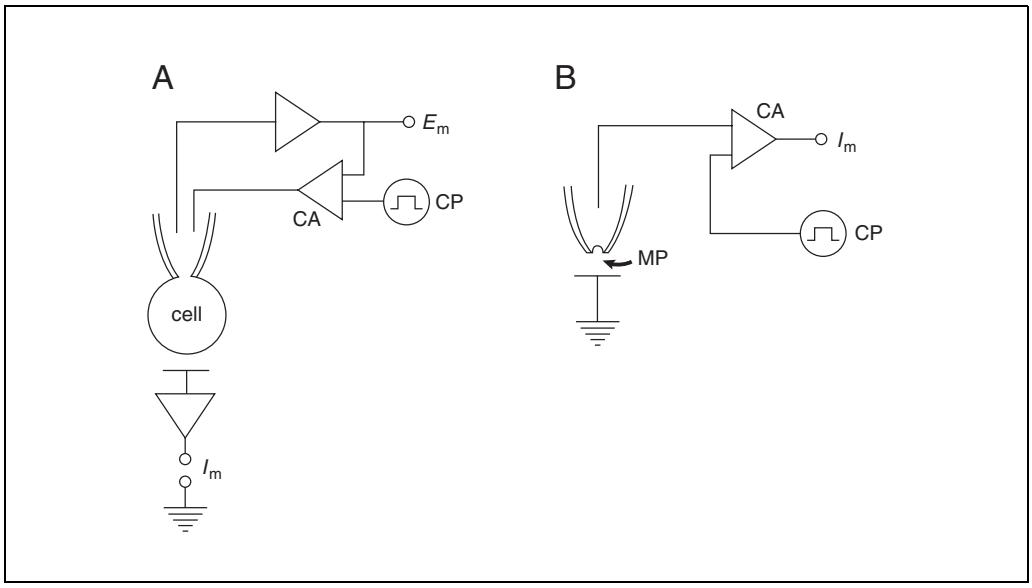

Figure 11.10.5 Schematic diagram of patch clamp. (**A**) Whole-cell patch clamp; (**B**) single-channel recording from an isolated membrane patch. Definitions: I_m, membrane current; E_m, membrane potential; CA, control amplifier; CP, command pulse; MP, membrane patch. See text for further explanation. From Narahashi (1992) and used with permission of CRC Press.

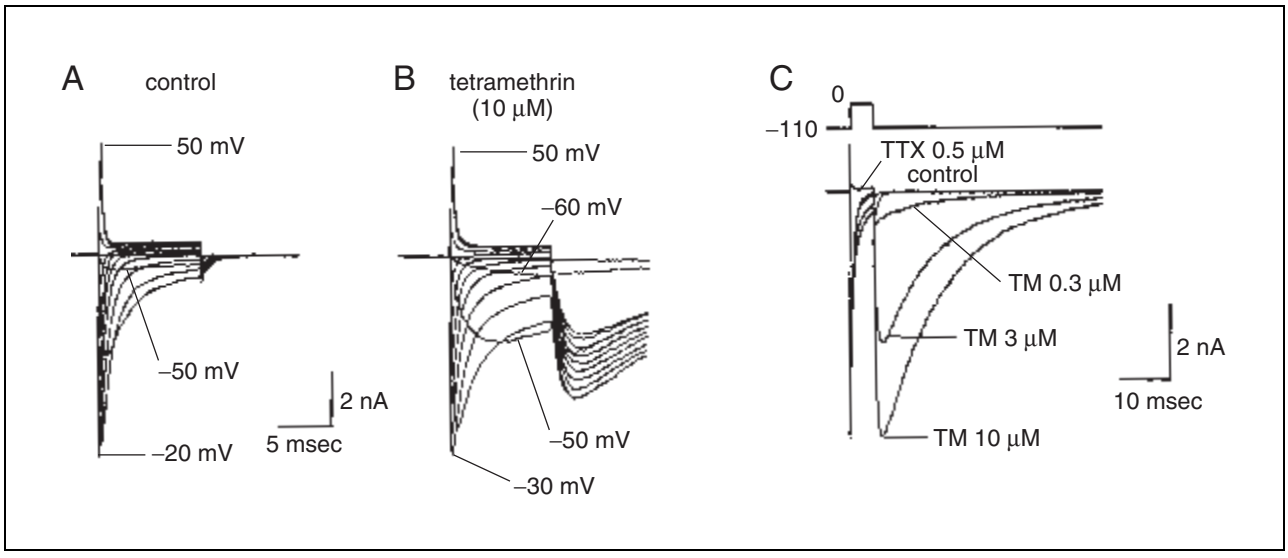

Figure 11.10.6 Effects of 10 μM tetramethrin on the current recorded from tetrodotoxin (TTX)–sensitive sodium channels in a rat cerebellar Purkinje cell. Currents were evoked by 10-msec depolarizations at a frequency of 0.1 Hz to test potentials ranging from –80 to +50 mV in 5-mV increments from a holding potential of –110 mV. (**A**) Currents under control condition. (**B**) Currents after exposure to 10 μM tetramethrin. (**C**) Concentration-dependent effect of tetramethrin. Currents were evoked by a 5-msec step depolarization to 0 mV from a holding potential of –110 mV under control conditions and in the presence of tetramethrin (0.3, 3, and 10 μM). TTX (0.5 μM) completely blocked both the peak current and tetramethrin-induced tail current. From Song and Narahashi (1996) and used with permission of The American Society for Pharmacology and Experimental Therapeutics.

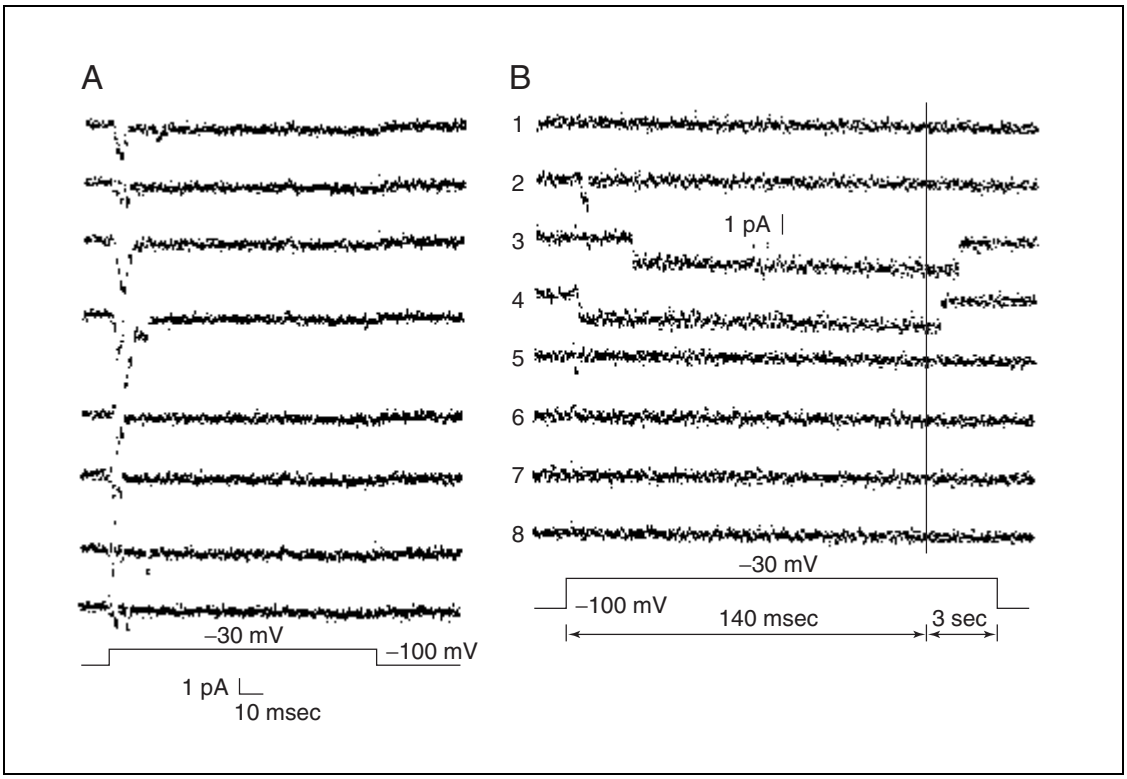

Figure 11.10.7 Effects of deltamethrin on single sodium channel currents recorded from an inside-out membrane patch isolated from a neuroblastoma cell (N1E–115). (**A**) Currents before drug treatment in response to 140-msec depolarizing steps from a holding potential of –100 mV to –30 mV with a 3-sec interpulse interval. Records were taken at a rate of 100 μsec per point. (**B**) Currents after exposure to 10 μM deltamethrin. The membrane patch was depolarized for 3140 msec from a holding potential of –100 mV to –30 mV. The interpulse interval was 3 sec. The time scale changes during the voltage step as indicated. During the first 140 msec, records were taken at a rate of 100 μsec per point and after the vertical line records were taken at a rate of 10 msec per point. From Chinn and Narahashi (1986) and used with permission of The Physiological Society.

external resistance (r_o) and internal resistance (r_i). The nerve membrane has membrane resistance (r_m) and membrane capacitance (c_m). When a current is injected to the axon through an intracellular microelectrode, the current and the resultant membrane potential change are distributed along the axon in a nonuniform manner (Fig. 11.10.2, top). The distributions of current and membrane potential change become uniform if the external and internal resistances are eliminated. This can be accomplished by placing a large, longitudinal metal electrode outside the axon and inserting a wire electrode inside (Fig. 11.10.2, middle). This condition is called space clamp, which is a prerequisite for voltage clamp. However, because of the presence of membrane capacitance, the current flowing across the membrane is complex, involving both the ionic current (i_i), through the open channels and the capacitive current (i_c). The capacitive current can be eliminated when the membrane current is measured while maintaining the membrane potential constant (Fig. 11.10.2, bottom). Thus, voltage clamp is accomplished allowing measurements of membrane ionic currents as a function of the membrane potential.

A prototype of simplified voltage clamp circuitry for the internally perfused squid giant axon is illustrated in Figure 11.10.3. The membrane potential is recorded by a glass capillary electrode inserted longitudinally to the axon while another glass capillary reference electrode is placed outside the axon. The membrane potential thus recorded is fed into a control amplifier to which a command pulse generated from a pulse generator is applied. The difference between the membrane potential and the command pulse is then amplified by the control amplifier, and a current is generated from the output of the amplifier and flows across the membrane until the membrane potential becomes equal to the command pulse. This is a feedback circuit, and the current can be measured by another amplifier (I_m).

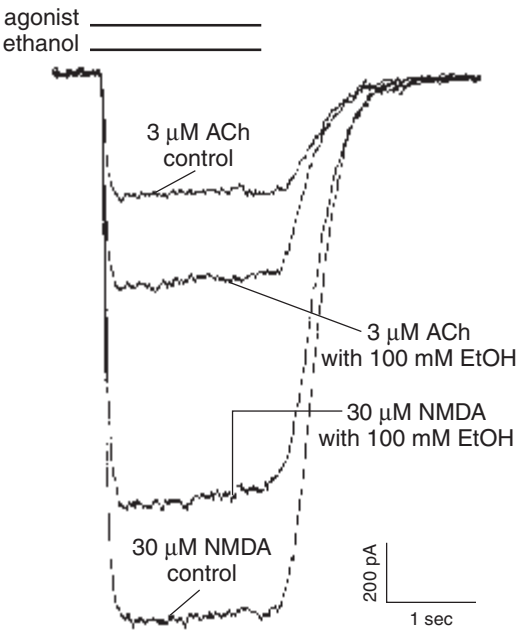

Figure 11.10.8 Effects of ethanol on ACh-induced current in α4β2-type ACh receptors and NMDA-induced current in a rat cortical neuron in long-term primary culture. Ethanol at 100 mM potentiates current induced by ACh at 3 μM while suppressing current induced by NMDA at 30 μM. Holding potential, −70 mV. From Aistrup et al. (1999) and used with permission of The American Society for Pharmacology and Experimental Therapeutics.

The membrane current (I_m) associated with a step depolarization of the membrane is schematically shown in Figure 11.10.4. Capacitive currents (I_c) flow upon step depolarization and repolarization to charge and discharge the membrane capacity, respectively. The membrane current comprises sodium current (I_{Na}) and potassium current (I_K). The equilibrium potentials for sodium (E_{Na}) and potassium (E_K) can be measured from the respective reversal potentials. Thus, sodium conductance (g_{Na}) and potassium conductance (g_K) can be calculated from Equations 11.10.1 and 11.10.2, respectively.

The classical voltage clamp as described above is difficult to apply to small cells such as brain neurons and myocytes because inserting two microelectrodes may damage the small cells quickly. Patch clamp, which is a variation of voltage clamp, has proven very powerful, as it can be applied to almost any cells to record whole-cell currents and single-channel currents (Hamill et al., 1981). Simplified schemes of patch-clamp circuitry are illustrated in Figure 11.10.5. One of the crucial points of patch clamp is a very high seal resistance (10 to 100 GW) at the orifice of the glass capillary electrode, which is placed onto the surface of the membrane. Figure 11.10.5A illustrates the circuitry for whole-cell patch clamp. After establishing the gigaohm seal, the cell membrane at the tip of the electrode is broken by applying negative pressure so that the electrode is electrically connected with the cell interior. Figure 11.10.5B shows single-channel patch-clamp circuitry using an outside-out or inside-out membrane patch (MP) isolated from the cell membrane. Single-channel current recording can also be made from a cell-attached membrane without isolating a membrane patch. Patch-clamp techniques are applicable to both voltage-gated and ligand-gated channels.

For more detailed aspects of nerve excitation, cable properties, and voltage-clamp and patch-clamp technologies, see Key References.

EXAMPLES OF CURRENT RECORDS

The effect of the pyrethroid insecticide tetramethrin on the sodium channel current recorded from rat cerebellar Purkinje neurons is illustrated in Figure 11.10.6 (Song and Narahashi, 1996). Figure 11.10.6A shows sodium currents associated with 10-msec step depolari-

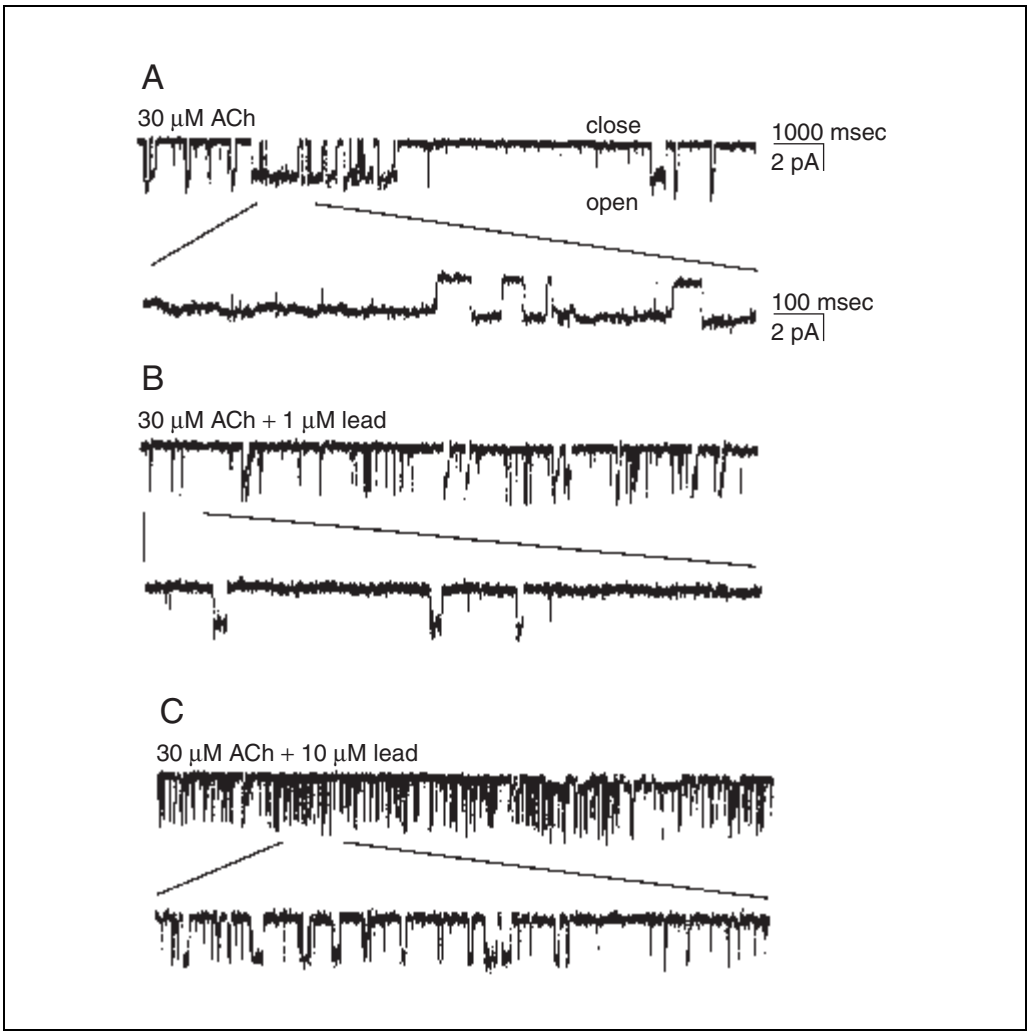

Figure 11.10.9 Single-channel currents induced by application of 30 μM ACh and coapplication of 30 μM ACh and 1 or 10 μM lead to cell-attached membrane patches of PC12 cells clamped at a membrane potential 40 mV more positive than the resting potential. (**A**) Currents induced by 30 μM ACh in the absence of lead occurred during brief isolated openings or during longer openings interrupted by a few short closures or gaps. (**B**) Coapplication of 30 μM ACh and 1 μM lead. Channel openings were shortened. (**C**) Coapplication of 30 μM ACh and 10 μM lead. Channel openings were further shortened. Small conductance state currents were observed. From Nagata et al. (1997) and used with permission of Elsevier Ltd.

zations at a frequency of 0.1 Hz to test potentials ranging from −80 mV to +50 mV in 5-mV increments from a holding potential of −110 mV. The sodium currents inactivated after reaching a peak. During application of 10 μM tetramethrin (Fig. 11.10.6B), the channel inactivation was partially inhibited, and large and slowly decaying tail currents were produced upon termination of depolarizing steps while the peak sodium currents remained unchanged. Figure 11.10.6C shows concentration dependence of tetramethrin effect on the tail current.

An example of single sodium channel currents before and during application of the pyrethroid insecticide deltamethrin at 10 μM in an N1E-115 neuroblastoma cell is shown in Figure 11.10.7 (Chinn and Narahashi, 1986). Currents were produced in an excised inside-out membrane patch by step depolarizations to −30 mV from a holding potentiation of −100 mV. Figure 11.10.7A represents several sample records of the control in which single sodium channels opened for a short period of time at the beginning of 140-msec step depolarizations. In the presence of deltamethrin (Fig. 11.10.7B), single sodium channel currents were greatly prolonged up to ~1 sec and appeared often with a long delay from the beginning of a depolarizing step. The amplitude of single-channel current was not changed by deltamethrin.

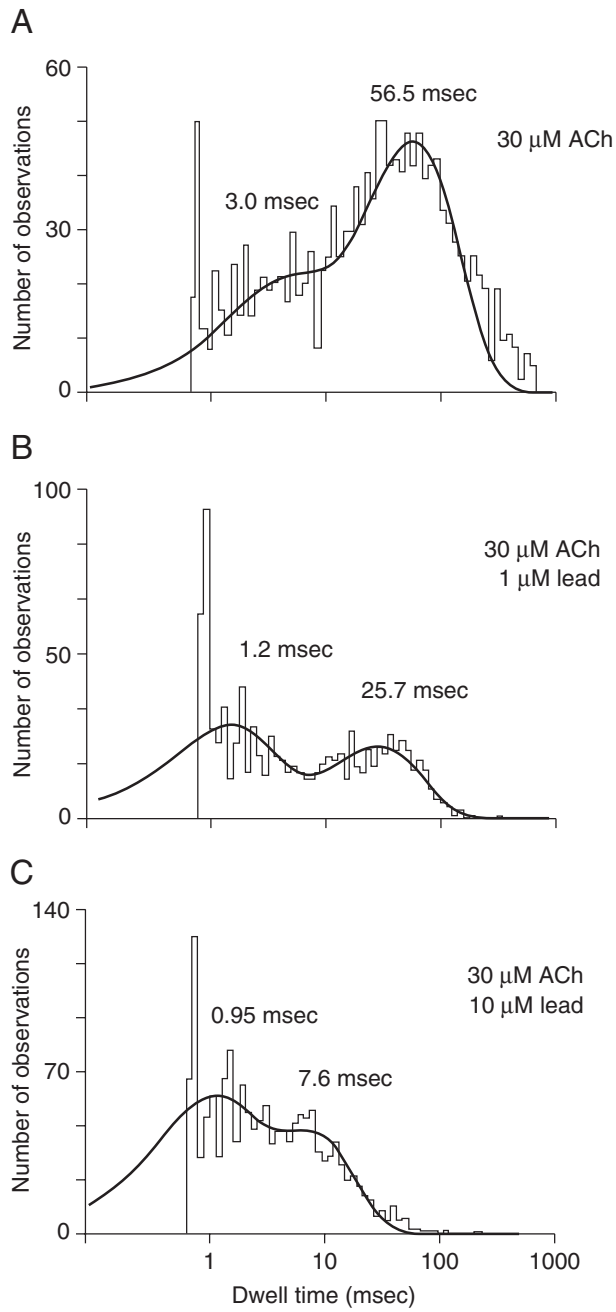

Figure 11.10.10 Open time distributions for (**A**) currents induced by 30 μM ACh; (**B**) coapplication of 30 μM ACh and 1 μM lead; and (**C**) coapplication of 30 μM ACh and 10 μM lead to cell-attached membrane patches of PC12 cells clamped at a membrane potential 40 mV more positive than the resting potential. The distributions are shown on a logarithmic time axis. The best fit of two exponential functions is shown. In (**A**; currents induced by 30 μM ACh), time constants were estimated to be 3.0 msec (75.9% of total observations) for the faster component and 56.5 msec (24.1%) for the slower component. In (**B**; coapplication of 1 μM lead and 30 μM ACh), time constants were estimated to be 1.2 msec (54.0%) for the faster component and 25.7 msec (46.0%) for the slower component. In (**C**; coapplication of 10 μM lead and 30 μM ACh), time constants were estimated to be 0.95 msec (50.5%) for the faster component and 7.6 msec (49.5%) for the slower component. From Nagata et al. (1997) and used with permission of Elsevier Ltd.

Examples of ligand-gated whole-cell currents are illustrated in Figure 11.10.8 (Aistrup et al., 1999). Acetylcholine or NMDA was applied via a U-tube system to a rat cortical neuron in long-term primary culture. ACh at 3 μM evoked an inward current, which was greatly potentiated by 100 mM ethanol. NMDA at 30 μM generated an inward current, which was suppressed by 100 mM ethanol.

Examples of ligand-gated single-channel currents recorded by the cell-attached patch clamp technique from a PC12 cell are shown in Figure 11.10.9 (Nagata et al., 1997). Currents were induced by 30 μM ACh contained in the pipet solution or by 30 μM ACh plus 1 μM or 10 μM lead contained in the pipet solution. Lead at 1 μM shortened the open time and lead at 10 μM increased the frequency of openings. The analyses of open time distribution are shown in Figure 11.10.10 indicating concentration-dependent decreases in open time by lead.

Electrophysiological Studies of Neurotoxicants on Central Synaptic Transmission in Acutely Isolated Brain Slices

Normal function of the brain requires rapid and precise communication between neurons. Individual neurons in the central nervous system (CNS) communicate with each other at synapses primarily by chemical synaptic transmission. For this process, electrical properties of the membrane transduce depolarization into release of a chemical transmitter stored in the sending neuron. Any chemical that interferes with this process, at the conduction of the electrical impulse, release of the chemical messenger, or its recognition by the receiving neuron, may potentially disrupt synaptic transmission and cause neurotoxicity in the central nervous system (CNS).

Effects of neurotoxic chemicals on central synaptic transmission can be assessed using electrophysiological recording techniques in freshly isolated brain slice preparations. All conventional electrophysiological recording techniques such as extracellular microelectrode recording, intracellular microelectrode recording, whole-cell patch clamp, and single-channel recordings that are used in cultured or acutely dissociated cells can now be applied to brain slices. As a result, the excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs, respectively) or excitatory or inhibitory postsynaptic currents (EPSCs or IPSCs, respectively) may be recorded. It is also possible to study central synaptic functions and synaptic plasticity such as long-term potentiation (LTP), a long-lasting increase in synaptic transmission in the CNS in response to a brief tetanic stimulation. The advantages and disadvantages of different recording techniques and their applications to neurotoxicology are discussed in Background Information.

Theoretically, slices for electrophysiological recordings can be made from almost any region of the brain. However, the regions of brain most commonly used as slices for studying central synaptic function are those with solid laminated architectures such as the hippocampus and cerebellum. In this unit, preparations of both hippocampal (see Support Protocol 1) and cerebellar (see Support Protocol 2) slices are described. Using these two slice models, three conventional recording techniques including extracellular microelectrode recording (see Basic Protocol 1), intracellular microelectrode recording (see Basic Protocol 2), and whole-cell patch clamp recording (see Basic Protocol 3) in brain slices will be discussed.

Depending on the region of brain (e.g., hippocampus, cerebellum, or neocortex) to be sliced and the type of recordings (extra- or intracellular microelectrode recording or whole-cell patch recording) to be made, three main methods in cutting brain slices have been employed. The first method is manually cutting the slices by hand using a razor strip or bow cutter. This method is widely used for tissues such as the neocortex, olfactory cortex, and cerebellum, where a large area tangential to a surface needs to be cut. The second method is semi-manually cutting slices from a larger tissue block using a razor-containing tissue chopper. This method can be used to cut any region of the brain that can be prepared into a tissue block, as described in Support Protocol 1 for preparation of hippocampal slices. The third method is cutting slices from a smaller tissue block using an oscillation tissue slicer or vibratome. Unlike the first two methods, which produce relatively thick slices used typically for extra- and intracellular microelectrode recordings (they also can be used for whole-cell patch clamp recordings using the so-called "blind" technique), the vibratome method can cut relatively thin slices (reliably cuts 150- to 200-μm slices) suitable for whole-cell patch clamp recordings. It is especially good for cutting fresh and slightly firm tissues such as the cerebellum. The vibratome method for preparation of thin cerebellar slices is described in Support Protocol 2.

STRATEGIC PLANNING

Which Type of Electrophysiological Recording Technique is Appropriate?

To study effects of neurotoxic chemicals on central synaptic transmission, the first issue to determine is what type of electrophysiological recordings (extracellular microelectrode recording, intracellular microelectrode recording, or whole-cell patch clamp recording) in the brain slice is needed for a particular experiment. In general, analysis of the field potentials (extracellular recording from a number of spatially localized cells) gives information about the average behavior of a neuronal population in response to effects of a given neurotoxic chemical, while single-cell studies (intracellular and whole-cell patch clamp recordings) give much more detailed information about the state of a particular cell during and after exposure to the neurotoxic chemical. Thus, selection of a recording method depends mainly on the primary goals of the proposed experiments. If one simply wants to screen a series of chemicals or test whether or not a given chemical affects central synaptic function, then conventional extracellular microelectrode recording in brain slices may be sufficient. If one is more interested in an in-depth analysis of the neurotoxic mechanisms underlying how a given chemical affects central synaptic transmission, then intracellular recording techniques including current clamp, discontinuous (sharp) single-electrode voltage clamp (dSEVC), and, especially, conventional whole-cell patch clamp recording would be preferable.

In addition, the availability and makeup of the electrophysiological setup, the research budget, and the investigators' experience in electrophysiological recordings are also factors in the selection of recording methods.

Which Region of Brain Tissues Should be Used for Preparation of Brain Slices?

In general, the ideal region of brain tissue for making slices should have the following characteristics: (1) slices can be prepared easily and reliably (e.g., hippocampus or cerebellum); (2) the structural landmarks are readily visible (e.g., the layers of pyramidal and granule cell in hippocampus or the layers of cerebellar Purkinje and granule cells and their fiber projections can be easily discerned); (3) the architecture is "laminated" such that the synaptic circuits are organized in a planar pattern so that they remain intact after slicing. In addition, for the purpose of neurotoxicological studies, the characteristics of the neurotoxicity of an agent, particularly the clinical symptoms, signs, and pathology resulting from exposure to the chemicals of interest, should be taken into account in selecting the region of brain tissue for slicing. For example, do particular sensory disturbances, motor dysfunctions, or behavioral changes occur? Are specific areas or regions of brain damaged? If one knows the chemical to be tested is particularly toxic to a particular brain region such as the cerebellum (e.g., methylmercury) or the hippocampus (e.g., trimethytin), then slices from these regions should be considered. Alternatively, if a chemical causes significant neural behavioral changes, loss of short-term memory, or learning disorders (e.g., lead), then regions associated with certain forms of learning and memory, such as the hippocampus, may be a better choice. If a chemical causes vision damage potentially via a central mechanism, then visual cortex slices should be considered.

What is Needed for a Basic Setup for Electrophysiological Recording in Brain Slice?

The basic components of a setup for electrophysiological recordings in brain slices are generally all similar among different laboratories; they include an antivibration table, a Faraday cage, an amplifier, a microscope, a computer, an oscilloscope, micromanipulators, a tape recorder (optional), pipet fabrication supplies (electrode puller and microforge), microelectrode holders, a recording chamber, a perfusion system, a temperature control system, and brain slicers. However, individual components may vary depending

on the requirements for a given experiment, type of recording, and the investigators' preference. Detailed electrophysiological setups in a laboratory have been described elsewhere by Penner (1995) and Finkel and Bookman (1997). Still, certain considerations for selection of some components may be worth mentioning in this unit.

Amplifier

The amplifier requirements for extracellular, intracellular, and patch-clamp recordings are different. For accurate measurement of intracellular membrane potential changes in intracellular recording, one important requirement for a microelectrode amplifier is to have a "Bridge" mode and to be able to perform "bridge balance" in order to eliminate the microelectrode voltage drop when passing currents across the microelectrode resistance. Usually, the microelectrode amplifier used for intracellular recording is also used for extracellular recording. However, because the signal for extracellular recording is typically very small and needs extensive amplification, a circuit with low-noise with a gain of at least 1000× is also required for an extracellular recording amplifier. Theoretically, all modern intracellular microelectrode amplifiers (e.g., Axoclamp-2; Axon Instrument) are capable of being used for both extra- and intracellular recordings. In addition to current clamp recordings, some intracellular microelectrode amplifiers such as the Axoclamp-2 can also be used for voltage-clamp recording in whole cells using the discontinuous single (sharp) electrode voltage clamp (dSEVC) recording method. In this type of amplifier, the single electrode performs both functions of voltage recording and current passing using time-sharing techniques, i.e., function of the electrode is switched rapidly between voltage recording (~70% of duty cycle) and current passing (~30% of duty cycle). Thus, the same system can be used for extracellular recording, conventional intracellular recording (current-clamp), and voltage-clamp recording (either patch pipets or sharp microelectrodes). Although all patch-clamp amplifiers (e.g., Axon's Axopatch 200B, Axopatch-1-D, and MultiClamp 700A; Warner's PC-505B; Bioscience Tools' WPC-100) are suitable for both single-channel and whole-cell recordings, some amplifiers may be better in one type of recording mode than others. For example, the Axopatch 200B provides very-low-noise recordings of single-channel current. Thus, if the single-channel recording is the primary method to be used in the experiments, this type of amplifier may be a better choice. On the other hand, if a whole-cell recording technique is routinely used in the experiments, then a different type of unit, such as the Axopatch 1-D amplifier, will work very well.

Recording chamber

In general, there are two types of brain slice chambers (the interface chamber and the submersion chamber) routinely used for electrophysiological recordings. The interface chamber usually consists of a small inner chamber with a fine-nylon mesh to hold the slice and an outer-bath chamber with a heating wire and oxygenation tubes. The slice is incubated in the inner chamber partially submerged in artificial cerebrospinal fluid (ACSF) with its upper surface exposed to a humidified atmosphere of 95% O_2/5% CO_2 to form an air-fluid interface. The main advantages of this type of chamber are that it provides better oxygenation of the tissue; the recording of responses, especially extracellular field potentials, is facilitated (responses are larger than those obtained in a submersion chamber); the stimulus artifacts are greatly reduced; and the temperature can easily be preheated to the desired level without a special and expensive control system. The major disadvantages are that the slice may easily dry out if the balance between input and output of medium is not adjusted perfectly; stability of the slice is not easy to maintain, and the slice on the nylon mesh can move up-and-down if the input and output of medium are not well balanced, drainage is not smooth or air bubbles appear under the nylon mesh; rapid change of the composition of the bath solution does not occur and thus exposure of slices to the test chemicals is not uniform, particularly the surface tissue; and it is not

suitable for conventional whole-cell patch-clamp recording. In the submersion type of chamber, the slice is immersed completely in oxygenated ACSF. The principal advantages are that the slice is in an environment that is more constant-free from perturbations in fluid flow, drainage, changes in "environmental" oxygen pressure, and appearance of air bubbles under the nylon mesh. Exposure of the slice to test chemicals is more uniform and the chemicals can be washed out rapidly because both sides of the slice are exposed to medium. The major disadvantages are that the field potentials are less easy to record due to shunting of currents via the bath solution; the stimulus artifacts are large; the perfusion rate has to be higher; and the series resistance may be a problem for whole-cell patch-clamp recording. Based on the authors' experience with a variety of chambers including interface and submersion chambers (home-made or commercially-produced) for neurotoxicological studies, a modified RC-26 (small volume) or RC-29 (large volume) submersion chamber assembled with a cell support (Warner Instruments) is suitable for all types of recordings in brain slices.

Perfusion system

There are many types of perfusion pumps or systems commercially available. For the purpose of general perfusion, a simple perfusion system consisting of several large syringes to feed the chamber by gravity is adequate. However, regardless of what kind of perfusion system is used, several points should be taken into consideration: the dead space or volume should be as small as possible; tubes used for perfusion should be resistant to chemicals and easy to clean and replace; and switching between solutions and control of perfusion rate should be easy. One common problem that occurs when using a multi-channel multistaltic pump to control both the perfusion and drainage of medium is that the balance between input and output of medium in the chamber is sometimes difficult to adjust. This may cause instability for recordings, especially when an interface chamber is used. This problem can usually be avoided with an RC-26-type chamber and a vacuum pump to control the drainage of the waste medium out of the recording chamber by suction (see Fig. 11.11.1).

Micromanipulators

The basic requirement for any micromanipulator is that no drift or vibration occur during recording, but requirements for fine control of movement of electrodes are different for extracellular, intracellular, and whole-cell patch-clamp recordings. For extracellular recording, a coarse-adjustment manually-operated micromanipulator such as a Narishige MP1 will work well. For intracellular recording, a manually-operated micromanipulator with fine-movement control may also work, but it will work much better if the fine movement of the micromanipulator is operated by a remote control system, as this reduces unwanted movement due to vibration applied to the manipulator by hand. For whole-cell recording in a brain slice, the manipulator should allow fine, smooth advancement of the electrode with a few microns per second or less. The best arrangement for a manipulator is when the manipulator and recording chamber are co-assembled on the same fixed platform (e.g., a Burleigh 1500 manipulator on a Gibraltar platform with an XY stage base). This greatly increases the recording stability.

Microscope

Usually, a low-power dissection microscope will work very well for extra- and intracellular microelectrode recordings in brain slices that have clear landmarks of synaptic pathways such as those from the hippocampus and cerebellum. However, for whole-cell recording in brain slices, a high-power upright microscope equipped with a Nomarski optical system is a must, unless the blind techniques are used to form the gigaohm seal. In most cases, an additional video camera system for the microscope is not necessary.

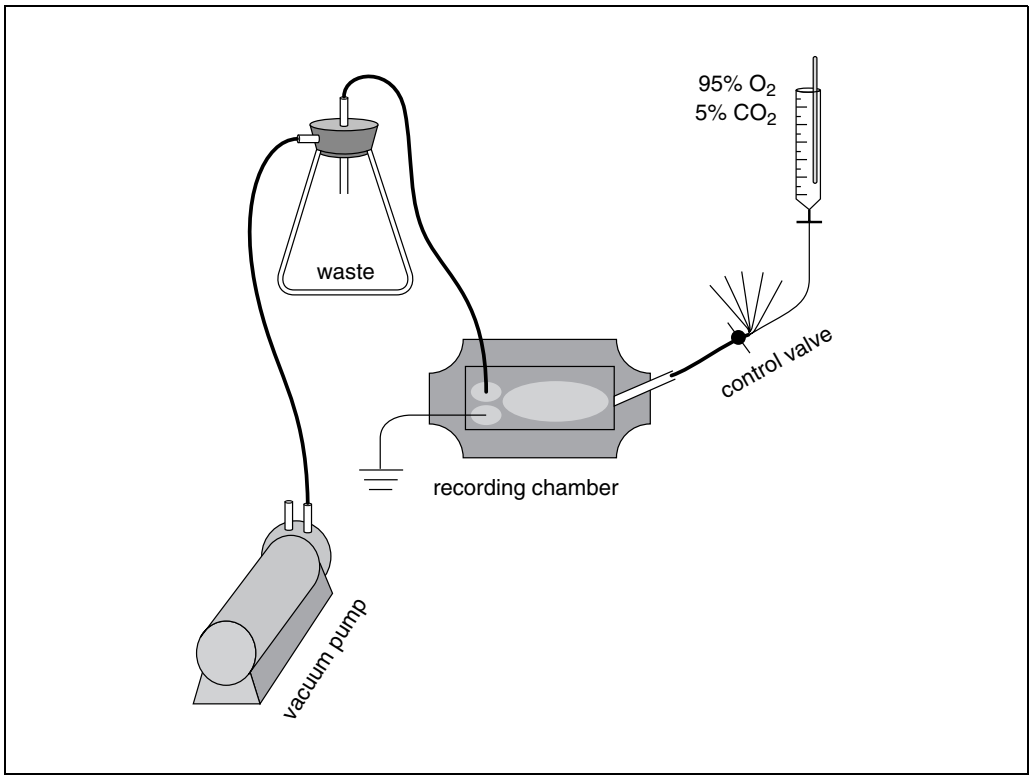

Figure 11.11.1 Schematic of the perfusion and drainage system for isolated brain slice recording. ACSF is bubbled continuously with 95% O_2/5% CO_2 in a 60-ml syringe. Six to eight input lines are controlled by a VC-6 Valve Control System (Warner Instruments) and connected to a modified RC-26 recording chamber with a glass coverslip bottom (Warner Instruments). The slice rests on a slice support so that both sides of a slice are exposed to the bath solution. The waste solution is drained away and collected into a 2000-ml flask by negative pressure with the tubing connected to a small vacuum pump (Cole-Palmer Instruments).

However, if one wishes to record from small cells, such as cerebellar granule cells or from the dendritic membranes, a video camera system may be helpful.

How to Identify Sites of Action of Neurotoxicants in Disruption of Central Synaptic Transmission?

In studying effects of neurotoxic chemicals on synaptic transmission in the CNS, one important question to ask is where and how the test chemical primarily acts to block or interfere with synaptic transmission (i.e., by pre- and/or postsynaptic mechanisms). To answer this question, several strategies can be used.

In extracellular recordings, one can compare time-courses of effects of the tested chemical on the field potentials of the postsynaptic neurons evoked by orthodromically stimulating the presynaptic fibers (Schaffer collaterals in the CA1 region of hippocampal slices) or by antidromically stimulating the axons (the alveus of hippocampal CA1 neurons) of the same population of postsynaptic neurons. The results obtained from this method may not give the precise sites where the chemical acts, but they may provide some useful clues for designing subsequent experiments.

In intracellular or whole-cell recording, quantal analysis of effects of the test chemical on spontaneously occurring and nerve-evoked postsynaptic potentials or currents can be examined. If the test chemical acts primarily by presynaptic mechanisms to reduce neurotransmitter release, then the number of quanta (i.e., quantal content) released from the presynaptic termini will be altered, the frequency of spontaneous or miniature

postsynaptic potentials or currents may be affected, but the amplitude of the postsynaptic response evoked by a quantum of transmitter (quantal size) should not be changed. In contrast, if the test chemical acts primarily at the postsynaptic sites (e.g., receptors) to antagonize the action of neurotransmitter, then the amplitudes (quantal size) of postsynaptic potentials or currents will be reduced, while the quantal content should not be changed. However, one exception is if the tested chemical (e.g., reserpine) acts presynaptically to deplete neurotransmitter and results in reduced quantal size, it may appear as a postsynaptic mechanism. Of course, if both the frequency and amplitudes of spontaneous and evoked postsynaptic responses are changed, then both pre- and postsynaptic mechanisms are likely to be involved in the effects of the test chemicals on synaptic transmission.

In intracellular or whole-cell recording, one can compare time-courses of effects of the test chemical on postsynaptic responses (EPSPs in intracellular recording or EPSCs in whole-cell voltage-clamp recording) evoked by stimulation of the presynaptic fibers or by direct application (iontophoresis, pressure ejection, or any brief pulse application) of neurotransmitters such as glutamate (Fig. 11.11.2). The rationale for comparing these responses is that fast application of neurotransmitter directly onto the dendrites of targeted neurons could mimic the process of synaptic activation yet bypass the synaptic release processes. If the test chemical acts primarily at presynaptic sites to interfere with transmitter release, then the response of the postsynaptic neuron to electrical stimulation of the presynaptic fibers would be expected to be blocked, whereas responses of the same neuron to fast application of neurotransmitter may not be affected.

One can compare time-courses of effects of neurotoxic chemicals on responses (action potentials) evoked by orthodromic stimulation of the presynaptic fibers by direct injection of depolarizing currents through the recording electrode at the postsynaptic neuronal soma, and by antidromic stimulation of the axon of the same neuron (Fig. 11.11.2). The rationale is that if the test chemical acts primarily by a synaptic mechanism to interfere with transmitter release or its postsynaptic response, then block of orthodromically-activated action potentials would be expected to occur earlier than block of action potentials evoked by current injection at the cell soma or by antidromic stimulation of the axon because the responses evoked by the latter two methods bypass the process of synaptic transmission. Actions at presynaptic versus postsynaptic sites cannot be differentiated by this method. However, if the test chemical primarily affects the processes of initiation or generation of action potentials, then time to block responses evoked by all three methods should be similar.

By analysis of the results obtained using these strategies, one can possibly identify where the test chemical has its primary action to block synaptic transmission.

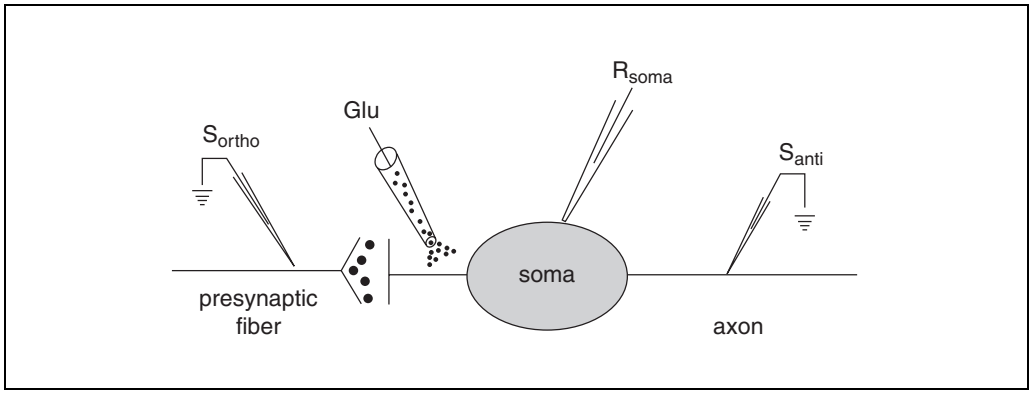

Figure 11.11.2 Schematic depiction of different methods for stimulation of a neuron. Abbreviations: Glu, direct application of glutamate onto the dendrites or soma of a neuron by iontophoresis or pressure ejection; R_{soma}, recording electrode on cell soma; S_{anti}, antidromic stimulation of the axon of the neuron; S_{ortho}, orthodromic stimulation of the presynaptic fibers.

Age of Animals for Preparation of Brain Slice

Theoretically, brain slices can be made from an animal of any age. However, it is generally believed that brain tissues of young animals have some advantages over those of older animals. For example, young animal brain tissues (1) are easier to dissect and prepare; (2) are more tolerant of anoxic damage, yielding a better chance to get good slices, and (3) use reduces the likelihood of space-clamp errors in voltage-clamp recordings. In older animals, the neurons, particularly the Purkinje cells in the cerebellum, usually have more extensive axonal and dendritic arborizations. If the process is very long or has complicated geometry, i.e., if it is highly branched, the voltage across the membrane in distant segments may differ markedly and make voltage clamp ineffective. Because membrane potentials in these distant segments of the processes will certainly deviate from the command potentials, space-clamp errors will occur. This can lead to distortions of the synaptic current recorded. In relatively young animals, while the synaptic circuits may already be established, synaptogenesis is not yet complete; as such dendritic processes may not yet have developed fully. Thus, using tissue from young animals will reduce the chances of space-clamp errors in dSEVC or whole-cell voltage-clamp recording in brain slices. If for reasons of experimental design it is necessary to use older-aged animals for slices, one can obviate some of these problems by simply pulling patches of membrane from the region of interest. This will avoid problems of space clamp.

Obviously, there are numerous other pertinent questions or considerations investigators should ask before designing experiments. For example, should the effects of a given chemical be compared on excitatory and inhibitory synaptic transmission? Should spontaneous and/or evoked synaptic responses be recorded? Should the synaptic potential (current-clamp) or currents (voltage-clamp) be measured? Should the recordings be performed at room temperature or at a temperature closer to the physiological temperature of 37°C? The authors will not discuss these issues here. Readers should refer to the detailed discussions of these and other similar issues by Langmoen and Andersen (1981), Schwartzkroin (1981), Johnston and Brown (1984), and Axon Guide (see Internet Resources).

EXTRACELLULAR MICROELECTRODE RECORDINGS IN HIPPOCAMPAL OR CEREBELLAR SLICES

BASIC PROTOCOL 1

Extracellular recording of field potentials from neurons in hippocampal slices is the most commonly used recording method for studying central synaptic function, synaptic plasticity, and pharmacological or neurotoxic effects of drugs or environmental chemicals on central synaptic transmission. Due to its well-defined tri-synaptic circuits (the perforant pathway–granule cell synapses, mossy fiber–CA3 synapses, and Schaffer collateral–CA1 synapses) and easy preparation and maintenance of stable long-lasting recording with relatively less-expensive equipment, extracellular recording in hippocampal slices is often the best starting point for those who lack, but wish to develop, experience in electrophysiological recordings in brain slices. Although this method is relatively simple, it can often be sufficient to answer general questions about effects of neurotoxic chemicals on central synaptic transmission, as well as direct further experimentation depending on the aims of the experiments.

Extracellular recording uses a relatively large tip microelectrode to record extracellular potential changes of a population of neurons in response to a given stimulus. The slices used for extracellular recording are 300 to 500 μm in thickness (see Support Protocol 1). The positioning of both recording and stimulating electrodes can be done easily with the aid of a low-power dissecting microscope. Stimulation of the presynaptic fibers (e.g., Schaffer collaterals) will evoke postsynaptic responses, which are referred to as field potentials or population spikes. Typically, an extracellular recording electrode can pick up several signal components (see Fig. 11.11.5A for an example): the presynaptic volley

corresponding to afferent spike activity, summed field excitatory postsynaptic potentials (fEPSPs), and population spikes (PSs). The amplitude, shape, and polarity of field potentials in a given slice structure may vary depending upon the relative location of the recording and/or stimulating electrodes. In this protocol, the basic steps for extracellular recording in hippocampal slices and its use in examining synaptic plasticity in brain slices will be discussed. With some minor modifications, the method can also be applied to record field potentials in other brain regions such as the cerebellum or lateral olfactory tract.

Materials

95% O_2/5% CO_2 saturated artificial cerebrospinal fluid (ACSF, see recipe)
95% O_2/5% CO_2 gas mixture source
300- to 400-μm healthy hippocampal slices (see Support Protocol 1)
3 M NaCl, optional

Perfusion system (see Fig. 11.11.1):
- 60-ml syringes
- Perfusion valve control (e.g., VC-6 valve control system, Warner Instruments)
- PE-160 tubing
- 2000-ml flask with tubing (Pyrex)
- Vacuum pump (Cole-Palmer Instruments)
- Recording chamber (interface or submersion chamber, e.g., a modified RC26 chamber assembled with a slice support, Warner Instruments)

Ag/AgCl ground electrode (e.g., REF-1L reference cell or E206 Ag/AgCl pellet electrode, Warner Instruments)

Basic electrophysiological setup:
- Microelectrode amplifier (e.g., Axoclamp-2 microelectrode clamp)
- Digidata 1200 interface (Axon Instruments)
- PC computer system installed with pClamp 8.x software
- Two manually-operated manipulators (e.g., MP1 Narishige manipulator, Narishige Scientific Instruments)
- Stimulator (Grass S88, Grass)
- Stimulus isolation unit (Grass SIU5, Grass)

Oscilloscope (Gould Instrument Systems).

Wide-bore Pasteur pipet (simply break the narrow tip end and insert it into a small rubber suction bulb)

U-shaped platinum-nylon mesh

Fiber-optic light (Dolan Jenner Industrials)

Dissection microscope (e.g., Wild M5A)

Extracellular recording pipets pulled from borosilicated glass capillaries (1.0-mm o.d., 0.5-mm i.d.; tip impedance of 5 to 15 MΩ when filled with ACSF or 3 to 4 M NaCl)

Glass microelectrode puller (e.g., Model P-97, Sutter Instruments)

Pipet filler: MicroFil MF28G needle (WPI)

Solution in-line heater SH-27B and TC-344B chamber system heater controller (Warner Instruments) or other alternative heating system (depending on the type of chamber being used), this may be required if experiments will be performed at 30° to 35°C

Concentric bipolar metal electrode or monopolar tungsten electrode (3 MΩ, FHC; alternatively, a broken-tip glass pipet filled with ACSF can also be used as the stimulation electrode)

NOTE: The oscilloscope can be replaced with the computer and monitor if appropriate software is available.

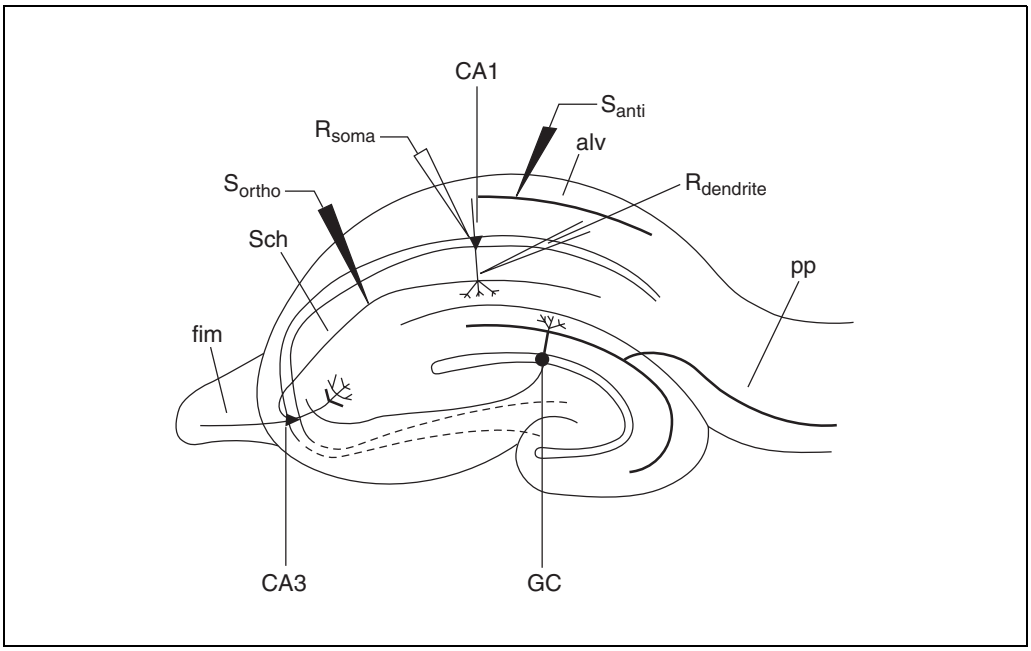

Figure 11.11.3 Schematic depiction of a structure of a transverse hippocampal slice and methods for extracellular and intracellular recordings in the CA1 pyramidal cell region by orthodromic stimulation of Schaffer collaterals and by antidromic stimulation of the alveus. Abbreviations: alv, alveus; CA1, CA1 pyramidal cell; CA3, CA3 pyramidal cell; fim, fimbria; GC, granule cells in the dentate region; PP, perforant pathway; $R_{dendrite}$, recording electrode at the apical dendrites of the CA1 pyramidal cells; R_{soma}, recording electrode at the CA1 pyramidal cell soma; S_{anti}, antidromic stimulation of the alveus; S_{ortho}, orthodromic stimulation of Schaffer collaterals.

Prepare perfusion systems and recording chamber

1. Set up the solution perfusion system and recording chamber (see Fig. 11.11.1). Turn on the vacuum. Pre-wash the recording chamber first with deionized water and then with ACSF aerated continuously with 95% O_2/5% CO_2. Make sure the reference or Ag/AgCl ground electrode is properly immersed in the bath. Turn on the basic electrophysiological setup (computer, stimulator, and amplifier) and oscilloscope.

2. Transfer a 300- to 400-µm hippocampal slice with a wide-bore Pasteur pipet into the recording chamber and gently place a U-shaped platinum frame with attached nylon mesh over the slice. Transilluminate the slice from below with a fiber-optic light. Adjust the perfusion rate to 2 to 4 ml/min and the buffer level as low as possible but be careful not to dry out the slice. Locate the CA1 pyramidal cell region under the dissection microscope (see Fig. 11.11.3).

Prepare electrodes

3. Fill an extracellular recording pipet with ACSF or 3 M NaCl, insert the pipet into the electrode holder (be sure to clean off any solution from the outside wall of the pipet) and then plug the electrode holder into the amplifier headstage (this step may vary depending on the amplifier).

4. Lower and advance the electrode into the bath. Set the oscilloscope on a proper sensitivity, i.e., mV/div level (e.g., 100 mV/div) and null the baseline. Generate 0.5 nA, 20-msec pulses from the concentric bipolar metal electrode or monopolar tungsten electrode stimulator. In "bridge mode," turn the bridge dial until the bridge is correctly balanced (see Fig. 11.11.4). Read the dial to get the electrode resistance value. Lower and advance the stimulating electrode into the bath.

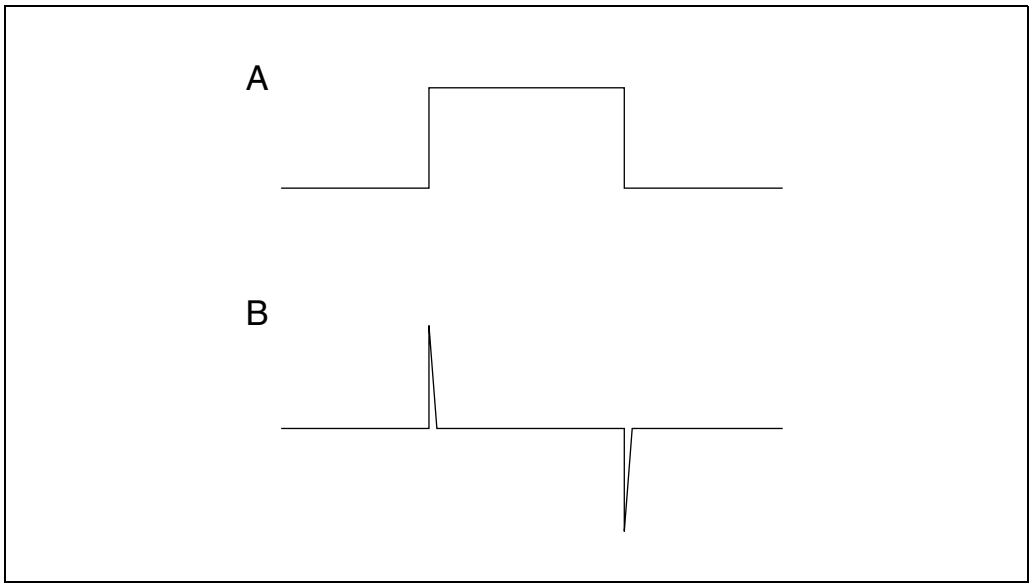

Figure 11.11.4 Schematic illustration of measurement of electrode resistance using the bridge balancing technique. (**A**) Response of electrode to a test current pulse (e.g., 0.5 nA, 20 msec), no bridge balance is used. (**B**) The bridge is correctly balanced.

Position electrodes and establish recordings

5. To record orthodromically activated fEPSPs in the CA1 region, carefully position the recording pipet ($R_{dendrite}$; Fig. 11.11.3) in the apical dendrites (stratum radiatum) of CA1 pyramidal cells and place the stimulating electrode in the Schaffer collaterals ~300 to 500 μm away from the recording electrode (S_{ortho}; Fig. 11.11.3).

6. Turn on the pulse generator to deliver stimuli at a frequency of 0.1 to 0.2 Hz, 0.1 msec, and an initial stimulus intensity (usually 3 to 5 V in the authors' experience using a Grass S88 stimulator) that produces ~50% to 60% of the maximum response.

   If no responses occur, first try to increase the stimulus intensity. If no responses still occur, reposition the stimulating electrode or the recording electrode until responses appear. If the response does not show a typical fEPSP shape, try to relocate the recording electrode at different depths and/or locations.

   Care should be taken in determining the initial stimulus intensity using the maximum responses or maximum amplitudes of fEPSPs, because when the fEPSP amplitude reaches a certain size in response to a given increased stimulus intensity, a population spike may be evoked. The appearance of a population spike in an opposite direction will certainly limit the amplitude of fEPSP for further increase (Fig. 11.11.5A) and will complicate the measurement of fEPSP amplitude, particularly if a chemical or drug were to increase the amplitude of the synaptic potential. Thus, rather than increasing the stimulus intensity to produce a peak response, it is better to set the stimulus intensity at the level at which a small population spike is just observable following the fEPSP trace. Then use this fEPSP amplitude as the peak response and reduce the stimulus intensity until it yields an fEPSP amplitude at ~50% of the peak response.

7. To record orthodromically-activated PSs in the CA1 region, simply move the recording electrode to the CA1 pyramidal cell body layer (R_{soma}; Fig. 11.11.3) while stimulating the Schaffer collaterals (S_{ortho}; Figs. 11.11.3 and 11.11.5B).

8. To obtain antidromically-evoked PSs in CA1 neurons, place the stimulating electrode in the alveus while the recording electrode remains in the CA1 pyramidal cell body layer (S_{anti} and R_{soma}; Fig. 11.11.3).

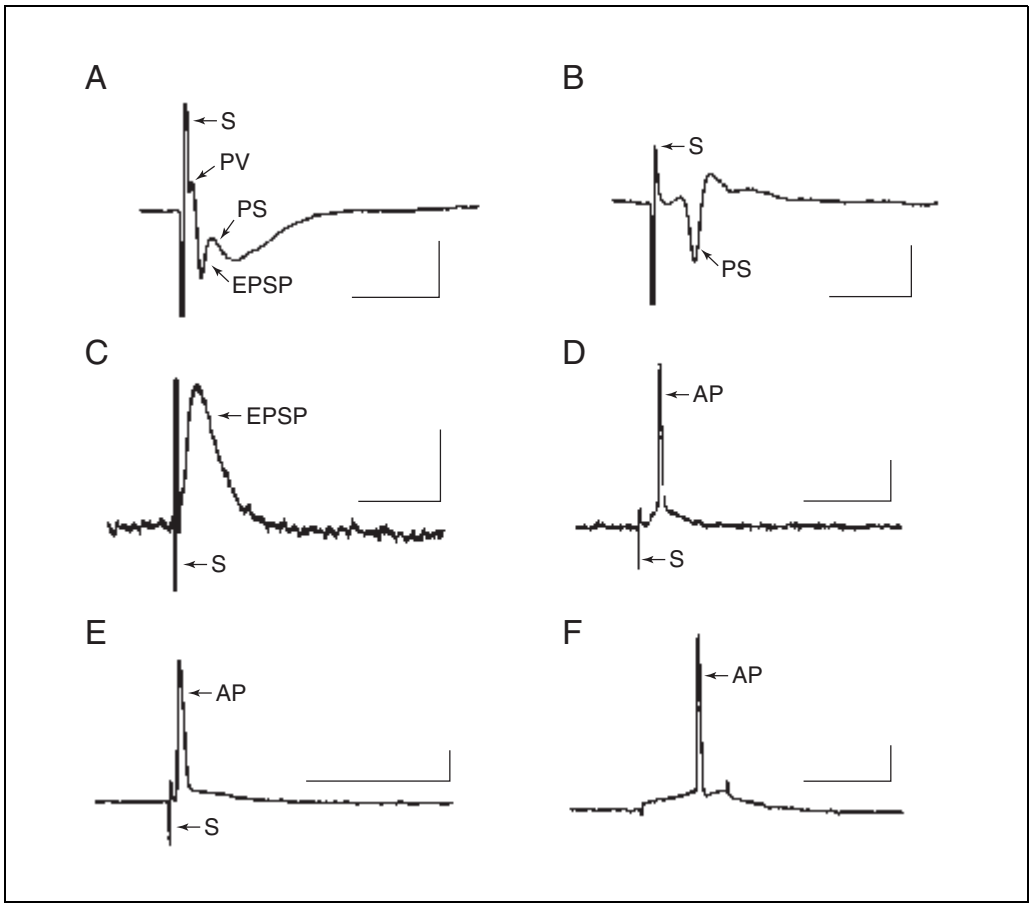

Figure 11.11.5 Representative demonstration of extracellularly recorded field potentials, intracellularly recorded excitatory postsynaptic potential (EPSP) and action potentials (APs) from the CA1 region of a hippocampal slice. (**A**) The Prevolley (PV) and the field EPSP (fEPSP) were recorded from the dendritic region of CA1 pyramidal cells by stimulating the Schaffer collaterals. Note that a positive deflection following the fEPSP was due to a strong stimulus intensity–evoked population spike (PS) at the somata. (**B**) The PS was recorded from a CA1 pyramidal cell soma area by stimulating the Schaffer collaterals. (**C**) The intracellular EPSP was recorded from an individual CA1 pyramidal cell soma by subthreshold stimulation of the Schaffer collaterals. (**D**) The AP was recorded from the same cell as in **C** but by suprathreshold stimulation of the Schaffer collaterals. (**E**) This AP was recorded from a CA1 pyramidal cell soma by antidromic stimulation of the alveus. (**F**) This AP was recorded from the same cell soma as in **E** but by injection of a depolarizing current directly through the recording electrode. "S" in each trace indicates the stimulus artifact. Calibration bars: vertical, 0.5 mV for **A** and **B**, 5 mV for **C**, 20 mV for **D**, **E**, and **F**; horizontal, 10 msec for **A**, **B**, and **E**, 20 msec for **C**, **D**, and **F**.

9. To induce long-term potentiation (LTP) of fEPSPs or PSs after the baseline response recording of fEPSPs or PSs has become stable for 30 min, apply a brief high-frequency conditioning stimulation (100 Hz, 1 sec) at the same stimulus intensity as that used to evoke the baseline responses and then return to the baseline frequency of stimulation (0.1 to 0.2 Hz, 0.1 msec) again.

   The slopes of fEPSPs or amplitudes of PSs should be increased significantly and maintained for at least 2 hr.

   Usually, field potential amplitude may increase spontaneously by 10% to 30% of the initial control value during the first 30 min of recordings. Thus exposure of slices to test chemicals and data collection should not begin until the responses have been stable for at least 30 min.

Collect data and analyze

10. To collect data in pClamp8, design a protocol in an event-detected mode in Clampex. Collect data before and after exposure to the test chemical.

11. Analysis of extracellular recording data is pretty straightforward. Analyze data using the LTP 2.22A program developed by Dr. William W. Anderson (see Internet Resources). Depending on the goals of the experiment, assess effects of the test chemical on central synaptic transmission based on the following parameters: (1) amplitudes of PSs and anti-PSs; (2) amplitude and slope of fEPSPs; (3) latency between stimulus artifact and onset of PSs or anti-PSs; (4) input/output curves (plots of presynaptic fiber volley amplitude versus stimulus intensity, fEPSP slope versus stimulus intensity, fEPSP versus presynaptic fiber volley amplitude or PS amplitude versus fEPSP slope); (5) induction and maintenance of LTP; and (6) time-courses and concentration-dependent responses to tested chemicals.

BASIC PROTOCOL 2

INTRACELLULAR RECORDING IN HIPPOCAMPAL SLICES

Unlike extracellular recording, which records responses occurring in a population of neurons, conventional intracellular recordings use a sharp electrode to penetrate the cell membrane and measure the transmembrane potential changes of that neuron at rest or in response to a given stimulus. Therefore, intracellular recording can provide more detailed information about effects of neurotoxic chemicals on the electrical behavior including resting membrane potentials, input resistance, whole-cell capacitance, synaptic responses, and action potentials (APs) of an individual neuron. Similar to extracellular recording, the initial positioning of recording and stimulating electrodes does not necessarily require a high-power microscope, this can be done simply with the aid of a dissecting microscope. However, due to the relatively small size of neurons, a much more stable recording system and more skill are required in order to obtain a stable and long-lasting intracellular recording. In this protocol, the basic steps for conventional intracellular recording in hippocampal CA1 pyramidal cells is discussed.

Materials

95% O_2/5% CO_2 saturated artificial cerebrospinal fluid (ACSF, see recipe)
95% O_2/5% CO_2 gas mixture source
300- to 400-μm healthy hippocampal slices (see Support Protocol 1)
3 to 4 M KCl or potassium acetate
Neurotransmitters of interest
500 mM glutamate in 100 mM NaCl (pH 8.0)

Perfusion system (see Fig. 11.11.1):
- 60-ml syringes
- Perfusion valve control (e.g., VC-6 valve control system, Warner Instruments)
- PE-160 tubing
- 2000-ml flask with tubing (Pyrex)
- Vacuum pump (Cole-Palmer Instruments)
- Recording chamber (interface or submersion chamber, e.g., a modified RC26 chamber assembled with a slice support, Warner Instruments)

Ag/AgCl ground electrode (e.g., REF-1L reference cell or E206 Ag/AgCl pellet electrode, Warner Instruments)
Wide-bore Pasteur pipet (simply break the narrow tip end and insert it into a small rubber suction bulb)
U-shaped platinum frame with attached nylon mesh
Microscope

Basic electrophysiological setup:
Microelectrode amplifier (e.g., Axoclamp-2 microelectrode clamp)
Digidata 1200 Interface (Axon Instruments)
PC or Macintosh computer system installed with pClamp 8.x software, MiniAnalysis 5.2.8 (Synaptosoft), or other available software
Two manipulators (one must have fine-movement control, preferably a remote, fine-movement control system—motorized, hydraulic, or piezoelectric control—e.g., MP1 Narishige manipulator, Narishige Scientific Instruments)
Grass S88 stimulator and Grass SIU5 stimulus isolation unit (Grass)
Intracellular recording pipets pulled from borosilicated glass capillaries (impedance of 80 to 120 MΩ for CA1 neurons when filled with 3 to 4 M KCl or potassium acetate

Prepare perfusion systems and recording chamber

1. Set up the solution perfusion system and chamber (see Fig. 11.11.1). Turn on the vacuum. Pre-wash the recording chamber first with deionized water and then ACSF aerated continuously with 95% O_2/5% CO_2. Make sure the reference or ground electrode is properly immersed in the bath. Turn on the computer, stimulator, amplifier, and oscilloscope.

2. Transfer a hippocampal slice into the recording chamber with a wide-bore pipet and gently place a U-shaped platinum frame with attached nylon mesh over the slice. Adjust the perfusion rate to 2 to 4 ml/min and the buffer level to an adequate level that just submerses the slice. Locate the CA1 pyramidal cell region under the microscope.

Prepare electrodes

3. Fill a glass intracellular recording pipet with 3 M KCl or potassium acetate. Insert the pipet into the electrode holder (be sure to clean off any solution from the outside wall of pipet) and insert the electrode holder into the amplifier headstage (this step may vary depending on the amplifier).

   Filling an intracellular recording pipet electrode is somewhat challenging initially. It is imperative to prevent the formation of bubbles in the tip of electrode. This is best done by taking advantage of capillary force and backfilling the electrodes. To do so, just put the backend of the electrodes in 3 M KCl or potassium acetate solution for 10 to 30 min. The solution will usually fill the tip automatically. Then back fill the rest of the tip with a Microfil, (do not fill the entire electrode yet), gently tap the electrode to remove any bubbles. Finally, back fill the rest of the electrode.

4. Lower and advance the electrode into the bath. Set the oscilloscope on a proper sensitivity, i.e., mV/div level, and null the baseline. Generate 0.5 nA, 20-msec pulses from the stimulator. In the bridge mode, turn the amplifier bridge dial until the bridge is correctly balanced (see Fig. 11.11.4) and read the electrode tip resistance from the dial. Lower and advance the stimulating electrode into the bath.

Position electrodes and establish recordings

5. To record orthodromically activated EPSPs in the CA1 pyramidal neurons, carefully position the recording electrode in the somal layer of CA1 pyramidal neurons and place the stimulating electrode in the Schaffer collaterals (S_{ortho}; Fig. 11.11.4) 300 to 500 μm away from the recording electrode (R_{soma}; Fig. 11.11.4).

6. Use the fine control on the micromanipulator to advance the electrode.

   When the tip of the electrode approaches and touches a cell, the resistance will increase and spontaneous activity of neurons can be seen as occasional small negative deflections (spikes) on the screen of the oscilloscope or computer monitor. When a large amplitude,

steady negative membrane potential drop occurs (usually −50 to −70 mV), or occasionally action potentials (60 to 80 mV in amplitude) occur, this indicates that the tip of the electrode has successfully impaled the cell membrane.

Injecting a steady negative DC current (0.1 to 0.3 nA) through the recording electrode after impalement usually helps to stabilize the cell. At this point, do not stimulate the cell, wait a few minutes to let the cell recover and allow the membrane to reseal around the electrode. After the resting membrane potential, action potential amplitude, and membrane input resistance gradually recover to the normal level, the number of spontaneous action potentials declines. The DC current injection can then be removed gradually.

Some devices can be used to aid the penetration of the cell membrane. Some investigators prefer to whistle the capacitance circuits to increase suddenly and transiently the capacitance compensation. This often leads to a successful impalement (on many amplifiers, a specific button called buzz or trick is used for this purpose). Other investigators like to penetrate the cell membrane by gently tapping the micromanipulators.

If the resting membrane potential recovers very slowly or does not recover at all, a small upward or downward movement of electrode may sometimes improve the cell membrane properties. This may indicate that the electrode tip has not penetrated the cell membrane completely, or conversely is now up against the opposite membrane or an intracellular organelle membrane. A well-penetrated CA1 pyramidal cell should typically have an action potential amplitude >60 mV, input resistance >15 MΩ and a stable resting membrane potential more negative than −55 mV.

7. After the cell has become stable, turn on the pulse generator to deliver stimuli at a frequency of 0.1 Hz, 0.1 msec, and an initial low-stimulus intensity.

   Gradually increasing the stimulus intensity should elicit a local graded positive deflection of membrane potential (i.e., EPSP). Further increasing the stimulus intensity above a certain level (threshold) will trigger a single all-or-none spike superimposed on the EPSP. Thus, the maximum EPSPs should be elicited at the stimulus intensity that is just below the threshold for spike generation (subthreshold stimulation). The evoked EPSPs normally have amplitudes of 3 to 10 mV (Fig. 11.11.5C). Usually, injecting a small, steady hyperpolarizing DC current may increase EPSP amplitude depending on the angle at which the slice is cut.

8. To initiate orthodromically activated action potentials, slightly increase the stimulus intensity just above the threshold level (suprathreshold stimulation; Fig. 11.11.5D).

   This should elicit a single action potential superimposed on the EPSP.

   Defining the threshold level for initiating action potentials is somewhat arbitrary. Usually it is defined as a stimulus intensity level for which 50% of the applied stimuli can evoke action potentials. No matter what level of stimulation will be used for initiating EPSPs or action potentials, it should be kept constant before and after exposure of slices to the test chemicals.

9. To obtain antidromically evoked action potentials in the CA1 cell soma, simply move the stimulating electrode to the alveus (S_{anti}; Fig. 11.11.3), while the recording electrode remains in the CA1 cell soma.

   Suprathreshold stimulation of the alveus usually elicits a single action potential that takes off directly from the baseline level with considerably shorter latency (Fig. 11.11.5E).

   Action potentials can be also elicited directly by injecting depolarizing currents into the CA1 pyramidal cell through the recording electrode (see Fig 11.11.5F). Low current intensity injection usually triggers only one long latency spike. With increasing current intensity, this spike may appear at progressively shorter latencies, followed by other spikes at regular intervals. Strong (1 to 3 nA), long-lasting stimulating pulses (1 to 5 sec) may trigger a high-frequency burst of spikes.

10. To evoke postsynaptic responses by direct application of neurotransmitters, use iontophoresis, pressure ejection, or other alternative fast application techniques. Apply neurotransmitters directly onto the apical dendrites of CA1 pyramidal neurons. For iontophoretic application of L-glutamate, fill a glass pipet (40 to 60 MΩ) with 500 mM glutamate in 100 mM NaCl (pH 8.0) and position it at the apical dendrites of CA1 neurons. Eject the glutamate by passing a 20 to 100 nA negative current for 30 to 40 msec with a retaining current of 0 to 5 nA.

    The retaining current keeps the glutamate from leaking out of the pipet.

    Alternatively, a picospritzer can be used for pressure ejection, e.g., Ultrafast Solution Switching System (Burleigh) or U-tube application system can be used to apply the desired neurotransmitter directly onto the apical dendrites of CA1 pyramidal cells.

    Care should be taken when using a direct application of neurotransmitters to bypass the neurotransmitter release process, because many receptors such as glutamate receptors, neuronal nicotinic acetylcholine receptors, or $GABA_A$ receptors can be easily and rapidly desensitized. This is important, because most neurotransmitter receptors desensitize if the transmitter agonist remains in continuous contact with the receptors. In order to avoid desensitization of receptors, the application pulse of transmitter should be as short as possible, while the intervals between application pulses should be as long as possible. For example, drug application could be every 10 sec with an application pulse of only 0.1 sec.

Collect data and analyze

While considerable thought should be given ahead of time to experimental design, one of the truly nice features of electrophysiological recording experiments is that one can modify the design on the fly to take advantage of the preparation as long as it remains viable. Seasoned electrophysiologists will routinely add on components to an ongoing experiment to make maximal use of a viable preparation.

11. Again, do not start exposure to test chemicals and data collection until the recording becomes stable. To acquire data in an acquisition program such as Clampex, design a protocol in event-detected mode to record evoked synaptic responses. Also, save data to a tape recorder or other system for backup and offline analysis purposes.

12. Analyze data using one of a variety of commercially available software programs such as pClamp 8.x, MiniAnalysis 5.2.8, or other available software. Depending on the aims of the experiment, assess effects of the test chemicals on synaptic transmission based on the following parameters: effects of the chemical on (1) the resting membrane potentials; (2) amplitudes and threshold of action potentials evoked by different methods; (3) latency from the stimulus artifact to the onset or peak of action potentials evoked by orthodromic or antidromic stimulation; (4) amplitude, latency from stimulus artifact to onset of intracellular EPSPs, 10% to 90% rise time, half-width (the time from the point at which the event has risen to half of the peak amplitude to the time at which it has decayed to half of the peak amplitude), and decay time; (5) time-courses and concentration-dependence of responses of the tested chemicals; (6) sites of action of chemical (presynaptic and/or postsynaptic mechanisms); and (7) ability of the tested chemical to alter the response to a known pharmacological agent.

BASIC PROTOCOL 3

WHOLE-CELL CURRENT RECORDINGS IN PURKINJE OR GRANULE CELLS IN CEREBELLAR SLICES

Compared to extra- and intracellular recordings, whole-cell patch-clamp recording in brain slices allows a more in-depth analysis of synaptic transmission between neurons in the central nervous system. Unlike patch-clamp recordings in cells that are either acutely dissociated or cultured (see *UNIT 11.12*), whole-cell patch-clamp recordings in brain slices usually require some special steps or treatments prior to making a gigaohm seal on the targeted neurons. Currently, three main methods or techniques are commonly used to obtain whole-cell recordings from neurons or glial cells in brain slices. They are so-called cleaning, blind, and blow-and-seal techniques (see Background Information). The blow-and-seal method, which combines the advantages of both the cleaning and the blind techniques, will be applied in this protocol to make whole-cell recordings in cerebellar Purkinje and granule cells. In this method, the thin cerebellar slice is placed in a submersion chamber mounted on the fixed stage of a high-power upright microscope equipped with Nomarski optics and an infrared CCD video camera system. The entire process including approaching the cell and making a seal on its membrane is visually monitored.

Materials

Thin 150- to 200-μm cerebellar slice (see Support Protocol 2)

ACSF (see recipe), ice cold and saturated with 95% O_2/5% CO_2

Intracellular pipet solution: the composition of pipet solution is highly dependent on the experimental purpose or design (see recipes for internal pipet solutions and KGlu-based pipet solution, and Critical Parameters)

Glutamate receptor blockers such as 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, 10 to 20 μM) for kainate/AMPA receptors and D,L-2-amino-5-phosphonopentanoic acid (APV, 50 to 100 μM) for NMDA receptors or CNQX, APV, and tetrodotoxin (TTX, 0.5 to 1 μM)

Electrophysiological setup:

- Axopatch 200B and Digidata 1200B interface (Axon Instrument); or a comparable circuit, microcomputer system installed with pClamp 8.x software and MiniAnalysis program 5.2.8 (Synaptosoft) or similar software for data analyses
- Two hydraulic or step-driven control micromanipulators such as the Burleigh 5000-150 series manipulators (Burleigh Instruments)
- Grass S88 stimulator and SIU5 stimulus isolation unit (Grass)

Platinum frame with attached nylon mesh

Microscope setup: Nikon E600FN (Zeiss Axioskop 2 FS or Olympus BX50WI) upright microscope equipped with Nomarski optics (at least 40× water-immersion objective, 2 mm long working distance), infrared CCD video camera system, and a black-and-white monitor (Sony). Ideally, mount the microscope on a fixed and stable platform, e.g., Gibraltar platform with an X-Y stage base, and mount all manipulators and chamber on the same platform.

Recording chamber (submersion chamber, e.g., an RC26 assembled with an SS-3 slice support, Warner Instruments)

Ag/AgCl ground electrode (e.g., REF-1L reference cell or E206 Ag/AgCl pellet electrode, Warner Instruments)

Pipet filler: MicroFil MF28G needle (WPI) or home-made pipet filler pulled from a 1-ml plastic syringe

Pipets coated with Sylgard 184 for whole-cell recording (1.5-μm o.d., 0.75-μm i.d. glass pipets) for Purkinje cells or (1.5-μm o.d., 1.0-μm i.d. glass pipets) for granule cells (see Critical Parameters)

10-ml syringes

continued

Stimulating electrode: a concentric bipolar metal electrode or monopolar tungsten electrode (3 MΩ, FHC; alternatively, a broken tip glass pipet filled with ACSF can be used as the stimulation electrode)

Prepare recording system

1. Turn on computer, amplifier, oscilloscope, and microscope. Load the data acquisition program such as Clampex of the pClamp 8.x software. Prewash the recording chamber with deionized water and then oxygenated ACSF. Check if the ground pellet is properly immersed in the bath. Check if the silver wire of the pipet holder needs to be chlorided or the pipet holder needs to be cleaned.

   The pipet holder should be cleaned regularly after use.

2. Transfer a thin (150- to 200-μm thick) sagittal cerebellar slice (see Support Protocol 2) from the holding chamber to the 150-μl RC-26 recording chamber assembled with an SS-3 slice support. Gently put a home-made platinum frame with attached nylon mesh over the slice, then perfuse the chamber continuously with oxygenated ACSF at a rate of 2 to 5 ml/min.

   The original RC-26 recording chamber does not have the SS-3 slice support; some slight modification is needed to assemble it. Even if an RC-29 recording chamber, which is assembled with the SS-3 slice support, is used, some modification may still need to be made to improve the accessibility for the electrodes.

   Regardless of the rate of perfusion used, make sure it is consistent for every experiment. This should be done before recordings begin, otherwise, it will be difficult to compare individual experiments from day to day. This is because the onset of effects of a given chemical is usually affected by the perfusion rate.

3. Lower the 40× water-immersion objective lens until it touches the bath solution to form a water column. Focus and select a healthy Purkinje cell or granule cell. For a better view of the granule cells using the video monitor, change the light path to video camera path of the microscope and switch the infrared filter into position. Adjust the light and zoom on tube to get a better image. When done, switch back to the regular light path.

   Healthy cells have smooth, soft, clearly visible, and phase-bright cell membranes under phase contrast. The healthy cell membrane can be easily dimpled by the ejected solution stream emanating from the tip of the approaching pipet with positive pressure to the back of pipet. Conversely, unhealthy cells usually have a uniform dark, rough and crinkled appearance with a shrunken cell body, or membrane with granular-like patches. Unhealthy Purkinje cells may also look like ghost cells and appear transparent.

Prepare recording pipet electrode

4. Obtain a freshly pulled and Sylgard-coated pipet for whole-cell recording in a Purkinje cell or granule cell (see Critical Parameters). Carefully polish the electrode to the desired shape and resistance (1.5 to 3 MΩ for Purkinje cell; 6 to 10 MΩ for granule cell) just before use.

5. Fill the pipet with intracellular pipet solution and insert it into the pipet holder, which is already tightly attached to the amplifier headstage.

   Filling a large-bore electrode for whole-cell recording in a large cell, such as a cerebellar Purkinje cell, is not difficult, but to fill a small-tip pipet for whole-cell recording in a much smaller cell such as a cerebellar granule cell may be challenging. One way is to drop one small drop of intracellular pipet solution on a piece of clean Parafilm and dip the tip of the pipet in the solution for a few seconds. Then back fill the pipet tip with a MicroFil MF28G needle or home-made pipet filler pulled from a 1-ml plastic syringe. Gently tap the pipet to remove any trapped air bubbles and then fill the pipet up to ~50% to 70% of its total length. Do not fill it entirely.

6. Apply gentle positive pressure to the back of the patch electrode either by mouth or through a 10-ml syringe (~0.1 ml) and then close the two-way (if using mouth) or three-way (if using syringe) valve to keep the pressure on.

   The primary purpose of applying positive pressure to the back of the pipet electrode is to prevent the particles on the surface of the bath solution from clogging the tip of the pipet electrode when the electrode tip is advanced into the bath. In addition, maintaining a positive pressure on the back of the pipet electrode is helpful in cleaning the tissue debris or surface tissue over the cell if deeper cells are chosen for recording (see below).

   Because most chemicals used in neurotoxicological experiments are very toxic, caution should be taken when using the mouth to apply positive pressure or suction to the pipet.

Position recording electrodes

7. Raise (defocus) the water-immersion objective lens slightly (do not lose the water column) to provide more working space for managing the pipet electrodes. Adjust the access angle of the recording electrode to be as large as possible.

   With the 2-mm working distance and access angle of 45° water-immersion objective (Nikon E600FN), the authors normally have a 35° to 40° electrode access angle.

   Make a mark on the manipulator once the access angle is optimally set, so subsequent attempts to adjust the electrode access angle can be made more rapidly.

8. Lower and advance the electrode tip into the bath solution, set the lowpass bessel filter at 5 kHz and a proper output gain level depending on the tip resistance of the recording pipet. Turn on the seal test switch on the amplifier or run Seal Test program in Clampex and monitor the response of the electrode to a test pulse on the computer screen or oscilloscope (experimenter's preference).

   One can directly read the electrode resistance from the built-in Seal Test program in Clampex if using pClamp 8.x software to acquire data, or alternatively calculate the electrode resistance using Ohm's law by measuring the current generated by a 10-msec and 5- to 10-mV test pulse (Fig. 11.11.6A).

   Electrode resistance should be monitored during electrode advancement. Any increase in resistance before touching the targeted cell indicates clogging of the electrode tip either by residual particles in the pipet, bath solution, or slice tissue debris; any of these will interfere with the formation of a high-resistance seal. Apply more positive pressure to clear the pipet tip or change to a new electrode.

9. Find the electrode under the 40× water-immersion objective lens. In the Seal Test mode, advance the electrode using the coarse control of the manipulator while continuously focusing on the tip of electrode until it is close to the targeted cell.

   Finding an electrode directly in the microscopic field under a 40× water-immersion objective lens is difficult for the first-time user. It can become very frustrating not to be able to find the electrode for several minutes. However, with practice, it will become easier. One way to do so is to raise the objective lens (as described in the step 7), and monitor, by eye, the advancement of the electrode tip from the side view until the electrode tip is approximately in the center of the objective lens. Then look through the eye piece and change focus to move the electrode back and forth until the shadow of the electrode is visible. Then focus directly on the electrode while advancing it towards the tissue.

10. Zero the baseline by adjusting the pipet offset of the amplifier (null the junction potential of electrode). Use the remote fine control (e.g., PCS-503 Axis Control Unit of a PCS-5200) of the manipulator to approach the selected cell soma slowly. Just before the tip of the pipet touches the cell membrane, watch for the tissue debris on the cell surface being blown away by the wave of ejected solution streaming out of the pipet tip (this helps to clean the surface of the targeted cell).

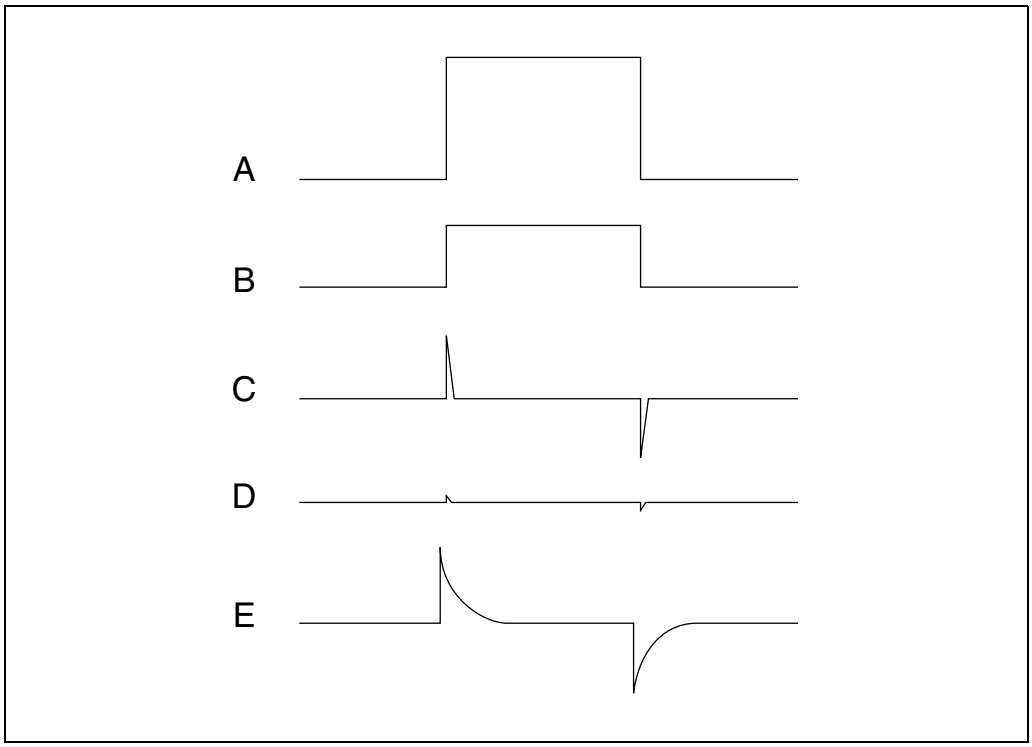

Figure 11.11.6 Schematic of steps involved in making a whole-cell recording. (**A**) Response of the patch pipet to a test pulse (e.g., 5 mV, 10 msec). (**B**) The current pulse decreases as the pipet tip touches the cell membrane (due to increased seal resistance). (**C**) Gigaohm seal formation after application of a slight negative pressure to the pipet. (**D**) After cancelling the capacitance transients. (**E**) After rupturing the cell membrane to establish whole-cell recording configuration (no whole-cell capacitance and series resistance compensation have yet been done).

If the ejected solution stream pushing away the surface tissue debris is not seen, either the pipet tip is clogged or no positive pressure is being added to the back of the pipet. In either case, a good gigaohm seal will not be obtained.

11. If recording from a Purkinje cell, continue to advance the electrode until it touches the cell and causes a slight dimple on the cell membrane. Then immediately release the positive pressure by opening the valve. At this point, the size of square current pulse on the screen of the computer or oscilloscope should decrease to ⅓ to ½ or the seal resistance should increase (Fig 11.11.6B). Apply slight negative pressure by mouth or syringe and a negative potential of −50 to −60 mV to the pipet until a gigaohm seal forms (Fig. 11.11.6C). Once the gigaohm seal is established, release the negative pressure and remove the negative holding potential.

If recording from a granule cell, these steps may be much easier if done while viewing the video monitor screen.

12. Cancel the capacitance transients by using the fast and slow pipet capacitance compensation circuits (Fig. 11.11.6D). To rupture the cell membrane, apply strong suction by mouth or use a 10-ml syringe or the zap button (see the amplifier manual for more information). Once the whole-cell recording configuration is established (Fig. 11.11.6E), examine the membrane capacitance (C_m), membrane resistance (R_m), and electrode access resistance (R_a) using the built-in Membrane Test program of Clampex or immediately perform whole-cell capacitance and series resistance compensation. Record these initial values.

Before rupturing the cell membrane, one should determine if it is important to record the initial zero-current potential (or resting membrane potential) when rupturing the mem-

brane or to monitor if the currents of interest run down or run up during dialysis of the cell with the pipet solution. To record the initial zero-current potential immediately after rupturing the membrane, run a ramp protocol over a range of voltages (e.g., from −120 mV to +80 mV, depending on the experimental aims and the cell type) immediately after rupturing the cell membrane. To monitor changes in the currents of interest during dialysis of the cell with intracellular pipet solution, run a properly designed single-voltage step immediately after rupturing the cell membrane. At the same time one should be able to make all the needed adjustments including whole-cell capacitance and series resistance compensation during the pulse intervals.

13. Start collecting data. To record spontaneous synaptic currents, run a gap-free protocol in Clampex with a membrane holding potential of −60 to 80 mV. To examine specific effects of neurotoxic chemicals on spontaneous inhibitory postsynaptic currents (sIPSPs) or miniature inhibitory postsynaptic currents (mIPSCs; Fig. 11.11.8), include glutamate receptor blockers such as 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, 10 to 20 μM) for kainate/AMPA receptors and D,L-2-amino-5-phosphonopentanoic acid (APV, 50 to 100 μM) for NMDA receptors or CNQX, APV, and tetrodotoxin (TTX, 0.5 to 1 μM) in the bath solution, in addition to using a CsCl-based pipet solution (see recipe).

    In contrast, if one is particularly interested in examining effects of chemicals on spontaneous or miniature excitatory postsynaptic currents (sEPSCs or mEPSCs), use a pipet solution with a reduced Cl^- concentration (see Reagents and Solutions). In addition, include a $GABA_A$ receptor antagonist such as bicuculline (10 to 20 μM) or picrotoxin (100 μM), or bicuculline or picrotoxin plus TTX in the bath solution.

14. To examine effects of the test chemicals on evoked synaptic responses in Purkinje cells, stimulate the climbing fibers or parallel fibers to generate climbing fiber–Purkinje cell (CF-EPSCs) or parallel fiber–Purkinje cell excitatory post-synaptic currents (PF-EPSCs). To record CF-EPSCs, establish the whole-cell recording configuration (R_{PC}; Fig. 11.11.7) on a Purkinje cell in a sagittal slice with a holding potential of −60 mV. Place a stimulating electrode (S_{CF}; Fig. 11.11.7) in the white matter or granule cell layer near the targeted Purkinje cell. Turn on the pulse generator to deliver stimuli at a frequency of 0.1 Hz, 0.1 msec and an initial low-stimulus intensity to stimulate the climbing fibers. Gradually increase the stimulus intensity until all-or-none CF-EPSC responses appear (Fig. 11.11.8).

15. To record PF-EPSCs (Fig. 11.11.8), place a stimulating electrode (S_{PF}; Fig. 11.11.7) in the molecular layer of a transverse slice and establish the whole-cell recording configuration on a Purkinje cell with a holding potential of −60 mV. Deliver stimuli at a frequency of 0.1 Hz, 0.1 msec and an initial low stimulus intensity. Gradually increase the stimulus intensity until it produces an EPSC amplitude of ~50% to 60% of the maximum response for a given cell.

16. To record the mossy fiber–activated granule cell excitatory postsynaptic currents (MF-EPSCs; Fig. 11.11.8), establish the whole-cell recording configuration (R_{GC}; Fig. 11.11.7) on a granule cell with a holding potential of −60 mV in either a sagittal or transverse slice and place a stimulating electrode in the white matter or granule cell layer near the targeted granule cell to activate the mossy fibers at 0.1 Hz, 0.1 msec, and an initial stimulus intensity that evokes EPSCs with amplitudes of ~50% to 60% of the maximum response for a given cell.

    The relative locations of stimulating and recording electrodes are important for evoking synaptic responses, particularly for CF-EPSC recordings. Adjustments of stimulating electrode location are often required to get evoked responses.

17. To generate a current-voltage (I-V) relationship of evoked synaptic responses, change the holding potentials manually from −100 to +60 mV. At each potential, record

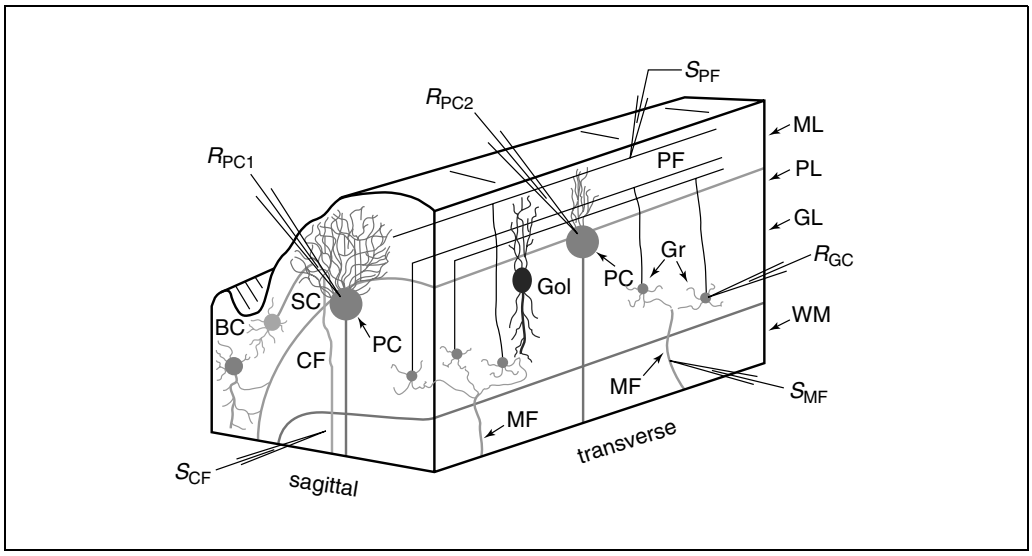

Figure 11.11.7 A schematic depiction of the architecture of the cerebellar cortex in sagittal and transverse slices, methods for whole-cell current recordings in Purkinje and granule cells, and locations of stimulating electrodes. Abbreviations: BC, basket cell; CF, climbing fiber; Gol, Golgi cell; GL, granule cell layer; Gr, granule cell; MF, mossy fiber; ML, molecular layer; PC, Purkinje cell; PF, parallel fiber; PL, Purkinje cell layer; R_{GC}, whole-cell recording electrode on a granule cell; R_{PC}, whole-cell recording electrode on a Purkinje cell in a transverse or sagittal slice; S_{CF}, stimulating electrode for climbing fiber; S_{MF}, stimulating electrode for mossy fiber; S_{PC}, stimulating electrode for parallel fiber.

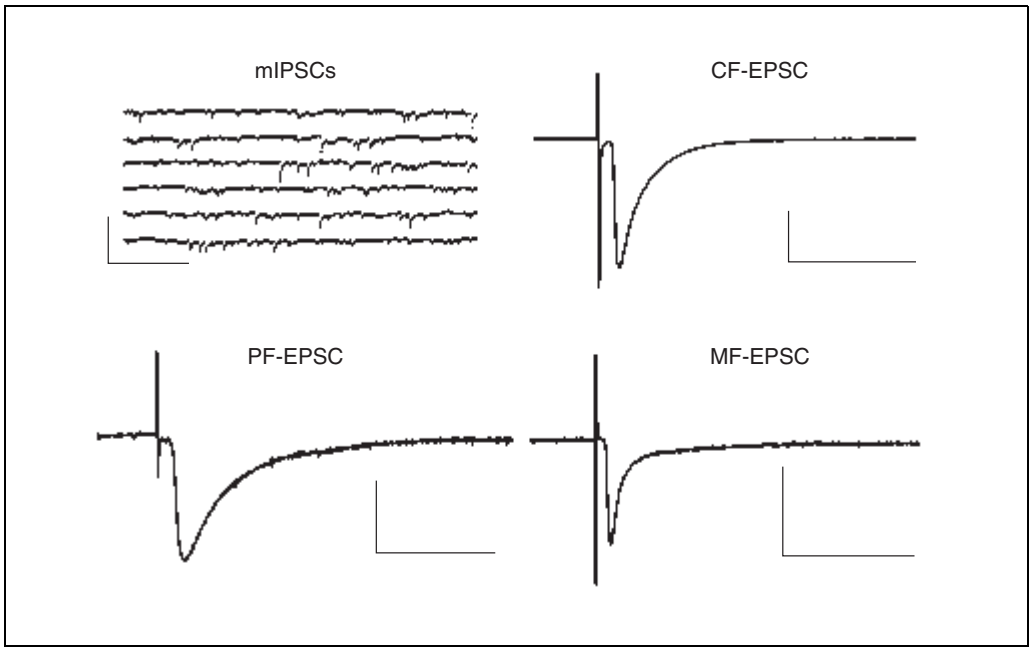

Figure 11.11.8 Representative depiction of miniature inhibitory postsynaptic currents (mIPSC), climbing fiber-Purkinje cell EPSC (CF-EPSC), parallel fiber- Purkinje cell EPSC (PF-EPSC), and mossy fiber-granule cell EPSC (MF-EPSC) recorded from a Purkinje cell or granule cell of sagittal or transverse cerebellar slices. The miniature spontaneous inhibitory postsynaptic currents (mIPSCs) were recorded from a Purkinje cell (R_{PC1}) in a sagittal slice in the presence of 0.5 μM TTX, 10 μM CNQX, and 100 μM APV. The CF-EPSC was recorded from the same Purkinje cell (R_{PC1}) by stimulation of climbing fibers with a broken-tipped glass pipet (S_{CF}) in the white matter near the Purkinje cell. The PF-EPSC was recorded from a Purkinje cell (R_{PC2}) in a transverse slice by stimulation of the parallel fiber in the molecular layer (S_{PF}). The MF-EPSC was recorded from a granule cell (R_{GC}) in a sagittal slice by stimulation of mossy fibers in the white matter (S_{MF}). Calibration bars: vertical, 200 pA for mIPSCs and MF-EPSC, 2 nA for CF-EPSC, 1 nA for PF-EPSC; horizontal, 1000 msec for mIPSCs, 20 msec for CF-EPSC, PF-EPSC, and MF-EPSC.

multiple traces (>10 traces depending on the trace-to-trace variation) for signal averaging.

Collect data and analyze

18. After the baseline recording becomes stable, expose the slice to the test chemicals and collect data. To acquire data in Clampex, design at least two different protocols. Design one protocol in the gap-free mode to record spontaneous synaptic responses. Design the other in the event-detected mode to record evoked synaptic responses. Filter currents at 1 to 5 kHz and digitize at 10 to 20 Hz. Save the data to a tape recorder, videotape, or optical disk for backup and offline analysis purposes.

19. Analyze data using Clampfit of pClamp 8.x and MiniAnalysis program 5.2.8 or other commercially available software. Assess the effects of the chemical on whole-cell synaptic currents in terms of (1) changes in frequency and amplitude of spontaneous responses; (2) changes in amplitudes of evoked responses; (3) changes in 10% to 90% rise time, half-width, or decay time of synaptic currents; (4) changes in I-V relationship, reversal potentials, or zero current potentials; (5) time-courses of effects of chemical on PF-EPSCs, CF-EPSCs, and MF-EPSCs and spontaneous synaptic currents; (6) concentration- and time-dependent responses and interaction of the test chemical with known relevant pharmacological agonists or antagonists.

SUPPORT PROTOCOL 1

PREPARATION OF ACUTELY ISOLATED HIPPOCAMPAL SLICES

This protocol is used to prepare hippocampal slices with the aid of a tissue chopper. The slices produced by this method are usually 300 to 500 μm in thickness and suitable for extracellular and intracellular microelectrode recordings, and even whole-cell patch-clamp recording using the so-called blind techniques.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Materials

95% O_2/5% CO_2–saturated slicing solution (see recipe), 4°C
95% O_2/5% CO_2 gas mixture cylinder
ACSF (see recipe)
Rubber cement
10- to 30-day-old rats (either gender; Sprague-Dawley or Charles River)

500-ml glass beaker
Whatman no. 1 or no. 2 filter paper
Tissue chopper
Single-edged and high-quality double-edged razor blades
Rat guillotine
Large surgical scissors
Small sharp dissecting scissors
Rongeurs
50- or 75-mm plastic petri dishes
Blunt plastic knives (remove sharp edges and smooth with fine sandpaper)
Fine, soft artist's paintbrush
Home-made slice holding chamber (Fig. 11.11.9)

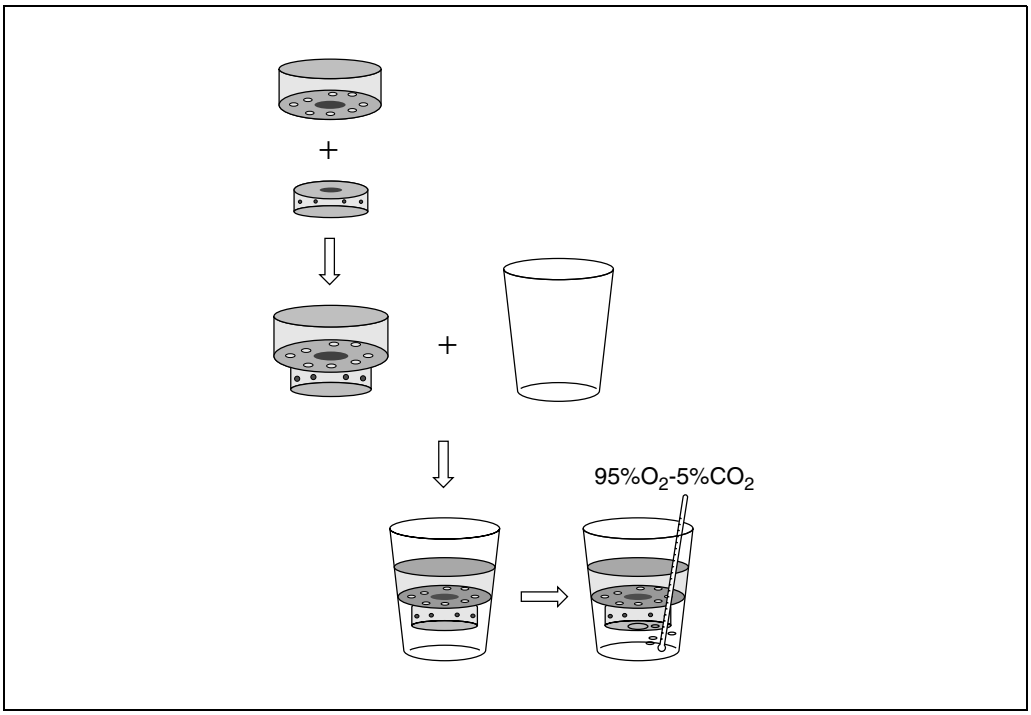

Figure 11.11.9 Diagram of a home-made slice holding chamber. To construct, drill a 20-mm diameter hole in the center and six to ten small holes around it in the bottom of a 60 × 15–cm plastic petri dish. Also, drill a 20-mm diameter hole in the bottom of a 35 × 10–plastic petri dish and several small holes in the wall. Glue a nylon mesh on top of the 35 × 10–cm plastic petri dish with super glue. Turn the 35 × 10–cm petri dish upside down and glue it to the bottom of the 60 × 15–cm petri dish (bottom to bottom). Place the two-petri-dish complex in a 100-ml plastic beaker. Add ACSF or slicing buffer and insert two small polyethylene tubes for aerating with a 95% O_2/5% CO_2 gas mixture.

Prepare slicing solution and tissue chopper

1. Make up 300 ml of cold slicing solution in a 500-ml glass beaker. Oxygenate it with a 95% O_2/5% CO_2 gas mixture for at least 15 min, and adjust pH to 7.35 to 7.4. Surround the beaker with ice and keep aerating it with the 95% O_2/5% CO_2 gas mixture. Make up 1000 ml of ACSF (see recipe).

2. Cut a piece of 3 × 5–cm Whatman no. 1 or no. 2 filter paper and glue it on the cutting platform of the tissue chopper with rubber cement. Carefully break a double-edged razor blade into two single-edged parts. Put one half into the blade clamper of the tissue chopper and loosely clamp it. Lower and gently place the blade cutting edge on the filter; make sure no gaps exist between the filter paper and the cutting edge of the blade. Then tighten the clamp. Return the chopper to the stop position and put it aside to avoid an accidental cut.

   Be sure to remove the blade from the tissue chopper after use.

Isolate hippocampus

3. Sacrifice 10- to 30-day-old rats using the proper procedures approved by an Institutional Animal Care and Use Committee and following the NIH guideline for animal care and use and then decapitate the animal with the rat guillotine.

   Anesthetics are often applied when sacrificing animals. However, care should be taken when using anesthetics for euthanasia prior to brain slice experiments, because anesthetics interact with both neurotransmitter receptors and voltage-gated channels. How readily an anesthetic can be removed from the brain will determine whether or not that agent affects the potentials or currents recorded in a slice. For example, if the purpose of a proposed

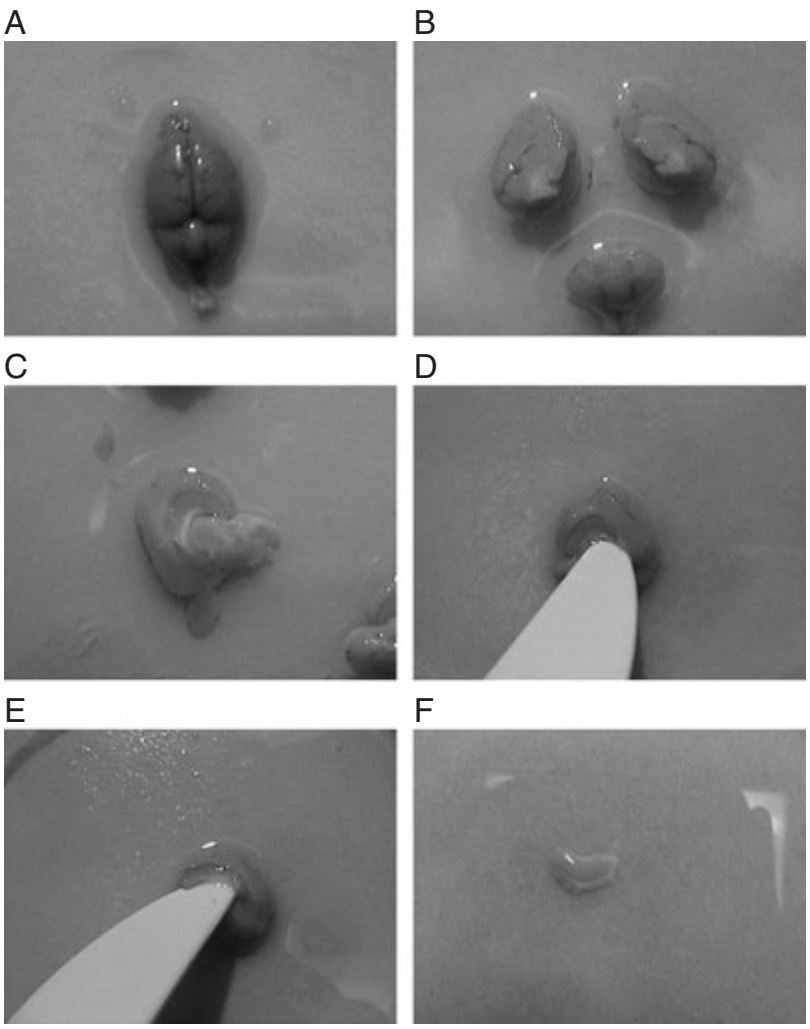

Figure 11.11.10 A photograph of a dissection of the hippocampus from rat brain. (**A**) Dorsal view of the whole brain. (**B**) Overview of the brain hemispheres and cerebellum after two cuts. (**C**) Exposure of the hippocampal formation. (**D**,**E**) Cutting the septal and temporal ends of the hippocampus. (**F**) Isolated hippocampus with the alveus side up.

experiment is to examine effects of certain insecticides on $GABA_A$ receptor–mediated inhibitory synaptic transmission, there could be pronounced interaction between the insecticide and the anesthetic, because most anesthetics can directly interact with $GABA_A$ receptors.

4. Use large surgical scissors to cut the scalp and small sharp dissecting scissors to cut the skull along the midline. Take care to avoid cutting or damaging the underlying brain tissue by keeping the tip of the scissors against the top inside wall of the skull. Pull the skull away with rongeurs.

5. Pour some cold slicing solution over the brain immediately after exposure of the brain. Remove the overlying membrane, detach all nerves and blood vessel connections, and isolate the whole brain.

6. Place the isolated brain immediately on the filter paper premoistened with the cold slicing solution in a 50- or 75-mm petri dish on ice (Fig. 11.11.10A). Wash the brain several times with the cold and oxygenated slicing solution.

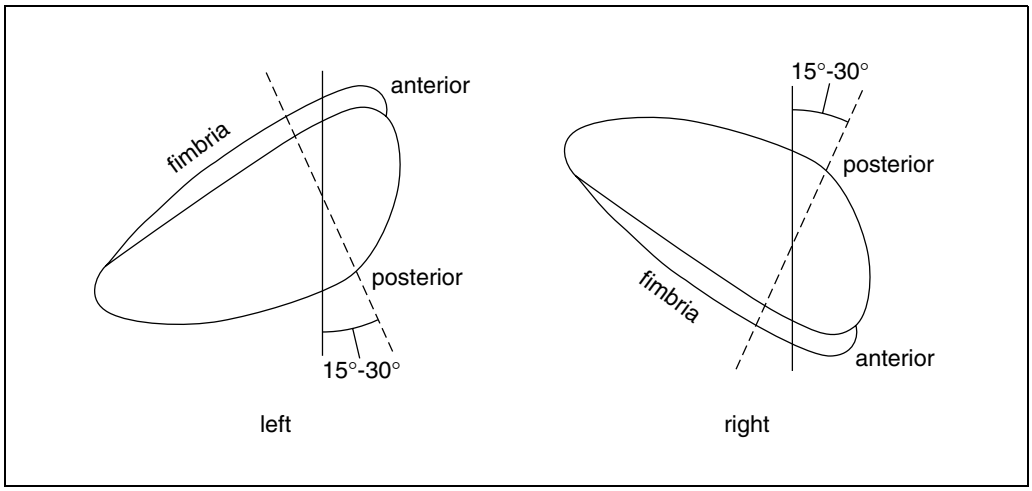

Figure 11.11.11 A diagram of the orientation and cutting angles for slicing the hippocampus. The solid lines represent the orientation of the razor blade. The broken lines indicate the transverse plane of the longitudinal axis of the hippocampus.

7. Dissect away the cerebellum and bisect the rest of the brain sagittally into two halves, rotate the hemispheres with their medial face up (Fig. 11.11.10B).

8. Gently hold down the brain-stem or hemibrain with a finger or plastic knife while using another knife to push the occipital cortex downwards until the whole medial and inferior side of the hippocampal formation are exposed (Fig. 11.11.10C). Cut both the septal and temporal ends of the hippocampus with a plastic knife (Fig. 11.11.10D,E) and rotate the knife gently to roll the hippocampus out of the brain tissue. With the hippocampal formation lying with the dentate area side down and the alveus side up, carefully trim the fimbria and free the hippocampus (Fig. 11.11.10F).

   It is essential that the brain be kept moist and cold during the isolation of the hippocampus. Although it is important to dissect quickly, take care not to damage tissue during dissection.

Slice the hippocampus

9. Thoroughly wet the filter paper on the platform of the tissue chopper with the slicing solution but without leaving excess fluid on the surface. Place one hippocampus with a fine, soft artist's paintbrush on the filter paper (the alveus side up). If the right hippocampus is used, gently rotate it clockwise to a ~15° to 30° angle; if the left hippocampus is used, rotate it counter-clockwise to a ~15° to 30° angle between the transverse plane and the longitudinal axis of the hippocampus (Fig. 11.11.11).

   Excitatory pathways are better preserved when slices are cut at an angle of 15° to 30° between the transverse axis and the longitudinal axis of the hippocampus, whereas the recurrent inhibitory pathways are better reserved if the angle is 30° to 45°.

10. Make the first transverse cut 2 to 3 mm from one end of the structure and discard it. Advance the platform 300 to 400 μm (or desired thickness of slice) and cut the tissue again. Use the wet fine, soft artist's paintbrush to transfer the slice into the home-made holding chamber containing oxygenated ACSF or slicing solution. Lift the knife and repeat the above steps five to eight times to yield five to eight slices.

    Very often, slices are damaged during transfer to the holding chamber with the wet paintbrush, especially for those who are inexperienced in slicing. To avoid this, do not immediately lift the knife after the blade cuts the tissue, but rather insert the wet paintbrush tip between the knife and the slice and then gently rotate the brush away from the blade lifting the slice to transfer it to the holding chamber.

11. Incubate slices in the holding chamber and aerate continuously with a 95% O_2/5% CO_2 gas mixture for at least 60 min before beginning any electrophysiological recordings.

Tubing used for oxygenation in the holding chamber should be small in diameter to avoid damaging slices with big bubbles. Two or more aerating tubes should be used to avoid anoxic damage to slices when using small oxygenation tubes and a low rate of oxygenation.

SUPPORT PROTOCOL 2

PREPARATION OF ACUTELY ISOLATED CEREBELLAR SLICES

This protocol describes the procedures using the vibratome method for making thin cerebellar slices for whole-cell patch-clamp recordings.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Materials

95% O_2/5% CO_2–saturated slicing solution (see recipe), 4°C
95% O_2/5% CO_2 gas mixture cylinder
ACSF (see recipe)
5% agar gel block or Sylgard 184 block (see recipe)
Cyanoacrylate glue (super-glue)
10- to 20-day-old rats (either gender; Sprague-Dawley or Charles River)

500-ml beaker
Single-edged and high-quality double-edged razor blades
Automatic oscillating tissue slicer (e.g., OTS-3000-05, FHC) or equivalent
Rat guillotine
Large surgical scissors
Small, sharp dissecting scissors
Rongeurs
Whatman no. 1 or no. 2 filter papers
50- or 75-mm plastic petri dishes
No. 5 fine-tip tweezers
Wide-bore Pasteur pipet
Home-made slice-holding chamber (Fig. 11.11.9)
35° to 37°C water bath

Prepare slicing solution and tissue slicer

1. Make up 300 ml of slicing solution in a 500-ml glass beaker and oxygenate vigorously with 95% O_2/5% CO_2 gas mixture for at least 15 min (pH to 7.35 to 7.4). Surround the beaker with ice and keep aerating the solution with the 95% O_2/5% CO_2 gas mixture. Make up 1000 ml of ACSF.

2. Carefully break a double-edged razor blade into two single-edged parts. Insert the broken edge of the half blade into the blade holder of the tissue slicer and clamp it tightly (insert a small piece of filter paper to help tighten the blade).

It is recommended that the blade have a section angle of 20° to the horizontal plane.

3. Glue a small (10 × 10 × 10–mm) 5% agar block on the tissue pedestal of the slicer (Fig 11.11.11) with cyanoacrylate glue. Clean up the cutting stage of the tissue pedestal and the cutting chamber.

Prepare cerebellar tissue block

4. Sacrifice the rat using the proper procedures approved by an Institutional Animal Care and Use Committee and following the NIH guideline for animal care and use; then, decapitate the animal with a rat guillotine.

5. Use large scissors to cut the scalp and small, sharp dissecting scissors to cut the skull along the midline. Take care to avoid cutting or damaging the underlying brain tissue by keeping the tip of the dissecting scissors against the top inside wall of the skull. Pull the skull away with rongeurs.

6. Pour some cold slicing solution over the brain immediately after exposure. Remove the overlying membrane, detach all nerve and blood vessel connections and isolate the whole brain.

7. Place the isolated brain immediately on Whatman no. 1 or no. 2 filter paper premoistened with cold slicing solution in a 50- or 75-mm plastic petri dish on ice (Fig. 11.11.10A). Wash the brain several times with the cold, oxygenated slicing solution. Separate the cerebellum from the rest of the brain by a transverse cut.

   To avoid damaging the cerebellum, the authors prefer to open the skull from the front part of the head towards the rear.

8. To cut sagittal slices, remove the brain stem and spinal cord and carefully peel off the soft membrane with two no. 5 fine-tip tweezers (alternatively, slightly trim a small area of the surface of the cerebellum for cutting).

   If this soft membrane on the surface of the cerebellum is not removed, it will push the tissue during slicing and will not yield good-quality slices.

9. Make one sagittal cut to remove one lobule, leave the other lobule intact for handling at a later time.

   Some investigators like to make a block of cerebellar vermis by two sagittal cuts.

   Leaving one lobule uncut will simplify subsequent handling and gluing of the tissue onto the tissue pedestal. Moreover, it will reduce the chances of damaging the cerebellar vermis.

Mount tissue on cutting stage

10. Cover a small area of the tissue pedestal near the agar block with a thin layer of cyanoacrylate glue but do not apply excessive glue. Use no. 5 fine-tip tweezers to hold it loosely or insert into the remaining lobule of cerebellar tissue block. Mount the tissue on the cutting stage of the tissue pedestal with the ventral side (mostly white matter tissue) of the cerebellar vermis block against the agar block and the sagittal cutting end of the cerebellar vermis block against the glue layer.

    Alternatively, if the cerebellar vermis block is isolated by two sagittal cuts, one may need to use a filter paper strip to transfer and mount the tissue block on the cutting stage of the tissue pedestal (Fig. 11.11.12).

11. To prepare transverse slices, use no. 5 fine-tip tweezers to hold the remaining lobule loosely and mount the cerebellar vermis block on the cutting stage with the ventral side against the agar block and the transection face on the glue layer.

12. Immediately assemble the tissue pedestal in the cutting chamber and pour enough cold, oxygenated slicing solution to submerge the tissue block fully and continue to aerate the solution in the chamber with the 95% O_2/5% CO_2 gas mixture. Mount the slicing chamber on the tissue slicer.

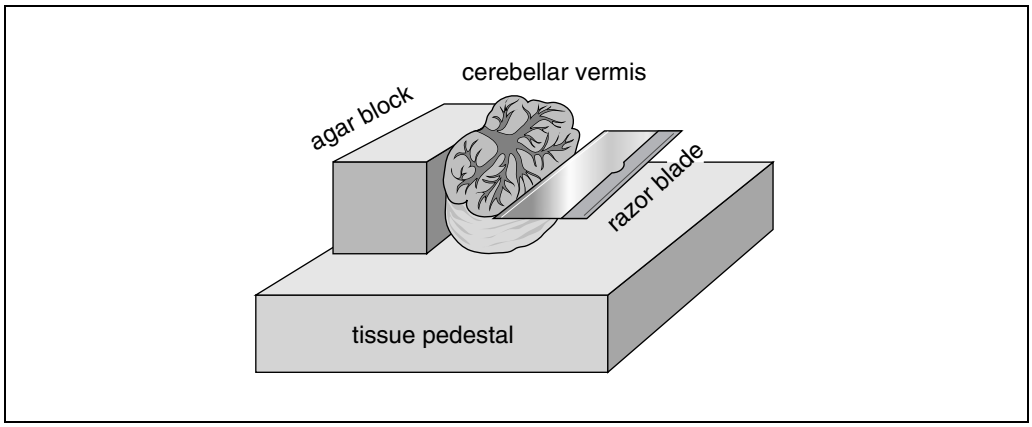

Figure 11.11.12 A diagram of the preparation of cerebellar slice using a OTS-3000-03 tissue slicer. The cerebellar vermis block is glued to the tissue pedestal with the ventral side against the agar block. The oscillation razor blade is advanced slowly into the tissue at an angle of 20° to the tissue pedestal.

Cut thin cerebellar slices

13. To cut sagittal slices, lower the blade all the way down until it is close to the level of the vermis portion. Adjust the slice thickness to 150 to 200 µm. Slice the tissue at a very slow rate of advancement and a high rate of horizontal oscillation (8 to 9 Hz). Discard the first few cuts that basically remove the remaining lobule tissue.

14. Collect five to eight slices generated from the vermis portion and transfer them with a wide-bore Pasteur pipet to the home-made slice-holding chamber containing ACSF or the slicing solution.

15. To cut transverse slices, similarly, discard the first few cuts, then collect and transfer three to five slices generated from the vermis to the home-made slice-holding chamber.

    Because the transverse slices are very easy to disperse, one may have to cut slightly thicker (e.g., 180- to 220-µm) slices than with the sagittal slices.

    It is essential that the blade cut the tissue smoothly to yield slices with even thickness. Anytime the blade pushes or compresses the tissue during slicing, this is an indication that there is residual membrane or small blood vessels remaining on the surface of the tissue block producing low-quality slices, especially in the transverse orientation. One way to recover is to back off the blade lightly and slightly trim the surface with a sharp blade, then resume cutting slices.

Incubate slices

16. Put the holding chamber in the pre-set 35°C water bath and continue to aerate the incubation solution with the 95% O_2/5% CO_2 gas mixture. Move the holding chamber out of the 35°C water bath after 60 min and leave it at room temperature until use.

    It is believed that incubation of slices at 35°C may improve the optical transparency of slices.

    The tubes used for oxygenation in the holding chamber should be small in diameter to avoid damaging slices with big bubbles. Two or more aerating tubes should be used to avoid anoxic damage to slices when using small tubes and a low rate of oxygenation.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ACSF

125 mM NaCl
2.5 mM KCl
1 mM MgCl
1.25 mM KH_2PO_4
26 mM $NaHCO_3$
2 mM $CaCl_2$
25 mM D-glucose
Adjust pH 7.35 to 7.4 by bubbling with a 95% O_2 /5% CO_2 gas mixture
Prepare fresh

ACSF can be stored up to several days at 4°C, but it must be bubbled with 95% O_2 /5% CO_2 gas before use.

Caution should be taken to avoid Ca^{2+} precipitation when preparing this solution. To prevent Ca^{2+} precipitation, add $CaCl_2$ last. In addition, it is preferable to aerate the solution first with the 95% O_2 /5% CO_2 gas mixture and then add the $CaCl_2$.

Similarly, caution should be taken with test chemicals and their solubility, particularly with heavy metals such as methylmercury and lead. These chemicals should be added to bath solution just before application. Additionally, it may be necessary to alter the anion composition to avoid precipitation of phosphate-based salts.

Internal pipet solutions

CsCl-based pipet solution:
140 mM CsCl
4 mM NaCl
0.5 mM $CaCl_2$
10 mM HEPES
5 mM EGTA
2 mM Mg-ATP
0.4 mM GTP
Adjust to pH 7.3 with CsOH
Store up to 1 month at −20°C

CsF-based pipet solution:
140 mM CsF
4 mM NaCl
0.5 mM $CaCl_2$
10 mM HEPES
5 mM EGTA
2 mM Mg-ATP
0.4 mM GTP
Adjust to pH 7.3 with CsOH
Store up to 1 month at −20°C

Potassium gluconate (KGlu)-based pipet solution

145 mM KGlu
5 mM $MgCl_2$
5 mM EGTA
10 mM HEPES
4 mM NaCl

continued

2 mM ATP
0.4 mM GTP
pH 7.3
Titrate with KOH
Store up to 1 month at –20°C

Slicing solution

125 mM NaCl
2.5 mM KCl
4 mM $MgCl_2$
1.25 mM KH_2PO_4
26 mM $NaHCO_3$
1 mM $CaCl_2$
25 mM D-glucose
Adjust pH 7.35 to 7.4 by bubbling with a 95% O_2/5% CO_2 gas mixture
Prepare fresh

Caution should be taken to avoid Ca^{2+} precipitation when preparing this solution. To prevent Ca^{2+} precipitation, add $CaCl_2$ last. In addition, it is preferable to aerate the solution first with a 95% O_2 /5% CO_2 gas mixture and then add the $CaCl_2$.

Sylgard 184

Mix one part of Sylgard 184 (Dow Corning) curing agent with 10 parts of Sylgard 184 silicone elastomer, dispense into 0.5-ml aliquots. Store up to 1 to 3 months at –20°C.

This solution is used for coating electrodes.

COMMENTARY

Background Information

Since reported by Yamamoto and McIlwain (1966) that synaptic field potentials could be evoked and recorded reliably from neurons in acutely isolated brain slices maintained in vitro, electrophysiological recordings in brain slices have become an important tool in investigating central synaptic functions. These brain-slice recordings have been widely used to study the pharmacological or neurotoxic effects of drugs or environmental chemicals on central synaptic transmission. Brain slices offer several major technical advantages over in vitro invertebrate preparations, cell culture, as well as whole brain in situ and in vivo methods for investigating mammalian CNS neurobiology, neurophysiology, and neurotoxicology. (1) Using a brain slice provides simple and precise control over the experimental conditions such as pH, temperature, and concentrations of tested chemicals, compared to the variables (e.g., blood pressure, CO_2 concentration, heart rate) that must be controlled during in vivo studies. (2) No anaesthetics, paralytics, or sedatives are necessary in slice preparations. This is particularly important if these drugs compete with the test chemicals for putative targets or interact directly with the test chemicals. (3) Using an isolated slice allows direct visual control over the positions of both recording and stimulating electrodes, avoiding the difficulties of stereotaxic techniques in vivo. The neurons being targeted can be easily located, identified, and accessed. (4) In contrast to most cell culture systems or acutely dissociated cells, the normal anatomical relationships and synaptic circuits remain relatively intact and healthy in a properly oriented brain slice. This is particularly advantageous in a highly laminated architecture such as the hippocampus and cerebellar cortex. (5) Use of an isolated slice greatly improves the stability of electrophysiological recordings and makes high-quality, long-lasting intracellular and whole-cell patch recordings possible. In short, the in vitro brain-slice recording techniques have greatly facilitated the investigation of the electrical properties and synaptic function of neurons in the CNS. Use of the brain slice has also greatly increased the knowledge of the effects of neurotoxic chemicals on the mammalian CNS in the last two decades. However, it should be kept in mind that the results obtained from in vitro brain slice experiments mimic but are not necessarily

identical to those obtained from in vivo experiments. In addition, the effective concentrations of the test chemicals used in brain slice experiments can often be much higher than those used in cell culture or acutely dissociated cells due to the larger mass of tissue providing non-specific binding sites for the drug or chemical. Moreover, the tissue acts as a diffusion barrier for drugs or chemicals, so the time course of the effect of a drug can vary significantly among surface cells and those located deeper in the brain slice. The effect of a drug on both surface cells and the deeper cells of the brain slice is still slower than on cells in culture where there is no diffusion barrier.

Electrical stimulation of neurons generates two main types of signals: either gradual changes in the membrane potentials (postsynaptic potentials, EPSPs) or all-or-none spikes (action potentials). These electrical signals can be recorded by placing a recording electrode close to a cell or a cell population (extracellular recording), by penetrating the cell membrane with a sharp pipet electrode (intracellular recording), or by forming a gigaohm seal of a glass pipet on the cell membrane of an intact cell and subsequently rupturing the membrane to gain access the cell interior (whole-cell patch-clamp recording). All of these recording techniques have been successfully applied to the brain slice preparation.

Extracellular recording refers to measurement of the potential changes across the cell membrane without penetrating the cell with a microelectrode. The extracellular signal is generated because the resistance or conductance of the extracellular fluid is not zero and the cell, whose membrane potential is not changed uniformly in response to a stimulus such that one part of the membrane is more depolarized than another part, will have current flow within it. Corresponding to the intracellular current change, there is a current flow in the extracellular fluid to complete the current circuit. The extracellular current is then picked up by an extracellular recording electrode. In general, extracellular signals are very small and, therefore, require extensive amplification. Because the signals recorded by the extracellular recording pipet electrodes are responses of a single neuron or a population of neurons, large responses can be generated only when the firing of many neighboring neurons is highly synchronized and the dipole orientation of these neurons is uniform. Therefore, the amplitude of the population spike is proportional to the numbers of neurons excited or stimulated.

Of all the recording techniques utilized for brain slices, extracellular recording is the most stable and easiest electrophysiological recording method, particularly in hippocampal slices. Extracellular recordings in hippocampal slices have been widely used to study the neurotoxic effects of chemicals—such as copper, ethanol, lead, lithium, mercury compounds, and trimethytin—on central synaptic transmission and synaptic plasticity such as long-term potentiation (LTP) or long-term depression (LTD). Recently, a new, substrate-integrated, planar microelectrode array (MEA)—a multiple-electrode extracellular recording technique—has been successfully introduced to record multiple single-unit spike activity in acutely isolated brain slices (Oka et al., 1999; Egert et al., 2002) and organotypic brain slice cultures (Stoppini et al., 1997) with up to 70 electrodes simultaneously. This provides a new, important, and potentially easy-to-use in vitro tool for the investigation of spiking neural networks and monitoring the dynamic interactions between groups of neurons on a millisecond-time scale. Extracellular recording in brain slices will remain a simple but useful in vitro tool for studying effects of neurotoxic chemicals on central synaptic function. The major advantage of extracellular recording is that it is relatively easy to make stable, long-lasting recordings with comparatively inexpensive equipment. The main disadvantages of extracellular recording are (1) because the very weak extracellular signals require higher amplification, background noise will also likely be amplified. Thus, it is important to use low-resistance pipet electrodes, a low-noise amplifier, and good shielding of the recording systems. (2) This technique cannot provide any information about changes in resting membrane potentials and input resistance, and it cannot provide detailed information about the precise sites of actions of neurotoxic chemicals on neurons. (3) It is nearly impossible to make direct comparison of amplitudes of field potentials from different individual experiments, because amplitudes of field potentials may vary greatly in different slices from the same animal, in different locations of the recording electrode in the same slice, or even in the same region of the same slice but with different depths of the electrode tips in tissue.

In contrast, intracellular recording uses a sharp electrode to penetrate the cell membrane and measure the responses of individual neurons at rest or to a stimulus. Therefore, it is possible to measure the entire gamut of changes

in the electrical behavior of a cell including resting membrane potentials, input resistance, whole-cell capacitance, action potentials, and postsynaptic potentials of an individual neuron in response to a presynaptic stimulus or direct application of neurotransmitters. It is also possible to do quantal analysis of the process of synaptic transmission and determine whether or not a given chemical affects function of the presynaptic nerve terminals. Moreover, when equipped with a bridge circuit in the intracellular recording amplifier, one can inject DC current into the cell through the same recording electrode to change the resting membrane potentials or directly excite the targeted cell. This allows one to analyze, in more detail, the site and mechanism of action of a given chemical on an individual neuron. In addition to the current-clamp recording, it is also possible to perform dSEVC by using time-sharing techniques in small cells to measure the postsynaptic currents and estimate the reversal potentials of a synaptic response. One major advantage of using dSEVC techniques is the possible avoidance of errors in the measurement due to voltage drops across the series resistance of the current-passing electrode that often occurs in whole-cell patch-clamp recordings. This is particularly useful and is an alternative choice if the series resistance of whole-cell patch-clamp recording is a major concern. In addition, because of the use of small-tip pipet electrodes, current rundown due to intracellular dialysis of the cell by the pipet solution may not be a major concern in dSEVC recordings as it is in conventional whole-cell recordings. However, the disadvantages of intracellular recordings are (1) it is difficult to make proper cell penetration and maintain a long, stable recording in small neurons. (2) Before penetrating the cell, even during recording, the bridge balance and electrode capacitance need to be properly adjusted and compensated, otherwise all measurements will be inaccurate. (3) Resting membrane potentials are influenced by the electrode tip potentials, and the tip potentials are influenced by the ionic microenvironment, which can change after penetration of a cell or by test chemicals, therefore, an exact measurement of the true membrane potentials may not be possible. (4) Penetration of the cell membrane may cause damage to the cell membrane and yield an unstable recording. (5) Because the electrodes used for the intracellular recordings usually have very sharp tips, it is difficult to inject large molecules into cells. (6) When measuring currents using the sharp intracellular electrode in dSEVC recording mode, it is generally difficult to voltage-clamp very fast responses because of constraints on the electrical circuitry or very large responses due to the amount of current needed to be injected, and the noise level is much greater than that in whole-cell patch-clamp recording.

In the last decades, the whole-cell voltage-clamp recording technique has been used widely to study synaptic transmission in brain slices (Blanton et al., 1989; Edwards et al., 1989; Konnerth, 1990; Stuart et al., 1993; Blitzer and Landau, 1994; Sakmann and Stuart, 1995; Plant et al., 1995). Compared to the extracellular and intracellular recording technique, whole-cell patch-clamp recording in brain slices offers more advantages by combining the brain-slice technique with the power of the patch-clamp techniques. First, whole-cell recording significantly improves the signal-to-noise ratio. Thus, it is better suited for detecting relatively small amplitude synaptic events, such as spontaneous or miniature EPSCs or IPSCs, than are conventional intracellular recording or the dSEVC recording (Henderson, 1993; Blitzer and Landau, 1994). Second, in whole-cell patch-clamp recording, access to the cell interior is much greater due to the relatively large tip of the recording pipet. Thus, relatively large molecules can enter the cell by diffusion from the electrode, permitting experiments involving the intracellular injection of protein and peptides, dialysis of the cell, intracellular pH-clamp, and even the intracellular application of drugs. Third, the low-resistance recording electrodes used in whole-cell patch-clamp recording are capable of passing large amounts of currents, particularly depolarizing currents, more effectively than are high-resistance sharp microelectrodes. Fourth, the whole-cell patch-clamp recording technique can be combined with other techniques such as fluorometric recording to measure simultaneous changes in currents and the intracellular ion concentration or the pH in single cells in brain slices. In addition, the whole-cell patch-clamp recording technique can also be used in combination with molecular biological tools such as single-cell RT-PCR to analyze the molecular basis for chemically induced changes in a particular ion channel or receptor. These provide a very powerful tool for studying neurotoxic mechanisms of chemicals.

Synaptic currents can be recorded using whole-cell patch-clamp recording techniques in both relatively thick (individual cells not necessarily visualized) or thin brain slices (neu-

ron cell soma or dendrites can be visualized under an upright microscope equipped with Nomarski optics and video camera systems). To date, three main techniques have been developed for making whole-cell patch-clamp recording in brain slices. These include the cleaning, blind, and blow-and-seal methods. The cleaning method was first introduced by Edwards et al. (1989). In this method, the cell membrane to be recorded from is cleaned prior to attempting to form a gigaohm seal. To do this, the debris and surface tissue over the targeted cells in the thin (150- to 200-μm) brain slice are first teased apart by gentle application of positive pressure to a broken-tipped pipet in order to eject a stream of bath solution and then removed by careful suction. The second method is the so-called blind technique introduced by Blanton et al. (1989). This procedure is similar to that used for conventional intracellular recording in thick brain slices (400 to 500 μm) and no specific optics, physical cleaning, or enzymatic treatment of tissue are required. To avoid occlusion of the pipet tip, a positive pressure is applied to the back of the pipet as it advances through the bath and slice. When the recording pipet tip contacts the cell membrane, the amplitude of the current pulses is reduced (increased resistance). Advancing the pipet a little more causes the amplitude of the current pulses to decrease further. Then a slight negative pressure is applied to the recording pipet to form a gigaohm seal and whole-cell recording is initiated. The third technique, blow-and-seal (Stuart et al., 1993), is the most commonly used method. It is a hybrid of the first two methods. In this procedure, similar to the blind technique, the tissue debris on the surface of the targeted neurons is not pre-cleaned, however, the advancement and placement of the recording electrode in thin brain slices is performed under visual control as in the clean procedure. Choosing which method to use depends on the investigator's preference, experience, and equipment.

The major problems associated with whole-cell patch-clamp recording are series resistance and current rundown. Unlike the dSEVC recording in which the single electrode handles both tasks of voltage recording and current passing using a time-sharing technique to avoid interaction between the two tasks, whole-cell patch-clamp recording uses the same pipet electrode doing both voltage recording and current passing simultaneously. The major problem associated with this is the series resistance–related voltage error in the measurement. In whole-cell voltage-clamp recording, the cell membrane potential is clamped by the command potential applied to the pipet electrode. The effectiveness of the voltage clamp depends on the size of the access resistance between the pipet electrode and the cell interior, and on the size of the currents across this resistance. In general, full access to the interior of the cell is not achieved after rupturing the cell membrane due to an obstruction caused by the broken membrane fragments or intracellular constituents. The access resistance is in series electrically with the membrane, therefore, it is also called series resistance. Any current passing through the pipet will induce a voltage drop across this series resistance and thus can introduce an error in the voltage clamp. The contribution of the access resistance to total series resistance can introduce a substantial error when making whole-cell voltage-clamp recording in brain slices. Therefore, a proper electrode coating and series resistance compensation are required to minimize this error. The rundown of currents in the whole-cell recording configuration is another common problem due to intracellular dialysis of the cell and loss of energy source, second messenger components, or a cofactor necessary to normal physiological functions. To minimize current rundown, some specific substances such as ATP and GTP should be included in the internal pipet solution.

Critical Parameters

Healthy brain slices

No matter what type of electrophysiological recording technique is to be used in brain slices, high-quality slice preparation is always the first and most important requirement for a successful experiment. Poor slices can be easily identified visually and electrophysiologically. Clearly translucent or increased whiteness of slices indicates that they are damaged and should not be used. In extracellular recording, a good slice should provide a single population spike in response to a low-intensity orthodromic stimulus. As the stimulus intensity increases, the population spike should gradually increase in size and decrease in latency. Typically, only a single spike is generated even at near maximum-intensity stimulus. On the other hand, if much higher stimulation intensity is required to evoke even small spikes, or multiple spikes are easily evoked by a low-intensity stimulus, then the slice may be damaged. In intracellular recording, in the absence of exter-

nal influences such as application of relevant drugs, a well-penetrated cell should typically have a stable membrane potential, spike amplitude, and input resistance over a long period of time. A moderate depolarizing pulse should evoke a regular, rhythmic train of spikes, which decreases in latency and increases in number as the depolarizing current intensity increases. In the whole-cell patch-clamp recording configuration, attaining a gigaohm seal or long-lasting recording on bad slices or cells is virtually impossible. Thus, the preparation and selection of healthy slices is very critical. To obtain good slices, all three crucial factors—time, care, and temperature—should be kept in mind during dissection and slicing. The shorter the time from decapitation of the animal to transfer of slices into a holding or recording chamber, the better the slices will be. Always take care not to damage the tissue mechanically during dissection and slicing, and the time should not be compromised during transfer of the slices. Always keep the tissue in cold, keeping all steps on ice if possible.

Fabrication of whole-cell recording electrodes

For a successful, low-noise whole-cell recording, optimal fabrication of the recording pipet is one of the most important steps. Detailed discussions of fabricating patch pipets have been presented elsewhere by Penner (1995) and Rae and Levis (1997). Certain concerns that are important for whole-cell recording in brain slices are discussed here. To reduce the series resistance and noise, a blunt, short-shank (bullet shape) and low-tip-resistance pipet is required for whole-cell recording. However, the geometries of recording pipets for whole-cell patch-clamp recording in brain slices are somewhat different from those used for whole-cell recording in culture or acutely dissociated cells. Due to the relatively small working space when using a water-immersion objective lens, which may impede the accessibility of the pipet to cells, the shank of the pipet is usually relatively longer than that used for conventional whole-cell recording in cultured or acutely dissociated cells. The pipet shape is nearly conical from the shoulder to the tip. When doing whole-cell recording in Purkinje and granule cells in cerebellar slices, the authors typically use two different types of glass pipets. For Purkinje cells, which are large and have extensive processes (and thus usually have large membrane capacitance), the authors prefer to use thick-walled glass to minimize the pipet capacitance. For granule cells, which are quite small, the tip of a recording pipet has to be very small, thus, having a much higher tip resistance. For granule cells, the authors usually use thin-walled glass pipets to minimize the series resistance. Because of the limited working space under a water-objective lens, the access angle for the recording pipet is relatively small. A large portion of the pipet tip is immersed in bath solution, which will cause noise and increased fast-transient capacitance. Therefore, coating the pipet tips with elastomer (e.g., Sylgard 184) is required for whole-cell recording in brain slices. Coating of the whole-cell recording pipet tip can prevent the formation of a thin film on the outside wall of a pipet, thereby reducing the associated noise, as well as the size and complexity of the fast-capacity transient. While the tips of the pipets used for whole-cell recordings in brain slices do not necessarily require fire-polishing, when they are coated with Sylgard 184, fire-polishing may be required.

The fabrication of conventional intracellular recording electrodes is not as important as that for whole-cell recording and no specific techniques are needed. However, if the tip of the intracellular recording electrode can be beveled, it will maintain the same sharpness of the electrode tip and minimize possible damage to the cell membrane when penetrating the cell. This will also reduce the high tip resistance–related background noise, particularly for dSEVC recordings.

Stability of recording systems

To maintain a stable, long-lasting recording, particularly in intracellular or whole-cell recording in brain slices, a rock-solid stable recording system is required. The slice should be well immobilized within the recording chamber. Perfusion and drainage of medium in and out of the chamber should be well balanced. All the potential sources described in The Technique Notes by Burleigh Instruments (see Internet Resources) that may cause significant pipet position drift should be eliminated.

Pipet solutions for whole-cell recording

Whole-cell recording of postsynaptic responses mediated by different neurotransmitters may require different internal pipet solutions. The choice of pipet solution primarily depends on the type of synaptic currents to be examined. For whole-cell recording of $GABA_A$ receptor–mediated inhibitory synaptic responses in Purkinje or granule cells, a CsCl-

based internal pipet solution (see recipe) is often used, whereas for glutamate-mediated excitatory synaptic responses in Purkinje or granule cells, several different pipet solutions including CsF-, potassium gluconate-, Cs-MOPs-, or $CsMeSO_3$-based solutions have been used. Care should be taken when a high concentration of F^- (CsF^--based solution) is used in the pipet solution, because F^- may interact with some types of glass pipets to cause precipitation and occlude the tip of the pipet. No matter what type of pipet solution is used, all pipet solutions should be filtered using a 0.2-µm syringe filter prior to filling the recording pipets.

The osmolarity of intracellular pipet solutions should be equal to or ~10% lower (hypoosmotic or hypotonic) than the external solution. It appears that whole-cell recordings usually last longer if the internal pipet solution is slightly hypoosmotic compared to the external solution. In some types of cells, whole-cell currents recorded with high-chloride pipet solutions may show some extent of rundown after establishing a whole-cell recording configuration. This rundown may be due to an osmotic imbalance caused by a combination of non-diffusible anions or high-molecular-weight material in the cell and highly diffusible Cl^- in the pipet solution. Very often, gluconate or even other anions are used to replace Cl^- in the pipet solution to avoid this osmotic imbalance and to obtain a more stable recording. However, one trade off of this is that using organic ions such as gluconate to replace inorganic ions such as Cl^- may increase both the pipet electrode resistance and the series resistance because organic ions have lower mobilities.

The pH of the intracellular pipet solution should be controlled at 7.2 to 7.3. Any change in intracellular pH may affect either directly or indirectly some types of currents such as inwardly rectifying potassium currents or calcium currents. Changes in intracellular pH may also cause changes in intracellular free calcium concentration, which may then secondarily affect the currents of interest. In most cases, the pipet solution is prepared as a relatively large volume of stock solution without the addition of ATP. ATP is added separately at a later time to a small volume of the stock solution to make the working pipet solution. When doing so, be sure to readjust the pH to 7.2 to 7.3, because adding an ATP salt (e.g., Mg-ATP) will lower the pH. In addition, care should be taken when acetate is used to replace Cl^- in the pipet solution, because it may cause intracellular pH changes in some types of cells.

A liquid junction potential exists between the internal pipet solution and the external solution in the whole-cell recording mode. This is another concern with which the investigator should be aware. The junction potential between solutions can be measured directly using a ceramic reference electrode filled with saturating KCl, or it can be estimated using the junction potential calculation tool provided in the pClamp8 program. This junction potential should be corrected accordingly during data analysis.

Space clamp errors

The most serious restriction on electrophysiological analysis of voltage-dependent synaptic responses in central neurons in brain slices is the lack of adequate space clamp. Space clamp effectiveness is always a concern in whole-cell voltage-clamp recording (dSEVC or whole-cell patch-clamp) of synaptic currents in neurons, especially in those neurons in slices with large soma, extensive dendritic arborizations, and/or long axons. In whole-cell recordings, voltage clamp of the cell membrane is maintained by the command potentials applied to the tip of the recording pipet. The basic assumption for whole-cell voltage-clamp is that isopotentiality exists in a spherical or round cell, i.e., all portions of the cell membrane are separated from the tip of the recording pipet by equal access resistance and the membrane is uniformly voltage clamped. A perfect space clamp is achieved when a perfect voltage clamp is applied to that portion of the membrane through which current is measured. For small round cells, this assumption probably holds true. In the CNS, however, neurons usually have extensive processes. Moreover, the membranes of the axons and dendrites are separated from the cell soma by the cytoplasmic resistance whose value is proportional to the distance from the recording site of each portion of the process membrane and the size of the cross section in that region of the cell. Just as current across the series resistance of the recording electrode will cause a voltage drop at the tip of the recording electrode, current flowing across the cytoplasmic access resistance of a dendrite or axon will also cause a voltage drop that may become substantial for the distal segment of the membrane. Thus, even though the somatic membrane potential may be voltage clamped adequately, the distal axonal or den-

Table 11.11.1 Troubleshooting Guide for Electrophysiological Recording in Brain Slices

Problems	Possible causes	Suggested solution
No test pulses showing on screen when doing Seal Test or Bridge Balance	Ground wire is not in bath solution, is not connected to the amplifier, or is broken	Check the ground pellet or wire in bath
	The silver wire in the patch pipet holder does not contact the pipet solution or the metal pin connector	Check electrode holder and make sure the silver wire is well connected with the pin connector and pipet solution
	Air bubbles exist between the electrode and extracellular or intracellular electrode holder	Make sure the electrode holder is filled with desired pipet solution before inserting the glass electrode
	Out of scale	Make sure the scaling factor on the computer and/or oscilloscope is set correctly
No postsynaptic response	Slice died due to lack of glucose in slicing or ACSF buffer (forgot to add glucose during preparation of solution)	Make new slices and be sure glucose is added to buffers
Cell is alive but no evoked postsynaptic responses occur	Synaptic inputs to this particular cell are transected or stimulating electrode is not located on the track of the presynaptic inputs	Try a different cell or try a different location with the stimulating electrode
Drift or unstable DC offset during experiments	Ground pellet in bath or silver wire in pipet is not well chlorided	Clean the wire and rechloride it
No solution stream flows out of the tip of pipet with positive pressure on the back of the pipet	Tip of the pipet is clogged by debris of glass, dust, tissue, or an air bubble	Apply strong pressure, or buzz the capacitance on amplifier, or change the pipet; clean glass pipet
	No positive pressure due to leak of tubing or two-(or three-) way valve	Check tubing and valve if they are leaking
	F^- in pipet solution interacts with glass to form precipitate at the tip of pipet	Use an alternative pipet solution
Going to whole-cell configuration before forming gigaohm seal	Membrane is too weak; applied too much negative pressure to the pipet; unhealthy cell	Find a better cell; reduce negative pressure applied to the pipet; find a better cell
Lose seal when rupturing membrane	Mechanical movement of pipet in electrode holder occurs when applying suction because the pipet in electrode holder is not sufficiently tightened or the rubber O-ring is aging	Tighten electrode holder; replace O-rings in pipet holder
	Unhealthy cell	Find a better cell
	Characteristic for certain types of cells	Try the perforated patch recording technique
Too much background noise	Recording system is not well shielded or grounded	Find the source of noise and ground it
	Pipet holder inside is wet or dirty	Clean the pipet holder regularly

dritic membrane potentials may be completely unaffected by the voltage clamp, and the time courses of synaptic currents, regenerative currents, and measurement of reversal potentials of synaptic responses will deviate substantially from the command potential. Unfortunately, unlike the series resistance of recording pipets that can be reduced by using lower-resistance electrodes and series resistance compensation with better electronics, poor space clamp cannot be reduced by simply using better electronics or electrodes. In the cerebellar slice, for example, space clamp of the small round granule cells may not be a problem. However, for the much larger cerebellar Purkinje cells with extensive dendritic arborizations, space clamp errors will be a significant concern. Thus, it is important, whenever possible, to prepare slices from young animals and to choose relatively small cells. Alternatively, one can abandon the whole-cell recording mode and make recordings of microscopic or single-channel events using the outside-out or inside-out patch recording configurations. In conjunction with so-called ensemble analyses, these techniques can allow one to extrapolate the microscopic events back to reconstruct a theoretical whole-cell or macroscopic current. These techniques are quite sophisticated though, and are beyond the scope of this unit.

Troubleshooting

Once the electrophysiological setup is well organized and shielded (grounded; see *UNIT 11.12*), most of the remaining problems are either slice-related or pipet electrode–related. The potential problems with poorly prepared slices have already been discussed. Thus, assuming that the preparation of slice was adequate, one should immediately check the electrode when one can not penetrate a cell or make a good seal, or when recordings are unstable or excessively noisy. Table 11.11.1 lists some common problems that may occur in electrophysiological recordings, particularly in whole-cell patch-clamp recordings.

Anticipated Results

Using Support Protocols 1 and 2, with practice, healthy hippocampal or cerebellar slices should routinely be obtained. The slices should be viable for at least 10 hr after preparation if properly maintained in an oxygenated environment. Using the techniques described in Basic Protocols 1 and 2, it should not be difficult to obtain stable, long-lasting extra- and intracellular recordings from hippocampal CA1 neurons. With these techniques, the authors routinely obtain reliable extra- and intracellular recordings lasting 3 to 4 hr, which should be long enough to complete experiments using even low concentrations of a given neurotoxicant. With just some minor modifications, these techniques should be also applicable to cerebellar or other brain slices to obtain long-lasting stable extra- and intracellular recordings. Using the steps described in Basic Protocol 3, the success rate for obtaining a gigaohm seal and whole-cell recordings from Purkinje cell soma could be as high as 100%. However, a much lower success rate is typical when recording from granule cells.

Time Considerations

Preparation of solutions (slicing solution and ACSF) including oxygenation may require 20 to 30 min. Sacrificing the animal and preparation of slices may require 5 to 10 min. Incubation of slices at 35°C requires ~60 min. During the period of incubation, the recording system is set up and several pipet electrodes are fabricated. Transferring the slice to the chamber and finding suitable cells may take several minutes. The actual time required for recording varies depending on the goal and type of experiments and the characteristics and concentrations of the tested chemicals. In general, at least 3 hr are required to complete one experiment from beginning to end.

Whole-Cell Patch-Clamp Electrophysiology of Voltage-Sensitive Channels

Patch-clamp techniques allow one to study the function of ion channels at the level of individual channels (cell attached, inside-out, or outside-out patches) or at the level of the entire population of channels within the cell membrane (whole-cell patch). These techniques can be coupled with biochemical/pharmacological techniques to study the modulation of ion channels as well as molecular biological techniques to study the relationships between structure and function of ion channels. Thus, patch-clamp techniques offer a powerful tool for the neurobiologist and neurotoxicologist. However, patch-clamp electrophysiology is technically demanding as well as cost intensive to initiate as a laboratory technique. This unit is designed to aid a novice electrophysiologist in assembling the required equipment, making whole-cell patch recordings, and conducting initial assessments of basic parameters of ion channel function in single neurons grown in culture, as well as highlight some considerations needed for conducting toxicological experiments. Focus will be placed on recording voltage-sensitive Ca^{2+} currents, but examination of other voltage-gated ion currents is possible with simple changes in protocols and/or buffer solutions. Examination of the function of ligand-gated ion channels would require the addition of methods for rapid drug application. *UNIT 11.11* covers the application of these techniques to brain slices.

STRATEGIC PLANNING

Conducting electrophysiological assessments of ion channel function requires substantial time and effort in assembling required equipment prior to conducting an experiment. There are several important factors that must be considered to ensure success.

First, adequate isolation of any source of vibration is critical. The vibration-isolation table will eliminate most sources. However, vibrations can be transduced by cables from the microscope or headstage (these will be connected to equipment not on the vibration-isolation table). Another source of vibrations can be from the air currents within the room or those produced by someone walking past the equipment. For this and other reasons, it is preferable to place the microscope in an area that is away from heating/cooling exhausts or intakes and away from high-traffic areas. Ground floors of a building, typically, are more stable, but many electrophysiologists record successfully on higher floors.

Second, unwanted electrical noise is the bane of patch-clamp experiments and can come from a variety of sources. This includes ground loop noise, magnetically-induced pickup power sources (e.g., the microscope lamp), and radiative pickup from the overhead lights, the computer monitor, nearby equipment, and other common electrical appliances. While elimination of electrical noise at times may seem like a trial-and-error process, a methodical approach will be useful. First, placing the microscope, chamber, and headstage inside a Faraday cage can reduce radiative electrical pickup of noise from lights and other sources. Second, it is useful to identify sources of noise by starting with a minimal setup: the oscilloscope and patch amplifier. Once noise is minimized with the minimal setup, begin to add other equipment one piece at a time while monitoring and reducing noise with each addition. Most patch-clamp amplifiers have a common ground jack to which multiple ground wires can be attached using alligator clips. Thus, potential sources of noise can be grounded using this technique, and the noise present can be examined to determine if grounding of a potential source is useful. Finally, there are a number of

Contributed by Timothy J. Shafer
Current Protocols in Toxicology (2003) 11.12.1-11.12.14

precautions that can be made to minimize the potential for interference by various sources. Microscope power sources can, in most cases, be attached to the light via remote (2- to 4-feet) cables, overhead lights can be turned off, the patch-clamp amplifier and computer monitor can be placed far apart or at least shielded, and if possible, all electrical devices required for patch-clamp experiments can be powered via an electrical circuit separate from other laboratory equipment.

This covers two major aspects of setting up electrophysiology equipment. There are two additional items that are necessary. First, the patch pipet holder should contain a narrow-gauge silver wire that slides inside the patch pipet and serves as the electrode. It is necessary to have a thin coating of silver chloride (AgCl) on this wire. This can be accomplished by briefly immersing the wire in molten AgCl, or by placing the wire in a bleach solution for at least 20 min—several hours is preferable. Second, it will probably be necessary to obtain a Ag/AgCl ground pellet and solder it to a wire to connect to the headstage. Ground pellets are available from several different vendors.

In terms of actually preparing for an experiment, solutions can (in most cases) be made the afternoon before the actual experiments and kept refrigerated (or even frozen, if longer storage times are desired). Because experimental protocols and data collection are via computer software, these can be designed and written in advance of conducting experiments as well. Utilization of patch-clamp electrophysiological techniques is most successful and fruitful when large blocks of time can be spent conducting experiments. Although it is possible to collect useful data in a couple of hours or an afternoon, this is often insufficient time to be truly productive. Thus, strategic planning can include not only preparation of buffers, test solutions, and experimental protocols and design ahead of time but also scheduling time and other commitments to allow for uninterrupted, or minimal interruptions of, time in the laboratory.

One final consideration is related to the cells of interest. If one desires to record currents from cells of a particular age, or record age-related changes (e.g., changes in current expression as a function of days in vitro for a primary cell in culture), this will require advance planning in the tissue culture laboratory to assure that cells are of the proper age on the day of the experiment.

BASIC PROTOCOL

EXAMINATION OF VOLTAGE-SENSITIVE Ca^{2+} CURRENTS IN NEURONS

Voltage-sensitive Ca^{2+} channels play critical roles in the nervous system, mediating neurotransmitter release, Ca^{2+}-dependent action potentials, and signal transduction via Ca^{2+}-dependent pathways (Catterall, 1998). This latter function is thought to be important in both the developing and adult nervous systems as a mechanism of activity-dependent changes in gene expression. Ca^{2+} channels are also targets of neurotoxicants, particularly of heavy metals. Recording voltage-sensitive Ca^{2+} currents presents unique challenges for electrophysiologists. First, currents mediated via these channels are typically much smaller than those mediated by Na^+ or K^+ channels. Thus, both intracellular and extracellular solutions typically contain components to either block and/or minimize Na^+ and K^+ currents in order to isolate the Ca^{2+} current. These components often include tetraethylammonium, cesium, and barium, which block potassium currents, and tetrodotoxin or QX-314, which block sodium currents. Second, Ca^{2+} channels exhibit great diversity: both physiological as well as pharmacological methods are often required to distinguish different types of Ca^{2+} currents. Thus, it is sometimes necessary to characterize the types of current present in a cell prior to conducting experiments with chemicals of interest.

Materials

Extracellular bath solution (see recipe)
Cells plated on glass coverslips (see Support Protocol)
Intracellular (patch pipet) solution (see recipe)
Tetrodotoxin stock solution (see recipe), optional
QX-314 solution (see recipe), optional

Glass blanks for pipets
Multistage pipet puller
Microforge/heated wire polisher
Chamber to hold cells
Inverted microscope with phase-contrast, DIC, or Hoffman modulation optics
Faraday cage (can be constructed inexpensively)
Hydrolic, motorized, or piezoelectric micromanipulators
Computer with monitor
Patch-clamp amplifier
Analog to digital (A/D) conversion board
Software
Vibration isolation table
Drug delivery device (optional, but recommended)
Oscilloscope

Prepare for experiment

1. Assemble the various pieces of equipment needed to conduct experiments.

   The microscope, manipulators, and headstage for the patch-clamp amplifier will be assembled on the vibration isolation table, inside the Faraday cage. The chamber to hold the cells will be secured on the stage of the microscope, and the micromanipulator will be either attached to the microscope or mounted on a separate stand near the microscope. The headstage will be mounted on the micromanipulator so that when the pipet holder (containing a patch pipet) is attached, the tip of the microelectrode can be manipulated to touch cells viewed when coverslips are placed in the chamber attached to the microscope stage. The computer, A/D conversion board, and patch clamp amplifier need to be connected. Typically, the connection between the computer and the A/D board is one simple cable, but the connections between the amplifier and A/D board will depend on the manufacturer of the equipment and the signals which one desires to collect in computer data files. Figure 11.12.1 illustrates the typical flow of information between the various components of the patch set-up.

2. Pull six to ten patch pipets from glass blanks with a multistage pipet puller.

   Glass blanks for patch pipets come in a variety of sizes and materials, each having differing properties that offer different advantages and disadvantages. It is useful to try several different varieties to determine which glass type and size works best with the pipet puller being utilized, the cell type being recorded from, and other requirements of the experiment (e.g., lower noise). Many glass blanks also contain a filament (a thin glass fiber) attached to the inner wall. For pipets with small tip openings, this filament helps to fill the pipet with intracellular solutions without trapping air bubbles in the tip of the electrode (this will prevent adequate recordings). An additional consideration is the thickness of the glass utilized; thicker walls provide better performance for big cells with large membrane capacitance, while thinner walls can be utilized for smaller cells to reduce series resistance.

3. Polish patch pipets by bringing the tip close to a heated platinum wire, microforge/heated wire polisher, long enough to just begin melting the glass.

   It is useful to have a microforge or microscope with high magnification (600×) to polish pipets. Visually, a slight contraction of the tip of the electrode will be observed with sufficient magnification. Remove from heat at the instant this is observed. The tip of the

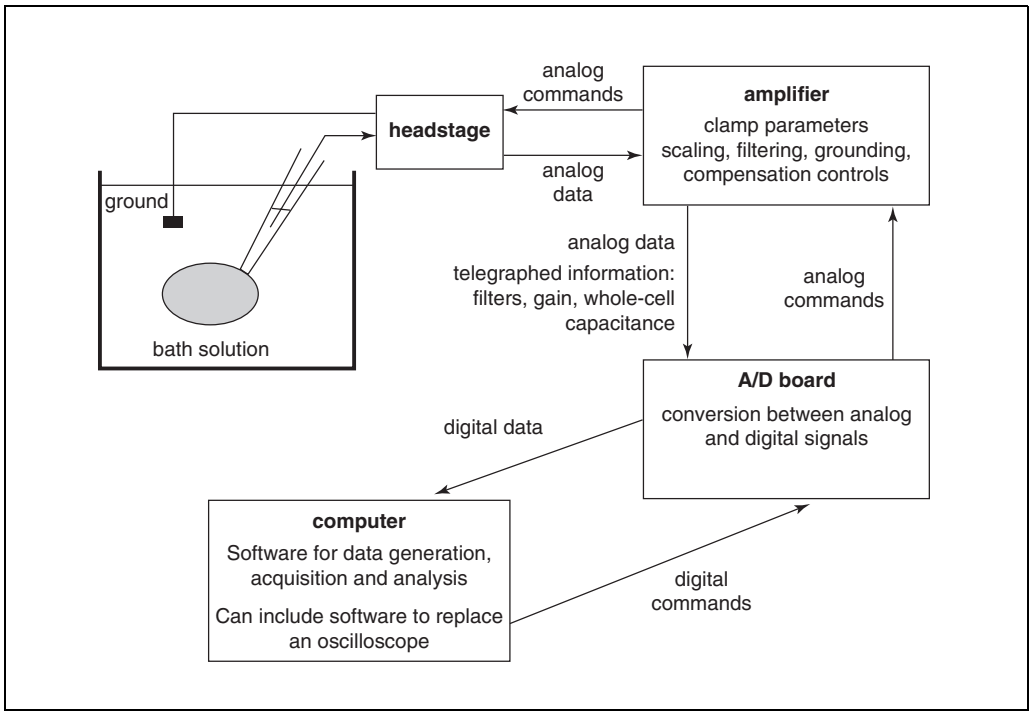

Figure 11.12.1 Diagram of patch clamp set-up and information flow. This schematic depicts the major electronic components of a patch-clamp electrophysiology setup, as well as the general functions of each component and the flow of information between them. Not depicted are other important items such as a Faraday cage, vibration-isolation table, drug delivery systems, and an oscilloscope. Many software programs have components that carry out the function of an oscilloscope. However, an oscilloscope can be useful in assessing noise and noise reduction.

electrode should be blunt, with a diameter of ~1 μm. When filled with intracellular solution, patch pipets should have a resistance of 2 to 6 MΩ, depending on the size of targeted cells. If needed, coat the tips of the pipets with Sylgard to reduce pipet capacitance.

4. Fill the chamber to hold the cells with extracellular solution and place a coverslip containing cells into the chamber. Using the microscope, select a cell to record from.

   Round- or regular-shaped cells tend to work best, and it is preferable to have a cell whose cell body is not in contact with other cell bodies, or, if possible, without extremely long neurites. These cells will be easier to maintain with an adequate space clamp.

   Although not absolutely required, having a microscope with optics providing a pseudo-three-dimensional image, such as phase-contrast, DIC, or Hoffmann modulation optics, is extremely useful. This will give the cells a three-dimensional appearance, which will facilitate manipulation of the patch pipet next to the cell without driving it into the bottom of the dish.

5. Fill a patch pipet with intracellular solution such that the end of the silver wire electrode is immersed within the intracellular solution.

   It is not necessary to completely fill the glass pipet with solution. Place the glass pipet into the pipet holder and immerse the tip into the bath solution. It is useful to apply positive pressure to the back of the pipet during this and subsequent steps. This is typically accomplished by blowing gently into a tube attached to the pipet holder (also see below), helping to prevent the pipet tip from becoming blocked with dust or debris.

6. Using the coarse and then fine adjustments on the micromanipulator, maneuver the patch pipet such that the tip of the pipet nearly touches the surface of the membrane of the cell to be recorded. Apply slight positive pressure to the pipet during this step.

7. While generating a test-pulse protocol (e.g., 5 mV depolarization for 5 msec), touch the tip of the pipet to the cell, release the positive pressure, and apply slight negative pressure (suction) to the back of the pipet.
8. Monitor the test pulse on either the oscilloscope or computer monitor to evaluate formation of a gigaohm seal between the cell membrane and patch pipet. If a gigaohm seal is detected, proceed to step 10.

   This is indicated by the elimination of current during the test pulse, such that only capacitive transients (from pipet capacitance) remain at the beginning and end of the test pulse. A cell-attached patch has now been formed.

   It will take trial and error to determine how much suction and how long to apply it in order to obtain a seal, as this will depend on the cells and environmental factors (such as the relative humidity, temperature, and other intangibles). Many people prefer to apply suction by placing a piece of tubing attached to the pipet holder into their mouth and sucking gently. This allows the experimenter to develop a feel for how much suction to apply. Depending on the substances utilized during experiments, this method may not be advisable. An alternative, safer method is to utilize a 1- or 3-ml syringe attached to the tubing via a stopcock.
9. (Conditional) In the event that the attempt is unsuccessful, obtain a new patch pipet before attempting to record from a different cell. Repeat steps 4 to 8 until a gigaohm seal is obtained.

   Formation of the gigaohm seal between the cell membrane and the surface of the glass is dependent upon having an extremely clean pipet tip surface (see Troubleshooting). Thus, a new pipet is needed for each attempt.
10. Using pipet capacitance compensation controls on the patch-clamp amplifier, reduce the pipet capacitive transients (also referred to as the fast transients) until they are eliminated.
11. In order to achieve the whole-cell configuration, apply additional negative pressure to the patch electrode or utilize the buzz button (on some amplifiers) to rupture the membrane underneath the tip of the patch pipet.

    A capacitive transient again appears at the beginning and end of the test pulse when this occurs. These transients are typically larger and longer lasting than the pipet capacitive transients and are the result of the capacitance of the cell membrane (whole-cell capacitance).
12. Using the controls on the patch-clamp amplifier, eliminate the whole-cell capacitance transients (this will be an iterative process involving the whole-cell capacitance, series resistance, series resistance compensation, and pipet capacitance compensation controls). Once whole-cell capacitance has been compensated, stop the test protocol and set membrane potential to desired holding potential or initiate control through software.
13. At this point, evaluate the cell to determine whether suitable recordings can be made, and then initiate the protocols required to evaluate various aspects of ion channel function, including activation and inactivation, current amplitude, and current-voltage response relationships.

    Depending on the conditions and cell type, stable recordings can be made for 10 to 40 min or more from each cell.

    One good indicator of the quality of the cell/recording is the steady-state holding current, which has to be injected in order to clamp the voltage at the desired membrane potential. This can often be obtained directly from the panel meters on the patch amplifier. This is a simple way of assessing the integrity of the seal resistance. Using Ohm's law ($V = I \times R$), the seal resistance (R) can be determined based on the steady-state holding current (I) and holding potential (V). The seal resistance (R) can be calculated by dividing the holding potential by the steady-state holding current. If this current is large, unstable, or increasing

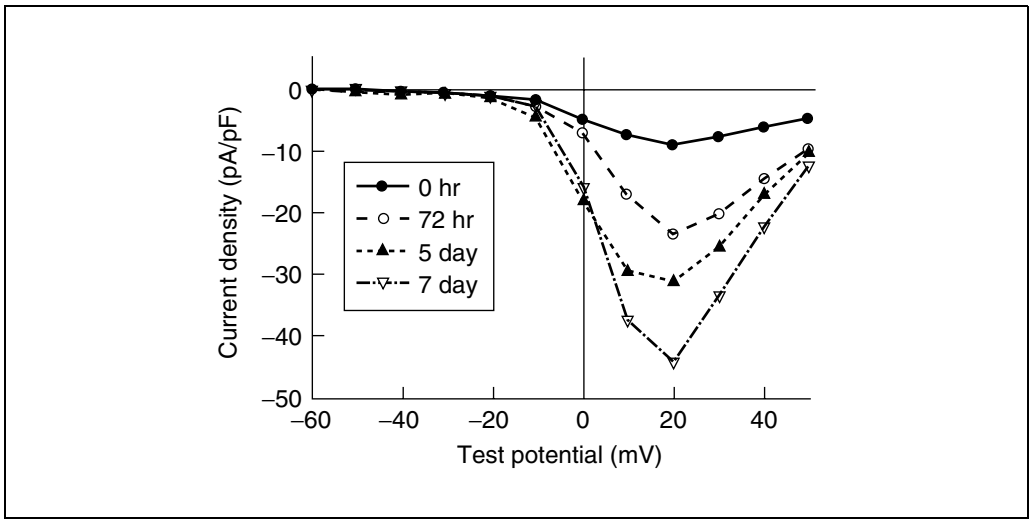

Figure 11.12.2 Current density–voltage relationship for Ca^{2+} current in PC12 cells following treatment with nerve growth factor (NGF). PC12 cells were plated onto glass coverslips and treated with NGF. At the indicated time intervals, coverslips were placed into extracellular buffer solution and whole-cell recordings were made. The current-voltage protocol described in the Basic Protocol, step 14a, was applied to cells, and then the peak amplitudes obtained at each test potential were divided by the capacitance of each cell to obtain the current density, which was plotted as a function of the test potential (in mV).

in amplitude, then the quality of data obtained will be poor. In many cases, it may not be possible to record long enough from that particular cell to complete a planned experiment.

14a. *Determining the current-voltage relationship for Ca^{2+} currents*: Generate current-voltage relationships (I/V curves) by assessing the current generated at different test potentials. A typical method to assess the I/V relationship uses a holding potential of −70 mV and delivers 140-msec depolarizing steps to the cell to evoke current responses. In the example in Figure 11.12.2, the first depolarizing step (test potential) is −60 mV, and subsequent depolarizing steps increase in 10-mV increments (e.g., to −50 mV, −40 mV, −30 mV, −20 mV, etc.) to a final level of +50 mV. From the data collected using this method, measure the peak amplitude of the Ca^{2+} current at each step level and then plot it against the test potential (mV) to generate a current-voltage plot (I/V curve).

In the example in Figure 11.12.2, the additional step of calculating current density has been taken. Typically, patch-clamp amplifiers, which have a telegraph feature (turned on), also send the whole-cell capacitance, gain settings, and other information to the computer, to be stored as part of the data file. Current density is determined by dividing the current amplitude by the whole-cell capacitance and is often calculated to normalize for differences in cell size.

14b. *Examining effects of acute neurotoxicants on Ca^{2+} currents:* In order to examine the acute effect of a neurotoxicant on Ca^{2+} currents, examine how the current amplitude or other parameters (activation, inactivation properties) change before and after application of a test compound. This method is quite simple: apply a single test potential repeatedly before, during, and, if desired, after application (washout) of a test compound, e.g., delivering a 140-msec depolarization step from a holding potential of −70 mV to +20 mV once every 10 sec. After achieving a stable baseline current, apply test compounds to the cell by a variety of methods, the simplest is a bath application, and record additional current responses. Plot the peak current amplitude versus time, although several other parameters, including end-current amplitude and activation and inactivation kinetics can also be examined.

An example of data collected utilizing this method is shown in Figure 11.12.3.

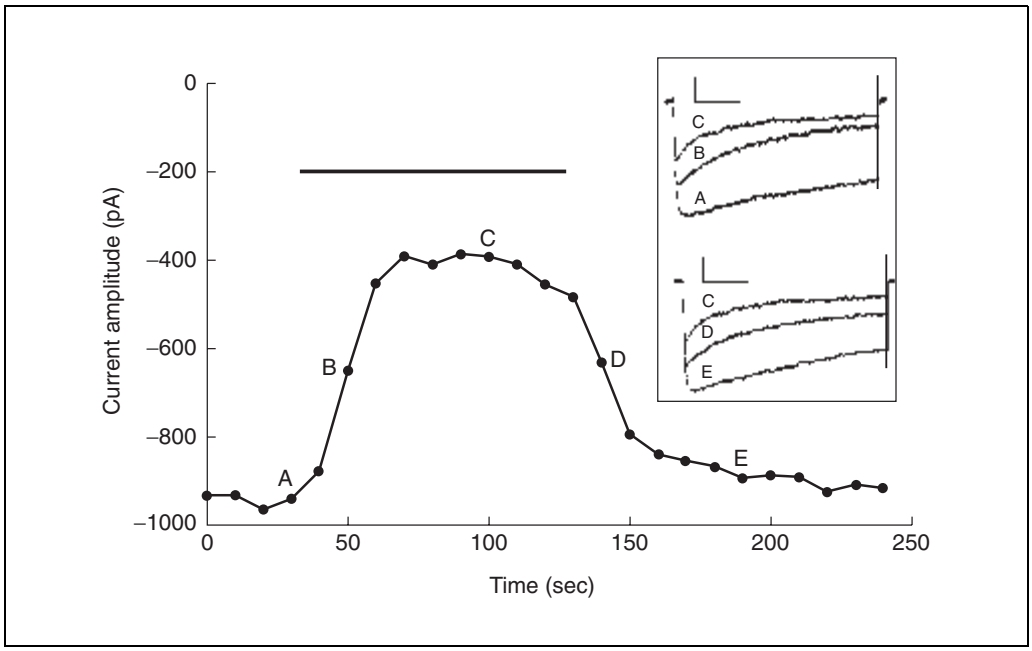

Figure 11.12.3 Reversible inhibition of Ca^{2+} currents in PC12 cells. The data presented in this figure were obtained using the protocol described in the Basic Protocol, step 14b. A test potential to +20 mV was delivered every 10 sec from a holding potential of –70 mV. When an inhibitor of Ca^{2+} channel function was applied to the bath solution (solid bar), peak current amplitude decreased rapidly. Stopping perfusion of the inhibitor (by washing) resulted in a rapid recovery of the current amplitude. The traces labeled A through E on the inset (trace C is repeated to facilitate comparisons) correspond to the points labeled A through E on the plot of the current amplitude versus time. In the inset, the scale bars correspond to 200 pA and 25 msec.

TISSUE CULTURE FOR PC12 CELLS

SUPPORT PROTOCOL

PC12 cells are a commonly used cell line for both neurobiological and neurotoxicological studies of differentiation, neurochemistry, and ion channel function. Maintenance of this cell line in culture and the preparation of plates for electrophysiology will be briefly discussed here. It should be noted that antibiotics can inhibit voltage-sensitive Ca^{2+} channels (Atchison et al., 1988) and are not used, therefore, requiring that all procedures must be conducted in a sterile environment.

Materials

PC12 cells

Dulbecco's modified Eagle medium (DMEM), supplemented with 44 mM $NaHCO_3$, 2 mM HEPES, 7.5% (v/v) fetal bovine serum (FBS), and 7.5% (v/v) horse serum

50 µg/ml poly-L-lysine

50 ng/ml human recombinant nerve growth factor (NGF) or 100 ng/ml mouse 7s NGF

25-cm^2 polystyrene culture flasks

25-mm glass coverslips, sterile

6- or 12-well polystyrene multiwell plates

15-ml conical centrifuge tubes

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Seed 1×10^6 undifferentiated PC12 cells into 25-cm^2 polystyrene culture flasks containing 10 ml supplemented DMEM. Incubate cells in a 37°C humidified, 5% CO_2 incubator. Feed the cells every 3 or 4 days by removing 5 ml of medium from the flask and replacing with 5 ml of fresh supplemented DMEM.

   After 1 week, the flask will contain ~18×10^6 cells, which can be utilized for step 2.

2. To prepare cells for electrophysiological recordings, place sterile glass coverslips into 6- or 12-well polystyrene plates and cover with 2 ml of sterile, deionized water containing 50 µg/ml poly-L-lysine. Let plates stand to the side while the steps below are completed.

3. Taking a flask of undifferentiated PC12 cells, dislodge the cells by rapidly striking the flask against the palm of the hand three to five times (if cultured on uncoated polystyrene flasks, the cells dislodge easily). Transfer the cell suspension into a 15-ml conical centrifuge tube and centrifuge 10 min at ~$1000 \times g$, room temperature. Discard the supernatant and resuspend the cells in ~5 ml of fresh supplemented DMEM.

4. Remove an aliquot of cells to count and determine the cell concentration (*APPENDIX 3B*). Adjust the cell concentration to ~7.4×10^{-4} cells/ml with supplemented DMEM.

   This concentration will give an adequate number of cells for recording while also supplying numerous individual (rather than clumps of) cells.

5. Wash the plates containing the coverslips (from step 2; 25-mm coverslips in 6-well plates) two times, each wash with 2 ml of sterile deionized water, then plate 2 ml/well of cell suspension. Place in the 37°C humidified, 5% CO_2 incubator.

6a. *If undifferentiated cells are desired for recording:* Allow the cells to adhere 2 to 3 hr and examine over the next several days, until they become confluent.

6b. *If differentiated cells are desired for recording*: After 2 hr, replace the medium in the well with 2 ml/well of supplemented DMEM and 50 ng/ml of human recombinant nerve growth factor (NGF) or 100 ng/ml mouse 7s NGF. Examine the cells after they acquire a neuronal phenotype.

   After 2 to 3 days, cells will differentiate to a neuronal phenotype, although Ca^{2+} current will continue to increase for 6 to 7 days.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Extracellular bath solution used for recording Ca^{2+} currents

To make 500 ml:
0.735 g $CaCl_2 \cdot 2H_2O$ (mol. wt. 147; 10 mM final)
0.9 g D-glucose (mol. wt. 180.2; 10 mM final)
2.38 g HEPES (mol. wt. 238; 20 mM final)
0.102 g $MgCl_2$ (mol. wt. 203.3; 1 mM final)
3.65 g NaCl (mol. wt. 58.5; 125 mM final)
0.83 g tetraethylammonium (TEA)·Cl (mol. wt. 165.7; 10 mM final)
pH to 7.4 with 5 M NaOH
Adjust to 340 mOsm with sucrose
To record for Ba^{2+} currents: Substitute 1.22 g/500 ml or 2.44 g/liter $BaCl_2$ (mol. wt. 244; 10 mM final) for $CaCl_2$ in the above extracellular bath solution.
Store for 7 to 10 days at 4°C or for 12 months at −20°C.

Intracellular (patch pipet) solution

To make 100 ml:
0.220 g ATP (mol. wt. 551.1; 4 mM final)
2.1 g CsCl (mol. wt. 168.4; 125 mM final)
0.190 g EGTA (mol. wt. 380.4; 5 mM final)
0.180 g D-glucose (mol. wt. 180.2l 10 mM final)
0.238 g HEPES (mol. wt. 238; 10 mM final)
0.020 g $MgCl_2$ (mol. wt. 203.3; 1 mM final)
0.165 g TEA·Cl (mol. wt. 165.7; 10 mM)
pH to 7.4 with 20% (w/v) aqueous solution TEA·OH
Adjust to 310 to 315 mOsm with sucrose
Store frozen in 5-ml aliquots up to 12 months at −20°C.

This buffer is an example of an intracellular (patch pipet) solution used for recording Ca^{2+} currents from PC12 cells.

QX-314 solution

As an alternative to using tetrodotoxin in the extracellular buffer, QX-314 must be applied via the intracellular solution to block function of voltage-sensitive Na^+ channels. Make a 10 mM solution of QX-314 bromide in distilled water and heat to ~70°C to dissolve. This solution can be diluted 1:100 in intracellular solution for which the osmolarity has been reduced by 10% by the addition of distilled water. Store frozen in 0.1-ml aliquots up to 6 months at −20°C.

Tetrodotoxin stock solution

Dissolve 1 mg of tetrodotoxin into 1.56 ml of acetate buffer (pH ~4 to 5) solution to make a 2 mM stock solution. This can be diluted 1:2000 directly into the extracellular buffer to give a final concentration of 1 μM tetrodotoxin. Store for 1 to 2 months at 4°C or dispense into 0.1-ml aliquots and store up to 6 months at −20°C.

CAUTION: Tetrodotoxin is extremely toxic and potentially lethal. Extreme caution should be exercised when handling this compound. Use the QX-314 solution (see recipe) as an alternative.

COMMENTARY

Background Information

One aspect of the tissues of the nervous system that makes it unique from other tissues is the degree to which electrical excitability is a critical component of its proper function (Hille, 2001). This aspect of the nervous system also renders it particularly sensitive to toxicants which are capable of disrupting function of the numerous ion channels that control, modulate, or depend on electrical activity. There are many excellent examples of neurotoxicity produced via direct disturbance of ion-channel function (Shafer, 1999), including the effect of pyrethroid insecticides on voltage-sensitive Na^+ channels (Narahashi et al., 1998), heavy metals on voltage-sensitive Ca^{2+} channels (Audesirk, 1993; Sirois and Atchison, 1996), organochlorine insecticides on $GABA_A$ receptors, and imidacloprid on nicotinic acetylcholine receptors (nAChR). Indirectly, other classes of neurotoxicants can also disturb ion-channel function and electrical activity. For example, overstimulation of nAChR function contributes to the toxicity observed following inhibition of acetlycholinesterase by organophosphate and carbamate insecticides. Activation of muscarinic acetylcholine receptors also often results in alterations of ion-channel function, although the resulting electrical changes typically occur over a period of seconds to minutes, rather than milliseconds (as with changes mediated directly by ion channels).

Electrophysiological techniques have proven indispensable in understanding the basic function of the nervous system as well as in elucidating the cellular mechanisms of a wide variety of neurotoxicants. In the early 1980s, Hamill and co-workers (1981) made significant

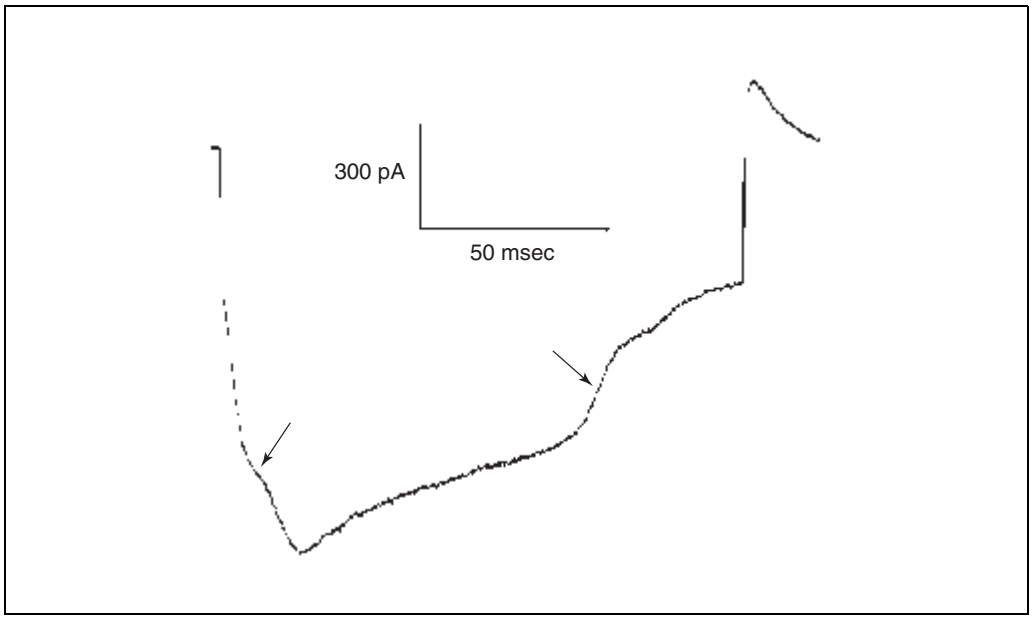

Figure 11.12.4 Example of a current trace from a cell where space clamp is poor. In this example trace, both the activation (left arrow) and inactivation (right arrow) of the Ca^{2+} current contains pronounced shoulders that indicate that the cell is inadequately space-clamped. Compare the shape of this current trace to the examples in the inset of Figure 11.12.3.

advances in recording techniques utilizing patch electrodes. Their work revolutionized the field of neurophysiology and dramatically increased the understanding of the mechanisms of action of a wide variety of insecticides, metals, and other compounds in neurotoxicology. In the future, this methodology will continue to play an important role in elucidating differences in species susceptibility and mechanisms of resistance to insecticides (Ffrench-Constant et al., 2000), as well as aid in designing novel insecticides.

Critical Parameters

There are a number of critical parameters required to obtain high-quality recordings and useful information regarding the effects of neurotoxicants on the mechanism of ion channel function. Good recordings begin with healthy cells and high-resistance seals. A number of other factors are important to ensure the integrity and reliability of the data, including correction for current rundown, minimization of electrical noise, and data collection (digitization) rates that are sufficiently fast where there is no vital information missing or lost. Of vital importance is the ability to completely control the membrane voltage at all points of the cell (space clamp). In cells with inadequate space clamp, the potential across the membrane does not change uniformly in terms of the rate and/or total change in membrane potential. Insufficient space clamp often arises because the cell is very large, has an irregular shape, contains long processes, or has established connections with other cells. An example of inadequate space clamp is shown in Figure 11.12.4. The shoulders in the current in Figure 11.12.4 are a common example of inadequate space clamp. In cells with inadequate space clamp, measurements of current amplitudes as well as kinetics are suspect, and data from cells with inadequate space clamp should be discarded.

Pulse protocol generation and data acquisition are almost always controlled via computer. Thus, it is important to understand the basics of digitization. Changes in membrane potential and current are analog events. To be controlled and stored by the computer, these analog events must be converted to digital events. When converting analog to digital, the analog signal, e.g., a membrane current, is sampled periodically and its value recorded for later reconstruction of the analog signal as a digital signal. The accuracy of reconstruction will depend on the rate at which samples are collected; the faster the rate of digitization, the more accurately the digital record will reflect the analog signal. Responses that occur more rapidly than, or close to, the sampling rate will be lost or degraded. Therefore, it is important to give some forethought to the type of signal to be recorded and the rate at which this signal occurs. Some software packages allow the sampling rate to

be changed over the course of recording a single event. For example, one may wish to examine tail current (a delayed current response that occurs upon membrane repolarization) more closely than current evoked during a depolarization and thus sample at a higher rate during that period of the recording. For specific information regarding data collection, consult the user's manual of the data acquisition software.

In order to record voltage-sensitive Ca^{2+} currents, it is necessary to block outward currents, usually carried by potassium. Thus, the solutions contain a K^+-channel blocker, tetraethylammonium (TEA), in place of K^+. Additionally, Ba^{2+}, which blocks both inwardly and outwardly rectifying K^+ channels, can be used to replace Ca^{2+}, particularly if Ca^{2+}-activated K^+ channels are present. Barium also offers an additional advantage as it does not cause Ca^{2+}-induced inactivation of Ca^{2+} currents. In order to investigate Ca^{2+} channel kinetics, it is also necessary to block function of voltage-sensitive Na^+ channels, either with tetrodotoxin or QX-314 (which must be applied intracellularly to be effective). In addition, for recording any voltage-sensitive current, it is necessary to determine the leak current present in each cell. Leak current flows in the direction of the voltage step and is linear. Typically, data-acquisition software includes online leak subtraction, which is achieved by delivery of a series of prepulses prior to delivery of the test pulse, followed by online subtraction (P/N protocols). The magnitude of the prepulses is determined by dividing the magnitude of the test pulse (P) by the number of prepulses to be delivered (N). The current flowing in response to the prepulses is averaged and scaled, then subtracted from the current subsequently recorded during the test pulse. The advantage of this protocol is that leak subtraction is simple and almost instantaneous. The disadvantage is that changes in leak associated with toxicant exposure might be overlooked because leak is not specifically examined. Manual subtraction of leak current can be conducted by writing protocols to examine this component specifically, then subtracting the leak current from the current data acquired using other protocols.

Compensation of pipet and whole-cell capacitance is an iterative process and can only be learned by experience. Most manufacturers of patch-clamp amplifiers include or make available a model cell for practice. Typically, these model cells have ports to attach the head stage, which electronically simulate a patch pipet in the bath solution, in the cell-attached patch mode and in the whole-cell patch mode. This model cell can be utilized to help minimize or eliminate unwanted electrical noise in the system and to practice adjustment of series resistance and capacitance compensations.

With respect to utilization of patch-clamp methods for toxicology, there are a couple of additional considerations. First, many neurotoxicants are highly lipophilic and difficult to wash out of biological tissues. Thus, plan to expose a coverslip to toxicant only one time. Even in the event a toxicant does have reversible effects, it may be unwise to record from multiple cells on the same coverslip because the effects of repeated exposure may be subtle. In addition, the data will have more statistical value if only one cell per coverslip is used. It should also be noted that ion-channel responses can change with the in vitro age of primary cells, passage number, or treatment (e.g., NGF) of clonal cell lines (see Fig. 11.12.2). Thus, it is either necessary to characterize such age- or passage-related changes thoroughly so that effects of toxicants can be examined during a period of stability, or to design experiments such that the same-day in vitro or passage number is utilized for each experiment. Also important in pharmacological as well as toxicological experiments is the method of application of compounds to the cells. The simplest method is to add the compound into the solution that is being perfused into the recording chamber. If the chamber volume is kept sufficiently small and/or the flow rate is sufficiently fast, rapid changes in the concentration of chemical applied to the cell are possible. A large number of perfusion devices are available that permits applications and changes in solutions in milliseconds or less and/or the ability to change through several different solutions in rapid succession, such as when generating a concentration-response curve.

Troubleshooting

For beginners, the key to successful recordings is the formation of a gigaohm seal between the patch pipet and the cell membrane. If an experienced patch-clamp experimenter is available, have them polish pipets until the beginner is adept at forming gigaohm seals. This will eliminate the variable in the learning stage. Failure to form gigaohm seals successfully is most likely to arise from improperly or inadequately fire-polished pipets, or dust, dirt, or debris on the pipet tip. Often the latter can be

seen on the tip of the pipet. Start each day with freshly made and polished pipets and store them in a covered dish until use. Alternatively, many electrophysiologists polish each patch pipet immediately prior to use. Applying positive pressure from the time the pipet enters the bath solution can help reduce the attachment of dust to the pipet tip. Filtering solutions can also reduce the amount of dust and other debris, and if needed, one can actually wash the glass blanks with deionized water followed by ethanol in order to reduce debris from the glass itself. If difficulty is encountered, begin with fire polishing and implement other steps such as filtering solutions and washing pipets only if needed. Over-polishing will typically result in sealing of the tip of the electrode. Thus, one end of the spectrum between not enough polishing and too much polishing is clearly defined.

Another key to gigaohm-seal formation is the health of the cells themselves. Unhealthy cells often have blebbed or other irregular membranes, and in many cases the membrane will rupture prior to obtaining a gigaohm seal. If this problem occurs, it may be wise to check the pH, osmolarity, and age of the buffer solution. If these parameters are within recommended ranges, then additional examination of the cells should be undertaken; bacterial contamination, serum deprivation, or depletion of nutrients in the medium (too long between additions of fresh medium) all can negatively impact the health and viability of the cells.

Anticipated Results

Utilizing the Basic Protocol and the Support Protocol, one can anticipate obtaining current-voltage relationships with a shape similar to that depicted in Figure 11.12.2. All voltage-sensitive ion channels have a characteristic I/V relationship that is determined by the electrochemical driving force across the membrane for the ion of interest. Changes in the shape of this curve in the presence of a neurotoxicant can provide information regarding the mechanism by which it inhibits ion-channel function. For example, if the toxicant inhibits current to a greater extent at high voltages and to a lesser extent at other voltages (voltage-dependent block), this suggests that the toxicant may interact with the pore of the channel. Cadmium (Chow, 1991) and other divalent heavy metals block voltage-sensitive Ca^{2+} channels (VSCC) in a voltage-dependent manner. The format chosen for expression of the data in Figure 11.12.2 allows for the illustration of some additional points. First, it is an example of a change in current characteristics over time in a clonal cell line and illustrates the need to be cognizant of such changes when conducting experiments. Age-dependent changes in ion-channel function have been reported in a variety of clonal and primary cell types. Second, when examining acute effects of toxicants, it is possible to use each cell as its own control, which will help to normalize data obtained. However, examination of subacute or chronic effects will require measuring different populations of control and toxicant-treated cells. The capacitance of the cell membrane can serve as a surrogate measure of cell size, as it is relatively constant as a function of membrane surface area and can be utilized to normalize for differences in cell size. This may be advantageous in decreasing variability and/or potentially alerting the experimenter to toxicant- or selection-induced differences in the population of cells sampled from control versus toxicant-treated cultures.

One might anticipate that exposure to neurotoxic or neuroactive substances would increase or decrease (as shown in Fig 11.12.3) the amplitude of ion channel currents. However, focusing solely on the peak amplitude of current might result in missing other important effects of toxicants on channel function. Such is the case in Figure 11.12.3. Although treatment with the toxicant decreased the peak current amplitude, two other (possibly related) effects are apparent from the current traces in the inset. First, there is a clear change in the inactivation kinetics of the treated currents; they appear to inactivate more rapidly in the presence of toxicant. Second, if the amplitude of current is measured at its peak (close to the left edge of the current traces) versus its end (to the right), it is apparent that the toxicant reduces the end current amplitude to a greater extent than it reduces the peak current amplitude. This result suggests several additional mechanistic questions to address. First, inactivation time constants should be compared in control versus treated cells. Second, because these are PC12 cells, they are likely to contain at least two (Shafer and Atchison, 1991), and possibly more types of VSCC (Colston et al., 1998). Thus, additional experiments should isolate different current subtypes and examine whether a specific subtype is more sensitive to the toxicant than others or whether the toxicant similarly affects the current amplitude and kinetics of all VSCC subtypes present. Additional informa-

tion regarding mechanisms of block can be obtained by changing the rate at which step depolarizations are applied. If a toxicant blocks current more rapidly or to a greater extent at higher frequencies of stimulation, this suggests that the toxicant has a higher affinity for the open state of the channel. Many local anesthetics produce a use-dependent block of Na^+ channels, and pentobarbital has been shown to cause use-dependent block of kainate- and quisqualate-activated currents (Marszalec and Narahashi, 1993).

Time Considerations

Successful recording of Ca^{2+} currents from a cell can take as little as 10 min, if preparation time is not considered. However, as mentioned above, large blocks of time in the laboratory will be more fruitful than shorter periods. This allows data to be collected from a sufficient number of cells to gain statistically reliable information regarding effects of toxicants on ion-channel function, as well as for failed attempts to obtain a good recording. Patience and perseverance are prerequisites for success when utilizing this technique. In addition to collecting the data, since multiple pieces of information can be obtained from a given recording (e.g., the amplitude of current at its peak and the end of the voltage step, activation times, inactivation times), data analysis can often be as or more time consuming than actual data collection.

Detection and Assessment of Xenobiotic-Induced Sensory Neuropathy

Painful peripheral neuropathy is not an uncommon result of chronic administration of medications. Perhaps the best known examples of such neuropathies are those resulting from antineoplastic agents used in the treatment of cancers and antiretroviral medications used in the treatment of HIV infection, but there are many other examples. The behavioral assessment of peripheral nerve function is therefore an important part of experiments directed at determining the toxicities of various xenobiotic compounds with intended medical purposes. The same techniques can be used to evaluate the toxic potential of industrially used or even naturally occurring compounds.

Though the specific type of painful neuropathy caused by various agents will differ, most drug-induced neuropathies are detectable using either momentary thermal or mechanical stimuli. This unit describes a pair of assays that can be performed together on the same groups of rats, and repeated over time with relatively stable baseline responses. The techniques described include the thermal paw flick assay (see Basic Protocol 1) and the mechanical von Frey fiber–based assay (see Basic Protocol 2). These protocols are quite humane and are not associated with distress or tissue damage to animals. In fact, variations of these assays are used in human clinical and experimental sensory testing. Both assays can be used repeatedly on groups of rodents undergoing prolonged exposures to the xenobiotics of interest. The use of a thermal and a second mechanical type of stimulus increases the power in being able to detect relevant sensory changes.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

THERMAL PAW FLICK ASSAY

BASIC PROTOCOL 1

This assay uses heat as the noxious stimulus, and the investigator times latency to removal of the hind paw from the heat as the measured parameter. This type of testing was initially described by Hargreaves et al. (Hargreaves et al., 1988). Modifications for use of mice are available (Li et al., 2001). The basic apparatus is a device capable of delivering a thermal stimulus of variable intensity coupled to a timing device. When this assay is employed to detect changes in sensory thresholds in response to the chronic administration of a xenobiotic, animals are typically assessed every 1 to 3 days. Those changes resulting in anesthesia of the hind paw will be associated with progressively prolonged latencies, whereas those resulting in the sensitization of the hind paw (thermal hyperalgesia) will be associated with declining latencies.

Materials

Rats
Thermal paw flick (Hargreaves) apparatus (IITC model 390 or similar)
Enclosures (if not included with other testing apparatus): ~15 × 15–cm area and ~30-cm high (if no lid is used) clear plastic (rats should not be restrained within enclosures)

1. Move animals from their housing facility to the testing area well ahead of the start of the experiment. Have the platform of the paw flick device at a steady-state temperature.

Contributed by J. David Clark
Current Protocols in Toxicology (2004) 11.13.1-11.13.8

The strain, gender, age, and source of rats should be concordant with those parameters used by the laboratory for biochemical or other toxicological studies.

The sample size is generally in the range of 7 to 10 rats/group for detection of 10% to 15% changes in thermal or mechanical nociceptive thresholds. Stronger experimental protocols generally employ a placebo or vehicle-treated group of animals thus allowing between-group comparisons.

The husbandry and handling of the animals should be standardized. Preferably, a single investigator should be responsible for a complete experiment.

Animals should be ordered and allowed to acclimate to the local housing facility for at least several days prior to use in behavioral experiments. Most investigators house two rats/cage with a 12:12 hr light/dark cycle and standard laboratory rat feed and water ad libitum. More reliable data are obtained when experiments are preceded by one or more mock testing sessions in which rats are transported, handled, and tested in exactly the same manner as would be in the case if actual data were being collected. Gentle handling should always be employed. The temperature of the glass testing platform is generally held a few degrees above room temperature, e.g., 27° to 30°C, to maintain a constant temperature from day to day. Temperatures above 30°C might overheat the animal.

2. Place animals on the testing platform and allow to acclimate for 20 min.

   The thermal paw flick (Hargreaves) devices generally consist of a source of thermal stimulation like a focused beam of intense light and a clear platform on which animals are placed thus allowing stimulation of the plantar surface of the hind paws. They should also allow testing of multiple animals on the same platform, have a temperature-controlled glass platform, and a timing mechanism linked to the activation and termination of the thermal source precise to at lease 0.1 sec.

   Inadequate or inconsistent acclimation times will adversely affect the quality of the data. The injection of test substances (if employed) should not occur during this acclimation period.

3. Position the source of thermal stimulation under one of the hind paws such that the beam of light will impinge upon the soft area of skin directly distal to the footpads (tori). Zero the timing device.

   The investigator should always stimulate the same hind paw of the same rat, or include in every data set measurements from both hind paws. Side-to-side variability is not uncommon. Preliminary testing can be used to determine the appropriate lamp output to obtain a 10 to 12 sec baseline latency in control animals. Do not test animals with obvious lesions of the hind paws.

4. Activate the light source/timer and leave in place until the animal lifts or flicks its hind paw. When the animal responds, stop the timer and stimulation. Make at least two and preferably three measurements for each paw tested each separated by ~2 min.

   The part of the paw tested must be in contact with the glass surface as the glass acts as a heat sink. If the paw is held above the glass the response time will be shorter. If liquid is present on the glass the response time will be longer. If urine is present it should be wiped away prior to beginning the assay. Occasionally, animals will walk away or display a non-specific behavior. Those measurements should be repeated.

5. After testing, return animals to their cages where they have access to food and water unless being used for additional testing.

   Other parameters to hold constant are: (1) personnel performing the tests; (2) time of day of testing; (3) the protocol for handling the animals including the type of gloves and protective clothing worn by investigators; (4) temperature and lighting of the room; and (5) noise level.

MECHANICAL VON FREY ASSAY

Testing for thresholds to noxious mechanical stimuli is often performed instead of or in addition to the thermal methods. In this section, a method for von Frey fiber–based assessment is presented, which is based on the methods described by Chaplan et al. (1994) to derive the 50% response threshold. Similar to the thermal technique described in Basic Protocol 1, this assay is typically applied every 1 to 3 days during the treatment of animals with the xenobiotic under study. Those changes resulting in anesthesia of the hind paw will be associated with progressively increased response thresholds, whereas those resulting in the sensitization of the hind paw (mechanical allodynia) will be associated with declining latencies.

Materials

Rats
Mesh platforms (IITC model 410 or similar)
von Frey fibers: sets of individual fibers or calibrated instruments of various designs are available (e.g., IITC model 2290 or Stoelting model 58011)
Enclosures (if not included with other testing apparatus): ~15 × 15–cm area and ~30-cm height (if no lid is used) clear plastic

1. Move animals from their housing facility to the testing area well ahead of the start of the experiment.

   The strain, gender, age, and source should be concordant with those parameters used by the laboratory for biochemical or other toxicological studies.

   The sample size is generally in the range of 7 to 10 rats/group for detection of 10% to 15% changes in thermal or mechanical nociceptive thresholds. Stronger experimental protocols generally employ a placebo or vehicle-treated group of animals thus allowing between-group comparisons.

   The husbandry and handling of the animals should be standardized. Preferably, a single investigator should be responsible for a complete experiment.

   Animals should be ordered and allowed to acclimate to the local housing facility for at least several days prior to use in behavioral experiments. Most investigators house two rats/cage with a 12:12 hr light/dark cycle and standard laboratory rat feed and water ad libitum. More reliable data are obtained when experiments are preceded by one or more mock testing sessions in which rats are transported, handled, and tested in exactly the same manner as would be the case if actual data were being collected. Gentle handling should always be employed.

2. Place animals on the mesh platform and allow to acclimate for 20 min.

   Overall size of the mesh platform should accommodate 2 to 3 animal enclosures with ~0.5 × 0.5–cm openings. The height should be >15 cm from the surface on which it is placed to allow von Frey fibers to be applied from below.

   Inadequate or inconsistent acclimation times will adversely affect the quality of the data. The injection of test substances (if employed) should not occur during this acclimation period.

3. Position equipment so that the von Frey fibers can be applied to the soft area of skin directly distal to the footpads (tori).

   The investigator should always stimulate the same hind paw of the same rat, or include in every data set measurements from both hind paws. Side-to-side variability is not uncommon. Do not test animals with obvious lesions on the hind paws.

4. Apply the first von Frey filament by applying upward pressure until a slight bend in the fiber is seen.

   Fiber sets are usually based on the Semmes Weinstein monofilament fiber progression.

   For rats, a typical set of fibers contains fibers of the following stiffnesses: 0.41, 0.70, 1.20, 2.00, 3.63, 5.50, 8.50, and 15.10 g. Fibers are applied for a maximum of 5 to 6 sec beginning with the 2.00-g fiber. They are applied in increasing stiffness until a response is obtained. A typical response is a sharp upward or lateral movement of the hind paw.

5. Once a positive response is obtained, apply the fiber of next lowest stiffness. If that fiber leads to a response, then apply the next lowest fiber, otherwise use the next higher stiffness fiber. Score a response as an "X" and the lack of response as an "O." Continue this process until four fibers have been applied after the first one causing a response.

   It is critical that each fiber be applied in the same manner and on the same hind paw location. Occasionally, a response will be equivocal and the same fiber will need to be re-applied. Fibers can be applied in rapid succession with only a few seconds passing between fiber applications. Since this up-down method is based on the successive application of fibers near the 50% response threshold, it is only necessary to perform the fiber application protocol once per test day.

6. After testing, return animals to their cages where they have access to food and water unless being used for additional testing.

   Other parameters to hold constant are: (1) personnel performing the tests; (2) time of day of testing; (3) the protocol for handling the animals including the type of gloves and protective clothing worn by investigators; (4) temperature and lighting of the room; and (5) noise level.

COMMENTARY

Background Information

Xenobiotics and sensory change

Painful peripheral neuropathy is not an uncommon result of chronic administration of medications. Perhaps the best known examples of such neuropathies are those resulting from antineoplastic agents, such as vincristine, cisplatinum, and paclitaxel, used in the treatment of cancers and antiretroviral medications, such as didanosine and stavudine, used in the treatment of HIV infection, but there are many other examples. These neuropathies can be either of transient or long-term durations and cause disability and suffering for the duration of their presence. Furthermore, the mechanisms for the neuropathies vary and can involve demylination, axonal degeneration, and death of the neuron itself. Excellent reviews discuss these issues in some detail (Peltier and Russell, 2002; Dieterich, 2003; Verstappen et al., 2003; Visovsky, 2003). Toxic peripheral neuropathies are not limited to those caused by medicinal compounds. Many naturally occurring substances and industrial byproducts have been associated with peripheral neuropathy particularly after chronic exposures. In the evaluation of new pharmaceutical candidate compounds, especially those with chemical or mechanistic similarities to compounds with known neurotoxicities, investigators should consider the possibility of painful neuropathy resulting from short- or long-term administration.

The field of pain research has been responsible for the development and validation of dozens of pain assessment techniques. Some of the chief differences between these assays involve the use of phasic (momentary) versus tonic (lasting) stimulation. The type of noxious stimulus that is used is variable as well, but generally falls within one of the following categories: thermal, mechanical, electrical, or chemical. While these assays are commonly referred to as "pain assays," keep in mind that pain has both sensory and emotional components. Because the animal's actual experiences after the application of a noxious stimulus in a laboratory cannot be positively ascertained, the results are commonly referred to as measures of "nociceptive" thresholds or behaviors referring to the fact that they result from the application of a noxious stimulus, which may or may not be experienced in a way similar to what the human experience would be.

The first test suggested for use in this unit is the paw flick assay, which uses a thermal

stimulus. This test was introduced by Hargreaves et al. (1988), and it represents an improvement on earlier methods of thermal nociceptive testing. The most commonly used alternative test utilizing thermal nociceptive input is the tail flick assay which has been in use for many decades. The tail flick assay involves positioning an animal's tail over a source of heat, usually a focused beam of light. The measurement made is the latency from the application of heat until the flick of the tail out of the path of the light. This test is robust for measuring the analgesic effects of many compounds but has several drawbacks. For example, when doing the tail flick assay, the animal needs to be restrained, which causes the animal stress. Stress-induced analgesia is a well-studied phenomenon (Fields, 2000; Bodnar and Hadjimarkou, 2003) and can confound the interpretation of results. Another problem is that the noxious stimulus is directed at an area of scaly skin on the tail of the animal. Humans do not have tails nor do they possess epidermis of the same type. Lastly, rats (and especially mice) tend to occasionally move or flick their tails for reasons unrelated to the application of noxious stimulation. This reduces the baseline latency that can be targeted in experiments. If one is hoping to detect a reduced response latency as would be expected if the animals were to develop hyperalgesia such as occurs after chronic treatment with paclitaxel (Authier et al., 2000), one would want to set a long baseline latency thus providing improved ability to detect reductions in latency. The paw flick assay circumvents many of these problems by allowing the study animals to roam freely in a non-stressful environment, directing the noxious stimulus at an area of glaborous skin similar to human palmar or plantar skin and allowing for long baselines (up to ~20 sec or so for rats) coupled with an unequivocal paw flick response essentially only seen after noxious stimulation. Disadvantages of the technique include the relative expense of the equipment, commercially available paw flick devices currently cost about two times that of a tail flick apparatus, and the greater time needed to complete the assay.

The second assay suggested in this unit is the mechanical von Frey fiber–based assay. There are alternative mechanical methods including the Randall-Sellito paw pinch assay which is also commonly used. The paw pinch assay involves placing the hind paw between the jaws of a device capable of delivering a controlled, usually ramped calibrated force that is applied until the animal attempts to remove the paw or vocalizes. This assay is widely used for the measurement of analgesic activity and in situations in which diminished sensitivity to noxious stimulation is expected. The von Frey assay outlined in this unit is widely used for the quantification of diminished mechanical sensory thresholds, which occur in some patients with painful peripheral neuropathies. Like the thermal paw flick assay, no restraint of the animal is necessary, and the test can be performed repeatedly with stable baseline responses. The equipment costs are modest if conventional nylon von Frey fibers are used. There are several disadvantages, however. The von Frey fibers are fragile and their stiffness tends to change both with repeated use over months or years in a laboratory and with differences in temperature and humidity (Levin et al., 1978). If the fibers are applied form the bottom, a force greater than the weight of the hind paw cannot be applied as that amount of force will simply lift the hind paw. Unfortunately, the baseline threshold is often not much less that the force required to lift the paw thus limiting the utility of this procedure in detecting neuropathies resulting in lowered sensory thresholds.

One might ask why more than one assay would or should be used in toxicological studies. The answer lies in the specialization of various types of nociceptors in the peripheral nervous system. In this respect, differences exist both in the types of noxious stimuli to which the nerve fibers will respond and the type of fibers which carry the nociceptive information from a single type of stimulus. For example, a noxious heat stimulus applied to the hind paw of a rat is carried by both A-δ myelinated and type C unmyelinated fibers. In fact, the rate of heating of the skin affects the mixture of fibers carrying the nociceptive information with high rates of heating causing a disproportionate number of A-δ fibers to be activated while slow rates cause a larger fraction of C fibers to participate in the response (Yeomans et al., 1996). Similar complexities exist for responses to mechanical stimuli with cutaneous nociceptive fibers of the A-δ and C types showing differential sensitivity to punctate and non-punctate stimuli as well as differential sensitization after trauma (Pogatzki et al., 2002). Each of these fiber types have correspondingly unique neurochemical characteristics and distinct areas within the spinal cord to which they project (Sandkuhler, 1996a,b). Furthermore, the distribution of neuromodulatory receptors such as opioid receptors is fiber-type specific. Thus, investigators concerned with the possibility of peripheral neuropathy might consider

casting their net widely in order to maximize the chances of detecting xenobiotic-induced alterations in nervous system function.

Critical Parameters and Troubleshooting

Several issues pertaining to the animal subjects are critical for obtaining reproducible data in animal behavioral testing. The animals in experimental groups treated in parallel or in sequential experiments need to be of the same gender, strain, and age. Animals should always be obtained from a single supplier for a set of experiments to control for genetic drift and pre-experimental husbandry conditions. The light-dark cycle, feed, temperature, bedding materials, number of animals per cage, and size of cages should all be kept constant.

Test conditions should be kept consistent for the course of the experiment. Many investigators prefer to expose animals to test conditions at least once in an independent test session before beginning to collect data. Behavioral testing is best done in dedicated space free of extraneous noise and odors and with good temperature control and with consistent lighting. Equipment should be wiped down after use with non-perfumed cleaners. The animals should be transported to the testing area well ahead of the test session and be allowed time to acclimate to any enclosures, which are used prior to beginning testing. Experiments should take place at the same time each day. Data tend to be most reliable if the animals are handled gently by the same individual during all test sessions.

The specific assays also should be performed meticulously. For example, the equipment should be the same for all experiments within a single group of studies. When using the paw flick apparatus, the glass surface should be allowed to reach target temperature well before the animals are placed upon it. The stimuli need to be applied in the same manner to a consistent area of the hind paws. The von Frey fibers need to be calibrated periodically, and damaged fibers replaced. Other parameters like the time between application of stimuli and the number of times a stimulus is applied should be standardized for a group of studies.

See Table 11.13.1 for common problems and their solutions.

Anticipated Results

The specific reproducibility of results and variance within the data collected will be influenced by many factors, some within the control of the investigators and some particular to the nature of specific protocols (Table 11.13.2). The thermal paw flick protocol has been used

Table 11.13.1 Troubleshooting Guide to Assessment of Sensory Neuropathy

Problem	Possible cause	Solution
Day-to-day baseline thermal latencies differ by >10% in control animals	Difference in acclimation period	Allow consistent period of acclimation >20 min
	Altered stimulus strength	Check lamp output
	Urine/feces on test surface	Clean surface
	Handling/husbandry changes	Maintain consistent conditions
Day-to-day baseline mechanical thresholds differ by <10% in control animals	Difference in acclimation period	Allow consistent period of acclimation >20 min
	Handling/husbandry changes	Maintain consistent conditions
	Changes in von Frey fibers	Recalibrate instrument
		Recalibrate von Frey fibers

Table 11.13.2 An Example of Data Obtained

	Thermal testing	Mechanical testing
Baseline	12.0 ± 1 sec	15.0 ± 1 g
Mild neuropathy	10.0 ± 1 sec	10.0 ± 1 g
Severe neuropathy	8.0 ± 1 sec	4.0 ± 0.5 g

Table 11.13.3 Response Pattern[a]

Fiber (g)	Response
2.00	O
3.63	O
5.50	X
3.63	O
5.50	X
3.63	O
5.50	X

[a]The value for Xf is 0.74, the value for δ is 0.224 and the value for κ is –0.458. The calculated value for the 50% threshold would be 4.34 g. This is an intuitively reasonable answer for the interpolated threshold since the 5.50 g fiber always yielded a response while the next lower 3.63 g fiber never caused a response.

by many investigators to identify changes in latencies as small as ~10% of the baseline or control values. For many treatments, the changes in mechanical thresholds tend to be more robust allowing greater sensitivity in detecting neuropathy when using mechanical assays. With preliminary data in hand, individual investigators can undertake power analyses to predict sample size requirements for particular protocols. Generally significance is sought at the 0.05 level with power of ≥90%. Group sizes of six to ten are employed by most investigators.

Analysis of the data collected will be influenced by the design of the actual experiments. In most experiments designed to detect neuropathy during or after exposure to xenobiotics, investigators will have repeated thermal and mechanical measurements for a control and an experimental group of animals. The key comparisons which will be made are: (1) between baseline nociceptive thresholds and those observed on days subsequent to the beginning of exposure to the xenobiotic, and (2) between control and experimental groups at various time points. The withdrawal latencies from noxious thermal stimulation involve time, a continuous variable. The mechanical withdrawal thresholds, if measured using a continuously variable force, can also be regarded as continuous. If a set of von Frey fibers is used according to the up-down paradigm, a more sophisticated analysis is required to determine the 50% response threshold.

The analysis of continuous variables across time and between groups is generally accomplished using a two-way ANOVA analysis with appropriate post-hoc testing. In most instances, testing for significance at the $P = 0.05$ level is considered standard. The amount of variance in the actual data obtained along with the chosen sample sizes may be used to arrive at an estimate of power if that parameter is desired.

The analysis of the non-parametric data obtained from von Frey mechanical testing is substantially more complex. A detailed discussion of the processing of such data can be found in the article by Chaplan et al. (1994) in which the approach to determining the 50% mechanical response threshold is presented. This interpolated parameter is the fiber stiffness necessary to cause a withdrawal response 50% of the time. In practice, the 50% response threshold in gram units is calculated using the following formula:

$$\text{Threshold(g)} = 10^{(\text{Xf} + \kappa\delta)}$$

Where Xf is the value in $\log_{10}$ units of the final von Frey fiber tested and δ is the mean difference in $\log_{10}$ units between the fiber forces used. For the suggested set of fibers that difference is 0.224. The parameter κ is a tabular value for the pattern of positive and negative responses. A detailed table of the possible patterns of responses and the corresponding κ values is presented by Chaplan et al. (1994). For situations in which no response is obtained for any fiber, the top fiber stiffness of 15.1 g is assigned. For situations in which responses are obtained with every fiber leads to a response, the value of the least stiff fiber is assigned. An example calculation can be seen in Table 11.13.3.

Time Considerations

The majority of the time involved in both of the tests is spent in transporting animals to the testing area, warming up the apparatus,

and allowing the animals to acclimate to the test chambers. Most of the commercial thermal paw flick devices take from 30 to 60 min to reach target temperature. With both techniques, ~20 min are required for the acclimation process. If the specific experimental design and available equipment requires that animals are tested in several groups, the total time can be quite lengthy.

Thermal paw flick testing, once the animals are acclimated, takes only a few moments for each measurement with two to three total measurements being made separated by ~5 min. For mechanical testing, ~2 min is required for each animal. In a typical experiment where two groups of eight rats are involved and four animals can be tested at a time with either technique, investigators generally test one group of rats while others are acclimating in the enclosures for the complimentary technique. The total time, including the waiting for acclimation, to do all of the behavioral testing for the two groups would be ~90 to 120 min.

Methods to Produce Brain Hyperthermia

Knowledge of the adverse effects of hyperthermia that are induced in human populations is limited. Sporadic reports in the past indicate that the central nervous system (CNS) is markedly affected by hyperthermia caused by seasonal increases in ambient temperature (Sharma and Hoopes, 2003; Sharma, 2004a). It is still not known, however, whether the sensitivity of the CNS to heat or the intensity of heat-related illnesses in human populations is influenced by acute or chronic vascular diseases; immunosuppression; or cardiovascular, renal, or pulmonary ailments. Thus, carefully controlled studies using hyperthermia in experimental models are needed to clarify these points.

Suitable animal models of hyperthermia that mimic clinical conditions have not been available thus far. The existing methods to induce local hyperthermia or whole-body hyperthermia (WBH) are based largely on the principles of heat treatment of tumors (Sminia et al., 1994). In these models, excessively high exposure temperatures (40° to 60°C) are used to induce local hyperthermia or WBH, which results in the death of a large number of animals. Moreover, these animal models of hyperthermia are not comparable to the local environmental situations to which human populations are normally exposed. Another model of hyperthermia has been developed to induce heat stroke in rats, rabbits, and other small mammals. The stroke models also use exposure to extreme temperatures (40° to 50°C) for 30 min to 2 hr. Because the skin temperature of laboratory animals varies between 21° and 26°C, exposure to such a high ambient temperature may result in an excessive thermal response, leading to a quick rise in body temperature above 41°C and thus causing death.

While keeping these methods in mind, the author has developed a rat model of mild hyperthermia in which the animals are exposed to 38°C for 4 hr; this method is described in the Basic Protocol. This mild hyperthermia model does not produce heat stroke and is quite comparable to average weather situations during summer months in various parts of the world including Europe and America. Alternate Protocols 1 and 2 describe two methods for inducing hyperthermia in anesthetized rats. Using this model, structural and functional changes in brain and spinal cord can be seen (Sharma, 1982, 1999). Support Protocol 2 describes the analysis of blood-brain barrier (BBB) permeability following heat stress, and Support Protocol 3 presents an easy method for measuring brain (or spinal cord) edema. Thus, the model could be useful for studying hyperthermia-induced brain dysfunction. Support Protocol 1 describes a method for quantifying the heat stress response through the analysis of gastric ulceration.

The influence of drug treatments on heat-related illnesses can also be examined using this model. Although most studies that used this model were performed on rats, it is quite likely that the model can be of use to study heat-related disorders in other small laboratory animals such as mice, guinea pigs, rabbits, and hamsters. A considerable number of human populations are suffering from cancer, diabetes, hypertension, and other heart-related illnesses. This model can be used to expand our knowledge of the sensitivity of heat-related illnesses to chronic disease conditions as well. This can be achieved by adjusting the specific modalities of heat stress (i.e., exposure temperature and duration) and by examining various stress-induced parameters in normal animals compared with animals subjected to experimental disease states.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

PRODUCING HYPERTHERMIA IN THE UNANESTHETIZED RAT

Further investigation using a suitable model of heat stress is needed to understand the cellular and molecular basis of the heat-induced adverse reaction in the body and to explore new therapeutic strategies in the field. This protocol results in the exposure of an unanesthetized rat to mild hyperthermia for a moderate period of time. It is also suitable for inducing hyperthermia in mice.

Materials

Rats or mice (age and sex controlled)
Paraffin oil *or* glycerine
70% (v/v) ethanol

Thermistor probe (see Internet Resources) suitable for rats or mice
Waterproof marker
Plastic cage, medium size
Thermometers, digital or ordinary mercury, with ±0.1°C accuracy
Biological oxygen demand (BOD) incubator (e.g., BS Pyromatic India, Asco, Raj Scientific Industries) or comparable heat chamber, preheated to desired temperature (e.g., 38°C)

Acclimate animal

1. One week prior to the experiment, take a rat or mouse from its cage by gently handling the animal. Do not lift the animal by the tail.

   Handling stress increases body temperature by approximately ±0.5° to 1°C. Maneuvers regarding measurement of rectal temperature also cause stress in animals, which raises body temperature (Fig. 11.14.1). Thus repeated handling is necessary to minimize stress effects during body temperature measurements.

   Lifting by the tail will induce severe stress in animals (i.e., it will increase their heart rate and respiration).

   Good-quality sterile gloves should be used while handling the animals to avoid accidental bites.

2. Place animal on a weighing pan large enough for easy movement. Record body weight, age, sex, and source of the animal. Also record date and time of the experiment.

   A preweighed restraint box, which will create unnecessary stress in the animal, should not be used.

Figure 11.14.1 *(at right)* Changes in (**A**-**C**) body temperature, (**D**) pain perception, (**E**) body weight, and (**F**) salivation in control and heat-stressed rats. (A) Handling alone alters the rectal temperature for 1 to 4 days; the rats then adapt to handling stress from day 5 onwards. A minimum of 7 days handling is necessary to avoid stress in animals. (B) Subjection of rats to heat stress at 38°C in a biological oxygen demand (BOD) incubator results in graded hyperthermia that is most severe after 4 hr. (C) The magnitude of hyperthermia is considerably less when rats are exposed to heat at 36°C. (D) Measurement of tail flick response in heat-exposed rats at 38°C did not show an analgesic or hyperalgesic response. This indicates that heat exposure did not influence normal pain pathways. (E) Changes in body weight during heat exposure of rats at 38°C. Less intake of water and evaporative heat loss through salivation appear to be the important factors in reducing the weight of rats exposed to heat stress. A significant reduction in body weight is seen after 4 hr of heat exposure. (F) Spread of saliva over snout of rats exposed to heat at 38°C. The area of spread (in millimeters) is maximum following 4 hr heat exposure in rats. This suggests that rats subjected to 4 hr heat stress did not develop heat stroke, which stops the production of saliva (see Background Information). $^{*}P < 0.05$, $^{**}P < 0.01$; ANOVA followed by Dunnet's test for multiple group comparison with one control group (A-E) or with the 30-min group (F). Values are mean ± SD of six to eight rats in each group.

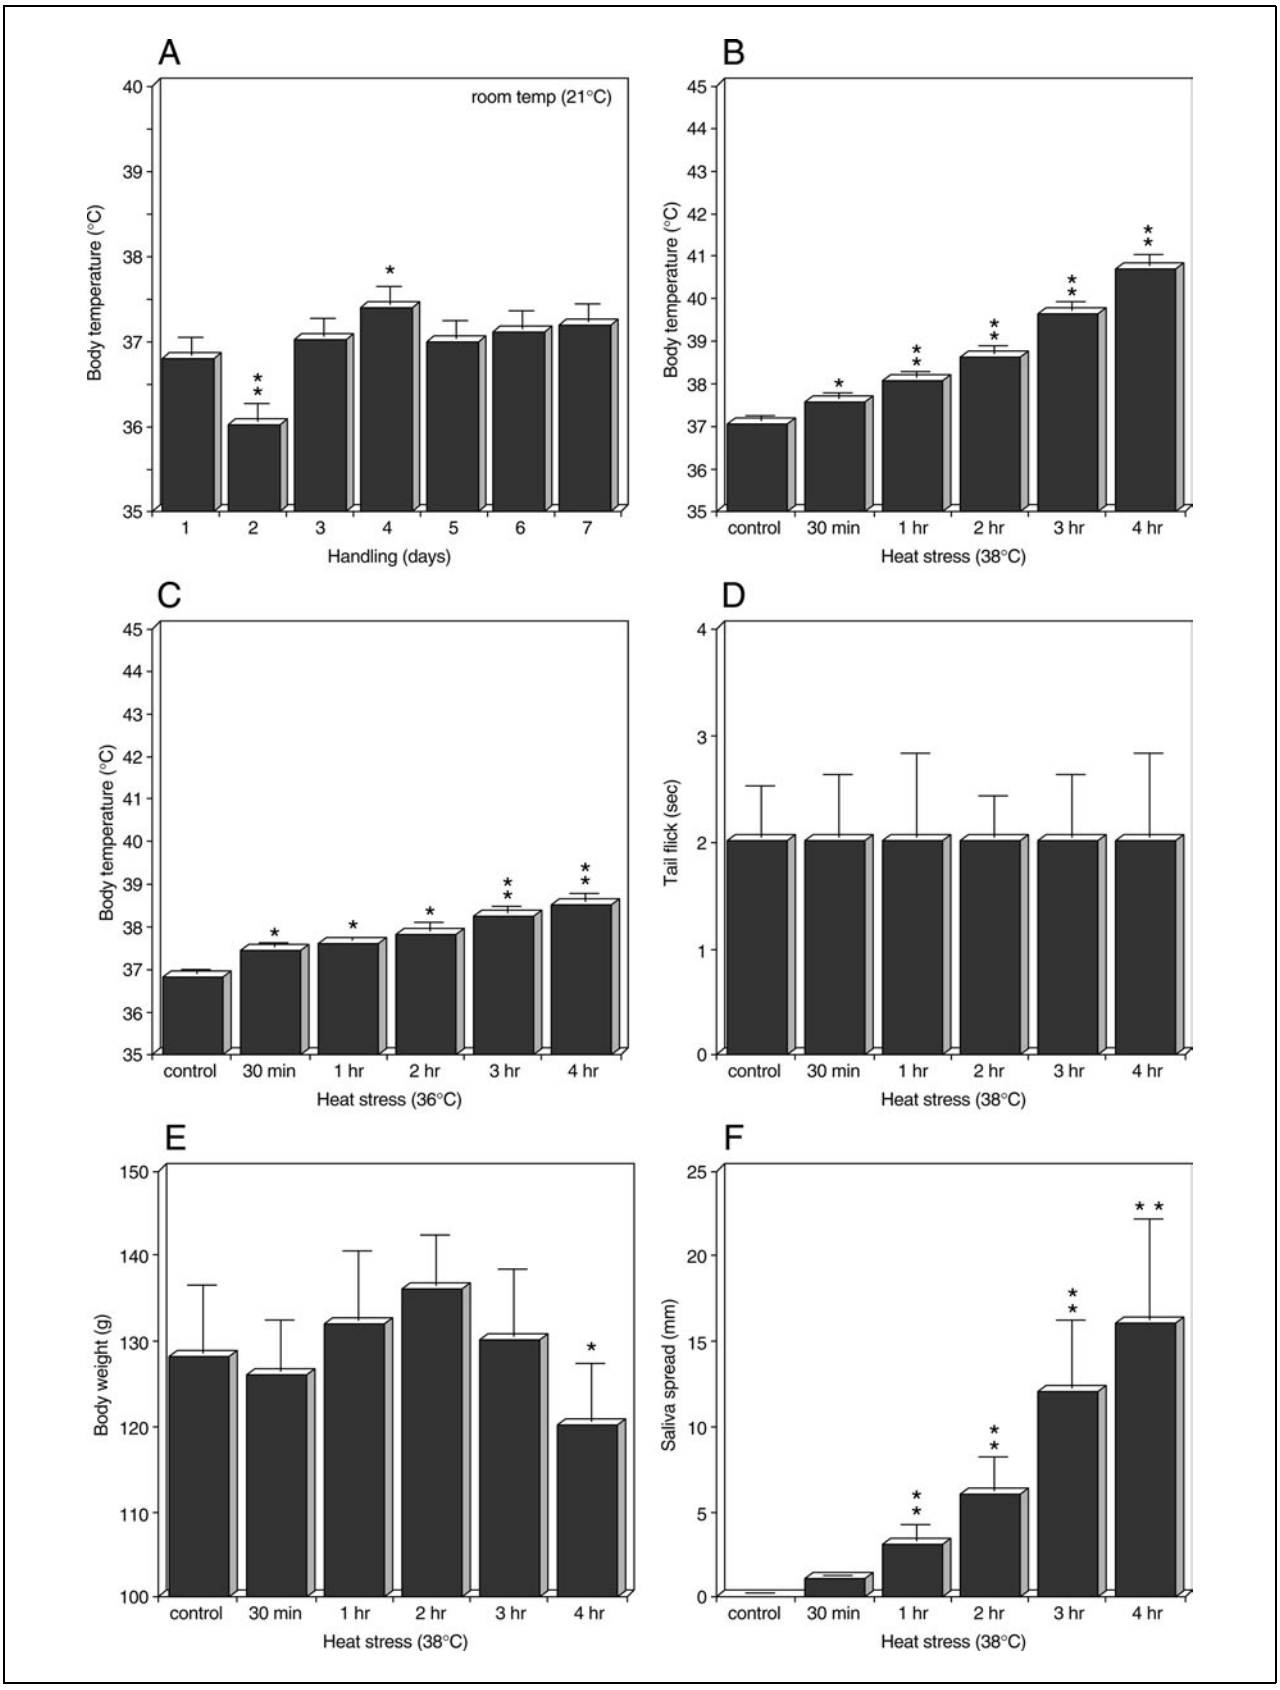

Figure 11.14.1 Legend at left.

Table 11.14.1 Heat Stress Model in the Rat[a]

Heat stress	Skin temperature (T_s)	Exposure temperature (T_e)	Heat load ($T_e - T_s$)	Relative humidity (%)	Wind velocity (cm/sec)	Exposure (hr)
BOD incubator	24°–26°C	36°–38°C	12°–14°C	47–50	24–26	1–4 (acute)
Room temperature[b]	24°–26°C	34°–36°C	10°–12°C	45–47	20–24	8–9 (1 week)

[a]Abbreviation: BOD, biological oxygen demand. Data modified from Sharma (1982) and Sharma and Dey (1987).
[b]Rats were kept at uncontrolled room temperature during the summer.

3. Hold animal gently by hand using its back skin. Avoid deep pressure on animals.
4. Dip a thermistor probe in paraffin oil or glycerin and gently insert probe deep into the rectum. Insert probe 2 cm for a mouse and 4 cm for a rat to obtain deep visceral temperature (i.e., liver temperature). Hold probe in place ≥60 sec to record a stable temperature.

   Thermistor probe size should vary according to the animals used. It is always good to have thinner thermistor probes (o.d. ~3 mm) suitable for rats or mice.

   The probe must be inserted very gently to avoid damaging internal organs and internal bleeding or microhemorrhages. For this purpose, the insertion depth should be carefully marked on the probe.

   Sometimes it is advisable to wrap the tail and the probe with adhesive tape.
5. Take the probe out gently and return animal to its cage. Clean the probe first with cotton followed by mild soap and water and sterilize it with 70% ethanol or as directed by the manufacturer. Be very careful to avoid damaging sensors on the tip of the probe.

   Care should be taken that animals don't bite the sensors

   Liquid paraffin (also known as paraffin oil or light white mineral oil) is applied topically to the thermistor. The liquid paraffin does not contain any stimulant or irritant and exerts no osmotic action. Its main use is as a lubricant, and very little of it is absorbed by the body. Its use in rectal temperature measurement is highly recommended because of its innocuous nature. Furthermore, it covers fecal masses and thus prevents absorption of toxins that may interfere with body temperature measurements.
6. Repeat steps 1 to 5 daily for all animals for 7 days.

   To avoid circadian variation, temperature measurements should be carried out at approximately the same time (±30 min) on each day.

Perform heat stress experiment

7. Place a thermometer on each shelf of a 38°C BOD incubator. Take the frontal temperature reading and compare with the inside manual thermometer. Confirm that all three temperature readings show 38°C (±0.1°C). Adjust the set temperature if needed to produce a consistent internal temperature of 38°C.

   One frequently used heat chamber is known as a BOD incubator (Table 11.14.1). The BOD incubators are made of double-wall steel construction for superior insulation and are equipped with forced air circulation for temperature uniformity inside the whole chamber (±0.5°C). These incubators can be used at a temperature range of +5° to +60° C with a precision of ±0.5°C.

   Poor air circulation within the chamber can lead to temperature variations at different shelves. If this is the case, the fan speed and air circulation should be checked.

8. At intervals of 10 to 15 min, remove an animal from its cage and record its body weight and body temperature (steps 1 to 5). Mark each animal with waterproof ink using numbers on the dorsal surface of the tail or by one to six encircling parallel lines as suitable according to the experimental set up.

   Depending on the animal handler's experience, an interval of 15 to 20 min may be used, along with a smaller number of animals for a given experiment (e.g., three to five rats), to allow adequate time for temperature measurement (step 13a or 13b).

9. Transfer animal to a medium-sized plastic cage in the BOD incubator. Place two or three animals in the cage and record the order in which they were added. Do not place more than two cages in the incubator per session and do not adjust the temperature during the first 10 min.

   For mice, two or three animals can be placed in a small-sized cage to save floor space, but crowding stress must be avoided and one must be able to record the movement and behavioral symptoms properly in individual animals. Also, placing more than six rats or mice in a BOD at once may cause minor changes in blood gases.

   Cages should contain suitable water bottles and, depending on the experimental design, food pellets.

   Placing rats into the chamber will lower the temperature slightly (±1°C) for some time (<10 min). Do not attempt to correct the internal temperature by increasing the temperature set on the front panel. The temperature is normally restored within 5 to 10 min.

Observe animal behavior

10. Observe each animal carefully from the glass window by opening the outer metal door of the BOD incubator. Follow the behavior at regular intervals (∼30 min) and look for mechanisms of heat loss (step 11) and indications of heat exhaustion (step 12; Table 11.14.2) according to the experimental protocol.

    Opening the outer metal door will not affect the internal heat chamber temperature.

    Initially, movement will increase. Exploratory behavior and an increase in locomotion, playing, and sometimes fighting is mainly due to an initial reaction to warm stress.

11. Score the incidence of spreading saliva over the snout and on parts of the belly.

    Salivation is the spreading of saliva over the snout and also on parts of the belly as an effective mechanism for heat dissipation. Because rodents lack sweat glands, this is their only effective means of lowering body temperature. Under extreme conditions, the belly

Table 11.14.2 Stress Symptoms and Physiological Variables in Control and Heat-Stressed Rats[a]

Parameters examined	Control[b] ($n = 8$)	Heat stress at 38°C in BOD chamber		
		1 hr ($n = 6$)	2 hr ($n = 8$)	4 hr ($n = 12$)
Rectal temperature (°C)	37.42 ± 0.23	38.41 ± 0.23*	39.24 ± 0.21**	41.48 ± 0.23***
Salivation	none	++	+++	++++
Prostration	none	none	none	++++
Gastric hemorrhage[c]	none	4 ± 3	8 ± 3	34 ± 8 (microhemorrhages)

[a] Abbreviations: BOD, biological oxygen demand; ++, mild; +++, moderate; ++++, severe; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$, Student's unpaired *t*-test. Data modified from Sharma (1982) and Sharma and Dey (1986b, 1987).

[b] Control rats were kept at room temperature (21° ± 1°C).

[c] The term microhemorrhages indicates that the mucosal lining of the stomach in certain regions has become proliferative and shows signs of bleeding, but individual hemorrhagic spots can not be identified (see Support Protocol 1).

can also be wet, but this may be caused by discharge of urine. Thus, spreading of saliva on the snout is a more reliable index.

The magnitude and intensity of salivation can be assessed qualitatively by observing the spread of saliva over the snout and belly. Saliva spreading over the snout is progressive in nature (Fig. 11.14.1). This can also be measured in millimeters after taking the animals out of the chamber for a short duration or at the end of the experiment.

Animals are most often observed to exhibit gnawing behavior, followed by sniffing and licking. These are normal behaviors in rodents that can become more frequent during the initial exposure (1 to 2 hr) to heat stress.

12. Carefully observe animals from 3 hr to end of experiment and score for prostration. Be certain that animals' snouts and nostrils are clear of obstructions (e.g., cage wall or small particles) during any heat prostration episodes.

The state of heat exhaustion is reflected by heat-induced prostration behavior that normally starts after 3 hr of heat stress (Table 11.14.2). In this situation, locomotion is depressed and animals become lethargic. Most animals remain confined to the corner of the cage in close association with other animals. The animals lie flat in a supine position and normally do not move. Their righting reflexes are not, however, lost. Most animals do not even move after gentle pushing. This stage is known as heat-induced prostration. At this stage the respiratory and heart rates are increased.

Heat-induced prostration can be graded qualitatively. The animals that do not move even after gentle pushing exhibit a maximum score for heat prostration. Simply lying in a prone or supine position for more than 2 min can be regarded as mild prostration.

If breathing is obstructed during heat prostration, death will occur because of asphyxia and not because of heat stress. Thus, careful monitoring of the animals from 3 hr of heat exposure and onwards is necessary.

Body temperature can be recorded once at the end of heat exposure or multiple times during the exposure.

Record body temperature

13a. *To record body temperature at the end of heat exposure:* Remove rats from the incubator one by one (separated by 5- to 10-min intervals) in the same order as they were placed in the cage (step 9). Record their body temperature at room temperature (steps 3 to 5).

Because the rats have been handled regularly and the measurements have been repeated often, only 2 to 3 min is needed for each rat.

Rats may be wrapped with a cotton towel during the recording of their body temperature. This will avoid additional temperature stress (difference between the heat chamber and room temperature). The body temperature can show a variation of $\pm 0.5^{\circ}C$ with or without the towel. (In hyperthermia experiments, changes in body temperature $>0.3^{\circ}C$ are considered significant.)

13b. *To record body temperature during heat exposure:* Remove a single animal from the cage in the chamber. Wrap it loosely with a cotton towel and record its body temperature (steps 3 to 5). Return animal to the cage in the heat chamber and wait 10 min before removing the next animal.

The heat chamber takes 5 to 6 min to readjust the temperature after an animal is removed and returned.

14. Record the body weight of individual animals after heat stress.

Most dramatic changes in body weight can be seen in animals between the third and fourth hours of heat exposure. This is the period when hyperthermia is most marked. Usually there is a decrease in body weight (<5% to 7%) after a 4-hr exposure. During this time, animals normally do not drink water. The spread of saliva and evaporative water loss could partially account for such a loss in body weight (Fig. 11.14.1).

HYPERTHERMIA INDUCED BY AN INFRARED HEAT LAMP

ALTERNATE PROTOCOL 1

Anesthetized animals can be exposed to hyperthermia using a heat lamp. Using an infrared heat lamp to induce hyperthermia is safe and also provides the opportunity to maintain the body temperature at any desired level (e.g., 42°C) for some time. This method represents passive heating, however, as physiological and psychological components of heat stress are lacking. In addition, the counter mechanisms to cope with the stress are seldom activated. This is evident by the fact that stress ulceration in the stomach is largely absent. On the other hand, the molecular mechanism of hyperthermia-induced cellular response appears to be activated by this method, as shown by the expression of heat shock proteins in the CNS and other tissues. Furthermore, histopathological examination of brains in these animals after 1 or 2 days survival following heat treatment shows mild to moderate cellular damage (H.S. Sharma, unpub. observ.). Thus, the method can be used to study the adverse effects of heat on CNS function.

Additional Materials *(also see Basic Protocol)*

Anesthetic (see Background Information and see Critical Parameters)
75-, 150-, or 200-W infrared lamp

1. Anesthetize a rat or mouse with a suitable anesthetic as permitted at your institution.
2. Insert a thermistor probe as described (see Basic Protocol, steps 3 and 4).
3. Expose animal to a 75-, 150-, or 200-W infrared lamp at a distance of 15 to 20 cm, while continuously recording body temperature.

   Care should be taken to avoid excessive heat on skin or localized heating at any point.

   The body temperature gradually rises (~1°C within 10 to 15 min depending on the wattage of the lamp used).

4. Adjust lamp height to control the body temperature rate of rise. When body temperature reaches the desired level (most commonly 42°C), maintain it for 15 to 30 min.

   Animals under anesthesia can tolerate a rectal temperature of ≤42°C. The animal may die, however, if body temperature is >42°C (i.e., 42.5°C).

5. Allow animal to revive from the anesthetic and return it to the appropriate cage.

   In these animals, no stress symptoms can be seen during heat exposure. Microhemorrhages in the stomach are also seldom seen in this model.

HYPERTHERMIA INDUCED IN HEAT CHAMBERS USING ANESTHETIZED ANIMALS

ALTERNATE PROTOCOL 2

Anesthetized animals can be exposed to elevated temperatures in heat chambers to induce hyperthermia. This method lacks the physiological and psychological effects of heat on the animals. In addition, the counter-physiological mechanisms to avoid heat are not activated; passive heating is induced, and thus the body's response to thermal stress is lacking. This method is useful, however, for studying hyperthermia-induced changes in organ function. It also results in a very low (and predictable) death rate. Using an anesthetized animal allows exposure to higher temperatures and allows exposure for a longer length of time. It is also an experimental approach that may be more readily accepted by an Institutional Animal Care and Use Committee. This protocol uses an exposure temperature of 42°C, but other temperatures can be used.

Additional Materials *(also see Basic Protocol)*

Anesthetic (see Background Information and see Critical Parameters)

1. Anesthetize a rat or mouse with a suitable anesthetic as permitted at your institution.
2. Insert a thermistor probe as described (see Basic Protocol, steps 3 and 4).
3. Place animal in a suitable cage in a 42°C BOD incubator (see Basic Protocol, step 7) for the duration of the exposure.

   These animals can be exposed to excessively high temperatures (i.e., 40° to 45°C) for a short duration of 30 min to 1 hr. The body temperature rises gradually in anesthetized rats or mice and may reach the exposure temperature within 1 hr.

   A laboratory incubator with free-flow air facilities can sometimes be used successfully instead of a BOD incubator.

4. When the body temperature reaches 42°C, maintain it for 30 min to 1 hr by adjusting the exposure temperature.

   For effective heat treatment, animals should be exposed for 1 hr. The death rate is very low and a fixed body temperature can be maintained according to the experimental design and purpose. Prolongation of heat exposure in the chamber or increasing the exposure temperature further will result in animal death, however, because of excessive heat-induced membrane and/or enzymatic damage. Thus care should be taken to avoid any further increase in body temperature >42°C.

   Under anesthesia, the control of thermoregulation is normally nonexistent. The increase in body temperature depends mainly on the level of the exposure temperature. Thus, if the anesthetized rats or mice are placed in a 38°C incubator, then their body temperature reaches 38°C within 1 to 2 hr and can be maintained for a long time (Sharma, 1982, 1999).

   For longer experiments, administration of additional anesthetic will be necessary (at ~1-hr intervals). If done properly, this will not alter the body temperature significantly. The average worker can easily administer anesthetics intraperitoneally (or by an other route) within 30 to 45 sec.

SUPPORT PROTOCOL 1

POSTMORTEM EVALUATION OF HEAT STRESS: MICROHEMORRHAGES IN THE STOMACH

Heat stress induces gastric ulceration in animals. The magnitude and intensity of gastric ulceration depend on the exposure temperature and duration (Sharma, 1982). In some cases, one can see individual hemorrhagic spots over a part of the mucosa or at various places in the inside of the stomach (Filaretova et al., 1998). In other cases, the mucosal lining of the stomach in certain regions has become proliferative and shows signs of bleeding, but no clear spots of hemorrhage can be identified (Toth, 1989). This situation is referred to as microhemorrhages. In cases where microhemorrhages are visible, some haemorrhagic spots may also be observed in other regions of the stomach in the same animal (e.g., Table 11.14.2).

To evaluate the individual responses of animals to heat stress, gastric ulceration should be evaluated at postmortem examination. The timing of euthanasia will depend on the experimental design and might be immediately after heat stress or hours or days after the initial heat exposure. Animals can be decapitated or they can be given an overdose of anesthetic to induce deep sleep before they are sacrificed.

Open the abdomen of a euthanized heat-stressed animal and remove the stomach. Make a midline incision into the stomach and wash the contents inside the stomach gently under running tap water at room temperature. Examine the mucosal wall of the entire stomach for microhemorrhages or petachae under a magnifying lens (fixation of the stomach in

formalin is not necessary). Many microhemorrhages are visible in the mucosal wall of the stomach as well as in the fundic and pyloric mucosa. Sometimes hemorrhagic spots are also seen that can be counted manually. Although hemorrhagic spots may heal to some extent after the heat stress is over, this process requires weeks and perhaps months to occur.

ASSESSING CHANGES IN BRAIN FUNCTION AFTER HEAT EXPOSURE

Apart from behavioral alterations, hyperthermia, and gastric ulceration following heat exposure, there are also subtle changes in brain function that can be evaluated within a short time. Some of the common changes in the brain following heat stress are alterations in the blood-brain barrier (BBB) permeability and development of vasogenic brain edema. Breakdown of the BBB can be visualized using several innocuous dyes, such as Evans blue, which normally binds to serum proteins after its administration into the circulation. Extravasation of Evans blue dye in the brain can be seen visually and can be documented using macrophotography (see Support Protocol 2). Alternatively, the dye that has entered the brain can also be measured using colorimetry (Sharma and Dey, 1986a). A change in BBB permeability is a measure of altered brain function, as this will induce changes in an electroencephalogram and may induce brain edema formation. The breakdown of the BBB to proteins, as shown by leakage of Evans blue, is associated with vasogenic brain edema formation and impairment of neuronal function. Edema is defined as an increase in water content that results in volume swelling of the brain. The brain water content can easily be measured (see Support Protocol 3).

Measuring Blood-Brain Barrier Permeability to Evans Blue

SUPPORT PROTOCOL 2

Evans blue (T-1824), an azo-dye, binds to serum proteins in vivo and is commonly used to determine blood volume in humans. In normal animals, the dye does not stain the brain or spinal cord because of the presence of a tight barrier between blood and brain (Rapoport, 1976). The other organs and tissues of the body are, however, stained deep blue. Thus, leakage of dye into the brain or spinal cord in experimental situations suggests a leaky blood-brain barrier (BBB). Extravasation of Evans blue in brain or spinal cord can be examined visually and eventually measured biochemically (Sharma and Dey, 1986b).

NOTE: Although this is a terminal procedure, infection can influence hyperthermia and blood-brain barrier permeability and thus all equipment and reagents used for surgical procedures should be sterile.

Materials

Rats or mice, control and heat-exposed
Equithesin solution (see recipe)
2% (w/v) Evans blue solution (see recipe)
Physiological (0.9% w/v NaCl) saline, room temperature and 4°C
4% (w/v) paraformaldehyde fixative (see recipe), optional

1-ml glass or plastic syringes, sterile
26- to 28-G needle (o.d., 0.3 to 0.4 mm)
Surgical instruments:
- Scalpel
- Forceps
- Fine scissors

Magnifying glass or stereomicroscope
Cotton wool, sterile

Intravenous perfusion setup, including infusion needle
21-G butterfly cannula (o.d., 0.8 mm)
2- or 3-way connector, optional

Additional reagents and equipment for sectioning rat brain, optional

Administer dye

1. Anesthetize a rat or mouse with equithesin anesthesia.

   In control animals, 0.3 ml/100 g body weight of equithesin is required. For heat-stressed animals, the dose should be reduced by 40% to 50%. Thus, 0.15 to 0.2 ml/100 g is sufficient to achieve the same grade of anesthesia in heat-exposed rats or mice.

2. Load a sterile 1-ml glass or plastic syringe with 2% Evans blue solution. Use 0.3 ml solution/100 g body weight.

   Usually, 0.3 ml/100 g body weight of Evans blue solution is sufficient to bind >70% of the plasma albumin in rats (Rapoport, 1976). About one molecule of Evans blue dye binds to twelve molecules of plasma albumin in circulation. Thus, enough Evans blue should be administered to bind ≥60% of plasma albumin (Sharma, 2004a).

3. Attach a 26- to 28-G hypodermic needle to the syringe and ensure that no air bubbles are present. Wipe off any dye that has leaked through the needle tip.

   Leakage of dye will stain the tissue immediately so that visualization of blood vessels is difficult.

4. Using a scalpel, excise the skin over the ventral surface of one hind leg to expose the femoral vein (∼6 to 8 mm). While working under an ordinary magnifying glass or stereomicroscope, carefully expose the femoral vein and remove membranes surrounding it. Regularly apply physiological saline to the exposed tissue and blood vessel to prevent drying.

   This will also help in clearly identifying the femoral vein.

5. Puncture the femoral vein with bevel of the needle facing upwards and insert needle ∼2 to 3 mm into the vein. Inject dye very slowly at first to see that the femoral vein is punctured correctly. When dye enters the vein freely, administer dye slowly at ∼0.8 to 1 ml/min. After completion of dye administration, carefully remove needle and plug the punctured vein with sterilized cotton wool with a little pressure.

   This will stop the bleeding within 5 to 10 sec.

6. Allow Evans blue dye to circulate for ≥5 min.

   The circulation time for dye (5 to 15 min) will not influence the permeability. This is because once the dye enters the brain it will bind to brain tissue for a long time. The circulation time for the dye (∼10 min) should, however, be kept fairly constant in a particular experimental group.

7. Attach tip of an infusion needle to a 21-G butterfly cannula and set up a commercial perfusion set to administer intravascular saline. Hang the saline perfusion bottle at 122.4 cm above the table. Check the flow of saline and remove any air bubbles from the tubing before perfusion.

   A saline perfusion bottle hung at a height of 122.4 cm corresponds to 90 mm Hg pressure multiplied by 13.6, the specific gravity of mercury, to correct the water column pressure.

8. Open the chest with a midline incision of the skin and cut the diaphragm to expose the heart. Using forceps lift the right auricle and cut with fine scissors.

9. Hold the butterfly cannula with the right hand while system is closed and gently lift the heart from the viscera and insert cannula into left ventricle. To confirm that the needle is in the left ventricle, watch for a free flow of blood into the cannula. Open the perfusion system to allow saline perfusion through the heart.

   The intracerebrovascular Evans blue dye should be washed out to assess extravasation of the dye-protein complex in the brain.

10. Perfuse with saline for 45 to 90 sec or until outgoing fluid from the right auricle is colorless.

    Usually, depending on the size of the rat and its blood volume (roughly 7 ml/100 g body weight), 30 to 45 sec is enough to wash out the remaining stained blood from the intracerebral blood vessels.

    Depending on the experimental protocol, the animal can be perfused with a formalin-based fixative or analyzed without fixation.

    Although the following steps are written for analysis of the brain, this will depend on the experimental design; the spinal cord may also be removed for analysis.

Analyze without fixation

11a. Open the skull carefully to expose the brain. Remove brain and place in cold 0.9% saline and examine for Evans blue extravasation (step 16).

    If the need arises, measurement of Evans blue in selected brain areas can be done according to previously published methods (Sharma, 1982; Sharma and Dey, 1986b). Although this method is used in unfixed tissue only, the presence of radioiodine tracers can be measured in fixed tissues as well. In the author's experience, there is no significant difference in radioactivity when counted in either unfixed or fixed material after spinal cord injury (Sharma et al., 1993).

    The brain (and/or spinal cord) should be kept in saline to prevent it from drying out. A wet surface does not, however, produce good photographs. Thus, if photographs of the brain need to be taken, it should be briefly blotted on filter paper and then photographed as quickly as possible before placing it back in saline.

Perfuse with fixative

11b. Set up another perfusion system that is filled with 4% paraformaldehyde fixative. Connect polyethylene tubing from the fixative setup to the butterfly cannula through a 2- or 3-way connector.

    A Somogyi fixative with picric acid (Somogyi and Takagi, 1982) is particularly useful if both light and electron microscopy will be used to analyze the brain sections.

12b. To perfuse the brain, open the connection to the fixative (while closing the outlet for saline) and perfuse brain with ~150 to 200 ml fixative solution (usually 6 to 8 min).

13b. Stop the perfusion by closing the system. Before perfusing another rat with saline, be sure to flush out remaining fixative in the tubing with saline.

    Presence of the fixative in the tubing during the saline perfusion in another rat will fix or coagulate the blood component immediately within the microvessels allowing poor washout of the intracerebral vessels.

14b. *Optional:* For enhanced fixation, completely wrap the whole animal in aluminum foil (excluding tail) and store overnight in a 4°C refrigerator.

    The enhanced fixation step is only necessary to prevent damage to the brain and spinal cord on their external surfaces as they are removed from the skull and the vertebral column, respectively. This is particularly important when the investigator is interested in cell changes or other morphological analyses in the cortex and/or spinal cord.

15b. Dissect out brain and place in the same fixative for 48 hr to 3 days at 4°C.

The dye in the brain will not be diluted or washed out in the fixative if kept at 4°C for ≤3 days. Complete fixation is necessary to provide an accurate assessment of neuronal structure at the microscopic level. Incomplete fixation may lead to compression during sectioning, which can give the false impression of edema, sponginess, and cell damage, even in the brains of normal animals.

Examine for extravasation

16. Visually examine the blue extravasation of dye over the dorsal and ventral surfaces of the brain. Look at the brain texture under a fluorescent lamp (white light) and

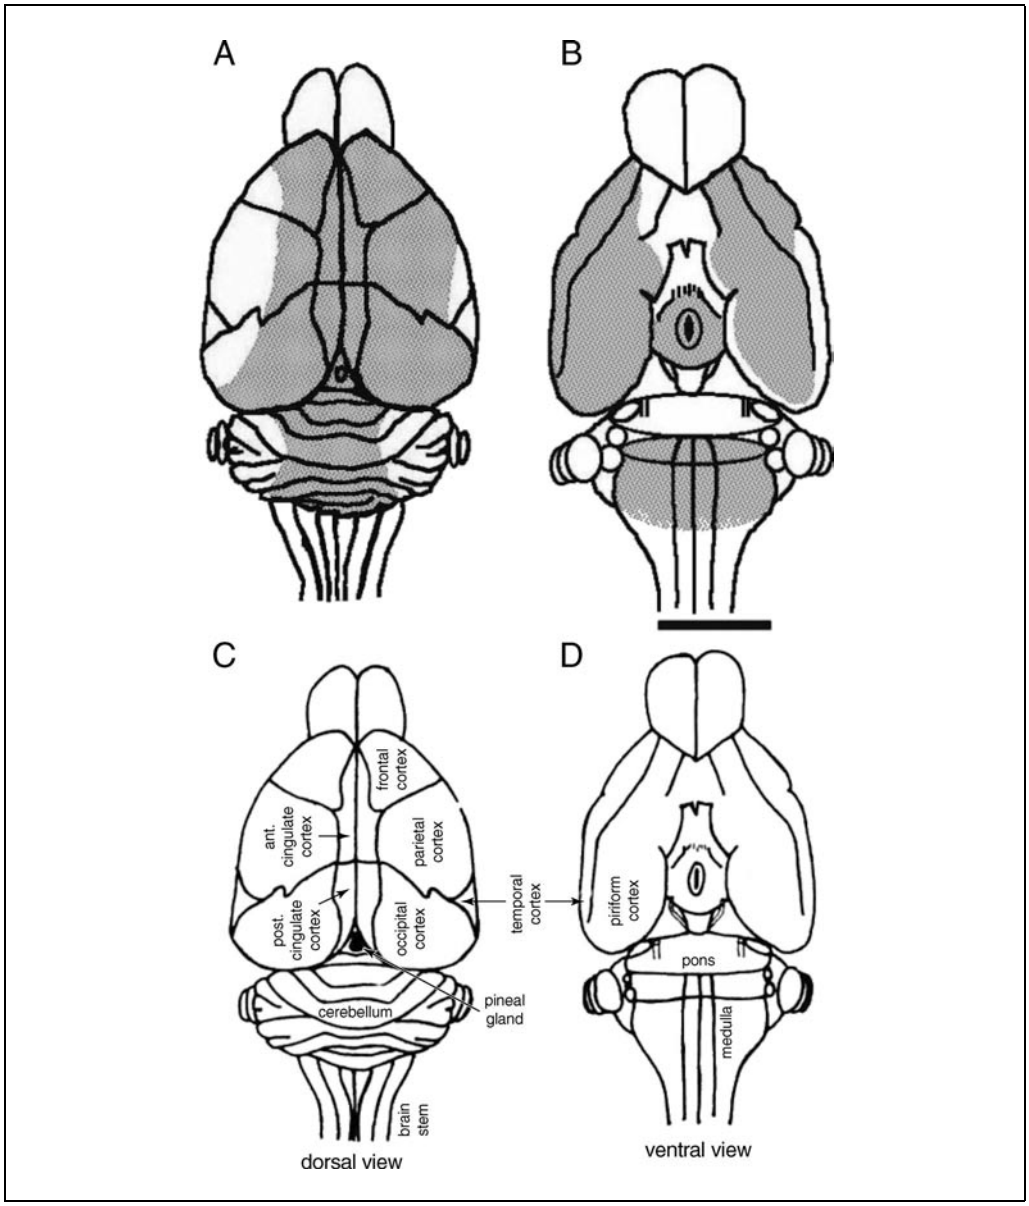

Figure 11.14.2 Representation of Evans blue albumin extravasation on the (**A,C**) dorsal and (**B,D**) ventral surfaces of the rat brain after 4 hr heat stress. Scale bar in B is 4 mm. Different regions of the cerebral cortex are divided using hypothetical solid black lines; extravasation is indicated by the shaded regions. Reprinted from The Blood-Spinal Cord and Brain Barriers in Health and Disease (H.S. Sharma and J. Westman, eds.), H.S. Sharma (2004b), Influence of serotonin on the blood-brain and blood-spinal cord barriers, pp. 117-158 and H.S. Sharma (2004a), Blood-brain and spinal cord barriers in stress, pp. 231-298, with permission from Elsevier. *This black and white facsimile of the figure is intended only as a placeholder; for fullcolor version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

compare with the brain from an normal animal. Identify the pineal gland, which always turns blue.

Extravasation of Evans blue into the cortex may be mild to moderate and may not be as blue as can be seen on the pineal gland. The pineal gland does not have a BBB. The cortical surfaces may turn light to moderate blue in certain areas (Figs. 11.14.2 and 11.14.3).

Pictures of the brain can be taken to document extravasation of Evans blue dye on the dorsal and ventral surfaces (Fig. 11.14.3).

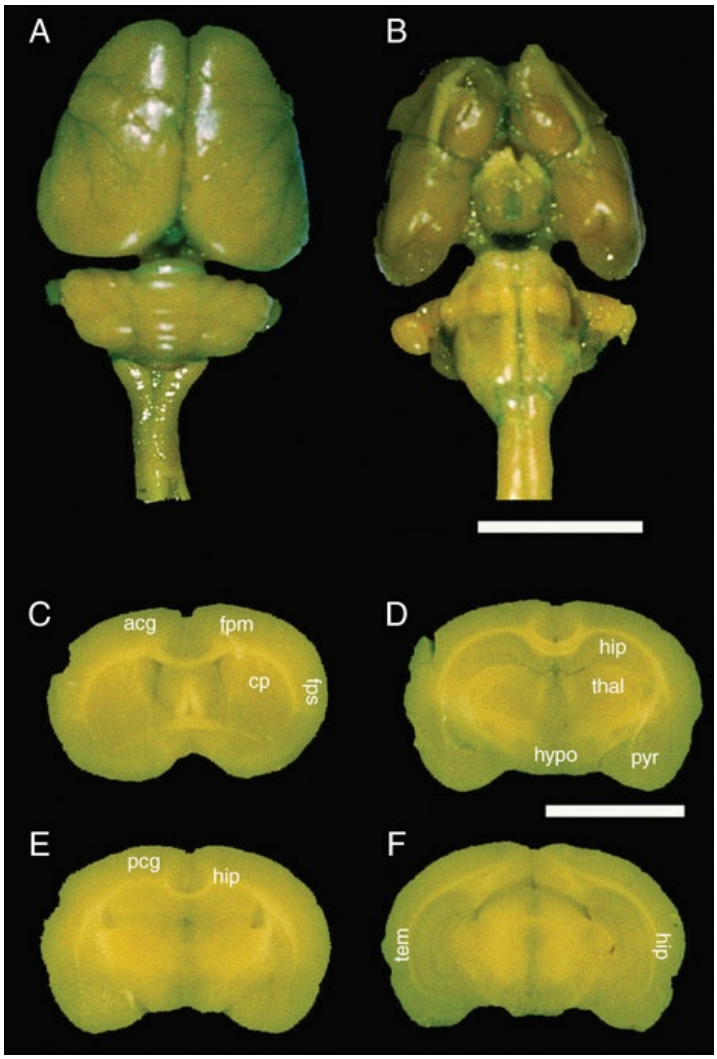

Figure 11.14.3 Evans blue extravasation on the dorsal and ventral surfaces as well as in the deeper parts of the rat brain following heat stress. (**A,B**) Mild to moderate Evans blue staining of somatosensory cortex, pyriform cortex (pyr), cerebellum, hypothalamus (hypo), pons, and brainstem are evident. (**C**-**F**) Coronal sections of rat brain from four different levels showing Evans blue extravasation in deep brain structures, such as (C) caudate-putamen (cp) and (D-F) hippocampus (hip), thalamus (thal), and hypothalamus. Abbreviations: acg, anterior cingulate cortex; fpm, frontal-parietal motor area; fps, frontal-parietal somatosensory area; pcg, posterior cingulate cortex; tem, temporal cortex. Coordinates from the bregma for coronal sections: C, +0.10 to +0.45; D, −3.25 to −3.90; E, −4.20 to −4.60; F, −5.25 to −6.65. Scale bars: B and D, 5 mm. Reprinted from The Blood-Spinal Cord and Brain Barriers in Health and Disease (H.S. Sharma and J. Westman, eds.), H.S. Sharma (2004a), Blood-brain and spinal cord barriers in stress, pp. 231-298, with permission from Elsevier. *This black and white facsimile of the figure is intended only as a placeholder; for fullcolor version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

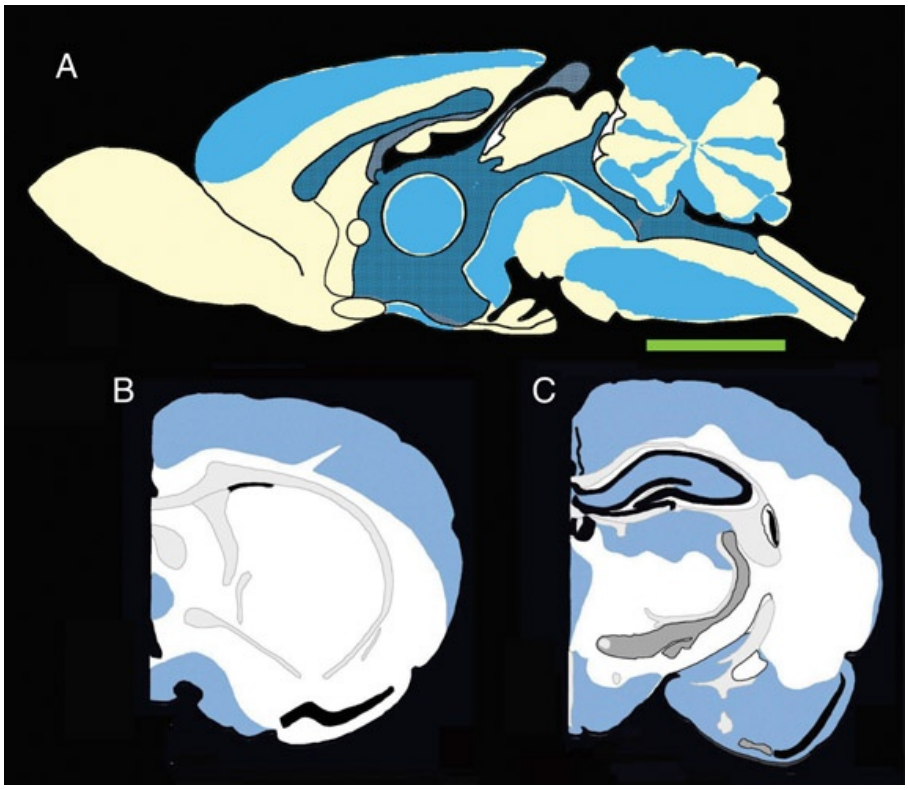

Figure 11.14.4 Extravasation of Evans blue following heat stress. (**A**) Representation of midsagittal section of the rat brain. Staining of cerebroventricular walls of the lateral ventricles, fourth ventricle, and median eminence is apparent. (**B,C**) Cross-sections of the brain passing through the caudate-putamen (+0.45 from bregma for B) and hippocampal (−3.25 from bregma for C) levels showed leakage of Evans blue in the primary somatosensory cortex, pyriform cortex, hippocampus, hypothalamus, and amygdala. Scale bar indicates 5 mm in A and 4 mm in B,C. Reprinted from The Blood-Spinal Cord and Brain Barriers in Health and Disease (H.S. Sharma and J. Westman, eds.), H.S. Sharma (2004a), Blood-brain and spinal cord barriers in stress, pp. 231-298, with permission from Elsevier. *This black and white facsimile of the figure is intended only as a placeholder; for fullcolor version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

17. Make a midline incision to see the inside penetration of the dye. Confirm that the choroid plexus has turned deep blue, as microvessels of the choroid plexus are not affected by the BBB. Examine the ventricular walls, which may show mild or faint blue staining. Using a magnifying lens, identify the extravasation of Evans blue in various regions of the brain.

    The dorsal surface of the hippocampus may also show faint staining as compared with controls.

18. *Optional:* Cut coronal sections (of one or both halves) of the brain at various levels and photograph the sections for documentation, if needed (Figs. 11.14.3 and 11.14.4).

SUPPORT PROTOCOL 3

Measurement of Brain Water Content

Another expected result in hyperthermia is an increase in brain water content representing brain edema formation. Edema is defined as an increase in water content of the nervous system that can occur in specific brain regions following several noxious insults (Cervós-Navarro and Ferszt, 1980; Sharma et al., 1998). Early clinical symptoms of brain edema include headache, nausea, vomiting, disturbances of consciousness, and occasionally coma (Reulen et al., 1990; Ito et al., 1994; Cervós-Navarro and Urich, 1995).

The edema fluid spreads over time and, depending on the magnitude and severity of the primary insult, the whole brain can be swollen within 24 hr (Cervós-Navarro and Ferszt, 1980). Progression of edema leads to herniation of the brain (Rapoport, 1976; Bradbury, 1979). A swollen brain in the closed cranial compartment results in death that is due to compression of vital centers and/or vascular infarction (Cervós-Navarro and Ferszt, 1980; Sharma et al., 1998).

Leakage of serum proteins in the brain after BBB disruption leads to vasogenic edema formation. Changes in osmotic pressure gradients across the blood-brain interface allow entry of water from the vascular compartment to the brain microfluid environment (Rapoport, 1976; Sharma et al., 1998; Sharma and Alm, 2002).

Brain edema formation can be assessed by measuring water content (Fig. 11.14.5). A simple method to determine brain water content based on dry and wet weight of the brain is described below.

Materials

Dissected rat brains after treatment with Evans blue (see Support Protocol 2), from both control and heat-stressed animals
Laboratory oven, 90°C

1. Place a whole rat brain or specific parts of it (e.g., cerebral cortex, hippocampus, cerebellum, or brainstem) on a preweighed filter paper and weigh immediately to record the wet weight of the sample. Analyze brains from heat-stressed and control animals in parallel. If dissected brain regions are used, dissect sample sizes for control and experimental brain regions as closely as possible (±50 to 80 mg).

   Because of swelling, the dry weight of the experimental group will be considerably reduced as compared with the control group. The ideal sample size for a brain is >100 mg (e.g., the wet weight of one hippocampus from a rat is ∼135 mg).

   Changes in the water content of the spinal cord can also be calculated. Spinal cord sample size should be ∼60 mg.

2. Place brain or brain parts in a laboratory oven at 90°C and dry for 48 hr.

   The oven temperature should be maintained at <100°C to avoid charring of samples.

3. Remove sample from oven and record its dry weight on the filter paper using the same electronic balance. Return sample to oven and continue drying for an additional 24 hr. Repeat weighing. If the two dry weights are constant, then total evaporation of water has occurred. If weight continues to decrease, continue repeated weighings at 12-hr intervals.

   In most cases, the dry weight is constant after 90 hr of drying.

4. Calculate the percent water content as follows: [(wet weight − dry weight)/wet weight] × 100.

   For example, the wet weight of a portion of the cerebral cortex is ∼300 mg and the dry weight of the sample is ∼70 mg. Therefore, the percent water content = (300 − 70)/300 × 100 = 76.66%.

   The whole-brain water content is considerably less (75% to 76%) than that of some regional brain samples (e.g., cerebral cortex, thalamus, hippocampus). Whole brain contains areas rich in white matter (i.e., brainstem reticular formation, pons, medulla, and parts of the cervical spinal cord). Gray matter contains more water (78% to 80%) than white matter (66% to 72%). Thus, a comparable tissue size and identical regions in control and experimental groups are important for determining regional brain water content.

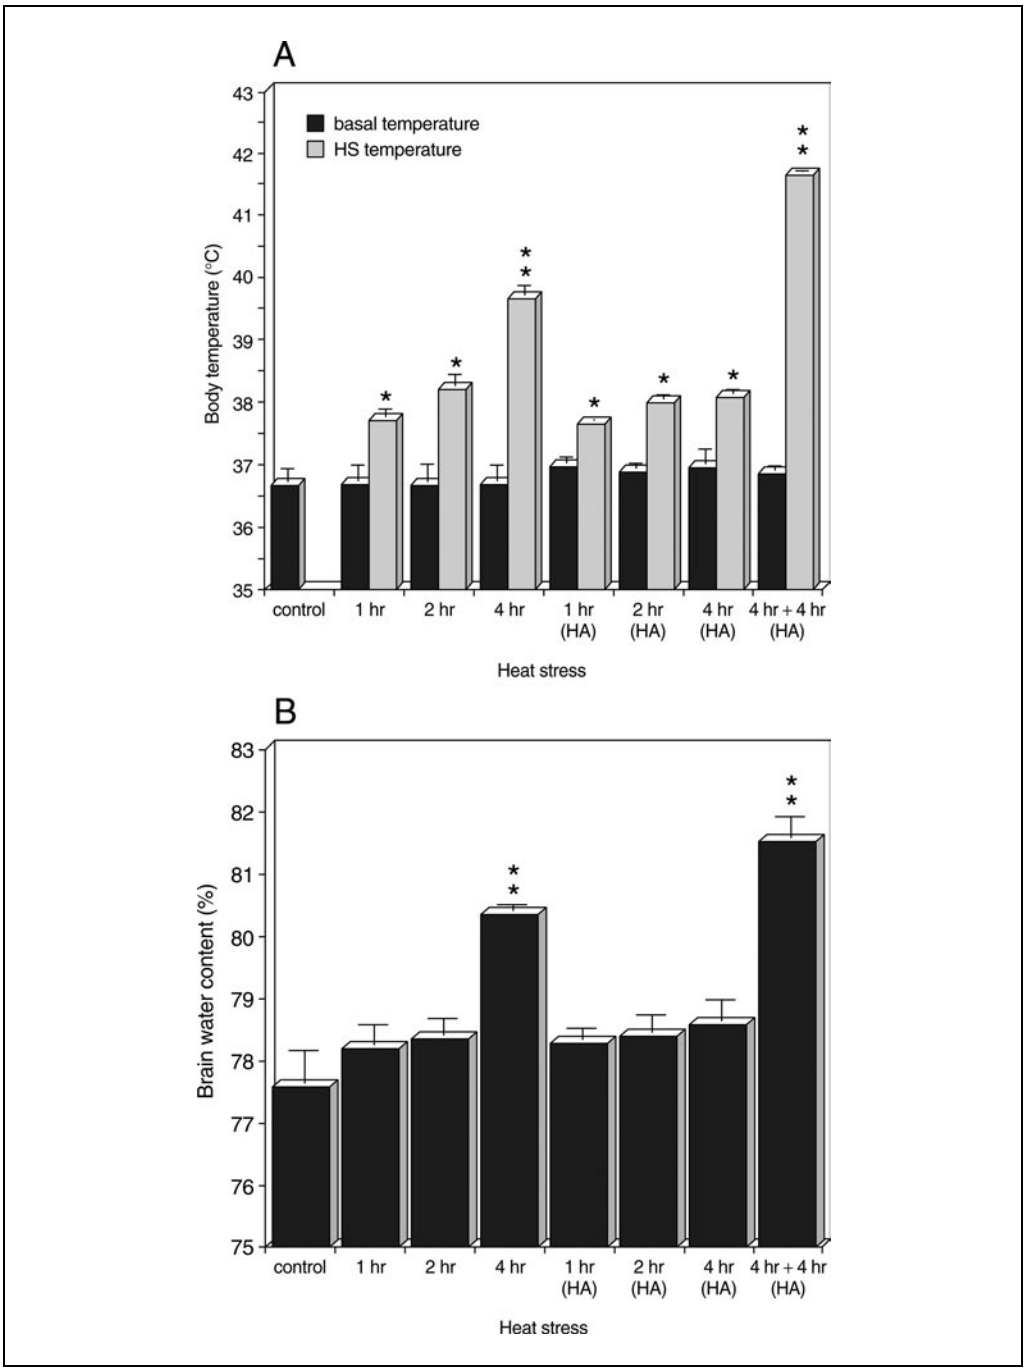

Figure 11.14.5 Changes in (**A**) rectal temperature and (**B**) brain edema formation in acute and chronic heat-exposed rats. Heat-adapted (HA) rats were exposed for 1 hr at 38°C for 7 days before the start of this experiment. A significant increase in rectal temperature was seen following 1-, 2-, and 4-hr heat exposure in the naive and HA rats, although the hyperthermia was milder in the HA rats. Brain water content increased significantly after 4 hr of heat stress (HS) at 38°C in the naive but not the HA rats. When the adapted rats were subjected to an additional 4 hr of heat exposure on the second day (4 hr + 4 hr), however, profound hyperthermia and edema formation can be seen. Values are mean ± SD from six to eight rats. $^{*}P < 0.05$, $^{**}P < 0.01$; ANOVA followed by Dunnet's test for multiple group comparison with one control group. Adapted from Sharma et al. (1986, 1992).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Equithesin solution

4.25 g chloral hydrate
0.97 g sodium pentobarbital
2.1 g magnesium sulfate
2.1 g propylene glycol
42.8 g ethanol, anhydrous
9 g sterile water (100 ml final vol)
Store up to 1 month at 4°C

Equithesin solution is also commercially available from Apoteket Produktion and Laboratorier.

Evans blue solution, 2%

Dissolve 2 g Evans blue (Sigma) in 90 ml sterile water. Use magnetic stirring if needed to completely dissolve the dye. Adjust volume to 100 ml. Filter solution using Whatman Filter 42 (pore size, 2.5 μm), which will take >2 hr. Store up to 1 year in a tightly sealed glass bottle at 4°C.

Paraformaldehyde fixative, 4%

Heat 500 ml double-distilled water in a 1-liter beaker to 60°C. Do not exceed 65°C. Add 40 g paraformaldehyde (4% final) and stir continuously using magnetic stirrer for several minutes. Add ~1 ml of 0.1 M NaOH and keep stirring until solution is clear. Filter solution through a Whatman no. 2 filter paper. Filter 500 ml of 0.2 M sodium phosphate buffer, pH 7.2 to 7.4 (see recipe; 0.1 M final) into container with fixative. Immediately pour solution into a 1-liter bottle that has been precooled on ice. Store up to 2 weeks at 4°C.

Sodium phosphate buffer, 0.2 M (pH 7.3)

For 1 liter, dissolve 21.8 g anhydrous sodium phosphate dibasic and 6.4 g anhydrous sodium phosphate monobasic in water. Check that pH is 7.3 (but 7.2 to 7.4 is fine). Lower the pH using phosphoric acid, if necessary, but do not use HCl. Keep bottle tightly sealed and store up to 4 weeks at 4°C in the dark.

COMMENTARY

Background Information

Heat stress

Heat-related deaths and mental illnesses have been well known since Biblical times (Contenau, 1954) as well as in the ancient Indian literature that dates back to 3000 BC. External heat injuries are associated with fire, burning, and rescue operations (Gauss and Meyer, 1917). On the other hand, heat illnesses are caused by exertion in a hot environment (Weisenburg, 1912; Malamud et al., 1946; Sterner, 1990). Heat treatment of tumors in the brain or in other parts of the body, commonly known as therapeutic hyperthermia, also induces several adverse reactions in the central nervous system (CNS; Hahn, 1982; Hoopes, 1991; Ryan et al., 1994). In addition, prolonged high fever (>40°C for several hours) because of bacterial and/or viral infections is often associated with short- or long-term mental anomalies (Hartman and Major, 1935; Alpers, 1936). Hyperthermia caused by diverse conditions influences cerebral circulation and metabolism (Siesjö, 1978; Sharma and Westman, 1998, 2000; Sharma, 1999, 2004a). The molecular mechanisms that underlie hyperthermia-induced brain dysfunction are not, however, well understood. Thus, a suitable animal model is needed to address this important problem faced by a large number of the human population to minimize their sufferings.

Heat stress represents the discomfort and physiological strain that follows physical exercise or daily work for long periods in a hot environment (air temperature >32°C; Knochel and Reed, 1994; Bouchama and Knochel, 2002). Hyperthermia denotes a rise in core body temperature above the hypothalamic set point (~37°C; Milton, 1993) that is caused by impairment of heat-dissipating mechanisms because of external (high environmental temperature) or internal (metabolic heat production) factors (Milton, 1993; Blatteis, 1997). Internal factors are often influenced by the use of drugs and acute and/or chronic diseases (Milton, 1993; Sharma and Westman, 1998).

Mild to moderate hyperthermia is characterized by a small rise in body temperature above 37°C, not exceeding 40°C (Knochel and Reed, 1994), and it is associated with heat exhaustion that causes intense thirst, weakness, discomfort, anxiety, dizziness, fainting, and headache (Milton, 1993; Bouchama and Knochel, 2002). Heat stroke represents severe heat illness that is characterized by hyperthermia >40°C associated with CNS abnormalities (e.g., delirium, convulsions, or coma; Malamud et al., 1946; Sterner, 1990; Knochel and Reed, 1994; Bouchama and Knochel, 2002). Heat stroke can occur either following exposure to environmental heat (classical heat stroke) or following strenuous exercise in a hot environment (exertional heat stroke; Knochel and Reed, 1994; Bouchama and Knochel, 2002).

Recently, heat illness caused by exposure to high ambient temperatures has been recognized as one of the most severe problems in society (Austin and Berry, 1956; Ellis, 1972; Sharma and Westman, 1998, 2000, 2004; Bouchama and Knochel, 2002). Sporadic postmortem reports of heat stroke victims suggest that the central nervous system (CNS) is one of the most vulnerable organs (Gauss and Meyer, 1917; Alpers, 1936; Malamud et al., 1946; Austin and Berry, 1956). Hyperthermia is associated with a systemic inflammatory response leading to multiorgan dysfunction in which encephalopathy predominates (Knochel and Reed, 1994; Bouchama and Knochel, 2002). In several parts of the world, heat-induced brain injury of young and adult athletes appears to be the third-largest killer, followed by cardiovascular and traumatic insults (Austin and Berry, 1956; Bouchama and Knochel, 2002).

Therapeutic hyperthermia, which induces a relatively fast increase in body temperature as compared with a hot environment or heat stroke (Bouchama and Knochel, 2002), is used to destroy deep-seated tumors in cancer patients (Hahn, 1982; Hoopes, 1991; Ryan et al., 1994). This method is still effective as a potential therapy for cancer treatment, in spite of several serious side effects (Hahn, 1982; Hoopes, 1991).

Thermal stress and nociceptive aspects

Rats exposed to heat stress do not appear to feel pain except for the discomfort caused by heat exposure. This is supported by evidence that either the mechanical or thermal nociceptive response of rats subjected to heat stress is not altered from that of an untreated group (Fig. 11.14.1). These observations are in line with the idea that this model of heat exposure does not damage the thermoreceptors and/or alter nociception. Furthermore, thermal discomfort that is seen in this model does not influence the animal's sensitivity to pain.

Heat stress and thermal load on the system

Hyperthermia induced in this model of heat stress is based on the amount of thermal overload imposed on the rats. The skin temperature in rats ranges between 24° and 25°C at room temperature (21°C). When rats are exposed to a heat chamber at 38°C, a heat overload of ~13° to 14°C (exposure temperature − skin temperature) is imposed on them (Table 11.14.1). This heat overload activates heat dissipation mechanisms to maintain normal body temperature (37 ± 0.5°C). During a 2- to 3-hr exposure, however, the rats are no longer able to maintain their body temperature effectively, leading to hyperthermia.

This heat stress–induced hyperthermia (body temperature >40°C) during 4-hr periods of heat exposure is directly related to the amount of initial heat load (i.e., the exposure temperature). Thus, exposure of rats to 36°C (a mild heat load of 11° to 12°C) results in considerably less hyperthermia (<39°C; Fig. 11.14.1).

It appears that the magnitude of heat load is crucial for the development of hyperthermia in animals following heat exposure. If the exposure temperature is increased from 38° to 39°C, most animals develop hyperthermia >41°C within 1 to 2 hr, resulting in the death of most animals (>70%) before 3 hr.

Heat stress and heat stroke

Rats subjected to heat stress in this model do not exhibit heat stroke. Heat stroke is characterized by excessively high body temperature (>41°C) with cessation of salivation and

urination and a very high mortality rate (>80%). Rats exposed to heat in this model exhibit copious salivation (Fig. 11.14.1) and urination. The body temperature normally does not exceed 41°C, and the mortality rate is quite low (<20%).

Brain temperature versus rectal temperature

Rectal temperature closely reflects brain temperature in many cases (Dickson et al., 1979; Macy et al., 1985). Thus when a probe is deeply inserted into the rectum, no difference in brain or rectal temperature was noted following whole-body hyperthermia in dogs and pigs (Dickson et al., 1979; Macy et al., 1985). In another study, when dogs with a brain tumor were exposed to 42°C for 60 min, liver and brain temperatures were only 0.1° and 0.2°C higher, respectively, than the rectal temperature. Data on the rise in brain temperature after whole-body heating in rats and mice are, however, still lacking.

Heat stress influences anesthesia

To study the morphological changes in cells and tissue after heat exposure, animals need to be anesthetized. The sensitivity of drugs to the CNS is markedly increased after heat stress (Sharma, 1982, 1999). Thus, the heat-exposed animals require an ~30% to 50% lower dose of anesthetic as compared with untreated animals, irrespective of the type of anesthetic that is chosen.

Use of anesthetics

Several anesthetics can be used in heat stress experiments depending on the local laboratory guidelines and permission from the respective authorities. A brief description of advantages and disadvantages regarding the use of particular anesthetics in heat stress is given below.

Urethane. Urethane (ethyl carbamate) is a colorless crystalline substance readily soluble in water (~1 g in 0.5 ml water at room temperature) with a neutral pH. Urethane is very safe from the anesthetic point of view because it induces only mild changes in the cardiovascular and respiratory system. Urethane normally does not influence sympathetic nervous system activity. For studies using neurophysiological parameters, urethane is a good choice for anesthesia because it mainly acts on the cortical level and does not depress the respiratory or cardiovascular centers in the brainstem.

The long-lasting effects of urethane (>12 hr) at the level of surgical anesthesia are another advantage in animal experiments (Flecknell, 1996). Thus, no maintenance doses of the anesthetic are needed. The dose of urethane that is needed for normal rats to achieve surgical anesthesia varies between 1 and 1.8 g/kg, intraperitoneally (Sharma, 1999). In the author's experience, 1.5 g/kg works very well in control rats weighing between 100 and 400 g (Sharma and Dey, 1986b). For heat-stressed animals, a reduction of ~30% to 50% of this dose is needed.

Urethane has some carcinogenic effects in animals, however, and thus the utmost care should be taken for its use in the laboratory and with respect to exposure in humans. Local safety regulations for the use and disposal of urethane should be followed strictly (Field and Lang, 1988).

Pentobarbital. Surgical-grade anesthesia in control rats can be achieved by sodium pentobarbital at a dose of 40 to 60 mg/kg, intraperitoneally. (Again, a 30% to 50% reduction of this dose is needed for heat-stressed animals.) This anesthesia, however, profoundly induces bronchial secretions that may sometimes be fatal. To avoid bronchial secretions and poor respiration during the experiment, pretreatment with atropine (0.1 mg/kg, subcutaneously, 20 to 30 min before induction of anesthesia) may be used, if this drug does not interfere with the experimental design and protocol.

The safety margin with pentobarbital anesthesia is very narrow. The effects of anesthesia are also short lasting (i.e., 60 to 80 min). Thus, for long-term experiments, maintenance doses are necessary, often at regular intervals of 45 to 60 min.

Use of pentobarbital anesthesia in heat stress is not recommended, particularly when the experiments involve neurophysiological studies (i.e., electroencephalogram or evoked potential studies). Heat stress often depresses brainstem reticular function. Thus, the use of pentobarbital anesthesia may interfere with the experiments.

Other anesthetics. A combination of ketamine and the muscle relaxant xylazine is commonly used as an anesthetic of choice in various laboratories. Under this anesthesia, however, several reflexes (e.g., blinking of eyes, swallowing, and movements of whiskers or vibrasse) are present, although the animal does not respond to pain stimuli. The duration of anesthesia is short lasting (~45 min to 1 hr) and depends on the dose used. To maintain the level of anesthesia, boosting doses are necessary. In general, 50% to 60% of the original dose is required every hour for this purpose,

although this amount should be determined empirically based on the individual objective and purpose of the experiments in question. The safety margin is considerably higher than that for sodium pentobarbital alone.

Thus, a good and safe anesthetic is still elusive. In some cases, a mixture of various anesthetics is used to produce a safe anesthesia of varying duration in animals. One such anesthetic that is widely used in small animals is equithesin. Equithesin is a mixture of sodium pentobarbital, ketamine, and a muscle relaxant (see Reagents and Solutions). The anesthetic is very safe at a dose of 3 ml/kg, intraperitoneally, for rats. Respiratory depression is seldom seen. The main drawback for this anesthetic, however, is its short duration (i.e., 30 to 40 min). Thus, repeated maintenance doses are necessary to maintain a certain level of anesthesia, and this is often difficult. The anesthetic works on the brainstem reticular formation, thus, excessive repeated doses may induce cardiovascular and respiratory depression, which may lead to animal death. The anesthetic is prepared in a mixture of lipid solvents (i.e., propylene glycol and ethanol). Thus, the anesthesia itself may influence brain function (Gaese and Ostwald, 2001). This aspect should be considered when studying the effects of drugs on brain function in animals after revival from the anesthesia.

Therapeutic hyperthermia

Whole-body hyperthermia and heat toxicity. Therapeutic hyperthermia has been used as a spontaneous cure of several kinds of tumor since the mid-19th century (Sharma and Hoopes, 2003). The technique is largely based on the ability of whole-body hyperthermia (WBH) to destroy deep-seated tumors and is effective against metastasis. Fluid loss, hemodynamic alterations, serum enzyme abnormalities, and other symptoms of variable severity are, however, commonly seen during clinical trials (Kapp and Lord, 1983). Several fatalities that occurred following heat treatment are thought to have been due to causes other than hyperthermia, per se. Recent studies, however, suggest that WBH can influence the structure and function of the CNS in a way that may contribute to some deaths during heat treatment of tumor patients (Sharma and Westman, 1998; Sharma, 1999; Sharma and Hoopes, 2003). Thus, the effective exposure temperature and CNS dysfunction over time require further investigations using this model (Kapp and Lord, 1983; Ryan et al., 1991a,b).

Clinical observations. The effects of WBH on human brain function are largely unknown (van der Zee, 1987). In brain tumor patients, the neurological outcome worsens when the brain temperature exceeds 39°C (Mellergard and Nordström, 1990). The rectal temperature adequately reflects the epidural space temperature, which is very similar to the tympanic membrane temperature (Cabanac, 1998). In human cases, endothelial cells, leukocytes, and epithelial cells are activated after WBH, and a variety of cytokines are produced (Chang, 1993; Gabay and Kushner, 1999). Increases in peripheral interleukin (IL)-1b, IL-6, IL-8, tumor necrosis factor-α (TNF-α), and the regulatory cytokine IL-10 are quite common (Katschinski et al., 1999; Bouchama and Knochel, 2002). These cytokines are involved in local and systemic inflammatory responses (Pedersen and Hoffman-Goetz, 2000). Because some of the cytokines have protective effects, several studies have recommended treatment of human tumors in the range of normally occurring fever (Chang, 1993; Cabanac, 1998; Gabay and Kushner, 1999; Katschinski et al., 1999; Pedersen and Hoffman-Goetz, 2000; Bouchama and Knochel, 2002). Patients with an advanced solid tumor tolerate 39° to 39.5°C for 3 to 6 hr and 39.5° to 40°C for 6 hr without any adverse cardiac, hepatic, or renal effects (Kraybill et al., 2002). Biopsy findings of brain pathologies were not, however, available from this study.

Brain pathology after WBH and heat stroke

Hyperthermia (40.5° to 43°C for 3 to 11 hr) following WBH results in fatality and visible organ injury (Gottschalk and Thomas, 1966). On the other hand, heat stroke–induced fatalities can be seen when the rectal temperature on admission ranges between 38° and 44°C (Bouchama and Knochel, 2002). Death occurs in 70% of cases in <24 hr (rectal temperature, 41.5° to 44°C), irrespective of hyperthermia following WBH or heat stroke (Sharma and Hoopes, 2003). In benign cases, the survival period varies between 1 and 12 days after the initial exposure (Malamud et al., 1946).

Severe brain pathologies in the cerebral cortex and cerebellum in human cases of hyperthermia are described by Malamud et al. (1946) and Gauss and Meyer (1917). This suggests that the CNS is highly vulnerable in heat-related illnesses in humans. A detailed study of other CNS regions (e.g., hippocampus, hypothalamus, and spinal cord) following heat injury at the light and electron microscopy levels has not, however, been carried out.

Local heat treatment of CNS tumors

Clinical cases. Local hyperthermia in the human nervous system is used to treat brain tumors. Tumor temperature of 42.5°C for 1 hr does not induce any adverse effects, although the temperature of normal tissue may rise as well (Zimmerman, 1940). For tumor tissue heated up to 44° to 49°C, the normal tissue temperature remained around 40°C (Tanaka et al., 1987). This heat treatment resulted in aggravation of peritumoral edema and a focal brain swelling (Tanaka et al., 1987). Deep heating has been applied in many patients, however, without apparent heat neurotoxicity (Petrovich et al., 1989). Because most studies are conducted under anesthesia, the state of brain function and cerebral metabolism as well as the effects of anesthesia on CNS function may influence the outcome (Salzman, 1990). To understand the effects of anesthetics on brain dysfunction following hyperthermia, additional work is needed.

Animal experiments. In some cases, local hyperthermia at a temperature of 42° to 43°C for 30 to 60 min is used to treat brain tumor tissue in animals (Sminia et al., 1994). Such heat doses lead to hemorrhages and necrosis in the surrounding brain tissue with limited changes in whole-body physiology (Kerner et al., 2002). Local or regional heating of the brain is often associated with edema formation and cell injury (van der Zee, 1987; Sminia et al., 1994). In experimental local brain heating, lethality after heat insult is common (Sminia et al., 1994). It appears that hyperthermia per se induces such lethality; however, this issue requires further investigation.

Previous studies on hyperthermia in animal models

Previously, several animal models have been used to study the therapeutic effects of hyperthermia on heat tolerance in various animal species. The exposure temperature, duration, survival periods, and parameters measured were, however, extremely varied. Thus, no comparisons can be made to understand the effects of therapeutic hyperthermia on CNS function (Table 11.14.3).

Exposure of dogs to 60°C hot air for 2 hr resulted in a rise in rectal and brain temperature up to 42.5°C without any signs of edema, as seen by changes in epidural pressure recordings. Histopathological studies show a generalized dilation of the subarachnoid space in three of four dogs. The details of cellular changes in the brain were not examined (Eshel et al., 1990).

On the other hand, spontaneous electrical activity or the auditory brainstem-evoked potentials in rats and cats are markedly affected following WBH (Marsh et al., 1984). Flattening of amplitude following WBH in rats occurs after a rise of rectal temperature from 36.75° to 42.65°C, corresponding to a rise in brainstem temperature from 35.25° to 41.5°C (Bulochnik and Zyablov, 1978; Marsh et al., 1984). Similar effects are seen in cats after elevation of cortical temperature to 44° to 45°C following WBH (Britt et al., 1984).

Microwave heating with 106.5 MHz for 60 min in dogs resulted in a rise of the left cardiac ventricle temperature to 42°C, and the lumbar spinal canal temperature rose to 42.5° to 43°C (Thrall et al., 1992). These dogs exhibited pelvic limb dysfunction 12 to 24 hr after hyperthermia. Histopathological examination revealed severe hemorrhage and edema in the lumber spinal cord (Eshel et al., 1990).

These observations indicate that the thermal sensitivity of nerve cells to hyperthermia varies in different regions of the CNS. A detailed mapping of thermal sensitivities of neurons in several regions of the CNS is required to further address this issue.

Brain edema

Types of brain edema. Brain edema is divided into two categories based on whether it is (1) vasogenic or (2) cytotoxic in origin (Klatzo and Seitelberger, 1967). The vasogenic brain edema formation is due to leakage of plasma proteins and water into the cerebral extracellular space because of breakdown of the BBB. Cytotoxic edema develops because of intracellular accumulation of water caused by alterations in cell metabolism (Rapoport, 1976). Heat stress produces both vasogenic and cytotoxic edema (Sharma et al., 1998).

Factors influencing brain edema formation. The protein osmotic pressure in brain is negligible. This is because the cerebrospinal fluid (CSF) protein concentration is extremely low. Furthermore, the CSF osmolality of nonprotein solutes is identical to plasma osmolality (Davson, 1967; Klatzo and Seitelberger, 1967; Rapoport, 1976). Thus, brain edema formation following CNS insults depends mainly on the leakage of the BBB. The driving force for water permeability in the brain is largely dependent on capillary hydrostatic pressure and the protein osmotic pressure (Staub, 1974; Rapoport, 1976). The rate of fluid accumulation depends on brain compliance, which varies in different regions as well as due to changes in local tissue pressure (Guyton, 1963).

Table 11.14.3 Effect of Heat on the Central Nervous System in Laboratory Animals[a]

Species	Exposure temperature (°C)	Tissue examined	Duration (min)	Pathological findings[b]
Dog	42–46[c]	Cerebral hemisphere	30	Edema, hemorrhages
	42–43.5[c]	Occipital cortex	50–70	Gray and white matter damage
	43–44[c]	Cerebral hemisphere	30	Necrosis, inflammation
	40–44[c]	Frontal cortex	30	Necrosis, gliosis
		Cerebral hemisphere		Fibrosis
Cat	45[c]	Forebrain	30	No change
	42–48[d]	Occipital cortex	50	Gray and white matter damage
	41–48[d]	Occipital cortex	50	Necrosis, inflammation
Mouse	42[e]	Spinal cord	60	Not known
	41.2–45.2[f]	Spinal cord	60	Not known
	42–3.5[e]	Spinal cord	20–100	Neuronal and vascular damage, demyelination
Rat	41.2–43.2[c]	Spinal cord	30–120	Neuronal damage, white matter necrosis, gliosis
	43.4–46[f]	Spinal cord	15–30	Not known
	42.6–43.8[c]	Spinal cord	60	Not known
Rabbit	42–43[f]	Whole brain	60	No change
	45[f]		few	Not known

[a]Compiled from Sminia et al. (1994).
[b]These observations are based on very crude pathological examinations done from 4 to 24 hr and 3, 7, 14, and 28 days after thermal insults. In some cases, details of the pathological examination were not available.
[c]Exposure to microwaves.
[d]Exposure to ultrasound.
[e]Exposure to water bath.
[f]Exposure to radiofrequencies.

Brain edema in heat-related illnesses. Edema of the leptomeninges and an increase in brain weight by several hundred grams are prominent in victims of heat-related illnesses (Malamud et al., 1946). Flattening of convolutions and softening of the brain tissue are the other features (Malamud et al., 1946; Austin and Berry, 1956).

Thus, edema appears to be the most prominent feature of hyperthermic brain injury in clinical cases. Very little emphasis is given, however, to the functional significance of brain edema formation in heat-related illnesses. Thus, further studies are needed in this direction.

Experimental hyperthermia in unanesthetized animals

Advantages. The model described in this unit simulates clinical conditions of mild to moderate hyperthermia (i.e., heat stress and heat exhaustion). The symptoms of heat stroke are largely absent in these rats. This is a physiological method to study heat-induced stress reactions in animals. This is evident by activation of the body's natural defense system against heat stress. The physiological response to actively dissipate heat from the body during heat exposure (i.e., salivation) is also operating in these rats. The stress reaction and thermoregulatory changes can easily be visualized during

heat exposure, which can help in predicting the outcome of the experiments. The exposure temperature is within the physiological range, and the chances of heat-induced degeneration of thermoreceptors and burring of skin receptors are unlikely.

Disadvantages. The level of hyperthermia may vary according to the individual response of animals to heat exposure. Thus, maintenance of a certain magnitude of hyperthermia in rats using this model is not possible. In some animals (<20%), body temperature may increase beyond 41.5°C after 4 hr heat exposure, causing death. Some animals may die 12 to 48 hr after heat exposure if the hyperthermia achieved at 4 hr is >41°C.

Critical Parameters

Thermistor probes

The use of thermistor probes (see Internet Resources) is necessary for high-accuracy temperature measurements. The size of the thermistor probe should be suitable for small laboratory animals (i.e., rats and mice). Frequent handling and measurement of body temperature are much more reliable using these probes as compared with normal thermometry. A thermistor probe can record temperature with high precision (±0.01°C) over the range of 0° to 100°C. These probes are stable over years and can measure temperature changes effectively with ±0.1°C accuracy.

Measuring brain edema

A good electronic balance able to detect ±0.01 mg should be placed in the area where the brain is dissected. The time lag between dissecting brain regions and recording the wet weight of the sample should always be kept to a minimum (~1 min). Long-time exposure of the brain samples to the environment may influence the wet weight depending on the humidity and air flow in the area where the experiment is conducted. It is not known whether control and treated brains are influenced by humidity and evaporative water loss in an identical manner.

The brain water content can be measured in animals immediately after heat exposure without the need for saline or formalin perfusion. In this case, obvious blood clots, if any, and major blood vessels over the surface of the brain should carefully be removed. The amount of blood in microvessels may vary and may affect the wet and dry weights of the samples, thus influencing the results. The influence of residual blood volume in brain capillaries can be avoided by perfusing with saline.

Pre-weighed filter papers are necessary to record the wet and dry weights of the sample. The weight of each filter varies markedly (~0.5 to 8 mg). Thus, individual recording of the weight of each filter paper is essential.

Administration of dye before versus after heat stress

Conscious rats. Administration of Evans blue dye in conscious rats either before heat stress (through a cannula implanted into the right jugular or femoral vein) or after termination of exposure (through these routes) does not influence the magnitude or intensity of extravasation in the brain tissue (Sharma, 2004a).

Influence of anesthesia. Likewise, extravasation of dye into the brain did not differ markedly when administered under anesthesia after heat stress. After heat exposure, no difference was seen in leakage of Evans blue dye in rats subjected to various kinds of anesthetics.

Duration of rest after heat stress. Opening of the BBB to Evans blue as a result of heat stress is seen up to 2 hr after the end of heat exposure in both conscious and anesthetized animals (Sharma, 2004a). Thus, to study BBB dysfunction, the dye or any other tracer can be administered in rats within a certain time interval after the termination of heat exposure. To study the reversibility of BBB function, administration of dye or tracers can be made at various time intervals after the termination of heat exposure.

Perfusion duration. The duration of saline infusion and/or formalin perfusion will not influence the magnitude and intensity of dye extravasation into the brain tissues. Because Evans blue dye will instantly bind to tissue proteins after it enters the brain, washout of the dye due to saline or formalin perfusion is quite unlikely. Care should be taken, however, to perfuse animals at ~90 mm Hg and not above to avoid rupturing microvessels, which may interfere with dye extravasation. A pressure of ~90 mm Hg is enough to keep vessels patent during the perfusion.

Anesthesia

To avoid lethality, do not administer a normal dose of anesthetics in heat-stressed rats. This effect of heat stress on anesthesia lasts even 1 to 2 hr after the end of heat exposure. For example, if normal animals require 1.5 g/kg urethane intraperitoneally for surgical-grade anesthesia, administer only 0.8 to 1 g/kg in

heat-stressed rats to achieve the same level of anesthesia. This is also true for other anesthetics, such as pentobarbital.

Anticipated Results

In general, >90% of unanesthetized rats respond to 4 hr heat stress and develop symptoms. More than 80% of rats recover after heat exposure. Approximately 20% may die during heat exposure if the body temperature exceeds 41.6°C. As mentioned above, after heat exposure, look for alterations in BBB permeability and development of brain edema. The whole brain in heat-stressed rats will show mild to moderate leakage of Evans blue (Fig. 11.14.4) and will appear swollen as compared with the control brain. The texture of brain tissue in heat-stressed rats is likely to be softer and spongy as compared with the control group. The brain weight is markedly increased. After a midsagittal section, blue staining (faint to mild) can be seen within the cerebral ventricles of heat-stressed rats (Figs. 11.14.3 and 11.14.4). Dye that has entered into the brain (Sharma, 1982; Sharma and Dey, 1987) and brain water (Sharma and Cervós-Navarro, 1990) can also be measured.

Time Considerations

Preparatory time is <30 min (to record body weight and body temperature in individual animals), after animals have undergone a week-long handling regime. Working time depends on the exposure duration and experimental design. Usually, for a 4-hr heat exposure protocol, allow 5 to 6 hr total time to complete one group of experiments on five or six rats.

CHAPTER 12
Biochemical and Molecular Neurotoxicology

INTRODUCTION

This chapter complements the behavioral and whole-animal approaches that are provided in the preceding chapter (Chapter 11, Neurotoxicology) by addressing biochemical and molecular methodologies, as well as in vitro approaches to study neurotoxicity. By providing information on the cellular substrates involved in behavioral changes and/or correlates of neuropathological lesions, biochemical and molecular approaches are relevant to the process of assessing the impact of human exposure to neurotoxicants. Knowledge of mechanisms of action of neurotoxicants can be useful in a number of areas: it allows the design and development of proper antidotes; it is useful in predicting possible interactions with other exogenous chemicals and/or preexisting alterations; it permits the development of biomarkers of effect for use in animal toxicity studies, as well as epidemiological investigations in humans; it offers the possibility of implementing in vitro alternatives for toxicity testing; and it adds an important component to the hazard characterization aspects of risk assessment process.

UNIT 12.1 presents an overview of the different approaches that can be used to study the effect of neurotoxicants with biochemical methods. As the targets of neurotoxicants can be numerous an investigator is faced with the issue of which parameters to investigate: various steps of neurotransmission, signal-transduction pathways, intermediate metabolism, markers of oxidative stress, are among the many end-points that can be studied.

The blood-brain barrier is constituted by specialized endotheliel cells that together with astrocytes act as a selective barrier that isolates the brain from potentially noxious substances. *UNIT 12.2* presents methodologies to investigate the functions of the blood-brain barrier in a dynamic in vitro system where the passage of chemicals, as well as the functional effects of neurotoxicants, can be measured.

Cells in culture are often used for neurotoxicological studies, particularly for the study of mechanisms of toxicity. *UNIT 12.3* and *UNIT 12.4* present methods for preparing primary hippocampal neuronal cultures and primary astrocyte cultures from rat brain and their applications to neurotoxicology. *UNIT 12.5* provides a description of two applications of analytical cytology to neurotoxicology, for measurements of intracellular calcium levels and of cell-cycle parameters. *UNIT 12.6*, on the other hand, describes stereological methods that allow counting of neuronal cells. *UNIT 12.7* describes the method for preparing rat cerebellar granule cells for culture. These cells are a widely used in vitro model system for neurotoxicology studies. Reactive gliosis is a characteristic feature of toxicant-induced injury in the central nervous system, and *UNIT 12.8* describes the measurement of glial fibrillary acidic protein (GFAP), which serves as a biochemical indicator of neurotoxicity.

UNIT 12.9 describes an unique in vitro cell system, the aggregating neural cell cultures, prepared from embryonic rat or mouse brains. This tridimensional system allows direct cell-to-cell interaction and is a promising tool for in vitro neurotoxicity testing. The issue of cell-cell interaction is also addressed in *UNIT 12.10*, which describes different methods to co-culture glial cells and neurons.
