Other types of human studies that have been employed in immunotoxicology are typically classified as observational or epidemiological. Observational studies can be of varying size and they can be cross-sectional (one point in time), retrospective, or prospective in nature; each design has advantages and disadvantages. The initial means of control in observational studies is introduced through the study design and the quality and validity of results can be greatly affected by the methods used to select the study sample and the rigor with which exposures and outcomes are measured. In addition to high costs, observational studies are challenging for many reasons, including potential confounding by host (age, gender, and lifestyle) and environmental (frequency of exposure to chemicals and infectious agents) factors. A secondary measure of control in observational studies is through the use of multivariable analysis techniques (e.g., regression modeling), providing there is sufficient sample size and information on potential confounders. Overall, well-designed epidemiological studies (e.g., absence of selection bias, exposure or outcome misclassification, control of confounding factors) can contribute valuable information to the assessment of risk due to immunotoxic exposures.

Existing immunotoxicology studies in humans tend to be based upon either fairly small sample sizes, often in individuals with transient high-level occupational exposures, or large groups with chronic low-level exposures. Although in some instances body burdens of chemicals have been determined, drawing broadly applicable conclusions from some of these studies is difficult. This is because subjects may have been exposed to chemicals other than those specifically addressed by the study, and characterization of chemical exposure may rely on subject recall or rough estimates of the duration and intensity of exposure. Furthermore, in contrast to experimental animals, functional assessment is considerably more difficult in humans as it requires antigen challenge, which involves some risk to the individual. When such studies have been undertaken, subjects have been provided commercial vaccines, such as hepatitis antigen (Weisglas-Kuperus et al., 2000; van Loveren et al., 2001; Yucesoy et al., 2001; Sleijffers et al., 2003). The cellular and humoral immune response to vaccination is thought to be a sensitive indicator of immunosuppression (Glaser et al., 1993) and can reflect susceptibility to infectious disease (Deseda-Tous et al., 1978; van Loveren et al., 2001). In most epidemiological studies, testing in humans has been limited to blood collection where peripheral cell counts and differentials, immunoglobulin levels, or immunophenotyping are performed. While certainly of value, it is generally agreed these are not highly sensitive indicators of immunosuppression, making it difficult to detect low-to-moderate levels of immunosuppression (ITC, 1999).

IMMUNODEFICIENCY AND RELATIONSHIP TO INFECTIOUS DISEASE

Environmental Chemicals

*PCB*s

The need to extend data obtained in experimental studies to humans has been recently reviewed (Tryphonas, 2001); however, epidemiologic data on the effects of chemical exposures on immune parameters and

infectious outcomes in human populations are limited. Some of the more complete immunotoxicology studies have focused on persistent organochlorine compounds formerly found in pesticides and industrial chemicals—e.g., polychlorinated biphenyls (PCBs)—in children following prenatal or perinatal exposure via maternal diet and breast milk. Accidental exposures of populations in Japan (Yusho) and China (Yu-Cheng) suggest an association of PCBs, their thermal breakdown products (quaterphenyls), and polychlorinated dibenzofurans, found in contaminated rice oil, with immune abnormalities and increased infections. Children born to exposed mothers between 1978 and 1987 in the Yu-Cheng population had lower levels of serum IgA and IgM, and a higher frequency of respiratory infections and otitis media compared to matched unexposed controls (Lu and Wu, 1985; Nakanishi et al., 1985; Yu et al., 1998).

The association between PCBs and increased frequency of otitis media in children has also been described in other populations. A study of 343 children in the United States (Michigan) showed no general association between organochlorine levels and prevalence of infections, but there was a positive association between polychlorinated biphenyls (PCBs) and DDE (the primary metabolite of DDT), or PCBs and hexachlorobenzene with otitis media (Karmaus et al., 2001). In a study of Inuit infants in Arctic Quebec, Canada (Dewailly et al., 2000), the relative risk of recurrent episodes (at least three per year) of otitis media was higher in breast-fed infants in the second and third highest percentile of organochlorines exposure, compared to the lowest. At three months of age, breast-fed infants with higher exposure levels had lower numbers of white blood cells and lymphocytes, and lower serum IgA levels at ages 7 and 12 months, compared to bottle-fed infants. In Dutch preschool children (Weisglas-Kuperus et al., 2000), PCB levels in breast milk (nonortho and planar PCBs) were also associated with increased recurrent otitis media and other symptoms of respiratory infection. In this sample, the body burden of PCBs at age 42 months was associated with higher prevalence of recurrent otitis media and chicken pox. PCB body burden was not associated with differences in lymphocyte markers outside the normal range for age-matched children, although levels in breast milk and cord blood were positively correlated with lymphocyte counts and various T-cell subsets. While these findings linking otitis media with PCB exposure are consistent across three studies, it was not possible to determine whether the changes in immune parameters mediated this association or simply represented parallel findings.

Pesticides

The immunotoxicity of pesticides following human exposure has been reviewed by several authors (Thomas et al., 1995; Vial et al., 1996; Voccia et al., 1999; Luebke, 2002). Although some studies have described associations between pesticide exposure, altered immune function, and increased rates of infection, sample sizes were generally small and, in some cases, patients were self-selected based on symptoms rather than exposure. Furthermore, the frequency of infections was typically estimated by recall over several years and immune function data were scarce. Not all studies suffer from these shortcomings. For example, a relatively large ($n = 1600$) and well-defined population living in and around Aberdeen, North Carolina, near a pesticide dump site (a priority Superfund site containing organochlorine pesticides, volatile organic compounds, and metals), was evaluated for immune function and frequency of viral infections. Compared to a neighboring community, residents of Aberdeen, ages 18 to 40, were found to have higher incidence of herpes zoster (reactivated herpes infection causing shingles), but no difference in the frequency of other infectious diseases (Arndt et al., 1999). In a substudy of 302 individuals, those living in Aberdeen had significantly higher age-adjusted levels of plasma DDE than those living in neighboring communities. Furthermore, higher levels of plasma DDE were related to lower lymphocyte responses to mitogens but higher absolute lymphocyte counts and IgA levels (Vine et al., 2001). In a separate analysis, residents living nearer to the pesticide dump site had both a lower lymphocyte response to mitogen stimulation and a greater likelihood of having a lower percentage of $CD16^+$ (NK) cells, ($<8\%$, the lower limit of the normal reference range; Vine et al., 2000). The association seen with reactivated herpes infection is plausible in light of these changes, given that NK cells play an important role in the generation of cytotoxic T-cells required to help control viral infections. These studies illustrate several challenges in demonstrating the effects of chemical exposures in a population-based setting. Although an infectious outcome (zoster) was associated with residential history of chemical exposure in Aberdeen, suggesting immunosuppression related to proximity to the dump sites, the more

extensive and expensive immune markers and serum indicators of exposure were only examined in a small subset of the original sample. Thus, it was not possible to further examine potential pathways leading to the association with zoster.

Heavy metals and solvents

There are human data pertaining to the effects of heavy metals or solvents, such as lead and benzene, respectively, much of which comes from occupational exposures. Other metals (e.g., mercury and cadmium) have been shown to have immunotoxic effects, as have mixed exposures, such as those experienced by welders exposed to metal fumes and gases. As recently reviewed by Antonini et al. (2003), welders may experience increased susceptibility to pulmonary infection and recurrent respiratory infections (Tuschl et al., 1997), possibly due to decreased NK activity or cell-mediated immunity. Although a number of human studies have evaluated immune system endpoints in occupationally exposed cohorts, immune function and infectious outcomes generally have not been reported for the same cohort.

Chronic Stress

Effect on common infection

It is well established that chronic psychological factors (stressors), such as separation and divorce, caregiving for Alzheimer's patients, or bereavement, produce low-to-moderate degrees of immunosuppression and increase infectious disease incidences (Cohen, 1995; Biondi and Zannino, 1997; Yang and Glaser, 2000; Kiecolt-Glaser et al., 2002). For example, in a study that followed 100 members of 16 families for 1 year, infections were four times more likely to occur following a family-related stress event than if no stress event occurred (Meyer and Haggerty, 1962). In a prospective cohort study, 246 individuals from 58 families were followed for the effects of family functioning and stress on the incidence of influenza infection (Clover et al., 1989). Examinations ~2 weeks after an influenza epidemic ended showed that infection was negatively associated with both cohesion and adaptability. In a study where humans were challenged with an infectious agent, 394 healthy subjects were assessed for psychological stress and subsequently administered nasal droplets containing respiratory syncytial virus (RSV) or coronavirus (Cohen et al., 1991). The rate of respiratory infections ($p < 0.005$) and clinical colds ($p < 0.02$), as determined by virus-specific antibody levels and viral isolation, increased in a dose-responsive manner with increasing degrees of psychological stress (Fig. 18.1.2). Although usually conducted in small cohorts, immune testing in chronically stressed individuals has provided some insights into the relationship between mild-to-moderate immunosuppression and disease (Kiecolt-Glaser et al., 1986, 1987). In chronic stress groups showing an increased rate of infections, total circulating T cell numbers can be reduced to as much as 20%

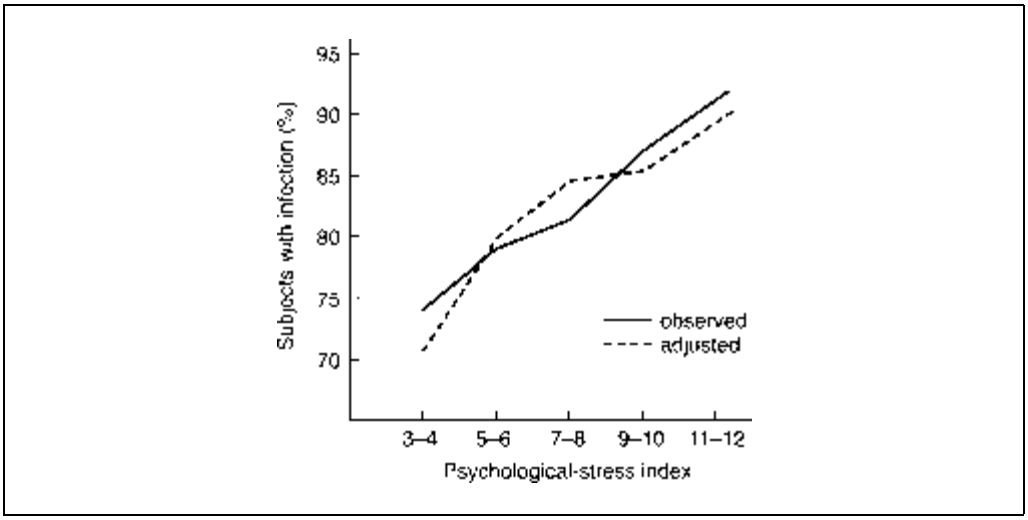

Figure 18.1.2 The rate of respiratory infections and clinical colds, as determined by virus-specific antibody levels and viral isolation, following challenge with nasal droplets containing respiratory syncytial virus or coronavirus, in individuals demonstrating increases in psychological-stress indices. Data are shown as observed association and association adjusted for standard control variables ($n = 397$). Adapted from Cohen et al. (1991).

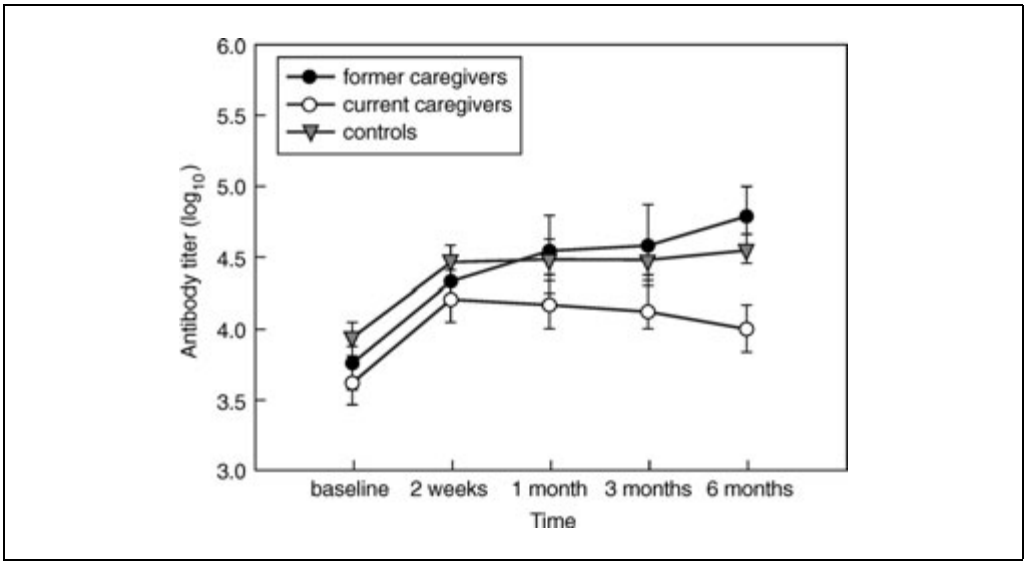

Figure 18.1.3 Pneumococcal vaccine responses in elderly caregivers, shown as antibody titer over the 6-month period following immunization. Controls are age-matched noncaregivers. Adapted from Glaser et al. (2000) with permission.

below control values, while the number of circulating B cells remain unaffected. Furthermore, CD4:CD8 ratios, while usually within normally reported ranges, can be reduced as much as 40% and NK cell activity by 10% to 25% below control values. Measurement of mitogen-stimulated T lymphocyte proliferation, although not generally considered a sensitive indicator for immune function, was reduced in the stressed population by ∼10% from control values. These changes are within the range of most reported normal values.

Effect on latent viruses

Associations between chronic stress and reactivation of latent viruses, such as CMV, HSV-1, or EBV, as measured either by clinical disease or elevations in specific antibody titers have also been observed (Kasl et al., 1979; Glaser et al., 1987, 1993; Esterling et al., 1993; Cohen, 1995; Biondi and Zannino, 1997; Yang and Glaser, 2000). An increase in specific antibody titers to latent viruses (i.e., seroconversion), which reflects viral activation and replication, precedes disease onset, although only ∼20% of seroconverters actually develop clinical manifestations. Studies have also been conducted to examine associations between psychological stress and the immune response following hepatitis B, influenza virus, or pneumococcal vaccination, (reviewed in Kiecolt-Glaser et al., 2002). In studies of students under defined academic stress, the ability to seroconvert following first and second immunizations with hepatitis B vaccine were highly associated with tests to measure stress levels. In studies involving influenza vaccinations, Alzheimer's disease caregivers responded less favorably to vaccination, with only 12 (38%) compared to 21 controls (66%) showing a 4-fold increase in antibody titer following immunization. A four-fold increase is considered an adequate response (Kiecolt-Glaser et al., 1996). As shown in Figure 18.1.3, even more striking were the effects on pneumococcal vaccine responses in caregivers, where a significant decrease in antibody titer occurred in current caregivers compared to controls over the 6-month period following immunization—$F(5.82,142.46) = 2.56$; $p < 0.03$; Glaser et al., 2000. Although acute stressors, like chronic stressors, also are moderately immunosuppressive, large interindividual differences exist due to the variability in stress-induced sympathetic nervous system activation, and most observed changes are short-lived (reviewed in Marsland et al., 2002).

Hematopoietic stem cell transplantation

Hematopoietic stem cell transplantation (HSCT), which came into general practice in the 1980s, is employed in the treatment of certain hematological malignancies, aplastic anemia, and inborn genetic errors originating in hematopoietic stem cells. Immunodeficiency can persist for well over a year following cell grafting due to pregrafting radiation treatment and is manifested as decreases in primary antibody responses and delayed hypersensitivity responses as well as lower $CD4^+$ cell

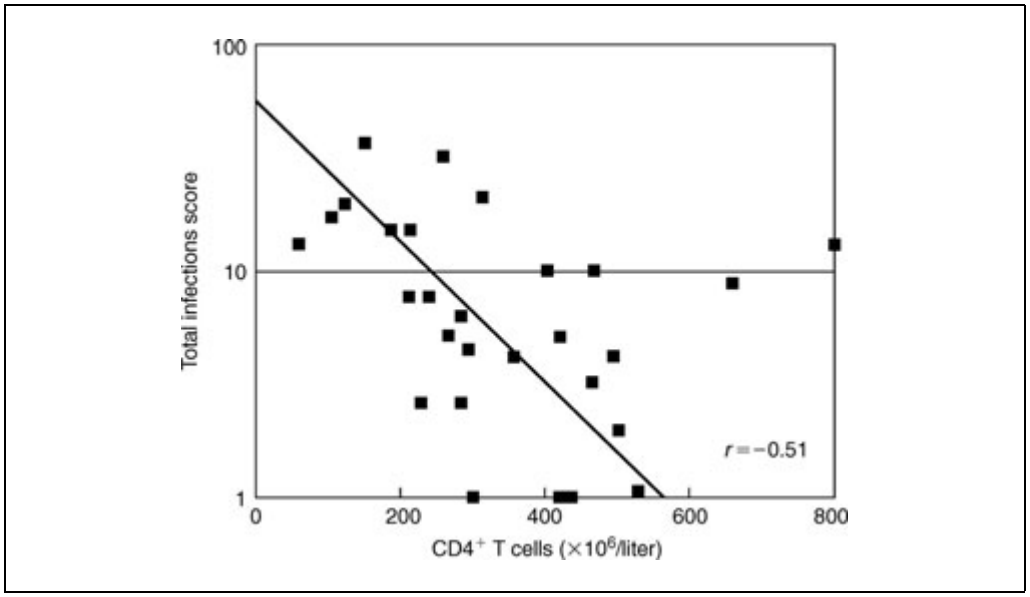

Figure 18.1.4 Twenty-nine patients were followed for 180 days preceding the one year post-transplant exam for $CD4^+$ T cell counts and total infection score, which includes frequency and severity. Reprinted with permission from Storek et al. (1997).

numbers and serum IgG2, IgG4, and IgA levels (Ochs et al., 1995). Thus, prospective studies provide an excellent model to help identify quantitative relationships between immune function and disease as the immune system undergoes recovery. Excluding upper-respiratory infections, which are seldom monitored in allogeneic bone marrow recipients, the incidence of infections exceeds 80% during the first 2 years post-engraftment, with 50% of the patients having three or more infections. Opportunistic infections predominate, with fungal infections being the most common followed by those of bacteria and viral origins (Ochs et al., 1995; Atkinson, 2000). Although infections that occur in the first month following transplant are most likely due to deficiencies in granulocytes, later infections appear to be due to deficiencies in $CD4^+$ T cells and B cells.

In a prospective study involving 108 transplant patients followed between days 100 and 365 post-engraftment, decreases in B, $CD4^+$, and $CD8^+$ lymphocytes, as well as total mononuclear cells, represented the strongest associations with infectious disease incidence ($P < 0.05$; Storek et al., 2000). A smaller but more detailed study by Storek et al. (1997), evaluating 29 patients for 180 days preceding the 1-year post-transplant exam, showed a highly significant inverse correlation ($P = 0.005$ in univariate analysis) between $CD4^+$ T cell counts and total infection score (i.e., frequency and severity) but not with $CD8^+$ T cell numbers, B cell numbers, serum immunoglobulin levels, or delayed hypersensitivity responses (Fig. 18.1.4). The significant association between disease and decreased $CD4^+$ T cell counts was primarily dependent upon activated cells, rather than memory T cell subpopulations. In comparing the efficacy of allogeneic marrow transplantation to blood stem cell transplantation, Storek et al. (2000) demonstrated that a 1.7-fold lower rate of infections in blood stem cell transplants corresponded to about a 4-fold higher $CD45RA^{high}$ (memory) $CD4^+$ T cells and about 2-fold higher count for $CD45RA^{low}$ (naive) $CD4^+$ T cells. In studies conducted by Small et al. (1999), which monitored immune cell recovery following bone marrow cell transplantation, the incidence of infections also correlated with $CD4^+$ cell counts. Only opportunistic infections were monitored, however, and they were almost exclusively present in patients considered severely immunosuppressed, with $CD4^+$ T cell counts of <200 cells/mm^3. The relationship between $CD4^+$ cell numbers and respiratory virus infections was examined over a 3- to 6-month period following transplantation in a small group of T-cell depleted (using anti-CD52 antibody treatment), stem cell recipients (Chakrabarti et al., 2001). The relationship between $CD4^+$ T cell numbers and the incidence of respiratory virus infection was relatively linear. The size of the population was small, however, and $CD4^+$ T cells in the experimental group did not progress

above 180 cells/mm^3, compared to 700 to 1100 cells/mm^3 found in the control group.

Although not well studied, HSCT patients also manifest deficiencies in humoral-mediated immunity, presumably due to insufficient T cell help, rather than direct B cell deficits. In this respect, Sheridan et al. (1990), in studying leukemia patients before and after allogeneic bone marrow transplantation, noted a high incidence of pneumococcal infections that were specifically associated with low-to-absent levels of detectable serum IgG2 and IgG4 levels.

Organ Transplants

Studies in organ transplant patients, particularly renal, have also provided insights into the long-term consequences of moderate immunosuppression. While immunosuppressive therapies have greatly improved over the past 40 years, transplant patients are still predisposed to high rates of malignancies and infections. Infection rates range between 65% and 70% during the first 6 months post-transplantation, with CMV representing 18% to 67% of the reported infections (Sia and Paya, 1998). With the advent of long-term monitoring, an increased incidence in cancer has also been noted in this population. For example, the risk of developing skin tumors following renal transplantation is 10% after 10 years and 40% after 20 years, while the incidence of squamous cell carcinoma is 250-fold higher and for basal cell carcinoma 10-fold higher than the general population (Hartevelt et al., 1990). The initial immunosuppressive therapy for renal transplant consists generally of a combination cyclosporin (CsA), azathioprine, and steroid cocktail. Therapies are subsequently reduced, but adjusted based upon the time following transplant, evidence of acute rejection, evidence of toxicity (usually serum creatinine levels), and white blood cell count, the latter of which is maintained above 4000 cells/mm^3. Jamil et al. (1999), examining 478 renal transplant patients, showed that the risk of lymphomas and infections during the first 6 months post-transplantation increased proportionally with the level of immunosuppressive therapy ranging from 1.5- to 3-fold. Urinary tract infections, which are associated with the transplant, were the most common type of infection in all groups, while severe bacterial infections (pneumonia and septicemia) and systemic/invasive fungal infections were almost exclusively associated with those on the most intensive immunosuppressive therapy. A high incidence of CMV antibodies occurred in all three groups with 9%, 29%, and 53% seroconverting, based upon the level of immunosuppressive therapy. In contrast to infectious diseases, there were fewer cases of squamous and basal cell carcinomas in the most aggressively treated group compared to the other groups, probably due to the anti-proliferative effects of some of the therapeutics. Wieneke et al. (1996), when also examining renal transplant patients, demonstrated that reduced IgG1 subclass levels and CD4 T cell counts were the best predictors for infections (relative risk increased from 9% in patients with normal values to 38% with lower values). Clark et al. (1993), following a small cohort of 27 patients, noted that by maintaining the level of CD3$^+$ lymphocytes to at least 500 cells/mm^3 a reduction in the number of serious viral infections occurred ($p < 0.04$).

IMMUNE SYSTEM, DISEASE, AND LIFE STAGE

The Neonate

Common infectious diseases occur more often and are usually more severe in the very young. In some cases, age-related physical or physiological differences in tissues or organs are responsible for the increased susceptibility to infections. However, in most cases, it is the relative immaturity of the immune system in the very young that prevents the host from making an adequate response to microorganisms. Neonates are particularly susceptible to infectious agents that require adult-like production of antibodies and complement to mediate phagocytosis and bacteria killing. This includes infections with encapsulated bacteria, (e.g., group B *Streptococcus* and *Haemophilus*), which, when combined with low expression levels of innate immune function, lead to inefficient bacterial killing and the subsequent development of infection.

Laboratory studies have provided qualitative and quantitative information on the differences in immune function that predispose neonates and young children to these infections. Bacteria that are commonly associated with neonatal sepsis and infections, such as gram negative *E. coli*, are initially controlled by polymorphonuclear leukocytes (PMNs), the first cells to arrive at sites of infection or tissue damage. PMNs in the newborn are not only produced at a lower rate than in adults (Wilson, 1986), but those produced have approximately half of the lysozyme and lactoferrin levels of adult cells (Ambruso et al., 1984) and only 30% of the adult content

Table 18.1.1 Distribution of Lymphocyte Subtypes in the Fetus, Newborn and Adult[a,b]

	Fetus				Neonate				Adult	
Marker	Percent	% of Adult	Absolute[c]	% of Adult	Percent	% of Adult	Absolute[c]	% of Adult	Percent	Absolute[c]

of bactericidal/permeability-increasing protein that are important in destroying microorganisms (Levy et al., 1999).

Recovery from most infections involves opsonization of bacteria by antibody and complement. At birth, neonates have nearly 70% of their total adult immunoglobulin (Ig) levels, and ~90% of adult IgG levels, although a significant portion of this is maternally-derived. This form of passive protection wanes as the maternal antibody is catabolized, and by 1 to 3 months of age, infants have only 30% of adult Ig levels (Stiehm and Fudenberg, 1966). Antibody synthesis progresses slowly with age, and it is still only ~70% of adult levels at 12 to 16 years of age (Stiehm and Fudenberg, 1966). Wolach et al. (1994) reported that serum of preterm infants and newborns also have only ~80% of adult levels of complement activity, and only 60% of C3, the main opsonizing complement component.

Although neonates have a higher percentage of total lymphocytes in their circulation compared to adults, ~90% of their thymus-derived lymphocytes are immature, compared to 50% in adults (Ciccimarra, 1994). Immature cells are incapable of making cytokines that are critical to mounting effective immune responses and generating long-lived memory cells. Phenotypic analyses of cord, neonatal, and adult peripheral blood has also shown differences in T cell subpopulations (Table 18.1.1), as well as differences in the balance of Th1 and Th2 cytokine production. At birth, the response is skewed in favor of Th2 cell responses (Upham et al., 2002), presumably decreasing the efficiency of host-protective responses, particularly to intracellular bacteria, while increasing the risk of developing allergic asthma. Similar age-related defects in immune function may also be a predisposing factor in repeated inner ear infections in young children. Faden (2001) noted that 5% to 10% of children experience four or more inner ear infections within the first year of life, particularly with *H. influenzae*. IgG antibody responses to conserved bacterial capsular proteins did not increase after 2 years of age in the infection-prone group, and T cell responses to the same antigen were also reduced, suggesting that repeated infections may be caused by subtle immunologic abnormalities in susceptible children.

The Elderly

The immune system of the elderly is characterized by a gradual decline in function (immunosenescence) which, in addition to underlying chronic diseases such as diabetes or emphysema (Burns and Goodwin, 1997), results in an increased incidence and severity of infections with common pathogens. In adults over 75 years of age, pneumonia and influenza together are the fourth leading cause of death (Yoshikawa, 1983). Although immunization is effective on a population basis, the CDC estimates that 90% of the excess deaths each year from influenza occur in individuals over 65 years old, due in part to poor vaccination responses (Fukuda et al., 1999). While the neonatal immune system is characterized by

Associating Changes in the Immune System with Clinical Diseases

Table 18.1.2 Effects of Aging on the Distribution of Lymphocyte Subtypes[a]

Marker	Young elderly (65–85)		Old elderly (>90)		Young adults (25–35)
	Absolute[b]	% of young adult	Absolute	% of young adult	Absolute[b]
Lymphocytes	1980 ± 620	89.6	1830 ± 680[c]	82.8	2210 ± 470
$CD2^+$	1730 ± 410[c]	87.4	1605 ± 470[c]	81.1	1980 ± 310
$CD3^+$	1510 ± 320[c]	81.6	1360 ± 380[c,d]	73.5	1850 ± 280
$CD4^+$	1115 ± 260[c]	89.6	1084 ± 290[c]	87.1	1245 ± 190
$CD8^+$	460 ± 190[c]	68.7	405 ± 220[c]	60.5	670 ± 145

[d]Significantly different from young elderly.

immature cells, the immune system in the elderly is characterized by normal numbers of mature cells but a decline in their ability to respond to imunogen (Shou et al., 1976; Wayne et al., 1990). Increased rates and severity of infection that occur in the elderly is the product of these effects as well as other physiological changes associated with the aging process. Physical effects include inefficient bladder function, decreased clearance of lung secretions, and reduced gastric acidity (Gavazzi and Krause, 2002), culminating in reduced barrier or clearance functions that normally reduce bacterial load in these organs. Various degrees of malnutrition and micronutrient deficiencies are also more common in the elderly and can contribute to decreased resistance (Lesourd, 1997). Although the relative distribution of immune cells does not change dramatically in the elderly, changes in the relative abundance of certain cell subpopulations do occur. Loss of naïve cells, which is secondary to thymic involution, appears in the third decade of life. Naïve T cells predominate in the circulation of young adults, while the relative distribution in the elderly shifts towards an increased proportion of memory cells. For example, Lesourd (1999) reported a 55% decrease in $CD45RA^+$ T cell counts and a 43% increase in $CD45RO^+$ cells in a population with an average age of 78 years, compared to 30 year olds (Table 18.1.2). Despite increased populations of specifically educated memory cells, many of these cells respond poorly, presumably because they have reached their replicative limit (Effros and Pawelec, 1997). Patterns of cytokine production also change with aging. Although contradictory results have been obtained in human studies, Cakman et al. (1996) reported that IFN-γ production is reduced by 70% while IL-4 production is increased by 4-fold in the elderly compared to 20 to 35 year olds. This may in part explain reduced cell-mediated resistance to influenza infection in the elderly.

Although the total numbers of circulating B cells do not change with age, B cell responses are also compromised in the elderly (Weksler, 2000). Immunization with diphtheria toxin in younger subjects produces higher antibody titers that persist longer than titers in older subjects. When evaluated at the single cell level, plasma cells in younger subjects are more plentiful and produce more antibody, on a per cell basis, than those from the elderly (Burns et al., 1993). In addition to functional changes in cellular and humoral immunity, innate immunity is suppressed in the elderly, including PMN function, which results from reduced superoxide production and shorter half-lives (Lord et al., 2001).

EXPERIMENTAL ANIMAL MODELS

As it is relatively difficult to determine the contribution of chronic low-level immunosuppression or the cumulative effects

Table 18.1.3 Commonly Employed Experimental Disease Resistance Models[a,b]

Challenge agent	Endpoint measured
Listeria monocytogenes	Liver CFU, spleen CFU, morbidity
Streptococcus pneumoniae	Morbidity
Plasmodium yoelli	Parasitemia
Influenza virus	Morbidity, viral titer/tissue burden
Cytomegalovirus	Morbidity, viral titer/tissue burden
Trichinella spiralis	Muscle larvae, parasite numbers
PYB6 sarcoma	Tumor incidence (subcutaneous)
B16F10 melanoma	Tumor burden (lung nodules)

[b] Abbreviations: CFU, colony forming units.

of modest changes in immune function to the background incidence of disease in the human population, several efforts have been made to examine these relationships in experimental groups. In the field of immunotoxicology, a set of tests, usually referred to as host resistance assays, have evolved in which groups of experimental animals are challenged with either an infectious agent or transplantable tumor at a challenge level sufficient to produce either a low incidence or minimal infectivity in the control group (Table 18.1.3). As the endpoints in these tests have evolved from relatively nonspecific (e.g., animal morbidity and mortality) to continuous measures, such as tumor numbers, viral titers, or bacterial cell counts, the sensitivity of these models has increased, although they are still limited by the number of animals that can be realistically devoted to any laboratory study and interanimal variability.

While there have been considerable efforts to establish interlaboratory variability and the robustness of tests to measure specific endpoints, such as antibody responses (Temple et al., 1993), histopathology (ICICIS, 1998; Kuper et al., 2000), quantitation of cell surface markers by flow cytometry (Burchiel et al., 1997; Zenger et al., 1998), or cytokine production (Langezaal et al., 2002; Hermann et al., 2003), there have been only two efforts that have evaluated the sensitivity and predictive value of individual measures of immune outcomes with host resistance tests. In 1979, under the auspices of the U.S. National Toxicology Program (NTP), a panel of experts gathered to prioritize a list of immunological and host resistance assays that would be suitable for use in mouse studies and a formal validation was initiated (Luster et al., 1988). A smaller effort was undertaken at the National Institute of Public Health and the Environment (RIVM) which focused on the rat and was based on the OECD #407 guideline (Vos, 1977, 1980; van Loveren and Vos, 1989). In both programs, host resistance tests were usually considered in a second or third testing level (tiered) evaluation, and only performed when there were indications of alterations in immune function in the first or second tiers. Data subsequently obtained from these validation programs indicated that host resistance assays, while correlated with immune tests, were not as sensitive as many of the functional tests.

Single-Parameter Studies

Predictive values of individual immune tests for host resistance

As recently reviewed (Germolec, 2003), several studies have addressed individual relationships between changes in immune measurements and host resistance tests routinely used in rodent studies. While it is rare for a single component of the immune system to be solely responsible for resistance to a specific infectious agent or tumor type, certain immune measures show significant correlations with the outcomes of individual host resistance assays. For example, reduction in NK cell activity has been correlated with increased susceptibility to challenge with PYB6 sarcoma cells, B16F10 melanoma cells, and murine CMV (Luster et al., 1988; 1993; Selgrade et al., 1992). Suppression of cell-mediated immunity, complement deficiency, and depressed macrophage and neutrophil function has been associated with decreased resistance to *Listeria monocytogenes* (Petit, 1980; Luster et al., 1988; Bradley, 1995b). Clearance of parasitic infections, such as *Plasmodium yoelii* and *Trichinella spiralis*, have both a cellular and

humoral component and decreased resistance has been shown following depression of both arms of the immune system (Luebke, 1995; van Loveren et al., 1995). While the predictive values of individual immune tests for host resistance have been shown to range from relatively good (plaque forming cell assay, 73%; NK cell activity, 73%; delayed type hypersensitivity response, 82%) to poor (lymphoproliferative response to LPS <50%), combinations of several immune tests allow for very high concordance (Luster et al., 1993), indicating that only two or three specific tests are required to screen adequately for immunotoxicity.

Tests for contributions of specific molecules

Deletion or functional blocking of specific immune components in experimental animals has been used to elucidate the relative contributions of specific molecules, signaling pathways, and cells to disease resistance (Hickman-Davis, 2001). This can be achieved via targeted gene disruption resulting in animals deficient in specific cell populations or soluble mediators which contribute to host defense (e.g., CD4 T cell knockouts), treatment of normal animals with selective toxic agents (e.g., the use of gadolinium chloride to block macrophage function), or administration of neutralizing antibodies against critical cell-specific surface receptors. A study by Wilson et al. (2001) was specifically designed to determine the magnitude of NK cell suppression that would translate into altered resistance in three disease models. The studies were conducted by NK cell depletion with an antibody to the cell surface molecule, Asialo GM1, using a treatment regimen that did not alter other standard immune function tests used in the assessment of immunotoxicity in rodents. These authors demonstrated that at low levels of tumor challenge, an approximate reduction of 50% or more in NK cell activity, now thought to be involved primarily in metastatic processes, was required before significant effects on resistance to NK-sensitive tumors could be observed. These studies also demonstrated that the level of suppression needed to alter host resistance was related to the challenge level of the tumor. Conversely, studies that have used monoclonal antibodies to effectively deplete $CD4^+$ and $CD8^+$ T lymphocytes have found little evidence of altered resistance to challenge with PYB6 sarcoma cells, a model which was thought to be dependent on cell-mediated immunity (Weaver et al., 2002).

Multiparameter Studies

Studies designed to address the contribution of a single immune parameter in host resistance will have limitations. In studies designed to specifically address these limitations, Keil et al. (2001) demonstrated that monitoring several immunological parameters concurrently provides information that might not be evident from studies using single tests. Using the prototypical immunosuppressive agent dexamethasone, these authors demonstrated that contrary to what would be expected based on the compound's suppressive effects on cytokine production, T cell function, and NK cell activity, relatively high levels of dexamethasone were needed to decrease resistance to *Listeria monocytogenes*. At doses that suppressed many immune parameters, an increase in neutrophil numbers, and nitrite production by peritoneal macrophages was observed. It was suggested that at lower doses of dexamethasone, the significant increase in the concentration of neutrophils in the blood, in conjunction with increased production of nitric oxide, compensated for the decrements in other immune parameters so that overall resistance to the pathogen was not compromised (Keil et al., 2001). Heryzk et al. (1997) have developed a testing paradigm that evaluates immune function within the context of resistance to a specific infection. Following infection with *Candida albicans*, a four-parameter model is used that includes survival, spleen colony forming units (CFU), muscle CFU, and antibody titers, and which the authors suggest allows an inclusive evaluation of both nonspecific, cell-, and humoral-mediated immune responses. This approach has proved successful in identifying both immunosuppressive and immunostimulatory compounds and has the advantage of being able to evaluate multiple immune endpoints in an intact animal and directly relate them to a clinical endpoint. The utility of the method as a screening tool has yet to be evaluated using large numbers of test articles or environmental chemicals, and the procedure is not widely used outside of the pharmaceutical industry.

Control of Variables

Variables, such as virulence and dose of the infectious agent that impact the ability to clear an infection in humans, can be controlled in experimental animal models. Using groups of mice that had received increasing doses of an immunsuppressive agent, Luster et al. (1993) challenged these mice with increasing doses

of PYB6 tumor cells in order to help clarify the dose-response relationship. It was observed that even immunologically normal animals, provided a sufficient number of tumor cells, develop a high frequency of tumors and the number of tumor cells required to produce tumors decreased proportionally to the degree of immunosuppression. This was interpreted to indicate that immune function–disease response relationships tended to be linear in nature, rather than threshold. Although it is not possible to confirm these relationships in humans, it was suggested that similar response relationships would also be applicable to humans, albeit with different slopes, provided other modifiers were not present. Similar relationships were suggested in studies of mice treated with cyclosporin and challenged with group B streptococcus, although studies using *L. monocytogenes* challenge indicated that the dose-response curve would be affected by the composite effects on all immune parameters (Keil et al., 2001).

THE SOCIAL AND ECONOMIC IMPACT OF SOME COMMON PATHOGENS

Impact of Mortality

The major purpose for undertaking immuntoxicology studies, whether in animal models or clinical studies, is to identify potential hazards and ultimately to assist in the risk assessment/management process. This decision process should take into account the social and economic impact of the potential health effects that would ensue. In order to begin establishing a framework for incorporating immunotoxicology data in the risk assessment/management process, it is necessary to identify the social and economic impact of infectious diseases in the general population. While precise information is not readily available, several sources indicate these to be significant and that even small changes in infectious disease frequency has a major impact. The impacts associated with mortality, and to a lesser extent morbidity, from common pathogens such as influenza and pneumonia, have been determined and can serve as a basis in the risk management process. Deaths have the most costly impact on society. In 2000, the age-adjusted death rate for influenza and pneumonia was 23.0 and 0.6 per 100,000, respectively, based on the 10th Revision of the International Statistical Classification of Diseases and Related Health Problems, 10th Revision coding (ICD-10, 1992). Together these infections were ranked as the seventh leading cause of death in the U.S. for all ages (Anderson, 2002). In 2000, the mortality rates for all infants from influenza and pneumonia were 7.5 deaths per 100,000 live births, a decline from 8.4 in 1999 (Hoyert et al., 2001; Minino et al., 2002). In both years, this number was dominated by pneumonia. Other conditions secondarily related to these illnesses, such as disorders related to low birth weights, respiratory distress, or bacterial sepsis, accounted for higher infant deaths (Minino et al., 2002), including neonates (<28 days of age); however, influenza and pneumonia still ranked seventh for post neonates (Anderson, 2002). For the ≥65 years age group, chronic lower respiratory disease and influenza-pneumonia were the fourth and fifth ranked leading causes of death in 2000, respectively (Anderson, 2002); however, pneumonitis due to aspirating solids and liquids into the lung is becoming a more common cause of death among the elderly and is now ranked as the fifteenth leading cause of death (Minino et al., 2002).

Cost

Economic impacts resulting from infectious diseases are captured by determining the number of deaths, hospitalizations, and outpatient or emergency room visits for specific illnesses, usually collected in national surveys, and applying formulas to convert these to dollars. Cost of illness methodology can handle, with some degree of confidence, the valuing of medical costs and productivity losses in an attempt to capture the burden of infectious disease mortality and morbidity. It should be noted, however, that most estimates of this burden do not account for reduced functional abilities, losses from pain and suffering, or the cost to the individual, family member, or co-worker from psychological or emotional stress. There are many other fundamentally unobservable quantities, such as the value of output that is lost as a result of an employee having an infectious disease episode. Valuing lost work days does not explain entire productivity loss but provides a comparison indicator.

An NIH-sponsored effort used methods from previous disease-specific results to estimate costs and applied inflation factors for the time period under consideration to estimate the total cost of influenza and pneumonia (ICD-9-CM, 1991). This amount included $18.6 billion for medical costs and $7 billion for productivity losses. Leigh et al. (2003) focused on

fourteen occupational illnesses to determine annual medical costs of occupational illnesses in the U.S. Within this population, estimates for pneumonia, using ICD-9-CM codes 480 to 482 and 484, which included only the 25 to 64 age group, was $24.7 million, with males accounting for $19.9 of the total. Otitis media (ICD-9-CM, 1991), the most common cause of hearing loss in children, occurs in 80% of children under 3 years of age and is the major reason for doctor or emergency room visits in this age group. According to the Agency for Health Care Research and Quality, formerly the Agency for Health Care Policy and Research, the 1991 annual cost for treating 2-year olds for otitis media was $1 billion. Estimates for 2000 places the figure at $5 billion, with $2.9 billion in direct costs and $2.1 billion in indirect costs (Kirstein, 2000). Langley et al. (1997) have estimated the annual cost of RSV infection at $17 million using ICD-9-CM code 466.1 in children younger than 4 years of age. The largest cost was associated with hospital services for the ~0.7% of infected children requiring admission. The average medical care expenditure for all children 2 years of age or younger was $22 per child.

CONCLUSIONS

For most toxic agents, adequate clinical data (i.e., exposure levels, disease incidence) are rarely available to accurately determine safe exposure levels without the need to include observations from either experimental models or human biomarkers studies. Thus, it is important that a scientifically sound framework be established that allows for the accurate and quantitative interpretation of experimental or biomarker data in the risk assessment process. For immunotoxicology data, this may require, for example, development of models to equate changes in leukocyte counts, $CD4^+$ cell numbers and/or immunoglobulin levels, which can be readily performed in humans, to changes in the background incidence or severity of infectious diseases. Although experimental animal models provide an opportunity to perform more informative immune tests and establish reliable exposure estimates, extrapolating these findings across species also introduces considerable uncertainty. While this review does not provide a specific framework to perform these extrapolations, the authors have attempted to provide background information on qualitative and quantitative relationships between immune parameters and disease that would be integral to such an effort. The following general conclusions can be surmised:

1. The major clinical, or at least most readily discernible, consequence of mild-to-moderate chronic immunosuppression is an increase in the incidence of infectious diseases. Only a few studies have addressed infectious disease severity or neoplastic diseases.

2. In addition to immunosuppression, many nonimmune factors can affect infectious disease incidences and should be considered in data interpretation. This is particularly evident with infections from common pathogens, such as influenza and pneumonia in the very young and elderly.

3. The type of infectious disease observed is often dependent upon the specific arm of the immune system that is affected. Thus, increased infections with obligate intracellular pathogens, such as viral infections, will most likely occur following suppression of cell mediated immunity while defects in phagocytic activity, such as neutropenia, will more likely increase susceptibility to facultative intracellular microbes.

4. Increases in infectious disease incidence following chronic immunosuppression can be caused by common pathogens, opportunistic microbes, or activation of latent viruses (most often from the herpes family). The ability to detect changes in the frequency of infections from common pathogens in epidemiological studies, (e.g., increased respiratory infections from influenza) has proved difficult, most likely due to the required complexity in the study design. Increased incidences of infection with opportunistic microbes can be readily observed in individuals with severe immunodeficiency, such as AIDS when immunological parameters, especially $CD4^+$ cell numbers, are reduced by $>50\%$ from control values.

5. It is considerably more difficult to ascertain health consequences from low-to-moderate levels of immunosuppression, as would be most likely to occur from exposure to immunotoxic agents than from severe immunosuppression. There are a number of studies, however, that indicate that these populations are at an increased risk to infection with common pathogens and latent viruses, particularly those from the Herpes family, but not to opportunistic infections. There are insufficient clinical data to determine whether the relationship between a decrease in immune response and an increase in infectious disease follows a linear or threshold relationship in humans. Studies in experimental animal models, however, support a linear relationship when

multiple immune system parameters are affected. However, threshold relationships occur when single immune parameters (e.g., NK cell activity) are targeted. These differences may be associated with redundancy in the immune system.

6. The major gap in clarifying the shape of the dose-response curve between immune response changes and disease risk is a lack of large-scale epidemiological studies in populations with mild-to-moderate immunodeficiency that have been monitored simultaneously for immune system parameters and clinical disease. Large studies that have been previously undertaken are of limited value. For example, the assessment of immune relationships in patients with AIDS-defining illnesses, such as *Pnuemocyctis carinii* pneumonia (PCP), CMV, and *Mycobaterium avium* complex (MAC) by the Multicohort AIDS centers were limited to individuals with $CD4^+$ T cell counts of $<500 \times 10^6$/liter (Pauli and Kopferschmitt-Kubler, 1991; Margolick et al., 1998; Amornkul et al., 1999). Interestingly, the 5-year cumulative probabilities for AIDS and infectious disease deaths in the latter stages show a relatively linear response from 0% to 76% occurrence in patients with $CD4^+$ cell counts between 500×10^6/liter and 200×10^6/liter, respectively (Vlahov et al., 1998). Furthermore, in one study where 864 patients failed to meet the study criteria ($CD4^+$ cell counts $>500 \times 10^6$/liter), 50 developed PCP, four developed CMV, and three developed MAC, indicating that opportunistic infection can occur in less immunosuppressed individuals but at a lower incidence (Lyles et al., 1999).

Acknowledgment

This review was prepared in conjuction with the Immunotoxicology Workgroup sponsored by the U.S. Environmental Protection Agency (EPA) Office of Research and Development (National Center for Environmental Assessment), EPA Office of Children's Health Protection, National Institute of Environmental Health Sciences (National Toxicology Program), and National Institute for Occupational Safety and Health (Health Effects Laboratory Division). Members of the workgroup not included as authors are: Drs. David Chen (EPA/OCPH), Marquea King (EPA/ORD/NCEA) and Yung Yang (EPA, OPPTS). Special thanks to Dr. Bob Sonawane (EPA/ORD/NCEA) for helping to organize this effort.

Local Lymph Node Assays

Skin sensitization resulting in allergic contact dermatitis (ACD), a delayed-type hypersensitivity reaction in the skin characterized by a tissue-damaging inflammatory response, is an important occupational disease and certainly the most common manifestation of chemical allergy in humans. A wide variety of natural and synthetic chemicals has been shown to be capable of causing ACD (Cronin, 1980). In common with other forms of allergic disease, the development of ACD proceeds in two phases. During the first of these, the induction phase, an inherently susceptible subject is exposed to amounts of the inducing contact allergen sufficient to provoke an immune response of the vigor (and quality) necessary for the acquisition of skin sensitization. If the now sensitized individual is subsequently exposed to the same chemical allergen (or to an immunologically cross-reactive chemical allergen) at the same or a different skin site, an accelerated and more aggressive secondary immune response will be elicited at the site of contact. This, in turn, will initiate the cutaneous inflammatory reaction recognized clinically as ACD. This latter reaction is the elicitation, or challenge, phase.

A variety of techniques has been developed to identify the hazards and risks of ACD potentially associated with exposure to chemicals at work, at home, or in the environment. These include several guinea pig tests in which skin sensitizing potential is measured as a function of challenge-induced skin reactions in previously sensitized animals (Magnusson and Kligman, 1970; Buehler, 1985). This unit describes an alternative approach, the murine local lymph node assay (LLNA). In this method, and in contrast to guinea pig tests, skin sensitization potential is assessed as a function of events associated with the induction phase. Specifically, the LLNA measures proliferative responses in skin-draining lymph nodes following topical exposure to a chemical. This approach is based on an understanding that the acquisition of skin sensitization is characterized by (and dependent upon) the expansion within regional lymph nodes of allergen-responsive T lymphocytes. Lymph node cell (LNC) proliferation is assessed by the incorporation in situ of radiolabeled ^{3}H-thymidine. The protocol for the standard LLNA, in which lymph nodes are pooled on an experimental group basis, is provided (see Basic Protocol), as is a modified method in which lymph nodes are pooled on an individual animal basis, providing the opportunity to employ statistical analyses (see Alternate Protocol). These methods have been developed for contact sensitization hazard assessment. In addition, it is possible to use LLNA data for the measurement of relative potency in the context of risk assessment (see Support Protocol).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (see *APPENDIX 1A*).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

STANDARD LOCAL LYMPH NODE ASSAY

BASIC PROTOCOL

The standard LLNA identifies contact sensitization hazard potential as a function of radiolabeled thymidine incorporation into the lymph nodes draining the site of topical

Contributed by Rebecca J. Dearman and Ian Kimber
Current Protocols in Toxicology (2004) 18.2.1-18.2.12

exposure to chemical. Mice ($n = 4$ per group) are topically exposed to various concentrations of test chemical or to vehicle alone daily for 3 consecutive days on the dorsum of both ears. Five days after the initiation of exposure, animals receive an intravenous injection of radiolabeled thymidine. Five hours later, the draining auricular lymph nodes are excised and pooled on an experimental group basis, a single cell suspension of LNC is prepared, and thymidine incorporation is measured by β-scintillation counting.

Materials

Young adult (6- to 16-week-old) female CBA mice: maintain in semibarriered conditions
Chemicals to be tested
Vehicle—e.g., 4:1 (v/v) acetone olive oil (AOO), methylethyl ketone, dimethylformamide, or dimethyl sulfoxide (DMSO)
2 Ci/mmol [^{3}H]thymidine: pass through a 0.45-μm filter to sterilize
PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
5% (w/v) trichloroacetic acid (TCA)
Scintillation fluid (e.g., Hi-Safe Optiphase)
Temperature-controlled hot box (Harvard Apparatus)
Mouse restraining tube with outlet for tail
1-ml graduated syringes with 25-G, 1-in. needles, sterile
200-G stainless steel mesh: cut into ~3-cm squares, wash in 70% ethanol, autoclave, and turn edges up to form a box
600-mm plastic petri dish
5-ml syringe plungers, sterile
10-ml plastic centrifuge tubes

Topically expose mice to chemical

1. Acclimatize young adult female CBA mice in cages of four animals per group for at least 2 days after arrival.
2. Prepare dosing solutions of the chemical to be tested in an appropriate vehicle, generally selecting three consecutive concentrations from the following: 50, 25, 10, 5, 2.5, 1, 0.5, 0.25, and 0.1% (w/v). Also prepare vehicle solution alone.

   Solutions must be prepared fresh, within 1 hr of dosing. Although in the context of hazard identification it may be desirable to select the highest test concentrations possible, this is not always practical. Poor solubility and/or concerns regarding acute or systemic toxicity may dictate a more conservative approach. Many organic vehicles may be used; however, water is inappropriate as a result of its high surface tension. This property makes it impossible to apply evenly and does not allow solutions containing it to remain in contact with the surface of the skin for a sufficient period of time for absorption. Experience indicates that the vehicles of choice, in order of preference, are AOO, methylethyl ketone, dimethylformamide, and DMSO (also see Critical Parameters and Troubleshooting). Vehicle selection is dictated by the relative solubility of the test material. For most purposes, AOO is suitable.

3. Dispense 25 μl chemical or vehicle alone on the dorsum of both ears of each animal ($n = 4$ per group) using a micropipettor with disposable tip, ensuring an even distribution over the surface of the ear.
4. Perform identical treatment (steps 2 and 3) once daily for the next 2 consecutive days, if possible at a similar time of day.
5. Rest the animals 2 days.

Inject thymidine

6. Prepare an 80 μCi/ml solution of tritiated thymidine in PBS, pH 7.2 to 7.4.

   CAUTION: *Gloves must be worn and the area in which thymidine is used must be swabbed and monitored regularly for radioactive contamination (also see APPENDIX 1A)*

7. Place the animals in a temperature-controlled hot box, one experimental group at a time, for 5 min to allow the veins to dilate.

   The temperature must not exceed 37°C.

8. Restrain each mouse individually using a restraining tube with an outlet for the tail and inject 0.25 ml of 80 μCi/ml radiolabeled thymidine (step 6) into the tail vein using a 1-ml graduated syringe and 25-G $\frac{5}{8}$-in. needle.

   Care must be taken to ensure syringe is free of air bubbles.

9. Return animals to cages and allow to rest 5 hr.

   CAUTION: *Any bedding or tray papers must be disposed of as radiolabel-contaminated waste, and cages must be decontaminated with Decon or similar detergent (also see APPENDIX 1A).*

Process lymph nodes

10. Euthanize animals by anesthetic overdose (e.g., Fluothane, Concord Pharmaceuticals) followed by cervical dislocation. Excise draining (auricular) lymph nodes, and pool for each experimental group in a small volume (~2 ml) PBS.

11. Place a square of 200-G stainless steel mesh into a 60-mm plastic petri dish containing 2 ml fresh PBS. Using tweezers, place the nodes onto the mesh square.

12. Prepare a single-cell suspension of lymph node cells (LNC) by gently disrupting the lymph nodes and pushing them through the mesh using the sterile plunger of a 5-ml syringe (i.e., by mechanical disaggregation).

13. Transfer the LNC from the petri dish into a 10-ml plastic centrifuge tube, rinsing the gauze and the petri dish with 10 ml fresh PBS. Wash the LNC twice in 10 ml fresh PBS by centrifuging 10 min at 100 × *g*, room temperature.

14. After the final wash, resuspend the cell pellet in 3 ml of 5% (w/v) TCA and store overnight at 4°C.

    Avoid clumping of LNC by ensuring pellet is completely resuspended in small volume of liquid before making up to final volume.

Determine incorporation

15. Centrifuge 10 min at 100 × *g*, room temperature. Discard the supernatant and resuspend in 1 ml fresh TCA. Transfer to 10 ml scintillation fluid and measure thymidine incorporation by β-scintillation counting.

    Avoid clumping of LNC by ensuring pellet is completely resuspended in a small volume of liquid before making up to final volume.

16. Record results as total disintegrations per minute per node (dpm/node) for each experimental group. Use the vehicle control group as the comparator in order to derive a stimulation index (SI) according to the following equation:

$$\text{SI} = \frac{\text{test dpm/node}}{\text{vehicle dpm/node}}$$

17. If appropriate doses and number of groups (usually 5) are used, determine the EC3 value as described (see Support Protocol)

ALTERNATE PROTOCOL

LOCAL LYMPH NODE ASSAY: ASSESSMENT OF PROLIFERATION FOR INDIVIDUAL ANIMALS

This alternate LLNA protocol is also for the identification of contact sensitization hazard potential as a function of radiolabeled thymidine incorporation into the lymph nodes draining the site of topical chemical exposure. Mice ($n = 5$ per group) are exposed topically on the dorsum of both ears to various concentrations of test chemical or to vehicle alone daily for 3 consecutive days. Five days after the initiation of exposure, animals receive an intravenous injection of radiolabeled thymidine. Five hours later, the draining auricular lymph nodes are excised, pooled for each individual animal, a single-cell suspension of LNC is prepared, and thymidine incorporation is measured by β-scintillation counting. Processing of lymph nodes on an individual animal basis provides the opportunity to assess interanimal variation in thymidine incorporation and allows the application of statistical analyses. This protocol is identical to that presented above (see Basic Protocol 1) except for the following steps.

1a. Acclimatize young adult female CBA mice in cages of five animals per group for at least 2 days after arrival.

10a. Euthanize animals, excise draining (auricular) lymph nodes, and pool for each individual animal in a small volume (~2 ml) PBS. Process each pair of lymph nodes separately.

16a. Record results as total disintegrations per minute per node (dpm/node) for each individual animal.

17a. For each test and vehicle control experimental group, calculate the mean dpm/node. Use the vehicle control group as the comparator in order to derive a stimulation index (SI) according to the following equation:

$$\text{SI} = \frac{\text{mean test dpm/node}}{\text{mean vehicle dpm/node}}$$

For each experimental group, normalize the data by obtaining log values.

18. Depending on whether data are parametric or nonparametric, apply Dunnett's *t* test or Krushal-Wallis test followed by Dunn's multiple comparison procedure, respectively (Loveless et al., 1996), to determine statistical significance of differences between test and control.

19. If appropriate doses and number of groups (usually 5) are used, determine EC3 value as described (see Support Protocol).

SUPPORT PROTOCOL

LOCAL LYMPH NODE ASSAY: POTENCY ASSESSMENT

The purpose of this protocol is the application of LLNA data for the measurement of the relative sensitizing potency of contact allergens. It is recognized that contact allergens vary substantially (at least four orders of magnitude) with respect to the relative potency with which they are able to induce contact sensitization. An understanding of relative potency of contact allergens can provide useful information that can contribute to the risk assessment process. Data (i.e., SI) derived using lymph nodes pooled on a group basis (see Basic Protocol) or derived using lymph nodes pooled per individual animal (see Alternate Protocol) are suitable for this purpose. In order to obtain accurate potency data from the LLNA, however, it is necessary to have some prior information regarding the activity of the material in tests for skin sensitization hazard to inform dose setting. It is usually necessary to increase the number of groups to 5 for accurate determination of EC3 values. Once the SI has been derived, the EC3 value (i.e., the estimated concentration of chemical required

to induce an SI of 3 relative to concurrent vehicle treated controls) can be obtained by linear interpolation using the equation: $EC3 = c + [(3 - d)/(b - d)] \times (a - c)$, where the data points lying immediately above and below the SI value of three have the coordinates (a, b) and (c, d), respectively. Note that the vehicle-treated control (SI = 1) cannot be used for the (c, d) data point.

COMMENTARY

Background Information

Allergic contact dermatitis (ACD), or contact sensitization, is the most common manifestation of chemical hypersensitivity response, with a wide variety of synthetic and natural chemicals implicated as causative agents. The prospective identification of skin sensitization hazard is therefore an important step in the safety assessment of new ingredients or products.

Contact sensitization tests based on elicitation reactions

Since the 1940s, a number of guinea pig tests have been available for the evaluation of contact sensitizing potential. The occluded patch test of Buehler and the Magnusson and Kligman guinea pig maximization test currently have the widest application for predictive assessment of contact sensitizing activity (Magnusson and Kligman, 1970; Buehler, 1985). All such tests employ a biphasic protocol in which animals are sensitized (induction phase) and subsequently challenged (elicitation phase) with the test chemical. Sensitization potential is determined by the visual assessment of challenge-induced erythematous skin reactions. Such tests have important limitations, including the fact that the endpoint of assessment of erythema is subjective and may lead to interpretative difficulties when colored or irritant chemicals are examined. It is normal practice to challenge with the maximum subirritant concentration of chemical. Therefore, with highly irritant materials, the concentration selected for challenge may be too low to elicit a dermal hypersensitivity reaction. The assays are also relatively time consuming and can require substantial amounts of test material.

Other test methods have been developed in mice, including the mouse ear swelling test (MEST; Gad et al., 1986) and mouse ear sensitization assay (MESA; Descotes, 1988), in which elicitation reactions are measured as a function of challenge-induced increases in ear thickness. Of these methods, the MEST assay has been evaluated most thoroughly. The reliability and sensitivity of this assay have been improved by the introduction of a vitamin A–supplemented diet, which results in enhanced ear swelling responses; however this assay has not been adopted widely (Thorne et al., 1991).

Induction tests for ACD: the local lymph node assay: history and development

The approach adopted in the authors' laboratory has been to investigate whether an understanding of the events occurring in the induction rather than the elicitation phase of contact sensitization could be applied to the development of alternative methods for the prospective identification of contact allergens. The primary immunological response to epicutaneously applied skin-sensitizing agents is dependent upon the recognition of, and response to, chemical antigens by T lymphocytes and is characterized by hyperplasia in the draining lymph nodes (Parrott and De Sousa, 1966; De Sousa and Parrott, 1969). Lymph node activation is reflected by an increase in node weight, the appearance of large pyroninophilic cells, and the induction of lymphocyte proliferation. In the authors' preliminary studies, each of these parameters was examined following topical exposure to chemical (Kimber et al., 1986; Kimber and Weisenberger, 1989). It was concluded that lymphocyte proliferation, measured by the incorporation of ^{3}H-thymidine, provided the most sensitive and reliable correlate of skin sensitizing potential. This is a relevant read out for the evaluation of skin sensitizing potential, as confirmed by the demonstration that the vigor and duration of lymphocyte proliferation directly influences the extent to which contact sensitization occurs and consequently the severity of the dermatitic reaction that will develop following challenge (Kimber and Dearman, 1991).

These preliminary studies (Kimber et al., 1986; Kimber and Weisenberger, 1989) defined the optimum conditions required to provoke and measure LNC proliferation, including investigation of the kinetics of the response and strain comparisons. It was found that exposure of mice to skin allergens on the dorsum of both ears caused hyperplasia in draining auricular lymph nodes, peripheral lymph

nodes that can be readily identified and excised. Daily exposure for 3 consecutive days produced a more vigorous response than did a single application of the same total amount of chemical. In comparative investigations, mice of the CBA strain were found to exhibit greater responses than did other strains examined (Kimber and Weisenberger, 1989). In these early studies, proliferation was measured in vitro following culture of isolated draining LNC with [^{3}H]thymidine. In subsequent experiments an important modification was introduced that improved the sensitivity of the assay: the measurement of proliferative activity in situ by intravenous injection of [^{3}H]thymidine. It is this version of the assay that has been the subject of extensive evaluation in the context of national and international collaborative trials, and it has been the subject of detailed comparisons with guinea pig tests and human data (reviewed in Gerberick et al., 2000; Basketter et al. 2002; Kimber et al. 2002). After a thorough and independent evaluation, the method was validated in the U.S.A. (Interagency Coordinating Committee on the Validation of Alternative Methods, 1999) and subsequently in Europe by the European Centre for the Validation of Alternative Methods (ECVAM; Balls and Hellsten, 2000). The LLNA has now been incorporated into a new test guideline, *Skin Sensitization: Local Lymph Node Assay*, (No. 429) by the Organization for Economic Cooperation and Development and was adopted formally in 2002 (OECD, 2002).

LLNA: hazard identification and potency assessment

As described herein, the basic LLNA protocol, in which lymphocyte proliferation is measured as a function of thymidine incorporation in situ and lymph nodes are processed per experimental group, and the alternative in which lymph nodes are processed per experimental animal, provide data suitable for identification of contact sensitizing hazard. Skin sensitizing chemicals are defined as those that, at one or more test concentrations, provoke a threefold or greater increase in LNC proliferation compared with concurrent vehicle-treated controls. Conversely, chemicals that fail at all test concentrations to elicit a positive response in the LLNA should be classified as lacking significant skin-sensitizing potential and should be handled and labeled according. Initially, the threshold value of three was chosen empirically on the basis of previous experience with the LLNA, as it offered good discrimination between contact allergens and nonsensitizers. Subsequently, a retrospective statistical analysis was performed on data from 134 chemicals tested in the LLNA using receiver operating characteristic (ROC) curves (Basketter et al., 1999). These analyses confirmed that the empirically derived threefold threshold is an acceptable practical value for hazard identification. In addition, if LLNA potency assessment is used (see Support Protocol), an estimate of the relative skin sensitizing potency of the material can be derived. For this purpose, an EC3 value (i.e., the amount of chemical sensitizer required to elicit a three-fold increase in LNC proliferative activity) is calculated. EC3 values are derived by linear interpolation of values either side of the threefold SI on a LLNA dose-response curve, with values generally expressed as percentage concentrations. Experience has revealed that EC3 values determined in this way are robust determinants of relative skin sensitizing potential; equivalent results have been obtained in different laboratories, and over time within a single laboratory (Loveless et al., 1996; Dearman et al., 1998; 2001). The estimates of skin sensitizing potency measured as a function of derived EC3 values are relevant for the induction of skin sensitization in humans. Collaborative studies were conducted in the U.S. and U.K. in partnerships between experimental laboratories performing the LLNA and clinical dermatologists, with the latter providing a view of the relative induction potency of two series of known chemical allergens. A close correlation between clinical assessments of potency and LLNA EC3 values was reported (Basketter et al., 2000; Gerberick et al., 2001). Stronger sensitizers, such as 2,4-dinitrochlorobenzene (DNCB) have lower EC3 values than more moderate sensitizers, such as hexyl cinnamic aldehyde (HCA). The current recommendation for the categorization of contact allergens with respect to relative sensitizing activity based on LLNA EC3 values is divided into four categories as shown in Table 18.2.1.

LLNA: advantages and disadvantages

Compared with guinea pig test methods, the LLNA offers the advantages of (1) having an objective and quantitative endpoint that is unaffected by the color of the test material, (2) having animal welfare advantages with respect to both refinement (no use of adjuvants, shaving, depilation, or occlusive bandages or patches) and reduction in animal usage, and (3) requiring smaller amounts of chemical and less time for completion. Additionally, the

Table 18.2.1 Recommended Categorization of Contact Allergens[a]

Category	EC3
Extreme	<0.1%
Strong	>0.1% to <1%
Moderate	>1% to <10%
Weak	>10% to <100%

[a]Refer to Kimber et al. (2003) for details.

weight of evidence suggests that in most cases, irritant nonsensitizing chemicals fail to elicit positive responses. The limitations of the assay are that it does not evaluate the elicitation response and cannot be used to test the dose cross-challenge reactions.

Critical Parameters and Troubleshooting

Vehicle and dose selection

The selection of dose and vehicle are of critical importance for the conduct of the LLNA. The dose selection when using the standard LLNA (see Basic Protocol) or individual animal LLNA (see Alternate Protocol) for contact sensitization hazard identification is based on providing the highest possible test concentration to maximize the potential for hazard identification. Test concentration selection will be limited by compatibility with the vehicle chosen and the suitability of the resultant preparation for unoccluded dermal application and should preclude local (dermal) trauma or systemic toxicity. Selection of doses when using LLNA potency assessment (see Support Protocol) for relative potency assessment is usually based on prior information in order to obtain concentrations that provoke SIs above and below the threshold value of three. A variety of organic solvents are suitable for the performance of the LLNA. The following are recommended, in order of preference: AOO, acetone, dimethylformamide, methyl ethyl ketone and DMSO. Aqueous vehicles are not recommended, although aqueous and aqueous-organic mixtures such as 3:1 (v/v) acetone to water have been used successfully.

Positive controls

It is advisable for a laboratory to regularly demonstrate that competence has been achieved with the assay. This can be effected by the use of a positive control material such as HCA, which is currently recommended by the OECD as a positive control for tests for contact sensitization. This chemical has been evaluated thoroughly in the LLNA, both in the context of interlaboratory trials and with respect to the stability of responses with time; furthermore, the comparative data are available in the literature (Loveless et al., 1996; Dearman et al., 1998, 2001). These experiments have demonstrated that HCA is identified routinely as a contact sensitizer in the LLNA, with comparable EC3 values obtained between laboratories and for repeat assays within the same laboratory.

Interpretation of abnormal vehicle control data

The interpretation of LLNA data requires that the proliferation achieved in test groups be compared with the background activity in concurrent vehicle-treated controls so that the SI can be derived. Clearly, the use of the vehicle-treated control value as the denominator in the calculation for deriving the SI means that if this value is abnormally high or low, it will impact markedly on the calculated SI and hence on the EC3 calculation. An abnormal level of thymidine incorporation may be due to technical difficulties with the assay (such as failed intravenous injections) or may reflect the health status of the animals; for example, relatively high levels of basal proliferation accompanied by increased lymph node size can be indicative of a viral infection or a lymphoproliferative disorder. It is apparent that for experienced competent laboratories, control levels of proliferation in the LLNA are relatively consistent, although the absolute values vary according to the testing laboratory. For example, a recent series of experiments in which background levels using the preferred vehicle, AOO, were compared across laboratories revealed that control values accumulated from 44 independent LLNAs performed in one laboratory ranged from 97 to 662, with a mean of 321, whereas in another laboratory values ranged from 211 to 1000, with a mean of 410 (Basketter et al., 2003). Some biological variation and interlaboratory variation is to be expected in basal levels of thymidine incorporation. The important point, however, is that despite the interlaboratory and

interexperimental variation in absolute control values, in these studies, each laboratory observed very little interexperimental variation in derived SI values or EC3 values for a given chemical. Furthermore, there was very little interlaboratory variation in these parameters (Dearman et al., 2001). It is necessary therefore to establish a normal range of control values for a given vehicle and to monitor any excursions from this range in any laboratory conducting the LLNA.

Interpretation of dose response

In many experiments, a typical dose response curve will be observed for chemical allergen–induced proliferation, with dose-dependent increases in proliferation that may or may not reach a plateau. In some cases, a bell-shaped curve is recorded, with thymidine incorporation reaching maximal levels at intermediate doses, while at higher doses, less vigorous proliferation is observed. This effect may be due to systemic toxicity at high doses, which may be monitored by general health checks such as the daily recording of weight gain on an individual animal basis. The existence of a bell-shaped curve should not affect the interpretation of the LLNA with respect to hazard identification or relative potency assessment. In some cases, the proliferative response to chemical may show a dose-dependent increase in thymidine incorporation that does not attain an SI of three at the maximum dose tested. In this case, the most judicious interpretation is that the chemical has potential to cause contact allergy, and if possible, a repeat assay using higher concentrations

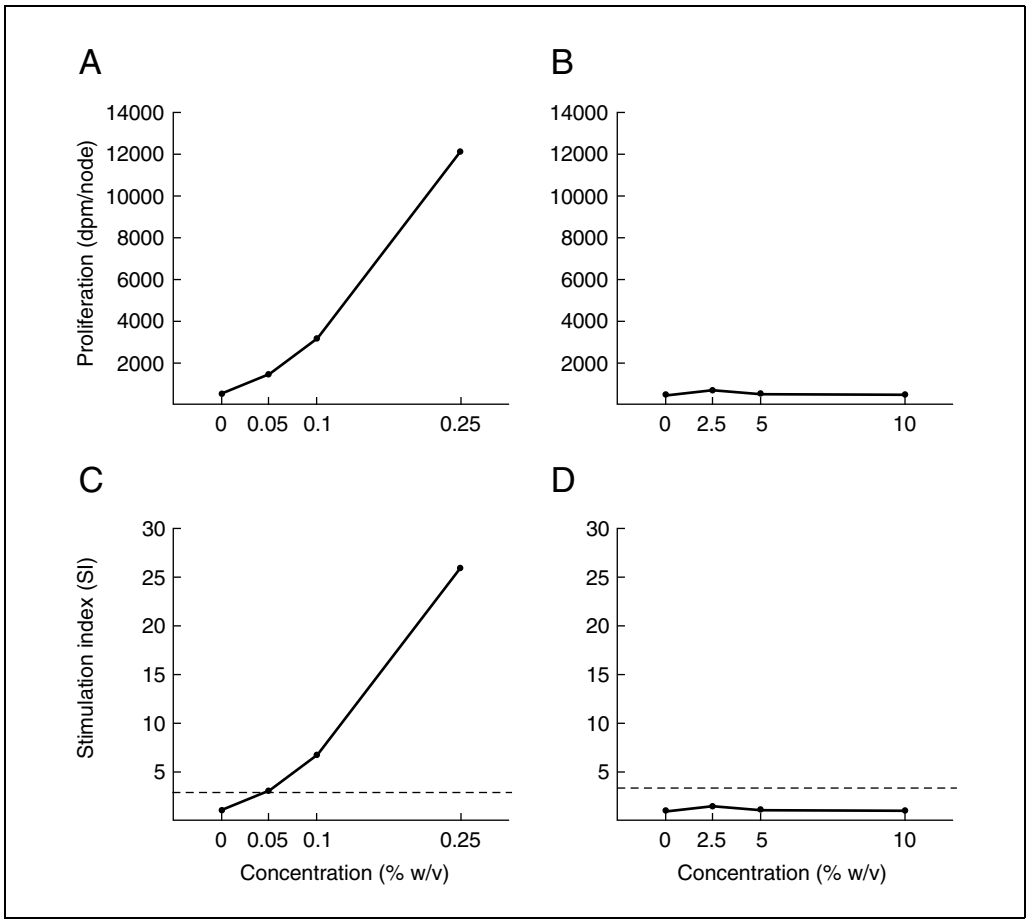

Figure 18.2.1 Typical results derived using standard LLNA (see Basic Protocol). CBA strain mice ($n = 4$) received 25 μl of various concentrations of (**A** and **C**) the potent contact allergen DNCB or (**B** and **D**) the nonsensitizing skin irritant *p*ABA, or vehicle (AOO) alone on the dorsum of both ears daily for 3 consecutive days. Five days after the initiation of exposure, all mice received an intravenous injection of radiolabeled thymidine. Five hours later, draining auricular lymph nodes were excised, pooled on a treatment group basis, and processed for β-scintillation counting. Results are expressed as group dpm/node in (A) and (B) or as a stimulation index (SI) relative to vehicle treated control groups in (C) and (D). An SI of 3 (current threshold value for a positive in the LLNA) is illustrated as a broken line in (C) and (D).

of material or an alternative vehicle should be performed.

Anticipated Results

Standard LLNA

Typical results derived using standard LLNA (see Basic Protocol), in which animals have been exposed to three concentrations of the potent contact allergen DNCB or to the nonsensitizing skin irritant *para*-aminobenzoic acid (*p*ABA), both formulated in AOO, are shown in Figure 18.2.1. Data are displayed as a function of dpm/node and as SI relative to concurrent vehicle-treated control values, the latter being the usual method for displaying results. Exposure to DNCB induced a marked dose-dependent increase in proliferation compared with vehicle-treated control mice, with all concentrations tested provoking an SI of greater than or equal to three. This material is therefore classified as a skin sensitizer. In contrast, the nonsensitizing skin irritant *p*ABA, despite testing at doses some 40-fold higher than those utilized for DNCB, failed to elicit increases in thymidine incorporation at any concentration examined. This material is therefore classified as lacking significant potential to cause skin sensitization.

Alternative LLNA

Typical results derived using the individual animal-based LLNA (see Alternate Protocol) are shown in Figure 18.2.2. Animals have been exposed to the same concentrations of DNCB or *p*ABA or to vehicle (AOO) alone

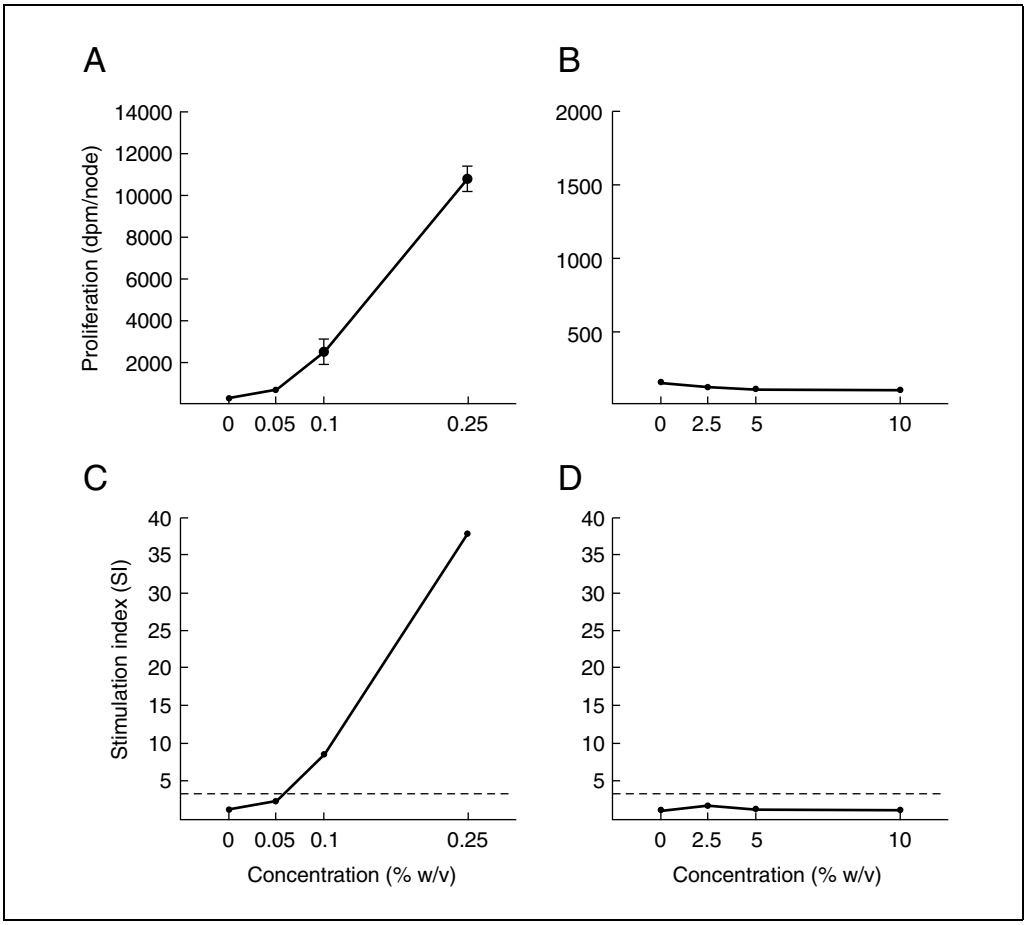

Figure 18.2.2 Typical results derived using the individual animal–based LLNA (see Alternate Protocol). CBA strain mice ($n = 5$) received 25 μl of various concentrations of (**A** and **C**) the potent contact allergen DNCB, (**B** and **D**) the nonsensitizing skin irritant *p*ABA, or vehicle (AOO) alone on the dorsum of both ears daily for 3 consecutive days. Five days after the initiation of exposure, all mice received an intravenous injection of radiolabeled thymidine. Five hours later, draining auricular lymph nodes were excised, pooled on an experimental animal basis, and processed for β-scintillation counting. Results are expressed as mean ± SE dpm/node per group in (A) and (B) or as a stimulation index (SI) relative to vehicle treated control groups in (C) and (D). An SI of 3 (current threshold value for a positive in the LLNA) is illustrated as a broken line.

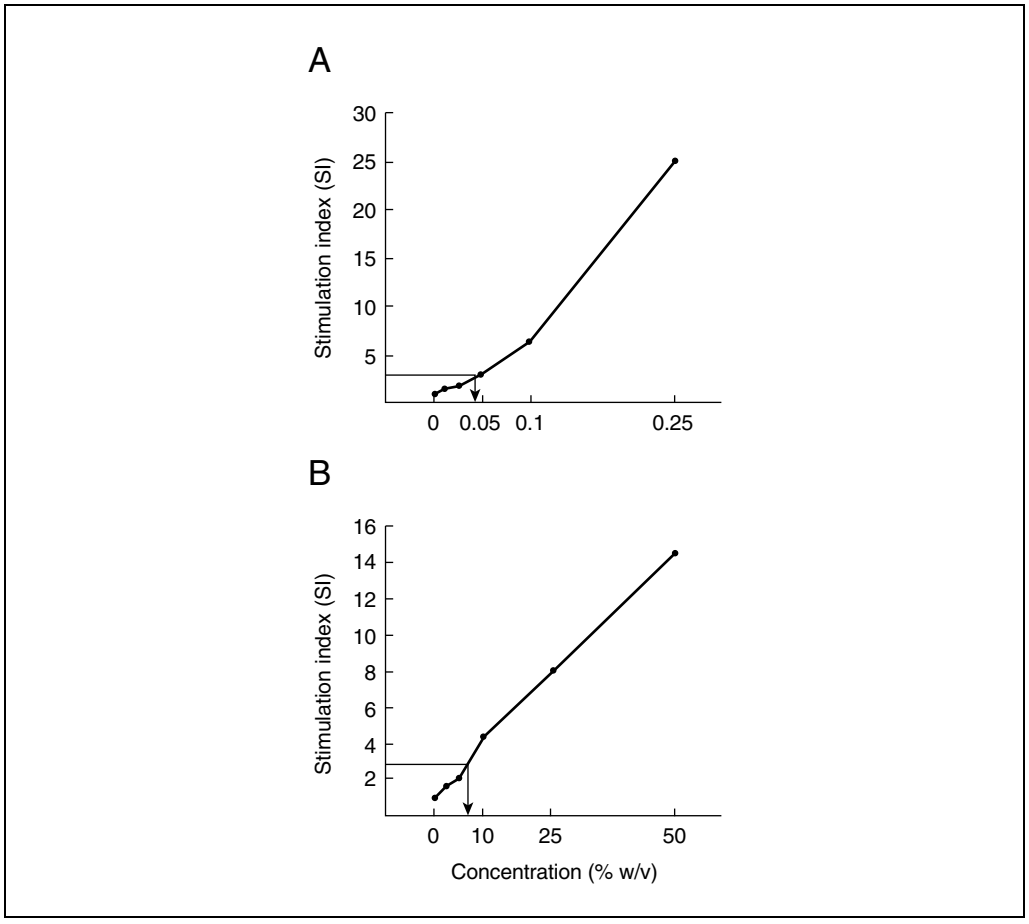

Figure 18.2.3 Typical results derived using LLNA for the assessment of relative skin sensitizing potency (see Support Protocol). CBA strain mice received 25 μl of various concentrations of (**A**) the potent contact allergen DNCB, (**B**) the more moderate allergen HCA, or vehicle (AOO) alone on the dorsum of both ears daily for 3 consecutive days. Five days after the initiation of exposure, all mice received an intravenous injection of radiolabeled thymidine. Five hours later, draining auricular lymph nodes were excised, pooled on a treatment group basis and processed for β-scintillation counting. Results are expressed as a stimulation index (SI) relative to vehicle treated control groups. The EC3 value (illustrated by an arrow) is calculated by linear interpolation.

as in the standard LLNA (see Basic Protocol) described above (Figure 18.2.1). In this experimental protocol, lymph nodes from individual animals were processed rather than lymph nodes pooled on an experimental group basis. Data are displayed as a function of mean ± SE dpm/node and as SI relative to concurrent vehicle-treated control values; the latter being the usual method of displaying the results. The modified protocol yields equivalent results to the standard LLNA, with DNCB identified as a skin sensitizer and *p*ABA classified as lacking significant potential to cause skin sensitization.

Skin sensitization potency

Typical results derived using LLNA for the assessment of relative skin sensitizing potency (see Support Protocol) are shown in Figure 18.2.3. Animals have been exposed to five concentrations of the potent contact allergen DNCB or to the more moderate skin sensitizer HCA, both formulated in the vehicle of choice for the LLNA, AOO. Data are displayed as SI relative to concurrent vehicle-treated control values. Both chemicals provoked marked dose-dependent increases in proliferation compared with vehicle-treated control mice. Both materials are therefore classified as skin sensitizers. In each case, concentrations of chemical have been selected that elicit SI values either side of an SI of 3. Thus the data are appropriate for the derivation of EC3 values: DNCB EC3 $= 0.025 + [(3 - 1.9)/(3.1 - 1.9)] \times (0.05 - 0.025) = 0.048\%$ and HCA EC3 $= 5 + [(3 - 2.12)/(4.35 - 2.12)] \times (10 - 5) = 7.0\%$. According to the recommendations of Kimber et al. (2003), DNCB is categorized as an extreme contact sensitizer, whereas HCA is classified as a moderate contact sensitizer.

Time Considerations

Topical exposure to chemical

For a LLNA assay with five concentrations of test chemical and vehicle control, it will take ~30 min to prepare the formulations. Topical application of test chemical/vehicle to six groups of mice will require ~30 min. This procedure will be repeated every day for 3 days.

Injection of thymidine and processing of lymph nodes

Preparation of dosing solution (thymidine) and loading syringes for a typical assay with six groups will take ~30 min. Intravenous injections for this number of groups will take 45 min to 1 hr. The mice are rested for 5 hr. Termination and excision of lymph nodes will require ~45 min to 1 hr. Processing of lymph nodes ready for overnight precipitation in 5% TCA will take ~2 hr. The following day, resuspension of lymph nodes in 5% TCA and addition of scintillation fluid will take ~30 min.

Murine Asthma Models

Immunotoxicity takes two general forms. One is an immunosuppression, resulting in an inability of the immune system to adequately defend against invaders such as cancer cells or pathogens. However, another type of immunotoxicity is an enhancement of the immune response or hyperreactivity of the immune system. In this situation, the offending substance or allergen is immunogenic and mobilizes the humoral and/or cellular arms of the immune system. Autoimmunity or hypersensitivity is the result. Asthma is one possible consequence of an increased immunoreactivity or an allergic response in the lung, either to environmental antigens or to antigens encountered in the workplace, i.e., occupational asthma.

The asthmatic response is divided into an induction phase (sensitization) and an effector (elicitation or challenge) phase. The induction phase involves the first exposure to a substance and a specific immune response is evoked. Re-exposure or challenge with the allergen then causes the effector phase—the asthmatic symptoms. Occupational asthma is categorized as immunological and non-immunological, depending on whether an induction phase or latent period is necessary to evoke the asthmatic symptoms. In addition, within the category of immunological occupational asthma, latitude is given for IgE, non-IgE, or unknown immune mechanisms that can lead to the asthma symptoms.

Regardless of cause, asthma is characterized by reversible airway obstruction, airway hyperresponsiveness to a variety of agonists including methacholine, mucus production, airway remodeling, and cell infiltration into the lung, particularly eosinophil infiltration. Various trigger factors for asthma, such as exercise, ozone, pollutants, viral infection, emotion, and passive smoke can have profound effects on the asthmatic response to allergens and exacerbate an ongoing inflammatory situation in the lung. In addition, high exposures to noxious substances have been reported to initiate asthmatic symptoms in the lung, without a latent period.

In toxicology, two primary areas of investigation prompt the measurement of the asthmatic response in an animal: (1) identification of chemicals or proteins that cause asthma, i.e., respiratory allergens, and (2) identification of exposures that will exacerbate existing asthma. Ovalbumin-induced asthma in the mouse is a model system that can readily be used to identify substances that could exacerbate existing asthma. The effect of exposure to a toxic substance on endpoints of the ovalbumin-induced asthmatic response is determined. With regard to identification of respiratory allergens, much effort has been expended to develop reliable methods. The LLNA (*UNIT 18.2*) can identify substances that have the potential to cause allergy after topical exposure, i.e., hazard identification. By determining if exposure to a substance results in proliferation of lymph node cells, the LLNA assay identifies substances that induce an immune response. Whether continued exposure to these substances, or exposure via the respiratory route, will result in asthma requires measurement of the asthma symptoms in an animal model after re-exposure or elicitation of the response.

With these potential uses in mind, the Basic Protocol describes a method to sensitize and challenge a mouse using the protein allergen ovalbumin to reliably elicit asthma symptoms. Ovalbumin is widely used in experimental systems in immunology and has been extensively used to explore the effector mechanisms in rodent models of asthma. In addition, ovalbumin is a known cause of occupational asthma in egg processing facilities. The assessment of characteristic asthma symptoms in the mouse are described by: airway

Contributed by Jean F. Regal
Current Protocols in Toxicology (2004) 18.3.1-18.3.21

hyperresponsiveness to the agonist methacholine in a conscious unrestrained mouse (see Support Protocol 1), cellular infiltration into the airspace (see Support Protocol 2), and cellular infiltration into the lung (see Support Protocol 3). As described here, the Support Protocols are used with mice sensitized and challenged with ovalbumin as in the Basic Protocol, however, they could also be used in non-sensitized animals to determine if inflammatory stimuli such as endotoxin, diesel exhaust, and other substances can cause airway hyperresponsiveness and cellular infiltration into the lung of the mouse.

BASIC PROTOCOL

MOUSE SENSITIZATION AND INTRANASAL CHALLENGE

Numerous methods are available for sensitization and challenge of a mouse using ovalbumin to elicit the symptoms of asthma. One such protocol that consistently results in an asthmatic response is described here using a Balb/c mouse. The mouse is injected by the intraperitoneal route with ovalbumin and alum as an adjuvant. After a selected waiting period for induction of the specific immune response, mice are then challenged intranasally on 3 successive days to elicit airway hyperresponsiveness and cellular infiltration into the lung. Depending on the purpose of the experiment, control mice are either sensitized with alum solution without ovalbumin, or challenged with water intranasally rather than ovalbumin. In some instances, both types of controls are indicated as well as animals sensitized with alum alone and challenged with water. After the time period of interest, the asthma symptoms are evaluated as outlined in Support Protocols 1, 2, and 3.

This protocol will be concerned with using ovalbumin as an antigen to sensitize and challenge the mouse. To determine if exposure to other chemicals or proteins results in asthma symptoms, the properties and normal exposure routes of the substance need to be taken into account. Convenient experimental systems are not always available, since many substances are not water soluble and the primary exposure is inhalation of dust. Some animal models of asthma caused by the occupational allergen trimellitic anhydride (TMA) have used sensitization of the mouse or guinea pig intradermally with TMA suspended in oil, followed by intratracheal challenge with TMA conjugated to albumin (Hayes et al., 1992b; Fraser et al., 1995; Regal et al., 2001). This method of sensitization and challenge with TMA resulted in eosinophil infiltration into the lung. Other methods of exposure to low-molecular-weight occupational allergens such as toluene diisocyanate and TMA have been tried, including inhalation of the dust (Hayes et al., 1992a), topical exposure to the dust (Zhang et al., 2002) and intratracheal exposure of oil suspensions of the molecule (Ebino et al., 2000). Various asthma endpoints have been examined after sensitization and challenge. In many of the studies, the primary concern was induction of the immune response as evidenced by IgE production or cytokine elaboration in local lymph nodes, i.e., hazard identification. Work still needs to be done to effectively and efficiently use rodent models of asthma to identify chemical or protein exposures that will cause asthma.

Materials

Ovalbumin for sensitization (see recipe)
Imject Alum aluminum hydroxide solution (Pierce Chemical)
Normal saline solution (endotoxin-free)
Mice of selected strain, age, and sex (e.g., Balb/c, 6 to 8 weeks old)
Ovalbumin for challenge (see recipe)
Ketamine/xylazine (see recipe)
Water (endotoxin-free)

2-ml polypropylene screw-cap vials
Micro stir bar
Animal balance (accurate to 0.1 g)
1-ml syringes and 27-G × 1/2-in. needles
100-μl pipet and tips

Sensitize with ovalbumin (day 1)

1. Thaw 1.2 ml ovalbumin for sensitization and begin stirring in a 2-ml screw-cap plastic vial with a micro stir bar. Add 0.4 ml Imject Alum dropwise to 1.2 ml solution of ovalbumin for sensitization or normal saline solution (endotoxin-free).

   This is enough ovalbumin for sensitization of 5 to 7 mice. Stir each vial continuously for 30 min at room temperature to allow adsorption of the antigen.

   Reagents and containers for sensitization and challenge should be endotoxin free. Use endotoxin-free reagents and sterile plastic ware. Alternatively, treat any glassware with E-Toxa clean concentrate (Sigma) or similar reagent to remove endotoxin contamination. Treating clean glassware at 175°C for a minimum of 3 hr will also destroy endotoxin. Ovalbumin can have endotoxin contamination. The amount of endotoxin contamination in a particular lot of ovalbumin can be determined using a Limulus Amebocyte Lysate assay supplied by Sigma (E-Toxate Kit) or BioWhittaker.

2. Weigh mouse and calculate volume for intraperitoneal injection at 0.2 ml/20 g mouse (0.5 mg ovalbumin/kg). Swirl the ovalbumin/aluminum hydroxide suspension prior to loading the calculated volume into a 1-ml syringe with attached 27-G × 1/2-in. needle.

3. Pick up mouse by the tail and allow the mouse to grab the cage top with its front paws. Pinch the skin at the nape of the neck firmly with thumb and forefinger of the other hand, holding the tail between the palm and other fingers.

4. Inject calculated volume intraperitoneally by tilting the animal slightly head down so the intestines fall forward, insert needle bevel up in the lower right quadrant of the abdomen, slightly off the midline, and then pull back slightly on the plunger before injecting to ensure that no fluid is withdrawn.

   The needle should be inserted high enough to avoid the bladder and the cecum and not deep enough to penetrate kidneys or spinal column.

   If yellow or greenish-brown fluid is withdrawn, the bladder or the cecum may have been penetrated. If this is the case, discard the syringe and its contents and start again.

5. Return the mouse to the cage. Repeat steps 2 through 5 if necessary, for other mice.

Intranasally challenge with ovalbumin (days 14 to 16)

6. Thaw ovalbumin solution for challenge and mix gently by inversion.

7. Weigh mouse and calculate volume of ketamine/xylazine solution for intramuscular injection (0.1 ml/20 g mouse). Load 1-ml syringe with 27-G × 1/2-in. needle with ketamine/xylazine.

   Ketamine is a Schedule III controlled substance and requires proper licensing and storage in an authorized locked cabinet.

8. Calculate volume of ovalbumin for challenge or water (endotoxin-free) for intranasal instillation (80 µl/20 g mouse; 5 mg/kg) and load 100-µl pipet with proper volume.

   Alternatively, a mouse serum albumin solution in water can be used as a control challenge.

9. Pick up mouse by the tail and allow it to grab the cage top with its front paws. Pinch the skin at the nape of the neck firmly with thumb and forefinger of the other hand, holding the tail and hind limb between the palm and other fingers.

10. Inject calculated volume of ketamine/xylazine (from step 7) into muscle of hind limb. Return mouse to cage until anesthesia takes effect in ~3 to 5 min.

11. Remove anesthetized mouse from cage and hold gently with nostrils pointing straight up. Using the 100-µl pipet, slowly drip calculated volume of ovalbumin for intranasal

instillation (from step 8) over nostrils, alternating nostrils until entire volume disappears from view. Return mouse to cage.

12. Repeat daily for 3 days at approximately the same time of day for each intranasal instillation.

A convenient challenge time is first thing in the morning so that the evaluation of airway hyperresponsiveness (see Support Protocol 1) and cellular infiltration (see Support Protocols 2 and 3) can be measured at 24 and/or 48 hr post-challenge.

SUPPORT PROTOCOL 1 MEASURING AIRWAY HYPERRESPONSIVENESS IN A CONSCIOUS UNRESTRAINED MOUSE

A hallmark of asthma in the human is increased reactivity of the airways to numerous different agonists, i.e., airway hyperresponsiveness. As the severity of the asthma increases, the reactivity of the airways to methacholine increases. A positive methacholine challenge test is used clinically in the differential diagnosis of asthma. In the mouse, various methods have been developed to measure pulmonary function. Whole-body plethysmography in conscious unrestrained animals (Hamelmann et al., 1997) uses changes in a plethysmograph box pressure to follow breathing patterns and calculate the dimensionless value-enhanced pause (PenH). The inspiratory time, the decay of the expiratory time, and the maximum changes in box pressure during inspiration and expiration are used to calculate PenH. Values of PenH have been shown to correlate with measures of pulmonary resistance and compliance obtained by invasive methods in anesthetized mice (Hamelmann et al., 1997). Various studies including a recent paper by Lundblad et al. (2002) have questioned the validity of PenH as a reliable indicator of bronchoconstriction in the mouse. Though the value of the method continues to be debated, it has the distinct advantage of being a high throughput, non-invasive method that allows measurement of individual animals over time, in the absence of confounding effects of anesthesia.

Materials

Methacholine (see recipe)
Mice sensitized and challenged with ovalbumin and appropriate control animals (see Basic Protocol)
Endotoxin-free saline

Buxco whole-body plethysmograph with Softmax XA software for whole-body flow-derived parameters (Buxco Electronics); four chambers monitored simultaneously
Balance (accurate to 0.1 g)

1. Remove methacholine stock solution from freezer.
2. Calibrate Buxco plethysmograph system per manufacturer's instructions.
3. Weigh mice.
4. For 4 animals, mix the following proportions of methacholine stock + endotoxin-free saline:

6 mg/ml	0.0625 ml + 3.9375 ml
12 mg/ml	0.125 ml + 3.875 ml
24 mg/ml	0.25 ml + 3.75 ml
48 mg/ml	0.5 ml + 3.5 ml
96 mg/ml	1 ml + 3 ml.

Place solutions on ice until loaded in the nebulizer cup.

5. Place mouse in whole-body plethysmograph box.

Depending on the available equipment, many mice can be monitored and exposed to methacholine simultaneously. Randomly assign treatments to each of the whole-body plethysmographs so as not to bias the results.

6. Place 4 ml endotoxin-free saline in the nebulizer cup. Nebulize for 2 min and then monitor respiratory variables for an additional 6 min during the drying phase.
7. Remove nebulizer cup and discard any remaining saline. Place 4 ml of 6 mg/ml methacholine in the nebulizer cup and repeat nebulization for 2 min plus a 6-min monitoring cycle.

   The changing of solutions in the nebulizer should be accomplished within 1 min or use a consistent time period between doses.
8. Repeat step 7 with 12, 24, 48 and 96 mg/ml methacholine, using the same 2-min nebulization period and 6-min monitoring cycle.
9. Remove the mice from the chambers and return them to their cages.
10. Export the data and save in Excel spreadsheet.
11. Refill nebulizer cup with 4 ml endotoxin-free saline and run another sequence to flush through the tubing.
12. Shut down the air flows, disassemble, and wipe clean all chambers before running a second set of animals.

    The system should also be recalibrated before running another set of animals.

MEASUREMENT OF CELLULAR INFILTRATION INTO THE AIRSPACE

SUPPORT PROTOCOL 2

A characteristic of the asthmatic response is eosinophil infiltration into the lung and airspace. Depending on the strain of mouse and the ovalbumin doses chosen for sensitization and challenge, cellular infiltration will be evident in the airspace and lung tissue of the animal anywhere from 6 hr after the last challenge to many days later. A common time point chosen is 48 hr after the last intranasal challenge, when both the measurement of airway hyperresponsiveness, as outlined in Support Protocol 1, and eosinophil infiltration are apparent. Cellular infiltration into the airspace is assessed using bronchoalveolar lavage (BAL). In this technique, the animal is euthanized, the trachea is cannulated, and PBS or other appropriate solution is introduced via the tracheal cannula to collect cells from the airway and alveolar space (also see *UNIT 18.4*). If airway hyperresponsiveness to methacholine is determined, wait at least 30 min before BAL to allow the methacholine-induced airway constriction to subside. This allows better recovery of BAL fluid and cells.

Materials

Mice sensitized and challenged with ovalbumin and appropriate control animals (see Basic Protocol)
Phosphate-buffered saline (PBS; *APPENDIX 2A*; or from GIBCO)
50 mg/ml pentobarbital sodium (Abbott)
Unopette Microcollection System solution (Becton Dickinson)
Normal guinea pig serum (Sigma)
Methanol
Modified Wrights' stain (Diff Quik, VWR)

Balance for weighing mice (accurate to 0.1 g)
10-ml beaker
3-ml syringes

Thread (4-0 silk)
Forceps (blunt, curved tip, serrated micro-dissecting forceps, Roboz Surgical Instruments)
Tracheal cannula (20-G needle, bevel filed off)
Dissecting scissors (5 1/2-in. blunt, Roboz Surgical Instruments)
Iris scissors (3-in., Roboz Surgical Instruments)
1.5-ml siliconized eppendorf tubes (low adhesion, Dot Scientific)
Refrigerated, low-speed centrifuge
Analytical balance (accurate to 0.001 g)
1.5-ml microcentrifuge tube
Neubauer hemacytometer (or automated cell counter such as a Coulter counter)
96-well U-bottomed microtiter plates (Sarstedt)
Shandon Cytospin 3 centrifuge (Shandon/Lipshaw)

Perform bronchoalveolar lavage (BAL)

1. Weigh the mouse sensitized and challenged with ovalbumin and appropriate control animals (see Basic Protocol).
2. Measure 1.8 ml endotoxin-free PBS for lavage into a 10-ml beaker. Prefill a 3-ml syringe with ~0.9 ml PBS and leave the syringe in the beaker.
3. Inject the mouse with 50 mg/ml pentobarbital (0.12 ml/20 g mouse) intraperitoneally.

   Once the animal does not respond to a toe pinch of the hind foot, it is ready for insertion of the tracheal cannula.

   If bleeding the mouse prior to BAL, be sure to monitor mouse continuously so that bleeding by retro-orbital or intracardiac method can be done before the heart stops beating or the blood pressure rapidly decreases. This dose of pentobarbital is intended to euthanize the animal.

   Pentobarbital is a Schedule II controlled substance and requires proper licensing and storage.
4. Immobilize the animal on its back. Make a midline incision over the trachea using dissecting scissors. Cut through muscle layers over the trachea and using the forceps, isolate the trachea and put two threads around it, each ~12 cm long. Make a loop in thread 1 over the trachea in preparation for tying a knot around the tracheal cannula (see Fig. 18.3.1). Tie a knot in thread 2, leaving a 4- to 5-cm diameter loop.

   When making an incision, stick to the midline so as to avoid severing arteries and veins. Be careful not to sever the trachea. When isolating the trachea, insert forceps with points together under the trachea and then spread the points apart underneath the trachea to spread the tissue. Grab both threads with the forceps and pull under the trachea to then form the loops of threads 1 and 2 as depicted in Figure 18.3.1.

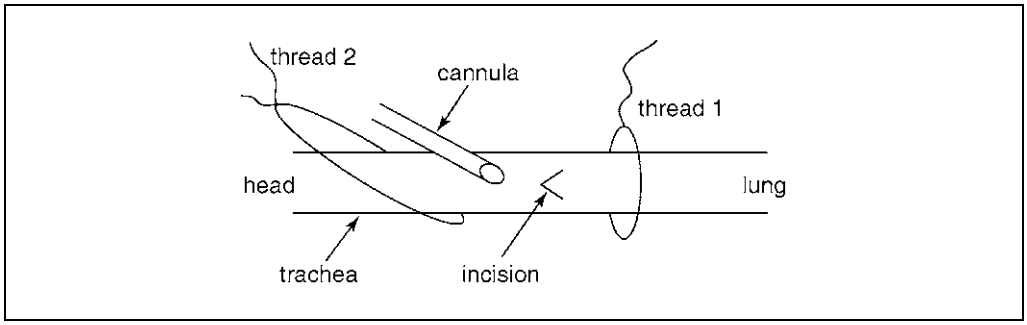

Figure 18.3.1 Schematic of tracheal cannulation of mouse.

5. Gently lift the loop of thread 1, nearest the lungs, to lift the trachea up. With iris scissors, make a V-shaped incision half way through the trachea. Insert the blunt needle cannula into the opening, advancing it ~3 to 5 mm into the trachea towards the lungs. Tie thread 1 securely with a single knot.

   Thread 2 can be used to put a small amount of tension on the trachea while making the incision and inserting the cannula.

6. Attach the 3-ml syringe containing room temperature PBS to the cannula. Gently deliver the volume of PBS into the lungs. Withdraw the fluid slowly until bubbles begin to appear, disengage the syringe from the cannula, and put the BAL fluid into a 1.5-ml siliconized eppendorf tube on ice. Repeat with the same volume of PBS and add to the BAL fluid already collected. Continue using the syringe to withdraw as much lavage fluid from the animal as possible.

   Throughout the procedure it is best to continue holding the hub of the cannula with one hand while manipulating the 3-ml syringe with the other hand until all of the lavage fluid is returned.

7. If the animal is to be used for assessment of cellular infiltration into the lung as well, proceed immediately to Support Protocol 3.

Count cells and determine differentials

8. Centrifuge the BAL fluid 12 min at ~600 × *g*, 4°C.

9. On an analytical balance, tare a 1.5-ml microcentrifuge tube. Using a 1-ml pipet, remove the supernatant from the cell pellet, being careful not to disturb the pellet. Add this BAL fluid to the tared 1.5-ml microcentrifuge tube. Record the weight of the BAL supernatant and freeze the supernatant (assume 1 g = 1 ml).

   Depending on the purpose of the experiment, antibodies, mediators, or other substances may be measured in the BAL supernatant.

10. Resuspend the cell pellet gently in 0.125 ml PBS and keep on ice.

11. Add 5 μl of cell suspension to 45 μl Unopette solution in a 1.5-ml microcentrifuge tube. Allow to sit for 10 min to ensure that any red blood cells are lysed.

    The Unopette Microcollection System solution is an ammonium oxalate diluent to lyse any red blood cells.

12. Load a standard Neubauer hemacytometer with the diluted cell suspension, in duplicate, and count the cells in each of the nine large squares, including those that lie on the top and left-hand perimeters. Do not count cells lying on the bottom and right-hand perimeters. Average the cell counts and calculate the number of white blood cells/ml of the original solution using the following formula:

    (Average no. of cells/9) × 10^5 = cells/ml in original cell suspension resuspended to 0.125 ml.

    Before loading the hemacytometer, make sure the cells are uniformly suspended in the liquid. In a control mouse, expect 1-10 × 10^4 cells total. In ovalbumin-sensitized and challenged animals, the number of white blood cells may be increased two to ten times.

13. Remove aliquots of 2 × 10^4 cells in 10- to 40-μl volume for cytospins. Dilute cells if necessary.

14. For cytospins, mix 2 × 10^4 cells, 130 μl PBS, 10 μl normal guinea pig serum, and 15 μl methanol in the well of a 96-well U-bottomed microtiter plate.

Table 18.3.1 Effect of Ovalbumin Challenge on Bronchoalveolar Lavage Cell Numbers[a]

Treatment	*N*	White blood cells ($\times 10^4$)	Macrophages ($\times 10^4$)	Eosinophils ($\times 10^4$)	Neutrophils ($\times 10^4$)
Water	5	6.5 ± 2.4	5.9 ± 2.3	0.04 ± 0.01	0.47 ± 0.20
Ovalbumin	8	7.8 ± 1.3	6.7 ± 1.1	0.29 ± 0.11[b]	0.79 ± 0.24

[a]Thirteen Balb/c mice were sensitized with ovalbumin and challenged with either ovalbumin or water as described in the Basic Protocol. At 48 hr after the last intranasal challenge, bronchoalveolar lavage was conducted as described in Support Protocol 2. Values represent mean ± SEM.
[b]$p<0.05$ compared to water treatment.

15. Add entire cell mixture to double cytospin funnel and cytospin 3 min at 1000 rpm with low acceleration, using double cytoslides for duplicate samples.
16. Air dry slides and stain with Diff Quik solution as recommended by the manufacturer.
17. Count 200 cells per spot (400 total), differentiating them as lymphocytes, macrophages, eosinophils, and neutrophils.
18. Express data as % cell type. Use total white blood cells from the mouse to calculate the total number of each cell type recovered from the mouse (typical results are seen in Table 18.3.1).

SUPPORT PROTOCOL 3

MEASURING CELLULAR INFILTRATION INTO THE LUNG

After sensitization and challenge of mice with ovalbumin (see Basic Protocol), depending on the experimental goals, a common scenario involves evaluation of airway hyperresponsiveness at 24 and/or 48 hr after the last intranasal challenge (see Support Protocol 1), followed by euthanasia of the mouse 30 to 60 min later for evaluation of cellular infiltration into the airspace and lung. The BAL as outlined in Support Protocol 2 is conducted, and then the lung lobes are removed as outlined in this protocol for the determination of eosinophil peroxidase (EPO) and myeloperoxidase (MPO) as indicators of the numbers of eosinophils and neutrophils, respectively, in the remaining lung tissue. Alternatively, the mouse can be euthanized and the lung lobes removed as outlined in this protocol without doing BAL.

Processing of lung lobes differs depending on whether EPO or MPO will be measured. For EPO, lung homogenates are centrifuged and the supernatant discarded. The resulting pellet is resuspended in the cetrimide buffer and sonicated prior to 2 cycles of freeze/thaw and sonication. EPO is tightly bound to membranes or contained within specific granules and is not liberated until the sonication and freeze/thaw cycles (Dimayuga et al., 1991). After freeze/thaw cycles and sonication, EPO activity is associated with both soluble and insoluble fractions, therefore, the assay of EPO uses both. For MPO, the enzyme is located within the primary granules of neutrophils. Extraction of MPO depends on disruption of the granules as well as the presence of cetrimide, which renders MPO soluble in aqueous solution (Bradley et al., 1982). The solubilized MPO is then separated from tissue debris by centrifugation. Aminotriazole is used in the MPO assay to inhibit any EPO contamination of the MPO sample.

Materials

Mice sensitized and challenged with ovalbumin and appropriate control animals (see Basic Protocol)
50 mg/ml pentobarbital sodium (Abbott)
Cetrimide (hexadecyltrimethylammonium bromide; see recipe)

Balance (accurate to 0.1 g)
2-ml glass vials (12 × 32–mm; Fisher)
Analytical balance (accurate to 0.0001 g)
Small hemostat (4 1/2-in.)
Dissecting scissors (5 1/2-in. blunt, Roboz Surgical Instruments)
Kimwipes in petri dish
Luxo magnifier (Daigger)
12 × 75–mm polystyrene round-bottomed tubes (Falcon)
Drying oven (Carbolite)
Homogenizer (Janke Kunkel Ultra-Turrax T-25, 24,000 rpm) with 8-mm generator probe for aqueous and organic solutions
250- and 50-ml beakers
Ear plugs
Forceps
1.0-ml pipet
Refrigerated, low-speed centrifuge
Sonicator (e.g., Daigger VC-130 ultrasonic processor) with microtip
Refrigerated, high-speed centrifuge and 12 × 75–mm high-speed centrifuge tubes
1.5-ml microcentrifuge tubes

Remove lung lobes

1. Weigh the mouse sensitized and challenged with ovalbumin and appropriate control animals (see Basic Protocol).
2. Preweigh a 2-ml glass vial on an analytical balance to 0.0001 g and record the weight.
3. Inject the mouse with 50 mg/ml pentobarbital (0.12 ml/20 g mouse) intraperitoneally.

   Once the animal does not respond to a toe pinch of the hind foot, it is ready for removal of the lungs.

   If bleeding the mouse prior to surgery, be sure to monitor mouse continuously so that bleeding by retro-orbital or intracardiac method can be done before the heart stops beating or the blood pressure rapidly decreases. This dose of pentobarbital is intended to euthanize the animal.

   Once the animal has been euthanized, the lung lobes should be removed as quickly as possible and placed on ice in cetrimide.

   Pentobarbital is a Schedule II controlled substance and requires proper licensing and storage.

4. Immobilize the animal on its back. Make a midline incision through the chest wall, being careful not to cut through the lungs. Clamp the trachea as high up as possible with a small hemostat, and use dissecting scissors to remove the heart and lungs intact, still attached to the trachea.
5. Invert the heart and lungs on a Kimwipe in a petri dish so the heart is underneath the lung lobes, as if observing by the dorsal view of the heart and lungs in situ.

   If the trachea is facing away, then the large left lobe is on the left side (see Fig. 18.3.2). Work quickly so tissue does not dry out.

6. Remove the inferior lobe of the right lung (see Fig. 18.3.2) for determination of MPO and the left lung lobe for determination of EPO. Be sure to trim pieces of the heart, esophagus, and fat tissue, using the Luxo magnifier for easy visualization.

   The remainder of the lung without the trachea is used to determine the wet/dry weight of the lung.

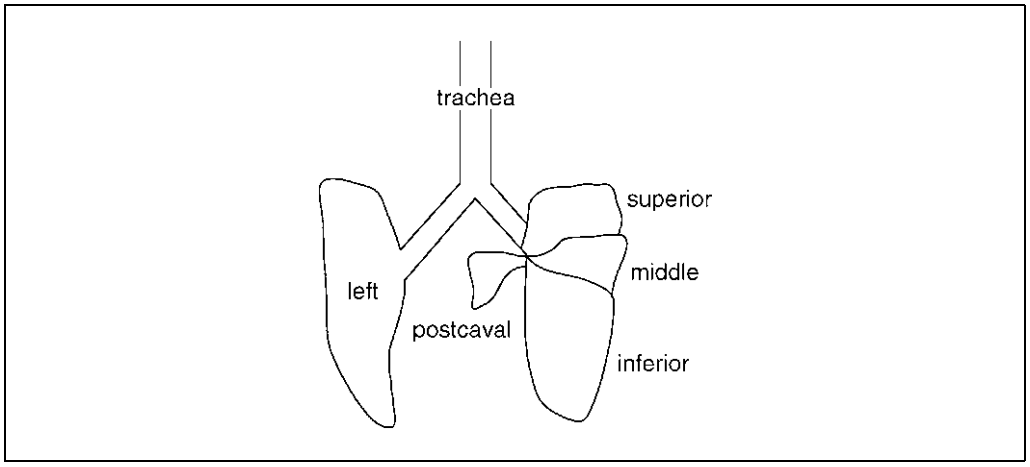

Figure 18.3.2 Schematic of dorsal view of mouse lung lobes. Lobes are named as described by Cook et al. (1983). The pattern of lobation may vary with the strain of mouse.

7. Tare a plastic 12 × 75–mm tube on the analytical balance and place the inferior lobe in the tube. Record the wet weight. Add 0.5 ml cetrimide to the tube and immediately place on ice.
8. Tare a second plastic 12 × 75–mm tube and place the left lobe in the tube. Record the wet weight. Add 0.5 ml cetrimide to the tube and immediately place on ice.
9. Place the wet/dry piece of lung in the preweighed 2-ml glass vial and record the weight of the vial plus the wet lung. Dry in a drying oven for 48 to 72 hr at 80°C to constant weight. Record weight of dried lung plus vial.

Homogenize left lung lobe and inferior lobe for enzyme assays

10. Rinse homogenizer by placing tip in 250-ml beaker of distilled water and turning it on for ∼15 sec.

    Use ear protection, e.g., ear plugs, when operating the homogenizer.

11. Wipe down tip thoroughly with Kimwipes and remove any debris remaining on tip with forceps.
12. Place the 12 × 75–mm tube containing lung lobe into a 50-ml beaker of wet ice.
13. Remove cap, and homogenize sample on ice ∼20 sec at 24,000 rpm.

    Take care to keep the sample on ice, and rotate the tube to homogenize the sample evenly.

14. Using a 1.0-ml pipet, rinse homogenizer with 0.5 ml of cetrimide, being sure to allow all liquid to drain into homogenized sample tube, giving a total volume of 1 ml plus the lung lobe.
15. Replace homogenized sample back on ice.

Prepare left lobe for eosinophil peroxidase (EPO) assay

16. Centrifuge the tube containing homogenized left lobe for 30 min at 400 × *g*, 4°C.
17. Discard supernatant and resuspend pellet in 0.5 ml cetrimide.
18. Sonicate for 15 sec, output 3, with tube on ice. Freeze sample at −20°C.

    Use ear protection when operating the homogenizer and sonicator.

19. Thaw, sonicate, and freeze (−20°C) the sample two additional times prior to determination of EPO (see Support Protocol 4). Store samples frozen at −20°C until assayed.

Place sample on ice immediately after thawing at room temperature. If samples are to be stored longer than 2 to 3 months, place at −70°C.

Prepare inferior lobe for MPO assay

20. Sonicate the sample containing the homogenized inferior lobe for 15 sec, output 3 with tube on ice. Freeze sample at −20°C.

    Use ear protection when operating the sonicator.

21. Thaw, sonicate, and freeze (−20°C) the sample two additional times prior to centrifugation.

    Place sample on ice immediately after thawing at room temperature.

22. Thaw sample, transfer to a 12 × 75–mm high-speed centrifuge tube, and centrifuge 30 min at 12,100 × *g*, 4°C.

23. Transfer supernatant to 1.5-ml microcentrifuge tube and store frozen at −20°C until assayed (see Support Protocol 5).

    If samples will be stored longer than 2 to 3 months, place at −70°C.

EOSINOPHIL PEROXIDASE (EPO) ASSAY

SUPPORT PROTOCOL 4

Eosinophils contain EPO and neutrophils contain MPO. Eosinophil peroxidase from tissues is measured as described by Strath et al. (1985) and Cheng et al. (1993). OD changes at 490 nm are monitored using the substrate solution *o*-phenylenediamine dihydrochloride (OPD) in a pH 8.0 buffer with 1 mM hydrogen peroxide. Assessment of EPO and MPO activity in a mixed cell population that contains both eosinophils and neutrophils is possible because of differences in the pH optimum for EPO and MPO (Worthington Enzyme Manual, 1972), as well as the ability of aminotriazole to inhibit EPO with minimal effects on MPO (Cramer et al., 1984). Thus, to achieve relative specificity for each enzyme, the EPO assay is conducted at pH 8.0, whereas the MPO assay is conducted at pH 6.0 in the presence of aminotriazole.

Materials

Homogenized left lung (see Support Protocol 3)
0.1% and 1% (v/v) Triton/Tris buffers (see recipes)
o-Phenylenediamine dihydrochloride (OPD; see recipe)
30% H_2O_2 (Sigma)

Spectrophotometer with visible light and kinetics software
Sonicator (Daigger) with microtip
Vortex
96-well U-bottomed microtiter plates (Sarstedt)
Glass cuvettes
Small squares of Parafilm (~2 × 2–cm)

CAUTION: Wear gloves throughout the procedure because OPD is a potential carcinogen. Hazardous waste containing OPD should be collected for proper disposal. Cover the work area with plastic-backed absorbent paper and wipe down all surfaces at the end with water.

1. Set up spectrophotometer for kinetic assays with a recommended starting point of determining OD every 5 sec for 2 min at a wavelength of 490 nm.

2. Thaw frozen homogenized left lung lobe sample (see Support Protocol 3, step 19). Keep tube on ice during assay.

    Place sample on ice immediately after thawing at room temperature.

3. Sonicate homogenized lung samples 15 sec on ice. Vortex before withdrawing 150 µl for dilution.
4. For a 1:2 dilution in a 96-well U-bottomed microtiter plate, mix 150 µl sample, 30 µl of 1% Triton/Tris buffer, and 120 µl of 0.1% Triton/Tris buffer. Serially dilute 70 µl of the 1:2 dilution back in 70 µl of 0.1% Triton/Tris buffer to a 1:4 dilution.
5. Place the following into cuvette, in order: 860 µl of 0.1% Triton/Tris buffer, 50 µl sample dilution, and 8.5 µl OPD. Top cuvette with Parafilm and invert to mix. Wipe sides of cuvette clean. Insert into the spectrophotometer and take a baseline reading at 490 nm. Remove cuvette from spectrophotometer.
6. Add 1 µl of 30% H_2O_2, place Parafilm on top, invert two times, and immediately place cuvette into spectrophotometer and begin to take kinetic readings.
7. When the reaction is complete, usually within 2 min, remove cuvette, pour contents into a hazardous waste container, rinse cuvette once with water, and pour into waste container. Finally, rinse cuvette eight to ten times with water and discard the waste down the drain.
8. If it is necessary to run an undiluted sample because the signal from the 1:2 dilution is very low, add 100 µl of 1:2 dilution to 810 µl of 0.1% Triton/Tris buffer, and 8.5 µl OPD. Take a baseline reading and then start the reaction as step 6 using 1 µl of 30% H_2O_2.

SUPPORT PROTOCOL 5

MYELOPEROXIDASE (MPO) ASSAY

Myeloperoxidase (MPO) is a constituent of neutrophil granules. For the assay of MPO, the hydrolysis of H_2O_2 is monitored by the change at 460 nm of *o*-dianisidine dihydrochloride (ODA) in a pH 6 phosphate buffer in the presence of the EPO inhibitor aminotriazole (AMT). Units of MPO activity are calculated as described in the Worthington Enzyme Manual (1972) and by Ormrod et al. (1987).

Materials

Frozen homogenized inferior lung lobe sample (see Support Protocol 3)
0.05 M potassium phosphate buffer, pH 6.0 (see recipe)
o-Dianisidine dihydrochloride (ODA; see recipe)
Aminotriazole (AMT; see recipe)
0.5 mM H_2O_2 (see recipe)

Spectrophotometer with visible light and kinetics software
Glass cuvettes
Small squares of parafilm (~2 × 2–cm)

CAUTION: Wear gloves throughout the procedure because ODA and AMT are potential carcinogens. Hazardous waste should be collected for proper disposal. Cover the work area with plastic-backed absorbent paper and wipe down all surfaces at the end with water.

1. Set up spectrophotometer for kinetic assays with a recommended starting point of determining OD every 5 sec for 3 min at a wavelength of 460 nm.
2. Thaw frozen homogenized inferior lung lobe sample (see Support Protocol 3, step 23). Keep sample tubes on ice during the assay.

Place sample on ice immediately after thawing at room temperature.

3. Place the following into cuvette, in order: 873 µl of 0.05 M potassium phosphate buffer, pH 6.0, 30 µl undiluted sample, 100 µl ODA, and 10 µl AMT. Top cuvette with Parafilm and invert two times to mix. Wipe sides of cuvette clean.

   If AMT solution yellows during the assay, discard aliquot and thaw a new one.

4. Insert cuvette into spectrophotometer. After 3 min, take baseline reading at a wavelength of 460 nm.

   This 3-min waiting period ensures that AMT has time to inhibit any EPO activity present.

5. Remove cuvette, add 10 µl of 0.5 mM H_2O_2, place Parafilm on top, invert two times, and immediately place cuvette into spectrophotometer and begin to take kinetic readings.

6. When the reaction is complete, usually within 3 min, remove cuvette, pour contents into hazardous waste container, rinse cuvette once with water, and pour into waste container. Finally, rinse cuvette eight to ten times with water and dispose of the waste down the drain.

7. If MPO activity is very low, double the sample size by adding 843 µl of 0.05 M potassium phosphate buffer, pH 6.0, 60 µl undiluted sample, 100 µl ODA, and 10 µl AMT. Wait 3 min, take a baseline reading, and then start the reaction as above using 10 µl of 0.5 mM H_2O_2.

   If ODA crystallizes in cuvette during the assay, discard the ODA aliquot and thaw a new one.

   The background reading is a good check to determine that the sample was added and that the ODA is not crystallizing (the background will be higher than normal).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Aminotriazole (AMT)

3-Amino-1,2,4 triazole (Sigma)
Dissolve at 42 mg/ml water (final concentration of 0.5 M)
Store in 0.2-ml aliquots up to 1 year at −20°C

Aminotriazole is a potential carcinogen, care should be taken when handling.

Cetrimide

Add 0.5 g cetrimide (Hexadecyltrimethylammonium bromide; Sigma) to 100 ml of 0.05 M potassium phosphate buffer, pH 6.0 (see recipe). Store up to 4 weeks at 4°C. Warm to room temperature before use.

H_2O_2, 0.5 mM

Add 8.5 µl of 30% H_2O_2 (Sigma) to 4.99 ml 0.05 M potassium phosphate buffer, pH 6.0 (see recipe). Prepare on the day of the assay, keep on ice, and discard any remaining solution at the end of the assays.

Ketamine/xylazine

1 ml 100 mg/ml ketamine
1 ml 20 mg/ml xylazine
8 ml normal saline solution
Mix and store up to 1 month at room temperature

Ketamine is a controlled substance (Schedule III) and requires proper licensing and storage in an authorized locked cabinet.

Methacholine

To 19.2 g acetyl-β-methylcholine chloride (Sigma), add endotoxin-free saline up to 50 ml in a graduated cylinder. Dissolve at room temperature, transfer solution to ice bath, and dispense into 1-ml aliquots. Final solution concentration is 0.384 g/ml. Freeze 1-ml aliquots up to 6 months at −80°C.

ODA

Dissolve 1.67 mg/ml *o*-dianisidine dihydrochloride (Sigma) in water. Store in 1-ml aliquots up to 1 year at −20°C.

o-Dianisidine dihydrochloride is a potential carcinogen, care should be taken when handling.

OPD

Dissolve 90 mg/ml *o*-phenylenediamine dihydrochloride (Sigma) in water. Store 50-µl aliquots up to 1 year at −20°C.

Ovalbumin for challenge

Dissolve 1.25 mg/ml ovalbumin (Grade V; Sigma) in endotoxin-free water. Allow to dissolve for 2 to 3 hr or overnight at 4°C. Stir gently and dispense into convenient aliquots (1-ml) for freezing at −20° or −80°C up to 2 years.

Ovalbumin can have endotoxin contamination. The amount of endotoxin contamination in a particular lot of ovalbumin can be determined using a Limulus Amebocyte Lysate assay. Reagents and kits for this assay are commercially available from, e.g., Sigma (E-Toxate Kit) or BioWhittaker.

Be sure to use endotoxin-free water and sterile plastic ware. Alternatively, treat any glassware with E-Toxa clean concentrate (Sigma) to remove endotoxin contamination. Treating clean glassware at 175°C for a minimum of 3 hr will also destroy endotoxin.

Ovalbumin for sensitization

Dissolve 0.067 mg/ml ovalbumin (Grade V; Sigma) in endotoxin-free saline. Allow to dissolve for 2 to 3 hr or overnight at 4°C. Stir gently and dispense into 1.2-ml aliquots in 2-ml polypropylene screw-cap vials for freezing at −20° or −80°C up to 2 years.

Ovalbumin can have endotoxin contamination. The amount of endotoxin contamination in a particular lot of ovalbumin can be determined using a Limulus Amebocyte Lysate assay. Reagents and kits for this assay are commercially available from, e.g., Sigma (E-Toxate Kit) or BioWhittaker.

Be sure to use endotoxin-free saline and sterile plastic ware. Alternatively, treat any glassware with E-Toxa clean concentrate (Sigma) to remove endotoxin contamination. Treating clean glassware at 175°C for a minimum of 3 hr will also destroy endotoxin.

Potassium phosphate buffer, 0.05 M (pH 6.0)

1.361 g KH_2PO_4 dissolved in ~150 ml water
pH to 6.0 with 0.1 M K_2HPO_4
Add water to 200 ml
Store up to 6 months at 4°C
Warm to room temperature before use

Triton/Tris buffer, 0.1% (v/w)

0.657 g Tris (50 mM) dissolved in ~60 ml water
Add 100 µl of Triton X-100

continued

Mix well with stir bar
Adjust pH to 8.0 with 2 N HCl
Add water to 100 ml
Store up to 1 month at 4°C
Warm to room temperature before use

Triton/Tris buffer, 1% (v/w)

0.657 g Tris (50 mM) dissolved in ~60 ml water
Add 1 ml of Triton X-100
Mix well with stir bar
Adjust pH to 8.0 with 2 N HCl
Add water to 100 ml
Store up to 1 month at 4°C
Warm to room temperature before use

COMMENTARY

Background Information

Numerous studies have investigated the mechanism of ovalbumin-induced asthma in the mouse. Recent reviews summarize particular aspects of the mechanism in murine asthma models (Wills-Karp, 2000; Leong and Huston, 2001; Abraham, 2003). Bernstein et al. (1999) provides an overview of the studies done in occupational asthma in humans and in animal models. It is apparent that a wide variety of mouse model systems are used in investigating the asthmatic response. Asthma is a chronic inflammatory immune disease with a prominent role for CD4+ T cells producing a Th2 pattern of cytokines. When appropriately sensitized and challenged, the characteristic components of the asthmatic response can be demonstrated in murine asthma models: immediate bronchoconstriction to antigen, increased airway microvascular permeability, airway hyperresponsiveness to an agonist such as methacholine, and inflammatory cell infiltration into the lung, particularly eosinophils. Mice readily make IgE antibody to parallel the human situation. The mouse model of asthma has the advantage that extensive information is available regarding the mouse genome and numerous inbred strains and transgenic mice are available to examine specific hypotheses. A disadvantage of the mouse model is that extensive exposure to the antigen along with the use of an adjuvant may be required to reproducibly elicit the asthmatic response in a short period of time. This is in contrast to a species such as the guinea pig where the lung is the target organ and bronchoconstriction and eosinophil infiltration readily occur after antigen exposure.

In mouse models, the expression of different components of the effector phase of the asthmatic response, and the magnitude and time course of those responses, may differ depending on the routes of sensitization and challenge with the allergen, the dose of antigen, as well as the inbred strain of animal used. When examining 12 different strains of mice, Brewer et al. (1999) found a wide range of responses in both airway hyperresponsiveness to methacholine (zero- to three-fold change) and eosinophilia in the BAL (2% to 60%). Karp et al. (2000), using different strains of mice, found that complement component C5 is a susceptibility locus for airway hyperresponsiveness in ovalbumin-induced asthma. Thus, C5 deficient strains of mice such as A/J mice very readily develop airway hyperresponsiveness to ovalbumin sensitization and challenge.

Zhang et al. (1997) directly compared different routes of ovalbumin administration (intranasally versus intraperitoneally) in Balb/c mice and concluded that without local allergen exposure intranasally the mice did not develop airway hyperresponsiveness. The dose of allergen is also important in determining the asthmatic response. Mice sensitized with low doses of ovalbumin and alum intraperitoneally presented with both eosinophilia in the lung and airway hyperresponsiveness, whereas higher sensitizing doses by the same route resulted in a reduced eosinophilia and the absence of airway hyperresponsiveness (Sakai et al., 1999).

For sensitization, numerous studies have employed ovalbumin plus alum sensitization intraperitoneally. Alternatively, repeated aerosol administration of ovalbumin has also been used for sensitization. With regard to the ovalbumin challenge, repeated aerosol administration or multiple intranasal challenges help ensure a strong reproducible asthmatic response. Intratracheal challenge can also be

used to elicit the asthmatic symptoms and avoids exposure of the upper airways, but it is somewhat more invasive. Aerosolizing the ovalbumin requires a nebulizer and exposure chamber, as well as greater quantities of ovalbumin. The intranasal route has the advantage of simplicity, convenience, and a known dose of ovalbumin is delivered to the animal. Southam et al. (2002) systematically examined the effects of anesthesia, instillation volume, and position of the animal on the delivery of ovalbumin to the lung by intranasal instillation. The Basic Protocol utilizes three successive intranasal challenges to elicit the asthmatic response in the mouse. However, fewer challenges may also be sufficient. Tomkinson et al. (2001) successfully used a single intranasal challenge with ovalbumin to determine the time course of the airway hyperresponsiveness and eosinophil infiltration into the lung of the mouse.

In an asthmatic response, antigen challenge itself initiates an airway obstruction. After the response to antigen, the asthmatic airway becomes hyperresponsive to numerous agonists, including acetylcholine. The airways are more responsive to a lower dose of acetylcholine and the maximal response is also increased. Methacholine is a muscarinic agonist that is not as susceptible as acetylcholine to spontaneous hydrolysis and thus is useful in experimental situations to stimulate the muscarinic receptor. Many different methods are available to assess airway hyperresponsiveness. The one presented in this unit is the measurement of PenH using whole-body plethysmography in a conscious unrestrained mouse. Besides being minimally invasive, this technique allows high throughput and is not confounded by anesthesia. Airway reactivity can be assessed in a single animal at multiple time points to evaluate the time course of the event. Studies have been done to validate the technique as a measure of airway obstruction (Hamelmann et al., 1997). However, the method has been criticized as an indirect and imprecise measure of pulmonary function that is subject to changes in temperature and humidity (Lundblad et al., 2002). One experimental strategy is the use of PenH as an initial measure of airway hyperresponsiveness, followed by selected studies using more traditional measures of pulmonary mechanics in an anesthetized animal. Such methods in anesthetized ventilated mice may include measure of the airway pressure time index (Ewart et al., 1995), measurement of input impedance using the forced oscillation technique (Gomes et al., 2000), or a plethysmographic method of measuring pulmonary resistance and compliance (Martin et al., 1988). Isolated tracheal strips from ovalbumin-sensitized and -challenged mice have also been used to evaluate airway hyperresponsiveness, using either methacholine (De Bie et al., 1996) or electrical field stimulation (Hamelmann et al., 1999) as the constricting stimulus.

Many studies have utilized eosinophil peroxidase (EPO) and myeloperoxidase (MPO) as indicators of eosinophils and neutrophils, respectively, in lung tissue. The assays are quantitative and representative of the tissue as a whole. Measurements of EPO and MPO do not require histological interpretation and many measurements can be done in a short period of time. However, no information regarding the site of localization of the eosinophils and neutrophils—i.e., perivascular, interstitial, peribronchial, parenchymal—is obtained by measuring EPO and MPO in homogenized lung tissue.

The literature regarding the assay of EPO activity from cells and tissues is quite varied as to the tissue fractions analyzed. Some studies utilize the supernatant fraction after homogenization, freeze thawing and sonication in a Triton/Tris or cetrimide buffer (Collins et al., 1995; Hessel et al., 1997; Humbles et al., 1997). Other studies use both the soluble and insoluble fractions after a similar tissue preparation (Cheng et al., 1993; Dimayuga et al., 1991; Pettipher et al., 1994; Kung et al., 1995; Turner et al., 1996). Therefore, since methods vary considerably, especially homogenization and sonication techniques and buffers, it is very important in each laboratory to check soluble and insoluble fractions for EPO activity and confirm that the activity is inhibited by aminotriazole.

Besides measurement of cellular infiltration into the lung and airway hyperresponsiveness, mouse models of asthma lend themselves to the measurement of numerous other parameters not covered in this unit. Serum samples can be obtained and used for the measurement of antibodies. Antibody, protein, cytokines, and chemokines can be measured in the BAL fluid. Evidence of cell secretion (EPO) or cell injury (lactate dehydrogenase) may be evident in the BAL fluid. With proper precautions, the lung lobes can be used for isolation of RNA, cytokine measurements, histology, or immunocytochemistry. Collagenase digestion of lung lobes can be used to isolate lymphocyte populations for characterization.

Critical Parameters and Troubleshooting

As with any experiment, appropriate control groups of animals are essential and the protocol for sensitization and challenge will depend on the experimental question. Endotoxin contamination of solutions needs to be minimized because endotoxin will lead to neutrophilia itself, independent of an allergic reaction. Tissues should be removed from the animal as quickly as possible, keeping cells and tissues on ice in between manipulations. All samples should be frozen within 8 hr of removal from the animal.

Standard mouse feed is generally free of ovalbumin. However, if difficulties arise in seeing airway hyperresponsiveness or cellular infiltration, the possibility of ovalbumin exposure in the feed should be considered. Excessive exposure to ovalbumin could lead to tolerance and lack of reactivity to the allergen. As always, good animal husbandry is key to healthy animals and successful experiments.

When measuring EPO and MPO, it is important to use low amounts of enzyme so that the reaction rate is linear. If too much sample is used, the linear portion of the reaction will occur before the OD readings have begun. In the EPO assay, sonication prior to using the sample for assay is essential. Large pieces of tissue debris can interfere with the kinetic measurements. Low amounts of EPO in the sample will sometimes be difficult to distinguish from background. It may be useful to run EPO samples with and without the EPO inhibitor AMT so that noise can be distinguished from signal.

Anticipated Results

PenH for each mouse is averaged over the entire 8-min monitoring period to obtain an average PenH for each saline or methacholine dose. Data can then be expressed as the average for each dose, or as the ratio of the methacholine response over the control saline response for each animal. A change in control PenH values over time may indicate that environmental conditions are affecting baseline airway function. For example, excessive mold in the bedding or dust exposure may affect baseline PenH for the animals, and thus affect the airway responsiveness to methacholine after ovalbumin sensitization and challenge. Typical PenH results for the sensitization and challenge described in the Basic Protocol are shown in Figure 18.3.3. The concentration response curve to methacholine in the control animals tends to plateau. In contrast, PenH continues to increase over the methacholine concentration range in ovalbumin sensitized and challenged animals. Airway hyperresponsiveness is more apparent at 24 hr after the last intranasal challenge compared to the 48-hr time-point. The time course of the response

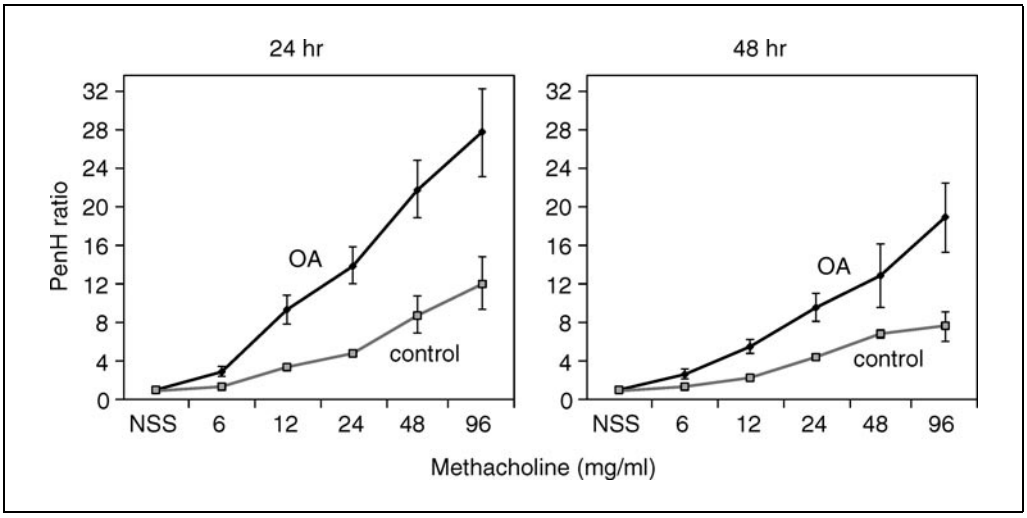

Figure 18.3.3 Six Balb/c mice were ovalbumin (OA)-sensitized and challenged as described in the Basic Protocol. At 24 and 48 hr after the last intranasal challenge, airway hyperresponsiveness to inhaled methacholine was determined as described in Support Protocol 1. PenH was determined and expressed as the PenH ratio (average PenH over the 8-min time interval with methacholine aerosol divided by the average PenH over the 8-min saline (NSS) aerosol exposure time). At 24 hr, the average PenH for NSS exposure was 0.58 $\pm$ 0.03 and 0.60 $\pm$ 0.09 for the control (water-challenged) and OA-challenged animals, respectively. At 48 hr, the average PenH for NSS exposure was 0.93 $\pm$ 0.06 and 0.80 $\pm$ 0.11 for the control (water-challenged) and OA-challenged animals, respectively. Values represent the mean $\pm$ SEM for 3 animals.

Table 18.3.2 Effect of Ovalbumin Challenge on EPO and MPO Measurements in the Lung[a]

[a] Six Balb/c mice were sensitized with ovalbumin (OA) and challenged 3 successive days with either ovalbumin or water as described in the Basic Protocol. The left lung lobe was removed for EPO measurements and the inferior lobe for MPO measurements as described in Support Protocol 3 at 48 hr after the last intranasal ovalbumin challenge. In this particular experiment, the postcaval lobe was used for wet/dry weight because the superior and middle lobes were used for RNA isolation. EPO, eosinophil peroxidase; MPO, myeloperoxidase.

[b] Lobe for wet/dry: Wet weight of postcaval lobe; Dry weight of postcaval lobe determined after 3 days at 80°C.

[c] Left lobe: Wet weight of left lobe; Dry weight calculated = (left lobe wet weight) × [(dry weight of lobe for wet dry)/(wet weight of lobe for wet dry)].

[d] Inferior lobe: Wet weight of inferior lobe; Dry weight calculated = (inferior lobe wet weight) × [(dry weight of lobe for wet dry)/(wet weight of lobe for wet dry)].

[e] EPO OD/min = OD/min in EPO assay for 50 µl undiluted sample.

[f] EPO total OD/min = EPO OD/min × 10. This is the total EPO for the 0.5-ml sample containing the whole left lobe.

[g] EPO/g dry weight = (EPO total OD/min)/(Left lobe dry weight calculated).

[h] MPO OD/min = OD/min in MPO assay for 30 µl undiluted sample.

[i] MPO total OD/min = (MPO OD/min) × (1 + Wet weight of inferior lobe − Dry weight calculated of inferior lobe)/0.030. This is the total MPO from the inferior lobe, accounting for the additional sample volume added by the water in the lung lobe.

[j] MPO total units = (MPO total OD/min)/11.3. MPO is expressed in units, where one unit is defined as that degrading 1 µmol of peroxide/min at 25°C, using the absorbancy index of H_2O_2 of 11.3 $(\mu mol/ml)^{-1}cm^{-1}$.

[k] MPO/g dry weight = (MPO total units)/(Inferior lobe dry weight calculated).

will differ depending on the sensitization and challenge regimen used.

Since Support Protocol 4 is a kinetic assay, the intent is to determine the initial reaction rate. Thus, the slope of the OD change over time is determined before it maximizes, and OD/min changes do not need to be large. The software for the kinetics program being used should be set to determine the OD/min from only the linear portion of the 2-min data-collection period. This is often no more than the first 30 to 60 sec. The number of sample dilutions assayed depends on the consistency of the OD/min readings obtained after they are corrected for the dilution. For ovalbumin-sensitized and -challenged mice, undiluted samples to 1:4 dilutions are usually within range. In samples with very few eosinophils, the kinetic readings show a great deal of noise due to the tissue debris. Background can be determined by conducting the assay in the presence of aminotriazole to inhibit EPO activity. Typical results are calculated as shown in Table 18.3.2 with OD/min values ranging from 0.031 to 0.693 for 50 μl of undiluted sample. In ovalbumin-challenged animals with higher EPO, the OD/min was determined on diluted samples and corrected for the dilution to arrive at the OD/min for a 50 μl undiluted sample. Final data is expressed as EPO/g dry weight lung, which is significantly greater for the ovalbumin-challenged animals compared to their water-challenged controls.

Since Support Protocol 5 is a kinetic assay, the intent is to determine the initial reaction rate. Thus, the slope of the OD change over time is determined before it maximizes, and OD/min changes do not need to be large. The software for the kinetics program being used should be set to determine the OD/min from only the linear portion of the 3-min data-collection period. This is often no more than the first 60 to 90 sec. The MPO activity should be completely inhibited by 0.1 mM sodium azide but not by 5 mM aminotriazole. In the absence of hydrogen peroxide, no change in OD should be evident. Typical results are shown in Table 18.3.2. OD/min for 30 μl undiluted sample range from 0.01 to 0.034. Final data is expressed as total MPO units/g dry weight of lung. As seen in Table 18.3.2, challenge with ovalbumin using the Basic Protocol does not result in a large increase in MPO in the lungs of sensitized mice as compared to water-challenged controls.

Time Considerations

The time from sensitization of the mouse to measurement of airway hyperresponsiveness and cellular infiltration is a 16-day period. Typically, 8 animals per day is a manageable number. This allows the intranasal challenge of 8 animals on 3 consecutive days first thing in the morning. Airway hyperresponsiveness measurements can then begin on the morning of the fourth or fifth day, depending on the experiment. Conducting methacholine dose response curves for the pulmonary function measurements requires ~2 hr for each group of mice. Thus, for 8 mice, measure airway hyperresponsiveness in 4 mice as Group 1 from 8 to 10 a.m. and 4 mice as Group 2 from 10 a.m. to 12 p.m. Then begin BAL and harvesting lung tissue in Group 1. For lavaging and removing lungs, allow ~10 to 15 min/mouse (2 hr total), with one person lavaging the lungs and another person removing the lung pieces. BAL cells can then be counted, cytospins made, lung tissue homogenized, and frozen by the end of the day. On the following day, further freeze/thaw and sonicate the lung homogenates, along with differential count of the cytospins can be completed. Later, EPO and MPO assays can be conducted. The wet/dry weight of the lung is available after 2 to 3 days of drying, and the final results may then be calculated.

Use of Bronchoalveolar Lavage to Detect Lung Injury

The lung is the portal of entry into the body for inhaled pollutants. The interaction of the pollutant with the cells lining the respiratory tract can provide information on the toxicity of the pollutant and the level of pollutant required to induce an inflammatory response. The affected cells release mediators into the epithelial lining fluid (ELF), which can be sampled by isotonic washing (lavage) of the respiratory tract. The bronchoalveolar lavage fluid (BALF) will contain both biochemical and cytological indicators (biomarkers) of the tissue response to the inhaled pollutant. The fact that these indicators can be quantified provides a means of developing a dose-response curve for the inhalation toxicity of the agent of interest and may provide a "no-effect" level of exposure for regulatory purposes. For more mechanistic research, analysis of BALF can be used to test specific hypotheses. Finally, new proteomic techniques that determine changes in protein expression profiles in BALF can be used to stage disease processes and, in some cases, may be used to predict disease outcome.

This unit describes methods of performing bronchoalveolar lavage in laboratory animals and the choice of washing fluids that may be used. In addition, a discussion of the various types of biomarkers of lung injury or disease that may be measured is also provided. Three procedures are described: bronchoalveolar lavage performed in large animals in vivo (see Basic Protocol and Alternate Protocol 1), bronchoalveolar lavage performed in the excised lung (see Alternate Protocol 2), and processing BALF and analysis of lung damage indicators (see Support Protocol). Some discussion of proteomic analysis of lavage fluid is also made. The topic of how to perform bronchoalveolar lavage in humans is not discussed in this unit.

STRATEGIC PLANNING

The purpose of the lavage procedure is to obtain samples of the ELF and cells from the respiratory tract for analysis of biomarkers of respiratory tract disease. Below are listed major questions to be considered before performing the procedure.

Anesthesia

Studies have shown that various anesthetic agents can be used for the BAL procedure, including isoflurane, halothane, and sodium pentobarbital. However, CO_2 is not a suitable agent because of its profound effects on the epithelial lining fluid of the lung (Henderson and Lowry, 1983). For the selection, correct dose and use of preanesthetic agents and general anesthesia, the reader should consult with a laboratory animal veterinarian.

Wash Fluid

Wash fluid must be isotonic to avoid damage to cells and tissue. Physiological saline (0.15 M) is commonly used, but phosphate-buffered saline or various balanced salt solutions have been used as well. An important consideration is whether to have Ca^{2+} and Mg^{2+} in the fluid. These cations are necessary for the adherence of the macrophages to surfaces and fewer cells will be obtained if the wash fluid contains Ca^{2+} and Mg^{2+}; however, the decision to include these cations or not will depend on the objective of the study. If the objective is to obtain as many cells as possible for later assays to be performed in vitro, one should not include the cations. If, however, the objective is to obtain only

Contributed by Rogene F. Henderson and Bruce A. Muggenburg
Current Protocols in Toxicology (2004) 18.4.1-18.4.10

those cells that are free and unattached in the alveoli, it would be advisable to include Ca^{2+} and Mg^{2+}.

Wash Volume

For a total lung lavage, such as that normally performed in a small laboratory animal, a recommended volume is 80% of the volume required to raise intrapulmonary pressure to 30 cm water pressure (Mauderly, 1977). Extensive experience in measuring this volume in various species in the authors' laboratory has indicated that the following volumes may be used as standard procedure: 7 ml in a 300-g male rat, 5 ml in a 200-g female rat, 4 ml in a 120-g Syrian hamster, and 1 ml in a 35-g mouse. For segmental lavages in dogs or nonhuman primates, volumes of 10 and 7.5 ml, respectively, have been used successfully.

Number of Washes

For the purposes of many toxicology studies, it is advantageous to use the least number of washes necessary to obtain a sample of the epithelial lining fluid, as further washes will only serve to dilute the parameters one is trying to measure. In a study in which the recovery of one component of BALF, protein, was measured in each of six sequential washes of the right lung of a dog, 50% of what was recovered in all six washes was obtained in the first wash and another 25% was recovered in the second (Henderson, 1988, 1989; Henderson and Muggenburg, 1992). Thus, 75% of the total was recovered in two washes. For most purposes, in a total lung lavage procedure, two to four washes should be sufficient to give an adequate sample of the epithelial lining fluid without diluting the contents beyond what is convenient to measure. In segmental lavages, the recovery of the initial wash is usually low (see next section), and five or six washes may be needed.

An exception to these recommendations is if the objective of the study is to obtain as many pulmonary alveolar macrophages as possible for functional assays performed in vitro. In this case, one may want to use numerous washes and even massage the lung (in excised lung wash procedures; see Alternate Protocol 2) between the instillation of the wash fluid and its withdrawal. There are also reports that few functional macrophages are removed by the initial washes, while later washes contain the most active cells. As in all research, the study must be designed to meet the objectives. If one wishes to disturb the lung as little as possible to detect an inflammatory response, a gentle approach with few washes should be used. If the purpose is to obtain the most functionally active macrophages for further study, more drastic approaches with numerous washes may be required.

Recovery of Wash Fluid

In a total lung lavage, one normally recovers 75% of the initial wash fluid and 100% of the instilled fluid in subsequent washes. If one does two washes, this equals 88% recovery of the total fluid instilled. In a segmental lavage in a large animal, one normally recovers 40% of the first 10-ml wash and 100% of subsequent 10-ml washes. If one performs five washes, the total recovery is ~88%. If the lung being lavaged is severely injured, one may have problems recovering the lavage fluid. If the lung is severely edematous, one could possibly get back more fluid than was put in. This presents some problems for normalization of the data as will be discussed later (see Anticipated Results). In general, the lavage procedure works best in detecting early signs of lung injury before the lung has become so severely affected as to cause problems with recovery of the lavage fluid.

If BAL is performed in vivo in a small laboratory animal, it is usually done as a total lung lavage. There are species differences in how well the whole lung lavage is tolerated, and

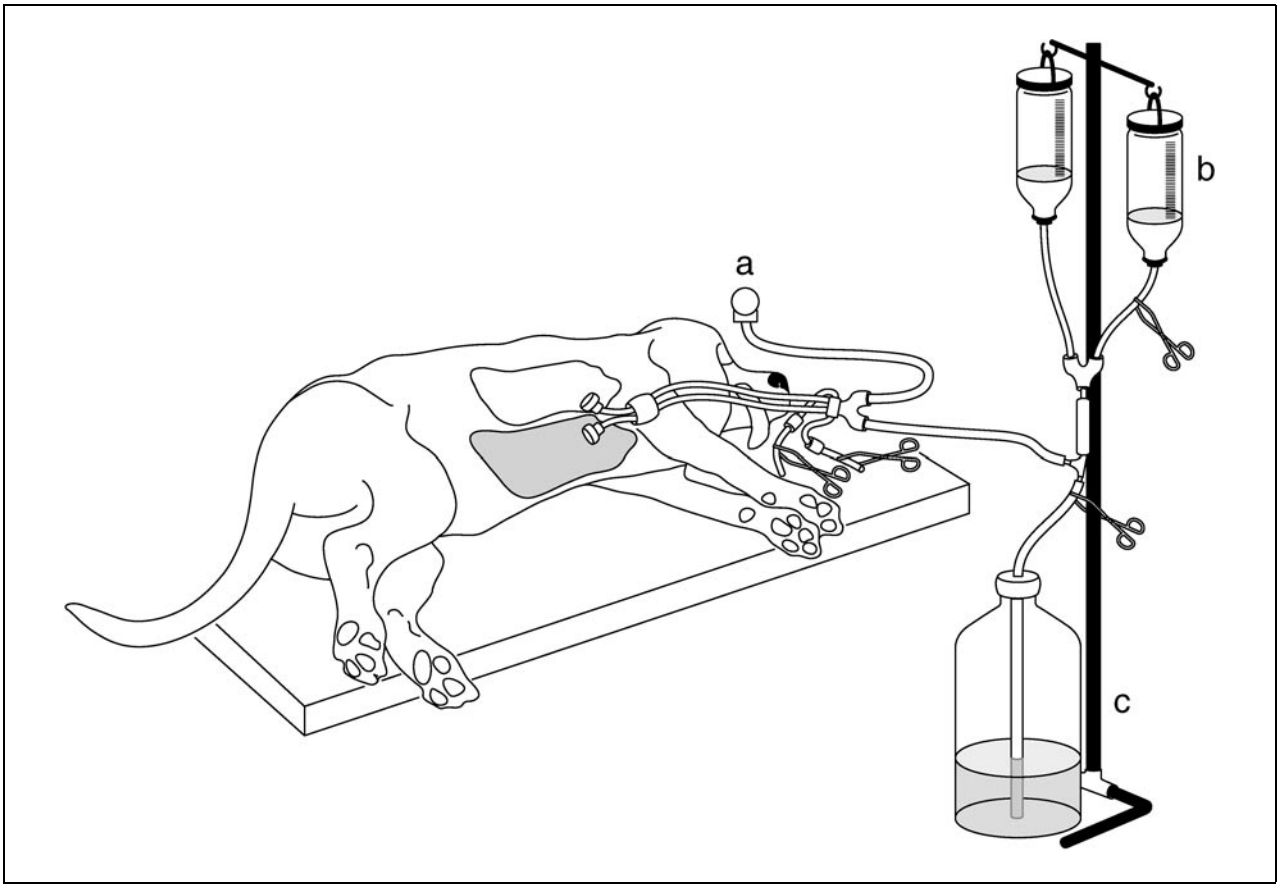

Figure 18.4.1 Schematic of bronchoalveolar lavage procedure in the beagle dog, including (a) anesthesia equipment, (b) wash fluid supply, and (c) receiving container. (From Boecker, B.B., Muggenburg, B.A., McClellan, R.O., et al.: *Health Phys* 1974; 26:505-517. Used by permission.)

the Syrian hamster, mouse, and rabbit appear to be more tolerant than the rat or guinea pig. Sequential lavages can be performed in this manner, if such a procedure is consistent with the experimental objectives of a study. However, for most purposes, the lavage of small laboratory animals is performed in the excised lung (see Alternate Protocol 2) because this involves less time and skill than the procedure performed in vivo.

Whole Lavage Apparatus

A lavage apparatus for use only in dogs or other large animals (Fig. 18.4.1) can be constructed from 3/8-in. internal diameter latex or polyethylene tubing, two 3/8-in. Y connectors, and one 3/8-in. T connector (Nalgene). The saline solution in 1-liter bottles can be 0.9% sodium chloride irrigation solution made by McGraw. Two containers are used so that it is unnecessary to change bottles during the procedure. The T connector is placed at the junction between the irrigation solution and the tube to the dog, and the anesthetic machine and the tube to the collection bottle on the floor. The second Y is used to divide the tubing to the dog and to the anesthetic machine. At the end of the tube to the dog, the connector from a plastic disposable endotracheal tube (Rusch) is attached to the tubing and this is the sized to make a quick disconnect to the Y connector. The other end of the tubing is slid over the end of the disposable endotracheal tube. For a 10-kg beagle, a 9-Fr. (from 8- to 9.5-Fr. for smaller or larger dogs, respectively) tube is generally of adequate size. A second endotracheal tube connector is placed at the end of the tubing to the anesthetic machine. Two large forceps or other clamps are needed to direct the flow of fluids to the dog, or to the collection container and to block off or open the line to the anesthetic machine.

BRONCHOALVEOLAR LAVAGE PERFORMED IN LARGE ANIMALS IN VIVO

In larger animals, BAL can be performed in the anesthetized subject by bronchoscopy as it is done in humans. A fiberoptic bronchoscope is wedged into an airway, and the broncholaveolar space distal to the tip of the bronchoscope is washed with wash fluid. There are several advantages to conducting segmental BAL in vivo. One can follow the progress of a tissue reaction or a disease state over time by repeated washing either of the same lobe or, if the reaction is fairly uniformly distributed throughout the lung, of different lobes. If one wants to test the pulmonary toxicity of a relatively insoluble substance, one can instill different amounts of the material in different lung lobes and subsequently wash the different lobes to conduct a type of dose-response study in one animal.

Depending on the question to be addressed, one may want to obtain ELF from only the bronchial region of the airways or from the deep lung (alveolar region). In small animals, one way to obtain lavage fluid from the two regions is to keep initial wash fluids separate from subsequent lavage fluids. The first wash is considered to have mainly bronchial material, and subsequent washes are considered to have mainly alveolar material. In large animals, another way to sample only the bronchial region is to place an inflatable balloon distal to the area to be washed (see Alternate Protocol 1). This will prevent lavage fluid from going beyond the bronchial region (as described for clinical procedures in Rennard et al., 1998). If a large BALF sample is desired, either the whole right or left lung can be lavaged.

Materials

Animal: dog or other large animal
Preanesthesia agents (e.g., acepromazine, ketamine, zylazine)
Atropine
General anesthetic: 5% (for induction) and 2% (for maintenance) isoflurane in O_2
Sterile wash fluid (see Strategic Planning)

Face mask
Endotracheal tube with balloon (Rusch)
Whole lavage apparatus (see Strategic Planning)

Additional reagents and equipment for storing and processing BALF fluid (see Support Protocol)

NOTE: Bronchoalveolar lavage of large animals in vivo should only be done under the supervision of a veterinarian or physician.

Prepare animal

1. Withhold food from the animal to be tested for 12 hr and water for 6 to 8 hr prior to the experiment.
2. Sedate the animal with preanesthetic agents.

   Phenothiazine-related agents, such as acepromazine can be used in dogs; ketamine or a ketamine-zylazine combination are the agents of choice for nonhuman primates.

3. Thirty minutes before anesthesia, administer atropine to control secretions.

Intubate

4. Induce general anesthesia via a face mask with an anesthetic gas such as isoflurane.
5. When a surgical plane of anesthesia has been achieved, insert endotracheal tube into tube a, shown in Fig. 18.4.1, and inflate balloon.

   At this point, a total lung lavage can be performed, or the fiberoptic bronchoscope can be inserted to perform a sublobar segmental lavage (see Alternate Protocol 1).

Position animal and induce apnea

6. Place the animal on its side, with the lung to be washed in the dependent (i.e., lower) position and connect the whole lavage apparatus (Fig. 18.4.1).

   If both lungs are to be washed in the same procedure, wash the right lung first, because it has the largest volume (Fig. 18.4.1).

7. Hyperventilate the animal for approximately 3 min to induce apnea (i.e., cessation of breathing by lowering the blood carbon dioxide levels).

Administer wash fluid

8. Close the clamp on the tube from the anesthesia machine and open the clamp on the tube from the sterile wash fluid reservoir.
9. Allow the wash fluid to fill the dependent lung to the predetermined volume.

   Use ~80% of functional residual capacity of the lung (equivalent to 80% of the volume required to raise intrapulmonary pressure to 30 cm H_2O) and consider the right lung to be 60% of the total lung (also see Strategic Planning)

Collect BALF

10. When the predetermined volume of wash fluid has entered the lung, immediately clamp off the tube from the wash fluid reservoir and open the clamp to the collection vessel on the floor to drain the fluid from the lung.
11. Before drainage is complete, open the clamp to the anesthetic machine to assist drainage.
12. Ventilate the animal several minutes to re-induce apnea and repeat the procedure (steps 9 to 11) as many times as required by the scientific question to be addressed (see Strategic Planning).
13. After the last wash, tilt the animal head-down to complete drainage from the lung. Store BALF as described (see Support Protocol).

Allow animal to recover

14. Ventilate the lung several times by hand to facilitate recovery. Remove the endotracheal tube when the cough reflex has returned.
15. Observe the animal carefully until it can maintain an upright posture.
16. Analyze and process BALF as described (see Support Protocol).

SEGMENTAL LAVAGE

ALTERNATE PROTOCOL 1

Segmental lavage or the lavage of a sublobar unit of the lung is performed with a fiberoptic bronchoscope. The scope is wedged into the region of the lung lobe of interest. Using isoflurane anesthesia, the animal breaths normally during the procedure and apnea is unnecessary. The airways in monkeys are generally more sensitive to minor submucosal hemorrhage and cough reflex than the dog. Thus, they require more care in manipulating the bronchoscope in the airways and careful attention to anesthesia.

Additional Materials *(also see Basic Protocol)*

Fiberoptic bronchoscope (e.g., Olympus, Pentex)
Syringes

1. Perform the same general anesthesia and intubation procedures as described for total lung lavage (see Basic Protocol, steps 1 to 5).

   The animal is usually placed in the prone position.

2. Insert a fiberoptic bronchoscope into the endotracheal tube and wedge the tip in the lobe of interest.

3. Use an appropriately sized syringe to instill wash fluid gently into the lobe.

   Recommended volumes are 10 ml for dogs weighing 5 to 15 kg, 10 ml for chimpanzees, and 7.5 ml for primates that weigh <10 kg.

4. Immediately suction the fluid out gently with an appropriately sized syringe. Transfer to an appropriate receiving container and store and process as described (see Support Protocol).

   The receiving container can be plastic.

5. Repeat the washing (steps 3 and 4) four to five times or as required by the scientific question being addressed.

6. After completion of the lavages, watch the animal carefully until it can maintain an upright posture.

7. Analyze and process BALF as described (see Support Protocol).

ALTERNATE PROTOCOL 2

BRONCHOALVEOLAR LAVAGE PERFORMED IN THE EXCISED LUNG

In this procedure, a catheter is tied into the trachea of the excised lung and a syringe is used to administer the lavage fluid (Fig. 18.4.2). The fluid is instilled slowly to prevent damage from the procedure itself, and the fluid is withdrawn as gently as possible. The advantage of doing lavage in excised lungs, besides the decreased time and skill requirements, is that it is easy to know what portion of the lung is being washed: it is easy to observe if a part of the lung is not expanded by the fluid. Also, in excised lungs, one normally washes the whole lung or a known portion of the lung. This makes normalization of the data more straightforward (see Anticipated Results). For these reasons, lavage of the excised lung from small laboratory animals has been the method of choice for use of BAL in screening tests for the pulmonary toxicity of inhaled or instilled materials. Studies have indicated little effect on the indicators of toxicity commonly measured in BALF whether the lavage is performed in vivo or in the excised lung.

Additional Materials *(also see Basic Protocol)*

Anesthetic for euthanasia (e.g., 5% halothane in O_2, sodium pentobarbital)
Dissection board and tools
Plastic tracheal catheter with Luer lock connector
Syringes

1. Weigh the animal and anesthetize.

   This can be achieved with 5% halothane in oxygen or sodium pentobarbital. Carbon dioxide should not be used because it increases the background level of some components of the epithelial lining fluid (see Strategic Planning).

2. Exsanguinate the animal via the carotid artery or by cardiac puncture.

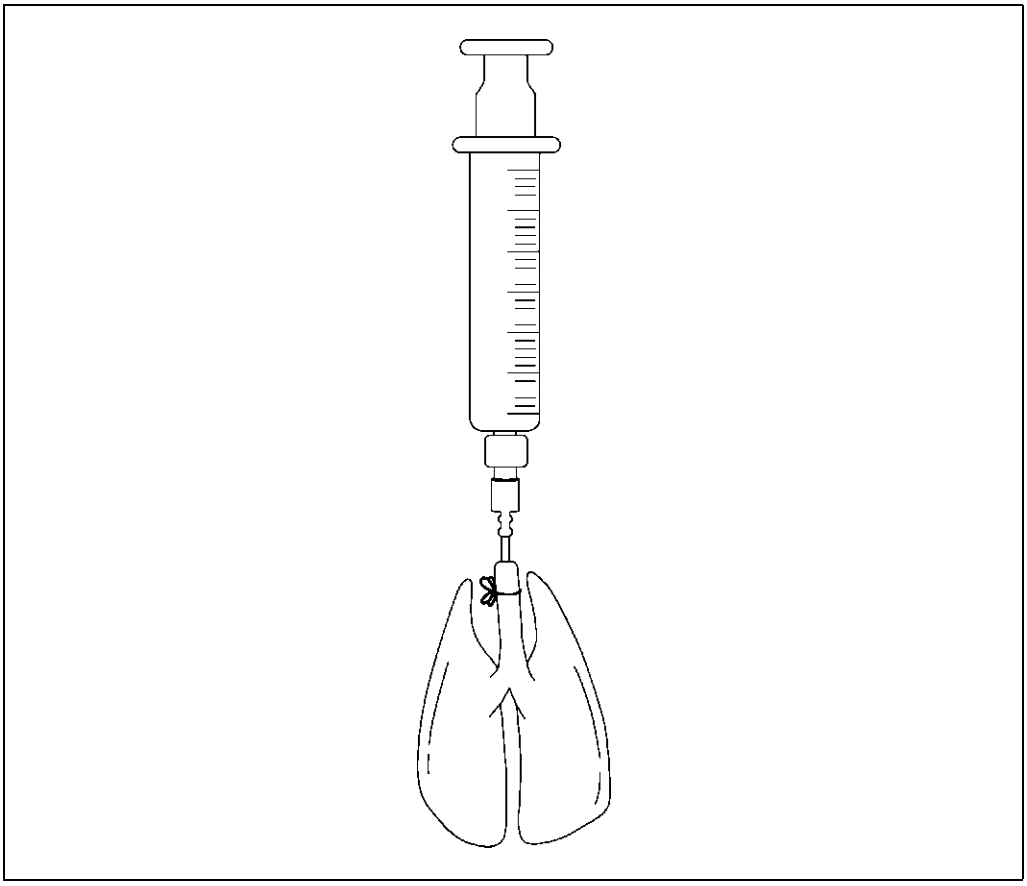

Figure 18.4.2 Total lung lavage in the excised lung.

3. Pin the animal to a dissection board, open the thoracic cavity, and remove the heart-lung block with trachea attached.
4. Place a plastic tracheal catheter with Luer lock connector into the trachea and tie in place. Attach an appropriately sized syringe containing the appropriate amount of wash fluid.
5. Use the syringe to slowly instill sterile wash fluid at a volume ~80% of the lung functional residual capacity into the lung until it appears to be fully extended. With gentle pressure, slowly withdraw the fluid.

   See the Strategic Planning for more information.
6. Repeat the procedure (step 5) as many times as required for the specific question being addressed.

   The first wash will contain more material from the upper respiratory tract than subsequent washes. In all cases, the components of the lavage fluid will be more dilute with each successive wash.
7. Measure the volume of lavage fluid recovered.

   In a healthy lung, one should achieve 75% recovery on the first wash and close to 100% recovery on subsequent washes. In a damaged lung, recovery may be less. In an edematous lung, recovery may appear greater, but this is rare.
8. Store and process BALF as described (see Support Protocol)

SUPPORT PROTOCOL

PROCESSING BRONCHOALVEOLAR LAVAGE FLUID (BALF) AND ANALYSIS OF LUNG DAMAGE INDICATORS

The lavage fluid obtained from the lung should be kept cold on ice, and the cells should be separated from the fluid as quickly as possible by centrifugation (10 min at 300 × *g* is adequate). The supernatant should be kept cold (0°C) and enzymatic activities should be measured as soon as possible (i.e., within the same day). Most enzymes are too dilute in the BALF to be stable to freezing. Three enzymes commonly analyzed are lactate dehydrogenase (indicator of cell death), β-glucuronidase (indicator of macrophage activation), and alkaline phosphatase (indicator of Type II cell secretions). Descriptions of these assays can be found in standard texts (see Bergmeyer, 1983). For other, more stable analytes, the supernatant may be stored for later analyses under conditions appropriate for the analyte. The samples may be concentrated using ultrafiltration through membranes of a small pore size to enhance analytical capabilities.

Additional Materials *(also see Basic Protocol)*

BALF (see Basic Protocol or Alternate Protocols 1 or 2)

Additional reagents and equipment for counting cells (*APPENDIX 3B*)

NOTE: Keep BALF on ice at all times.

1. Measure the volume of the BALF.
2. Centrifuge 10 min at 300 × g, room temperature, to remove the cells as soon as possible and thus avoid lysis.
3. Save the supernatant on ice for later analyses. Resuspend the cell pellet in 1 ml wash fluid and save for cell counting.
4. Conduct a total (*APPENDIX 3B*) and differential cell count.

   A Wright-Giemsa type stain is commonly used (Strober et al., 1997) to allow differential counting.

5. For the differential count, record both the absolute number of each cell type and the percentage of the total number of cells (see Background Information).
6. Analyze the supernatant for enzymatic, protein, and lipid factors that are indicative of a damaged lung or of a specific stage in lung disease (see Background Information).

   Enzymatic activity must be measured immediately, because most enzymes will not be stable in the diluted state of the BALF. Care must be taken to determine the conditions for stability of each factor to be measured and appropriate precautions taken to preserve the analyte.

7. If applicable, analyze the protein expression profile by proteomic techniques (see Background Information).

COMMENTARY

Background Information

Indicators of lung damage

In toxicology studies of inhaled or instilled agents, both the degree of an induced inflammatory response and the time course of recovery from or intensification of the process can be followed by analysis of BALF. The lavage fluid is analyzed for cellular and biochemical indicators or toxicity and inflammation.

Cell counts. The total and differential cell count in BALF is an informative measure of the inflammation in the respiratory tract. The major cell type (>90%) in BALF from a healthy animal is the pulmonary macrophage. Neutrophils are rare, and an influx of these cells is a sensitive indicator of an inflammatory response. Lymphocytes are not often seen in BALF from rats, mice, and hamsters, but

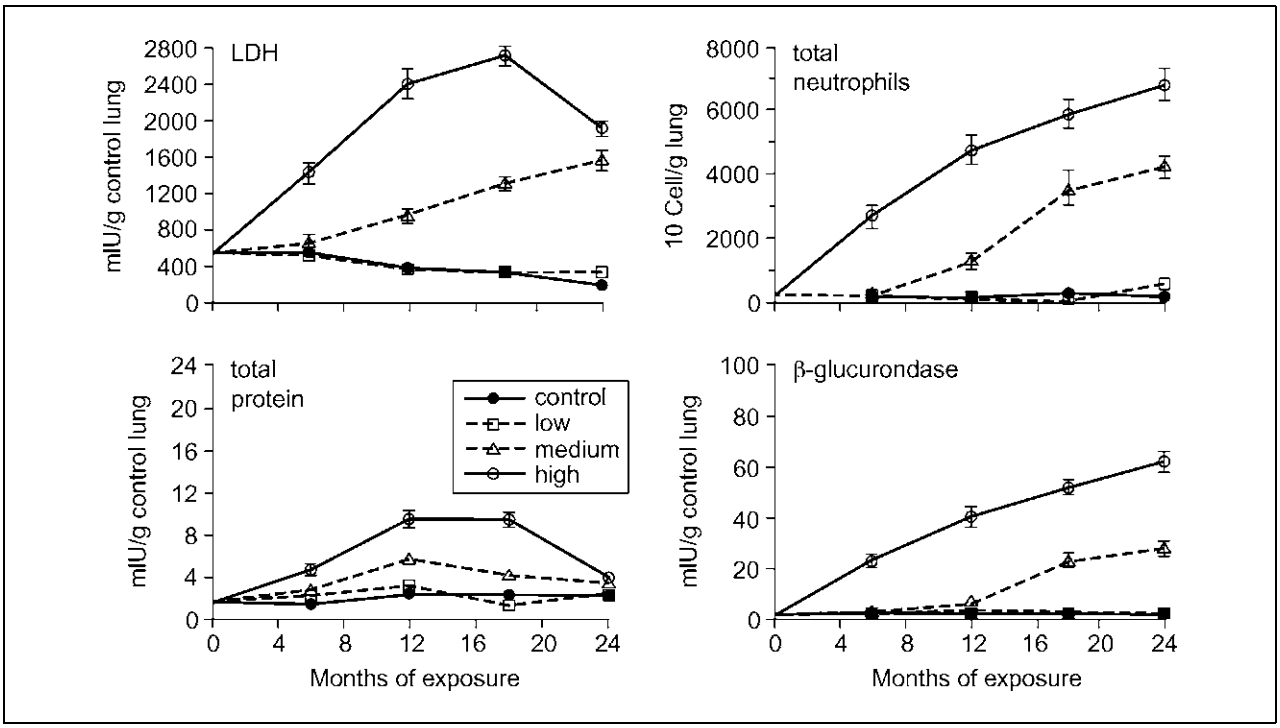

Figure 18.4.3 Bronchoalveolar lavage parameters in rats chronically exposed to diesel exhaust. Rats were exposed to diluted diesel exhaust at three levels (0.35 mg of particles/m^3, 3.5 mg/m^3, or 7.0 mg/m^3) for 24 months. Every 6 months a subset of animals was lavaged (excised lungs) and the BALF analyzed for indicators of lung damage or inflammation. The data were able to delineate a clear dose and time dependent response.

may represent up to 10% of BALF cells in larger animals such as sheep, horses, and monkeys. BALF from guinea pigs will contain eosinophils. An immune-based inflammatory response is indicated by an increase in lymphocytes or eosinophils in BALF.

Biochemical content. The biochemical content of BALF is also informative. Protein content in the lavage fluid can be used to monitor increased permeability of the alveolar-capillary barrier, which occurs in an inflammatory response. Lactate dehydrogenase is a cytoplasmic enzyme whose extracellular presence indicates cell death. β-glucuronidase activity in the extracellular fluid is a measure of activated macrophages, and alkaline phosphatase is an enzyme associated with Type II cell secretions. Proinflammatory cytokines can be measured in the lavage fluid or, as is frequently done, as secretions from cultured cells retrieved from the lavage fluid. Early biochemical mediators of pulmonary inflammation are tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), which are cytokines released from the resident macrophages that promote the adherence of circulating inflammatory cells to the endothelium. These cytokines stimulate the release of chemoattractant factors such as IL-8 (a major chemoattractant for neutrophils in primates), macrophage inflammatory protein-2 (MIP-2, a neutrophilic chemoattractant in rodents), IL-6, and macrophage chemoattractant protein-1 (MCP-1, attracts inflammatory cells into the alveoli).

Proteomics. To measure the degree of inflammation, one need not go beyond the analysis of total and differential cell counts plus some of the biochemical parameters mentioned above; however, if mechanistic questions are to be addressed, the hypotheses to be tested will determine other pertinent analytes to be measured in BALF. A promising new approach called proteomics makes use of mass spectrometric techniques that allow analysis of the total protein expression profile (PEP) in body fluids such as BALF. Software packages allow comparison of PEP in BALF from healthy versus disease states. Such analyses may one day aid in the diagnosis and staging of disease processes in the respiratory tract, but they are not fully developed today.

Critical Parameters and Troubleshooting

Relatively few problems are encountered in this rather simple technique. If lavage of the excised lung is planned, one must be careful not to nick the lungs in removing them; lavage fluid will drain from any opening made

in the lung. One must remove the cells from the fluid as quickly and gently as possible to avoid leakage of enzymes from the lavaged cells into the supernatant. Enzymes must be assayed on the same day the fluid is collected unless prior studies have shown the enzymes to be stable under storage conditions. In studies on the response to inhaled or instilled material, it is possible that enough of the toxicant will be removed in the lavage fluid, especially if taken immediately after exposure, to inhibit assays for some of the parameters. This possibility should always be taken into consideration.

Anticipated Results

Because the volume of lavage fluid used is adjusted for the size of the lung being lavaged, if the technique used is consistent between animals, it is valid to normalize the data to the volume of recovered fluid—i.e., to use the concentration of the analyte in the BALF. If an edematous lung is lavaged, and the volume of fluid recovered is variable and greater than that instilled, one can calculate the total amount of analyte recovered (amount per volume times the volume) in order to make comparisons among the test animals. To compare data from different studies conducted in different species under different conditions, one can normalize the total amount of the analyte removed to the volume of lung washed (Henderson, 1989). An example of the type of data one might obtain with analysis of BALF in a toxicology study is shown in Fig. 18.4.3.

Time Considerations

Bronchoalveolar lavage studies involving up to 30 small animals can be completed in 1 day.

Measuring Lymphocyte Transcription Factor Activity by ELISA

The primary function of the immune system is to provide host resistance to infectious microorganisms and malignant disease. This requires the complex interaction between cells via a series of biochemical and molecular events, culminating in altered gene expression. Initiation of transcription by sequence-specific DNA-binding proteins known as transcription factors (TFs) is the principle point at which the expression of most genes is regulated. Thus, an understanding of nuclear events affected by environmental toxicants and their mechanisms of action is critical to understanding toxic phenomena. For example, α,β-unsaturated aldehydes inhibit NFκB p50 DNA binding, while saturated aldehydes have no effect (Fig. 18.5.1). The level of p50 DNA binding correlates well with the level of IL-2 produced (Fig. 18.5.2).

Transcription factors affect fundamental biologic processes and have been implicated in numerous human diseases. Appropriate temporal and spatial activation of transcription factors is crucial for target cell function. It is not surprising that many new assays have been developed to improve the sensitivity and convenience of measuring transcription factor DNA-binding activity. Traditional methods utilize radiolabeled target DNA in gel-shift or electrophoretic mobility shift assays (EMSA). Even with the advancement of nonisotopic (chemiluminescent) detection, EMSA is cumbersome, not amenable to high-throughput applications, and has limited sensitivity. This unit will focus on colorimetric enzyme-linked immunosorbent assays (ELISA) to measure DNA-binding activity.

Colorimetric ELISA-based procedures have been developed to detect specific transcription factor activities in cell extracts (Shen et al., 2002). The sensitivity of ELISA can be up to ten-fold higher than electrophoretic mobility shift assays (Benotmane et al., 1997), and up to 96 reactions can be performed in 3 to 4 hr. Extracts are added to the

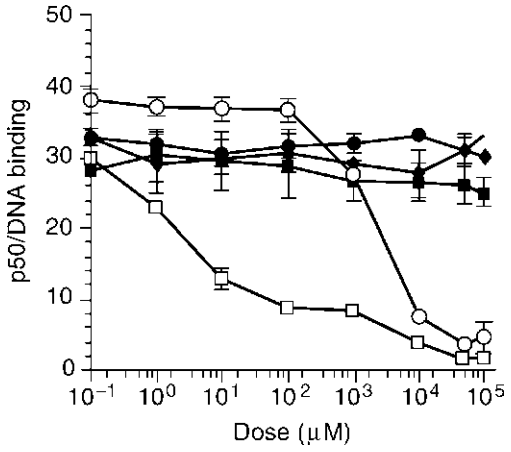

Figure 18.5.1 Inhibition of p50 DNA binding by cigarette smoke aldehydes. The ability of the various aldehydes to inhibit the interaction between recombinant p50 and the NF-κB promoter region was measured using a BD Mercury NF-κB/p50 TransFactor Kit. A saturating concentration of p50 (160 pmol) was treated with 0 to 100 mM acrolein (empty circles), crotonaldehyde (empty squares), acetaldehyde (colored squares), propionaldehyde (colored circles), or butyraldehyde (colored diamonds) and then added to wells coated with NF-κB consensus sequence (GGGGATCCC). The amount of p50 bound was measured using anti-p50, HRP-conjugated anti-rabbit IgG, and TMB and the results expressed as mOD/min. Results are the mean ±SE of two experiments.

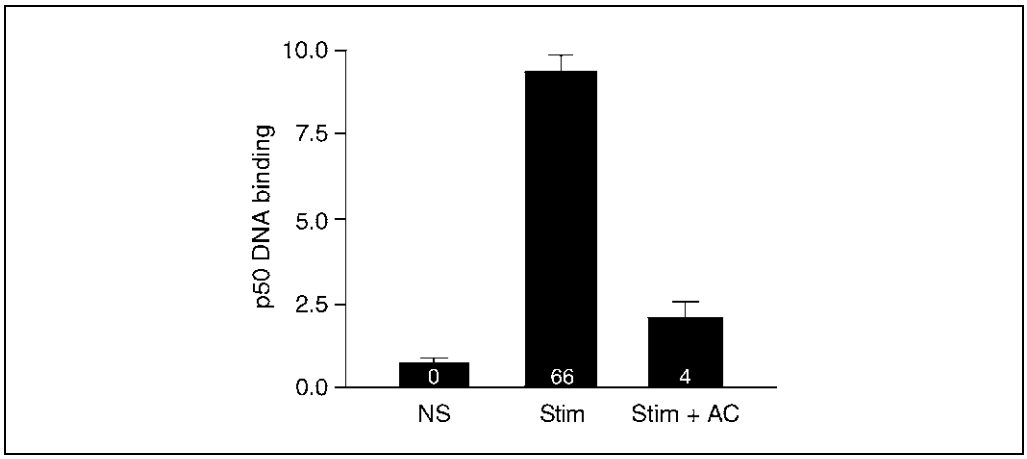

Figure 18.5.2 Acrolein blocks induction of p50 DNA activity. Jurkat T cells were treated with 10 μM acrolein (AC) for 3 hr and then stimulated with anti-CD3 plus PMA for 24 hr. Culture supernatants were analyzed for IL-2 levels, shown in white numbers as pg/ml. Nuclear extracts were prepared and assayed for p50 DNA binding using a 42-mer NF-κB consensus target sequence. NS, non-stimulated.

96-well plate precoated with a transcription factor DNA-binding consensus sequence and detected with an antibody specific to the transcription factor of interest. Thus, DNA ELISAs are easily adapted to study a large number of samples or parameters, as plates can be coated with the same DNA consensus sequence, or with DNA specific for different factors, to study multiple transcription factors in parallel. In short, ELISA provides increased speed and throughput, and allows improved sensitivity and convenience over the traditional methodologies. There are three protocols for this procedure: coat DNA to plates (see Support Protocol 1), prepare nuclear extracts (see Support Protocol 2), and perform DNA-binding ELISA (see Basic Protocol).

BASIC PROTOCOL

DNA-BINDING ELISA

To perform the ELISA, individual wells of a 96-well plate are precoated with oligonucleotides containing the DNA consensus binding sequence for a specific factor. Nuclear extracts are incubated in the wells to allow the transcription factor, if present, to bind its sequence. Unbound proteins are washed away, and primary antibody specific for that factor is added. Following incubation with horseradish peroxidase (HRP)-conjugated secondary antibody and substrate, color intensity is measured using a standard microtiter plate reader. The amount of signal detected correlates to the amount of transcription factor bound on the plate and is represented as the optical density (OD_{655}) for each sample. For quantitative results, a standard curve can be generated using purified transcription factor. As with EMSA, specificity of binding can be confirmed with mutant dsDNA (coated to wells) and competition assays (unbound wild-type dsDNA). Positive control reactions can be performed routinely to ensure reliability.

Materials

Blocking buffer (see recipe)
ELISA plate precoated with wild-type and mutant dsDNA (see Support Protocol 1)
Nuclear extract (see Support Protocol 2)
PBS (see recipe)
Wild-type competitor oligonucleotides
Wash buffer (see recipe)
Primary antibody
Secondary antibody e.g., anti-rabbit IgG-HRP or anti-mouse IgG-HRP (Clontech)

TMB substrate (Sigma)
Stop solution: 1 M H_2SO_4 (optional)
Microtiter plate reader

1. Incubate 150 µl blocking buffer per well of the precoated ELISA plate for 15 min at room temperature.
2. Prepare samples, in triplicate, by thawing nuclear extracts slowly on ice and diluting 6 µg extract to 50 µl with PBS. For background control, use 50 µl PBS alone. For competition assays, use 500 ng wild-type competitor oligonucleotide per sample.

   Extract and competitor oligonucleotide concentrations may need to be optimized (by measuring linearity of response) depending on the assay.
3. Remove blocking buffer and add 50 µl sample per well. Incubate 60 min at room temperature.
4. Wash wells three times with 150 µl wash buffer per well, incubating 4 min each wash. Decant final wash.
5. Dilute primary antibody (specific for transcription factor of interest) in blocking buffer (optimize by testing 1 to 500 ng/ml). Add 100 µl diluted primary antibody per well. Incubate 60 min at room temperature.
6. Wash wells three times with 150 µl wash buffer per well, incubating 4 min each wash. Decant final wash.
7. Dilute appropriate secondary antibody (1:1000 for anti-rabbit IgG-HRP or 1:200 for anti-mouse IgG-HRP) in blocking buffer. Incubate 100 µl secondary antibody per well for 30 min at room temperature.
8. Wash wells four times with 250 µl wash buffer per well, incubating 4 min each wash. Decant final wash.
9. Add 100 µl TMB substrate per well. Incubate 10 min at room temperature.

   Reading of plates without the addition of stop solutions allows the same wells to be read at various timepoints, which allows one to identify the optimal time for color development.
10. Measure absorbance of the plate wells at 655 nm with a microplate reader.

    If 1M H_2SO_4 is used as a stop solution (100 µl per well), read plates at 450 nm.

    The amount of signal detected correlates to the amount of transcription factor bound onto the plate and is represented as the optical density (OD_{655}) for each sample.
11. For quantitative results, generate a standard curve using purified transcription factor (1 to 100 ng).

COAT PLATES WITH DNA

SUPPORT PROTOCOL 1

DNA has a low binding affinity to unmodified microtiter plate surfaces, but immobilization of DNA onto plastic surfaces can be accomplished quickly and simply using Reacti-Bind DNA coating solution (Pierce). DNA diluted in Reacti-Bind is incubated in plates a minimum of 1 to 2 hr at room temperature. Unbound DNA is washed away using PBS and dry plates can be stored up to 1 month at 4°C. The use of ELISA plates that can be separated into eight 12-well strips (or even 96 individual wells) provides greater flexibility than standard microtiter plates.

Materials

ssDNA: consensus sequence of transcription factor of interest (e.g., BD Mercury TransFactor Kit, BD Biosciences)
TE buffer (see recipe)
Reacti-Bind DNA coating solution (Pierce)
PBS (see recipe)

ELISA plate precoated with wild-type and mutant dsDNA
13 × 100–mm glass test tube

1. Anneal ssDNA oligonucleotides (≥20 nucleotides in length) by mixing equal molar amounts of sense and anti-sense oligonucleotides and heating to 94°C. Slowly cool to room temperature and store at −20°C.
2. Incubate 1 vol (2.5 to 25 μg DNA/plate) DNA (diluted in water or TE buffer) with 1 vol Reacti-Bind DNA coating solution in a 13 × 100–mm glass test tube for 10 min at room temperature.

   The final DNA concentration should be between 0.5 and 5 μg/ml and must be empirically determined for each transcription factor.

   Reacti-Bind solution will immobilize DNA onto any plastic, including Eppendorf tubes.
3. Add 50 μl DNA per well of a 96-well, polystyrene plate. Incubate 2 hr to overnight at room temperature.
4. Wash unbound DNA with 100 μl PBS/well, remove liquid and store dry plates up to 1 month at 4°C.

SUPPORT PROTOCOL 2

PREPARE NUCLEAR EXTRACTS

To prepare nuclear extracts, washed cells are suspended in hypotonic buffer and allowed to swell (Dignam et al., 1983). Nuclei are pelleted and the cytosolic fraction is removed. Nuclei are resuspended in high-salt buffer to release soluble proteins from nuclei and then normalized with low-salt buffer. Following centrifugation, nuclear extracts are assayed for protein concentration and frozen in liquid nitrogen for storage.

Materials

Cells, e.g., PBMC (>10^6 cells)
PBS (see recipe), ice cold
Hypotonic buffer (see recipe), ice cold
High-salt buffer (see recipe), ice cold
Low-salt buffer (see recipe), ice cold
BCA or Bradford protein concentration kit (Sigma)
Liquid nitrogen
1.5-ml microcentrifuge tubes, prechilled

1. Harvest cells by Ficoll centrifugation (5 min at 500 × g, 4°C) and wash two times in ice-cold PBS. Remove and discard supernatant.
2. Add a volume of ice-cold hypotonic buffer equal to five times the cell pellet volume (e.g., 50 μl for 1 × 10^7 PBMC). Resuspend the cells gently, avoiding the production of foam. Incubate 10 min on ice. Mix gently by finger-flicking.
3. Pellet nuclei by centrifuging 10 min at 12,000 × *g*, 4°C. Carefully remove and discard supernatant (cytosolic fraction). Resuspend the nuclei pellet in a volume of ice-cold high-salt buffer equal to the original cell pellet volume (e.g., 40 μl for 1 × 10^7 PBMC). Incubate 15 min on ice.

4. Add an equal volume of ice-cold low-salt buffer (e.g., 40 μl for 1×10^7 PBMC).
5. Pellet cellular debris by centrifuging 10 min at 12,000 × *g*, 4°C.
6. Transfer supernanant (nuclear extract) to pre-chilled 1.5-ml microcentrifuge tube, discard pellet. Remove aliquot for determination of protein concentration (usually in the range of 0.25 to 1 μg/μl).

   This buffer is compatible with Bradford and BCA protein assays.
7. Snap-freeze nuclear extracts in 20- to 30-μl aliquots and store up to 6 months at −70°C. Avoid repeated freeze-thaws.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking buffer

1.6 g BSA (final 4%)
40 ml PBS
Store up to 6 months at −20°C

High-salt buffer

400 μl 500 mM HEPES, pH 7.9
15 μl 1 M $MgCl_2$
2.5 ml glycerol
10 μl 200 mM EDTA
840 μl 5 M NaCl
6.235 ml H_2O
Store up to 6 months at 4°C
Add fresh: 1 μl 0.5 M DTT and protease inhibitors (Sigma) per 500 μl buffer

Hypotonic buffer

400 μl 500 mM HEPES, pH 7.9
30 μl 1 M $MgCl_2$
66.7 μl 3M KCl
18.9 ml H_2O
Store up to 6 months at 4°C
Add fresh: 1 μl 0.5 M DTT, 2.5 μl NP-40, and protease inhibitors (Sigma) per 500 μl buffer

Low-salt buffer

400 μl 500 mM HEPES, pH 7.9
10 μl 200 mM EDTA
9.59 ml H_2O
Store up to 6 months at 4°C
Add fresh: 1 μl 0.5 M DTT and protease inhibitors (Sigma) per 500 μl buffer

PBS, 10 × (pH 7.2)

For 1 liter:
80 g NaCl
2 g KCl
11.5 g $Na_2HPO_4 \cdot 7H_2O$
2 g KH_2PO_4
Store up to 6 months at room temperature

TE buffer

10 mM Tris·Cl, pH 8.0
1 mM EDTA
Store up to 6 months at room temperature

Wash buffer

1 liter PBS (see recipe)
2 ml Tween-20 (final 0.2%)
Store up to 1 month at room temperature

COMMENTARY

Background Information

The regulation of gene expression in a coordinated manner and in response to various stimuli requires elaborate cellular machinery, focusing on sequence-specific DNA-binding proteins known as transcription factors (TFs). TFs control promoter activity through modification of basal transcription machinery and/or chromatin organization. The importance of these factors is demonstrated by their abundant representation in the human genome (>2000 genes code for TFs). A new classification system has been proposed grouping TFs according to their connections with signaling pathways, thereby providing a functional perspective to each TF (Brivanlou and Darnell, 2002).

Despite many similarities, each transcription factor possesses unique properties with regard to tissue expression patterns, response to receptor signals, and target gene specificity. Briefly, common factors such as NFκB, NFAT, and AP1 are known for regulating immune and inflammatory responses. Factors including LKLF, Tob, GILZ, and FOXO have been shown to participate in actively maintaining quiescence in lymphocytes, while Myc and E2F1 are the primary TFs involved in controlling cell growth, cell cycle progression, differentiation, and apoptosis. Fox3p is critical for generation of T regulatory cells. Finally, Th1:Th2 cytokine ratios are maintained by a balance of STAT4, Tbet, IRF1, IRF2,

Table 18.5.1 Troubleshooting Guidelines

Problem	Possible cause	Solution
Lack of signal or weak signal	Omission or improper preparation of reagent	Optimize dsDNA, primary antibody concentration
	Sample had less than optimal protein concentration or was mishandled	Test positive control
	Plate reader did not perform properly (i.e., UV light not warmed up)	Warm up UV light
High background	Inadequate washing	Wash four times
	Improper preparation of reagent (i.e., antibody concentrations too high)	Lower antibody concentration
	Overdeveloping	Decrease TMB incubation time and/or use stop solution
High background in sample wells	Sample concentration too high	Generate a dose response curve
	Improper dilution of antibody	Redilute antibody
Weak signal in sample wells	Sample concentration too low	Generate a dose response curve
	Improper dilution of antibody	Use more antibody

and STAT6, GATA3, respectively (for review, see Li-Weber and Krammer, 2003; Yusuf and Fruman, 2003).

Critical Parameters

This protocol uses dsDNA and antibody to detect TF activity and the results depend on the specificity of those reagents. Although TFs are sequence specific, many TFs within a family bind to the same DNA sequence. Similarly, many antibodies can cross-react with heterologous proteins. A number of controls should be performed to ensure specificity. Positive controls can include nuclear extracts or recombinant TF that have been tested and shown to have a standard amount of the desired TF DNA-binding activity. Note that a loss of DNA-binding activity can be seen with repeated freezing and thawing of these samples. Negative controls include buffer alone, nuclear extracts from cells lacking desired TF DNA-binding activity, and mutant DNA-coated wells. Samples lacking TF DNA binding activity address nonspecific antibody binding, and mutant consensus sequence wells account for nonspecific DNA binding from samples. Finally, the use of competitor DNA controls demonstrate the specificity of the DNA/protein interactions.

Troubleshooting

For troubleshooting guidelines, see Table 18.5.1.

Anticipated Results

Linearity. To ensure linearity, optimize ELISA for the specific samples by plotting a dose-response curve (0 to 30 μg nuclear extract).

Reproducibility. Due to the convenient and high-throughput nature of the ELISA, positive-control reactions (extract with known transcription factor activity or pure protein) can be performed routinely.

Specificity. As with EMSA, specificity of binding can be confirmed with mutant dsDNA (coated to wells) and competition assays (unbound wild-type dsDNA).

Sensitivity. The sensitivity of ELISA can be up to ten-fold higher than with EMSA. In some assays, as low as 1 nM pure transcription factor can be detected, but this can vary greatly. Individual results will depend upon abundance of transcription factor of interest in samples, its reactivity with target DNA coated on plate, and quality of primary antibody used.

Time Considerations

To coat plates, 2 to 24 hr is required. Plates can be prepared in advance. Store dry plates at 4°C. Preparing extracts requires 2 to 3 hr and can be prepared in advance. Store extracts at −70°C. To perform the assay, it takes 3 to 4 hr.

Measuring the Activity of Cytolytic Lymphocytes

There are two major sub-populations of lymphocytes with cytolytic activity: differentiated $CD8^+$ T cells (i.e., cytotoxic T lymphocytes or CTL) and natural killer (NK) cells. In some instances, $CD4^+$ T cells can acquire a cytolytic phenotype, but this occurs very rarely (Kagi et al., 1996). Cytolytic lymphocytes play an important role in resistance to intracellular pathogens. Specifically, CTL primarily kill host cells that are infected with viruses, whereas NK cells kill virally and bacterially infected host cells. Additionally, both CTL and NK cells recognize and kill certain types of tumor cells, and in some instances cells infected with bacteria are targets of CTL-mediated killing. This unit will focus on measuring CTL and NK cytolytic activity using an ex vivo chromium release assay.

The lysis of a target cell by NK cells and CTL requires cell-cell contact between the cytolytic lymphocyte (termed the effector cell) and the target cell. This interaction is directed by different molecules, which differ between CTL and NK cells (Russell and Ley, 2002). It is important to understand the distinctions between these two types of cells when one measures the activity of cytolytic lymphocytes. A brief overview of the mechanisms used by CTL and NK cells is provided in the following section.

CTL-mediated target cell lysis. The acquisition of killing ability by $CD8^+$ T cells requires the initial activation, clonal expansion, and differentiation of naïve $CD8^+$ T cells, which develop into CTL. In other words, naïve $CD8^+$ T cells do not have cytolytic capacity, whereas differentiated $CD8^+$ T cells (CTL) have acquired this ability. CTL recognize and react to a large variety of molecules, including major and minor histocompatibility molecules and peptides expressed in the context of syngeneic MHC class I molecules. These peptides are derived from proteins expressed within the cell, often from intracellular pathogens or tumors. CTL recognize these peptide/MHC class I complexes using T cell receptors (TCR). Each $CD8^+$ T cell expresses TCR that recognize a unique peptide/MHC class I complex, which confers the specificity of the response. While only $\sim 1{:}10^5$ CTL are specific for a given peptide/MHC class I complex, $\sim$10% of T cells in the body recognize allogeneic MHC molecules; therefore, in terms of measuring CTL activity, it is often useful to exploit the higher frequency of allo-reactive CTL.

NK cell-mediated target cell lysis. In contrast to $CD8^+$ T cells, NK cells do not require prior exposure to antigen in order to acquire cytolytic activity. NK cells also lack antigen-specific receptors. Instead, the cytolytic activity of NK cells is controlled by the expression of a large family of cell surface receptors referred to as the NK gene complex (Yokoyama and Plougastel, 2003). Members of this family act as either inhibitory or stimulatory receptors. Using these receptors, NK cells distinguish healthy syngeneic cells from infected cells and tumor cells.

While this aspect of NK cell function is well accepted, the overall mechanisms that control target cell recognition by NK cells remains an active area of study, and the ligands for many NK cell receptors have yet to be identified. One well-established pathway for NK cell recognition of target cells is often referred to as the "missing self hypothesis." This model is predicated on the idea that NK cells require a constant off signal, delivered through the interaction of cell surface inhibitory receptors with MHC class I molecules on host cells. In the absence of this signal, NK cells become activated and kill the cell in which they have come in contact. This inhibitory signal would be absent, for example,

Contributed by B. Paige Lawrence
Current Protocols in Toxicology (2004) 18.6.1-18.6.27

when aberrant MHC molecules are expressed or when a cell has down-modulated MHC class I expression due to viral infection. The NK-specific target cells used in the assays described here rely on this mechanism, as the target cells do not express MHC class I, making them susceptible to NK cell–mediated lysis and resistant to killing by CTL.

The basis for the protocol described here is measuring the killing of CTL-specific or NK cell–specific targets in an in vitro chromium release assay. Measurement of CTL activity requires priming of cells to obtain a clonally expanded and differentiated population of CTL. Three separate protocols for examining the activity of cytolytic T cells are provided in this unit. Methods for measuring CTL-specific cytolytic activity following in vitro (see Basic Protocol 1) and in vivo (see Alternate Protocols 1 and 2) priming are described. In contrast to CTL, the cytolytic activity of NK cells can be measured in the absence of antigen priming, and this method is described in Basic Protocol 2.

In all of these protocols, single-cell suspensions of effector and target cells are prepared separately. The target cells are labeled with ^{51}Cr, and then the effector and target cells are cultured together. The amount of target cell lysis is determined by measuring the amount of ^{51}Cr released into the culture medium after incubation for several hours. Separate controls are included to determine the maximum amount of ^{51}Cr released, as well as spontaneous or background release from the labeled target cells. Additional controls are suggested to validate the specificity of the assay system.

There is a large variation in possible effector and target cells that can be used to examine the activity of cytolytic lymphocytes. For the protocols described here, the effector cells are derived from mouse spleen. The target cells are either spleen cells from mice that express a different MHC haplotype, virus-infected cells, or cells derived from cultured cell lines. The reader should be aware that Basic Protocol 1 and underlying principles can be easily adapted. For example, one could use other antigens for in vivo priming, use effector cells derived from another organ, or even derive effector and target cells from another species (e.g., rat).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

BASIC PROTOCOL 1

CHROMIUM RELEASE ASSAY FOR MEASURING CTL ACTIVITY FOLLOWING IN VITRO SENSITIZATION OF MOUSE SPLEEN CELLS

This protocol consists of following four separate parts: (1) effector cell sensitization (in vitro); (2) target cell preparation and labeling with ^{51}Cr; (3) collection of effector cells; and (4) chromium release assay.

Each part is conducted separately; however, target cell preparation and labeling with ^{51}Cr (∼3 hr) and collection of effector cells need to be carried out such that the time between the completion of both does not exceed 30 min.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer.

Materials

Stimulator/target cells (e.g., spleen cells), single-cell suspension
Control target cells (to test specificity of cytolytic activity; e.g., syngeneic spleen cells), optional
Effector cells (e.g., alloantigen-sensitized spleen cells, also called responder cells)
Control effector cells (non-sensitized spleen cells or cells that were sensitized using an irrelevant antigen)
Complete RPMI (cRMPI, see recipe)
0.5 mg/ml mitomycin C in cRPMI
Lipopolysaccharide (LPS) or concanavalin A (Con A) (both available from Sigma)
Phosphate buffered saline (PBS), sterile and low-endotoxin (e.g., GIBCO, Invitrogen)
Serum-free RPMI (sfRPMI, see recipe)
≥5 mCi/ml $Na_2{}^{51}CrO_4$, sterile, aqueous solution (10 to 35 mCi/ml and 200 to 500 mCi/mg Cr; e.g., Amersham Biosciences)
0.5% SDS (see recipe)

Coulter counter or hemacytometer
24- or 96-well flat-bottom cell culture plates
25-cm^2 tissue culture flasks or 100-mm tissue culture dishes
15-ml and 50-ml conical centrifuge tubes with screw caps (sterile, polystyrene or polypropylene; e.g., Corning or Falcon)
96-well round-bottom microtiter plates
Multi-channel micropipettor (50- to 200-µl) with disposable tips
Reagent reservoirs, disposable
12 × 75–mm glass test tubes
Gamma counter

Additional reagents and equipment for counting cells and determining viability (*APPENDIX 3B*)

Sensitize CTL

1. In a 15-ml centrifuge tube, prepare separate, single cell suspensions of spleen cells from allogeneic strains of mice,—e.g., C57Bl/6 or 129 (H-2^b) and BALB/c or DBA (H-2^d)—see Support Protocol 1 for the preparation of spleen cells.

   Spleen cells from one strain will become the effector cells. In other words, these cells will recognize and respond to the different MHC class I haplotype of the spleen cells from the allogeneic mouse strain. In culture, these cells will clonally expand and differentiate into CTL. In the context of in vitro stimulation, these cells are also referred to as the responder cells.

   Splenocytes obtained from the other strain will serve as the stimulator cells in this portion of the assay. To measure the response of the effector cells, it is necessary to prevent the stimulator cells from dividing. This can be accomplished pharmacologically, as described here, or by irradiation (3000 rad) prior to co-culture.

2. Count the cells using a hemacytometer (*APPENDIX 3E*) or Coulter counter.

3. Resuspend the responder spleen cells in cRPMI at a final concentration of 5–10 × 10^6/ml.

4. Resuspend the stimulator cells at ~1 × 10^7 cells/ml in cRPMI. Add 0.5 mg/ml mitomycin C to the stimulator cells, such that the final concentration of mitomycin C is 25 µg/ml. Incubate the cells with mitomycin C 20 min at 37°C or in a 37°C water bath.

   Mitomycin C is light sensitive, therefore if a water bath is used, the cells should be protected from light.

If irradiation is used to block cell division, substitute steps 4 and 5 with cellular irradiation and proceed to step 7.

5. Fill 15- or 50-ml tube containing stimulator cells with ~10 ml cRMPI and centrifuge 5 min at 200 × *g*, room temperature.

6. Discard the supernatant. Wash the cells four more times with 15 ml cRPMI per wash. Centrifuge to pellet the cells between each wash (as in step 5). Pipet cells up and down in the medium to improve the efficiency of washing.

   It is imperative that all mitomycin C is removed from these cells prior to co-culture with the responder spleen cells.

   If irradiation was used instead of treatment with mitomycin C, then one wash is sufficient.

7. Resuspend the washed stimulator spleen cells in cRPMI at a final concentration of 2.5–5 × 10^6/ml.

   The optimal concentration of responder and stimulator cells will vary depending on the strains of mice used. Therefore, it is necessary to conduct a small pilot study to determine the optimal concentration for this assay. A suggested titration experiment is as follows: use three concentrations of responder cells (e.g., 10, 5, and 2.5 × 10^6 cells/ml) and three concentrations of stimulator cells (e.g., 5, 2.5, and 1.25 × 10^6 cells/ml). Set up the wells such that each concentration of responder cells is co-cultured with each concentration of stimulator cells. Perform the titration in duplicate.

8. Add 1 ml of the responder cells and 1 ml of the stimulator cells to the wells of a 24-well flat-bottom cell culture plate.

   The final number of cells should not exceed 12 × 10^6 cells in a volume of 2 ml.

   At the end of this in vitro co-culture, it is necessary to recover effector cells from the wells. Therefore, one must prepare culture wells that will generate the required number of effector cells. After a 5-day culture, cellular recovery is between 50% and 90% of the total number of responder cells initially added to the culture.

   Cultures can be scaled up or down as needed, but the ratio of responder to stimulator cells and the ratio of cells to culture volume and surface area needs to remain fixed.

   Recombinant IL-2 can be added to the cultures (10 to 50 U/ml) to improve CTL generation; however, the addition of IL-2 can bypass the function of other cells (e.g., $CD4^+$ T cells).

9. Incubate the cells for 5 days at 37°C.

   Although the cultures need to be covered to maintain asceptic conditions, do not seal the lids (i.e., allow air exchange).

Prepare target cells

10. Prepare a single cell suspension of spleen cells derived from the same strain of mouse used as the stimulator cells (see Support Protocol 1 for the preparation of spleen cells).

    These cells will be used as the target cells for the in vitro CTL assay.

    (Optional) For control target cells, obtain a single cell suspension of spleen cells from a naïve mouse that is the same strain used to generate the effector (responder) cells. Label the cells with ^{51}Cr.

11. Count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.

12. To activate the spleen cells (in vitro) using a mitogen, resuspend the cells at 5 × 10^6/ml in cRPMI containing either ~10 mg/ml LPS or ~2 μg/ml Con A.

Quiescent splenocytes from naïve mice do not take up ^{51}Cr well and are prone to spontaneous leakage of ^{51}Cr after labeling. To avoid low maximal release and high spontaneous release in the assay, it is necessary to activate the cells prior to labeling. Alternatives to using polyclonally activated spleen cells include cell lines and tumor cells. If these are used, it is generally not necessary to treat with a mitogen prior to labeling with chromium. If cultured cell lines or tumor cells are used, they must be of the same MHC haplotype as the stimulator splenocytes.

13. Transfer the cells to a 25-cm^2 tissue culture flask containing 10 to 12 ml cRPMI medium and stand flask upright in a 37°C incubator. Incubate 48 to 72 hr.

    Alternatively, the cells can be transferred to tissue culture dishes (e.g., 100-mm dishes) in a final volume of ~10-ml medium per dish (i.e., 50×10^6 cells/dish). Culture the cells in a 37°C, 5% CO_2 humidified incubator for 48 to 72 hr prior to labeling with ^{51}Cr.

Label target cells with ^{51}Cr

14. Collect the activated spleen cells (step 13), transfer to a 15-ml conical tube, and count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter and determine % viable cells.

15. Wash the cells one time with 10 ml sterile PBS and then one time with 10 ml sfRPMI. Centrifuge 10 min at $200 \times g$, room temperature, to pellet the cells between washes. Discard the supernatant and resuspend the cells at 1×10^7 viable cells/ml in sfRPMI.

16. In a 15-ml conical tube, add 3–5 $\times$ 10^6 cells (150 to 250 µl) and 200 µCi ^{51}Cr (dilute stock $Na_2{}^{51}CrO_4$ in sfRPMI to 2 mCi/ml and add 100 µl).

    Scale up or down as needed but keep the proportion constant. It is very important to keep the volume to a minimum. Use of excess volume will lead to poor labeling efficiency.

17. Incubate the labeled cells at 37°C for 2 hr (do not exceed 2 hr because cells will start to die). After the first hour, gently mix the cells by swirling the tube (do not vortex or invert tube).

18. Wash cells three times with cRPMI using a minimum volume of 2 to 5 ml per wash. Centrifuge cells 10 min at $200 \times g$, room temperature, to pellet cells.

    Do not reduce the number of washes or a very high spontaneous release will occur.

    Do not use a vortex or other type of mechanical mixing device. Resuspend the cells by gently pipeting up and down.

19. Determine the number of viable cells (*APPENDIX 3B*).

    Do not skip this step. Even the most careful washing procedure results in the loss of some cells.

20. Resuspend the labeled cells at 1×10^6 cells/ml in cRPMI. Dilute an aliquot (or all cells, depending on the size of the assay) to 1×10^5 cells/ml in cRPMI.

    The concentration of diluted labeled cells (i.e., target cells) can be scaled up or down depending upon the number of effector cells used in the assay, but keep the ratio the same. For example, if the assay starts with an E:T ratio of 200:1 (2×10^6 effector cells:1 $\times 10^4$ target cells), then each assay well needs 1×10^4 cells in 100 µl. If the assay starts at the same E:T ratio, but only 2×10^5 effector cells are used, then the target cells need to be diluted such that each assay well contains 1×10^3 labeled cells.

    Labeled cells can remain up to 30 min at room temperature without compromising viability. Do not place the cells at 4°C.

Collect effector cells

21. Use a 1000-µl capacity micropipettor to harvest the effector cells. Remove the nonadherent cells by gentle aspiration. Transfer cells to a 15-ml conical tube and centrifuge 5 min at 200 × *g*, room temperature. Resuspend in cRPMI.

    To increase the number of cells recovered, wash wells with 1 ml of cRPMI, however, this step must be performed with the utmost care to avoid dislodging partially adherent stimulatory cells from the well.

22. Count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.

23. Resuspend the effector cells in cRPMI at a concentration such that 100 µl will contain the number of cells needed for the uppermost E:T ratio.

    The cells can be maintained up to 4 hr at room temperature with no appreciable loss of cytolytic activity. Gentle resuspension every 30 min is advised.

Carry out chromium release assay

24. Using round-bottom 96-well plates, plate a series of six 2-fold dilutions in the wells, starting with 200 µl of effector cells.

    a. Starting one column to the right of the first column in the 96-well plate, add 100 µl cRPMI (i.e., add medium to columns 2 to 6 and 8 to 12).
    b. With effector cells resuspended at 20×10^6 cells/ml, add 200 µl cells to the first well in each row (column 1 or column 7). These cells will serve as the 200:1 E:T ratio.
    c. With a micropipettor (single- or 8-channel), transfer 100 µl of the cells in column 1 to column 2. Genlty pipet up and down five times to mix cells with the medium. This will create a well for the 100:1 E:T ratio.
    d. Transfer 100 µl of the cells from column 2 to column 3. Mix by pipetting up and down, and continue down the dilution series. At the last well in the series (6 or 12), be certain to discard 100 µl after mixing (i.e., when finished, all wells should contain only 100 µl of effector cells).

    Each dilution series will use half of a row across the plate. Using this system, a dilution series of effector cells from 15 separate treatment groups can be assayed on one plate. (One set of eight wells should be reserved to assess maximal and spontaneous release, see step 25). For example, if the first E:T ratio is 200:1 with 2×10^6 effector cells, then the effector cells should be resuspended at a concentration of 20×10^6 cells/ml. The following description is for a series beginning at 200:1 and ending at 6.25:1, beginning with an E:T ratio of 2×10^6 effector cells:1×10^4 target cells.

    Generally, it is not necessary to extend the series below 6.25:1.

25. Set up maximum release (MR) and spontaneous release (SR) wells as follows:

    a. For MR wells, add 100 µl of 0.5% SDS to three wells.
    b. For SR wells, add 100 µl of cRPMI to three wells.

    For assays that will require more than one 96-well plate, each plate should have MR and SR wells to control for possible variation between plates.

26. Gently resuspend ^{51}Cr-labeled target cells. Add 100 µl ^{51}Cr-labeled target cells to each well, including the MR and SR wells. Carefully centrifuge plate 2 to 3 min at 200 × *g*, room temperature.

    This step is very important because cell-cell contact is necessary to initiate target cell recognition. Failure to centrifuge the cells will result in negligible specific ^{51}Cr release.

27. Incubate cells 5 hr in a 37°C, 5% CO_2 humidified incubator. Keep a cover or lid on the plate, but do not seal it.

28. Harvest 100 µl supernatant from each well and transfer to a 12 × 75–mm glass test tube. Be careful not to aspirate cells.

    Carefully remove the plates from the incubator in the order in which they were placed into the incubator without bumping or jostling them.

29. Count samples on a gamma counter (1-min counts are generally sufficient). Use the following formula to calculate the percent cytolytic activity:

$$\%\ \text{cytolytic activity} = \left(\frac{\text{sensitized effector cell CPM} - \text{control effector cell CPM}}{(\text{MR} - \text{SR})} \right) \times 100$$

    where CPM stands for counts per minute.

CHROMIUM RELEASE ASSAY FOR MEASURING CTL ACTIVITY FOLLOWING IN VIVO SENSITIZATION WITH ALLOGENEIC CELLS

ALTERNATE PROTOCOL 1

CTL can be generated in vivo using a large variety of antigens. Injection of allogeneic tumor cells and viral infection are the two most commonly used methods. This protocol is similar to Basic Protocol 1 and consists of four parts: (1) effector cell sensitization (in vivo: 9 to 10 days); (2) target cell preparation and labeling with ^{51}Cr; (3) collection of effector cells; and (4) chromium release assay.

Each of these parts is conducted separately; however, target cell preparation and collection of effector cells need to be carried out such that the time between the completion of these parts does not exceed 30 min. The chromium release assay is conducted as described in Basic Protocol 1. The steps described here pertain to the generation of CTL using P815 tumor cells. The sensitization of CTL using influenza virus is described in Alternate Protocol 2.

This procedure requires the propagation of P815 mastocytoma cells in DBA (H-2^d) mice. To generate CTL, P815 cells are injected into C57Bl/6 (H-2^b) mice. Spleen cells isolated from sensitized C57Bl/6 mice will have P815-specific CTL, with the maximum frequency of these CTL and peak cytolytic activity 9 to 10 days after sensitization.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer.

Materials

DBA mouse (see Support Protocol 2)
Target cells (e.g., a single-cell suspension of P815 mastocytoma cells; ATCC no. TIB-64)
Hank's balanced salt solution (HBSS, e.g., GIBCO, Invitrogen; see recipe)
C57Bl/6 mice
Phosphate buffered saline (PBS), sterile and low-endotoxin (e.g., GIBCO, Invitrogen)
Serum-free RPMI (sfRPMI, see recipe)
≥5 mCi/ml $Na_2{}^{51}CrO_4$ sterile, aqueous solution (10 to 35 mCi/ml and 200 to 500 mCi/mg Cr; e.g., Amersham Biosciences)
Control target cells (e.g., syngeneic spleen cells), optional
Complete RPMI (cRMPI, see recipe)
Effector cells (e.g., P815-sensitized spleen cells; see Support Protocol 1)

Control effector cells (non-sensitized spleen cells or cells that were sensitized using an irrelevant antigen)

15- and 50-ml conical centrifuge tubes with screw caps (sterile, polystyrene or polypropylene; e.g., Corning, Falcon)

26-G × 1/2-in. needle and 1-ml syringe

Additional reagents and equipment for counting cells (*APPENDIX 3B*), and chromium release assay (see Basic Protocol 1)

Sensitize CTL

1. Using a 50-ml centrifuge tube, collect ascites fluid from a DBA mouse (see Support Protocol 2 for the in vivo maintenance and passaging of P815 cells in the peritoneal cavity of DBA mice).
2. Centrifuge cells 10 min at 200 × *g*, room temperature, to remove ascites fluid.
3. Wash the P815 cells once by gently resuspending in 25 ml HBSS. Repeat step 2.
4. Resuspend cells in 25 ml HBSS. Remove an aliquot to determine cell count and viability (using trypan blue and hemacytometer; *APPENDIX 3B*). Adjust to a final concentration of 2×10^7 viable cells/ml in HBSS.
5. Inject C57Bl/6 mice (i.p.) with 0.5 ml of P815 tumor cells (i.e., 1×10^7 cells) using a 26-G × 1/2-in. needle attached to a 1-ml syringe.

   The maximum frequency of P815-specific CTL and peak cytolytic activity in the spleen of sensitized C57Bl/6 mice occurs 9 to 10 days after sensitization (i.e., 9 to 10 days after P815 cells are injected).

Prepare target cells

6. Acquire a single-cell suspension of P815 cells (as described in steps 1 through 4) and place into a 15-ml conical centrifuge tube.

   Steps 6 to 16 take ~3 hr. It is important to coordinate this procedure with the isolation of effector cells such that the time between labeling of the target cells and plating with effector cells does not exceed 30 min.

   It is advisable to start with at least two times the number of cells needed for the assay.

   Collecting P815 cells from a DBA host 7 to 8 days after the injection of cells generally results in the recovery of 5–7 × 10^8 viable P815 cells.

7. Wash cells one time with 10 ml sterile PBS and then one time with 10 ml sfRPMI. Centrifuge 10 min at 200 × *g*, room temperature, to pellet the cells between washes.
8. Resuspend cells at 2×10^7 viable cells/ml in sfRPMI.
9. In a 15-ml conical tube, add 3–5 × 10^6 P815 cells (150 to 250 µl) and 200 µCi ^{51}Cr (dilute ≥5 mCi/ml $Na_2{}^{51}CrO_4$ stock in sfRPMI to 2 mCi/ml, then add 100 µl).

   Scale up or down as needed but keep the proportion constant.

   It is very important to keep the volume to a minimum. Use of excess volume will lead to poor labeling efficiency.

   (Optional) For control target cells, one can use any type of cell or cell line that is not from an H-2^d mouse strain. The authors recommend to prepare a single-cell suspension of spleen cells from a naïve C57Bl/6 mouse and label with ^{51}Cr using this protocol.

10. Incubate labeled cells 2 hr at 37°C (do not exceed 2 hr because cells start to die). After the first hour, gently mix the cells by swirling the tube (do not vortex or invert tube).

11. Wash the cells three times with cRPMI using a minimum volume of 2 to 5 ml per wash. Centrifuge cells 10 min at 200 × *g*, room temperature, to pellet cells.

    Do not reduce the number of washes or a very high spontaneous release will occur.

    Do not use a vortexer or other type of mechanical mixing device. Resuspend the cells by gently pipeting up and down.

12. Determine the number of viable cells (*APPENDIX 3B*).

    Do not skip this step. Even the most careful washing procedure results in the loss of some cells.

13. Resuspend the labeled cells at 1×10^6 cells/ml in cRPMI.

14. Dilute an aliquot (or all cells, depending on the size of the assay) to 1×10^5 cells/ml in cRPMI.

    The concentration of diluted labeled cells (i.e., target cells) can be scaled up or down depending upon the number of effector cells used in the assay, but keep the ratio the same. For example, if the assay starts with an E:T ratio of 200:1 (2×10^6 effector cells:1 $\times 10^4$ target cells), then each assay needs 1×10^4 cells in 100 µl. If the assay starts at the same E:T ratio, but only 2×10^5 effector cells are used, then the target cells need to be diluted such that each assay well contains 1×10^3 labeled cells.

    Labeled cells can remain up to 30 min at room temperature without compromising viability. Do not place cells at 4°C.

Collect effector cells

15. Prepare a single-cell suspension of spleen cells from sensitized and naïve C57Bl/6 mice (see Support Protocol 1).

    The optimal time for measuring P815-specific cytolytic activity is 9 to 10 days after sensitization.

16. Count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.

17. Resuspend the spleen cells in cRPMI at a concentration such that 100 µl contains the number of cells needed for the uppermost E:T ratio.

    For the instructions provided below, the effector cells are resuspended at a final concentration of 2×10^7/ml.

Perform chromium release assay

18. Follow Basic Protocol 1, steps 24 to 29.

CHROMIUM RELEASE ASSAY FOR MEASURING CTL ACTIVITY FOLLOWING IN VIVO SENSITIZATION WITH INFLUENZA A VIRUS

ALTERNATE PROTOCOL 2

Virus-specific CTL are generated when mice are exposed to human influenza viruses. Generally, this experimental model system involves intranasal inoculation with murine-adapted strains of human influenza A virus, leading to a robust response in the lung and lymph nodes that drain the respiratory tract. This paradigm requires the use of live virus, which has many benefits as an experimental model, including relevance to human health, activation of multiple components of the immune system, and others. The primary disadvantage is that it requires the handling and use of an infectious human pathogen, which limits the ability of many laboratories to use this system.

As an alternative to using live virus, CTL can be induced by the i.p. injection of inactivated virus, which sensitizes virus-specific $CD8^+$ T cells in the spleen (Nonacs et al., 1992; Kos and Engleman, 1996; Cho et al., 2003). Thus, by injecting inactivated virus, one can sensitize animals to influenza virus and measure virus-specific CTL activity in a system in which an infectious agent and biological safety level (BSL)-2 laboratory are not needed.

Another advantage of administering the virus by i.p. injection is that the virus does not compromise the overall survival of the host.

The disadvantage of using inactivated virus instead of infectious virus is that some of the other immune pathways stimulated during infection are absent. Therefore, i.p. injection of virus should not be considered a model of infection, nor can it be used to correlate changes in the activity of CTL with host resistance. In fact, the i.p. injection of live influenza virus does not model infection because murine-adapted strains of human influenza A viruses cannot replicate in the peritoneal cavity. Thus, i.p. administration elicits an immune response but not the pathological sequelae that accompany infection of the respiratory tract with infectious virus. If an experimental system warrants testing the activity of cytotoxic lymphocytes in the context of host resistance, then infectious virus should be administered intranasally. This route leads to a robust CTL response in the lung and the lymph nodes that drain the pulmonary cavity, and CTL activity can be measured in lung, bronchoalveolar lavage cells, and peribronchiolar lymph nodes (Warren et al., 2000; Mitchell and Lawrence, 2003a,b). This approach requires the handling of infectious virus using BSL-2 facilities and laboratory safety practices appropriate to handling pathogens of this nature. Readers who are unfamiliar with growth, purification, and handling of influenza viruses and the requirements for a BSL-2 laboratory are referred to Barrett and Inglis (1985) and Biosafety in Microbiological and Biomedical Laboratories (see Internet Resources).

Stimulation of CTL by i.p. injection of influenza virus is described in this protocol. To measure the activity of virus-specific cytolytic activity in the spleen, it is necessary to first expose the mouse to influenza A virus and then culture isolated spleen cells for 5 days with virus-infected cells. The in vitro re-stimulation is necessary because it amplifies the size of the virus-specific CTL pool such that it can be measured by the chromium release assay. The overall protocol is similar to Alternate Protocol 1 and consists of the following four parts: (1) effector cell sensitization (in vivo 5 to 9 days; in vitro 5 days); (2) target cell preparation and labeling with ^{51}Cr; (3) collection of effector cells; and (4) chromium release assay.

Each of these parts is conducted separately; however, target cell preparation (~4 hr) and effector cell collection need to be carried out such that the time between the completion of target cell preparation and effector cell collection does not exceed 30 min. The chromium release assay is conducted as described in Basic Protocol 1.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer.

Materials

Influenza A virus stock (mouse-adapted, inactivated, e.g., SPAFAS/Charles River)
Phosphate buffered saline (PBS), sterile and low-endotoxin (e.g., GIBCO)
Mice
Effector cells (i.e., spleen cells from an infected mouse; see Support Protocol 1)
Control effector cells (non-sensitized spleen cells or cells from a mouse that was sensitized using an irrelevant antigen)
Complete RPMI (cRMPI, see recipe)
Serum-free RPMI (sfRPMI, see recipe)
0.5 mg/ml mitomycin C in cRPMI
Target cells (i.e., virus-infected or viral peptide–pulsed cells, e.g., MC57G cells, ATCC# CRL-2295; see Support Protocol 4)

Control target cells (e.g., ^{51}Cr-labeled MC57G cells that were not exposed to virus or viral peptide), optional

≥5 mCi/ml $Na_2{}^{51}CrO_4$ sterile, aqueous solution (10 to 35 mCi/ml and 200 to 500 mCi/mg Cr; e.g., Amersham Biosciences)

0.5% SDS (see recipe)

15- and 50-ml conical centrifuge tubes with screw caps (sterile, polystyrene or polypropylene; e.g., Corning or Falcon)

24-well tissue culture plates

Beckman Allegra GS-6 (or equivalent) refrigerated centrifuge with swinging bucket rotor

20-, 200-, and 1000-µl micropipettors with disposable tips

96-well U-bottom plates

12 × 75–mm glass test tubes

Gamma counter

Additional reagents and equipment for counting cells (*APPENDIX 3B*)

Sensitize effector cells

1. Inject (i.p.) mice (e.g., C57Bl/6, H-2^b) with 500 µl inactivated influenza A virus diluted in PBS.

   Spleen cells isolated from sensitized C57Bl6 mice will have virus-specific CTL, with the maximum frequency of these CTL and peak cytolytic activity 8 to 10 days after sensitization. These cells can be detected at the time of sacrifice using flow cytometry; however, to measure virus-specific cytolytic activity by chromium release assay, it is necessary to further expand this population of cells in vitro.

   The optimal concentration of virus used will vary depending on the strains of virus and mice used. It is therefore necessary to conduct a small pilot study to determine the optimal dose for this assay. A suggested titration experiment is as follows: use four inocula of virus (e.g., 250, 500, 1000, and 2000 HAU/mouse). Perform the titration in triplicate.

   Recommended strains of murine-adapted human influenza virus include the following: A/HKx31, A/NT60/68, A/WSN/33, and A/PR8/34. These strains are suggested because in immunocompetent mice, i.p. administration has been previously shown to induce a CTL response in the spleen (Nonacs et al., 1992; Kos and Engleman, 1996; Cho et al., 2003).

2. Eight to ten days after injection with virus, sacrifice the mice and prepare separate, single cell suspensions of spleen cells from each treated mouse (see Support Protocol 1 for the preparation of spleen cells). To obtain control effector cells, sacrifice a naïve mouse (or a mouse that was sensitized with an irrelevant antigen).

3. Count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.

4. Resuspend the spleen cells in cRPMI at a final concentration of 1–2 × 10^7/ml.

   The cells prepared in this portion of the assay will serve to stimulate the proliferation of the virus-specific CD8$^+$ T cells in vitro, permitting the expansion of this pool for use in a chromium release assay. It is necessary to prevent the stimulator cells from dividing in this co-culture. This can be accomplished pharmacologically, as described here, or by irradiation (3000 rad) prior to co-culture.

5. Prepare a single cell suspension of spleen cells from a naive syngeneic mouse.

   An alternative to using syngeneic spleen cells is to use a dendritic cell (DC) cell line (Warren et al., 2000; Mitchell and Lawrence, 2003a,b). The DC cell line must be derived from a mouse that expresses the same MHC haplotype as the mice that were sensitized with influenza virus.

6. Wash the cells two times with sfRPMI. Centrifuge cells 10 min at 200 × *g*, room temperature. Remove and discard the medium.

7. Resuspend the washed cells at 2×10^6/ml in sfRPMI.

   Usually 20–50 $\times$ 10^6/(10 to 25 ml) cells is necessary to set up cultures for the in vitro restimulation of spleen cells from virus-sensitized mice.

8. Add influenza virus stock such that the final concentration is 300 to 500 HAU/ml. Incubate cells with virus 3 hr in a 37°C incubator. Gently mix the cells at 60-min intervals.

   Do not use medium with serum during this step because FBS contains inhibitors of viral infection.

   Do not exceed 3 hr or the cells will start to die.

9. After exposure to virus, centrifuge (as in step 6) the infected stimulator cells. Discard the supernatant and resuspend the pelleted cells at $\sim 1 \times 10^7$ cells/ml in cRPMI. Add 0.5 mg/ml mitomycin C to the stimulator cells, such that the final concentration of mitomycin C is 25 μg/ml. Incubate the cells with mitomycin C for 20 min at 37°C in an incubator or water bath.

   Mitomycin C is light sensitive. If a water bath is used for this incubation, the cells should be protected from light.

   If irradiation is used to block cell division, substitute step 9 with cellular irradiation and proceed to step 11.

10. Fill the 15-ml tube containing stimulator cells with cRPMI and centrifuge 5 min at $200 \times g$, room temperature.

11. Discard the supernatant. Wash the cells four additional times with 15 ml of cRPMI per wash. Centrifuge (as in step 10) to pellet the cells between each wash. Pipet cells up and down in the medium to improve the efficiency of washing, as it is imperative that all mitomycin C is removed from these cells prior to co-culture with the responder spleen cells.

    If irradiation was used rather than treatment with mitomycin C, then one wash is sufficient.

12. Resuspend the washed stimulator spleen cells in cRPMI at a final concentration of $0.5–1 \times 10^7$ cells/ml.

13. Set up in vitro cultures in a 24-well tissue culture plate. Combine 2×10^6 infected, mitomycin C–treated spleen cells (or cultured DC) with 4×10^6 spleen cells from each animal in the experiment (6×10^6 cells in 2 ml final volume).

    At the end of this in vitro co-culture, it is necessary to recover effector cells from the wells. Therefore, one must prepare culture wells that will generate the required number of effector cells. After a 5-day culture, cellular recovery is between 50% and 90% of the total number of responder cells initially added to the culture.

    Cultures can be scaled up or down as needed, but the ratio of responder to stimulator cells and the ratio of cells to culture volume and surface area needs to remain fixed.

    Recombinant IL-2 can be added to the cultures (10 to 50 U/ml) to improve CTL generation, however, the addition of IL-2 can bypass the function of other cells (e.g., $CD4^+$ T cells).

14. Incubate the cells for 5 days at 37°C.

    Although the cultures need to be covered to maintain asceptic conditions, do not seal the lids (i.e., allow air exchange).

Prepare target cells and label with ^{51}Cr

15. Acquire a single cell suspension of MC57G cells (see Support Protocol 4 for the growth and maintenance of MC57G cells) and place into a 15-ml conical centrifuge tube.

    It is advisable to start with at least two times the number of cells needed for the assay.

    The best targets for H-2D^b-infected mice are MC57G fibroblasts, although EL-4 cells will also work. Syngeneic splenocytes should be avoided because they have been reported to give highly variable results.

16. Wash cells one time with sterile PBS and then one time with sfRPMI. Centrifuge 10 min at 200 × *g*, room temperature, to pellet the cells between washes.

17. Resuspend the MC57G cells at 1–2 × 10^7 viable cells/ml in sfRPMI.

    It is essential that the in vitro infection be conducted in the absence of serum in the medium because FBS contains enzymes that will inhibit the infection of the cells by influenza viruses.

18. Set up the infection and labeling in 15-ml polypropylene tubes by adding the following items to the tube:

    2 × 10^6 MC57G cells (in 200 µl)
    virus or peptide in 50 µl
    200 µCi ^{51}Cr in 100 µl (dilute ≥5 mCi/ml $Na_2{}^{51}CrO_4$ stock in sfRPMI to 2 mCi/ml).

    It is advisable to conduct a preliminary titration experiment to determine the dose of virus or viral peptide. Generally, 300 to 500 HAU/ml virus is used for in vitro infection or a final concentration of 1 µM nucleoprotein (NP) peptide.

    The final volume for this labeling is 350 µl for 2 × 10^6 cells. Scale up or down as needed but keep the proportion constant.

    It is very important to keep the volume to a minimum. Use of excess volume will lead to poor labeling efficiency.

    (Optional) For control target cells, add 50 µl sfRPMI in place of virus or viral peptide and label with ^{51}Cr using this protocol.

19. Incubate the labeled cells 2 hr at 37°C (do not exceed 2 hr because cells will start to die). After the first hour, gently mix the cells by swirling the tube (do not vortex or invert tube).

20. Wash cells five times with cRPMI using a minimum volume of 2 to 5 ml per wash. Centrifuge cells 10 min at 200 × *g*, room temperature, to pellet cells.

    Do not reduce the number of washes because a very high spontaneous release will occur.

    Do not use a vortexer or other type of mechanical mixing device. Resuspend the cells by gently pipeting up and down.

21. Determine the number of viable cells (*APPENDIX 3B*).

    Do not skip this step. Even the most careful washing procedure results in the loss of some cells.

22. Resuspend the labeled cells at 1 × 10^6 cells/ml in cRPMI.

23. Dilute an aliquot (or all cells, depending on the size of the assay) to 1 × 10^5 cells/ml in cRPMI.

The concentration of diluted labeled cells (i.e., target cells) can be scaled up or down depending upon the number of effector cells used in the assay, but keep the ratio the same. For example, if the assay starts with an E:T ratio of 200:1 (2×10^6 effector cells:1 $\times 10^4$ target cells), then each assay well will need 1×10^4 cells in 100 µl. If the assay starts at the same E:T ratio, but only 2×10^5 effector cells are used, then the target cells need to be diluted such that each assay well contains 1×10^3 labeled cells.

Labeled cells can remain up to 30 min at room temperature without compromising viability. Do not place cells at 4°C.

Collect effector cells

24. Use a 1000-µl capacity micropipettor to gently harvest the nonadherent effector cells by aspiration. Transfer cells to a 15-ml conical tube and centrifuge cells 5 min at 200 × *g*, room temperature. Resuspend in cRPMI.

    To increase the number of cells recovered, wells can be washed with 1 ml of medium, however, this step must be performed with the utmost care to avoid dislodging partially adherent cells from the well.

25. Count the cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.

26. Resuspend the effector cells in cRPMI at a concentration such that 100 µl will contain the number of cells needed for the uppermost E:T ratio.

    The cells can be maintained up to 4 hr at room temperature with no appreciable loss of cytolytic activity. Gentle resuspension every 30 min is advised.

Perform chromium release assay

27. Using 96-well U-bottom plates, plate a series of six two-fold dilutions in the wells, starting with 200 µl of effector cells. Each dilution series will use half of a row across the plate. Using this system, a dilution series of effector cells from 15 separate treatment groups can be assayed on one plate. (One set of eight wells should be reserved to assess maximal and spontaneous release, see step 28). For example, if the first E:T ratio is 200:1 with 2×10^6 effector cells, then the effector cells should be resuspended at a concentration of 20×10^6 cells/ml. The following description is for a series beginning at 200:1 and ending at 6.25:1, beginning with an E:T ratio of 2×10^6 effector cells:1×10^4 target cells.

    a. Starting one column to the right of the first column in the 96-well plate, add 100 µl cRPMI (i.e., add medium to columns 2 to 6 and 8 to 12).
    b. With effector cells resuspended at 20×10^6 cells/ml, add 200 µl cells to the first well in each row (column 1 or column 7) to serve as the 200:1 E:T ratio.
    c. With a micropipettor (single or 8-channel), transfer 100 µl of the cells in column 1 to column 2. Genlty pipet up and down five times to mix cells with the medium to create a well for the 100:1 E:T ratio.
    d. Transfer 100 µl of the cells from column 2 to column 3. Mix by pipetting up and down, and continue down the dilution series. At the last well in the series, be certain to discard 100 µl after mixing (i.e., when finished, all wells should contain only 100 µl of effector cells).

    Generally, it is not necessary to extend the series below 6.25:1.

28. Set up maximum release (MR) and spontaneous release (SR) wells as follows:

    a. For MR wells, add 100 µl of 0.5% SDS to three wells.
    b. For SR wells, add 100 µl of cRPMI to three wells.

    For assays that will require more than one 96-well plate, each plate should have MR and SR wells to control for possible variation between plates.

29. Gently resuspend ^{51}Cr-labeled target cells. Add 100 µl ^{51}Cr-labeled target cells to each well, including the MR and SR wells. Carefully centrifuge plate 2 to 3 min at 200 × *g*.

    This step is very important because cell-cell contact is necessary to initiate target cell recognition. Failure to centrifuge the cells will result in negligible specific ^{51}Cr release.

30. Incubate cells 5 hr at 37°C. Keep a cover or lid on the plate, but do not seal it.

31. Harvest 100 µl supernatant from each well and transfer to a 12 × 75–mm glass test tube. Be careful not to aspirate cells.

    Carefully remove the plates from the incubator in the order in which they were placed into the incubator without bumping or jostling them.

32. Count samples on a gamma counter (1-min counts are generally sufficient). Use the following formula to calculate the percent cytolytic activity:

$$\%\ \text{cytolytic activity} = \left(\frac{\text{sensitized effector cell CPM} - \text{control effector cell CPM}}{(\text{MR} - \text{SR})} \right) \times 100$$

    where CPM stands for counts per minute.

CHROMIUM RELEASE ASSAY FOR MEASURING NK CELL ACTIVITY

BASIC PROTOCOL 2

The cytolytic activity of NK cells is an innate function of these cells; however, cytolytic activity can be further boosted by the addition of NK cell stimulatory factors. A common reagent used to stimulate NK cell cytolytic activity is polyinosinic acid-polycytidylic acid (poly I:C). Poly I:C stimulates interferon production, which in turn stimulates NK cells. Thus, there are three ways to measure NK cell cytotoxic activity: (1) native activity, (2) in vitro–boosted activity, and (3) in vivo–boosted activity. All three of these options are described in this protocol. For any of these three options, the fundamental protocol consists of two separate components: (1) preparing target cell and labeling with ^{51}Cr, and (2) preparing effector cell and assay set-up.

Steps 1 through 7 take ~3 hr. It is important to coordinate this procedure with the isolation of effector cells such that the time between labeling of the target cells and plating with effector cells does not exceed 30 min. Yac-1 murine lymphoma cells are the prototype tumor target cells to test for murine NK cell cytolytic activity.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer.

Materials

Target cells (e.g., a single cell suspension of Yac-1 tumor cells, ATCC no. TIB-160; see Support Protocol 3)
Yac-1 growth medium (see recipe)
Control target cells (to test specificity of cytolytic activity; e.g., syngeneic spleen cells), optional
Phosphate buffered saline (PBS), sterile and low-endotoxin (e.g., GIBCO, Invitrogen)
Complete RPMI (cRMPI, see recipe)
Serum-free RPMI (sfRPMI, see recipe)
≥5 mCi/ml $Na_2{}^{51}CrO_4$ aqueous solution (10 to 35 mCi/ml and 200 to 500 mCi/mg Cr; Amersham Biosciences)

Effector cells (spleen cells; see Support Protocol 1)
Control effector cells (e.g., a single cell suspension of thymocytes from a syngenic mouse)
0.5% SDS (see recipe)
500 μg/ml polyinosinic acid-polycytidylic acid (poly I:C) in HBSS or PBS, optional
25-cm^2 culture flasks
15- and 50-ml conical centrifuge tubes with screw caps (sterile, polystyrene or polypropylene; e.g., Corning, Falcon)
96-well round-bottom microtiter plates
Beckman Allegra GS-6 (or equivalent) refrigerated centrifuge with swinging bucket rotor
12 × 75–mm glass test tubes
Gamma counter
Additional reagents and equipment for counting cells (*APPENDIX 3B*), and chromium release assay (see Basic Protocol 1)

Prepare target cells and label with ^{51}Cr

1. Twenty-four hours prior to the assay, passage cultured Yac-1 cells, and plate at 5 × 10^6 per 25-cm^2 flask in Yac-1 growth medium (see Support Protocol 3 for the growth and maintenance of Yac-1 cells).

   Use only Yac-1 cells that are in log phase growth, otherwise the cells may not label well with ^{51}Cr.

2. On the day of the assay, acquire a single-cell suspension of Yac-1 cells and place into a 15-ml conical centrifuge tube.

   It is advisable to start with at least two times the number of cells needed for the assay.

3. Wash cells one time with sterile PBS and then one time with cRPMI. Centrifuge 10 min at 200 × *g*, room temperature. to pellet the cells between washes. Discard supernatant.

4. Label the pelleted Yac-1 target cells using the following ratio: for 5 × 10^6 Yac-1 cells, add 200 μl sfRPMI and 200 μCi ^{51}Cr (dilute ≥5 mCi/ml $Na_2{}^{51}CrO_4$ stock in cRPMI to 2 mCi/ml, then add 100 μl). Incubate 60 min at 37°C.

   Scale up or down as needed but keep the proportion constant. It is very important to keep the volume to a minimum. Use of excess volume will lead to poor labeling efficiency.

5. Wash cells two times with Yac-1 growth medium by centrifuging 10 min at 200 × *g*, room temperature.

6. Resuspend cells with 10 ml Yac-1 growth medium and incubate 30 min at 37°C to allow nonspecific leakage of ^{51}Cr. Repeat wash as in step 5.

7. Resuspend cells in 5-ml cRPMI and determine cell concentration using a hemacytometer (*APPENDIX 3B*). Prepare a cell suspension of 1 × 10^5/ml in cRPMI.

Prepare effector cell and set up assay

For native NK cytotoxicity

8a. Prepare a single cell suspension of spleen cells from mice (see Support Protocol 1). Prepare a single-cell suspension of thymocytes similar to that of the splenocytes, without the lysis of red blood cells.

   The spleen cells will provide the NK cells and the thymocytes will serve as the control effector cells (i.e., there is no NK cell cytolytic activity in a population of thymocytes).

9a. Dilute the effector cells (i.e., spleen and thymus cells) and then plate into 96-well round-bottom well tissue culture plates in triplicate using the following steps:

a. Start with a cell suspension of 1.2×10^7 in 600 µl in a 12 × 100–mm culture tube,

b. In triplicate wells of a 96-well plate, add 100 µl of cells from step a,

These cells will serve as the effector cells for the 200:1 E:T ratio.

c. To the cells remaining in the culture tube(s), add 300 µl cRPMI, mix by gentle vortexing, and add 100 µl of these cells to three separate wells,

These cells will serve as the effector cells for the 100:1 E:T ratio.

d. Repeat step c two additional times, to generate samples at E:T ratios of 50:1 and 25:1, respectively.

10a. Set up the maximum release (MR) and spontaneous release (SR) wells as follows:

a. for MR wells, add 100 µl of 0.5% SDS to 3 wells,

b. for SR wells, add 100 µl of cRPMI to 3 wells.

For assays that will require more than one 96-well plate, each plate should have MR and SR wells to control for possible variation between plates.

11a. Gently resuspend the ^{51}Cr-labeled Yac-1 cells. Add 100 µl (1×10^4) ^{51}Cr-labeled target cells to every well, including MR and SR wells.

12a. Carefully centrifuge the plate 2 to 3 min at 200 × *g*, room temperature.

This step is very important because cell-cell contact is necessary to intitiate target cell recognition. Failure to centrifuge the cells will result in negligible specific ^{51}Cr release.

13a. Incubate cells 4 hr at 37°C. Keep a cover or lid on the plate, but do not seal it.

14a. Harvest 100 µl supernatant from each well and transfer to a 12 × 75–mm glass test tube. Be careful not to aspirate cells.

Remove the plates from the incubator in the order in which they were placed into the incubator without bumping or jostling them.

15a. Count samples on a gamma counter (1-min counts are generally sufficient). Use the following formula to calculate the percent cytolytic activity:

$$\% \text{ specific lysis} = \frac{\text{test sample} - \text{thymocyte}}{\text{MR} - \text{SR}} \times 100$$

For in vitro–boosted NK cytotoxicity

8b. Perform steps 8a and 9a.

9b. Add 25 µg poly I:C to each well in a volume of 50 µl.

10b. Incubate cultures 2 hr at 37°C.

11b. Proceed directly to step 10a and continue with the assay to step 15a.

For in vivo–boosted NK activity

8c. Prior to sacrifice (18 hr prior), administer 100 µg poly I:C to mice (i.p.) in a volume of 200 µl.

9c. Perform the assay as described for native NK cell activity (steps 8a through 15a, above).

SUPPORT PROTOCOL 1

PREPARATION OF A SINGLE -CELL SUSPENSION OF MURINE SPLEEN CELLS

This protocol describes the removal of a spleen from a mouse and the preparation of a single cell suspension of spleen cells. Careful preparation of splenocytes using this method should yield 80–120 $\times$ 10^6 viable nucleated cells, depending upon the age and strain of the mice used. All animals used should be housed in specific pathogen-free conditions and all media should be free from bacterial endotoxin and other immunostimulatory contaminants. Cells isolated from animals should be used as quickly as possible after animal sacrifice.

Materials

Mouse of appropriate strain
70% ethanol
sfRPMI (see recipe), ice cold
cRPMI (see recipe), ice cold
Sterile distilled water, endotoxin tested for cell culture (e.g., GIBCO, Invitrogen), ice cold
10× HBSS (e.g., GIBCO, Invitrogen; see recipe)

15-ml centrifuge tubes
4-in. dressing forceps
4 3/4-in. surgical scissors
60 × 15–mm cell culture dishes
Frosted microscope slides (25 × 75 × 1–mm)
Plastic transfer pipets (optional)
5- and 10-ml sterile serological pipets
Refrigerated centrifuge (e.g., Beckman GS-6 or equivalent)

Additional reagents and equipment for counting cells (*APPENDIX 3B*)

Remove spleen

1. For each animal, label two 15-ml centrifuge tubes (sterile if necessary) with a designation of treatment or animal number.
2. Euthanize mouse by asphyxiation using CO_2 or other approved method.
3. Thoroughly soak the abdominal hair using 70% ethanol.
4. Using 4-in. dressing forceps and 4 3/4-in. scissors, snip the skin on the lower abdominal area, and peel back the skin in both directions over the entire abdomen.
5. Using dressing forceps and scissors, open the peritoneal cavity and remove the spleen; trim free of connective tissue and fat as necessary.

   If sterile conditions are required, a second set of instruments that remain sterile will be needed for this step.

6. Place the spleen in the bottom half of a labeled 60 × 15–mm culture dish containing 5 ml ice-cold sfRPMI. Use a separate dish for the spleen from each animal.

Process into a single cell suspension

7. Press the spleen between the frosted ends of two microscope slides using a gentle circular motion until only the empty capsule remains.

   To ensure maximal cellular viability, it is important to avoid an up-and-down motion with the frosted ends of the two slides. The slides should remain in contact with each other as they are rubbed together in a circular pattern. Do not pull them apart until the empty capsule is all that remains.

8. Transfer the cell suspension using a plastic transfer pipet or sterile serological pipet to a labeled 15-ml conical centrifuge tube. Rinse the dish and capsule with an additional 3 ml sfRPMI and add to the cell suspension. Pipet the suspension up and down several times to disperse clumps.
9. Centrifuge samples 10 min at 200 × *g*, 4°C.
10. Resuspend cell pellet using a 5-ml serological pipet in 2 to 5 ml sfRPMI or cRPMI.
11. (Optional) Wash samples one additional time by repeating steps 9 and 10.
12. Remove red blood cells (RBC) by hypotonic lysis using the following steps:
    a. After centrifugation in step 9, aspirate the supernatant using a 5-ml pipet.
    b. Dislodge the cell pellet from the tube bottom by gently nudging with the tip of a 1000-µl micropipettor. Do not aspirate the dry pellet into the pipet tip.
    c. Add 4.5 ml cold distilled water and vortex the cells for 5 to 10 sec (do not exceed 10 sec). Quench hypotonic lysis by immediately adding 0.5 ml of 10× HBSS and vortex gently for 1 sec. Add 5 ml cRPMI and place the cells on ice. Proceed to the next tube of cells.
    d. Centrifuge samples as in step 9 and resuspend cells in 5 ml cRPMI.

    RBC removal using other methods, e.g., ammonium chloride or density gradient centrifugation, are viable alternatives.
13. Settle debris and clumps by letting the resuspended cells sit on ice for 8 to 10 min.
14. Transfer the clump-free supernatant using a transfer pipet (or sterile 5-ml pipet) to a new tube. Record the volume.
15. Determine cell concentrations using a Coulter counter or hemacytometer (*APPENDIX 3B*).
16. Determine viability of the spleen cell suspension using the trypan blue dye assay.

GROWTH AND MAINTENANCE OF P815 CELLS

SUPPORT PROTOCOL 2

Propagation of P815 mastocytoma cells in the peritoneal cavity of a DBA mouse is the recommended method for growing and maintaining these cells. Passaging this cell line in vivo results in tumor cells that elicit a robust CTL response when injected into allogeneic mice (e.g., C57Bl/6). This cell line can be propagated in vitro using standard tissue culture techniques, however this method is not recommended because it generally results in a reduced response.

Additional Materials *(also see Support Protocol 1)*

P815 cells (ATCC no. TIB-64)
DBA mice

Biological safety cabinet (level 2)
10-ml syringe
20- to 22-G × 1-in. needles
Small scissors
4-in. fine-tipped forceps
50-ml centrifuge tubes
Vortexer

Thaw stocks of P815 cells and inject into DBA mice

1. Place 10 ml warmed (37°C) HBSS in a 15-ml conical tube.
2. Using aseptic technique (i.e., standard cell culture methods), rapidly thaw the P815 cells and transfer the cell suspension to the 15-ml conical tube containing warmed HBSS.
3. Centrifuge the cells 10 min at 200 × *g*, room temperature. Remove and discard HBSS.
4. Resuspend P815 cells in 2 to 5 ml HBSS. Remove an aliquot of cells and determine the number of viable cells (*APPENDIX 3B*).
5. Resuspend the cells in HBSS at 1.2×10^6 viable cells/ml. Immediately inject 6×10^5 cells (0.5 ml) i.p. into each DBA recipient.

   For routine propagation of this cell line, it is advisable to inject two DBA hosts.

   Injection of 6×10^5 cells will yield 3–5 × 10^8 tumor cells 7 days later. The DBA mice will succumb to this tumor after ~9 days. Therefore, it is strongly advised to sacrifice the mice no later than 8 days after the injection of tumor cells.

Harvest P815 cells in ascites fluid

6. Working inside a biological safety cabinet, fill a 10-ml syringe with 10 ml cold HBSS and attach a 20- to 22-G needle.
7. Sacrifice a DBA mouse by asphyxiation with CO_2 or other approved method.
8. With the mouse lying on its back, thoroughly soak the fur with 70% ethanol.
9. Make a small incision in the skin and reveal peritoneum.

   It is important to not knick or puncture the peritoneal lining during this step.

10. With sterile forceps, carefully lift the peritoneal lining and insert the needle with the bevel facing down. Insert the needle only ~1 cm and do not puncture organs.
11. Inject HBSS rapidly to flush the peritoneal cavity. Using gloved fingertips, carefully massage peritoneal cavity and then withdraw as much fluid as possible (8 to 10 ml).
12. Remove and discard the needle and transfer the cells to a 50-ml centrifuge tube. Add 20 ml cold HBSS. Centrifuge 10 min at 200 × *g*, room temperature, to pellet cells.
13. Resuspend cells in 10 to 20 ml cold HBSS. Pipet cells up and down several times to disperse clumps.
14. Using a hemacytometer and trypan blue, determine the number of viable P815 cells (*APPENDIX 3B*).

    The cells are ready for injection into new DBA hosts (routine maintenance), injection into allogeneic mice (sensitization), or indefinite cryopreservation.

SUPPORT PROTOCOL 3

GROWTH AND MAINTENANCE OF YAC-1 TUMOR CELLS

Yac-1 cells are a murine lymphoma cell line that was derived from an A/Sn mouse. The cells are sensitive to killing by natural killer (NK) cells and are very useful measuring NK cell activity in an in vitro chromium release assay. These cells are not susceptible to the cytotoxic action of CTL. Yac-1 cells can be grown and maintained in vitro using standard tissue culture techniques. These are rapidly growing cells and require that the medium be replaced every 2 to 3 days. This is important to note because poorly cultured cells do not label well with ^{51}Cr.

Additional Materials *(see also Support Protocol 1)*

Yac-1 cells (ATCC no. TIB-160)
Yac-1 cell growth medium (see recipe)

Biological safety cabinet (level 2)
25- and 75-cm^2 tissue culture flasks

Additional reagents and equipment for counting cells and determining viability (*APPENDIX 3B*)

Prepare cultures of Yac-1 cells

1. Approximately 2 weeks prior to measuring NK cell activity using a chromium release assay, thaw the Yac-1 tumor cells using the following procedure:
   a. Warm Yac-1 cell medium in a 37°C water bath and place ~10 ml warmed medium into a 15-ml conical centrifuge tube.
   b. Obtain a vial of frozen Yac-1 cells. Thaw the cells rapidly. Working in a biological safety cabinet and using proper cell culture techniques, immediately transfer the cells into the 15-ml conical tube containing warmed Yac-1 medium.
2. Centrifuge cells 10 min at 200 × *g*, room temperature.
3. Remove and discard the Yac-1 medium which contains dead cells and DMSO.
4. Using a serological pipet, resuspend cells in 10 ml fresh Yac-1 cell medium. Pipet up and down several times to disperse cell clumps. Transfer cells to two 25-cm^2 tissue culture flasks (i.e., 5 ml medium/flask). Incubate cells at 37°C with the caps loosened to permit gas exchange.
5. Monitor cells daily, feed at 2- to 3-day intervals with fresh medium, and sub-culture when log-phase growth is observed.

Maintain and passage Yac-1 cells

6. To passage cells, withdraw Yac-1 medium from flask and transfer into a 15-ml conical centrifuge tube.

   There may be some cells that remain attached to the bottom of the flask. To remove these cells, rinse the flask with warm PBS and add the PBS to the tube containing the medium and cells.

7. Centrifuge cells 10 min at 200 × *g*, room temperature. Discard the supernatant.
8. Resuspend cells in Yac-1 cell medium. Remove an aliquot and determine the number of cells using a hemacytometer (*APPENDIX 3B*) or Coulter counter.
9. Seed new 25-cm^2 tissue culture flasks with 1×10^5 viable Yac-1 cells/flask (6 to 8 ml medium), or 75-cm^2 tissue culture flasks with 5×10^5 Yac-1 cells/flask (15 to 20 ml medium).

   These cells will double every 16 to 18 hr.

10. Sub-culture every 3 to 4 days.

GROWTH AND MAINTENANCE OF MC57G FIBROBLASTS

SUPPORT PROTOCOL 4

MC57G cells are a murine fibrosarcoma cell line derived from a C57Bl/6 mouse. These cells express both $H\text{-}2K^b$ and $H\text{-}2D^b$ and are susceptible to infection by many viruses, including influenza A viruses. MC57G cells can be grown and maintained in vitro using standard tissue culture techniques. These are rapidly growing cells and require that the

medium be replaced every 2 to 3 days. This is important to note because poorly cultured cells do not label well with ^{51}Cr.

Materials

MC57G (ATCC #CRL-2295)
MC57G growth medium (see recipe)
Cell culture–grade sterile PBS (e.g., from GIBCO, Invitrogen)
0.25% trypsin solution in PBS
15- and 50-ml conical centrifuge tubes
37°C water bath
75-cm^2 tissue culture flasks
37°C, 5% CO_2 humidified incubator

Prepare cultures of MC57G cells

1. Approximately 2 weeks prior to measuring virus-specific CTL activity using a chromium release assay, thaw the MC57G fibroblasts using the following procedure:
   a. Warm MC57G growth medium in a 37°C water bath. Place ~10 ml warmed medium into a 15-ml conical centrifuge tube.
   b. Thaw a vial of frozen MC57G cells rapidly. Working in a biological safety cabinet and using proper cell culture techniques, immediately transfer cells into the 15-ml conical tube containing warmed medium.
2. Centrifuge cells 10 min at 200 × *g*, room temperature.
3. Remove and discard the MC57G growth medium, which contains dead cells and DMSO.
4. Using a serological pipet, resuspend the cells in 10 ml fresh MC57G growth medium. Pipet the pellet up and down several times to disperse cell clumps. Transfer cells to two 75-cm^2 tissue culture flasks (15 to 20 ml medium/flask). Incubate cells at 37°C with the caps loosened to permit gas exchange.
5. Monitor cells daily, feed every 2 to 3 days, and sub-culture when log-phase growth is observed.

Maintain and passage MC57G cells

6. Sub-culture when the cell monolayer is ~90% confluent (every 3 to 4 days).

   At confluency, there should be ~30–40 × 10^6 viable cells/75-cm^2 tissue culture flask.

7. Aspirate medium and rinse the cell monolayer with 5 to 10 ml PBS.
8. Remove cells from the flask by adding 3 ml of 0.25% trypsin solution to each 75-cm^2 cell culture flask. Rock the flask back and forth to evenly distribute the trypsin solution.
9. At room temperature, continue to gently rock the flask(s) for 1 to 2 min. Watch the monolayer of cells carefully and when the monolayer sloughs off, immediately add 10 ml warm MC57G growth medium.

   Do not use PBS for this step. The serum in the medium contains trypsin inhibitors that will neutralize the trypsin solution.

10. Transfer the cells into a 15-ml conical tube and centrifuge 10 min at 200 × *g*, room temperature.

11. Decant the supernatant and resuspend cell pellet using 10 ml MC57G growth medium. Gently pipet cells up and down to disperse clumps.
12. Plate cells into 75-cm^2 tissue culture flasks in 15 to 20 ml warmed MC57G growth medium and incubate at 37°C.

    Plating 0.5–1 × 10^6 cells/ flask will typically yield a confluent flask in ∼5 days.

13. Exchange the medium after 48 to 72 hr of culture.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all recipes and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete RPMI (cRPMI)

RPMI 1640 media, containing:
10% FBS
2 mM L-glutamine
1 mM sodium pyruvate
10 mM HEPES
100 U/ml penicillin
100 μg/ml streptomycin
50 μM 2-mercaptoethanol (optional, but be consistent)
Filter sterilize
Store up to 2 to 4 months at 4°C protected from light

HBSS

To make a 500-ml Hank's balanced salt solution (HBSS) with HEPES, for added buffering capacity, add:
50 ml 10× HBSS (e.g., GIBCO, Invitrogen)
445 ml H_2O, double-processed cell culture and endotoxin tested
5 ml 1 M HEPES, cell-culture tested
Adjust pH to 7.2 to 7.4, if necessary, with 1 N NaOH
Filter sterilize
Store up to 2 to 6 months at 4°C protected from light

MC57G growth medium

DMEM supplemented with:
10% (v/v) FBS
2 mM L-glutamine
1 mM sodium pyruvate
50 μg/ml gentamycin
Filter sterilize.
Store up to 2 to 4 months at 4°C protected from light

SDS, 0.5% (w/v)

Dissolve 0.5 g sodium dodecyl sulfate in 100 ml water. Store up to 1 year at room temperature.

Serum-free RPMI (sfRPMI)

RPMI 1640 medium containing 1% bovine serum albumin (BSA) and 10 mM HEPES, pH 7.4. Filter sterilize and store up to 2 to 4 months at 4°C protected from light.

Trypan blue, 0.4% (w/v)

Dissolve 0.4 g trypan blue in PBS or HBSS. Filter through Whatman no. 1 paper. Store >1 year at 4°C or up to 4 to 6 months at room temperature.

CAUTION: *Trypan blue is believed to be carcinogenic and teratogenic. Wear gloves and a particulate filter mask while working with it in powder form. Additionally, tubes containing trypan blue and cells need to be filled with dilute (~2%) bleach prior to being discarded.*

Yac-1 growth medium

RPMI 1640 media containing:
10% FBS
2 mM L-glutamine
1.5 g/liter sodium bicarbonate
4.5 g/liter glucose
10 mM HEPES
1 mM sodium pyruvate
100 U/ml penicillin
100 μg/ml streptomycin
Filter sterilize
Store up to 2 to 4 months at 4°C protected from light

COMMENTARY

Background Information

A major function of lymphocytes is the detection and destruction of infected cells and tumor cells. One mechanism by which lymphocytes carry out this function is by causing the death of antigen-bearing target cells. The two types of lymphocytes that have the capability to recognize and directly destroy target cells are CTL and NK cells. Although the mechanisms by which CTL and NK cells recognize their targets differ, the cytolytic machinery used by these two types of cells is very similar (Kagi et al., 1996; Russell and Ley, 2002). Moreover, given that the cytolytic function of lymphocytes constitutes a major component of host protection from pathogens and tumor cells, methods to measure this activity are well established and form a critical aspect of functional assessments of the immune system.

Since the molecular machinery that underlies the lysis of target cells is similar, the primary way in which one can distinguish killing by CTL from killing by NK cells is by understanding and exploiting the distinct constraints on target cell recognition by these two types of cells. CTL must recognize antigenic peptides in association with class I MHC molecules. Moreover, generating CTL requires sensitization of naïve T cells with antigen, followed by the clonal expansion and differentiation of naïve cells into CTL. Antigen recognition by NK cells is not MHC-restricted and sensitization with antigen is not required, because the cytolytic activity of NK cells is an innate feature of these cells. These distinctions can be used to separately quantify the activity of these two types of cytolytic lymphocytes. For example, Yac-1 tumor cells do not express class I MHC. This makes these cells highly sensitive to lysis by NK cells and resistant to recognition by CTL. In contrast, P815 tumor cells are sensitive to lysis by allo-reactive CTL, but because they express class I MHC molecules, they are resistant to killing by NK cells. In contrast to the effector cell selectivity of these two types of target cells, cells infected with influenza virus are susceptible to recognition and killing by CTL and NK cells.

A major consideration when using the protocols described in this unit is determining what specific aspect of immune function is to be tested and then selecting the most appropriate protocol(s) to accomplish this goal. For example, exogeneous agents that adversely affect cell proliferation would be expected to impair the generation of a CTL response, but not affect the native activity NK cells. Exogenous agents that interfere with cell-cell contact, exocytosis, or cellular trafficking would likely diminish CTL and NK cell cytolytic activity. Thus, these assays can be used in the following applications:

Table 18.6.1 Troubleshooting Guide for Assessing Cytolytic Activity of Lymphocytes

Problem	Possible cause	Solution
High (>5%) non-specific lysis, as indicated by high counts per minute in spontaneous release (SR) wells	Insufficient washing of target cells Poor target cell viability	Add more washes or increase the volume of medium used in each wash. Poor target cell viability after labeling.
Very low counts per minute in MR wells	Poor ^{51}Cr uptake by target cells Poor target cell viability	Use the freshest ^{51}Cr available, and do not use if decayed (even decaying by one half-life can adversely affect the sensitivity of these assays). Poor target cell viability after labeling.
Very low counts per minute in samples containing (or expected to contain) effector cells	Improper effector cell sensitization. Poor cellular viability.	Validate the efficacy of effector cell sensitizaiton using an alternate method (e.g., flow cytometry, cytokine production, or proliferation). Use cells isolated from animals as quickly as possible after the animal is sacrificed. Check the pH of solutions and wash the cells more gently.
Poor target cell viability after ^{51}Cr labeling	Poor cellular viability prior to labeling Cells were not used within 30 min of labeling	Use only viable cells. Wash cells more gently and very carefully maintain solution pH. Do not let the labeled target cells sit unused for >30 min.

1. To test whether in vitro exposure to a chemical affects the clonal expansion and differentiation of T cells (see Basic Protocol 1).

2. To test whether in vivo exposure to a chemical affects the clonal expansion and differentiation of T cells (see Alternate Protocols 1 and 2).

3. To determine whether exposure to a particular substance affects the inherent cytolytic function of NK cells (see Basic Protocol 2).

4. To determine whether exposure to a substance has differential effects on the native and boosted cytolytic activity of NK cells (see Basic Protocol 2).

5. To determine whether exposure to an agent exhibits differential or selective effects on CTL and NK cells (a combination of Basic Protocol 1 or Alternate Protocols 1 or 2 and Basic Protocol 2 in separate but simultaneous assays).

Critical Parameters

All animals used for these procedures should be housed in specific pathogen-free conditions and all media should be free from bacterial endotoxin and other immunostimulatory contaminants. Cells isolated from animals should be used as quickly as possible after animal sacrifice.

Troubleshooting

See Table 18.6.1 for troubleshooting tips.

Anticipated Results

If the effector cells recognize and kill the target cells, then the counts per minute and calculated percent specific cytolytic activity should increase with increasing E:T ratios, as depicted in Figure 18.6.1. On the other hand, the amount of cytolytic activity in wells set up using control effector cells should not change with increasing E:T ratios. In fact, the counts per minute in wells containing the negative control cells cultured with target cells ought to be about the same as the spontaneous release of the target cells.

The maximum achievable percent cytolytic activity will vary depending upon the type of

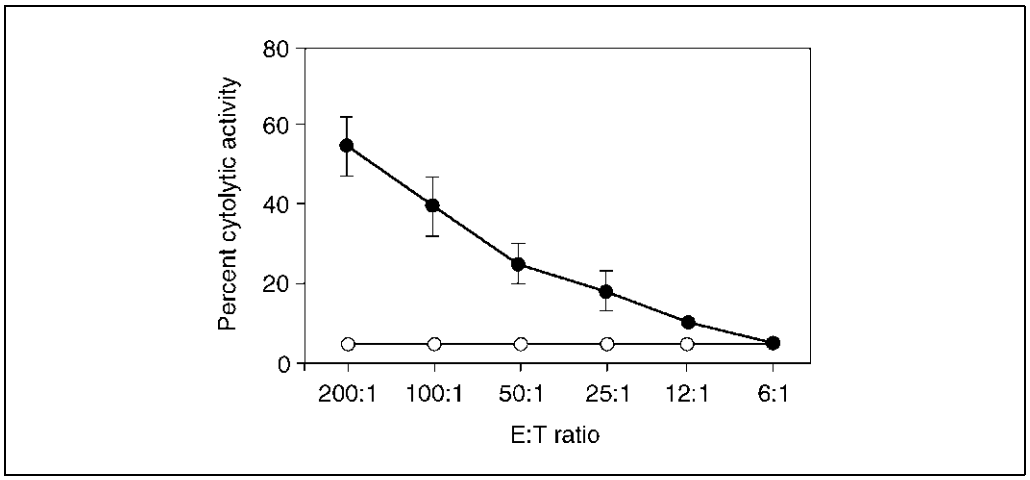

Figure 18.6.1 This graph depicts the average cytolytic activity of spleen cells in an in vitro chromium release assay. Spleen cells were isolated from a C57B1/6 mouse 9 days after i.p. injection with P815 mastocytoma cells (closed circles). As a control, spleen cells from a naïve mouse (open circles) were cultured with the labeled-P815 cells, which served as the target cells for this assay.

effector cells used and how they were sensitized. Lysis of 25% to 60% of the target cells at the highest E:T ratio is the typical range expected in chromium release assays for both NK cells and CTL. Lysis of 100% of the target cells by the effector cells should not be expected, and if observed, it likely indicates a technical problem with the assay. When measuring the activity of NK cells, treatment with poly I:C should lead to increased activity compared to native NK cell activity toward Yac-1 tumor cells, however, the magnitude of this change is not more than 2-fold (e.g., increasing the percent cytolytic activity from 35% to 50% at an E:T ratio of 100:1 is typical).

Time Considerations

A chromium release assay requires 1 full day. It takes ~3 hr to collect the effector cells and label the target cells, and these steps need to be performed simultaneously. The total time required to set up the assay (i.e., combine the effector and target cells) depends upon the size of the assay, but generally takes ~1 hr. The cells need to be incubated for 4 to 5 hr prior to harvesting supernatants. The duration of this step depends upon the size of the assay (number of 96-well plates), but generally takes ~1 hr.

While general steps and overall time commitment for the chromium release assays described here is similar among the protocols described, the total amount of time required to measure the cytolytic activity of CTL and NK cells is very different. $CD8^+$ T cells require sensitization with antigen to develop into CTL. Therefore, whether one uses an in vitro or in vivo approach, it takes 5 to 10 days to generate a population of CTL. The innate and in vitro–boosted cytolytic activity of NK cells can be measured in 1 day. However, if one wants to stimulate NK cells in vivo prior to measuring the cytolytic activity, then the assay will require 1 additional day for this step.

Solid-Phase Immunoassays

Solid-phase quantitative immunoassays can be configured in a multitude of ways to detect the presence and concentration of a specific antigen or an antibody of a particular isotype and specificity. These assays can provide a wealth of information about cellular and molecular events that are altered by toxicant exposure. For example, these assays can produce information related to antibody or antigen concentrations, the affinity and avidity of the interactions that produce immune complexes, and the organ, tissue, cellular, and subcellular distribution of target molecules (Probst et al., 1995). In the context of toxicological assessment, these assays provide a window on the effects that chemical and physical agents can have on developmental processes and effector mechanisms in the body. Since the immune system itself is often a target of toxin effects, evaluation of immune function can be extremely informative, but these same assay formats can be used to probe other biological systems with equal ease.

STRATEGIC PLANNING

The enzyme-linked immunosorbent assay (ELISA) is a multi-step process in which a target molecule (e.g., an antigen) is first immobilized onto an insoluble substrate—most often composed of polystyrene or another plastic in a 96-well microtiter plate configuration. Ordinarily, this immobilization is a non-specific binding event and must be followed with a blocking reagent to saturate any other non-specific binding sites on the substrate. A number of different kinds of reagents have been used to block subsequent non-specific binding, and examples of some of the common blocking agents are listed in Table 18.7.1. Bovine serum albumin (BSA) is most commonly used, but has some drawbacks under certain circumstances. BSA is a particularly sticky protein that can increase undesirable non-specific interactions. Moreover, polyvalent sera that have been raised against cultured cells may have secondary reactivity against BSA that was carried along with the immunizing cells from the fetal bovine serum that is often used to supplement culture media. Teleostean fish gelatin has the advantage of being antigenically distinct from the antigens present in samples associated with many common applications of the ELISA technology, and thus it will not often produce spurious cross-reactions. Since this protein derives from cold-water fish, it is soluble at room temperature, and will not gel in the microplate wells.

Table 18.7.1 Blocking Agents

Blocking agent	Suppliers	Commonly used concentration range
Bovine serum albumin (BSA)	Jackson ImmunoResearch Laboratories Sigma-Aldrich	1%–10%
Casein	Sigma-Aldrich	5%–10%
45% Teleostean fish gelatin in water	Sigma-Aldrich	1%–5% dilution of stock solution
Non-fat dried milk (NFDM)	Local grocery store, Sigma Chemical	2%–5%
Goat serum	Sigma-Aldrich	1%–10%

Table 18.7.2 Enzymes Used in Conjugates and Representative ELISA Substrates

Enzyme	Complementary substrates	Detection method for substrate	Enzyme limitations
Alkaline phosphatase (AP)	a. Para-nitrophenyl phosphate (PNPP) b. 4-Methyl-umbelliferyl phosphate (4-MUP)	a. Measure absorption at 405 nm b. Excitation at 360 nm and emission at 440 nm	Samples that contain a high level of endogenous phosphatase are not compatible with this enzyme conjugate
ß-galactosidase (ß-gal)	a. *o*-Nitrophenyl-ß-D-galactopyranosidase (ONPG) b. 4-Methyl-umbelliferyl-ß-D-galactopyranosidase (MUM-Gal)	a. Measure absorption at 405 nm b. Excitation at 360 nm and emission at 440 nm	This enzyme is not as active as the alternatives and produces a lower signal over time
Horseradish peroxidase (HRP)	a. 3,3′,5,5′-Tetramethylbenzidine (TMB) b. 2,2′-Azino-di-(3-ethylbenz-thiazoline sulfonic acid (ABTS)	a. Measure endpoint at 370 or 655 nm, or acidify and measure at 450 nm b. Measure at 416 nm 405 nm will also work	Do not use this enzyme conjugate if the sample contains oxidizing or reducing agents, or some preservatives

Once the surface has been blocked, the complementary molecular partner (e.g., a cognate antibody conjugated to an enzyme label) can be added to the surface and allowed to selectively interact with the target molecule. Following an appropriate period, the surface can be washed to remove any unbound antibody-enzyme conjugate. The next step is to add an appropriate substrate for that enzyme. The more enzyme that is present, the more substrate will be converted to a product that can be measured in a microtiter plate reader. Measurements of the amount of substrate conversion to product can be interpreted to indicate the degree of antibody-enzyme conjugate that has bound to the surface. A list of the most common enzyme labels and their substrates is provided in Table 18.7.2. Substrates must be stable until they interact with enzyme, must produce a soluble product, and should have a large extinction coefficient to maximize the signal-to-noise ratio. In some cases, fluorescent substrates can improve the sensitivity of an assay by 100- to 1000-fold over an absorbance assay, but these assays do require fluorescent microtiter plate readers that are more expensive and less commonplace than standard absorbance microtiter plate spectrophotometers. In addition to the listed substrates, there are also commercially available chemiluminescent substrates (often used with horseradish peroxidase–labeled antibody conjugates) that can further enhance the detection limits of ELISA. The disadvantage of chemiluminescent systems is that the signal persists for only a brief time (for 5 to 30 min) and then begins to degrade. Moreover, readings must be taken in a microtiter plate luminometer.

Another substrate alternative that can enhance the sensitivity of the ELISA is an enzymatic recycling system (e.g., commercially available from Invitrogen). In this type of substrate system, immobilized alkaline phosphatase catalyzes the conversion of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) to reduced nicotinamide adenine dinucleotide (NADH). The NADH can then participate in a cyclic reaction in which diaphorase reduces a tetrazolium salt (iodonitrotetrazolium violet or INT-violet) to colored formazan and produces oxidized NAD^+. To continue the cycle, NAD^+ is then reduced back to NADH and ethanol is oxidized to acetaldehyde in the presence of alcohol dehydrogenase. The NADH can be recycled through this process and yields an approximately ten-fold signal amplification over that of standard ELISA protocols when absorption is read at 495 nm.

One of the initial issues to be considered for the design of an ELISA is the availability of antibodies specific for the target to be assessed. There are many sources of commercial antibodies that produce reagents of differing specificity, concentration, purity, quality, isotype, and species of origin. Identification of the appropriate reagent must take into account the singular or multiple applications for which the antibody will be used. For example, it may prove useful to employ a polyclonal antibody that cross-reacts with homologous antigens from different species to facilitate the assessment of cellular functions in cell cultures of different origins. Alternatively, a monoclonal antibody may enhance the specificity of the antibody/antigen interaction by minimizing the appearance of cross-reactions that decrease the signal-to-noise ratio of the assay. Equally important, it may prove useful to employ antibodies that are biotinylated to facilitate the use of a spectrum of different labeling reagents that have each been coupled to avidin. In this way, the same biotinylated antibody reagents incubated with an avidin-enzyme conjugate that could be used for an ELISA would also be useful in fluorescent assays when incubated with an avidin-fluorescent tag.

Once the appropriate antibodies have been identified, it is often useful to obtain a source of purified antigen for use as a standard in the reaction. While this is not always possible (or economical), it can serve to enrich the interpretations that are possible from data generated by the ELISA.

Having obtained the central reagents, the next step is to select the specific kind of ELISA that will be used. Figure 18.7.1 illustrates the most commonly used ELISA configurations.

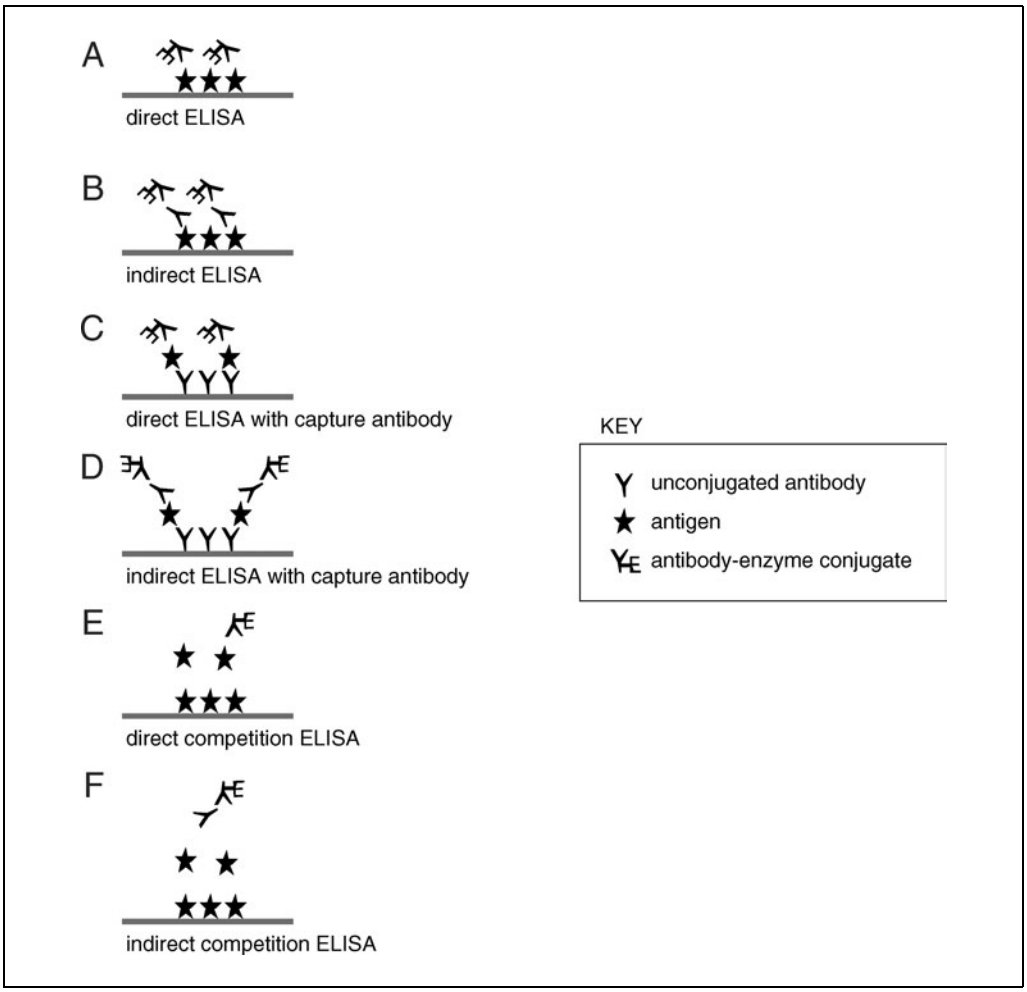

Figure 18.7.1 ELISA protocol formats.

The simplest of these assays is the direct ELISA (Fig. 18.7.1A). This assay is usually configured with non-specifically adsorbed target antigen on the surface of the microtiter plate well. The amount of adsorbed antigen is detected using a pre-established amount of cognate antibody coupled to an enzyme label. The more antigen that is immobilized on the surface, the more antibody-enzyme conjugate will subsequently bind. Ultimately, the larger the amount of enzyme that is immobilized after binding to the surface, the more detection reagent will be converted to a signal that can be measured by light absorption, fluorescence, or luminescence. A common variation of this assay is used to quantitate the amount of antibody specific for a particular antigen that is present in a sample. In this version of the ELISA (Fig. 18.7.1B), known amounts of antigen are immobilized on the surface of the microtiter plate well. After blocking the surface to prevent further non-specific binding, the surface is incubated with the sample that may contain antibody specific for the target antigen. If there is antibody present in the sample, it will be retained on the surface after washing, and will serve as a target for a secondary antibody that has been conjugated to enzyme. The anti-immunoglobulin-enzyme conjugate is added in a standardized amount (usually in excess), and thus the amount of signal that develops is directly proportional to the amount of primary antibody that has bound to the surface.

If the antigen to be detected is present in a heterogenous sample mixture that also contains other molecules, the actual detection of antigen will be subject to the influences of the competitive binding of those different molecules from the sample. For this reason, an ELISA that employs a capture antibody is more commonly used (Fig. 18.7.1C and D). Unconjugated antibodies against the target antigen are first immobilized on the substrate, and the surface is then blocked to prevent further irrelevant binding to the surface. At this point, antigen that is incubated on this surface will be captured by specific binding to the capture antibody. Irrelevant molecules will be left unbound. After washing away unbound molecules, antigen that remains bound to the surface can then be detected with antibody-enzyme conjugate in a direct ELISA with capture antibody, or in an indirect ELISA configuration.

Finally, the ELISA can be configured as a competition assay (Fig. 18.7.1E and F). In these assays, soluble antibodies will bind to immobilized antigen unless additional free antigen is added to the solution. As the amount of free antigen in solution increases, the amount of antibody that will bind to the immobilized substrate decreases. Antibody binding is again determined by the amount of directly conjugated enzyme that is present in a direct ELISA, or by subsequent measures of the amount of anti-immunoglobulin antibody-enzyme conjugate binding that can be made in an indirect ELISA. Competition ELISAs are particularly useful for measurements of antigen concentration in complex mixtures when the unknown samples that may contain antigen are compared to similar samples that contain known amounts of purified antigen.

The ELISPOT (enzyme-linked immunoSPOT) assay is a useful variation of the basic ELISA format. While ELISA measures the concentrations of analyte in solution, the ELISPOT enumerates cells that are actively secreting a specific protein (e.g., cytokine or immunoglobulin) in a heterogeneous population of cells. This assay differs from the basic ELISA protocol in both the configuration of the microtiter plate, and in the chemical characteristics of the enzyme substrate that is used. The microtiter plate wells that are used have filter bottoms. The filters are first coated with sterile capture antibody or antigen. Cells are then added to the wells of the plate and settle to the filter surface. Cells that secrete molecules that can be bound by the capture antibody, or cells secreting antibodies specific for immobilized antigen will secrete those molecules to a region immediately surrounding the cell. The analyte will bind to the filter-immobilized cognate molecule in highest concentrations nearby the cell source of the analyte. As analyte diffuses away from the cell, its concentration diminishes. Following an appropriate incubation period,

a secondary antibody-enzyme conjugate that is specific for the analyte is added and allowed to bind. Finally, enzyme substrate that produces a precipitating colored product is added. As the substrate is converted to this precipitating product, color will accumulate in specific regions of the filter that correspond to the original locations of the cells that secreted the analyte. These spots of accumulated color are proportional to the amount of analyte bound to the filter, and the precipitate spots can be counted microscopically and compared to the number of cells originally added to each individual well.

A new version of the solid-phase immunoassays is the grating-coupled surface plasmon resonance (GCSPR) assay. This assay has been used as a label-free variant of ELISA, and offers some interesting advantages over the more commonly used ELISA. GCSPR is based on the phenomenon of energy transfer that occurs at a metal-dielectric interface (e.g., the interface between gold and water) when light energy is coupled to the electrons within the metal. Under certain optical conditions, the energy of the light excites electron movement within the metal. This excitation reduces the intensity of the reflected light. SPR technologies match the wave vector of the illuminating beam of light with the plasmon wave vector using a prism (the Kretschman configuration) or with a grating embossed on the gold surface. There is a critical angle at which this vector matching is best, and at which the energy transfer into the metal is largest. The angle at which maximum energy transfer occurs is referred to as the SPR angle. Because the measurement of energy transfer is sensitive to the refractive index of the dielectric/metal interface, the addition of proteins to the surface (which have a higher index of refraction than water) will increase the angle at which coupling occurs. Antibodies or other capture molecules immobilized on the surface that subsequently capture analyte from the sample solution will cause an increase in the critical angle of reflection. GCSPR offers a significant advantage over the Kretschman configuration because the entire surface of the sensor chip can be illuminated, and images of the chip surface across a range of illuminating angles can be captured. Individual regions of interest (ROI) on the chip surface can be computationally assessed for protein capture by immobilized antibody according to the changes in SPR angle at each ROI. Thus, GCSPR offers a microarray format for the simultaneous analysis of multiple proteins in solution from a single small volume sample.

This unit describes several prototypical variations of these three types of solid-phase immunoassays and considers the use of these assays in the evaluation of toxic chemical effects on biological systems. Several different configurations of ELISA are described in Basic Protocol 1 (direct ELISA), Alternate Protocol 1 (indirect ELISA), and Alternate Protocol 2 (competitive ELISA). Basic Protocol 2 describes the ELISPOT assay, and Basic Protocol 3 describes the GCSPR protein microarray application.

DIRECT ENZYME-LINKED IMMUNOSORBENT ASSAYS

BASIC PROTOCOL 1

In this simplest of ELISA configurations (Fig. 18.7.2), known and potential sources of antigen are first incubated in wells of a microtiter plate. The known antigen solutions act as positive controls for those wells in which potential sources of antigen are added. It is advantageous to maximize antigen coupling to the surface, and so antigen is often diluted in a coupling buffer that will facilitate binding to the microtiter plate material. Incubation of the antigen solution in the well can be done for up to 1 hr at 37°C, or overnight at 4°C. Then the antigen is aspirated from the well, and the well is filled with a larger volume of blocking agent in phosphate-buffered saline. After blocking, the well is washed and then incubated with the antibody-enzyme conjugate, washed again, and then substrate is added. After incubating the substrate in the wells for a defined period, a single, endpoint reading can be taken to measure the amount of substrate conversion to product. Alternatively, a kinetic measurement can be made in which multiple sequential measurements of the optical density of the substrate are taken and then converted to a milli-optical density

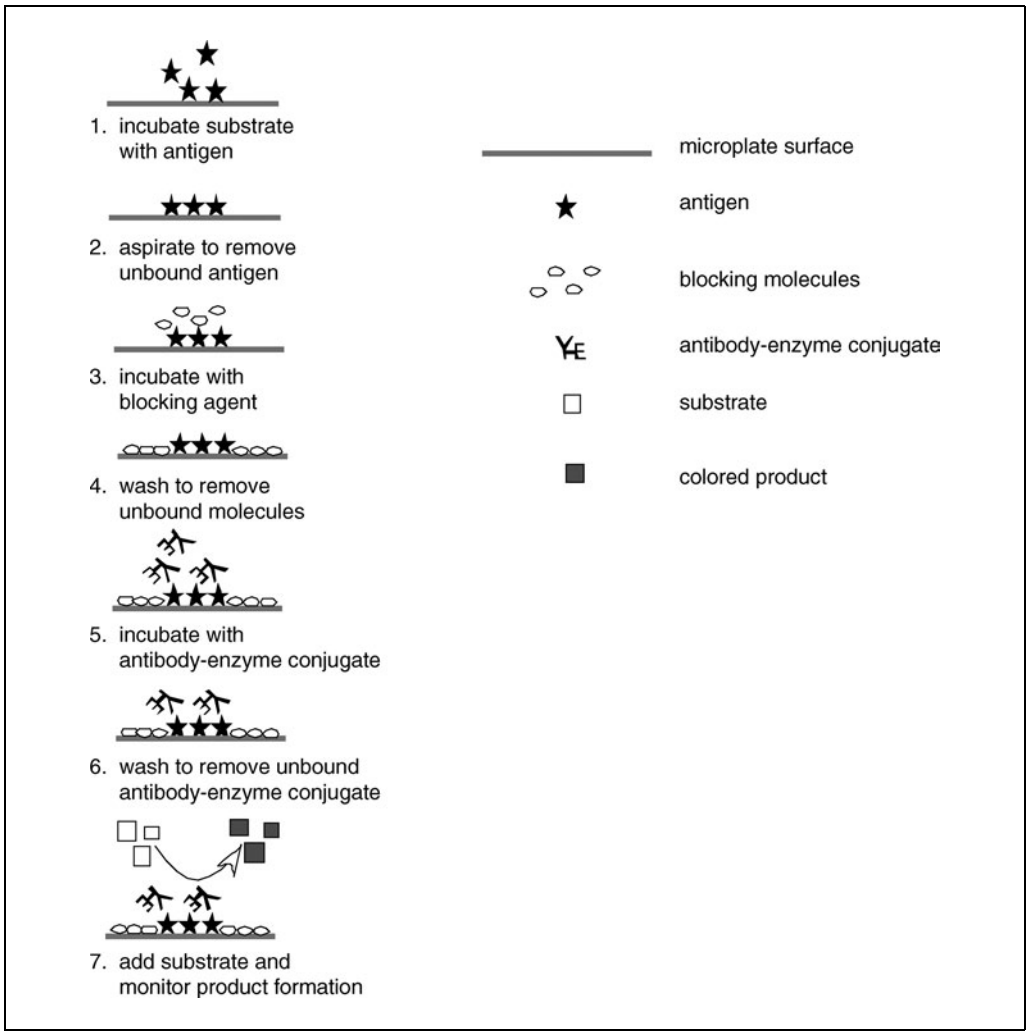

Figure 18.7.2 Sequential ELISA steps.

(mO.D.)/min reading, or a rate of substrate conversion. This second approach to quantifying the amount of enzyme in the well has the advantage of diminishing the differences that might result from the pipetting sequence. Wells initially loaded with substrate have more time to develop color than will wells loaded at a later time, but if the wells have equivalent amounts of enzyme, the rates of substrate conversion to colored product should be equal. Another advantage of the kinetic measurement of substrate conversion is that measurements can be started immediately after substrate addition. Usually 5 to 10 min of sequential measurements at 20- to 30-sec intervals from each well are sufficient to produce reliable estimates of substrate conversion rates. It is important to ensure that the conversion rate is linear and does not plateau, or the mathematical estimate of the absolute rate will be lower than the real rate. For that reason, the plate should be shaken in between readings to prevent substrate depletion at the surface of the microtiter plate well, and the assay should be set up to avoid approaching the maximum O.D. that the instrument can measure. For the same reason, substrate should be present in excess in each well. If the plate reader does not offer the capacity to do kinetic measurements, then the substrate should be incubated in each well for a fixed period of time (usually 30 min at 37°C), and the individual wells measured as an endpoint assay. If the rates of substrate conversion are rapid, the activity of the enzyme should be stopped before reading the plate. This is usually done by changing the pH of the substrate solution; for alkaline phosphatase conjugates conversion of *p*-nitrophenyl phosphate disodium hexahydrate (PNPP), the reaction can be stopped with the addition of 3 N NaOH.

Materials

Antigen diluted in ELISA coupling buffer (see recipe for ELISA coupling buffer)
Blocking reagent (Table 18.7.1)
ELISA wash buffer (see recipe)
Antibody-enzyme conjugate (e.g., Southern Biotech)
Substrate (Table 18.7.2) dissolved in the appropriate substrate buffer (e.g., for alkaline phosphatase-based assays, the most common substrate is *p*-nitrophenyl phosphate, PNPP, Sigma; see recipe)
96-well flat-bottom microtiter plates (plates specifically treated to enhance binding of hydrophobic or hydrophyllic proteins, or DNA molecules; e.g., Immulon 2 HB plates, Thermo Electron)
37°C incubator
Automated plate washer (optional)
Plate sealer (adhesive-backed mylar sheets, Fisher)
Microtiter plate reader with appropriate wavelength filters (e.g., Molecular Devices, Bio-Tek Instruments, Thermo Electron, and Tecan)
Plate shaker

Determine working dilutions of antigen and antibody-enzyme conjugate

1. Determine working dilutions of the antibody-enzyme conjugate and the immobilized target molecule in a 96-well microtiter plate. Set up the microtiter plate in a checkerboard fashion: with replicate wells containing 100 µl serial doubling dilutions of cognate antigen (approximate initial range: 10 µg/well to 0.01 µg/well) arranged across the plate from left to right. Use an underplate well indicator to guide the distribution of reagents. Incubate 60 min at 37°C.

   Include wells that lack one or both of the antigen and antibody-enzyme conjugate to determine the rate of spontaneous conversion of the chromogenic substrate to colored product. All measurements should be made in at least three replicate wells to allow the subsequent calculation of standard deviation, which should ideally be <5% of the average values for the triplicate wells. It is also useful to retain several microliters of the stock dilution of the antibody-enzyme conjugate to add to unused substrate in a separate tube to assure that the enzyme can produce color when the substrate is present.

   One of the commonplace errors in microtiter plate assays is the deposition of the wrong reagent to the wrong well. There are a number of ways to help avoid these mistakes, including plate holders that sequentially illuminate a light emitting diode beneath the wells in a specified pattern. For most uses, it is sufficient to place a photocopy of the plate underneath the plate with each well individually indicated.

   Eight- or twelve-channel pipettors can enable the transfer of replicate volumes to whole rows or columns of the plate at the same time. Since speed and consistency is critical to ensuring accurate results, these pipettors can prove quite useful. However, many of these pipettors can exhibit inconsistent volume transfer between channels, often owing to inconsistent seals of the disposable tips to the pipet shaft. Moreover, forcefully fitting the tip on the shaft to ensure a seal can slow the assay set up because of difficulty in removing the tips after use. If these pipettors are used, they should be pre-calibrated to ensure volume transfers are equivalent between channels.

   Microtiter plates can be irradiated with UV light in the laboratory to further enhance binding to the surface; this manipulation is detailed in the sample protocol for anti-double stranded DNA antibody ELISA (Amoura et al., 1994).

2. Wash the plate three times with at least three complete changes of 250 µl wash buffer/well.

   It is possible to wash the wells of the microtiter plate manually with a simple siphon system that drains wash buffer through tubing to a Pasteur pipet. Using a clamp to restrict the flow of wash buffer, liquid can be added to each well individually. The initial fluid is

removed from the wells by inverting the plate over the sink and sharply flicking the fluid out. After the wells have been emptied, the plate should be inverted and rapped against a few layers of paper towels to remove the last vestiges of remaining fluid and to blot the surface of the plate. Then, wash buffer is added to each well, and the wash cycle repeated two more times. The efficacy of each wash cycle can be increased by allowing the wash buffer to sit in each well (a soak step) for 2 to 5 min. Another inexpensive washing station can be made with a Bel-Art Vaccu-Pette/96 (http://www.bel-art.com/) and a 60-ml syringe, which can be configured to deliver wash buffer to all 96-wells in a microtiter plate simultaneously. There are a number of commercially available automated plate washers that can further improve the consistency and stringency of washing each well at each of the different wash steps, and which are invaluable when more than a couple of plates are used in a single assay. Automated microtiter plate washers have added features to further increase the success of the wash step, including shaking and soaking steps. Suppliers of this equipment include many of the manufacturers of microtiter plate readers.

3. Add 150 µl ELISA blocking buffer and incubate 60 min at 37°C.
4. Wash wells three times with ELISA wash buffer.
5. Add 100 µl serial doubling dilutions of antibody-enzyme conjugate (approximate range: 1:250 to 1:8000) arranged from the top row to the bottom row. Mix and incubate 1 hr at 37°C.

   Antibody-enzyme conjugates can be obtained commercially from a wide variety of sources. The most commonly available conjugates incorporate alkaline phosphatase, and can be used at dilutions from 1:250 to 1:8000 of the stock solutions that are provided by many commercial suppliers. It is important to store undiluted antibody-enzyme conjugates at 4°C to prevent aggregation and enzyme inactivation that can occur with repeated cycles of freeze-thawing.

   Mixing the contents of the microplate wells can be accomplished by the onboard shakers that many microplate readers now incorporate, or with freestanding shakers that are also commercially available. In its cheapest form, holding a microplate to the top of a vortex mixer will provide adequate mixing force, but other freestanding mixers designed for microtiter plates are also available. Whenever the microplates are shaken, a plate sealer should be used to prevent fluid transfer between wells, and care should be taken to preserve the optical clarity of the undersurface of all wells.

6. Wash plate three times with ELISA wash buffer.

   Incubations times, incubation temperatures, blocking conditions, washing conditions, and substrate concentrations should all be similar in the final assay to what is used to determine the working dilutions of antibody and antigen.

7. Add 100 µl substrate in appropriate substrate buffer, mix, and incubate 30 min at 37°C.
8. Measure substrate conversion to product using a microtiter plate reader at 405 nm, and use the patterns of enzyme activity to determine at what antibody-enzyme conjugate concentration the signal-to-noise ratio is most favorable and simultaneously economical.

   Endpoint reading of the microtiter plate is often done after a 30- or 60-min incubation at 37°C. Alternatively, reading can be done repeatedly immediately after substrate addition and a kinetic rate of substrate conversion determined (in mO.D./min). An example of data produced from a kinetic read is shown in Figure 18.7.3.

9. Set incubator to 37°C. Pre-run automated plate washer (if available) to replace distilled water in tubing with wash buffer.

   The incubator speeds the reaction and shortens the assay. It also ensures that the conditions of the assay do not vary over time as room air temperature might vary. A simple small

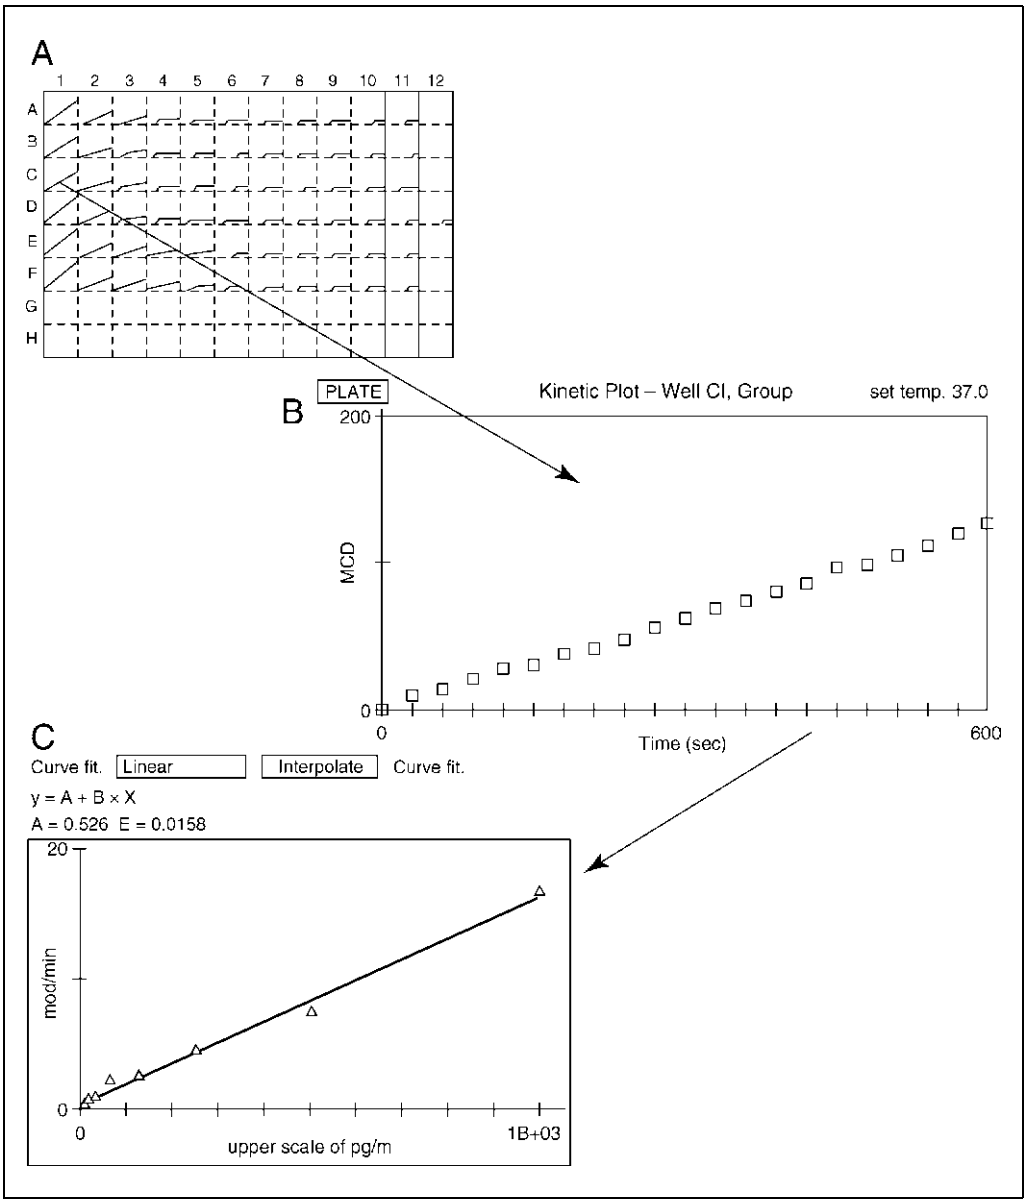

Figure 18.7.3 Each well of the microtiter plate is measured multiple times. (**A**) In this example, 20 measurements were done over a 6-min incubation. The individual kinetic plots can be examined individually (**B**), and the rates that are associated with each can be used to construct a standard curve (**C**).

incubator with ambient air is sufficient for this assay (some microplate readers have internal incubators that can be used for this purpose).

Prepare appropriate dilutions of antigen and antibody

10. Dilute samples that contain antigen in coupling buffer and pipet 100 µl of the antigen solution into the wells of a microtiter plate. Cover the filled wells with a plate sealer and incubate 60 min at 37°C.

    It is important to include wells for non-specific binding controls (often these are isotype-matched antibody-enzyme conjugates that are specific for an irrelevant antigen) and for positive- and negative-antigen control reactions (where known amounts of antigen are added to the well, or antigen is omitted from the coupling buffer that is placed in the wells).

    It is useful to hold the pipet tip at a consistent angle relative to the top surface of the plate, and to be consistent in the depth of pipet tip insertion into the well (ideally, the pipettor

should be held at ~45° and the tip inserted so that its end rests about half way down the well side). This ensures that the fluid is not adsorbed to the upper wall of the well, in an area that will later remain unblocked.

With additional experimentation, it may be possible to reduce incubation times to ≤30 min, although this abbreviation may come at the expense of sensitivity or with the use of higher concentrations of reagents. The plate sealer is removed at the end of each step by holding the plate firmly on a solid surface and slowly peeling the sealer off. It can be reused at each step if no liquid is transferred to the underside of the sealer.

Adhesive-backed mylar sheets prevent evaporation and inadvertent fluid transfer between wells that can alter the results and diminish the sensitivity of an ELISA. It is advantageous to seal the wells of the plate during each incubation, especially if the assay is done at 37°C to prevent changes in liquid volumes and salt concentrations due to evaporation.

Perform ELISA

11. Aspirate the antigen using a plate washer, or flick the antigen out over a sink by inverting the plate with a rapid downward motion. Blot the top of the plate with paper towels, and then add 150 µl of blocking solution. Incubate wells 60 min at 37°C.

    A larger volume of blocking solution (than the volumes used in other steps) is added to ensure that all possible non-specific binding sites near the meniscus of the antibody-enzyme conjugate solution will have been occupied before the conjugate is added to the well.

12. Empty the wells as in step 11, and wash manually or with an automated plate washer. If the plates are washed manually, add wash buffer to each well and immediately flick out wash buffer. Perform several more rapid washing steps, and then fill the wells with wash buffer and allow to soak 5 min before finally removing the wash buffer. If an automated washer is used, include a 5-min soak step after the first two of three cycles of washes to ensure non-adsorbed proteins are removed.

13. Immediately following removal of the wash buffer, add 100 µl antibody-enzyme conjugate at the optimal concentration to each well. Then re-seal wells with the plate sealer and incubate 60 min at 37°C.

    The dilution of antibody-enzyme conjugate is pre-determined during preliminary experiments (see steps 1 through 8).

14. Wash wells as described in step 12.

15. Finally, remove the final wash buffer, add 100 µl substrate in substrate buffer, and incubate plate 30 min at 37°C. Add an equal volume of 0.075 N NaOH to stop the reaction. Take an endpoint reading at 405 nm. Alternatively, for kinetic measurements, immediately place the plate, without stop solution, in a kinetic microtiter plate reader and measure at 20-sec intervals with shaking for 10 min.

    Standard microtiter plate spectrophotometers measure in the visible wavelengths, other reader formats can also measure fluorescence and/or luminescence.

ALTERNATE PROTOCOL 1

INDIRECT ELISA

An indirect ELISA (also called a sandwich assay) takes advantage of the commonly available antibody-enzyme conjugates that will bind to antibodies of specific isotypes, light chains, and from particular species. These reagents allow the experimental assessment of primary unlabeled antibodies from clinical samples, or from experimental culture or animal systems that would be impractical to prepare as individual conjugates to antibody. In essence, indirect ELISA is a modified direct ELISA where additional steps are added after the blocking step to allow initial binding of the primary, unconjugated test antibody, which is then indirectly measured as the target for binding by the secondary antibody-enzyme conjugate. Preliminary experiments to determine working dilutions are set up

essentially as described in Basic Protocol 1, steps 1 to 8. Several dilutions of antigen are each combined with several dilutions of unconjugated primary antibody and conjugated secondary antibody to establish optimum conditions for sensitivity.

Additional Materials *(also see Basic Protocol 1)*

Unconjugated primary antibody/antiserum reagent

1. Follow Basic Protocol 1, steps 10 through 12.
2. While the antigen solution is incubating in the wells, dilute the unconjugated primary antibody through a series of doubling dilutions from 1:10 to 1:10,240. Make at least 350 μl of each dilution to allow 100 μl to be added to each well in triplicate.
3. Add 100 μl of the diluted unconjugated primary antibody to the appropriate wells, seal, and incubate for 60 min at 37°C.
4. Wash the wells as described in Basic Protocol 1, step 12, and then add diluted antibody-enzyme conjugate to each well as described in Basic Protocol 1, step 13. Seal and incubate the wells for 60 min at 37°C.

   In many cases, this secondary antibody will be specific for the isotype of the primary antibody. Care should be taken to match the specificity of the secondary antibody based on species of animal from which the primary antibody was obtained. The secondary antibody can also be specific for both heavy and light chains of the primary antibody, or it can be a polyclonal antibody that is specific for a collection of immunoglobulin determinants of the different isotypes of antibody that might be in an antiserum that has been used as the primary antibody. It is also possible to use an antibody specific for a particular light chain of the primary antibody. For some species (e.g., mouse) one of the two light chain types is the predominant form, making an anti-light chain antibody a broad spectrum reagent for detection of many different primary antibodies.

5. Continue with Basic Protocol 1, steps 14 and 15.

COMPETITION ELISA

ALTERNATE PROTOCOL 2

A competition ELISA is essentially a direct or indirect ELISA in which the antigen-specific antibody is pre-incubated with soluble preparations of known solutions of antigen, or with unknown solutions that may include antigenic determinants. In this assay, antigen present in low concentrations in heterogenous mixtures of protein (e.g., secreted proteins in serum) can be quantified by comparison to a standard curve of purified protein.

Additional Materials *(also see Basic Protocol 1)*

Soluble antigen in purified form
Goat anti-mouse Ig-alkaline phosphatase conjugate that recognizes both heavy and light chains

Coat microtiter plate

1. Coat the 96-well flat-bottom microtiter plate (Immulon 2) with antigen diluted to 10 μg/ml in coating buffer by adding 100 μl to each well to immobilize 1 μg/well. Cover the wells with a plate sealer and incubate 1 hr at 37°C or overnight at 4°C.

Prepare samples and standards

2. While plate is incubating, prepare standards.

   a. Label 1.5-ml microcentrifuge tubes for each standard.
   b. For the first standard, add 160 μl of antigen from 1 mg/ml stock to the first tube and 240 μl of binding buffer (total volume is 400 μl).
   c. Add 200 μl of binding buffer to the remaining tubes.

d. Take 200 µl from the first tube and transfer into the second tube. Mix and transfer 200 µl to the next tube. Repeat this doubling serial dilution for the remaining tubes. Remove 200 µl from the last tube to ensure that all tubes have the same volume. Store all tubes on ice until use.

3. To prepare samples, add 200 µl of cell lysates, serum dilutions, or other unknown samples to 1.5-ml microcentrifuge tubes and keep all tubes on ice.

Preincubate antibody

4. Prepare pre-determined dilution of antibody specific for the target antigen in binding buffer, and add 200 µl of this diluted antibody to the tubes that already contain 200 µl of known antigen concentration standards or unknown samples.

   The final dilution of the antibody in each well will be two times the stock dilution, and the final concentrations of antigen will be half the dilution added. The antibody dilution to be used in this step is determined in a preliminary indirect ELISA where the titer of the antibody is determined. A dilution that is the penultimate dilution before the ELISA signal begins to significantly decline is the best to choose. This dilution will be halved by the addition to standards or sample. Any soluble antigen in the standards or the sample will reduce the amount that is available to bind the immobilized antigen on the microtiter plate surface. It is critical that all assay conditions (e.g., incubation times, antigen and antibody preparations, temperatures, and wash conditions) be identical between experiments that establish the dilution of primary antibody to be used.

5. Vortex all standard and sample tubes and incubate 1 hr at 37°C.

Perform competitive ELISA

6. After standards and samples have been added to the primary antibody, aspirate the antigen-coated plate, and block each well by adding 150 µl blocking buffer.

7. Microcentrifuge the tubes containing standard or sample for 10 min at 5000 rpm.

8. During the last 5 min of the microcentrifugation in step 8, take out the plate being blocked and wash three times with wash buffer using an automated plate washer.

9. Add 100 µl of standards and samples in triplicate to appropriate wells of a microtiter plate, seal with plate sealer, and incubate 1 hr at 37°C.

10. Wash plate three times with wash buffer using an automated plate washer.

11. Add 100 µl of a predetermined dilution of goat anti-mouse Ig-alkaline phosphatase conjugate (e.g., 1:500) to each well and incubate for 1 hr at 37°C.

    This dilution will have been predetermined at the same time that the primary antibody dilution was established.

12. Wash plate three times with wash buffer using an automated plate washer.

Detect binding

13. Add 100 µl of alkaline phosphatase substrate buffer to all wells.

14. Immediately read the plate at 405 nm for 10 min at 30-sec intervals in a kinetic plate reader, or as an endpoint read as described in Basic Protocol 1, step 8.

BASIC PROTOCOL 2

ELISPOT ASSAY

The ELISPOT assay, originally described >20 years ago (Czerkinsky et al., 1983; Sedgwick and Holt, 1983) can provide information about the number of cells in a population that are secreting a specific protein (usually a cytokine or immunoglobulin). Cytokine secretion can be interpreted to indicate pathways of immune activation such as T_h1- or T_h2-dependent pathways (Lalvani et al., 2001), and immunoglobulin secretion

can indicate either antigen-specific responses to antigen challenge, or total amounts of specific isotype production indicative of overall immune capacity. There are some suppliers of complete ELISPOT kits (e.g., Sanquin; Mabtech; and Diaclone), but it is often far more economical to develop the specific ELISPOT assay for an antigen of specific interest in the laboratory. In the prototype assay described below, antigen coupled to the membrane surface serves as a target for the quantification of cells secreting an antibody specific for that antigen.

Materials

Antigen
ELISPOT coating buffer (see recipe)
ELISPOT wash buffer (see recipe)
RPMI-1640 supplemented with 10% FBS or ELISPOT blocking buffer (see recipe)
Test cells
Capture and detection antibodies for the target molecule of interest
ELISPOT assay diluent
ELISPOT culture medium
ELISPOT substrate solution: BCIP (5-bromo,4-chloro,3-indolylphosphate)/NBT (Kirkegaard and Perry)

96-well filtration plates with sterile surfactant-free membrane (e.g., Millipore)
Automated plate washer (optional)
ELISPOT reader (ImmunoBiosys, Zeiss, Sanquin, or A. EL. VIS) *or* dissecting microscope and digital image analysis software (e.g., ImageJ available as freeware at *http://rsb.info.nih.gov/ij/*)

Add antigen to plates

1. Incubate ELISPOT plate with 100 µl/well of filter-sterilized (0.2-µm filter) antigen at 100 µg/ml in ELISPOT coating buffer. Incubate specificity control wells with 100 µl/well of an irrelevant antigen at 100 µg/ml in ELISPOT coating buffer. Incubate overnight at 4°C.

   These 96-well filtration plates with sterile surfactant-free membranes have filters on the bottom, which have a pore size of 0.45µm and are comprised of hydrophobic PVDF.

2. Wash three times with sterile ELISPOT wash buffer in an automated plate washer, or wash plates manually.

3. Block plate with 200 µl/well sterile RPMI-1640 supplemented with 10% FBS for 1.5 to 2 hr at room temperature, or with ELISPOT blocking buffer.

Add cells

4. Add 100 µl of the test cell populations in sterile RPMI-1640 supplemented with 10% FBS to each well at serially diluted cell suspensions of 10^6/well to 10^4/well in triplicate and incubate in a 37°C, 5% CO_2 humidified incubator for 24 hr.

5. Wash wells three times with ELISPOT wash buffer manually or in an automated plate washer.

Perform ELISPOT assay

6. Add 100 µl/well of ELISPOT detection antibody at 1 µg/ml in PBS (usually ~1:500 dilution of antibody) and incubate 2 hr at 37°C.

   It is important that the specificities of the capture and detection antibodies are compatible. The pair must be capable of binding to distinct epitopes on the same target molecule simultaneously.

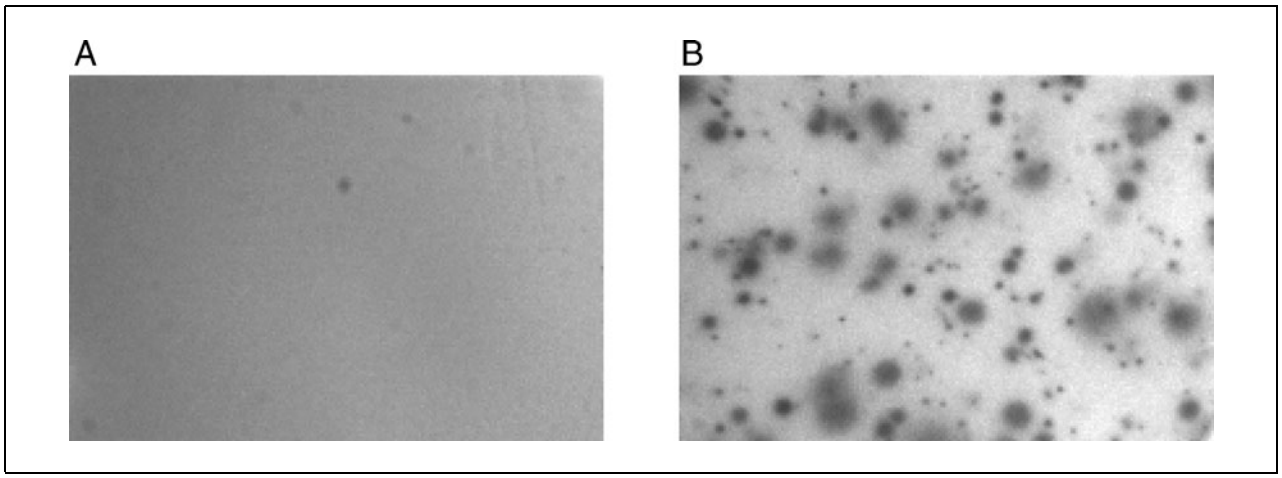

Figure 18.7.4 Examples of colored precipitate spots generated in the ELISPOT assay. (**A**) Control well containing unstimulated cells. (**B**) Well containing stimulated cells.

7. Wash three times with ELISPOT wash buffer manually or in an automated plate washer.
8. Add 100 µl/well of ELISPOT substrate solution and develop for 10 to 30 min at room temperature until spots appear.
9. Wash plate three times with 200 µl/well distilled water.
10. Air-dry the plate and count spots by using a dissecting microscope or ELISPOT reader.

Legitimate spots will be round and larger than a cell in size (usually 75 to 400 µm in diameter) when viewed with a dissecting microscope. An example of these spots can be seen in Figure 18.7.4. Artifacts will have eccentric shapes, and staining will not be uniform across the spot. It is often useful to look at a well that has not been seeded with cells before the staining protocol was done to identify known artifacts. While the trained eye is still best at identifying spots, it is advisable to have coded the wells so that enumeration can be done without bias.

BASIC PROTOCOL 3

GRATING-COUPLED SURFACE PLASMON RESONANCE IMMUNOASSAY

GCSPR is a new assay that offers the sensitivity of an ELISA in a microarray format (Fig. 18.7.5). This format enables the simultaneous evaluation of small volume samples to determine the presence of a large number of different antigenic determinants (Brockman and Fernández, 2001). Currently available chips have an active area that is ~1 cm^2, and can accommodate ~400 individual spots. With replicates, this allows for the assessment of >100 antibody/antigen interactions at the same time in a real-time assay that is label free. Currently, there is only one commercial supplier of GCSPR instrumentation (HTS Biosystems).

Materials

Ethanol
Capture antibody
Antigen
PBS (see recipe)
GCSPR blocking reagent
Analyte solution

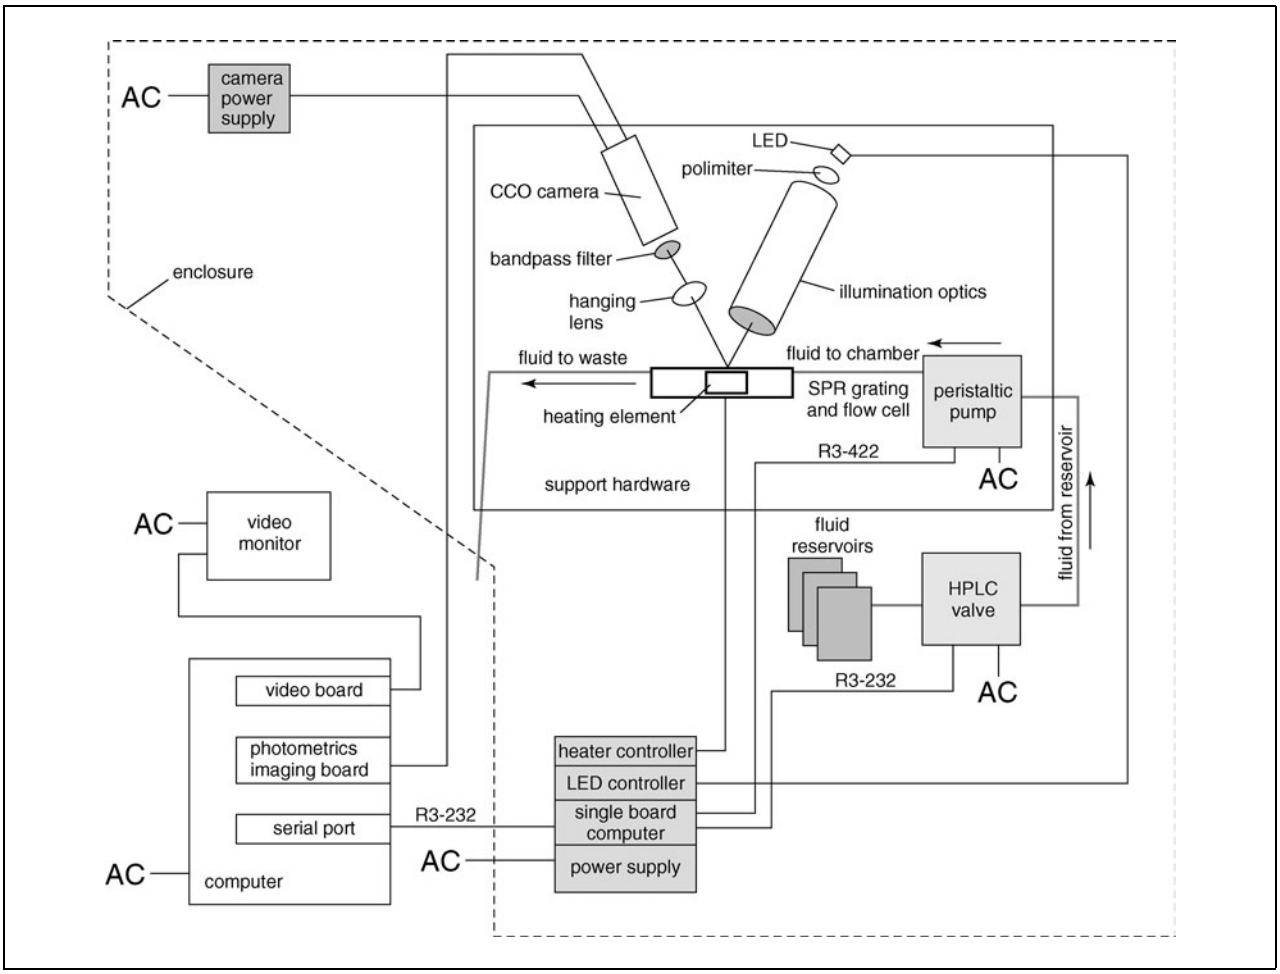

Figure 18.7.5 GCSPR optical diagram.

MicroCaster System, 8-pin manual arrayer (Schleicher and Schuell Bioscience), or another spotting system
GCSPR sensor chips (Applied Biosystems)
96-well microtiter plates
37°C incubator and humid box
Applied Biosystems 8500 affinity chip analyzer

1. Rinse pins of arrayer sequentially in ethanol and distilled water.
2. Rinse gold sensor chip surface sequentially in ethanol and distilled water. Allow to air dry.
3. Place chip in arrayer with the notch in the upper right hand corner. Determine which pins will spot inside the active area of the chip (the part of the chip that has the diffraction grating embossed on it).
4. Place captured antibodies in wells of a 96-well microtiter plate. Dip pins into antibody solutions.
5. Transfer samples to active area of chip on slide. Designate regions of interest (ROIs).
6. Move chip using MicroCaster indexing system and repeat for desired number of spots. Move chip in a horizontal direction.
7. Use a sharp needle to make a small scratch in the chip underneath the spots for orientation (make this mark at least 1 mm away from the ROIs).

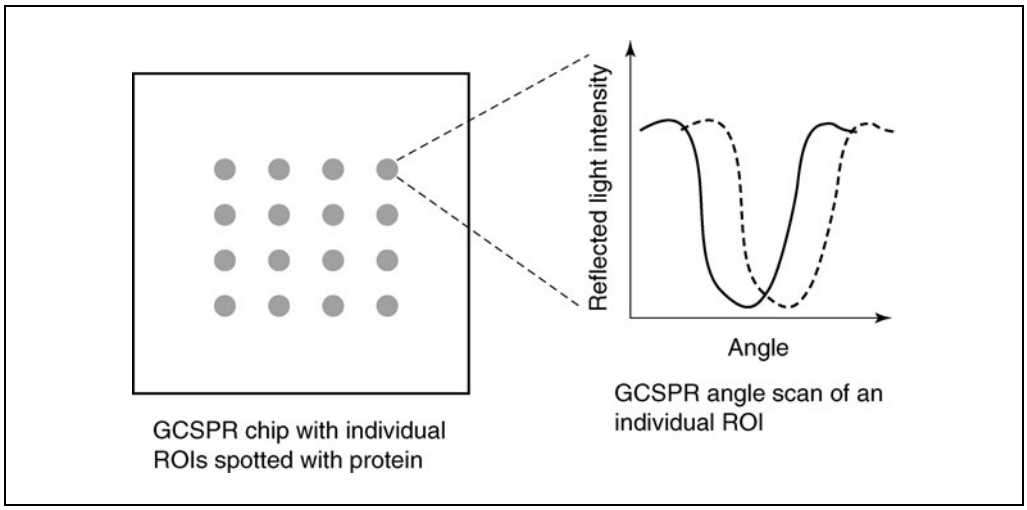

Figure 18.7.6 The GCSPR chip is illuminated following spotting of the chip surface with the capture antibody and reflected light intensity is measured at a range of angles (solid line). Following exposure of the chip to cognate antigen, the angle scan is repeated, and reflected light intensity is again measured (dashed line). The increase in the angle at which the maximum coupling occurs, which is the angle that has the least light reflected, is an indication of antigen binding to the capture antibody. The magnitude of this angle shift is a measure of the increase in molecular mass at the ROI.

8. Place spotted chips in 37°C incubator inside a humid box for 30 min to allow antibody to bind to the chip surface. Install chip in reader.
9. Initiate liquid flow at 200 µl/min and pass PBS over chip surface, take initial GCSPR data to assess the amount of protein that remains bound to the chip (compare to empty ROIs where no capture antibody has been placed)
10. Pass GCSPR blocking reagent over chip surface.
11. Pass analyte solution over surface and take GCSPR data to assess the change in the GCSPR angle (the illumination angle at which the greatest coupling and thus least reflection of light occurs).
12. Assess angle shift increases as an indicator of antigen capture (Fig. 18.7.6).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline phosphatase substrate buffer

9.7% (w/v) diethanolamine
0.02% (w/v) NaN_3
0.01% (w/v) $MgCl_2$, pH 9.8
Store buffer for several months at 4°C. Add *p*-nitrophenyl phosphate (1 mg/ml PNPP; Sigma) 10 min before use to allow the PNPP to dissolve.

Tablet or capsule forms of the substrate can simplify addition to the buffer.

ELISA blocking buffer (BSA-based)

PBS (see recipe)
0.2% (w/v) NaN_3
10% (w/v) BSA
Store up to 1 week at 4°C.

ELISA coupling buffer

15 mM $NaHCO_3$
35 mM Na_2CO_3
0.2% (w/v) NaN_3, pH 9.6
Store up to 6 months at 4°C

CAUTION: *NaN_3 is a toxic substance and should be handled with gloves and filter mask to avoid ingestion. Discarded solutions with azide should be substantially diluted with running water if poured down the drain to avoid the formation of lead azide in the pipes (a contact explosive).*

ELISA wash buffer

PBS
0.2% (w/v) NaN_3
0.05% (v/v) Tween 20, pH 7.2
Store up to 6 months at 4°C

ELISPOT blocking buffer

1% (w/v) Teleostean gelatin or 5% (w/v) nonfat dry milk in PBS (no azide). Store up to 1 week at 4°C.

ELISPOT coating buffer

1.57% (w/v) Na_2CO_3
2.93% (w/v) $NaHCO_3$
0.2% (w/v) NaN_3, pH 9.7
Store up to 6 months at 4°C

ELISPOT substrate solution

Prepare stock solutions of nitroblue tetrazolium (100 mg NBT/2 ml of 70% dimethylformamide in water) and bromo-4-chloro-3-indolyl phosphate (100 mg BCIP in 100% DMF). Add 33 µl NBT stock plus 17 µl BCIP stock to buffer comprised of 100 mM Tris·Cl, pH 9.5, 100 mM NaCl, and 5 mM $MgCl_2$. Use working substrate within 1 hr. Store NBT and BCIP stock solutions at −18°C.

ELISPOT wash buffer

PBS (see recipe)
0.05% (w/v) NaN_3
Store up to 6 months at 4°C

Phosphate buffered saline (PBS)

8 g/liter NaCl
0.2 g/liter KCl
1.15 g/liter Na_2HPO_4
0.2 g/liter KH_2PO_4
Store up to 6 months at 4°C

COMMENTARY

Background Information

ELISA has supplanted the radioimmunoassay (RIA) as the method of choice for measuring antibody/antigen interactions. Depending on the particular configuration used, a wealth of information can be obtained with ELISA. For the most part, this assay can enable the characterization of cellular antigens, soluble antigens, and the antibodies that detect these targets. It is important to design

Table 18.7.3 Troubleshooting Guide to ELISA/ELISPOT

Problem	Possible cause	Solution
No color development	Enzyme or substrate may be bad or left out of final step	Retain unused diluted antibody-enzyme conjugate and prepared substrate. Test for enzyme activity by mixing 10-µl aliquot of the diluted conjugate with 100 µl of substrate.
	Antibody-enzyme conjugate denatured or aggregated	Do not freeze-thaw conjugate, store at 4°C
Excess color development; non-linear changes in optical density with changes in antigen or antibody concentration	Some plate readers produce linear measurements up to an O.D. of 2.0. Others are linear to an O.D. of 3.0	Dilute the antigen or the antibody to reduce the amount of enzyme that is bound in the well
False positives in ELISA/ELISPOT	Antibody-enzyme conjugates will aggregate under some conditions and become quite sticky	To reduce non-specific binding, centrifuge conjugate in microcentrifuge at top speed, or ultrafilter diluted conjugate just before use.
		Inappropriate cross-reactivity may exist in the antigen-specific antibody preparation, or contaminating antigens may be present.

the ELISA with potential cross-reactions in mind, and to include both positive and negative controls in the assay for quality control. It is equally important, especially in the context of toxicological assessments, to ensure that the toxic agent does not have an undue influence over the performance of the assay. For example, toxins may diminish viability of input cell populations in the ELISPOT assay, which could alter the interpretation of results. Metals can alter structural features of target molecules, making their detection less certain. Lead has been shown to interact with IFN-γ in this way (David Lawrence, pers. comm.). Thus, it may be useful to run preliminary assays in the presence of the toxicant itself to assess the impact of this reagent on the ability of the antigen to adsorb to the microtiter plate surface, on the ability of the antibody to bind antigen, and on the enzymatic conversion of substrate to product.

Troubleshooting

See Table 18.7.3 for a list of possible problems, possible causes, and solutions.

Anticipated Results

Typically, ELISA can distinguish proteins in complex solutions at concentrations in the micro- to nanogram range, but specifically selected antibodies can be sufficiently sensitive to detect antigen in the picogram range. It is usually useful to test several dilutions of antigen or antibody to exclude artifactual results by showing that the reaction behaves as predicted (i.e., a ten-fold dilution will produce a ten-fold decrease in signal). For measurements of humoral immune responses, it is often of value to determine the titer of the solution—at what dilution the reactivity diminishes below a specific defined value. In assay configurations where the antigen must couple to a capture antibody and to an antibody-enzyme conjugate, care must be taken to match the antibody pairs; otherwise steric interference will impede the simultaneous binding of both antibodies to the antigen, thus making the assay unsuccessful.

The ELISPOT assay is an outgrowth of the plaque assay, where cells in soft agar were assayed for the secretion of antibody that could lyse erythrocytes in an overlying layer of agarose. As cells secret relevant antibodies, they diffuse into the overlying layer containing the erythrocytes, and will bind to the erythrocyte membranes. After this incubation is complete, a solution containing complement proteins (often a dilution of guinea pig serum) is added to the top of the agarose layers and allowed to saturate the agarose. Where antibody has bound to erythrocyte membranes, the complement cascade will be activated, and cells will lyse. This can be seen as a clearing of the granular erythrocyte suspension (visualized as a clear plaque) and can further be identified by

the lymophocyte that is located in the center of the plaque. The ELISPOT assay is a more universal assay because the antigens that can be assayed need not be naturally or artificially located on the erythrocyte membranes. An optimized ELISPOT can detect two to three secreting cells per 10^5 input cells.

The GCSPR protein microarray platform is a further improvement on the basic assessment of antigen-antibody interactions. Sensitivity of the GCSPR assay approximates that of an ELISA, and may be further improved as the sensing technology is improved, and as the chemistry of antigen immobilization is enhanced. Moreover, current investigations are underway to explore the application of the GCSPR to ELISPOT-type investigations.

Each of these assays can be used to assess the impact of toxins on the immune response by assessment of the degree of immunity that develops in the presence of different levels of toxin.

Time Considerations

ELISA usually takes about a half day to complete, but this can be accelerated by increasing the antigen and antibody concentrations as the time per step is shortened. Alternatively, the assay can incorporate an overnight step to prepare the initial antigen-bound plate, or can employ plates that have been commercially prepared to reduce the time before experimental sample is applied.

ELISPOT can take several hours to prepare, including the preparation of cells from harvested tissue or from cell culture. Once the cell culture incubation phase is complete (overnight incubation), the remainder of the assay can take an additional 1 to 2 hr to complete. Once stained, the spots can be enumerated under the microscope; this usually will take 1 or 2 hr to complete.

GCSPR assays can take 1 or 2 hr to complete; on a per antigen basis, this assay can be the fastest of those discussed here since several hundred spots can be assessed on a single chip.

Immune Cell Phenotyping Using Flow Cytometry

Immunophenotyping is a general term used to describe the use of fluorescently labeled antibodies to identify and quantify distinct subpopulations of cells within a heterogeneous population of cells. Frequently, the term is used more specifically to refer to the characterization of subsets of cells associated with the immune system (i.e., immune cell phenotyping). In either case, the antibodies used for immunophenotyping are usually specific for cell surface proteins that are known to be differentially expressed on discrete subsets of cells. Immunophenotyping can be carried out using either flow cytometry or immunohistochemical analysis. However, flow cytometry is often the method of choice, because it permits the acquisition of nonsubjective data on thousands of cells within seconds. Furthermore, each cell suspension can be labeled with several different antibodies simultaneously, and the fluorescence associated with each antibody can be collected on a per-cell basis as correlated data. Modern flow cytometers can routinely measure five or more different fluorescence emissions simultaneously, providing the means to easily detect unique subsets within a heterogeneous population of cells. More recently, cell surface phenotyping with immunofluorescent probes has been performed to ascertain the functional status (e.g., DNA or cytokine content, mitochondrial membrane integrity, glutathione status) of cells, making multiparameter flow cytometry a very powerful tool for characterizing the activation state of a cell. The only drawback of flow cytometry is that cells must be stained and analyzed in a single-cell suspension, which is easier to prepare from some tissues than from others. Because cells derived from blood and lymphoid tissues are readily maintained in suspension, flow cytometry has been widely used to phenotype these cells.

Immunophenotyping of lymphoid tissues, particularly spleen and thymus, has been used in the field of immunotoxicology for many years as part of a tiered screening approach for detecting immunotoxicity following chemical exposure. Since thymic involution frequently occurs after toxicant exposure, changes in thymocyte immunophenotypes are commonly evaluated. Similarly, just as white blood cell (WBC) counts and differentials have been used for many years to assess immune status in toxicant-exposed animals, newer screening approaches such as immunophenotyping of spleen and/or lymph nodes have been used to quantify frequencies of the major lymphocyte subtypes (B cells, T cells, and T cell subsets) following chemical exposure. In studies conducted by the National Toxicology Program, the utility of immune cell phenotyping has been validated using a large database of environmental toxins and certain pharmaceutical agents. In these studies, changes in lymphocyte phenotypes in the spleen or thymus following toxicant exposure was identified as one of the best single correlates with toxicant-induced changes in host resistance to pathogens or tumors (Luster et al., 1993). However, even though immunophenotyping of the spleen and thymus may correlate with toxic chemical exposure, it is not necessarily a robust predictor of immunotoxicity, particularly when naive animals are exposed to toxicants. Some highly immunotoxic chemicals, including cyclosporin A and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), do not alter splenic immunophenotypes in the absence of antigen challenge (Kerkvliet and Brauner, 1990; Vandebriel et al., 1999). Likewise, changes in thymic phenotypes can occur indirectly, through stress-induced effects on the thymus that are independent of direct immunotoxicity. Thus, it is generally agreed that immunophenotypic analysis of B cells, T cells, and T cell subsets present in the thymus and/or spleen should be used in conjunction with conventional assessments of immune function when screening for the immunotoxic effects of drugs and chemicals (Immunotoxicology Technical Committee, 2001; Food and Drug Administration, 2002).

Contributed by Julie A. Oughton and Nancy I. Kerkvliet
Current Protocols in Toxicology (2005) 18.8.1-18.8.24

Although immunotoxicology studies have focused primarily on the phenotypic analysis of B cells and T cell subsets in spleen and/or thymus from naive mice, several extended applications of immunophenotyping are emerging in the immunotoxicological literature. One important extension is the analysis of peripheral blood cells from mice and rats (Oughton et al., 1995; Nygaard and Lovik, 2002; Funatake et al., 2004). The use of peripheral blood samples from rodents allows more direct comparisons to be made with toxicity data that may be available from human studies, which nearly always rely on peripheral blood samples. Analysis of blood also allows evaluation of systemic changes that may result from toxicant effects in lymphoid tissues, as well as the testing of multiple samples obtained from the same animal over an extended time.

Another important addition to standard immunophenotyping techniques is the analysis of activation markers. Most cells in the immune system respond to antigenic stimulation by altering their expression of a number of different proteins on the cell surface. Many of these proteins are known to be involved in the functional response of the cell (e.g., adhesion, migration, costimulation), while others may reflect the cell's antigenic history (as in memory cells). Evaluation of activation markers is likely to provide an enhanced ability to detect immunotoxic effects. For example, when mice were exposed to low doses of TCDD for more than a year, no changes in major T- and B cell subsets were observed. However, analysis of the naive/memory phenotypes of $CD4^+$ T cells revealed that TCDD exposure had significantly reduced the proportion of memory cells present (Oughton et al., 1995). Likewise, evaluation of activation markers in the context of an ongoing immune response may provide novel insight into the selective targets and mechanisms of action of immunotoxic chemicals. Several laboratories are now using immunophenotyping to track the effects of toxicants on the activation and fate of antigen-specific T cells following antigenic challenge, with very exciting results (Shepherd et al., 2000; Mitchell and Lawrence, 2003; Funatake et al., 2004).

Since the specific antibodies that one might use for immunophenotyping will vary depending on the species tested, the flow cytometer used, and the experimental questions being asked, the following protocol describes a generic approach to the staining of cells with fluorescently labeled monoclonal antibodies (MAbs) to assess cell surface protein expression. Work in the authors' laboratory has primarily involved mouse cells; however, all aspects of this unit easily apply to the analysis of cells from rats, dogs, and horses. The first protocol (Basic Protocol 1) describes the procedure by which cells obtained from lymphoid tissue are stained with fluorochrome-conjugated MAbs (direct staining method). A second protocol (Alternate Protocol) describes two indirect methods for the staining of cells with primary MAbs that are not conjugated to a fluorochrome. Finally, a third protocol (Basic Protocol 2) describes the staining of peripheral blood cells with MAbs.

Support protocols are presented for the preparation of lymphoid cells (Support Protocol 1), the fixation of cells (Support Protocol 2), and discrimination of dead cells (Support Protocol 3). When freshly stained cells cannot be analyzed immediately, samples must be fixed so that the cells are stable for storage (Support Protocol 2). Furthermore, because the inclusion of dead cells in flow cytometric analysis can lead to the misinterpretation of data and possibly to the rendering of erroneous conclusions, it is desirable to assess cell viability using DNA dyes (Support Protocol 3).

Finally, a procedure for the determination of optimal antibody concentrations is presented in Support Protocol 4.

NOTE: The investigator should consult the manufacturer's instruction manual for specific information regarding the operation of his or her flow cytometer.

DIRECT STAINING OF CELLS PREPARED FROM LYMPHOID TISSUES

BASIC PROTOCOL 1

This is the preferred method for staining cells obtained from lymphoid tissues (e.g., spleen, thymus, lymph nodes). Basic Protocol 1 is appropriate for immunophenotyping of cells from either rats or mice. Because this method uses MAbs that are directly conjugated to fluorochromes, staining is simple and quick and usually produces little background signal.

Toxicology studies usually involve the assessment of lymphoid tissues from several individual animals in a number of different treatment groups. For example, a 3-dose-plus-control experiment that examined spleen and thymus from 5 animals per treatment group would yield 40 individual cell samples that needed to be stained, usually in more than one staining configuration. Processing of large numbers of samples can be facilitated by staining cells in V-bottom 96-well microtiter plates, as opposed to 12 × 75–mm tubes. These plates can be centrifuged using a microtiter plate carrier, and the contents of the wells can be mixed easily using a vortex mixer (such as the Vortex-Genie 2, VWR Scientific Products) equipped with a platform head for a microtiter plate. Use of a multichannel pipettor (such as the 12-channel Pipet-Lite multichannel pipet from Rainin Instrument) facilitates rapid dispensing of media into the wells, as well as quick transfer of samples to Titertubes (Bio-Rad) for flow cytometric analysis. Titertubes are small tubes that can easily be inserted into 12 × 75–mm disposable tubes, which are commonly used to run samples on a flow cytometer. The abovementioned products greatly increase productivity and also simplify the processing of large numbers of samples. To help keep track of stained samples, a template of the microtiter plate can be prepared in which descriptions of the contents of each well (e.g., animal source, MAbs used) are recorded. In lieu of microtiter plates, cells can be stained in 12 × 75–mm plastic tubes or microcentrifuge tubes.

Materials

Tissue of interest (e.g., lymphoid cells, Support Protocol 1)
Fc receptor (FcR)-blocking immunoglobulin (Ig; e.g., normal rat IgG) solution, 200 μg/ml
MAbs *or* isotype Igs directly conjugated to fluorochromes
PBS supplemented with sodium azide and BSA (PAB; see recipe)
Micropipettor *or* multichannel pipettor with tips
96-well V-bottom microtiter plates, disposable 12 × 75–mm polystyrene tubes, or microcentrifuge tubes
Centrifuge, refrigerated and equipped with a microtiter plate carrier
Vortex mixer equipped with a platform head for a microtiter plate
Titertubes (Bio-Rad Laboratories; optional)
Additional reagents and equipment for preparation of lymphocyte suspension to be analyzed (Support Protocol 1)

NOTE: Several steps need to be performed to minimize antibody cross-linking and the subsequent internalization of cell surface receptors that may occur when these receptors are bound to MAbs. This process is often referred to as *capping* of the antigen-antibody complex. Some cell surface molecules are less likely to cap than others; however, surface immunoglobulin on B cells can cap almost instantaneously. The addition of sodium azide (final concentration, 0.1% w/v) to the staining medium will help to prevent capping. In addition, all cell preparations and staining procedures, including wash steps, should be performed at 4°C, a condition achieved by incubating the cells on ice. Staining samples on ice also reduces the off-rate constant associated with antibody binding by a factor of 10 compared with the off-rate constant at 25°C.

Prepare lymphocyte samples for staining

1. Prepare a single-cell suspension of lymphocytes in 5% HBSS. Lyse red blood cells (RBCs) if present in large numbers (Support Protocol 1).

2. Using a micropipettor or microchannel pipettor, dispense 1–4 × 10^6 cells into each well of a V-bottom 96-well microtiter plate.

   Alternatively, dispense cells into 12 × 75–mm tubes or microcentrifuge tubes.

3. Pellet cells by centrifugation for 3 min at 200 to 1500 × *g*, 4°C.

   The range of centrifugation speeds quoted in this step reflects the fact that no one speed is accepted by the entire flow cytometry community. Although 1500 × g may sound excessive, this is the speed most commonly used by Stewart and Stewart (2001a) in order to minimize the loss of cells during washing.

4. Remove supernatant by holding the plate over a sink and inverting with a flick of the wrist or by decanting liquid from tubes. Blot the plate or the lip of each plastic tube on an absorbent towel to remove excess supernatant.

5. Vortex plate or tubes lightly to resuspend cell pellet.

Label with fluorochrome-conjugated MAbs

6. Add 50 µl FcR-blocking Ig (10 µg) to each cell suspension. Vortex cells lightly and incubate on ice for 10 min.

   A number of cells (especially myeloid cells) have receptors for the Fc portion of an immunoglobulin and will bind to any MAb. In order to assess the antigen-specific binding of a MAb, FcR must be blocked using normal IgG from the same animal species as the selected MAb. For example, for cells stained with rat anti–mouse CD4 MAb, normal rat IgG should be used to block FcR-mediated binding. As an alternative, a MAb specific for mouse FcR (CD16/CD32) can be used, although this involves a substantially higher cost.

   FcR should not be blocked when assessing FcR expression.

7. Without removing the FcR-blocking reagent, add the appropriate fluorochrome-labeled MAbs (see Support Protocol 4 for determination of optimal antibody concentrations) or isotype Igs to each well or tube. Vortex plate or tubes and incubate cells on ice for 10 min, protected from light.

   Cells can be stained with a number of MAbs simultaneously as long as there are no interactions among these MAbs. For large studies, a cocktail of all the MAbs of interest can be used to stain each sample. For example, if cells are to be stained for CD3, CD4, and CD8, a single cocktail including all three MAbs can be prepared in a total volume of 10 µl. Cocktail staining greatly expedites sample preparation and ensures that all samples are stained uniformly.

   Over time, MAbs in solution tend to form aggregates. Cells that express Fc receptors can bind these antibody aggregates with far greater avidity than they can antibody monomers. Aggregates should be removed by microcentrifugation of the antibody solution for 5 min at 12,000 to 13,000 rpm, 4°C, prior to staining.

   Fluorochromes [especially the phycoerythrin (PE)–Cy5 and PE-Cy7 tandem conjugates] are particularly sensitive to photodegradation. Therefore, all staining procedures should be conducted in subdued light.

8. Add 150 µl PAB to each well or tube and centrifuge for 3 min at 200 to 1500 × *g*, 4°C. Remove supernatant as in step 4.

9. To remove unbound MAb, which can contribute to background fluorescence, wash cells once by adding PAB (total volume in microtiter plate not to exceed 200 μl) to each well or tube and centrifuging for 3 min at 200 to 1500 × *g*, 4°C. Remove supernatant as in step 4.

10. Resuspend cells in 500 μl PAB with gentle vortexing.

    For samples prepared in microtiter plates, resuspend each cell pellet in 200 μl PAB. Next, using a multichannel pipettor, transfer the contents of each well to a Titertube and add an additional 300 μl PAB, for a total volume of 500 μl. These Titertubes can then be inserted into 12 × 75–mm plastic tubes for flow cytometric analysis.

11. Keep samples on ice until analyzed using a flow cytometer.

    If stained cells cannot be analyzed on the day of preparation, they must be fixed for longer-term storage (Support Protocol 2).

INDIRECT STAINING OF CELLS PREPARED FROM LYMPHOID CELLS

ALTERNATE PROTOCOL

In general, it is best to stain lymphoid cells with a MAb that is directly conjugated to a fluorochrome (i.e., using the direct method). It is relatively easy to obtain MAbs specific for mouse or rat markers in a number of conjugated forms from commercial sources. However, there are very few mouse or rat MAbs that are conjugated to PE–Texas Red. This will impact studies requiring four or five colors for immunophenotypic analysis, since one MAb may require a second-step staining reagent. This concern is even more relevant when dealing with species other than mice, rats, or humans, as it is very difficult to find commercial sources of fluorochrome-conjugated MAbs for such species. In those situations, it may be necessary to resort to one of two indirect staining methods.

In one method, cells are incubated first with an unconjugated primary MAb and then with a fluorochrome-conjugated antibody that is specific for the primary antibody. For instance, if cells are stained with an unconjugated rat IgG_{2a} MAb that is specific for mouse CD4, the secondary antibody would be a fluorochrome-conjugated antibody that is specific for rat IgG. In most cases, the secondary antibody will be a polyclonal anti-Ig antibody, although Ig isotype–specific MAbs can sometimes be obtained from commercial sources. In this example, one can limit cross-reactivity of the secondary antibody with all other IgG isotypes by restricting the specificity of the secondary antibody to the rat IgG_{2a} isotype, if available. To minimize FcR-mediated binding of the secondary anti-Ig antibody, it is preferable to use the $F(ab')_2$ fragment rather than the whole immunoglobulin.

An alternative indirect staining method relies on the use of a biotin-conjugated primary antibody, which is then detected with fluorochrome-conjugated streptavidin (SA). This biotin-SA method is the preferred indirect staining approach, because reagent interactions, which are often associated with the use of anti-Ig antibodies, are less of a concern. In addition, there are commercially available SA conjugates to a variety of fluorochromes, making SA useful in multicolor staining protocols. However, as with directly conjugated MAbs, biotin-conjugated MAbs are not always available.

The use of secondary anti-Ig antibodies can be circumvented by labeling purified MAbs with specific fluorochromes in the laboratory. Detailed methods for MAb conjugation are available on the Internet (Roederer, 1997), and conjugation kits can be obtained from commercial vendors. The authors have had success using the Zenon Alexa Fluor 488 Mouse IgG Labeling Kit (Molecular Probes, 2004a) to label unconjugated MAbs. Using this antibody labeling kit, small quantities (≥0.4 μg) of primary MAbs can easily be conjugated to fluorescent labels. Currently, the Zenon system can only be used with mouse IgG_1, mouse IgG_{2a}, mouse IgG_{2b}, rabbit IgG, and human IgG antibodies.

Additional Materials *(see also Basic Protocol 1)*

Unconjugated primary MAb *or* biotin-labeled primary MAb
Fluorochrome-conjugated anti-Ig $F(ab')_2$ fragment (for use with unconjugated primary MAb) *or* fluorochrome-conjugated streptavidin (for use with biotin-labeled primary MAb)

1. Stain cells with primary MAbs according to steps 1 through 9 of Basic Protocol 1.

   If necessary, a combination of several fluorochrome-conjugated MAbs plus one non-fluorochrome-conjugated MAb (preferably a biotinylated MAb) can be used in a single MAb cocktail.

2. Resuspend cells in 50 µl PAB with gentle vortexing.
3. Add fluorochrome-labeled streptavidin or an appropriate secondary antibody. Vortex lightly and incubate on ice for 20 min.
4. Add 150 to 200 µl PAB and centrifuge cells for 3 min at 200 to 1500 × *g*, 4°C. Remove supernatant as in Basic Protocol 1, step 4.
5. Wash cells once in PAB as in Basic Protocol 1, step 9.
6. Resuspend cells in 500 µl PAB with gentle vortexing.

   Alternatively, for samples prepared in microtiter plates, resuspend each cell pellet in 200 µl PAB. Next, using a multichannel pipettor, transfer the contents of each well to a Titertube and add an additional 300 µl PAB, for a total volume of 500 µl. These Titertubes can then be inserted into 12 × 75–mm plastic tubes for flow cytometric analysis.

7. Keep samples on ice until analyzed using a flow cytometer.

   If stained cells cannot be analyzed on the day of preparation, they must be fixed for longer-term storage (Support Protocol 2).

SUPPORT PROTOCOL 1

PREPARATION OF CELLS FROM LYMPHOID ORGANS

The processing of mouse lymphoid organs into single-cell suspensions is a fairly simple procedure.

Materials

Lymphoid organ of interest
HBSS supplemented with 5% (v/v) FBS (5% HBSS; see recipe)
Endotoxin-screened distilled water for cell culture (Gibco)
10× HBSS (Sigma)
ACK lysis buffer (optional; see recipe)
60 × 15–mm untreated culture dish
25 × 75 × 1–mm frosted glass microscope slides
15-ml conical centrifuge tubes
12 × 75–mm disposable cell culture tubes
Coulter counter or hemacytometer

1. Transfer a freshly dissected lymphoid organ to a 60 × 15–mm culture dish containing 4 ml of 5% HBSS.
2. When ready for processing, place the lymphoid organ between the frosted ends of two glass microscope slides. Disrupt the organ by gently pressing the frosted ends in a circular motion until only the empty capsule remains.

3. Transfer the resulting cell suspension to a 15-ml conical centrifuge tube. Rinse the culture dish and capsule with a combined total of 3 ml of 5% HBSS and then add this liquid to the cell suspension.

4. Centrifuge the cell suspension for 10 min at 200 × *g*, 4°C. Discard supernatant.

For spleen cell preparations

5a. Lyse RBCs by adding 4.5 ml cold distilled water (for cell culture) to the cell pellet and resuspending with gentle vortexing for 10 sec. After vortexing, immediately add 0.5 ml of 10× HBSS to restore isotonicity, followed by an additional 5 ml of 5% HBSS. Centrifuge cells as in step 4, discard supernatant, and resuspend the cell pellet in 10 ml of 5% HBSS with gentle vortexing.

This procedure also lyses dead cells. If it is necessary to preserve dead cells (e.g., for apoptosis studies), RBCs can be removed by (1) resuspending the cell pellet in 5 ml of a standard ammonium chloride lysing solution (ACK lysing buffer; see recipe) and vortexing briefly; (2) incubating the resuspended pellet for 5 min at room temperature; (3) adding 5 ml of 5% HBSS (inverting the tube several times to mix); and then (4) centrifuging the cells for 10 min at 200 × g, 4°C, and discarding the supernatant.

In general, the viability of spleen cell suspensions will be substantially higher when the hypotonic lysis method (>95%), as opposed to the ammonium chloride lysis method (85%), is used.

6a. Let cell debris settle for 10 min on ice, and then remove the cell-rich supernatant and transfer to a clean tube.

For thymus and lymph node cell preparations

5b. Resuspend the cell pellet in 10 ml of 5% HBSS with gentle vortexing.

6b. Let cell debris and clumps settle for 8 to 10 min on ice, and then remove the cell-rich supernatant and transfer to a clean tube.

7. Determine cell concentration using a Coulter counter or hemacytometer (*APPENDIX 3B*). Use 5% HBSS to adjust the final concentration of the cell suspension to 10–40 × 10^6 cells/ml.

CELL FIXATION

SUPPORT PROTOCOL 2

If it is not possible to analyze freshly stained cells on the day of preparation, the cells must be fixed in electron microscopy (EM)–grade formaldehyde (such as Ultrapure formaldehyde, Polysciences) prior to storage at 4°C. Fixation not only cross-links proteins to make cells stable for storage but also inactivates the infectious activity of any viruses present. Hence, cell fixation is highly advisable when handling biological specimens capable of transmitting infection, and especially when handling human-derived cells.

Fixed samples should be analyzed within 5 days of fixation, since prolonged storage can result in increased autofluorescence. This is usually not a problem when antigens that are expressed at high levels are being analyzed. However, increased autofluorescence may make it more difficult to resolve negative cells from dimly stained cells. Cell fixation often leads to increased cell aggregation; therefore, it may be prudent to filter samples through a 40-μm nylon mesh prior to running them on the flow cytometer.

Additional Materials *(see also Basic Protocol 1)*

1% formaldehyde: 10% (v/v) Ultrapure EM-grade formaldehyde (Polysciences) diluted 1:10 in PAB (see recipe)
40-μm nylon mesh (Small Parts, Inc.; optional)

1. Stain cells with MAbs according to steps 1 through 9 of Basic Protocol 1 or steps 1 through 5 of the Alternate Protocol.
2. Resuspend cell pellet in residual supernatant by gently vortexing.

   Cells must be thoroughly resuspended prior to fixation. If gentle vortexing does not completely resuspend the cell pellets in the microtiter plate, use a multichannel pipettor (equipped with plastic tips) to break up the pellets.

3. Add 200 µl 1% formaldehyde to each well and store cells on ice, protected from light, for 30 min.

   If necessary, cells can be stored overnight in 1% (v/v) formaldehyde at 4°C.

4. Prior to flow cytometric analysis, centrifuge cells 3 min at 1500 × *g*, 4°C. Remove supernatant as in Basic Protocol 1, step 4, and resuspend the cell pellet in 500 µl PAB.

   After resuspension in PAB, it may be desirable to filter samples through a nylon mesh to remove cell aggregates, as this will prevent clogging of the flow cell nozzle.

BASIC PROTOCOL 2

STAINING OF PERIPHERAL BLOOD LEUKOCYTES

This protocol details the immunophenotyping of peripheral blood leukocytes, a process often referred to as a "whole-blood" technique, as RBC lysis takes place after the sample has been stained with specific MAbs. It is appropriate for the immunophenotyping of blood cells from a number of animal species, including mouse, rat, horse, and dog.

Materials

Animals of interest
Sodium heparin, 250 IU per ml in PBS (*APPENDIX 2A*)
PBS supplemented with sodium azide and BSA (PAB; see recipe)
FcR-blocking Ig solution, 2 mg/ml (note that concentration differs from that used in Basic Protocol 1)
Appropriate primary MAbs and (if necessary) secondary antibodies
FACS Lysing Solution (BD Biosciences), diluted 1:10 in distilled water according to the manufacturer's instructions
1-cc syringe equipped with 22-G needle
Coulter counter
Disposable 12 × 75–mm polystyrene tubes

NOTE: Staining conditions are similar to those noted in Basic Protocol 1. However, all staining procedures should be performed in 12 × 75–mm polystyrene tubes, not microtiter plates.

NOTE: Be sure to protect sample from light during incubation with fluorochrome-conjugated MAbs.

Prepare peripheral blood leukocytes for staining

1. Using aseptic technique (*APPENDIX 3B*), collect blood (by cardiac puncture for mice) in a 1-cc syringe containing sodium heparin.

   A sufficient amount of heparin can be drawn into the syringe barrel by simply pulling the plunger back to the 0.05-cc mark.

   In order to reduce animal-to-animal variation, the same volume of blood should be collected from each animal (for example, ~500 µl from each mouse).

2. Determine WBC concentration of blood sample using a Coulter counter.
3. Add 50 to 100 µl blood to a 12 × 75–mm polystyrene tube.

4. Wash cells twice by adding 2 to 3 ml PAB to tube, centrifuging for 5 min at 1500 × *g*, 4°C, and removing supernatant.

   This wash step minimizes artifactual staining of serum Igs with MAbs. Washing is performed by adding 2 ml PAB and centrifuging cells for 5 min at 1500 × g, 4°C. This centrifugation speed is required to produce a soft pellet of blood cells.

   The supernatant is removed by carefully decanting it and then touching the lip of the tube to an absorbent towel. Alternatively, the supernatant can be aspirated, taking care not to disturb the soft cell pellet.

5. Resuspend blood cells in residual medium (~100 µl) by gently vortexing.

Label with fluorochrome-conjugated MAbs

6. To block FcR-mediated binding of Igs, add 5 µl FcR-blocking Ig (10 µg) to the cell suspension. Vortex cells lightly and incubate on ice for 10 min (Basic Protocol 1, step 6).

7. Without removing the FcR-blocking reagent, add the appropriate MAbs (see Support Protocol 4 for determination of optimal antibody concentrations) to the cell suspension, vortex gently, and incubate on ice for 10 min.

   All MAbs can be added concurrently in this step (Basic Protocol 1, step 7). It is highly advisable to include a MAb to CD45 to help define the leukocyte gate during data acquisition and analysis.

8. If all MAbs are fluorochrome-conjugated, proceed to step 11.

9. Add 2 ml PAB to sample and centrifuge for 5 min at 1500 × *g*, 4°C. Remove supernatant and wash cells once with PAB as in step 4.

10. Add secondary antibodies to sample, vortex gently, and incubate on ice for 20 min.

11. Without removing or washing away the MAbs, add 2.0 ml FACS Lysing Solution, 1:10 dilution.

    FACS Lysing Solution does not lyse nucleated erythrocytes, which are present in certain animal species.

12. Vortex cells thoroughly and incubate for 10 min at room temperature.

13. Centrifuge sample for 5 min at 1500 × *g*, 4°C. Remove supernatant and wash cells once with PAB as in step 4.

14. Resuspend cells in 500 µl PAB with gentle vortexing.

15. Keep samples on ice until analyzed using a flow cytometer.

    The FACS Lysing Solution contains formaldehyde, so no further cell fixation is required for longer-term storage.

ASSESSMENT OF CELL VIABILITY

SUPPORT PROTOCOL 3

Cell viability should routinely be assessed in all flow cytometric analyses. Because the membrane integrity of dead cells has been compromised, most antibodies will freely pass through such membranes and stain dead cells nonspecifically. This nonspecific staining can make data difficult, if not impossible, to interpret and ultimately lead to erroneous conclusions.

In general, cell viability is high (>95%) when lymphoid cells are taken directly from animal tissues, unless the mechanical process used to create single-cell suspensions has resulted in large numbers of dead cells. In contrast, the viability of cultured cells can be quite low, especially when these cells are chemically treated. In either case, to minimize

cell death during sample processing, all cell preparations and staining procedures (including wash steps) should be performed at 4°C or on ice and in the presence of BSA or heat-inactivated FBS. The elimination of dead cells prior to staining is not recommended, since any manipulation of the cell sample could lead to the inadvertent loss of viable cells. Cells should be stained promptly after they are harvested and, if not fixed, analyzed in a flow cytometer as soon as possible.

To assess cell viability, a sample of unstained cells is incubated with a DNA dye, such as propidium iodide (PI) or 7-aminoactinomycin D (7-AAD); dead cells will stain positively for either of these two nuclear dyes. Next, a data acquisition region is placed around the positively stained cells. By color-eventing or backgating on the PI^+ or $7\text{-}AAD^+$ cells present, one can easily discern that most, *but not all*, dead cells exhibit lower forward scatter (FS) and higher side scatter (SS) than do viable cells. A gating region is then established around a cluster of viable cells (PI-negative) on the basis of their light scatter profile. This gating region can be used for all subsequent samples, even if these samples do not include a viability indicator. However, the best method for excluding dead cells from data analysis is to use a vital DNA dye in all samples. Some of the more common vital dyes used in multicolor analyses are PI, 7-AAD, TO-PRO-3 (Molecular Probes), and pyronin Y(G) [PY(G)].

Materials

Nuclear staining compound dissolved in PBS (*APPENDIX 2A*): 200 μg/ml PI, 250 μg/ml 7-AAD, 250 μg /ml TO-PRO-3 (Molecular Probes), or 200 μg/ml PY(G)

12 × 75–mm polystyrene tubes
Flow cytometer

1. Add 500 μl cells (1–2 × 10^6; unfixed and unstained) to a 12 × 75–mm polystyrene tube.
2. Add 5 μl PI to tube.

   Alternatively, add 4 μl 7-AAD, 4 μl TO-PRO-3, or 5 μl PY(G).

3. Incubate cells on ice for at least 5 min.
4. Analyze cells by flow cytometry.

SUPPORT PROTOCOL 4

TITRATION TO DETERMINE OPTIMUM ANTIBODY CONCENTRATION

The single most important factor in selecting an appropriate antibody is antibody quality. Good antibodies are characterized by their high specificities and high binding affinities, which allow specific staining to be distinguished from nonspecific staining. However, even with high-quality antibodies, it is important to determine the optimal staining concentration (or titer) for each MAb. This titer will ensure that cells are stained under saturating conditions. Under such conditions, specific fluorescence will not be readily influenced by cell number or incubation time (Kantor and Roederer, 1997). The method for titrating MAbs has previously been described by Stewart and Stewart (2001a).

Materials

Lymphoid cell suspension of interest (see Support Protocol 1)
Fc receptor (FcR)-blocking immunoglobulin (Ig) solution, 200 μg/ml
Fluorochrome-conjugated antibody solutions to be tested

Centrifuge fitted with a microtiter plate adapter
Vortex mixer fitted with a microtiter plate adapter
Flow cytometer

1. Add 2×10^6 lymphoid cells to each of five wells in a 96-well microtiter plate.
2. Centrifuge cells for 3 min at 200 to 1500 × *g*, 4°C, in a centrifuge fitted with a microtiter plate adapter.
3. Block FcR-mediated binding by adding 50 µl FcR-blocking Ig to each well, vortexing gently using a vortex mixer fitted with a microtiter plate adapter, and then incubating samples for 10 min on ice.
4. Without removing the FcR-blocking Ig added in step 3, add 0.125, 0.25, 0.5, 1.0, and 2.0 µg of MAb, respectively, to the five wells containing lymphoid cells. Vortex cells gently and incubate for 10 min on ice.
5. Acquire immunofluorescence data using a flow cytometer
6. Create a two-parameter histogram of forward scatter versus side scatter and establish an appropriate gating region that encompasses the majority of viable cells.
7. Display fluorescence data from viable cells in single-parameter histograms. Establish one region that encompasses the negative population and a second region that brackets the positive population. Determine the median channel of fluorescence (MCF) for each region.
8. Compute the signal-to-noise (S/N) ratio, treating the positive population as the signal (S) and the negative population as the noise (N). Plot the calculated S/N ratios as a function of MAb concentration.
9. Identify the optimal MAb titer (i.e., the titer that produces the highest S/N ratio).

Once the optimal titer is determined, it is not necessary to increase the amount of antibody used for staining unless the number of cells per sample exceeds 20 million. Even then, the amount of antibody needed for staining will only increase by a factor of two or three. However, it cannot be stressed enough that time and effort should be taken to optimize staining conditions (staining temperature, antibody concentration, staining time, and cell number) prior to any study. Doing so can also save money, as the manufacturer's recommended staining concentration is often higher than necessary.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see APPENDIX 2A; for suppliers, see SUPPLIERS APPENDIX.

ACK lysing buffer

0.15 M NH_4Cl
10 mM $KHCO_3$
0.1 mM disodium EDTA
Adjust pH to between 7.2 and 7.4 using 1 M HCl
Filter sterilize using a 0.2-µm filter
Store at room temperature
If the buffer is stored for an extended period, check its pH before use.

HBSS, pH 7.2, supplemented with 5% (v/v) FBS

1× Hanks' balanced salt solution (HBSS; Sigma) containing:
1 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES)
5% (v/v) fetal bovine serum (FBS), low-endotoxin, characterized (HyClone)
1 mM sodium pyruvate
Adjust pH to 7.2 using 1 N NaOH
Store up to 1 month at 4°C

PBS, pH 7.2, supplemented with sodium azide and BSA

Dulbecco's PBS, calcium- and magnesium-free (e.g., Life Technologies), containing:
0.1% (w/v) sodium azide
1% (w/v) BSA
Adjust pH to 7.2 using 1 N NaOH or 1 N HCl
Filter solution through 0.22-μm filter paper
Store up to 1 month at 4°C

EDTA (1 mM) can be added to reduce cellular aggregation.

CAUTION: *Be extremely careful when handling sodium azide.*

COMMENTARY

Background Information

Secondary anti-Ig antibodies

Although indirect staining with secondary fluorochrome-conjugated anti-Ig antibodies is the least desirable staining method, due to problems with nonspecific staining, there are certain precautions that can be exercised to minimize these problems. The secondary anti-Ig antibody is usually a polyclonal anti-Ig antibody that is specific for a large number of epitopes on the primary antibody. Since polyclonal secondary antibodies will be directed against all the Ig isotypes (e.g., IgG, IgA, IgM) found in the serum of the animal from which they were derived, these antibodies should be purified by affinity chromatography so that their binding is restricted to the heavy chain of the appropriate Ig isotype. The binding of the secondary anti-Ig antibody can be further restricted by selecting a reagent with no light-chain activity (i.e., one that is Fc fragment–specific). This will further ensure that the anti-Ig antibody is highly specific for a particular class of Ig (e.g., IgG) and thus minimize cross-reactions with other Ig isotypes. In addition, it is essential to use the F(ab) or $F(ab')_2$ fragment of the affinity-purified secondary antibody to minimize FcR-mediated binding and, hence, reduce background staining. For example, a goat $F(ab')_2$ anti–mouse IgG antibody (heavy and light chain–specific, purified by affinity chromatography) is specific for the heavy chain of mouse IgG but will also bind to other Igs that have the same light chain as IgG (e.g., IgA, IgM). Therefore, this reagent is not specific for mouse IgG at all. The authors have had great success using polyclonal secondary antibodies purchased from Jackson ImmunoResearch Laboratories.

The binding of a secondary antibody can be further restricted to a specific Ig isotype and subclass. For example, if a rat IgG_1 MAb specific for CD4 were being used as the primary MAb, one could select a secondary MAb specific for rat IgG_1, if available.

In all cases, it is necessary to determine the optimum antibody titer as well as assess the binding specificity of the secondary anti-Ig antibody prior to a study. First, the secondary antibody should not react with any cellular epitope. This can be assessed by simply incubating the cells of interest with the secondary antibody alone. The signal produced by this staining should be nearly identical to the signal yielded by unstained cells. If not, the reagent is inappropriate and should be replaced. Second, if this secondary antibody is used in multicolor analyses, it should not cross-react with any other MAb used for staining. To test for potential reagent interactions, incubate two samples of cells with the fluorochrome-conjugated MAb, followed by washing. Next, add the secondary anti-Ig antibody to one sample and PAB to the other sample. The fluorescence pattern of the sample stained with the secondary anti-Ig reagent should be nearly identical to the pattern produced by the sample stained with PAB. If the fluorescence pattern is different, the secondary antibody in question should not be used in multicolor analyses.

Fluorochrome choice

Fluorochrome choice is highly contingent on the availability of the laser lines available on a particular flow cytometer. For instance, the Beckman Coulter XL flow cytometer is equipped with a single argon ion laser tuned to a wavelength of 488 nm, the most common wavelength used in flow cytometry. This instrument can handle up to four fluorescent emissions, all from dyes that can be excited by the 488-nm wavelength, but it cannot process the signal generated by a MAb conjugated to allophycocyanin (APC), which must be excited by a 633-nm laser line. However, APC signals can be processed on any benchtop analyzer, such as the FACScalibur

(BD Biosciences) or the FC500 (Beckman Coulter), that is equipped with a HeNe laser.

For multicolor analyses, there are a number of factors to be considered when selecting a MAb conjugated to a particular fluorochrome. This selection is particularly important when using antigens that are expressed at low density, as some fluorochromes have higher absorption coefficients and/or higher quantum yields than others, making them more suitable for detecting weakly expressed antigens. In order to achieve the highest possible staining intensity, select antibodies conjugated to the brightest possible fluorochromes, e.g., in order, from brightest to dullest—PE, PE-Cy5, PE–Texas Red, APC, and FITC. In general, the fluorescence emitted by MAbs conjugated to PE, PE-Cy5, and APC is 5 to 10 times brighter than the fluorescence emitted by FITC conjugates. PE is often the fluorochrome of choice when examining the expression of an antigen that is expressed at low levels (e.g., CD25, CD69) or detecting the presence of intracellular cytokines.

New fluorochromes are continually being developed, and they can be used in addition to or instead of the dyes mentioned above. Molecular Probes (2004b) has produced a new series of dyes, called the Alexa Fluor dyes, that exhibit more intense fluorescence than do other spectrally similar conjugates. For example, Alexa488, whose fluorescence spectrum is nearly identical to that of fluorescein isothiocyanate (FITC), is considered by many to be the best FITC-like reagent. A number of MAbs conjugated to Alexa488 can be obtained from commercial sources. If the experiment necessitates the use of a second-step reagent, the authors use fluorochrome-labeled SA, which is readily available from commercial sources, to stain biotin-labeled MAbs. For simple one- or two-color analyses, the second-step reagent of choice for the authors is PE-labeled SA, which will stain at the highest possible level. For multicolor studies, the authors routinely use a tandem conjugate PE–Texas Red–labeled SA. It is possible that PE-Alexa610-labeled SA, by virtue of its low background staining, may be a better option than the PE–Texas Red fluorochrome, which can exhibit the high background staining that is typical of Texas Red dyes. The authors rarely use FITC-labeled SA but have had great success with Alexa488-labeled SA, which is far superior to its FITC-labeled counterpart.

All MAbs should be stored in the dark, as most fluorochromes are photosensitive. PE-Cy5 and PE-Cy7 tandem conjugates are particularly sensitive to photodegradation. This phenomenon can easily be recognized by an increase in the PE signal and a concomitant decrease in the Cy5 or Cy7 signal. Use of cyanine tandem dyes can result in increased background staining, as these dyes can bind to monocytes and B cells. However, this binding is highly species-dependent; for instance, background binding can be high in mice with autoimmune disorders. Thus, again, it is prudent to assess the background staining of the reagents used prior to a large study.

Multicolor staining combinations for routine immunophenotyping of murine cells

Table 18.8.1 presents examples of possible staining strategies that can be used to phenotype various cell populations in the mouse. It is becoming increasingly clear that no single marker can be used to specifically identify a unique subset of cells. For instance, expression of CD4 and CD8a is not restricted to T cells, as these molecules are also expressed on subsets of dendritic cells ($CD11c^+$). In addition, CD4 is expressed on a subset of natural killer (NK) cells. Thus, in order to ensure that only T cells are analyzed, a MAb specific for CD3e, a marker that is expressed on thymocytes and mature T cells, can be included in the MAb cocktail. The authors have also found that the correlated expression of two markers, CD11b and Gr-1, is needed to phenotype either macrophages or granulocytes in mouse spleen. Both of these cell types express CD11b and Gr-1; however, the level of Gr-1 is lower on macrophages than on granulocytes. The two populations are more clearly resolved by including additional markers that are expressed on the macrophage, such as F4/80, CD86, or CD54 (Choi et al., 2003). It is essential to recognize that many markers can be expressed at varying levels on different cell types.

Critical Parameters

Autofluorescence

Cellular autofluorescence is most often associated with myeloid cells, due to the presence of intracellular flavins in such cells. These flavins are easily excited by the 488-nm laser line, with peak emission occurring around 525 nm. Therefore, any signal generated by autofluorescent cells will be processed by the same photomultiplier tube (PMT) that processes FITC fluorescence. It is obvious that the presence of highly autofluorescent cells can contribute an unwanted addition to the FITC signal. Autofluorescence can

Table 18.8.1 Examples of Possible Antibody Combinations for Staining Mouse Leukocytes Using Five Fluorochrome-Labeled Monoclonal Antibodies in a Staining Cocktail, with Analysis Performed on an FC500 Flow Cytometer (Beckman Coulter) with Dual Laser Excitation at 488 nm and 633 nm[a]

Cell type(s)	Possible combination of stains
T cells, NK cells	FITC-anti-CD4 PE-anti-CD3e Biotin-anti-NK1.1[b] PE-Cy5–anti-CD8[c] PE-Cy7–anti-CD45[d,e]
Viable T cells	FITC-anti-CD4 PE-anti-CD3e Biotin-anti-NK1.1[b] 7-AAD[f] PE-Cy7–anti-CD8
Granulocytes, dendritic cells, B cells, macrophages	FITC-anti-Gr-1 PE-anti-CD11c ECD-anti-B220[g] PE-Cy5–anti-CD11b PE-Cy7–anti-CD45
Activated T cells	FITC-anti-CD8 PE-anti-CD25 ECD-anti-CD4 PE-Cy5–anti-CD62L[h] PE-Cy7–anti-CD8

[a]Abbreviations: 7-AAD, 7-aminoactinomycin D; APC, allophycocyanin; FITC, fluorescein isothiocyanate; MAb, monoclonal antibody; NK, natural killer; PE, phycoerythrin.

[b]This biotinylated MAb necessitates the use of streptavidin labeled with PE–Texas Red or equivalent.

[c]PE-Cy5-labeled MAb could be replaced by a MAb conjugated to APC or equivalent.

[d]PE-Cy7-labeled MAb could be replaced by a MAb conjugated to APC-Cy7 or equivalent.

[e]CD45 is a pan-leukocyte marker that is very useful in discriminating leukocytes from contaminating red blood cells, especially in the phenotyping of peripheral blood cells. A gating region can be established on the $CD45^+$ leukocyte population as defined in a two-parameter histogram of side scatter versus CD45 expression.

[f]7-AAD is a DNA dye used as a viability indicator in unfixed cell samples. Its peak emission wavelength is 660 nm.

[g]ECD is the trade name for the PE–Texas Red tandem conjugate produced by Beckman Coulter. Very few mouse marker–specific MAbs that are directly conjugated to this fluorochrome are available.

[h]Because CD62L can easily be shed from the surface of cells, it is imperative to keep cells on ice throughout staining and data acquisition. The authors recommend that samples stained with anti-CD62L be kept on ice until loaded manually onto the flow cytometer for data collection. The use of a multisample carousel is not recommended when analyzing cells stained for CD62L, since cells cannot be kept cold while on such a device.

be particularly bothersome when measuring weak FITC fluorescence signals. If there are excessive numbers of myeloid cells in the experimental samples, the resulting high level of autofluorescence may make it difficult to interpret data. A sample of unstained cells can be used to determine the contribution of cellular autofluorescence to the background fluorescence signal as well as the minimum level of fluorescence exhibited by cells.

There are several approaches that can be used to circumvent the problems associated with cellular autofluorescence. When studying myeloid cells, it may be prudent to use MAbs that are conjugated to APC or APC-Cy7, as these dyes can be excited by a HeNe laser and emit at wavelengths greater than 600 nm, beyond the emission spectrum for cellular autofluorescence. When immunophenotyping lymphocytes in a sample containing elevated numbers of myeloid cells, one could include a MAb that specifically identifies the myeloid cells (such as one specific for Gr-1, a marker of myeloid/granulocyte lineage). The use of such an antibody allows one to gate out granulocytes and macrophages, thereby eliminating cellular autofluorescence from analysis.

Blocking FcR-mediated binding

There are two ways that an antibody can specifically bind to cells. Antibodies can bind to a specific antigen (epitope-specific binding) through their antigen-binding sites, the F(ab′) fragment, or they can bind to myeloid cells that express receptors for the Fc portion of the Ig. Even though FcR-mediated binding is not antigen-specific, it is highly specific and needs to be eliminated in order to assess antigen-specific staining.

FcR should be blocked with normal Ig prior to staining with epitope-specific MAbs. The authors typically incubate cells for 10 min at 4°C with purified normal Ig (Jackson ImmunoResearch Laboratories) taken from the same species that produced the antibodies used for staining. For instance, if a rat IgG_{2a} anti-CD4 MAb is used, FcR-mediated binding should be blocked with an excess of purified rat IgG. The use of 10 μg of normal IgG in a staining volume of 50 μl (final concentration, 200 μg/ml) should be sufficient to block FcR. After 10 min of blocking, the MAbs are added directly to the samples without removing the FcR block, so that epitope-specific staining can proceed in the presence of FcR-block. Another approach to blocking FcR is to incubate cells with an unconjugated MAb that is specific for the FcR (CD16/CD32). It should be noted that this approach is more expensive than the former approach. In any case, do not block FcR if there is interest in assessing FcR expression.

Isotype controls

Isotype controls are also used to determine the minimum level of cellular fluorescence following staining and to assess the effectiveness of FcR blocking. An isotype control must match the primary MAb in terms of isotype and subclass, as well as fluorochrome label and concentration. For example, the appropriate isotype control for cells incubated with 0.5 μg FITC-labeled rat IgG_{2a} MAb (specific for mouse CD4) is 0.5 μg FITC-labeled normal rat IgG_{2a}. The appropriate isotype control for cells stained with biotin-labeled rat IgG_1 MAb (specific for CD8) is treatment with biotin-labeled normal rat IgG_1, followed by incubation with fluorochrome-conjugated SA.

For multicolor analyses, one isotype control sample can be set up to assess all the MAb isotypes in a single tube. It is not necessary to analyze each isotype control separately. For example, a sample of cells can be incubated, in the presence of an FcR block, with a cocktail of isotype-matched Igs for each specific MAb used in the staining procedure. The fluorescence pattern of the isotype control should be nearly identical to that of the autofluorescence control. When this is not the case, it is indicative of an improperly titrated MAb, a poor-quality MAb, or both. This could have a profound effect on one's ability to interpret positive fluorescence, especially when studying antigens that are expressed either transiently or at very low levels.

In general, the authors have found that some isotype Igs (e.g., IgM, IgG_{2b}) exhibit more background staining than others, which can complicate the analysis of antigens expressed at very low levels. This is particularly relevant in analysis of intracellular antigens. In these cases, a cold block control is performed to verify antibody specificity. This can easily be accomplished by comparing the fluorescence of two cell samples, with one being pretreated with a cold blocking MAb (i.e., the same clone as the experimental MAb, but with no conjugate) for 15 min prior to the addition of the fluorochrome-conjugated MAb. The binding of the fluorochrome-conjugated MAb should be completely inhibited by the cold block. For example, to assess the expression of CD25, which can be present at low levels on activated T cells, cells are pretreated with unlabeled purified anti-CD25 MAb (at a 3-fold higher concentration compared with the conjugated MAb) for 15 min prior to the addition of the fluorochrome-conjugated anti-CD25 MAb. This sample should represent a true negative control for CD25 staining. Background staining for cell surface expression of CD69, another T cell marker that is transiently up-regulated upon activation, can be assessed similarly. Due to the complexities involved in multicolor analyses, it is prudent to invest a little time to test these conditions prior to a large study.

Background staining exhibited by cells stained with multiple reagents is very different from that seen in unstained cells or isotype controls, due to the broadening artifacts produced by compensation (see below) and/or reagent-reagent interactions. Therefore, the best negative control for any given marker in a multicolor stain is a sample of cells stained with all but one reagent (commonly referred to as "fluorescence minus one," or FMO). For example, when assessing CD25 expression on antigen-specific D011.10 T cells, the best negative control for CD25 expression is a cocktail containing MAbs to CD3, CD4, and KJ-126 (to identify the antigen-specific T cells in the D011.10 model) plus an isotype control for the CD25 MAb. In this way, the level of negative

staining for CD25 expression can be assessed by gating on the antigen-specific T cells.

Dead cells

Cell viability must be assessed in each experimental study. Since most MAbs freely pass through the cell membranes of dead and damaged cells, dead cells will stain positively even if there is no specificity for a particular MAb. This nonspecific fluorescence can interfere with data analysis, and if ignored, it can result in erroneous interpretation of the data.

For exclusion of dead cells, vital DNA dyes such as PI, 7-AAD, and TO-PRO-3 can be added to unfixed cell samples prior to analysis. These dyes cannot be used to assess the viability of cells that are permeabilized (as for intracellular staining) or fixed, since they will leak out of fixed cells. On the other hand, the vital dye ethidium monoazide (EMA; final concentration, 1 to 5 μg/ml) can be used to label dead cells prior to fixation (Reidy et al., 1991). Once inside a dead cell, EMA can be photochemically cross-linked to the DNA by exposure to visible light. This cross-linking allows EMA to be retained by fixed cells.

Compensation

One of the most critical issues in performing multicolor phenotyping is dealing with overlaps in the spectral emissions of different fluorochromes. Once excited by the laser, a fluorochrome will emit a broad band of light. Even though a band-pass filter is often placed in front of a PMT to restrict the wavelengths of light that are transmitted to the tube, it is nearly impossible to exclude all of the light emitted by the other fluorochromes used in multicolor staining. Because of these spectral overlaps, each fluorochrome will contribute an unwanted light signal to several PMTs that are not assigned to detect that fluorochrome. For example, there is significant overlap in the spectral emissions of FITC and PE, so much so that some of the FITC emission spills over into the PE PMT and it must be eliminated from this PMT before analyzing PE fluorescence. By the same accord, PE contributes an unwanted signal to the FITC PMT, albeit at much lower levels, and this signal must be eliminated from the FITC PMT. If not eliminated, these spillovers will make a "false" contribution to the data. The process by which these false contributions are eliminated electronically is called compensation.

Compensation is one of the least understood processes in multicolor analyses. It is important to consider compensation not only from the standpoint of applying it correctly but also from the perspective of designing and analyzing multicolor experiments. Investigators need to be able to recognize data that has resulted from improper compensation, as failure to do so can easily result in data misinterpretation. Any spillover signal not completely compensated (i.e., undercompensated) out of a PMT can result in an overestimation of the positive population. Proper compensation is always essential when measuring antigen density by MCF.

Compensation is often considered a process by which unwanted fluorescent signals are "subtracted" from the true fluorescent signal. However, compensation is not a subtraction process, but rather a straightforward application of linear algebra by which a proportion of the unwanted signal is eliminated from the true fluorescent signal. For some fluorochrome combinations, such as FITC and PE-Cy5 or APC, there is little, if any, overlap in spectral emissions; therefore, compensation is negligible. However, there is considerable overlap in the emission spectra of the PE, PE–Texas Red, and PE-Cy5 dyes, enough to make compensation quite challenging even for investigators who routinely perform multicolor analyses.

In order to set up compensation properly, a sample of cells must be stained with a representative reagent for each fluorochrome used in the experiment. The number of compensation controls will be equivalent to the number of fluorochromes used in staining. For example, five-color staining requires five compensation controls, one for each fluorochrome. It is not necessary to use the same MAbs in the experiment as in the compensation controls. This is especially true when a particular experimental reagent is expected to stain just a small subset of cells. For example, the frequency of antigen-specific T cells ($KJ1\text{-}26^+CD4^+$) adoptively transferred in the D011.10 model can be as low as 0.3% one day after injection with ovalbumin. Thus, it would be very difficult, if not impossible, to properly set compensation levels using the conjugated MAb that stains $KJ1\text{-}26^+$ cells. What is important is using the brightest possible reagents for compensation controls. Therefore, the authors routinely set up compensation controls using CD45, CD8a, CD19, or CD45R MAbs conjugated to the appropriate fluorochromes. These markers are expressed at high levels on most immune cells, making it much easier to properly set compensation levels. In order to set up compensation properly, the compensation control sample must contain at least two populations—specifically, one bright population and one

negative or not-so-bright population. When examining spleen cells, there will be two distinct populations that stain for MAbs to CD8a and CD45R; one is positive, and the other is negative. Because CD45 stains all leukocytes, it is necessary to add an aliquot of unstained cells to the CD45 compensation control after the staining process but just prior to flow analysis to artificially create a negative population.

There are two ways to perform compensation. Hardware compensation is performed during data acquisition, whereas software compensation is performed during data analysis. Because of the complexity of five-color analyses, the authors routinely collect flow cytometric data without performing hardware compensation in such analyses. Instead, prior to analyzing the experimental data using offline software, the data collected from compensation controls are used to perform software compensation using WinList software (Verity). The authors have found no disparity in the results obtained using software compensation as compared with hardware compensation.

Compensation controls must be evaluated in every possible pairwise combination using two-parameter histograms. For example, in studies using FITC, PE, and PE-Cy5 fluorochromes in a single sample, the FITC compensation control must be evaluated using the following two-parameter histograms: FITC versus PE and FITC versus PE-Cy5. Two-color samples require the assessment of just one pairwise combination, three-color samples require three combinations, four-color samples require six combinations; and five-color samples require ten combinations. Thus, it should be readily apparent that the complexity of compensation increases substantially with the addition of each fluorochrome. To properly set compensation levels, the center of the positive cell population (i.e., as determined by the median fluorescence intensity) is lined up with the center of the negative cell population. This is accomplished by adjusting compensation until the median channel for the positive population is equal to the median channel for the negative population. It is important to ensure that the fluorescence distribution for the negative population is not piled up on the baseline axis, as this will make it nearly impossible to determine the median channel and, thus, very difficult to set up compensation properly. An in-depth discussion on compensation can be found online (Roederer, 2000).

Not all flow cytometers can handle all the possible pairwise combinations that may be necessary for hardware compensation. For example, the Beckman Coulter FC500 and XL flow cytometers are capable of handling the pairwise compensation involving FITC and PE-Cy5, but the BD FACSCalibur is not. It can be argued that, in general, there is minimal, if any, FITC emission that spills over into the PE-Cy5 PMT. However, when using carboxyfluorescein diacetate succinimidyl ester (CFSE), a low but measurable signal from this dye can spill over into the PE-Cy5 PMT. Thus, when using the BD FACSCalibur, in lieu of hardware compensation, one must rely on software compensation to eliminate unwanted CFSE signal from the PE-Cy5 detector.

It is possible to minimize the need for compensation by carefully selecting reagents that are conjugated to fluorochromes whose emissions have little or no spectral overlap. For two-color analyses, the authors often select MAbs that are conjugated to FITC and either APC or PE-Cy5, since there is little, if any, overlap between the emission spectrum of FITC and the emission spectra of the latter two dyes. Beyond two-color analyses, fluorochrome choice gets more complicated with each additional fluorochrome. In general, PE–Texas Red–conjugated MAbs are used by the authors only when performing five-color immunophenotyping, as this fluorochrome has considerable spectral overlap with both PE and PE-Cy5 emissions, making compensation quite challenging. Of lesser importance, there are very few MAbs that are directly conjugated to PE–Texas Red, and two-step staining procedures are therefore often required. If a HeNe laser is available, the authors often select APC- or APC-Cy7-labeled reagents over PE-Cy5 conjugates.

Control samples

In order to ensure that data are collected and interpreted correctly, several control samples must be faithfully evaluated prior to running the experimental samples. These include controls to assess cellular autofluorescence, nonspecific binding, FcR-mediated binding, and compensation.

Sometimes, the number of essential control samples exceeds the number of experimental samples. However, it is only through the proper use of all appropriate control samples that data can be collected and interpreted correctly. Controls can be performed for each animal, but this can easily lead to excessive numbers of control samples. For large studies, a pool of cells is created for each treatment group, and this pool is used to test for autofluorescence and isotype staining. In this way, a pool will

contain representative cells from each animal in a given treatment group. For example, in an experimental study in which the effects of three different dose levels of a chemical are examined, there will be four pools of cells, each representing a particular treatment group (one for the vehicle control group and one for each of the three dose levels). Each treatment pool will have its own autofluorescence control and its own isotype control, resulting in a total of four autofluorescence controls and four isotype controls.

To assess autofluorescence, a sample of unstained cells (with no MAbs added) is processed in a similar fashion as for all experimental samples. This sample should always be analyzed first in an experiment. To begin, the voltages for the photodetectors collecting the light-scatter signals (both forward scatter and side scatter) are adjusted to define the cells of interest. Second, the voltage of each PMT is adjusted to place the negative cell population in the first log decade of the histogram. It is important to apply enough voltage to ensure that the majority of cells are off of the baseline; this assures that any positive staining will fall beyond the first log decade. In essence, this control sample provides the baseline representing the minimum (or negative) fluorescence exhibited by cells.

The next control to be analyzed is the isotype control. The fluorescence pattern of the isotype control should be similar to that of the unstained control if FcR-mediated binding has been blocked effectively. If not, one would need to evaluate the isotype controls used in the experiment. Like the autofluorescence control, the isotype control also determines the minimum level of fluorescence that is exhibited by cells.

For multicolor experiments, compensation controls must be analyzed in order to account for any spectral overlap not removed by filters. The number of compensation controls will be equivalent to the number of fluorochromes used in staining. Compensation is greatly simplified in four- or five-color analyses when the PMTs are balanced, with their voltages set at nearly identical levels. However, it is crucial to remember that once compensation is set, any change in the PMT voltages will necessitate repetition of the entire compensation process.

Standardization of flow cytometric data

There are three sources of error that can be introduced during immunophenotypic analysis: specifically, instrumental, technical, and biological. However, the amount of error introduced by the instrument can easily be minimized. The instrument's overall performance should be routinely evaluated prior to data acquisition using standardized beads, such as Beckman Coulter Flow-Check beads. These beads will assess the instrument's fluidics and optics to ensure proper alignment of the laser with the sample stream. Once the fluidics and optics have been checked, the authors routinely run a sample of Flow-Set beads (Beckman Coulter) to further standardize the instrument's settings. These beads mimic the immunofluorescence exhibited by human and mouse cells and can be used at the voltages required for immunophenotypic analyses. The voltages and gain settings for each photodetector are adjusted to position the fluorescence emitted by the beads within a prescribed region, a process commonly referred to as channel positioning. In this way, any apparent change in marker expression over time can be expected to be biologically relevant, and not a result of changes in the instrument.

Once it has been established that the instrument is performing under the expected experimental conditions, negative controls (autofluorescence and isotype) can be analyzed to ensure that the negative population falls within the first log decade for each channel being measured. Next, compensation controls should be performed to remove any unwanted fluorescence from the various PMTs due to overlaps in the spectral emissions of the fluorochromes used. It should be noted that improper compensation can result in false-positive or false-negative results, so great care should be exercised when performing these controls.

Once the instrument's settings have been established, the authors routinely run a control sample, referred to as the verification control, in order to determine whether the system will provide accurate information. This control sample is stained with a set of MAbs that are conjugated to the same fluorochromes used in the experimental study but are specific for well-recognized markers. For example, in a five-color staining experiment (using MAbs conjugated to FITC, PE, PE–Texas Red, APC, and APC-Cy7), the verification tube would contain MAbs specific for CD4, CD8, CD3, CD45R, and Gr-1, with each of these MAbs being conjugated to one of the fluorochromes used in the study. In general, spleen cells from a naive mouse are used in these controls. Not only are the authors familiar with the staining profiles of these markers, but they have established a historical record that they can use for comparison with the observed relative

frequencies. In short, this verification control is expected to yield easily recognizable data that enable the authors to make any necessary final changes to compensation values. Once the verification control has produced the expected results, one can be confident that the flow cytometer will provide accurate results for the experimental samples.

Data analysis

The authors routinely acquire listmode data on 10,000 cells of interest when performing multiparametric analysis. For example, when immunophenotyping spleen cells for lineage-specific markers (such as markers of B cell, T cell, macrophage, or granulocyte lineage), they typically collect flow cytometric data on 10,000 viable spleen cells. If the authors are interested in analyzing cell surface markers gated on a discrete subset, such as antigen-specific $CD4^+$ cells in the D011.1 model (which can represent as little as 0.5% to 4% of the total population), they collect data on 10,000 antigen-specific $CD4^+$ cells. Following data acquisition, flow cytometric data can be displayed in either single-parameter or two-parameter histograms to monitor the cells of interest. In this way, gating and analysis strategies can be fine-tuned.

Figure 18.8.1 illustrates one approach to the analysis of five-color flow cytometric data. The data represented in this figure are derived from studies monitoring the events of T cell activation in the graft-versus-host (GvH) response. T cells (both $CD4^+$ and $CD8^+$) were purified from the spleens of C57Bl/6 mice ($H\text{-}2^b$; referred to as donors) and injected into C57Bl/6 ($H\text{-}2^b$) $\times$ DBA/2 F_1 mice ($H\text{-}2^d$; referred to as hosts). The donor T cells recognize the $H\text{-}2^d$ antigens contributed by the DBA/2 strain in the F_1 host and become activated. Two days after the injection of these donor T cells, the F_1 mice were sacrificed, and their spleens were processed into single-cell suspensions. Spleen cells were then stained simultaneously with a cocktail of five MAbs specific for CD4, $H\text{-}2D^d$, CD28, CD25, and CD62L.

As shown in Figure 18.8.1A, a cluster of spleen cells was first identified by its light scatter profile (FS vs. SS), as is customary in flow cytometry. A rectilinear region was then established to exclude dead cells, debris, and cell aggregates from further analysis. This process is referred to as gating. The FS-versus-SS profile of dead cells, as determined by PI uptake, indicated that these cells were located below the gating region (data not shown). In general, the authors find that the viability of their splenic suspensions often exceeds 97%. When immunophenotyping blood cells, the authors routinely include a MAb to the pan-leukocyte marker CD45, which allows them to set a gate around all the leukocytes present, thereby eliminating, or gating out, residual RBCs and platelets; this is most often performed by setting a gate around the appropriate cell clusters as defined by their CD45-versus-SS profiles.

Two days after adoptive transfer into F_1 mice, one can easily identify a small but distinct cluster of cells that represent the donor $CD4^+$ cells (Fig. 18.8.1B). These cells are identified by their expression of CD4 and their lack of expression for $H2D^d$. As shown in this two-parameter histogram, the majority of cells, which are the host cells, express $H2D^d$. Only a small population of cells lacks $H2D^d$ expression, representing the donor T cells. An elliptical region has been set to establish a gate for these $CD4^+$ donor cells so that their expression of the T cell activation markers CD28, CD62L, and CD25 can be monitored throughout the course of the GvH response.

Gating on the donor $CD4^+$ cells (10,000) as shown in Figure 18.8.1B, one can generate single-parameter histograms that illustrate the expression of the T cell activation markers (Fig. 18.8.1C). The immunofluorescent profile for each marker is illustrated in the filled histograms, while the open histograms illustrate negative staining as determined by their appropriate isotype controls. Two populations can easily be distinguished on the basis of the differential expression of CD62L, $CD62L^{pos}$, and $CD62L^{neg}$. However, the staining profiles for CD25 or CD28, as seen in single-parameter histograms (Fig. 18.8.1C), are more homogeneous.

Figure 18.8.1D illustrates the power of multiparametric analysis. Multiple subpopulations can be resolved by displaying the correlated expression of two markers in two-parameter histograms. While there is a hint of two populations in each of the single-parameter histograms for CD25 and CD28 expression, one could easily identify two cell clusters by correlating the expression of these two markers in a two-parameter histogram. It is interesting to note that three distinct cell clusters can be distinguished on the basis of the correlated expression of CD62L and CD25 expression. One strategy is to "color-event" the events of interest. As shown in Figure 18.8.1D, two regions have been set around the cells that have down-regulated their expression of CD62L, one population expresses CD25 (color-evented red), and another does not express CD25

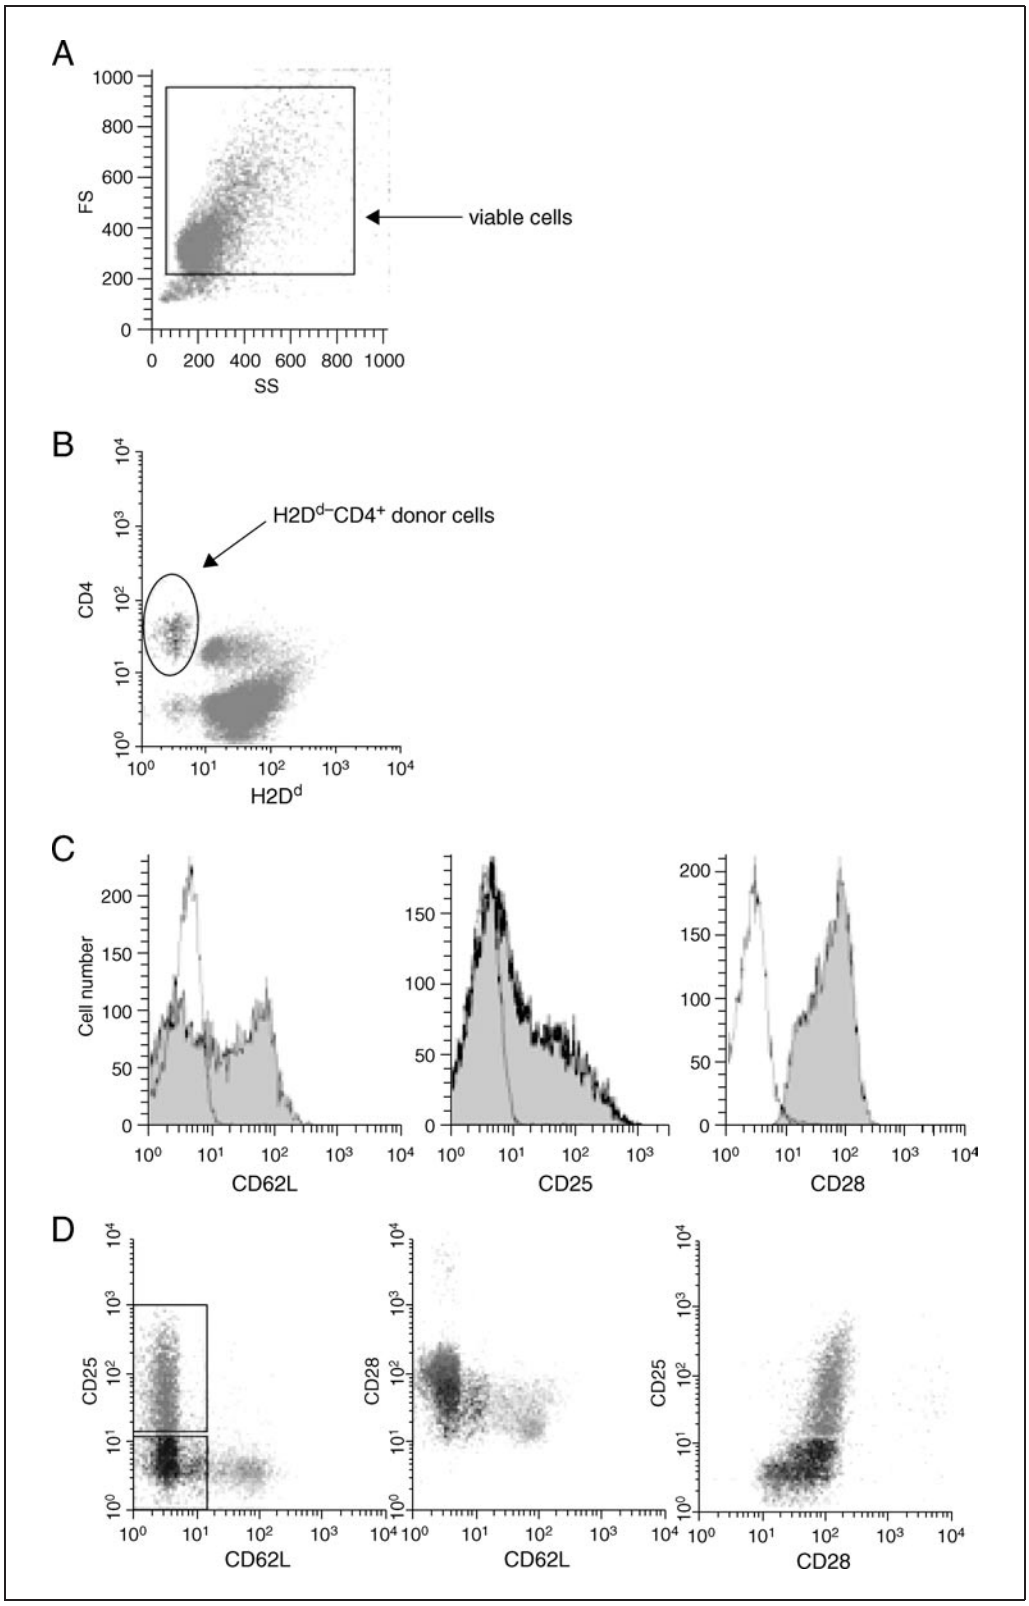

Figure 18.8.1 Legend at right.

(color-evented blue). The cells that have retained their CD62L expression have been color-evented gray. In this way, the expression of all their markers can be easily visualized for each population in all the histograms. For instance, the red population also expresses high levels of CD28 and elevated levels of CD4. In contrast, the blue population expresses intermediate levels of CD28 and CD4. By definition, both the red and blue cells are considered activated T cells since they have down-regulated their expression of CD62L; however, the red cells are further along in the activation pathway since they have also up-regulated their expression of CD25, which occurs only after several cell divisions. The gray population represents $CD4^+$ cells that have not become activated by day two of the GvH response.

There is a new approach in visualizing flow cytometric data, i.e., changing the traditional four-decade logarithmic scale for immunofluorescent data displayed in two-parameter histograms to a new Logicle axis (Tung et al., 2004). The plot axes have been redefined to allow the log-transformed scale to have a zero as well as a negative region. There are several advantages to this approach. Once data have been properly compensated, a large number of negative cells pile up in the first channel, against the axis, as these cells exhibit little to no fluorescence. Using the new Logicle scale, these negative cells can be visualized as distinct cell clusters. In addition, this new approach also makes it easier to assess compensation. Both FlowJo (Tree Star) and WinList (Verity Software House) offer the option to display flow cytometric data using the new Logicle axis.

Statistics

The data shown in Figure 18.8.1 represent the response of one individual animal. In most immunotoxicological studies, the authors use four to six animals per treatment group. In order to determine a treatment effect, data derived from the treatment group must be compared with data from the vehicle control group. The authors will often include a group of naive animals ($N = 2$ to 3) in order to monitor the antigen-induced response of the control animals.

In general, the authors prefer to present flow cytometric data in the form of histograms and use statistics to state the level of confidence in the accuracy of each result. Flow cytometric data are usually presented as the frequency of any given population that expresses a particular marker and/or as a measure of the intensity of the fluorescent or light scatter signals. There are three measures commonly used to describe the central tendency when assessing fluorescence intensity: mean, median, and mode. The mean fluorescence can be significantly skewed higher or lower by the presence of a few outliers. Therefore, when possible, one should use the median fluorescence of the positives, since

Figure 18.8.1 *(at left)* Five-color analysis of T cell activation in a graft versus host (GvH) model. T cells purified from the spleens of C57Bl/6 mice ($H\text{-}2^b$; referred to as donors) were injected into C57Bl/6 ($H\text{-}2^b$) x DBA/2 ($H\text{-}2^d$) F_1 mice. These donor T cells recognize the $H\text{-}2^d$ antigens contributed by the DBA/2 strain in the F_1 host and become activated. Two days after the injection of donor T cells, the F_1 mice were killed, and their spleens were processed into single-cell suspensions. The spleen cells were stained simultaneously with MAbs to CD4, $H\text{-}2D^d$, CD28, CD25, and CD62L. Cells were analyzed using an FC500 flow cytometer (Beckman Coulter). (**A**) Viable cells were identified on the basis of their forward scatter (FS)–versus–side scatter (SS) profiles. (**B**) $CD4^+$ donor cells (elliptical region) were identified by their expression of CD4 and their lack of expression of $H2D^d$. In this sample, the donor $CD4^+$ cells represent 1.9% of the total spleen cell population. (**C**) Expression of the T cell activation molecules CD28, CD25, and CD62L was assessed in single-parameter histograms by gating on 10,000 donor $CD4^+$ cells. Cells with positive staining for the specified MAbs are represented by the gray-filled histograms. Open histograms represent negative staining associated with the isotype control antibodies. (**D**) Correlated expression of activation molecules on donor $CD4^+$ cells as illustrated in two-parameter histograms. Donor $CD4^+$ cells that have up-regulated expression of CD25 are color-evented as red events. Using color-eventing, a distinct cluster of donor $CD4^+CD25^+$ cells that also express low levels of CD62L and high levels of CD28 is readily identifiable. When the data are displayed in a two-parameter histogram, the presence of at least three $CD4^+$ subpopulations distinguished by their differential expression of CD25 and CD62L is evident (far left histogram). It is interesting to note that not all cells with low CD62L expression exhibit high CD25 expression. Also of interest is that $CD4^+CD25^+$ cells have up-regulated expression of CD4, as shown in (B). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*

the median is generally a more robust estimate of central tendency than the mean.

The precision in cell counting, or the extent to which replicate samples agree with each other, is highly dependent on the number of events sampled. The statistic which is most often used to measure precision is the coefficient of variation (CV), which can be determined using the following simple equation:

$$CV = [(\sqrt{N})/N] \times 100\%$$

where N is the number of events sampled and the square root of N represents the expected standard deviation. As the difference between two populations becomes smaller, better and better precision (i.e., a lower CV) is needed. For example, the CV for 25 cells is 20%; for 100 cells, 10%; and for 10,000 cells, 1%. In the authors' laboratory, in order to attain high precision, flow cytometric data are routinely collected on a minimum of 10,000 cells of interest, whether one is acquiring 10,000 viable cells or 10,000 antigen-specific T cells (such as the $CD4^+$ donor cells shown in Fig. 18.8.1B).

Anticipated Results

The objective in flow cytometric analyses is to resolve epitope-positive cells from epitope-negative cells with a high degree of precision and accuracy. Sometimes, it is necessary to select a MAb that is labeled with a fluorochrome such as PE in order to maximize the resolution of positive cells from negative cells, especially when assessing dim immunofluorescence. However, there are several procedures that can be employed to ensure the collection of accurate results.

Proper setup will help to eliminate instrumental error as a source of variation within an experiment. The systematic process by which an instrument's performance is validated is known as quality control, and this process should be conducted for every experiment. There are several sequential quality control steps that should be followed (as discussed in Critical Parameters): (1) the use of standardized beads, such as Flow-Check fluorospheres (Beckman Coulter), to check laser alignment as well as the fluidics and optics of the system; (2) the use of standardized beads, such as Flow-Set fluorospheres (Beckman Coulter), for channel positioning (to ensure that changes observed in time-course studies are the result of biological effects and not of changes in the instrument); (3) the use of compensation controls to remove unwanted fluorescence from fluorochromes with overlapping spectral emissions; and (4) the use of a verification control to establish the accuracy of the results yielded by the system. Once the instrument has been validated, there are several technical issues that must be addressed, such as cellular autofluorescence, FcR-mediated binding, and the presence of dead cells, which can result in the collection of inaccurate data and possibly lead to data misinterpretation or erroneous conclusions.

It is easy to obtain high precision in flow cytometric data; this can be done by simply collecting data on a minimum of 10,000 cells of interest. As an example, when assessing activation markers on $CD4^+$ T cells, data should be collected by gating on 10,000 of these cells. The precision of a given measurement is usually characterized by the statistic CV, and for 10,000 events, the expected CV would be 1%. Thus, the assessment of 10,000 cells of interest will help to ensure that small differences between two populations may still be biologically significant.

It is only through these steps that one can be confident that the results obtained are accurate, and this can ensure the validity of data interpretation. This is of utmost importance when assessing treatment effects in toxicological studies. Treatment effects can be discerned by changes in the relative frequency of a particular lineage-specific population (e.g., $CD4^+$ T cells, B cells, macrophages) or by changes in the relative frequency of a specific subset within these major leukocyte populations (e.g., activated $CD4^+$ T cells, cytolytic T effector cells). Sometimes it is necessary to report changes in the MCF for a particular marker, especially when all the cells of interest homogeneously express that marker (e.g., CD11a, CD54). However, the bottom line in flow cytometric analysis is that each result is expected to accurately reflect the cell population(s) being sampled. In this way, one can be assured that the data can be correctly interpreted and valid conclusions derived. In-depth discussions on the issues presented can be found in Stewart and Stewart (2001b) and Shapiro (2003).

Time Considerations

The time required to process, stain, and analyze samples is contingent on many factors, including the number of animals in the experiment and the number of staining combinations. The time needed to prepare single-cell suspensions from lymphoid tissues depends on the organ to be processed (spleen, thymus, and/or lymph nodes). Spleen cell suspensions will require an extra

step in sample processing to remove RBCs, whereas thymus and lymph node cell suspensions will not. The use of microtiter plates will greatly expedite the staining of large numbers of samples derived from lymphoid organs. Even though blood samples require no further processing once the blood is collected, the staining process requires the use of test tubes or microcentrifuge tubes, making sample manipulation more time-consuming. The time required for cell staining is dependent on the number of cell samples to be stained and the staining method employed (direct or indirect). In general, the direct staining method will take 10 min for FcR blocking and 10 min for incubation with fluorochrome-conjugated MAbs, followed by 10 to 20 min for wash steps. Indirect staining will require an additional 20 min to incubate cells with the second-step reagent, followed by 10 to 20 min for wash steps. The time necessary to acquire flow cytometric data will vary depending on cell concentration and on the total number of events to be collected. For example, it should take less than 1 min per sample to collect 10,000 to 20,000 events when determining the various lineage-specific populations in a sample of spleen cells. However, it will definitely take longer to collect 10,000 events when gating on a smaller population. Instrumental setup will take much longer for multicolor analyses as compared with one-color analyses, as proper compensation will need to be established in multicolor studies. The time involved in data analysis is contingent on the number of fluorochromes used in each MAb cocktail as well as the number of samples processed. Data analysis can take as little as just a few minutes per sample for samples stained with one fluorochrome-conjugated MAb and as many as several hours for samples stained with five different colors.

In Vitro Model for Modulation of Helper T Cell Differentiation and Activation

This unit provides an in vitro model for evaluating the effects of toxicants on murine helper T cell (T_H) reactivities. Protocols are included for studying the effects of such compounds on the development of precursor or naive $CD4^+$ T_H cells (T_{H0} cells) into type-1 (T_{H1}) or type-2 (T_{H2}) T helper effectors (see Basic Protocol 1) and on antigen-specific activation of cloned T_{H1} or T_{H2} cells (see Basic Protocol 2). The T_{H1} and T_{H2} subsets can be distinguished by patterns of cytokine secretion, and they exhibit different helper function for cell-mediated or humoral immunity (Mosmann and Coffman, 1989; Romagnani, 1996). In general, the T_H subsets are best differentiated by their quantitative expression of select cytokines (T_{H0}, low levels of IL-2, IL-4, and IFN-γ; T_{H1}, high levels of IL-2 and IFN-γ; T_{H2}, IL-4, IL-5, IL-6, IL-10, and IL-13). For analysis of T_{H0} differentiation, use of T cells from clonotypic transgenic mice—i.e., DO11.10 ovalbumin-specific transgenic (OV-tg) mice—is described. T_{H1} and T_{H2} reactivities are most readily assayed with use of cloned T cell lines (Sanderson et al., 1985; Fiorentino et al., 1989). A helper T cell clone, namely the egg white conalbumin–specific D10.G4.1 T_{H2} clone from ATCC, is the only commercially available clone at the moment; therefore it is recommended that readers contact authors cited in this unit who have worked with specific helper T cell lines.

An in vitro antigen-specific system is valuable for assessing the influence of toxins and toxicants on antigen-dependent interactions between antigen-presenting cells and T cells. The effect of a toxicant on T_H development can be investigated by evaluating its modulation of the acquisition of IL-4- or IFN-γ-producing ability in vitro with antigen-primed naive $CD4^+$ T cells. For example, spleens from DO11.10 OVA-tg mice suit the present investigation, because a large proportion (>50%) of the T cells are OVA-specific, naive (if raised in a pathogen-restricted environment), $CD4^+$ T cells. Cloned T cell lines are also available and useful for evaluating toxicant-mediated alteration of antigen-dependent helper T cell activation resulting in cytokine secretion. The cloned T_{H1} (D1.6) and T_{H2} (CDC35) lines can be activated in vitro with rabbit IgG (RGG), if presented properly by I-A^d (major histocompatibility complex class II antigen, MHC II) antigen-presenting cells (APC), which include macrophages, dendritic cells, and B cells in the spleen or lymph nodes of H-2^d mice (e.g., BALB/c mice).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

ANTIGEN-DEPENDENT DEVELOPMENT OF NAIVE HELPER T CELLS TO MEMORY T CELLS

BASIC PROTOCOL 1

In this procedure, splenocytes from unimmunized OVA-tg mice are stimulated with ovalbumin (OVA) in the presence or absence of a test toxicant. T cells are expanded at 72 hr under the same culture conditions as were used for the primary stimulation, and harvested on Day 7. The cells are then washed and restimulated with OVA and antigen-presenting cells (APC) in the absence of the test toxicant. Culture supernatants collected at 48 hr are used for IL-4 and IFN-γ quantification by ELISA (*UNIT 18.7*).

Contributed by Yong Heo
Current Protocols in Toxicology (2005) 18.9.1-18.9.10

Materials

OVA-tg mice (The Jackson Laboratory)
RPMI 1640 medium (e.g., Invitrogen), ice-cold
Red blood cell (RBC) lysing buffer (see recipe)
Phosphate-buffered saline (PBS), pH 7.2 to 7.4 (*APPENDIX 2A*)
Complete RPMI medium (see recipe)
OVA antigen solution (see recipe)
Recombinant human interleukin 2 (IL-2; e.g., Roche)
Experimental toxicant(s) (e.g., $PbCl_2$)
Physiological saline: 0.9% (w/v) NaCl
BALB/c mice (The Jackson Laboratory)
60 × 15–mm petri dishes
Frosted-end microscope slides, sterilized by autoclaving
6- and 15-ml conical polypropylene centrifuge tubes
Low-speed refrigerated centrifuge (e.g., Beckman GPKR or equivalent equipped with GH3.7 swinging-bucket rotor)
Hemacytometer or automatic cell counter (e.g., Beckman Coulter)
24- and 12-well culture plates
^{137}Cs γ irradiator
Sandwich ELISA kits for IL-4 and IFN-γ (e.g., BD Pharmingen; optional)
Additional reagents and equipment for counting cells (*APPENDIX 3B*) and sandwich ELISA (*UNIT 18.7*; also see Heo et al., 1996)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Prepare a single-cell suspension of spleen cells

1. Collect spleen from OVA-tg mouse and place it in a 60 × 15–mm petri dish containing 6 ml ice-cold RPMI.
2. Homogenize spleen as follows. Wet two frosted-end microscope slides with ice-cold RPMI. Place spleen between the frosted surfaces of the two slides and gently grind into small pieces to dissociate the spleen and free the cells. Rinse the slides with the medium to recover remaining cells.

   It is necessary to work under a laminar flow hood from this point on to maintain sterility.
3. Transfer the homogenate to a 15-ml centrifuge tube. Rinse the petri dish with 1 ml RPMI to collect remaining cells and transfer this to the tube containing the rest of the homogenate. Place tube on ice and allow cells to settle 3 min.

   This incubation on ice serves to remove dead cells and other tissue debris, which settle by gravity.
4. Collect supernatant from the settled homogenate and transfer to another 15-ml centrifuge tube. Centrifuge 10 min at 350 × *g*, 4°C. Aspirate and discard supernatant. Resuspend cell pellet in the residual liquid by tapping tube with fingers.
5. Add 2.5 ml RBC lysing buffer and incubate ~3 min at room temperature. Centrifuge 10 min at 350 × *g*, room temperature, and discard supernatant.

   It is recommended that RBC lysis not exceed 3 min, because viability of other spleen cells could be affected if the incubation lasts longer.

6. Wash cells by resuspending cell pellet in 10 ml cold PBS, centrifuging 10 min at 350 × *g*, 4°C, and discarding supernatant. Repeat the wash step. Resuspend the cell pellet in 2 ml ice-cold complete RPMI medium and count cells using a hemacytometer or automated cell counter (*APPENDIX 3B*).

   Anticipate 60 × 10^6 spleen cells from one 4- to 6-week old OVA-tg mouse.

Perform primary stimulation and expansion

7. Determine cell number required for the experiment and resuspend the appropriate number of cells in ice-cold complete RPMI. Adjust the final suspension to 2 × 10^6 cells/ml.

8. Place a 1-ml aliquot of cell suspension into each well of a 24-well culture plate (prepare sufficient wells to test each experimental condition in duplicate). To each of these cell-containing wells, add 0.5 mg OVA antigen and 10 to 12 U human recombinant IL-2. Immediately add experimental toxicant such as $PbCl_2$ to appropriate wells. Incubate 72 hr.

   It is advisable to include a control well with medium only (no OVA and experimental additives). The final culture volumes of all wells should be made equal by substituting an appropriate amount of vehicle solution, such as physiological saline, for antigen or additives. The appropriate final concentrations of toxicant should be determined with consideration of cytotoxicity, determined by propidium iodide uptake assayed by flow cytometry. It is generally appropriate to use a nanomolar to micromolar range of concentrations for heavy metals or organic compounds.

9. At 72 hr, resuspend cells by vigorous pipetting with Pasteur pipet and transfer cells from each well of the 24-well culture plate to an individual 6 ml-polypropylene tube. Centrifuge 10 min at 350 × *g*, 4°C, and discard supernatants. Resuspend each cell pellet in 2 ml ice-cold complete RPMI and transfer cell suspension from each 6-ml tube to an individual well of a 12-well culture plate.

10. To the wells of the 12-well plate, add the same reagents that were added in step 8, but at 2-fold doses (e.g., 1 mg OVA and 20 to 24 U recombinant IL-2 per well, plus twice the dose of experimental toxicant). Incubate plates an additional 72 hr.

11. At end of expansion period (day 7) harvest cells by vigorous pipetting with 10 ml-pipet and transfer to 15 ml-centrifuge tubes. Centrifuge 10 min at 350 × *g*, 4°C, and discard supernatants. Wash cells three times using the technique described in step 5. Resuspend each cell pellet in 1 ml ice-cold complete RPMI and count viable cells by trypan blue exclusion (*APPENDIX 3B*).

    Anticipate 12–18 × 10^6 cells from one well with OVA only, without experimental additives.

    In the author's experience, it is not a problem to keep the cells from this step, which have undergone primary stimulation, on ice during the preparation of the APCs in steps 12 and 13, which will take ∼1 hr. However, it is also possible to prepare the APCs just before harvesting the cells that have undergone primary stimulation.

Set up cultures of restimulating memory cells (antigen-presenting cells, APC)

12. Prepare a single-cell suspension from BALB/c mouse spleen as described in steps 1 to 6.

    Anticipate 6–10 × 10^7 spleen cells from one 2- to 3-month old BALB/c mouse.

13. Using a ^{137}Cs γ irradiator, deliver 20 Gy of irradiation to the BALB/c mouse spleen cell suspension.

    These cells will function as antigen-presenting cells in the following restimulation steps.

14. Prepare 24-well culture plates, adding to each well:

    2.5×10^6 irradiated BALB/c mouse spleen cells in complete RPMI
    0.5 mg OVA antigen
    10 to 12 U recombinant human IL-2.

15. To each well, add the 2×10^5 of the cells obtained in step 11 (i.e., those that have undergone the primary stimulation), adjusting the final volume of each well to 1.3 ml with complete RPMI. Incubate 48 hr.

    The restimulation is perfomed in the absence of experimental additives to evaluate whether experimental additives present during the primary stimulation of naive helper T cells could direct skewing of helper T cell development toward the type-1 or type-2 helper T cell phenotype.

16. At the end of restimulation, transfer the culture suspension from each well to an individual 6 ml-centrifuge tube. Centrifuge 10 min at $350 \times g$, 4°C, and collect each supernatant in an individual 1.7-ml microcentrifuge tube. Keep the supernatants in freezer below −20°C prior to cytokine ELISA.

Determine skewing of naive helper T cells differentiation

17. Determine level of IL-4 and IFN-γ for each individual culture supernatant by a sandwich ELISA (*UNIT 18.7*).

    IL-4 and IFN-γ in culture supernatants can be quantitated by a sandwich ELISA method described in the literature (Heo et al. 1996) or supplied commercially (e.g., BD PharMingen). Briefly 96-well Immulon 4 plates (Dynex) are coated by overnight incubation at 4°C with capture MAb (100 μl/well; 2 μg/ml). The plates are washed three times and, after a 2-hr incubation with 200 μl per well of PBS containing 10% heat-inactivated FBS at room temperature, the supernatants or the cytokine standards are added to appropriate wells in duplicate. After overnight incubation at 4°C, the plates are washed six times and 100 μl per well (1 μg/ml) of biotinylated detection MAb is added. Plates are then incubated at room temperature for 2 hr, washed six times, and further incubated with 100 μl per well (2.5 μg/ml) of avidin-peroxidase for ∼1 hr before detection using the substrate, 2,2′-azino-bis (3-ethylbenzthiazoline 6-sulfonic acid). Absorbance is measured at 405 nm. The amounts of cytokines are calculated from the linear portion of the standard curves. The capture/detection MAb pairs are as follows: IL-4, BVD4-1D11/BVD6-24G2; IFN-γ, R4-6A2/XMG1.2. It is necessary to dilute the supernatants ≥ 10-fold for IFN-γ, but supernatants are used undiluted for IL-4 measurement.

18. Calculate IL-4 versus IFN-γ ratio, and compare the ratio with that for the OVA antigen control (OVA supplementation in the absence of experimental additives at primary stimulation described in step 8).

    The IL-4:IFN-γ ratio is calculated by dividing the amount of IL-4 by the amount of IFN-γ in supernatants from each individual well.

BASIC PROTOCOL 2

ANTIGEN-DEPENDENT ACTIVATION OF CLONED T_H CELLS

In this procedure, resting D1.6 T_{H1} (Kurt-Jones et al., 1987) and CDC35 T_{H2} cells (Tony et al., 1985) are stimulated in the presence or absence of a test toxicant with irradiated BALB/c mouse splenocytes and antigen (RGG). Culture supernatants are collected at 48 hr and used for IL-4 and IFN-γ quantification by ELISA.

Materials

BALB/c mice (The Jackson Laboratory)
T_H cells: D1.6 T_{H1} clone and CDC35 T_{H2} clone (available from Dr. David Lawrence, New York State Department of Health; *david.lawrence@wadsworth.org*)
Recombinant human interleukin 2 (IL-2; e.g., Roche)

RGG antigen stock solution (see recipe)
Complete RPMI medium (see recipe)
RPMI 1640 medium (e.g., Invitrogen)
Ficoll-Paque (Amersham Biosciences)
Phosphate-buffered saline (PBS), pH 7.2 to 7.4 (*APPENDIX 2A*)
Experimental toxicant(s) (e.g., $PbCl_2$)
Physiological saline: 0.9% w/v NaCl
^{137}Cs γ irradiator
12- and 24-well culture plates
15- and 50-ml conical polypropylene centrifuge tubes
15-ml conical polystyrene centrifuge tubes
Low-speed refrigerated centrifuge (e.g., Beckman GPKR or equivalent equipped with GH3.7 swinging-bucket rotor)
Additional reagents and equipment for counting cells (*APPENDIX 3B*), preparing mouse spleen cells (see Basic Protocol 1, steps 1 to 6), and sandwich ELISA (*UNIT 18.7*; also see Heo et al., 1996)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Prepare irradiated spleen cells

1. Prepare a single-cell suspension from BALB/c mouse spleen (see Basic Protocol 1, steps 1 to 6).

   Anticipate 6–10 $\times$ 10^7 spleen cells from one 2- to 3-month old BALB/c mouse.

2. Using a ^{137}Cs γ irradiator, deliver 20 Gy of irradiation to the BALB/c mouse spleen cell suspension.

   These cells will function as antigen-presenting cells in the following steps.

Prepare lymphocytes

3. Prepare resting T_H cells by adding the following to each well of a 12-well culture plate:

   5×10^6 irradiated BALB/c mouse spleen cells in complete RPMI
   2×10^5 T_{H1} or T_{H2} cells
   20 to 24 U recombinant human IL-2
   0.2 mg RGG antigen
   Complete RPMI to 2 ml.

   Incubate plate 2 weeks.

4. Resuspend the resting T_H cells by vigorous pipetting with a Pasteur pipet and transfer the contents of all wells containing T_{H1} cells to one 50-ml conical polypropylene centrifuge tube and the contents of all wells containing T_{H2} cells to a second 50-ml polypropylene centrifuge tube. Rinse each well with 1 ml plain RPMI 1640 medium to collect remaining cells, and transfer to the corresponding 50-ml tube containing the rest of the cells. Centrifuge the tubes 10 min at 350 $\times$ *g*, 4°C, and discard the supernatants.

5. Resuspend each cell pellet in the residual liquid by tapping the tube with the fingers, and add 2 ml complete RPMI to each of the pellets.

6. For each tube prepared in steps 2 and 3, prepare a 15-ml conical polystyrene centrifuge tube containing 3 ml Ficoll-Paque. Carefully layer the 2-ml cell suspension (step 3) on top of the Ficoll-Paque.

   It is preferable to use polystyrene centrifuge tube for Ficoll-Paque density gradient isolation of viable cells because the tube is clear, making it easier to identify the lymphocyte layer.

7. Centrifuge the Ficoll-Paque gradients 15 min at 800 × *g*, room temperature. Using a sterile Pasteur pipet, transfer the lymphocyte layer to a clean 15-ml polypropylene centrifuge tube.

   The lymphocyte layer is generally found at the interface between the RPMI solution and the Ficoll-Paque.

8. Wash cells three times, each time by adding 10 ml ice-cold PBS, centrifuging 10 min at 350 × *g*, 4°C, and removing the supernatant. Resuspend cells in 1 to 2 ml complete RPMI. Take an aliquot and count viable cells (*APPENDIX 3B*).

Set up cultures for stimulation

9. Prepare irradiated BALB/c mouse spleen cells (in complete RPMI) as described in steps 1 and 2 of this protocol. Prepare 24-well culture plates, adding to each well:

   2.5×10^6 irradiated BALB/c mouse spleen cells in complete RPMI
   1×10^5 T_{H1} or T_{H2} cells (from step 8)
   10 to 12 U recombinant human IL-2.

   Adjust the volume of each well to 1 ml with complete RPMI.

10. Add 0.1 mg RGG antigen to each well. Add experimental toxicants, e.g., $PbCl_2$, to appropriate wells. For each individual experimental condition, set up duplicate wells.

    It is desirable to include a control well with cells only (no RGG or experimental additives). The final culture volumes of all wells should be made equal by substituting appropriate amount of vehicle solution, such as physiological saline, for the RGG antigen or experimental toxicants. In the author's experience, the final culture volume in each well will be equal to 1.3 ml.

11. Incubate plates 48 hr. Collect supernatant from each well in an individual 1.7-ml microcentrifuge tube. Keep the supernatants in freezer below −20°C prior to cytokine ELISA.

Evaluate cytokine expression

12. Determine level of IL-4 for T_{H2} supernatants or IFN-γ for T_{H1} supernatants by a sandwich ELISA (*UNIT 18.7*; also see Basic Protocol 1, step 17 annotation). Compare cytokine levels in experimental samples with those obtained for the RGG antigen control (RGG only without experimental additives; see step 10 annotation).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete RPMI medium

RPMI 1640 medium (e.g., Invitrogen) containing:
10% (v/v) fetal bovine serum (FBS), heat-inactivated 1 hr at 56°C
2 mM L-glutamine
50 μM 2-mercaptoethanol
1 mM sodium pyruvate
1× nonessential amino acids (Invitrogen)

continued

1× penicillin/streptomycin/neomycin (PSN) mixture (Invitrogen)
0.075% (w/v) $NaHCO_3$
Store up to 1 week at 4°C.

OVA antigen stock solution

Completely dissolve 2 g ovalbumin (OVA; Sigma, grade V; endotoxin < 10) in 100 ml physiological saline (0.9% w/v NaCl) and filter sterilize through a 0.45-μm low-protein-binding membrane filter (Corning). Determine OVA concentration by spectrophotometry at 280 nm, dividing the optical density value at that wavelength by 0.735 to obtain the concentration of OVA in mg/ml. Aliquot and store indefinitely in freezer below −20°C.

RBC lysing buffer

4.415 g NH_4Cl (0.15 M)
0.5 g $KHCO_3$ (10 mM)
18.6 mg Na_2EDTA (0.1 mM)
440 ml deionized, distilled H_2O
Adjust pH to 7.2 to 7.4 with 1 N HCl.
Add H_2O to 500 ml.
Filter sterilize through a 0.22-μm membrane filter.
Store indefinitely at room temperature.

RGG antigen stock solution

Completely dissolve 0.2 g rabbit IgG (RGG, Sigma cat. no. I-5006) in 100 ml physiological saline (0.9% w/v NaCl) and filter sterilize through a 0.45-μm low-protein-binding membrane filter. Determine RGG concentration by spectrophotometry at 280 nm, dividing the optical density value at that wavelength by 1.5 to obtain the concentration of RGG in mg/ml. Aliquot and store indefinitely in freezer below −20°C.

COMMENTARY

Background Information

Helper T cells have been subdivided into at least two distinct subsets based on the pattern of cytokine secretion; type-1 T cells produce IL-2 and IFN-γ (and other cytokines), but not IL-4, IL-5, or IL-10, while type-2 T cells produce IL-4, IL-5, and IL-10 (and other cytokines), but not IL-2 or IFN-γ (Cherwinski et al., 1987; Kurt-Jones et al., 1987). Among those cytokines, IL-4 and IFN-γ are known to be the cytokines most useful for defining the effector T_{H2} and T_{H1} phenotype subsets, respectively (Sedar and Paul, 1994). The production of distinct cytokines is believed to play a major role in the predominance of T_{H2} cells over T_{H1} cells or vice versa, which results in alteration of immune homeostasis between cell-mediated and humoral immunity, leading to various immunopathologic states such as lowered protection against microorganismal infection, allergic state, or autoimmune diseases. Concerning immune-modulatory ability of xenobiotics, differential influences of heavy metals (e.g., mercury and lead) or diesel exhaust particles on helper T cell activities have been demonstrated, which can cause aberrant cell-mediated immunity or humoral immunity (Prigent et al., 1995; Heo et al., 1996, 2001).

Murine T lymphocytes reactive with OVA have been primarily studied with the aim of obtaining specific T cell subsets in the presence of syngeneic BALB/c mouse spleen cells as a source of APC (Hsieh et al., 1992). When T cells from nonimmunized OVA-tg mice are stimulated in vitro with OVA and APC in the presence of immunotoxicant for 6 days, and subsequently restimulated in the absence of the immunotoxicant, these T cells acquire the capacity to produce substantial amounts of T_{H1} (e.g., IFN-γ) and T_{H2} (e.g., IL-4) cytokines, but they display an altered ratio of IL-4 versus IFN-γ compared with T cells primed with OVA only. The in vitro differentiation model described in Basic Protocol 1 might be close to the in vivo environmental conditions in which differentiation occurs. Basic Protocol 1 can be further extended using naive $CD4^+$ T cells from OVA-tg/RAG (recombinase activating gene)$2^{-/-}$ mice, in which endogenous T cell receptor TCR-α expression

is completely depleted and $CD44^+/LECAM^{low}$ memory T cells and B cells are not present (Rulifson et al., 1997). Owing to the complete lack of memory T cells and any TCR other than the DO11.10 clonotype in the OVA-tg/RAG $2^{-/-}$ mice, it is possible to exclude possible contamination with memory T cells in the in vitro differentiation model using OVA-tg mice. Mice bearing transgenic T cell receptor specific for hen egg lysozyme (Desbarats et al., 1999), pigeon cytochrome *c* (Vratsanos et al., 2001), or myelin basic protein (Olivares-Villagómez et al., 1998) could be used for antigen-dependent differentiation of naive helper T cells to memory T cells.

Cell lines expressing I-A^d (e.g., A20, K46R, 2PK3, BCL_1 B cell line, or PU5, WEHI-265 monocytic cell line) can be employed as antigen-presenting cells (APC) for activating the CDC35 or D1.6 T_H cells (Walker et al., 1982; Harris et al., 1984; Zuckerman et al., 1988; Spencer et al., 1993). Use of cell lines for the APC source provides two advantages: first, mice do not have to be sacrificed, and, second, homogeneous preparations of B cells versus monocytic lines can be compared. Furthermore, dendritic cells with high levels of MHC class II expression also can be used as APC; these are prepared by plastic adherence and rosetting with antibody-coated sheep erythrocytes following collagenase digestion of a BALB/c splenocyte suspension (Inaba et al., 1998).

Resting cloned CDC35 or D1.6 T_H cells can also be stimulated with polyclonal stimulators such as immobilized anti-mouse CD3 or phorbol 12-myristate 13-acetate (PMA) plus ionomycin (Basic Protocol 2). To investigate signaling pathways modulated by immunotoxicant, the author recommends parallel use of antigen/APC-dependent TCR-mediated stimulation with RGG and irradiated syngeneic APC, accessory cell–independent CD3/TCR complex–mediated stimulation with immobilized anti-CD3, and stimulation bypassing phospholipase C–initiated early signaling events with PMA for activation of protein kinase C, plus a calcium ionophore for upregulation of intracellular free calcium (Heo et al., 1997).

Critical Parameters and Troubleshooting

Experience has shown that cells should be completely harvested through vigorous pipetting at the time of expansion and restimulation of OVA-specific T cells (Basic Protocol 1). It will be necessary to rinse culture wells once with RPMI and collect the rinsed-out suspension as well.

It is recommended that exogenous recombinant IL-2 be added for in vitro differentiation of naive T_H cells and activation of T_H clones. Although cloned T_H cells can proliferate and be activated in culture when stimulated with antigen in the absence of exogenous IL-2, better growth of T_H cells is obtained when these are cultured with both IL-2 and antigen. IL-2 is known not to have direct effects on T_H subset differentiation (Duncan and Lawrence, 1995).

When an irradiation source is not available, treatment of APC with mitomycin C (a DNA cross-linking agent) can be used; like irradiation, this preserves the antigen-presenting function of syngeneic antigen-presenting cells. Mitomycin C should be completely washed out prior to mixing the APC with cloned T_H cells, because mitomycin C exerts its cytotoxicity by blocking cell division. Since activated lymphocytes will tend to enlarge, microscopic examination of the cultures for blasts will give an indication of successful activation. Meanwhile, to obtain T_H clonal cells at stationary phase, the cells should be passaged at least 14 days after initiating culture with soluble antigen (Kimoto and Fathman, 1982).

With all assays, it is critical that cultures in each well be adjusted to equal final volumes in order to correctly compare the resulting levels of cytokines. Experience has shown that recovery of live lymphocytes from spleen or culture wells is significantly enhanced if the resuspensions after each centrifugation are done by first discarding the supernatant, then resuspending the cells by tapping the tube with the fingers, and finally adding the solution for resuspension, in that order.

Anticipated Results

Using Basic Protocol 1, ~50 ng/ml of IFN-γ and 1 ng/ml of IL-4 will be detected in a well in which 2×10^5 OVA-specific T_H cells, differentiated in the absence of experimental additives, are stimulated with 2.5×10^6 APC. Skewing of T_H cell development toward the T_{H2} phenotype has been reported in the presence of heavy metal (25 μM Pb) during the primary stimulation of naive T_H cells with OVA. With this concentration of Pb, Heo et al. (1997) detected 1.2±0.2 ng/ml IL-4 and 32±7 ng/ml IFN-γ, while with no experimental additives, they detected 0.8±0.2 ng/ml IL-4 and 57±9 ng/ml IFN-γ. Using Basic Protocol 2, the levels of IL-4 and IFN-γ from CDC35 T_{H2} and D1.6 T_{H1} cells stimulated with RGG alone will be ~2 to 4 ng/ml and 4 to 8 ng/ml, respectively.

Pb-induced differential effects on activities of T_{H2} and T_{H1} cells has been demonstrated using CDC35 T_{H2} and D1.6 T_{H1} clones, in that the levels of IL-4 from CDC35 and IFN-γ from D1.6 clonal cells were 1.6±0.6 and 3.5±0.1 ng/ml, respectively. Addition of 25 μM Pb enhanced IL-4 production to 128% and inhibited IFN-γ production to 53% (Heo et al., 1997).

Time Considerations

In Basic Protocol 1, 2 to 3 hr of work are required for the steps from removal of spleens up to the point where the cells are ready for incubation on culture plates. Following an additional 6 days of primary stimulation and expansion, preparation of antigen-presenting cells and mixed culture with resting OVA-specific T_H cells takes ~4 hr. In Basic Protocol 2, preparing APCs and setting up the mixed culture with resting D1.6 or CDC35 T_H clonal cells takes ~4 hr. The exact length of time will depend on the size of the experiment and the skill of investigator.

USEFUL INFORMATION

Safe Use of Radioisotopes

The use of radioisotopes to label specific molecules in a defined way has greatly furthered the discovery and dissection of biochemical pathways. The development of methods to inexpensively synthesize such tagged biological compounds on an industrial scale has enabled them to be used routinely in laboratory protocols, including many detailed in this manual. Although most of these protocols involve the use of only microcurie (μCi) amounts of radioactivity, some (particularly those describing the metabolic labeling of proteins or nucleic acids within cells) require amounts on the order of millicuries (mCi). In all cases where radioisotopes are used, depending on the quantity and nature of the isotope, certain precautions must be taken to ensure the safety of the scientist. This appendix outlines a few such considerations relevant to the isotopes most frequently used in biological research.

In designing safe protocols for the use of radioactivity, the importance of common sense, based on an understanding of the general principles of isotopic decay and the importance of continuous monitoring with a hand-held radioactivity monitor (e.g., Geiger counter), cannot be overemphasized. In addition, it is also critical to take into account the rules, regulations, and limitations imposed by each specific institution. These are usually not optional considerations: an institution's license to use radioactivity normally depends on strict adherence to such rules.

Many of the protocols described have evolved (and are evolving still) over the years. The authors are indebted to those who have trained them in the safe use of radioactivity, in particular to the members of the Salk Institute Radiation Safety Department. Most of the designs for the shields and other safety equipment shown in Figures A.1A.2A, A.1A.3, and A.1A.4 were created at the Salk Institute in collaboration with Dave Clarkin and Mario Tengco. Safety equipment of similar design is available from several commercial vendors, including CBS Scientific and Research Products International.

BACKGROUND INFORMATION

The Decay Process

As anyone who has taken a basic chemistry course will remember, each element is characterized by its atomic number, defined as the number of orbital electrons or the number of protons in the nucleus of that atom. Isotopes of a given element exist because some atoms of each element, while by definition having the same number of protons, have a different number of neutrons and therefore a different nuclear weight. It should be noted that the number of electrons outside the nucleus remains the same for all isotopes of a given element, and so all isotopes of a given element are equivalent with respect to their chemical reactivity.

Radioactive decay occurs when subatomic particles are released from the nucleus of an atom of a heavy isotope. This often results in the conversion of an atom of one isotope to an isotope of a different element, because the original isotope's atomic number changes after decay. The subatomic particles released from naturally occurring radioisotopes are of three basic types: α and β particles and γ rays (see Table A.1A.1).

An α particle is essentially the nucleus of a helium atom, or two protons plus two neutrons. It is a relatively large, heavy particle that moves slowly and usually only across short distances before it encounters some other atom with which it interacts. These particles are released from isotopes with large nuclei (atomic number >82; e.g., plutonium or uranium); such isotopes are not commonly used in biological research.

In contrast to α particles, β particles are light, high-speed charged particles. Negatively charged β particles are essentially electrons of nuclear origin that are released when a neutron is converted to a proton. Release of a β particle thus changes the atomic number and elemental status of the isotope.

γ radiation has both particle and wave properties; its wavelength falls within the range of X-ray wavelengths. The distinction between γ rays and X rays was made when primitive X-ray machines produced X rays with a wavelength longer than those of the γ rays produced naturally by radioisotopes. Modern X-ray machines

Table A.1A.1 Physical Characteristics of Commonly Used Radionuclides[a]

Nuclide	Half-life	Emission	Energy, max (MeV)	Range of emission, max	Approx. specific activity at 100% enrichment (Ci/mg)	Atom resulting from decay	Target organ
^{3}H	12.43 years	β	0.0186	0.42 cm (air)	9.6	$^{3}_{2}He$	Whole body
^{14}C	5370 years	β	0.156	21.8 cm (air)	4.4 mCi/mg	$^{14}_{7}N$	Bone, fat
^{32}P[b]	14.3 days	β	1.71	610 cm (air) 0.8 cm (water) 0.76 cm (Plexiglas)	285	$^{33}_{16}S$	Bone
^{33}P[b]	25.4 days	β	0.249	49 cm	156	$^{33}_{16}S$	Bone
^{35}S	87.4 days	β	0.167	24.4 cm (air)	43	$^{35}_{17}Cl$	Testes
^{125}I[c]	60 days	γ	0.27–0.035	0.2 mm (lead)	14.2	$^{125}_{52}Te$	Thyroid
^{131}I[c]	8.04 days	β	0.606	165 cm (air)	123	$^{130}_{54}Xe$	Thyroid
		γ	0.364	2.4 cm (lead)			

[a]Table compiled based on information in Lederer et al. (1967) and Shleien (1987).
[b]Recommended shielding is Plexiglas; half-value layer measurement is 1 cm.
[c]Recommended shielding is lead; half-value layer measurement is 0.02 mm.

produce a much broader spectrum of wavelengths, including γ radiation; currently this sort of X-ray radiation is termed γ when it is of nuclear origin. Unlike β-particle release, the release of γ radiation by itself produces an isotopic change rather than an elemental one; however, the resultant nuclei are unstable and often decay further, releasing β particles.

The energy of all α particles and γ rays (measured in electron volts) is fixed, because they are of specific composition or wavelength. The energy of β particles, however, varies depending on the atom they originate from (and with concomitant release of neutrinos or antineutrinos that serve to balance the conservation of energy aspect of the decay equation). Thus there are (relatively) high-energy β particles released during the decay of ^{32}P and low-energy β particles released when tritium (^{3}H) decays.

Isotopic decay usually involves a chain or sequence of events rather than a single loss of a particle, because the resultant, equally unstable atoms try to achieve equilibrium. During this course of decay, secondary forms of radiation can be generated that may also pose a hazard to workers. For example, when high-energy β particles released during the decay of ^{32}P encounter the nuclei of atoms with a large atomic number, a strong interaction occurs. The β particle loses some energy in the form of a photon. Such photons are called Bremsstrahlung radiation; they are detectable using a monitor suitable for the detection of γ or X rays.

Following their release, α, β, and γ emissions (as well as secondary forms of radiation) travel varying average distances at varying average speeds, depending on their energy and the density of the material through which they are moving. The distance they actually travel before encountering either the electrons or nucleus of another atom is termed their degree of penetrance. This value is expressed as an average for each type of particle. The energy of the particles released (and therefore their potential penetrance) thus dictates what type of shielding, if any, is necessary for protection against the radiation generated by the decay of a given isotope. α, β, and γ emissions all have the potential, upon encountering an atom, to knock out its electrons, thereby creating ions. Thus, these three types of emissions are called ionizing radiation. The formation of such ions may result in the perturbation of biological processes: therein lies the danger associated with radioactivity!

Measuring Radioactivity and Individual Exposure to It

The radioactivity of a given substance is measured in terms of its ionizing activity. A curie (Ci) by definition is the amount of radioactive material that will produce 3.7×10^{10} disintegrations per second (see Table A.1A.2). This, not coincidentally, happens to be the number of disintegrations that occur during the decay of one gram of radium and its decay products. Exposure to such radiation is measured as the amount of energy absorbed by the recipient, which, of course, is directly related to the potential damage such radiation may cause. One rad is the dose of radiation that will

Table A.1A.2 Conversion Factors for Radioactivity

Measurement of Radioactivity

The SI unit for measurement of radioactivity is the becquerel:

1 becquerel (Bq) = 1 disintegration per second

The more commonly encountered unit is the curie (Ci):

1 Ci = 3.7×10^{10} Bq
= 2.22×10^{12} disintegrations per minute (dpm)
1 millicurie (mCi) = 3.7×10^{7} Bq = 2.22×10^{9} dpm
1 microcurie (μCi) = 3.7×10^{4} Bq = 2.22×10^{6} dpm

Conversion factors:

1 day = 1.44×10^{3} min = 8.64×10^{4} sec
1 year = 5.26×10^{5} min = 3.16×10^{7}sec
counts per minute (cpm) = dpm × (counting efficiency)

Measurement of Dose

The SI unit for energy absorbed from radiation is the gray (Gy):

1 Gy = 1 joule/kg

Older units of absorbed energy are the rad (r) and roentgen (R):

1 r = 100 ergs/g = 10^{-2} Gy
1 R = 0.877 r in air = 0.93 – 0.98 r in water and tissue

The SI unit for radiation dosage is the sievert (Sv), which takes into account the empirically determined relative biological effectiveness (RBE) of a given form of radiation:

dosage [Sv] = RBE × dosage [Gy]

$$\text{RBE} = \frac{\text{(biological effect of a dose of standard radiation [Gy])}}{\text{(biological effect of a dose of other radiation [Gy])}}$$

RBE = 1 for commonly encountered radionuclides

The older unit for dosage is the rem (roentgen-equivalent-man):

1 rem = 0.01 Sv

cause 100 ergs of energy to be absorbed per gram of irradiated material. Another unit commonly used to measure radiation doses is the rem; this is related to the rad but takes into account a "quality factor" based on the type of ionizing radiation being received. For β particles and γ or X rays this factor is 1; therefore, rems β equal rads β. In contrast, the quality factor associated with α particles is 20, so an exposure of one rad due to α particles would be recorded as 20 rem.

The amount or dose of radiation received by materials (cells, scientists, etc.) near the source depends not only on the specific type and energy (penetrance) of the radiation being produced, but also on the subject's distance from the source, the existence of any intervening layers of attenuating material (shielding), and the length of time spent in the vicinity of the radiation source. To best measure such doses, every person working with or around radioactivity should wear an appropriate type of radiation detection badge (in addition to carrying a portable radiation monitor that can give an immediate, approximate reading). This is normally a requirement for compliance with an institution's license to use radioisotopes. Such badges are usually furnished by the safety department and collected at regular intervals for reading by a contracted company. At most institutions, the old-style film badges have been replaced with the more accurate TLDs (thermoluminescent dosimeters). These take advantage of chemicals such as calcium or lithium fluorides which, following exposure to ionizing radiation, will luminesce at temperatures below their normal thermal luminescence threshold. Different types of badges are sensitive to different types of radiation: always be sure to wear one that is appropriate for detecting exposure to the isotope being used! In most places pregnant women are asked to wear a more sensitive (and more expensive) dosimeter to better monitor their (and the developing fetus') exposure. Most often workers will be asked to wear a radiation detection badge on the labcoat lapel in order to measure whole-body radiation. When working with ^{32}P or ^{125}I it is also advisable to wear a ring badge to measure exposure to the unshielded extremities (fingers). The

limit set for "acceptable" exposure to whole-body radiation is several-fold less than the limit set for extremities. Nevertheless, the authors have found that the exposure recorded on ring badges is often significant with respect to the limit for extremities set by our institution.

What is known about the effects on humans of exposure to low levels of radiation (i.e., levels which would be received when briefly handling millicurie or microcurie amounts of radioactivity)? Not much, for the obvious reason that direct studies have not been undertaken. Accordingly, guidelines for exposure levels are set using extrapolations—either by extrapolating down from population statistics obtained following accidents or disasters (the Chernobyl meltdown, atomic bombings) or by extrapolating up from numbers obtained from animal experiments. Each form of extrapolation is subject to caveats, and given that predictions based on such extrapolations cannot be perfect, most health and safety personnel aim for radiation exposure levels said to be ALARA or "as low as reasonably achievable." Further discussion of exposure limits and the statistics on which they are based may be found in B. Shleien's health physics text (Shleien, 1987). Limiting exposure to radiation can be accomplished by adjusting several parameters of the exposure: the duration of exposure, distance from the source, and the density of the material (air, water, shielding) between the individual and the source.

Time is of the essence

When designing any experiment using radioactivity, every effort should be made to limit the time spent directly handling the vials or tubes containing the radioactive material. Speed should be encouraged in all manipulations, though not to the point of recklessness! Have everything needed for the experiment ready at hand before the radioactivity is introduced into the work area.

Distance helps to determine dose

When possible, experiments involving radioactivity should be performed in an area separate from the rest of the lab. Many institutions require that such work be performed in a designated "hot lab"; however, if many people in the laboratory routinely use radioisotopes, it is less than feasible to move them all into what is usually a smaller space. No matter where an individual is working, it is his or her responsibility to monitor the work area and ensure his or her own safety and the safety of those working nearby by using adequate shielding. Obviously, when handling the radioactive samples, it is necessary to work rapidly behind any required shielding. To protect bystanders, remember that the intensity of radiation from a source (moving through air) falls off in proportion to the square of the distance. Thus, if standing 1 foot away from a source for 5 min would result in an exposure of 45 units, standing 3 feet away for the same amount of time would result in an exposure $(1/3)^2$ of 45 units, or 5 units. This factor is also relevant when considering the storage of large amounts of radioactivity, particularly ^{125}I or ^{32}P, as no amount of shielding can completely eliminate radiation.

Shielding is the key to safety

As mentioned above, the energy of the particle(s) released during the decay of an isotope determines what, if any, type of shielding is appropriate (see Table A.1A.3). β particles released during the decay of ^{14}C and ^{35}S possess roughly ten times the energy of those released when ^{3}H decays. All three β particles are of relatively low energy, do not travel very far in air, and cannot penetrate solid surfaces. No barriers are necessary for shielding against this type of β radiation. The major health threat from these isotopes occurs through their accidental ingestion, inhalation, or injection.

β particles released during the decay of ^{32}P have 10-fold higher energy than those released from ^{14}C and pose a significant threat to workers. (One reported hazard is the potential for induction of cataracts in the unshielded eye.) The fact that these high-energy beta particles can potentially generate significant amounts of Bremsstrahlung radiation is the reason that low-density materials are used as the primary layer of shielding for ^{32}P β radiation. Water, glass, and plastic are suitable low-density materials (as opposed to lead). Obviously water is unsuitable as a shielding layer for work on the bench, although it does a reasonable job when samples are incubating in a water bath. Shields made from a thickness of glass sufficient to stop these particles would be extremely heavy and cumbersome (as well as dangerous if dropped). Fortunately, plastic or acrylic materials—variously called Plexiglas, Perspex, or Lucite—are available for shielding against ^{32}P β radiation. Shields as well as storage boxes constructed of various thicknesses of Plexiglas are necessary equipment in laboratories where ^{32}P is used. When millicurie amounts of ^{32}P are used at one time it is necessary to also block the Bremsstra-

Table A.1A.3 Shielding Radioactive Emission[a]

β emitters

Energy (MeV)	Mass (mg)/cm^2 to reduce intensity by 50%	Thickness (mm) to reduce intensity by 50%			
		Water	Glass	Lead	Plexiglas
0.1	1.3	0.013	0.005	0.0011	0.0125
1.0	48	0.48	0.192	0.042	0.38
2.0	130	1.3	0.52	0.115	1.1
5.0	400	4.0	1.6	0.35	4.2

γ emitters

Energy (MeV)	Thickness of material (cm) to attenuate a broad beam of γ-rays by a factor of 10			
	Water	Aluminum	Iron	Lead
0.5	54.6	20.3	6.1	1.8
1.0	70.0	24.4	8.2	3.8
2.0	76.0	32.0	11.0	5.9
3.0	89.0	37.0	12.0	6.4

hlung radiation by adding a layer of high-density material (such as 4 to 6 mm lead) to the outside of the Plexiglas shield (covering the side farthest from the radioactive source).

γ rays released during the decay of ^{125}I have much higher penetrance than the β particles from ^{32}P decay; this radiation must be stopped by very-high-density material, such as lead. Lead foil of varying thicknesses (2 to 6 mm) can be purchased in rolls and can be cut and molded to cover any container, or taped to a Plexiglas shield (used in this instance for support). Obviously this latter arrangement has the disadvantage that it is impossible to see what one is doing through the shield. For routine shielding of manipulations involving ^{125}I, it is useful to purchase a lead-impregnated Plexiglas shield that is transparent, albeit inevitably very heavy (as well as relatively expensive).

Although it seems logical that the use of more radioactivity necessitates the use of thicker layers of shielding, it is also true that no shielding material is capable of completely stopping all radiation. When deciding how thick is "thick enough," consult the half-value layer measurement for each type of shielding material. This number gives the thickness of a given material necessary to stop half the radiation from a source; Table A.1A.3 lists half-value layer measurements for the β particles released from isotopes commonly used in the biology laboratory. In general, 1 to 2 cm of Plexiglas and/or 0.02 mm of lead are sufficient to shield the amounts of radioactivity used in most experiments.

GENERAL PRECAUTIONS

Before going on to a discussion of specific precautions to be taken with individual isotopes, a short list of general precautions to be taken with all isotopes seems pertinent:

1. Know the rules. Be sure that each individual is authorized to use each particular isotope and uses it in an authorized work area.

2. Don the appropriate apparel. Whenever working at the lab bench, it is good safety practice to wear a labcoat for protection. Disposable paper/synthetic coats of various styles are commercially available: at $4 each these may be conveniently thrown out if contaminated with radioactivity during an experiment, rather than held for decay as might be preferable with cloth coats costing about $30 each. As an alternative, disposable sleeves can be purchased and worn over those of the usual cloth coat. Other necessary accessories include radiation safety badges, gloves, and protective eyewear. It's handy to wear two pairs of gloves at once when using radioactivity; when the outer pair becomes contaminated, it is possible to strip it off and continue working without interruption.

3. Protect the work area as well as the workers. Lab benches and the bases of any shields used should be covered with some sort of disposable, preferably absorbent, paper sheet. Underpads or diapers (the kind normally used in hospitals) are convenient for this purpose.

4. Use appropriate designated equipment. It is very convenient, where use justifies

the expense, to have a few adjustable pipettors dedicated for use with each particular isotope. Likewise, it is good practice to use only certain labeled centrifuges and microcentrifuge rotors for radioactive samples so that all the lab's rotors do not become contaminated. Although such equipment should be cleaned after each use, complete decontamination is often not possible. A few pipettors or a single microcentrifuge can easily be stored (and used) behind appropriate shielding. Actually, contamination of the insides and tip ends of pipettors can be greatly reduced by using tips supplied with internal aerosol barriers; these have recently become very popular for setting up PCR reactions and are available to fit a variety of pipettors. To prevent contamination of the outside of the pipettor's barrel, simply wrap the hand-grip in Parafilm, which can be discarded later. Several manufacturers sell disposable paper inserts for their microcentrifuges that protect the wall of the rotor chamber from contamination that might spin off the outside of sample tubes. Trying to fashion homemade liners of this sort is not recommended, as we have had disastrous experiences using laminated adhesive paper that "unstuck" during microcentrifuge spins. These liners would get caught by the rotor, shattering sample tubes and creating an even bigger mess!

5. Know where to dispose of radioactive waste, both liquid and solid. Most institutions require that radioactive waste be segregated by isotope. This is done not only so that appropriate shielding can be placed around waste containers, but so that some waste can be allowed to decay prior to disposal through normal trash channels (see Table A.1A.4 and Fig. A.1A.1). With a decreasing number of radioactive waste disposal facilities able or willing to accept radioactive waste for burial (and a concomitant increase in dumping charges from those that still do), this practice of on-site decay can save an institution thousands of dollars a year in disposal charges.

6. Label your label! It is only common courtesy (as well as common sense) to alert coworkers to the existence of anything and everything radioactive that is left where they may come in contact with it! A simple piece of tape affixed to the sample box—with the investigator's name, the amount and type of isotope, and the date written on it—should do the trick. Yellow hazard tape printed with the international symbol for radioactivity is commercially available in a variety of widths.

7. Monitor radioactivity early and often. Portable radiation detection monitors are essential equipment for every laboratory using radioactivity. No matter how much or how little radioactivity is being used, the investigator should keep a hand-held monitor nearby—and it should be on! Turn it on before touching any radioactivity to avoid contaminating the monitor's switch. Use a monitor with the appropriate detection capacity (β for ^{35}S and ^{32}P; γ for ^{125}I) before, during, and after all procedures. The more frequently fingers and relevant equipment are monitored, the more quickly a spill or glove contamination will be detected. Such timely detection will keep both the potential mess and the cleanup time to a minimum. Because low-energy β emitters such as ^{3}H cannot be detected using such monitors, wipe tests of the bench and equipment used are necessary to ensure that contamination of the work area did not occur.

SPECIFIC PRECAUTIONS

The following sections describe precautions to be taken with individual isotopes in specific forms. Although the sections dealing with ^{35}S- or ^{32}P-labeling of proteins in intact cells are presented in terms of mammalian cells, most of the instructions are also pertinent (with minimal and obvious modifications) to the labeling of proteins in other cells (bacterial, insect, etc.).

Working with ^{35}S

Using ^{35}S to label cellular proteins and proteins translated in vitro

As discussed above, the β radiation generated during ^{35}S decay is not strong enough to make barrier forms of shielding necessary. The risk associated with ^{35}S comes primarily through its ingestion and subsequent concentration in various target organs, particularly the testes. Although willful ingestion of ^{35}S seems unlikely, accidental or unknowing ingestion may be more common. As reported several years ago (Meisenhelder and Hunter, 1988), ^{35}S-labeled methionine and cysteine, which are routinely used to label proteins in intact cells and by in vitro translation, break down chemically to generate a volatile radioactive component. The breakdown occurs independent of cellular metabolism. Thus the radioactive component is generated to the same extent in stock vials as in cell culture dishes. The process seems to be promoted by freezing and thawing ^{35}S-labeled materials. The exact identity of this component is not known, although it is probably SO_2 or CH_3SH. What is known is that it dissolves read-

Table A.1A.4 Decay factors for calculating the amount of radioactivity present at a given time after a reference date. For example, a vial containing 1.85 MBq (50 μCi) of a ^{35}S-labeled compound on the reference date will have the following activity 33 days later: 1.85 × 0.770 = 1.42 MBq; 50 × 0.770 = 38.5 μCi.

Figure A.1A.1 Correlation of loss of radioactivity with elapsing half-lives of an isotope.

ily in water and is absorbed by activated charcoal or copper.

The amount of this volatile radioactive component released, despite stabilizers added by the manufacturers, is about 1/8000 of the total radioactivity present. The amount of this radioactivity that a scientist is likely to inhale while using these compounds is presumably even smaller. Nevertheless, such a component can potentially contaminate a wide area because of its volatility, and also tends to concentrate in target organs. Thus, it is advisable to thaw vials of ^{35}S-labeled amino acids in a controlled area such as a hood equipped with a charcoal filter. This charcoal filter will become quite contaminated and should be changed every few months. If such an area is not available, the stock vial should be thawed using a needle attached to a charcoal-packed syringe to vent and trap the volatile compound.

Anyone who has ever added ^{35}S-labeled amino acids to dishes of cells for even short periods knows that the incubator(s) used for such labelings quickly becomes highly contaminated with ^{35}S. Such contamination is not limited to the dish itself, nor to the shelf on which the dish was placed. Rather, the radioactive component's solubility in water allows it to circulate throughout the moist atmosphere of the incubator and contaminate all the inside surfaces of the incubator. For this reason, in laboratories where such metabolic labelings are routine, it is highly convenient to designate one incubator to be used solely for working with ^{35}S-labeled samples. Such an incubator can be fitted with a large honeycomb-style filter, the size of an incubator shelf, made of pressed, activated charcoal. These filters are available from local air-quality-control companies. Such a filter will quickly become quite contaminated with radioactivity and should therefore be monitored and changed as necessary (usually about every three months if the incubator is used several times a week). The water used to humidify the incubator will also become quite "hot" (contaminated with radioactivity); keeping the water in a shallow glass pan on the bottom of the incubator makes it easy to change it after every use, thus preventing contamination from accumulating. Even with the charcoal filter and water as absorbents, the shelves, fan, and inner glass door of the incubator will become contaminated, as will the tray on which the cells are carried and incubated. Routine wipe tests and cleaning when necessary will help to minimize potential spread of this contamination.

If such labelings are done infrequently or there is no "spare" incubator, dishes of cells can be placed in a box during incubation. This box should be made of plastic, which is generally more easily decontaminated than metal. Along with the dishes of cells, a small sachet made of activated charcoal wrapped loosely in tissue (Kimwipes work well) should be placed in the box. If the box is sealed, it will obviously need to be gassed with the correct mixture of CO_2; otherwise small holes can be incorporated into the box design to allow equilibration with the incubator's atmosphere. In either case, the incubator used for the labeling should be carefully monitored for radioactivity after each experiment.

Working with ^{32}P

Microcurie amounts of ^{32}P

The amount of ^{32}P-labeled nucleotide used to label nucleic acid probes for northern or Southern blotting is typically under 250 µCi, and the amount of [γ-^{32}P]ATP used for in vitro phosphorylation of proteins does not usually exceed 50 µCi for a single kinase reaction (or several hundred microcuries per experiment). However, handling even these small amounts, given the time spent on such experiments, can result in an unacceptable level of exposure if proper shielding is not employed. With no intervening shielding, the dose rate 1 cm away from 1 mCi ^{32}P is 200,000 mrads/hr; the local dose rate to basal cells resulting from a skin contamination of 1 µCi/cm^2 is 9200 mrads/hr (Shleien, 1987). Such a skin contamination could be easily attained though careless pipetting and the resultant creation of an aerosol of radioactive microdroplets, because the concentration of a typical stock solution of labeled nucleotide may be 10 µCi/µl.

For proper protection during this sort of experiment, besides the usual personal attire (glasses, coat, safety badges, and gloves) it is necessary to use some form of Plexiglas screen between the body and the samples (see Fig. A.1A.2A). Check the level of radiation coming through the outside of the shield with a portable monitor to be sure the thickness of the Plexiglas is adequate. Hands can be shielded from some exposure by placing the sample tubes in a solid Plexiglas rack, which is also useful for transporting samples from the bench to a centrifuge or water bath (see Fig. A.1A.2B).

Experiments of these types often include an incubation step performed at a specific temperature, usually in a water bath. Although the water

surrounding the tubes or hybridization bags will effectively stop β radiation, shielding should be added over the top of the tubes (where there is no water)—e.g., a simple flat piece of Plexiglas. If the frequency of usage justifies the expense, an entire lid for the water bath can be constructed from Plexiglas. When hybridization reactions are performed in bags, care should be taken to monitor (and shield) the apparatus used to heat-seal the bags.

The waste generated during the experiments should also be shielded. It is convenient to have a temporary waste container right on the bench. Discard pipet tips and other solid waste into a beaker lined with a plastic bag and placed behind the shield. This bag can then be emptied into the appropriate shielded laboratory waste container when the experiment is done. Liquid waste can be pipetted into a disposable tube set in a stable rack behind the shield (see Fig. A.1A.2C).

When radiolabeled probes or proteins must be gel-purified, it may be necessary to shield the gel apparatus during electrophoresis if the samples are particularly hot. Be advised that the electrophoresis buffer is likely to become very radioactive if the unincorporated label is allowed to run off the bottom of the gel; check with a radiation safety officer for instructions on how to dispose of such buffer. It is also prudent to check the gel plates with a portable detection monitor after the electrophoresis is completed, because they sometimes become contaminated as well.

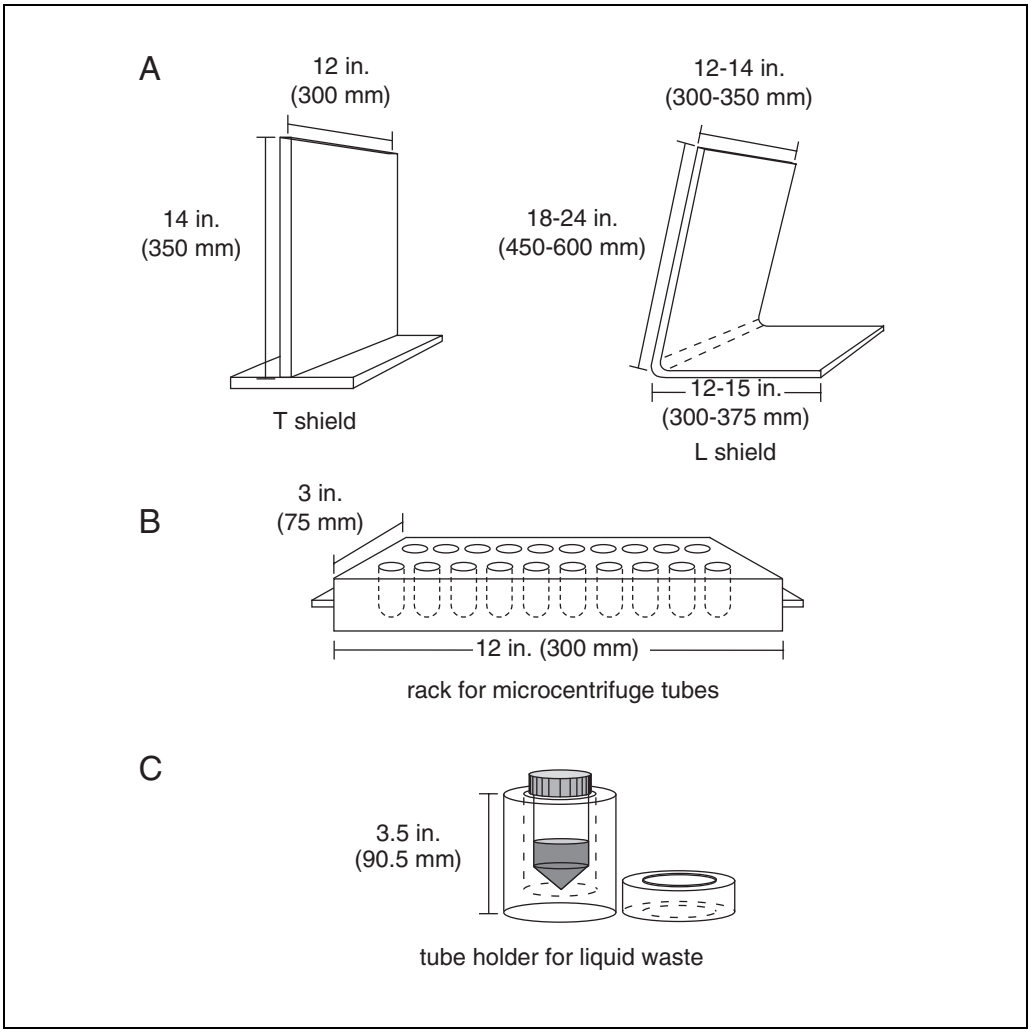

Figure A.1A.2 Plexiglas shielding for ^{32}P. (**A**) Two portable shields (L and T design) made of 0.5-in. Plexiglas. Either can be used to directly shield the scientist from the radioactivity he or she is using. Turned on its side, the L-shaped shield can be used to construct two sides of a cage around a temporary work area, providing shielding for other workers directly across or to the sides of the person working with ^{32}P. (**B**) Tube rack for samples in microcentrifuge tubes. (**C**) Tube holder for liquid waste collection.

Millicurie amounts of ^{32}P

In order to study protein phosphorylation in intact mammalian cells, cells in tissue culture dishes are incubated in phosphate-free medium with ^{32}P-labeled orthophosphate for a period of several hours or overnight to label the proteins. The amount of ^{32}P used in such labelings can be substantial. Cells are normally incubated in 1 to 2 mCi of ^{32}P/ml labeling medium; for each 6-cm dish of cells, 2.5 to 5 mCi ^{32}P may be used. When this figure is multiplied by the number of dishes necessary per sample, and the number of different samples in each experiment, it is clear that the amount of ^{32}P used in one experiment can easily reach 25 mCi or more. Because so much radioactivity is used in the initial labeling phase of such experiments, it is necessary for a researcher to take extra precautions in order to adequately shield him or herself and coworkers.

When adding label to dishes of cells, it is important to work as rapidly as possible. An important contribution to the speed of these manipulations is to have everything that will be needed at hand before even introducing the label into the work area. Prepare the work area, arranging shielding and covering the bench with diapers, in advance. Set out all necessary items, including any pipettors and tips needed, a portable detection monitor, extra gloves, and a cell house (see Fig. A.1A.3A).

Work involving this much radioactivity should be done behind a Plexiglas shield at least ¾ in. (2 cm) thick; the addition of a layer of lead to the outside lower section of this shield to stop Bremsstrahlung radiation is also needed. If one shield can be dedicated to this purpose at a specific location, a sheet of lead several centimeters thick can be permanently screwed to the

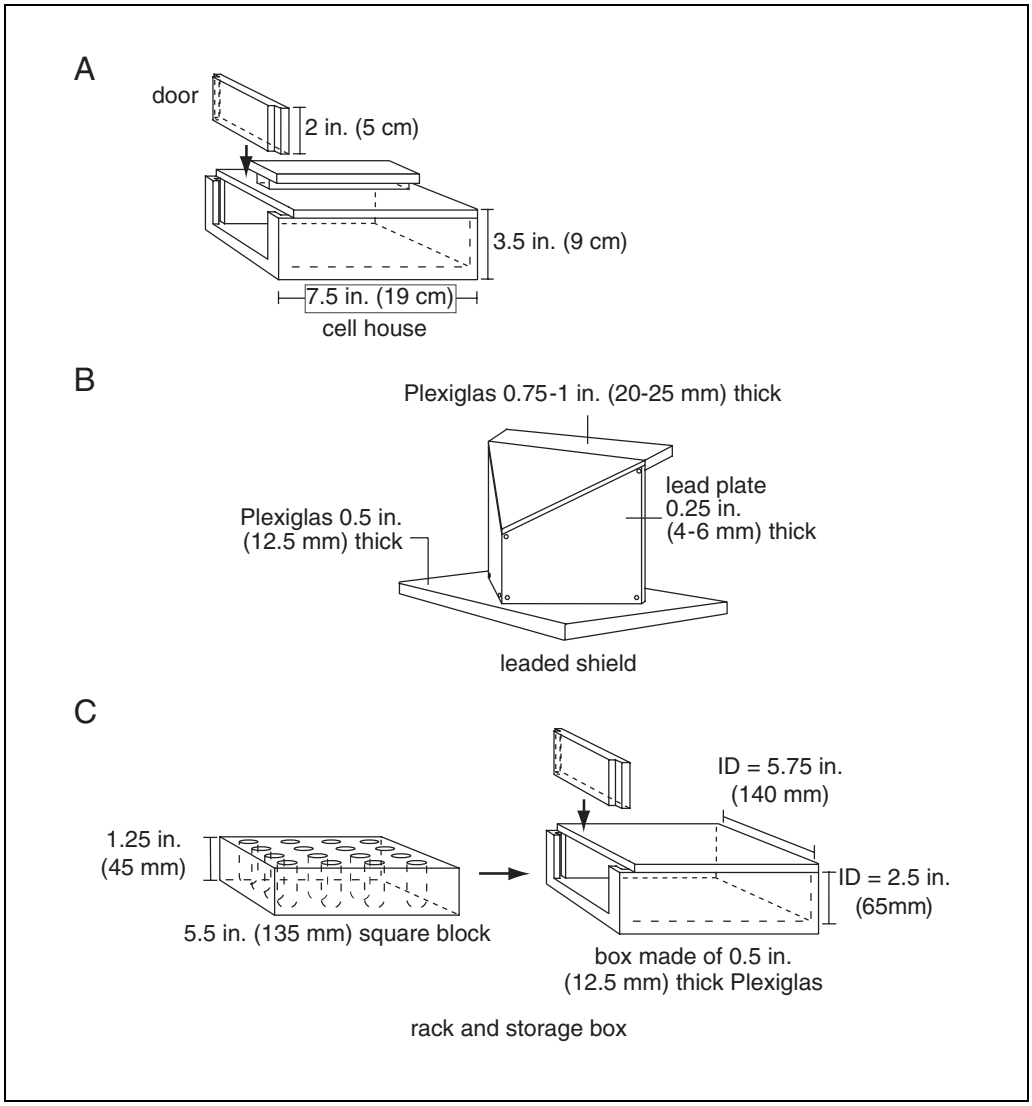

Figure A.1A.3 (**A**) Box for cell incubation (a "cell house"). (**B**) Stationary leaded shield. (**C**) Sample storage rack and box made of 0.5-in. Plexiglas. Abbreviations: ID, interior dimension.

Plexiglas (as shown in Fig. A.1A.3B); however, this lead makes the shield extremely heavy and therefore less than portable. If space constraints do not permit the existence of such a permanent labeling station, a layer or two of lead foil can be taped temporarily to the outside of the Plexiglas shield.

Again, each worker should take care to shield not only him or herself, but bystanders on all sides. Handling of label should be done away from the central laboratory if possible to take maximum advantage of distance as an additional form of shielding. It is also advisable not to perform such experiments in a tissue culture room or any other room that is designed for a purpose vital to the whole laboratory. An accident involving this much ^{32}P would seriously inconvenience future work in the area, if not make it altogether uninhabitable! If care is taken to minimize the amount of time the dish of cells is open when adding the label, use of a controlled air hood to prevent fungal or bacterial contamination of the cells should not be necessary.

Once the label has been added to the dishes of cells, they will also need to be shielded for transport to and from the incubator and other work areas. Plexiglas boxes that are open at one end (for insertion of the dishes) and have a handle on top (for safe carrying) make ideal "cell houses" (see Figure A.1A.3A). A Plexiglas door that slides into grooves at the open end is important to prevent dishes from sliding out if the box is tilted at all during transport. If this door is only two-thirds the height of the house wall, the open slot thus created will allow equilibration of the CO_2 level within the house with that in the incubator. Obviously, this slot will also allow a substantial stream of radiation to pass out of the cell house, so the house should be carried and placed in the incubator with its door facing away from the worker (and others)!

Following incubation with label and any treatments or other experimental manipulations, the cells are usually lysed in some type of detergent buffer. It is during this lysis procedure that a worker's hands receive their greatest exposure to radiation, because it is necessary to directly handle the dishes over a period of several minutes. It is therefore very important to streamline this procedure and use any shielding whenever possible. If the cell lysates must be made at 4°C, as required by most protocols, working on a bench in a cold room is preferable to placing the dishes on a slippery bed of ice. In either case, make the lysate using the same sort of shielding (with lead if necessary) that was used when initially adding the label. Pipet the labeling medium and any solution used to rinse unincorporated radioactivity from the cells into a small tube held in a solid Plexiglas holder (shown in Fig. A.1A.2C). The contents of this tube can later be poured into the appropriate liquid waste receptacle. If possible, it is a good practice to keep this high-specific-activity ^{32}P liquid waste separate from the lower-activity waste generated in other procedures so that it can be removed from the laboratory as soon as possible following the experiment. If it is necessary to store it in the laboratory for any time, the shielding for the waste container should also include a layer of lead.

The solid waste generated in the lysis part of these experiments (pipet tips, disposable pipets, cell scrapers, and dishes) is very hot and should be placed immediately into some sort of shielded container to avoid further exposure of

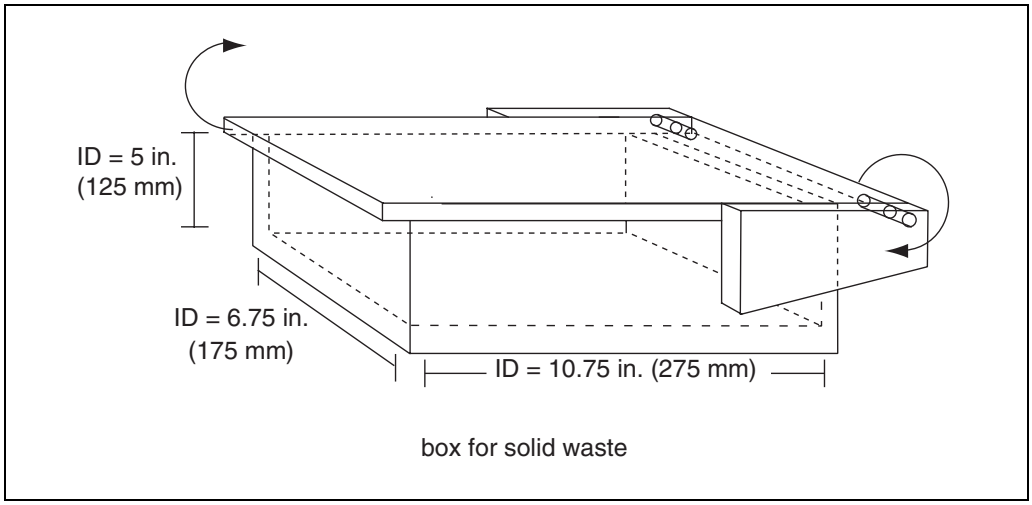

Figure A.1A.4 Box for solid waste collection made of 0.5-in. Plexiglas. Abbreviation: ID, interior dimension.

the hands. A Plexiglas box similar in design to that in Figure A.1A.4 is convenient; placed to the side of the shield and lined with a plastic bag, it will safely hold all radioactive waste during the experiment and is light enough to be easily carried to the main laboratory waste container where the plastic bag (and its contents) can be dumped after the experiment is done. If the lid of the box protrudes an inch or so over the front wall, it can be lifted using the back of a hand, thus decreasing the possibility of contaminating it with hot gloves.

When scraping the cell lysates from the dishes, it is good practice to add them to microcentrifuge tubes that are shielded in a solid Plexiglas rack; this will help to further reduce the exposure to which the hands are subjected. At this point, the lysates are usually centrifuged at high speed (>10,000 × *g*) to clear them of unsolubilized cell material. Use screw-cap tubes for this clarification step, as these will contain the labeled lysate more securely than flip-top tubes, which may open during centrifugation. No matter what type of tube is used, the rotor of the centrifuge often becomes contaminated, most probably due to tiny drops of lysate (aerosol) initially present on the rim of the tubes that are spun off during centrifugation. Monitor the rotor and wipe it out after each use.

The amount of ^{32}P taken up by cells during the incubation period varies considerably, depending on the growth state of the culture as well as on the cell type and its sensitivity to radiation. This makes it difficult to predict the percentage of the radioactivity initially added to the cells that is incorporated into the cell lysate; however, this figure probably does not exceed 10%. Thus, the amount of radioactivity being handled decreases dramatically after lysis, making effective shielding much simpler. However, at least ten times more radioactivity than is usual in other sorts of experiments is still involved! It is easy to determine if the shielding is adequate—just use both β and γ portable monitors to measure the radiation coming through it. Again, be sure to check that people working nearby (including those across the bench) are also adequately shielded. It is sometimes necessary to construct a sort of cage of Plexiglas shields around the ice bucket that contains the lysates.

At the end of the day or the experiment, it may be necessary to store radioactive samples; in some experiments, it may be desirable to save the cell lysates. These very hot samples are best stored in tubes placed in solid Plexiglas racks that can then be put into Plexiglas boxes (see Fig. A.1A.3C). Such boxes may be of similar construction to the cell houses described above; however, they should have a door that completely covers the opening. Be sure to check the γ radiation coming through these layers and add lead outside if necessary.

Working with ^{33}P

Using ^{33}P-labeled nucleotides to label nucleic acid probes or proteins

Several of the major companies that manufacture radiolabeled biological molecules have recently introduced nucleotides labeled with ^{33}P (both α- and γ-labeled forms). ^{33}P offers a clear advantage over ^{32}P with respect to ease of handling, because the energy of the β particles it releases lies between that of ^{35}S and ^{32}P and thus its use does not require as many layers of Plexiglas and lead shielding as for ^{32}P. In fact, the β radiation emitted can barely penetrate through gloves and the surface layer of skin, so the hazard associated with exposure to even millicurie amounts of ^{33}P is thought to be insignificant (as reported in the DuPont NEN product brochure). Gel bands visualized on autoradiographs of ^{33}P-labeled compounds are sharper than bands labeled with ^{32}P because the lower-energy β radiation does not have the scatter associated with that from ^{32}P. The half-life of ^{33}P is also longer (25 days compared to 14 days for ^{32}P). Despite its higher cost, these features have led many researchers to choose ^{33}P-labeled nucleotides for use in experiments such as band/gel shift assays where discrimination of closely-spaced gel bands is important.

The best way to determine what degree of shielding is needed when using ^{33}P is to monitor the source using a portable β monitor and add layers of Plexiglas as necessary.

Working with ^{125}I

Using ^{125}I to detect immune complexes (immunoblots)

^{125}I that is covalently attached to a molecule such as staphylococcal protein A is not volatile and therefore is much less hazardous than the unbound or free form. Most institutions do not insist that work with bound ^{125}I be performed in a hood, but shielding of the γ radiation is still necessary. Lead is a good high-density material for stopping these γ rays; its drawbacks are its weight and opacity. Commercially available shields for ^{125}I are made of lead-impregnated Plexiglas—though heavy, these are at least see-through. Alternatively, a piece of lead foil may be taped to a structural support, although this

arrangement does not provide shielding for the head as a worker peers over the lead!

Incubations of the membrane or blot with the [^{125}I] protein A solution and subsequent washes are usually done on a shaker. For shielding during these steps, a piece of lead foil may simply be wrapped around the container. Solutions of ^{125}I can be conveniently stored for repeated use in a rack placed in a lead box.

Using ^{125}I to label proteins or peptides in vitro

Any experiments that call for the use of free, unbound ^{125}I should be done behind a shield in a hood that contains a charcoal filter to absorb the volatile iodine. Most institutions require that such experiments be done in a special hot lab to which access is limited. Ingested or inhaled iodine is concentrated in the thyroid; a portable γ monitor should therefore be used to scan the neck and throat before beginning and after completing each experiment. Similar scans should routinely be performed on all members of any laboratory in which unbound iodine is used.

DEALING WITH ACCIDENTS

Despite the best intentions and utmost caution, accidents happen! Accidents involving spills of radioactivity are particularly insidious because they can be virtually undetectable yet pose a significant threat to laboratory workers. For this reason it is best to foster a community spirit in any laboratory where radioisotopes are routinely used—a sense of cooperativity that extends from shielding each other properly to helping each other clean up when such accidents occur.

The specific measures to be taken following an accident involving radioactivity naturally depend on the type and amount of the isotope involved, the chemical or biological hazards of the material it is associated with, and the physical parameters of the spill (i.e., where and onto what the isotope was "misplaced"). However, following any accident there are several immediate steps that should be taken:

1. Alert coworkers as well as Radiation Safety personnel to the fact that there has been an accident. This will give them the opportunity to shield themselves if necessary—and to help clean up as well!

2. Restrict access to and away from the site of the accident to ensure that any uncontained radioactive material is not spread around the laboratory. When leaving the site be sure to monitor the bottoms of the shoes as well as the rest of the body.

3. Take care of all contaminated personnel first, evacuating others if necessary. If anyone's skin is contaminated, first use a portable monitor to identify specific areas of contamination. Then wipe these areas with a damp tissue to remove as much surface radioactivity as possible. Try to scrub only small areas at a time to keep the contamination localized. If the contamination is not easily removed with paper tissues, try a sponge or an abrasive pad, but be careful not to break the skin! Sometimes soaking is required: do this only after all easily removed contamination is gone and keep the soaked area to a minimum. Contaminated strands of hair can be washed (or perhaps a new hairstyle may be in order).

4. When attempting to clean any contaminated equipment, floors, benches, etc., begin by soaking up any visible radioactive liquid with an absorbent material. Use a small amount of soap and water to clean the contaminated area, keeping the area wiped each time to a minimum to avoid smearing the contamination over an even greater surface. Many surfaces prove resistant to even Herculean cleaning efforts; in these instances the best that can be done is to remove all contamination possible and then shield whatever is left until the radioactivity decays sufficiently for safety.

Transgenic and Gene-Targeted Mouse Lines for Toxicology Studies

The isolation of mammalian genes is of utmost importance to toxicology because of the contributions these studies can make to the understanding of normal physiology and development as well as chemical-induced perturbations of normal biochemical processes. The development of methods that allow functional expression of specific genes, including human genes, in experimental animal models provides exciting and novel avenues for investigation into gene-environment interactions. Likewise, the ability to delete the function of a normal gene in living animals (e.g., "knockout" mice) also provides a unique approach to studying gene function. Methods for the direct microinjection of DNA into pronuclei of fertilized embryos are well established (see *UNIT 1.3*). Foreign genes can be incorporated into somatic germ-line tissues, with expression of these elements in the progeny of founder mice. An additional gene-transfer technology in mice involves the use of stem cells from the early embryo, so-called embryonic stem (ES) cells. The capacity of ES cells to undergo differentiation makes them useful for investigating the effects of genetic modifications of either gain or loss of function. These pluripotent genetically modified ES cells can then be targeted with specific genes and vectors aimed at creating point mutations or null mutations.

During the past several years, a large number of genetically engineered mouse models have been described and utilized for toxicology studies, including carcinogenicity testing, mutation analysis, chemical bioassays and risk assessment, gene action and the environment, and environmental stress response mechanisms. Table A.1B.1 briefly describes a selected number of transgenic and gene-targeted mouse models that have been used, or may be of interest, in investigations and testing relevant to the field of toxicology. The table is designed as an introductory guide and not an exhaustive and conclusive reference source. A number of the models are available from the Induced Mutant Mouse Resource at The Jackson Laboratory (*http://www.jax.org*), while others are available commercially from various animal vendors. Many, however, are only available from the individuals who originally described them. Attempts to increase the number and capacity of mutant mouse resource centers may provide the means of making more of these genetically altered mouse lines available to the toxicological community (Battey et al., 1999).

Atm Ataxia telangiectasia, mutated	Tm	Causes growth retardation, neurologic dysfunction, infertility, immunologic abnormalities, lymphoreticular malignancies, chromosomal instability, and extreme sensitivity to ionizing radiation. Model for evaluating role of gene in normal cellular function and as a model for ataxia-telangiectasia.	Barlow et al., 1996. *Cell* 86:159; Xu et al., 1996. *Genes Dev.* 10:2411	JL
bcl-2 2-bcl-2	Tg	Expression of high levels of protein in thymocytes and peripheral T cells. Model for evaluating variable resistance to chemotherapy regimens.	Siegel et al., 1992. *PNAS* 89:7003	—
bcl-2 B cell leukemia lymphoma bcl-2-Ig NL bcl-2-Ig SM	Tg	Extended B cell survival with follicular lymphoproliferation. Model for studying pathogenesis of B lymphoid neoplasms.	McDonnell et al., 1989. *Cell* 57:79	—
bcl-2 H2K-BCL-2	Tg	Overexpression in cells of hematolymphoid system. Model for increasing resistance of animals to apoptosis-inducing challenges like irradiation.	Domen et al., 1998. *Blood* 91:2272	—
bcl-2 NSE-Hu-BCL-2	Tg	Overexpression in cells of the nervous system, protects neuronal cells from ischemia-induced death and causes neuronal hypertrophy. Model for evaluating role of gene in developing nervous system and neurodegenerative disorders.	Martinou et al., 1994. *Neuron* 13:1017	—
bcl-2 HHK1 Human keratin 1 (Hk-1)	Tg	Epidermal expression yields multifocal hyperplasia with keratinocytes more resistant to cell death from radiation and chemical carcinogen exposure. Model for evaluating pathogenesis of nonmelanoma skin cancers.	Rodriguez-Villanueva et al., 1998. *Oncogene* 16:853	—
brca1 Breast cancer susceptibility gene 1	Tm	Embryonic lethality prior to gastrulation on day 7.5. Evaluation of role of gene in cellular proliferation during embryogenesis, cell cycle progression regulation, and function during oncogenesis.	Hakem et al., 1996. *Cell* 85:1009	—
brca2 Breast cancer susceptibility gene 2	Tm	Causes embryonic developmental arrest at day 6.5 and hypersensitivity to γ irradiation. Model for evaluation of role of gene in DNA repair and tumor suppression.	Sharan et al., 1997. *Nature* 386:804	—
cat Catalase	Tg	Increased catalase activity attenuates adriamycin-induced cardiotoxicity.	Kang et al., 1996. *JBC* 271:12610	—

continued

Table A.1B.1 Transgenic and Gene-Targeted Mice for Toxicology Studies, continued

Gene symbol and name	Mutant type[a]	Description	Reference(s)	Available from[b]
CEA Carcinoembryonic antigen gene cosCEA1	Tg	Epithelial spatiotemporal expression pattern similar to humans. Model for tumor immunotherapy.	Eades-Perner et al., 1994. *Cancer Res.* 54:4169	—
CEA TgN(CEAGe)18FJP	Tg	Overexpression in large intestine, cecum, and stomach. Model for antigen-specific vaccine studies, antibody-targeting studies, and other forms of immunotherapy.	Clarke et al., 1998. *Cancer Res.* 58:1469	—
COX-1 Cyclooxygenase-1 Ptgs1	Tm	Null mutation yields a decreased incidence of indomethacin-induced gastric ulceration, reduced platelet aggregation, and decreased response to arachidonic acid. Model for the evaluation of physiological roles of COX-1 and COX-2.	Langenbach et al., 1995. *Cell* 83:483	—
COX-2 Cyclooxygenase-2	Tm	Targeted disruption yields severe nephropathy and exhibits increased susceptibility to peritonitis. Models for COX isoform evaluation and improvement of NSAIDs, mitigation of endotoxin-induced hepatocellular cytotoxicity, and evaluation of COX-2 in early pregnancy.	Dinchuk et al., 1995. *Nature* 378:406; Lim et al., 1997. *Cell* 91:197	—
CRP C-reactive protein	Tg	Inflammation-induced liver-specific expression. Model to study liver development and regeneration.	Ciliberto et al., 1987. *EMBO J.* 6:4017	—
cyD1 Cyclin D1 EBVED-L2 cyD1	Tg	Epithelial dysplasia. Model for evaluating associated malignancies.	Mueller et al., 1997. *Cancer Res.* 57:5542	—
cyp Cytochrome P-450 1a-1 Cyp 1a-1-CAT	Tg	Exposure to an aromatic hydrocarbon increases hepatic expression of transgene, which may be gender-related. Model for evaluating the gender-related expression of the gene.	Jones et al., 1991. *NAR* 19:6547	—
Cyp Cytochrome P-450 1a-1, 1a-2	Tm	Neonatal lethality via respiratory distress. Potential neonatal respiratory distress syndrome models.	Pineau et al., 1995. *PNAS* 92:5134; Diliberto et al., 1997. *Biochem. Biophys. Res. Commun.* 236:431	JL
Cyp Cytochrome P-450 CYP2B2-19 CYP2B2-39	Tm	Negative and positive regulation of transgene by phenobarbital administration. Phenobarbital induction mechanism system model.	Ramsden et al., 1993. *JBC* 268:21722	—

Cyp Cytochrome P-450 Cyp2C2-luc	Tm	Modulation of tissue expression post male castration and post testosterone/rat growth hormone treatment in female. Model for evaluating transcriptional regulation of gene.	Li et al., 1996a. *Mol. Cell Endocrinol.* 120:77	—
Cyp Cytochrome P-450 MT-1-CYP3A7	Tm	Liver, kidney, lung, spleen, testis, small intestine, thymus, brain, skin, and heart expression. Model for studying the toxicological significance of P-450s during embryonic development.	Li et al., 1996b. *Arch. Biochem. Biophys.* 329:235	—
E2F1 K5-E2F1	Tg	Epidermal hyperplasia and decreased hair growth. Role in epithelial growth and tumorgenesis.	Pierce et al., 1998. *Oncogene* 16:1267	—
E2F1 Transcriptional activator gene	Tm	Model for evaluating role in apoptosis and cell proliferation suppression.	Field et al., 1996. *Cell* 85:549; Yamasaki et al., 1996. *Cell* 85:537	JL
fasL fas ligand fasL/TCR-β Fas ligand	Tg	Higher numbers of T cells in the thymus, lymph node, and spleen with increased numbers of T cells resistant to Fas-mediated apoptosis. Model for evaluating Fas-mediated apoptosis.	Cheng et al., 1997. *J. Immunol.* 159:674	—
fos MT-c-fos-209-4 MT-c-fos-211-5	Tg	Expression yields early abnormal bone development. Model for studying pathways responsible for specificity of induced tumorgenesis.	Ruther et al., 1987. *Nature* 325:412	—
$G\alpha_{I2}$ G-protein subunit that functions as tumor-suppressor gene	Tm	Gene deficiency yields growth retardation, lethal diffuse colitis, alteration in thymocyte maturation and function, plus colonic adenocarcinoma. Model for ulcerative colitis and colonic carcinogenesis.	Rudolph et al., 1995. *Nature Genet.* 10:143	—
GPx-1 Glutathione peroxidase	Tg	Increased activity confers increased tolerance to ischemia-reperfusion injury, H_2O_2-induced DNA-strand breakage in lens epithelial cells, and paraquat toxicity. Model for brain hydroperoxide metabolism and oxidative stress homeostasis. Model for evaluating thermoregulation and processes involving actions of hydroxy and lipid peroxidases.	Mirault et al., 1994. *Ann. N.Y. Acad. Sci.* 738:104; Mirochnitchenko et al., 1995. *PNAS* 92:8120; Yoshida et al., 1996. *J. Mol. Cell. Cardiol.* 28:1759; Reddy et al., 1997. *Ophthalmologica* 211:192; Cheng et al., 1998. *J. Nutr.* 128:1070	—
GPx-1 Glutathione peroxidase	Tm	Null mutant mice are more susceptible to acute paraquat toxicity and myocardial ischemia-reperfusion injury.	Cheng et al., 1998. *J. Nutr.* 128:1070	—
GST mu Mu-class glutathione transferase	Tg	Renal convoluted tubular epithelium expression. Model for in vivo study of GST modulation in carcinogenesis and drug toxicity.	Connelly et al., 1993. *Pathobiology* 61:7	—

continued

Table A.1B.1 Transgenic and Gene-Targeted Mice for Toxicology Studies, continued

Gene symbol and name	Mutant type[a]	Description	Reference(s)	Available from[b]
GST pi Pi-class glutathione transferase	Tm	Increased incidence of epithelial tumorgenesis after carcinogen exposure. Role as a determinant of carcinogen exposure and cancer susceptibility.	Henderson et al., 1998. *PNAS* 95:5275	—
HO-1 Heme oxygenase	Tg	Protein overexpression in neurons of various brain regions. Model for evaluating the function of carbon monoxide as a neuromodulator, iron as a gene regulator, and bile pigments as in vivo antioxidants.	Maines et al., 1998. *J. Neurochem.* 70:2057	—
HO-2 Heme oxygenase	Tm	Model for evaluation of role of carbon monoxide as retrograde neuronal messenger.	Poss et al., 1995. *Neuron* 15:867	—
hsp-70 Heat-shock protein	Tg	Increased myocardial expression demonstrates cardioprotective effect against ischemia. Model for evaluating cardiac post-ischemic recovery.	Marber et al., 1995. *J. Clin. Invest.* 95:1446; Radford et al., 1996. *PNAS* 93:2339	—
IL-6 Interleukin 6	Tm	Impairment of immune and acute-phase inflammatory responses. Model for studying response to injury or infection.	Kopf et al., 1994. *Nature* 368:339	—
IL-6 Interleukin 6 Eμ-IL-6	Tg	Polyclonal plasmacytosis of thymus, lymph node, spleen, lung, liver, and kidney. Useful in determining role of gene in polyclonal and monoclonal plasma cell abnormalities.	Suematsu et al., 1989. *PNAS* 86:7547	JL
L2hD	Tg	Tongue, esophagus, and forestomach epithelial dysplasia. Model of upper-digestive tract tumor initiation.	Nakagawa et al., 1997. *Oncogene* 14:1185	—
LacI β-galactosidase λ shuttle vector	Tm	Plasmid rescue from genome. Used in induced mutation assays.	Kohler et al., 1991. *PNAS* 88:7958	—
LacZ β-galactosidase λ shuttle vector	Tm	Plasmid rescue from genome. Used in induced mutation assays.	Gossen et al., 1989. *PNAS* 86:7971	JL
LCAT Lecithin cholesterol acyltransferase	Tg	Increased total cholesterol and HDL cholesterol levels. Model of hyperalphalipoprotenemia.	Vaisman et al., 1995. *JBC* 270:12269	—
lipox Lipoxygenase	Tm	Specific expression in endothelial cells of vessel walls and pulmonary epithelium. System for direct expression of molecules by vascular wall to evaluate select proteins.	Harats et al., 1995. *J. Clin. Invest.* 95:1335	—

MAO-A Monamine oxidase A Tg(H2-INF-β)8	Tm	Increased CNS serotonin and norepinephrine levels. Model for MAO-A deficiency.	Cases et al., 1995. *Science* 268:1763	—
MAO-B Monamine oxidase B pNSE	Tg	Neuronal-specific overexpression. Model for evaluating effects of high MAO-B levels on development and possible role in neurologic disease.	Andersen et al., 1992. *Ann. N.Y. Acad. Sci.* 648:241	—
Mdr-1a Multidrug resistance 1	Tm	Deficiency of the blood-brain barrier with subsequent sensitivity to drugs. Model for compartmental drug accumulation.	Schinkel et al., 1994. *Cell* 77:491	—
mdr-1a Multidrug resistance 1 β-actin/MDR1	Tg	Overexpression in bone marrow confers resistance to cytotoxic drug–induced leukopenia. Model for evaluating MDR1-dependent multidrug resistance and high- dose chemotherapy regimens.	Galski et al., 1989. *Mol. Cell Bio.* 9:4357	TF
mgmt Methylguanine-DNA methyltransferase DNA repair protein	Tg	Overexpressed in liver and brain. Possible use in evaluation of cellular resistance to DNA-alkylation toxicity and tumor induction.	Walter et al., 1993. *Carcinogenesis* 14:1537	—
Mgmt Methylguanine-DNA methyltransferase DNA repair protein	Tm	Significant reduction in skin tumor incidence post topical carcinogen application. Model for studying role in prevention of tumor initiation.	Becker et al., 1996. *Cancer Res.* 56:3244	JL
MS2 DNA mismatch repair gene	Tm	Null mutation yields microsatellite instability in several tissues, increased incidence of sarcomas and lymphomas, and male infertility. Model for evaluation of role in DNA repair, genetic recombination, and meiotic chromosome synapsis.	Baker et al., 1995. *Cell* 82:309	—
MSH2 DNA mismatch repair gene	Tm	Deficiency yields increased incidence of lymphoid tumors with microsatellite instabilities in 2-month-old mice. Model for evaluating progression of tumors and screening carcinogenic and anticancer agents.	Reitmair et al., 1995. *Nature Genet.* 11:64	—
myc (c-myc) Proto-oncogene B cell promoters	Tg	Overexpression yields B cell lymphomas or no increase in tumor incidence. Models for evaluating lymphoma development, B cell ontogeny, and immunoglobulin regulation.	Adams et al., 1985. *Nature* 318:533	JL, CR

continued

Table A.1B.1 Transgenic and Gene-Targeted Mice for Toxicology Studies, continued

Gene symbol and name	Mutant type[a]	Description	Reference(s)	Available from[b]
myc (c-myc) Proto-oncogene Pth-mycn	Tg	Neuroectodermal expression yields neuroblastoma development. Model for evaluating pathogenesis and therapy of neuroblastoma.	Weiss et al., 1997. *EMBO J.* 16:2985	—
myc (c-myc) Proto-oncogene T cell promoter	Tg	Increased incidence of spontaneous T cell tumors and inducible leukemia. System for screening novel *myc* genes involved in T cell lymphoma.	Stewart et al., 1993. *Int. J. Cancer* 53:1023	—
neu (c-neu) c-neu/erbB2 TG.NK	Tg	All mice fed a specifically formulated diet developed palpable mammary tumors by 28 weeks of age. Model for evaluation of dietary intervention strategies for breast cancer.	Rao et al., 1997. *Breast Cancer Res. Treat.* 45:149	—
neu (c-neu) Proto-oncogene MMTV-c-neu	Tg	One-step mammary tumor induction, used to study major determinants of malignant progression of tumors.	Muller et al., 1988. *Cell* 54:105	CR
NOS2 Nitric oxide synthase gene	Tg	Overexpression of NOS2 in pancreatic islets. Model for the evaluation of NOS2 in pancreatic β-cell degeneration.	Takamura et al., 1998. *JBC* 273:2493	—
NOS2 Nitric oxide synthase gene neuronal NOS	Tm	Neuronal NOS deficiency yields gastric distention, pyloric stenosis, and decreased NOS catalytic activity. Model of infantile pyloric stenosis.	Huang et al., 1993. *Cell* 75:1273	BK, JL
$p27^{Kip1}$ Cyclin-dependent kinase inhibitor	Tm	Targeted deletion results in multiorgan hyperplasia, gigantism, tumorgenesis, and female sterility. Model for the evaluation of $p27^{Kip1}$ function.	Fero et al., 1996. *Cell* 85:733	—
p53 Tumor suppressor gene	Tm	Development of spontaneous tumors by 6 months of age. Model for studying role in tumorigenesis and testing suspected carcinogens.	Donehower et al., 1992. *Nature* 356:215	JL, TF
p53 Tumor suppressor gene p53 172^{R-H}	Tg	Decrease in spontaneous tumors with concurrent acceleration of carcinogen and oncogene-mediated tumorgenesis. Model for evaluation of early events in mammary tumorgenesis. Preclinical model for new chemotherapeutic testing.	Li et al., 1998. *Oncogene* 16:997	—
paf Platelet activating factor PARF	Tg	Bronchial hyperreactivity, increased endotoxin lethality, and melanocytic tumorgenesis. Model for study of bronchial asthma and endotoxin-induced death.	Ishii et al., 1997. *EMBO J.* 16:133	—

pepck-ada Phosphoenolpyruvate carboxykinase Bacterial O^6 alkylguanine-DNA alkyltransferase	Tg	Expression in liver and kidney regulated by dietary manipulation. Model for evaluating role of DNA repair in protection from carcinogenesis induced by *N*-nitro compounds.	Lim et al., 1990. *Cancer Res.* 50:1701	—
pgis Prostacyclin synthase hSPC-rPGIS	Tg	Selective pulmonary prostacyclin expression. Lung displays less hypoxic vasoconstriction. Model for evaluation of role in vasoconstriction.	Geraci et al., 1998. *Chest* 114:99S	—
pim-1 *pim-1* proto-oncogene Eμ-pim-1	Tg	Overexpression promotes development of lymphomas before 7 months of age. Model for evaluating the cooperation between pim-1 and myc in lymphomagenesis.	van Lohuizen et al., 1989. *Cell* 56:673	TF
pim-2 *pim-2* proto-oncogene	Tg	Increased incidence of T cell lymphomas. Model for evaluating the tumorigenic properties of pim-2.	Allen et al., 1997. *Oncogene* 15:1133	—
PLA2 Phospholipase A2	Tm	Null mutation yielded reduced fertility and decreased the ischemic brain injury associated with cerebral arterial occlusion. Model for evaluation of regulation of eicosanoid and platelet activation factor in inflammation process.	Bonventre et al., 1997. *Nature* 390:622	—
RAR Retinoic acid receptor	Tg	Expression induces craniofacial abnormalities. Model for evaluating mechanism of gene regulation by retinoic acid.	Damm et al., 1993. *PNAS* 90:2989	—
RAR Retinoic acid receptor βRARE-LacZ	Tg	Specific epidermal expression. Model for determination of sites of transcriptional activation by retinoic acid.	Tsou et al., 1994. *Exp. Cell Res.* 214:27	—
RAR Retinoic acid receptor HK1-RARα403	Tm	Neonatal lethality due to loss of epidermal barrier function and transepidermal water. Model for evaluating lipid metabolism modulation in relation to epidermal formation and functional maintenance.	Imakado et al., 1995. *Genes Dev.* 9:317	—
ras Activated v-Ha-*ras* oncogene TG.AC	Tg	Multiple skin papilloma induction with further development to neoplasia. Model for screening tumor promoters and assessing antitumor and antiproliferative agents.	Leder et al., 1990. *PNAS* 87:9178	TF, CR
ras c-Ha-*ras* ras H2	Tg	Increased incidence of tumorgenesis in vascular endothelium, lymphocytes, skin, lung, and Harderian gland epithelium. Model for evaluation of somatic point mutations associated with transgene. Bioassay model for rapid carcinogenicity testing.	Saitoh et al.,1990. *Oncogene* 5:1195; Yamamoto et al., 1998. *Environ. Health Perspect.* 106(suppl. 1):57	—

continued

Table A.1B.1 Transgenic and Gene-Targeted Mice for Toxicology Studies, continued

Gene symbol and name	Mutant type[a]	Description	Reference(s)	Available from[b]
ras Ha-*ras* oncogene Whey acidic protein (wap)-ras	Tg	Increased incidence of mammary and salivary gland tumors. Model for in vivo evaluation of molecular mechanisms of proto-oncogene activation.	Andres et al., 1987. *PNAS* 84:1299	JL
Rb Retinoblastoma tumor-suppressor gene	Tm	Neuronal cell death and defective erythropoiesis in 14-15 day old homozygous pups and development of pituitary tumors in heterozygous adult mice. Model for evaluating normal function in cells and for human familial retinoblastoma. Heterozygous mice exhibit high incidence of spontaneous pituitary tumors between 2 and 11 months of age. Model for addressing tissue-specific tumor predisposition by inactivation of ubiquitously expressed tumor-suppressor gene.	Jacks et al., 1992. *Nature* 359:295; Hu et al., 1994. *Oncogene* 9:1021	JL
ret Proto-oncogene MMTV/ret	Tg	Increased incidence of mammary, salivary, and male reproductive tract tumors. Model for evaluating oncogenicity of activated *ret* gene.	Iwamoto et al., 1990. *Oncogene* 5:535	—
Ret Proto-oncogene MT/ret	Tg	Aberrant melanogenesis with melanocytic tumor development. Model for systematic development of melanocytic tumors.	Iwamoto et al., 1991. *EMBO J.* 10:3167	—
Ret Proto-oncogene ret/ptc1	Tm	Progressive thyroid tumors. Model for evaluating neoplastic progression of human thyroid carcinomas.	Santoro et al., 1996. *Oncogene* 12:1821	—
*SA*β*-gal, SA*β*-geo, and ROSA*β*-geo*	Tm	β-gal promoter trap selection for identification of active promoters/genes.	Friedrich and Soriano, 1991. *Genes Dev.* 5:1513	—
Smad3 Transforming growth factor β-receptor gene	Tm	Mouse model of colorectal adenocarcinoma with lymph node metastasis.	Zhu et al., 1998. *Cell* 94:703	—
SOD-1 Copper-zinc superoxide dismutase	Tg	Increased Cu-Zn SOD activity in CNS. Animal model of Down's syndrome. Increased Cu-Zn SOD expression in nervous tissue confers protection against various forms of brain trauma and focal cerebral ischemia. Model for evaluation of role of oxygen in ischemic and traumatic injury.	Epstein et al., 1987. *PNAS* 84:8044; Chan et al., 1994. *Ann. N.Y. Acad. Sci.* 738:93	JL
SOD-1 Copper-zinc superoxide dismutase	Tm	Null mutant mice show a pronounced sensitivity to paraquat and myocardial ischemia reperfusion injury.	Ho et al., 1998. *Environ. Health Perspect.* 106:1219	—

SOD-2 Manganese superoxide dismutase SP-C-Mn-SOD-hGH	Tg	Increased expression confers pulmonary epithelial cell protection against oxygen injury. Used to study the primary role of lung epithelial cell gene expression in oxygen-injury protection.	Wispe et al., 1992. *JBC* 267:23937	—
Tcr-α/β T cell receptor α/β chain genes	Tg	Expression of type II collagen–specific T cell receptor transgenes accelerates onset of arthritis in DBA/1 inbred mice.	Osman et al., 1998. *Int. Immunol.* 10:1613	—
TGF-α/c-myc Transforming growth factor α and the proto-oncogene c-myc	Tg double	Model of oxidation DNA damage and acceleration of hepatocarcinogenesis.	Factor et al., 1998. *JBC* 273:15846	JL
TNF-α Tumor necrosis factor	Tg	Development of chronic inflammatory polyarthritis with prevention possible by administration of anti-hTNF monoclonal antibody. Model for human arthritis.	Keffer et al., 1991. *EMBO J.* 10:4025	—
TNF-α Tumor necrosis factor CD2-TNF	Tm	Diffuse vascular thrombosis and tissue necrosis neutralizable by human TNF mAb administration. Model for evaluating the different contributions of the two TNF receptors in thymus development and signaling.	Probert et al., 1993. *J. Immunol.* 151:1894	JL, TF
tpl-2 Tumor progression loci 2, an oncogenic kinase	Tg	Expression of truncated protein in thymocytes predisposes to development of T cell lymphomas. Model for studying involvement in oncogenesis.	Ceci et al., 1997. *Genes Dev.* 11:688	—
trx Thioredoxin, a reduction/oxidation active protein Ins-TRX	Tm	Reduced incidence of diabetes. Used to assess oxidative stress in pancreatic β cell destruction in autoimmune diabetes.	Hotta et al., 1998. *J. Exp. Med.* 188:1445	—
XPA Xeroderma pigmentosum, group A	Tm	Deletion yields increased susceptibility to ultraviolet-B and carcinogen–induced skin and eye tumors and papillomas. Model for human XPA.	deVries et al., 1995. *Nature* 377:169; O'Neill, 1996. 24:642	—
XPC Xeroderma pigmentosum, group C	Tm	Gene deficiency yields increased susceptibility to ultraviolet-induced carcinogenesis. Animal model for human XPC.	Sands et al., 1995. *Nature* 377:162	TF

[a]Abbreviations: Tg, transgenic; Tm, targeted mutation.

[b]Abbreviations: BK, B & K Universal; JL, The Jackson Laboratory; CR, Charles River Labs; TF, Taconic Farms. See *SUPPLIERS APPENDIX* for contact information. If no commercial supplier is listed, consult the author of the cited paper.

LABORATORY STOCK SOLUTIONS AND EQUIPMENT

Common Stock Solutions and Buffers

This section describes the preparation of buffers and reagents used in this manual. When preparing solutions, use Milli-Q-purified water (or equivalent) and reagents of the highest available grade. Sterilization—by filtration through a 0.22-µm filter or by autoclaving—is recommended for most solutions stored at room temperature. Where storage conditions are not specified, store up to 6 months at room temperature. Discard any solution that shows evidence of contamination, precipitation, or discoloration.

Standardized and reference reagents are sometimes required—e.g., for quality control, positive and negative controls, equipment calibration, and assay validation. Environmental and chemical standards are available from a number of suppliers, including the National Institute of Standards and Technology (NIST), AccuStandard Inc., and Sigma Chemical Co. Consult the *LabGuide*, published annually by the American Chemical Society (ACS) for other suppliers (e.g., ACS, 1999).

Acid, concentrated stock solutions

See Table A.2A.1.

Ammonium acetate, 10 M

Dissolve 385.4 g ammonium acetate in 150 ml H_2O
Add H_2O to 500 ml

Ammonium hydroxide, concentrated stock solution

See Table A.2A.1.

Ammonium sulfate, saturated

76 g ammonium sulfate
100 ml H_2O
Heat with stirring to just below boiling point
Let stand overnight at room temperature

Table A.2A.1 Molarities and Specific Gravities of Concentrated Acids and Bases[a]

Acid/base	Molecular weight	% by weight	Molarity (approx.)	Specific gravity	1 M solution (ml/liter)
Acetic acid (glacial)	60.05	99.6	17.4	1.05	57.5
Ammonium hydroxide	35.0	28	14.8	0.90	67.6
Formic acid	46.03	90	23.6	1.205	42.4
		98	25.9	1.22	38.5
Hydrochloric acid	36.46	36	11.6	1.18	85.9
Nitric acid	63.01	70	15.7	1.42	63.7
Perchloric acid	100.46	60	9.2	1.54	108.8
		72	12.2	1.70	82.1
Phosphoric acid	98.00	85	14.7	1.70	67.8
Sulfuric acid	98.07	98	18.3	1.835	54.5

[a]*CAUTION:* Handle strong acids and bases carefully.

Current Protocols in Toxicology (1999) A.2A.1-A.2A.6

ATP, 100 mM

1 g ATP (adenosine triphosphate)
12 ml H_2O
Adjust pH to 7.0 with 4 M NaOH
Adjust volume to 16.7 ml with H_2O
Store in aliquots indefinitely at −20°C

Base, concentrated stock solutions

See Table A.2A.1.

$CaCl_2$, 1 M

147 g $CaCl_2 \cdot 2H_2O$
H_2O to 1 liter

Carbonate buffer

1.6 g Na_2CO_3 (15 mM final)
2.9 g $NaHCO_3$ (35 mM final)
0.2 g NaN_3 (3.1 mM final)
H_2O to 1 liter
Adjust to pH 9.5

CAUTION: *Sodium azide is poisonous; follow appropriate precautions for handling, storage, and disposal.*

CMF-DPBS (calcium- and magnesium-free Dulbecco's phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
2.16 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM)
0.20 g KH_2PO_4 (1.1 mM)
H_2O to 1 liter

DPBS (Dulbecco's phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
0.20 g KH_2PO_4 (1.1 mM)
0.10 g $MgCl_2 \cdot 6H_2O$ (0.5 mM)
2.16 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM)
0.10 g anhydrous $CaCl_2$ (0.9 mM)
H_2O to 1 liter

DTT (dithiothreitol), 1 M

Dissolve 1.55 g DTT in 10 ml water and filter sterilize. Store in aliquots at −20°C.

EDTA (ethylenediaminetetraacetic acid), 0.5 M (pH 8.0)

Dissolve 186.1 g disodium EDTA dihydrate in 700 ml water. Adjust pH to 8.0 with 10 M NaOH (~50 ml; add slowly). Add water to 1 liter and filter sterilize.

Begin titrating before the sample is completely dissolved. EDTA, even the disodium salt, is difficult to dissolve at this concentration unless the pH is increased to between 7 and 8.

HBSS (Hanks' balanced salt solution)

0.40 g KCl (5.4 mM final)
0.09 g $Na_2HPO_4 \cdot 7H_2O$ (0.3 mM final)
0.06 g KH_2PO_4 (0.4 mM final)
0.35 g $NaHCO_3$ (4.2 mM final)
0.14 g $CaCl_2$ (1.3 mM final)
0.10 g $MgCl_2 \cdot 6H_2O$ (0.5 mM final)

continued

0.10 g $MgSO_4 \cdot 7H_2O$ (0.6 mM final)
8.0 g NaCl (137 mM final)
1.0 g D-glucose (5.6 mM final)
0.2 g phenol red (0.02%; optional)
Add H_2O to l liter and adjust pH to 7.4 with 1 M HCl or 1 M NaOH
Filter sterilize and store up to 1 month at 4°C

HBSS may be made or purchased without Ca^{2+} and Mg^{2+} (CMF-HBSS). These components are optional and usually have no effect on an experiment; in a few cases, however, their presence may be detrimental. Consult individual protocols to see if the presence or absence of these components is recommended.

Bottles should be kept tightly closed to prevent CO_2 loss and subsequent alkalinization.

HCl, 1 M

Mix in the following order:
913.8 ml H_2O
86.2 ml concentrated HCl

KCl, 1 M

74.6 g KCl
H_2O to 1 liter

$MgCl_2$, 1 M

20.3 g $MgCl_2 \cdot 6H_2O$
H_2O to 100 ml

$MgSO_4$, 1 M

24.6 g $MgSO_4 \cdot 7H_2O$
H_2O to 100 ml

NaCl, 5 M

292 g NaCl
H_2O to 1 liter

NaCl (saline), 0.9% (w/v)

9 g NaCl (154 mM final)
H_2O to 1 liter

NaOH, 10 M

Dissolve 400 g NaOH in 450 ml H_2O
H_2O to 1 liter

PBS (phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
0.24 g KH_2PO_4 (1.4 mM)
1.44 g Na_2HPO_4 (0.01 M)
H_2O to 1 liter

Potassium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid per liter (0.2 M) in water.

Solution B: 19.6 g potassium acetate ($KC_2H_3O_2$) per liter (0.2 M) in water.

Referring to Table A.2A.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 100 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

continued

This may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium acetate in the same volume. Acetate buffers show concentration-dependent pH changes, so check the pH by diluting an aliquot of concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.2, prepare closest higher pH, then titrate with solution A.

Potassium phosphate buffer, 0.1 M

Solution A: 27.2 g KH_2PO_4 per liter (0.2 M final) in water.

Solution B: 34.8 g K_2HPO_4 per liter (0.2 M final) in water.

Referring to Table A.2A.3 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 200 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This buffer may be made as a 5- or 10-fold concentrate simply by scaling up the amount of potassium phosphate in the same final volume. Phosphate buffers show concentration-dependent changes in pH, so check the pH of the concentrate by diluting an aliquot to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.3, prepare closest higher pH, then titrate with solution A.

Table A.2A.2 Preparation of 0.1 M Sodium and Potassium Acetate Buffers[a]

Desired pH	Solution A (ml)	Solution B (ml)
3.6	46.3	3.7
3.8	44.0	6.0
4.0	41.0	9.0
4.2	36.8	13.2
4.4	30.5	19.5
4.6	25.5	24.5
4.8	20.0	30.0
5.0	14.8	35.2
5.2	10.5	39.5
5.4	8.8	41.2
5.6	4.8	45.2

[a]Adapted by permission from CRC (1975).

Table A.2A.3 Preparation of 0.1 M Sodium and Potassium Phosphate Buffers[a]

Desired pH	Solution A (ml)	Solution B (ml)	Desired pH	Solution A (ml)	Solution B (ml)
5.7	93.5	6.5	6.9	45.0	55.0
5.8	92.0	8.0	7.0	39.0	61.0
5.9	90.0	10.0	7.1	33.0	67.0
6.0	87.7	12.3	7.2	28.0	72.0
6.1	85.0	15.0	7.3	23.0	77.0
6.2	81.5	18.5	7.4	19.0	81.0
6.3	77.5	22.5	7.5	16.0	84.0
6.4	73.5	26.5	7.6	13.0	87.0
6.5	68.5	31.5	7.7	10.5	90.5
6.6	62.5	37.5	7.8	8.5	91.5
6.7	56.5	43.5	7.9	7.0	93.0
6.8	51.0	49.0	8.0	5.3	94.7

Table A.2A.4 Preparation of SDS Sample Buffer

Ingredient	2×	4×	Final conc. in 1× buffer
0.5 M Tris·Cl, pH 6.8[a]	2.5 ml	5.0 ml	62.5 mM
SDS	0.4 g	0.8 g	2% (w/v)
Glycerol	2.0 ml	4.0 ml	10% (v/v)
Bromphenol blue	20 mg	40 mg	0.1% (w/v)
2-Mercaptoethanol[b,c]	400 µl	800 µl	~300 mM
H_2O	to 10 ml	to 10 ml	—

[a]See recipe below.
[b]Alternatively, dithiothreitol (DTT), at a final concentration of 100 mM, can be substituted for 2-mercaptoethanol.
[c]Add just before use.

SDS, 20% (w/v)

Dissolve 20 g SDS (sodium dodecyl sulfate or sodium lauryl sulfate) in H_2O to 100 ml total volume with stirring. Filter sterilize using a 0.45-µm filter.

It may be necessary to heat the solution slightly to fully dissolve the powder.

SDS electrophoresis buffer, 5×

15.1 g Tris base
72.0 g glycine
5.0 g SDS
Distilled, deionized H_2O to 1 liter
Store up to 1 month at 0° to 4°C
Dilute to 1× before use

Do not adjust the pH of the stock solution; the pH is 8.3 when diluted to 1×.

Use purified SDS if appropriate.

SDS sample buffer

See Table A.2A.4.

Sodium acetate, 3 M

Dissolve 408 g sodium acetate trihydrate ($NaC_2H_3O_2{\cdot}3H_2O$) in 800 ml H_2O
Adjust pH to 4.8, 5.0, or 5.2 (as desired) with 3 M acetic acid (see Table A.2A.1)
Add H_2O to 1 liter
Filter sterilize

Sodium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid per liter (0.2 M) in water.

Solution B: 27.2 g sodium acetate ($NaC_2H_3O_2{\cdot}3H_2O$) per liter (0.2 M) in water.

Referring to Table A.2A.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 100 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium acetate in the same volume. Acetate buffers show concentration-dependent pH changes, so check the pH by diluting an aliquot of concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.2, prepare closest higher pH, then titrate with solution A.

Sodium phosphate buffer, 0.1 M

Solution A: 27.6 g $NaH_2PO_4 \cdot H_2O$ per liter (0.2 M final) in water.

Solution B: 53.65 g $Na_2HPO_4 \cdot 7H_2O$ per liter (0.2 M) in water.

Referring to Table A.2A.3 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 200 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This buffer may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium phosphate in the same final volume. Phosphate buffers show concentration-dependent changes in pH, so check the pH by diluting an aliquot of the concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.3, prepare closest higher pH, then titrate with solution A.

TBS (Tris-buffered saline)

100 mM Tris·Cl, pH 7.5 (see recipe below)
0.9% (w/v) NaCl
Store up to several months at 4°C

Tris·Cl, 1 M

Dissolve 121 g Tris base in 800 ml H_2O
Adjust to desired pH with concentrated HCl
Adjust volume to 1 liter with H_2O
Filter sterilize if necessary
Store up to 6 months at 4°C or room temperature

Approximately 70 ml HCl is needed to achieve a pH 7.4 solution, and ~42 ml for a solution that is pH 8.0.

IMPORTANT NOTE: *The pH of Tris buffers changes significantly with temperature, decreasing approximately 0.028 pH units per 1°C. Tris-buffered solutions should be adjusted to the desired pH at the temperature at which they will be used. Because the pK_a of Tris is 8.08, Tris should not be used as a buffer below pH ~7.2 or above pH ~9.0.*

Standard Laboratory Equipment

Listed below are pieces of equipment that are standard in the modern toxicology laboratory—i.e., items used extensively in this manual and thus not usually included in the individual materials lists. No attempt has been made to list all items required for each procedure in the Materials list of each protocol; rather, those lists note those items that might not be readily available in the laboratory or that require special preparation. See *SUPPLIERS APPENDIX* for contact information for commercial vendors of laboratory equipment.

Applicator, cotton-tipped and wooden

Autoclave

Bag sealer

Balances, analytical and preparative

Beakers

Bench protectors, plastic-backed (including "blue" pads)

Biohazard disposal containers and bags

Biosafety cabinet, tissue culture or laminar flow hood; filters air and maintains air flow pattern to protect cultured cells from investigator and vice versa

Bottles, glass, plastic, and squirt

Bunsen burners

Centrifuges, low-speed (to 20,000 rpm) refrigerated, ultracentrifuge (20,000 to 80,000 rpm), large-capacity low-speed, tabletop, with appropriate rotors and adapters

Centrifuge tubes and bottles, plastic and glass, various sizes

Clamps

Conical centrifuge tubes, plastic and glass

Containers, assortment of glass and plastic, for gel and membrane washes

Coplin jars, glass, for 25 × 75–mm slides

Cuvettes, glass and quartz

Desiccator and desiccant

Dry ice

Electrophoresis equipment, agarose and acrylamide, full-size and mini, with power supplies

Film developing system and darkroom

Filtration apparatus

Forceps

Freezers, –20°C, –70°C, and liquid nitrogen

Fume hood

Geiger counter

Gel dryer

Gloves, disposable plastic and heat-resistant

Graduated cylinders

Heating blocks, thermostatically controlled for test tubes and microcentrifuge tubes

Homogenizer

Humidified CO_2 incubator

Ice bucket

Ice maker

Immersion oil for microscopy

Lab coats

Laboratory glassware

Light box

Liquid nitrogen

Lyophilizer

Magnetic stirrer, with and without heater, and stir bars

Markers, including indelible markers, china-marking pens, and luminescent markers

Microcentrifuge, Eppendorf-type with 12,000 to 14,000 rpm maximum speed

Microcentrifuge tubes, 0.2-, 0.5-, 1.5-, 2-ml

Mortar and pestle

Ovens, drying and microwave

Paper cutter, large

Paper towels

Parafilm

Pasteur pipets and bulbs

pH meter

pH paper

Pipets, graduated

Pipettors, adjustable delivery, 0.5- to 10-µl, 10- to 200-µl, and 200- to 1000-µl

Plastic wrap (e.g., Saran Wrap)

Polaroid camera or video documentation system

Power supplies, 300-V for polyacrylamide gels, 2000- to 3000-V for other applications

Current Protocols in Toxicology (1999) A.2B.1-A.2B.2

Racks, test tube and microcentrifuge tubes

Radiation shield, Lucite or Plexiglas

Radioactive waste containers for liquid and solid wastes

Refrigerator, 4°C

Ring stand and rings

Rubber policemen or plastic scrapers

Rubber stoppers

Safety glasses

Scalpels and blades

Scintillation counter, β

Scissors

Shakers, orbital and platform, room temperature or 37°C

Spectrophotometer, visible and UV range

Speedvac evaporator

Syringes and needles

Tape, masking, electrician's black, autoclave, and Time tape

Test tubes, glass and plastic, various sizes, with and without caps

Timer

Toolbox with common tools

Trays, plastic and glass, various sizes

Tubing, rubber and Tygon

UV transparent plastic wrap (e.g., Saran Wrap)

Vacuum desiccator

Vacuum oven

Vacuum supply

Vortex mixers

Waring Blendor or equivalent blender

Water bath with adjustable temperature

Water purification system

X-ray film cassettes and intensifying screens

Molecular Biology Techniques

Protocols presented in *Current Protocols in Toxicology* (CPTX) may include molecular biological, biochemical, and other biological techniques that may not be fully described in this manual. Although it may be reasonable to assume that readers have at least a basic understanding of these techniques, there are times when a full step-by-step description of a procedure is helpful. For that reason we have included the following table (Table A.3A.1), which lists common molecular biology techniques, some of which are described in this manual and provides references to specific units in its sister publications *Current Protocols in Molecular Biology* (CPMB; Ausubel et al., 1999), *Current Protocols in Immunology* (CPI; Coligan et al., 1999), and *Current Protocols in Cell Biology* (CPCB; Bonifacino et al., 1999), which describe the methods in more detail. Protocols for some of these techniques will be added as units or as sections of this appendix in future supplements. Alternatively, the reader may wish to consult any of the many other texts and manuals specifically devoted to recombinant DNA technology and biochemical analysis.

Techniques for Mammalian Cell Tissue Culture

Tissue culture technology has found wide application in biological research. Monolayer cell cultures and suspension are utilized in cytogenetic, biochemical, and molecular laboratories for diagnostic as well as research studies. In most cases, cells or tissues must be grown in culture for days or weeks to obtain sufficient numbers of cells for analysis. Maintenance of cells in long-term culture requires strict adherence to aseptic technique to avoid contamination and potential loss of valuable cell lines. The first section of this appendix discusses basic principles of aseptic technique.

An important factor influencing the growth of cells in culture is the choice of tissue culture medium. Many different recipes for tissue culture media are available and each laboratory must determine which medium best suits their needs. Individual laboratories may elect to use commercially prepared medium or prepare their own. Commercially available medium can be obtained as a sterile and ready-to-use liquid, in a concentrated liquid form, or in a powdered form. Besides providing nutrients for growing cells, medium is generally supplemented with antibiotics, fungicides, or both to inhibit contamination. The second section of this appendix discusses medium preparation.

As cells reach confluency, they must be subcultured or passaged. Failure to subculture confluent cells results in reduced mitotic index and eventually in cell death. The first step in subculturing monolayers is to detach cells from the surface of the primary culture vessel by trypsinization or mechanical means (see Basic Protocol). The resultant cell suspension is then subdivided, or reseeded, into fresh cultures. Suspension cells are more easily passaged (see Alternate Protocol). Secondary cultures are checked for growth, fed periodically, and may be subsequently subcultured to produce tertiary cultures, etc. The time between passaging cells varies with the cell line and depends on the growth rate.

Support protocols describe freezing of monolayer (see Support Protocol 1) and suspension cells (see Support Protocol 2), thawing and recovery of cells (see Support Protocol 3), cell counting using a hemacytometer (see Support Protocol 4), and preparation of cells for transport (see Support Protocol 5).

ASEPTIC TECHNIQUE

It is essential that aseptic technique be maintained when working with cell cultures. Aseptic technique involves a number of precautions to protect both the cultured cells and the laboratory worker from infection. Laboratory workers must realize that cells handled in the lab are potentially infectious and should be handled with caution. Protective apparel such as gloves, lab coats or aprons, and eyewear should be worn when appropriate (Knutsen, 1997). Care should be taken when handling sharp objects such as needles, scissors, scalpel blades, and glass that could puncture the skin. Sterile disposable plastic supplies may be used to avoid the risk of broken or splintered glass (Rooney and Czepulkowski, 1992).

Frequently, specimens received in the laboratory are not sterile, and cultures prepared from these specimens may become contaminated with bacteria, fungus, or yeast. The presence of microorganisms can inhibit growth, kill cell cultures, or lead to inconsistencies in test results. The contaminants deplete nutrients in the medium and may produce substances that are toxic to cells. Antibiotics (penicillin, streptomycin, kanamycin, or gentamycin) and fungicides (amphotericin B or mycostatin) may be added to tissue culture medium to combat potential contaminants (see Table A.3B.1). An antibiotic/an-

Contributed by Mary C. Phelan
Current Protocols in Toxicology (1999) A.3B.1-A.3B.15

timycotic solution or lyophilized powder that contains penicillin, streptomycin, and amphotericin B is available from Sigma. The solution can be used to wash specimens prior to culture and can be added to medium used for tissue culture. Similar preparations are available from other suppliers.

All materials that come into direct contact with cultures must be sterile. Sterile disposable dishes, flasks, pipets, etc., can be obtained directly from manufacturers. Reusable glassware must be washed, rinsed thoroughly, then sterilized by autoclaving or by dry heat before reusing. With dry heat, glassware should be heated 90 min to 2 hr at 160°C to ensure sterility. Materials that may be damaged by very high temperatures can be autoclaved 20 min at 120°C and 15 psi. All media, reagents, and other solutions that come into contact with the cultures must also be sterile; medium may be obtained as a sterile liquid from the manufacturer, autoclaved if not heat-sensitive, or filter sterilized. Supplements can be added to media prior to filtration, or they can be added aseptically after filtration. Filters with 0.20- to 0.22-μm pore size should be used to remove small gram-negative bacteria from culture media and solutions.

Contamination can occur at any step in handling cultured cells. Care should be taken when pipetting media or other solutions for tissue culture. The necks of bottles and flasks, as well as the tips of the pipets, should be flamed before the pipet is introduced into the bottle. If the pipet tip comes into contact with the benchtop or any other nonsterile surface, it should be discarded and a fresh pipet obtained. Forceps and scissors used in tissue culture can be rapidly sterilized by dipping in 70% alcohol and flaming.

Although tissue culture work can be done on an open bench if aseptic methods are strictly enforced, many labs prefer to perform tissue culture work in a room or low-traffic area reserved specifically for that purpose. At the very least, biological safety cabinets are recommended to protect the cultures as well as the laboratory worker. In a laminar-flow hood, the flow of air protects the work area from dust and contamination and acts as a barrier between the work surface and the worker. Many different styles of safety hoods are available and the laboratory should consider the types of samples being processed and the types of potential pathogenic exposure in making a selection. Manufacturer recommendations should be followed regarding routine maintenance checks on air flow and filters. For day-to-day use, the cabinet should be turned on for at least 5 min prior to beginning work. All work surfaces both inside and outside of the hood should be kept clean and disinfected daily and after each use.

Some safety cabinets are equipped with ultraviolet (UV) lights for decontamination of work surfaces. However, use of UV lamps is no longer recommended, as it is generally ineffective (Knutsen, 1997). UV lamps may actually produce a false sense of security as they maintain a visible blue glow long after their germicidal effectiveness is lost. Effectiveness diminishes over time as the glass tube gradually loses its ability to transmit short UV wavelengths, and it may also be reduced by dust on the glass tube, distance from the work surface, temperature, and air movement. Even when the UV output is adequate, the rays must directly strike a microorganism in order to kill it; bacteria or mold spores hidden below the surface of a material or outside the direct path of the rays will not be destroyed. Another rule of thumb is that anything that can be seen cannot be killed by UV. UV lamps will only destroy microorganisms such as bacteria, virus, and mold spores; they will not destroy insects or other large organisms (Westinghouse Electric Company, 1976). The current recommendation is that work surfaces be wiped down with ethanol instead of relying on UV lamps, although some labs use the lamps in addition to ethanol wipes to decontaminate work areas. A special metering device is available to measure the output of UV lamps, and the lamps should be replaced when they fall below the minimum requirements for protection (Westinghouse Electric Company, 1976).

Cultures should be checked routinely for contamination. Indicators in the tissue culture medium change color when contamination is present: for example, medium that contains phenol red changes to yellow because of increased acidity. Cloudiness and turbidity are also observed in contaminated cultures. Once contamination is confirmed with a microscope, infected cultures are generally discarded. Keeping contaminated cultures increases the risk of contaminating other cultures. Sometimes a contaminated cell line can be salvaged by treating it with various combinations of antibiotics and antimycotics in an attempt to eradicate the infection (e.g., see Fitch et al., 1997). However, such treatment may adversely affect cell growth and is often unsuccessful in any case. In addition to microscopically detectable bacteria and fungi, cultures can be contaminated by mycoplasma, which require more elaborate procedures to detect (Coté, 1999).

PREPARING CULTURE MEDIUM

Choice of tissue culture medium comes from experience. An individual laboratory must select the medium that best suits the type of cells being cultured. Chemically defined media are available in liquid or powdered form from a number of suppliers. Sterile, ready-to-use medium has the advantage of being convenient, although it is more costly than other forms. Powdered medium must be reconstituted with tissue culture–grade water according to manufacturer's directions. Distilled or deionized water is not of sufficiently high quality for medium preparation; double- or triple-distilled water or commercially available tissue culture water should be used. The medium should be filter sterilized and transferred to sterile bottles. Prepared medium can generally be stored ≤1 month in a 4°C refrigerator. Laboratories using large volumes of medium may choose to prepare their own medium from standard recipes. This is the most economical approach, but it is time-consuming.

Basic media such as Eagle's minimal essential medium (MEM), Dulbecco's modified Eagle medium (DMEM), Glasgow modified Eagle's medium (GMEM), and RPMI 1640 and Ham's F10 nutrient mixtures (e.g., Life Technologies) are composed of amino acids, glucose, salts, vitamins, and other nutrients. A basic medium is supplemented by addition of L-glutamine, antibiotics (typically penicillin and streptomycin sulfate), and usually serum to formulate a "complete medium." Where serum is added, the amount is indicated as a percentage of fetal bovine serum (FBS) or other serum. Some media are also supplemented with antimycotics, nonessential amino acids, various growth factors, and/or drugs that provide selective growth conditions. Supplements should be added to medium prior to sterilization or filtration, or added aseptically just before use.

The optimum pH for most mammalian cell cultures is 7.2 to 7.4. Adjust the medium's pH as necessary after all supplements are added. Buffers such as bicarbonate and HEPES are routinely used in tissue culture medium to prevent fluctuations in pH that might adversely affect cell growth. HEPES is especially useful in solutions used for procedures that do not take place in a controlled-CO_2 environment.

Most cultured cells will tolerate a wide range of osmotic pressure and an osmolarity between 260 and 320 mOsm/kg is acceptable for most cells. The osmolarity of human plasma is ~290 mOsm/kg, and this is probably the optimum for human cells in culture as well (Freshney, 1993).

Fetal bovine serum (FBS) is the most frequently used serum supplement. Calf serum, horse serum, and human serum are also used; some cell lines are maintained in serum-free medium (Freshney, 1993). Complete medium is supplemented with 5% to 30% (v/v) serum, depending on the requirements of the particular cell type being cultured. Serum

Table A.3B.1 Working Concentrations of Antibiotics and Fungicides for Mammalian Cell Culture

Additive	Final concentration
Penicillin	50–100 U/ml
Streptomycin sulfate	50–100 µg/ml
Kanamycin	100 µg/ml
Gentamycin	50 µg/ml
Mycostatin	20 µg/ml
Amphotericin B	0.25 µg/ml

that has been heat inactivated (30 min to 1 hr at 56°C; see recipe) is generally preferred, because this inactivates complement and is thought to reduce the number of contaminants. Serum is obtained frozen, then is thawed, divided into smaller portions, and refrozen until needed.

There is considerable lot-to-lot variation in FBS. Most suppliers will provide a sample of a specific lot and reserve a supply of that lot while the serum is tested for its suitability. The suitability of a serum lot depends upon the use. Frequently the ability of serum to promote cell growth equivalent to a laboratory standard is used to evaluate a serum lot. Once an acceptable lot is identified, enough of that lot should be purchased to meet the culture needs of the laboratory for an extended period of time.

Commercially prepared media containing L-glutamine are available, but many laboratories choose to obtain medium without L-glutamine and then add it to a final concentration of 2 mM just before use. L-glutamine is an unstable amino acid that, upon storage, converts to a form cells cannot use. Breakdown of L-glutamine is temperature and pH dependent. At 4°C, 80% of the L-glutamine remains after 3 weeks, but at incubator temperature (35°C) the amount diminishes more rapidly (Brown and Lawce, 1997). To prevent degradation, 100× L-glutamine (see recipe) should be stored frozen in aliquots until needed.

As well as practicing good aseptic technique, most laboratories add antimicrobial agents to medium to further reduce the risk of contamination. A combination of penicillin and streptomycin is the most commonly used antibiotic additive; kanamycin and gentamycin are used alone. Mycostatin and amphotericin B are the most commonly used fungicides (Rooney and Czepulkowski, 1992). Table A.3B.1 lists suggested working concentrations for the most commonly used antibiotics and antimycotics. Combining antibiotics in tissue culture medium can be tricky, as some antibiotics are not compatible, and one may inhibit the action of another. Furthermore, combined antibiotics may be cytotoxic at lower concentrations than is true for the individual antibiotics. In addition, prolonged use of antibiotics may cause cell lines to develop antibiotic resistance. For this reason, some laboratories add antibiotics and/or fungicides to medium when initially establishing a culture but eliminate them from medium used in later subcultures.

All tissue culture medium, whether prepared commercially or within the laboratory, should be tested for sterility prior to use. A small aliquot from each lot of medium is incubated 48 hr at 37°C and monitored for evidence of contamination such as turbidity (infected medium will be cloudy) and color change (if phenol red is the indicator, infected medium will turn yellow). Any contaminated medium should be discarded.

TRYPSINIZING AND SUBCULTURING CELLS FROM A MONOLAYER

BASIC PROTOCOL

A primary culture is grown to confluency in a 60-mm petri dish or 25-cm^2 tissue culture flask containing 5 ml tissue culture medium. Cells are dispersed by trypsin treatment and then reseeded into secondary cultures. The process of removing cells from the primary culture and transferring them to secondary cultures constitutes a passage or subculture.

Materials

Cells cultures
HBSS *without* Ca^{2+} and Mg^{2+} (*APPENDIX 2A*), 37°C
0.25% (w/v) trypsin/0.2% EDTA solution (see recipe), 37°C
Complete medium with serum: e.g., DMEM supplemented with 10% to 15% (v/v) FBS (complete DMEM-10; see recipe), 37°C

Sterile Pasteur pipets
37°C warming tray or incubator
Tissue culture plasticware or glassware including pipets and 25-cm^2 flasks or 60-mm petri dishes, sterile

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Remove all medium from culture with a sterile Pasteur pipet. Wash adhering cell monolayer once or twice with a small volume of 37°C HBSS without Ca^{2+} and Mg^{2+} to remove any residual FBS, which may inhibit the action of trypsin.

   Use a buffered salt solution that is Ca^{2+}- and Mg^{2+}-free to wash cells. Ca^{2+} and Mg^{2+} in the salt solution can cause cells to stick together.

   If this is the first medium change from primary culture, rather than discarding medium that is removed from primary culture, transfer it to a fresh dish or flask. The medium contains unattached cells that may attach and grow, thereby providing a backup culture.

2. Add enough 37°C trypsin/EDTA solution to culture to cover adhering cell layer.
3. Place plate on a 37°C warming tray 1 to 2 min. Tap bottom of plate on the countertop to dislodge cells. Check culture with an inverted microscope to be sure that cells are rounded up and detached from the surface.

   If cells are not sufficiently detached, return plate to warming tray for an additional minute or two.

4. Add 2 ml of 37°C complete medium. Draw cell suspension into a Pasteur pipet and rinse cell layer two or three times to dissociate cells and to dislodge any remaining adherent cells. As soon as cells are detached, add serum or medium containing serum to inhibit further trypsin activity that might damage cells.

   If cultures are to be split 1/3 or 1/4 rather than 1/2, add sufficient medium such that 1 ml of cell suspension can be transferred into each fresh culture vessel.

5. Add an equal volume of cell suspension to fresh dishes or flasks that have been appropriately labeled.

   Alternatively, cells can be counted using a hemacytometer (see Support Protocol 4) or Coulter counter and diluted to the desired density so a specific number of cells can be added to each culture vessel. A final concentration of ~5×10^4 cells/ml is appropriate for most subcultures.

   For primary cultures and early subcultures, 60-mm petri dishes or 25-cm^2 flasks are generally used; larger petri dishes or flasks (e.g., 150-mm dishes or 75-cm^2 flasks) may be used for later subcultures.

   Cultures should be labeled with cell line identification, lab number, date of subculture, and passage number.

6. Add 4 ml fresh medium to each new culture. Incubate in a humidified 37°C, 5% CO_2 incubator.

   If using 75-cm^2 culture flasks, add 9 ml medium per flask.

   Some labs now use incubators with 5% CO_2 and 4% O_2. The low oxygen concentration is thought to simulate the in vivo environment of cells and to enhance cell growth. However, some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH.

7. If necessary, feed subconfluent cultures after 3 or 4 days by removing old medium and adding fresh 37°C medium.

8. Passage secondary culture when it becomes confluent by repeating steps 1 to 7, and continue to passage as necessary.

ALTERNATE PROTOCOL

PASSAGING CELLS IN SUSPENSION CULTURE

A suspension culture is grown in culture flasks in a humidified 37°C, 5% CO_2 incubator. Passaging of suspension cultures is somewhat less complicated than passaging of monolayer cultures. Because the cells are suspended in medium rather than attached to a surface, it is not necessary to disperse them enzymatically before passaging. However, before passaging, cells must be maintained in culture by feeding every 2 to 3 days until they reach confluency (i.e., until the cells clump together in the suspension and the medium appears turbid when the flask is swirled).

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Feed cells as follows every 2 to 3 days until the cultures are confluent:

   a. Remove flask of suspension cells from incubator, taking care not to disturb those that have settled to the flask bottom.

   b. Aseptically remove and discard about one-third of the medium from flask and replace with an equal volume of prewarmed (37°C) medium. If the cells are growing rapidly, add an additional 10% medium by volume in order to maintain optimum concentration of 1×10^6 cells/ml. Gently swirl flask to resuspend cells.

   c. Return flask to incubator. If there is <15 ml of medium in the flask, incubate flask in horizontal position to enhance cell/medium contact.

      At higher volumes of medium the flask can be incubated in the vertical position.

      If using a 25-cm^2 flask, there should be 20 to 30 ml of medium in the flask at confluency.

2. On the days cultures are not being fed, check them by swirling flask to resuspend cells and observing color changes in the medium that indicate good metabolic growth.

3. When cultures are confluent (~2.5×10^6 cells/ml), passage culture as follows:

   a. Remove flask from incubator and swirl flask so that cells are evenly distributed in the medium.

   b. Aseptically remove half of the volume of cell suspension and place into a fresh flask.

   c. Feed each flask with 7 to 10 ml prewarmed medium and return flask to incubator.

      Some labs prefer to split the cells 1:3 or 1:4, although increasing the split ratio will result in a longer interval before subcultures reach confluency.

FREEZING HUMAN CELLS GROWN IN MONOLAYER CULTURES

SUPPORT PROTOCOL 1

It is sometimes desirable to store cell lines for future study. To preserve cells, avoid senescence, reduce the risk of contamination, and minimize effects of genetic drift, cell lines may be frozen for long-term storage. Without the use of a cryoprotective agent freezing would be lethal to the cells in most cases. Generally, a cryoprotective agent such as dimethylsulfoxide (DMSO) is used in conjunction with complete medium for preserving cells at −70°C or lower. DMSO acts to reduce the freezing point and allows a slower cooling rate. Gradual freezing reduces the risk of ice crystal formation and cell damage.

Materials

Log-phase monolayer culture of cells in petri dish
Complete medium
Freezing medium: complete medium with 10% to 20% (v/v) FBS (e.g., complete DMEM-20 or complete RPMI-20; see recipe) supplemented with 5% to 10% (v/v) DMSO, 4°C
Benchtop clinical centrifuge (e.g., Fisher Centrific or Clay Adams Dynac) with 45° fixed-angle or swinging-bucket rotor

1. Trypsinize log-phase monolayer culture of cells from plate (see Basic Protocol, steps 1 to 4).

   It is best to use cells in log-phase growth for cryopreservation.

2. Transfer cell suspension to a sterile centrifuge tube and add 2 ml complete medium with serum. Centrifuge 5 min at 300 to 350 × *g* (~1500 rpm in Fisher Centrific rotor), room temperature.

   Cells from three or more dishes from the same subculture of the same patient can be combined in one tube.

3. Remove supernatant and add 1 ml of 4°C freezing medium. Resuspend pellet.

4. Add 4 ml of 4°C freezing medium, mix cells thoroughly, and place on wet ice.

5. Count cells using a hemacytometer (see Support Protocol 4). Dilute with more freezing medium as necessary to get a final cell concentration of 10^6 or 10^7 cells/ml.

   To freeze cells from a nearly confluent 25-cm^2 flask, resuspend in roughly 3 ml freezing medium.

6. Pipet 1-ml aliquots of cell suspension into labeled 2-ml cryovials. Tighten caps on vials.

7. Place vials 1 hr to overnight in a −70°C freezer, then transfer to liquid nitrogen storage freezer.

   Alternatively, freeze cells in a freezing chamber in the neck of a Dewar flask according to manufacturer's instructions. Some laboratories place vials directly into the liquid nitrogen freezer, omitting the gradual temperature drop. Although this is contrary to the general recommendation to gradually reduce the temperature, laboratories that routinely use a direct-freezing technique report no loss of cell viability on recovery.

   Liquid nitrogen is a potential source of contamination. It may seep into vials between the cap and tube. For this reason, some investigators prefer to freeze cells in flame-sealed glass vials.

   IMPORTANT NOTE: *Keep accurate records of the identity and location of cells stored in liquid nitrogen freezers. Cells may be stored for many years and proper information is imperative for locating a particular line for future use.*

SUPPORT PROTOCOL 2

FREEZING CELLS GROWN IN SUSPENSION CULTURE

Freezing cells from suspension culture is similar in principle to freezing cells from monolayer. The major difference is that suspension cultures need not be trypsinized.

1. Transfer cell suspension to a centrifuge tube and centrifuge 10 min at 300 to 350 × *g* (~1500 rpm in Fisher Centrific centrifuge), room temperature.
2. Remove supernatant and resuspend pellet in 4°C freezing medium at a density of 10^6 to 10^7 cells/ml.

   Some laboratories freeze lymphoblastoid lines at the higher cell density because they plan to recover them in a larger volume of medium and because there may be a greater loss of cell viability upon recovery as compared to other types of cells (e.g., fibroblasts).

3. Transfer 1-ml aliquots of cell suspension into labeled cryovials and freeze as for monolayer cultures.

   Liquid nitrogen is a potential source of contamination. It may seep into vials between the cap and tube. For this reason, some investigators prefer to freeze cells in flame-sealed glass vials.

SUPPORT PROTOCOL 3

THAWING AND RECOVERING FROZEN CELL CULTURES

When cryopreserved cells are needed for study, they should be thawed rapidly and plated at high density to optimize recovery.

CAUTION: Protective clothing, particularly insulated gloves and goggles, should be worn when removing frozen vials or ampules from the liquid nitrogen freezer. The room containing the liquid nitrogen freezer should be well-ventilated. Care should be taken not to spill liquid nitrogen on the skin.

Materials

Cryopreserved cells stored in liquid nitrogen freezer
70% (v/v) ethanol
Complete medium containing 20% FBS, 37°C: e.g., complete DMEM-20 or complete RPMI-20 (see recipes), 37°C
Tissue culture dish or flask

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Remove vial of cells from liquid nitrogen freezer and immediately place it into a 37°C water bath. Agitate vial continuously until medium is thawed.

   The medium usually thaws in <60 sec.

   Cells should be thawed as quickly as possible to prevent formation of ice crystals which can cause cell lysis. Try to avoid getting water around the cap of the vial.

2. Wipe top of vial with 70% ethanol before opening.

   Some labs prefer to submerge the vial in 70% ethanol and air dry before opening.

3. Transfer thawed cell suspension into a sterile centrifuge tube containing 2 ml warm complete medium containing 20% FBS. Centrifuge 10 min at 150 to 200 × *g* (~1000 rpm in Fisher Centrific), room temperature. Discard supernatant.

   Cells are washed with fresh medium to remove residual DMSO.

4. Gently resuspend cell pellet in small amount (~1 ml) of complete medium/20% FBS and transfer to properly labeled culture dish or flask containing the appropriate amount of medium.

   Cultures are reestablished at a higher cell density than that used for original cultures because there is some cell death associated with freezing. Generally, 1 ml cell suspension is reseeded in 5 to 20 ml medium.

5. Check cultures after ~24 hr to ensure that cells have attached to the plate.

6. Change medium after 5 to 7 days or when pH indicator (e.g., phenol red) in medium changes color. Keep cultures in medium with 20% FBS until cells are reestablished.

   If recovery rate is extremely low, only a subpopulation of the original culture may be growing; be extra careful of this when working with cell lines known to be mosaic.

DETERMINING CELL NUMBER AND VIABILITY WITH A HEMACYTOMETER AND TRYPAN BLUE STAINING

SUPPORT PROTOCOL 4

Determining the number of cells in culture is important in standardization of culture conditions and in performing accurate quantitation experiments. A hemacytometer is a thick glass slide with a central area designed as a counting chamber.

The exact design of the hemacytometer may vary; the one described here is the Improved Neubauer from Baxter Scientific (Fig. A.3B.1). The central portion of the slide is the counting platform, which is bordered by a 1-mm groove. The central platform is divided into two counting chambers by a transverse groove. Each counting chamber consists of a silver footplate on which is etched a 3 × 3–mm grid. This grid is divided into nine secondary squares, each 1 × 1 mm. The four corner squares and the central square are used for determining the cell count. The corner squares are further divided into 16 tertiary squares and the central square into 25 tertiary squares to aid in cell counting.

Accompanying the hemacytometer slide is a thick, even-surfaced coverslip. Ordinary coverslips may have uneven surfaces, which can introduce errors in cell counting; therefore, it is imperative that the coverslip provided with the hemacytometer be used in determining cell number.

Cell suspension is applied to a defined area and counted so cell density can be calculated.

Materials

70% (v/v) ethanol
Cell suspension
0.4% (w/v) trypan blue *or* 0.4% (w/v) nigrosin, prepared in HBSS (*APPENDIX 2A*)

Hemacytometer with coverslip (Improved Neubauer, Baxter Scientific)
Hand-held counter

Prepare hemacytometer

1. Clean surface of hemacytometer slide and coverslip with 70% alcohol.

   Coverslip and slide should be clean, dry, and free from lint, fingerprints, and watermarks.

2. Wet edge of coverslip slightly with tap water and press over grooves on hemacytometer. The coverslip should rest evenly over the silver counting area.

Prepare cell suspension

3. For cells grown in monolayer cultures, detach cells from surface of dish using trypsin (see Basic Protocol, steps 1 to 4).

4. Dilute cells as needed to obtain a uniform suspension. Disperse any clumps.

   When using the hemacytometer, a maximum cell count of 20 to 50 cells per 1-mm square is recommended.

Load hemacytometer

5. Use a sterile Pasteur pipet to transfer cell suspension to edge of hemacytometer counting chamber. Hold tip of pipet under the coverslip and dispense one drop of suspension.

   Suspension will be drawn under the coverslip by capillary action.

   The hemacytometer should be considered nonsterile. If cell suspension is to be used for cultures, do not reuse the pipet and do not return any excess cell suspension in the pipet to the original suspension.

6. Fill second counting chamber.

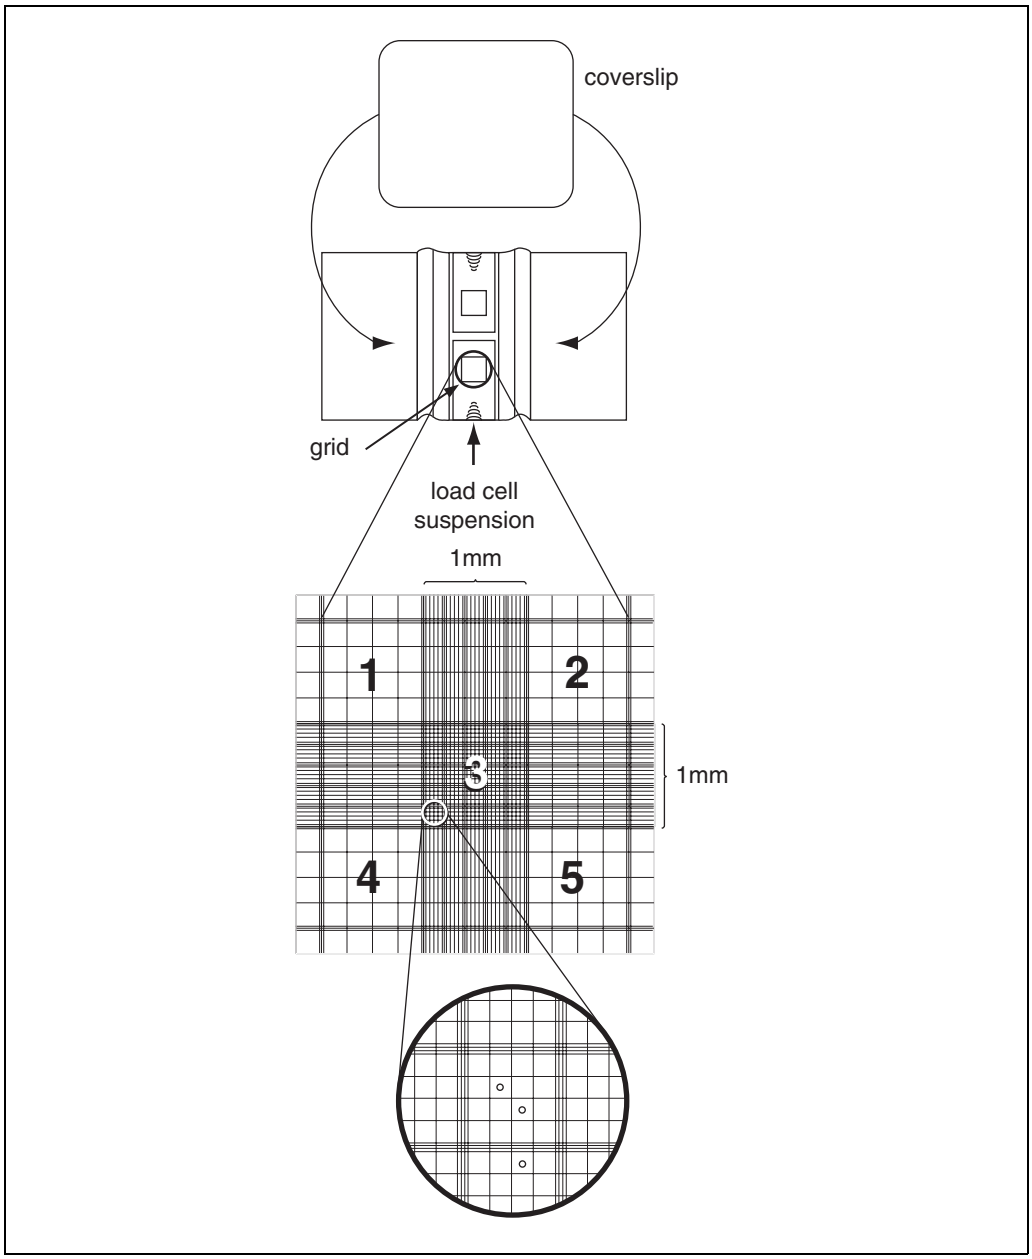

Figure A.3B.1 Hemacytometer slide (Improved Neubauer) and coverslip. Coverslip is applied to slide and cell suspension is added to counting chamber using a Pasteur pipet. Each counting chamber has a 3 × 3–mm grid (enlarged). The four corner squares (1, 2, 4, and 5) and the central square (3) are counted on each side of the hemacytometer (numbers added).

Count cells

7. Allow cells to settle for a few minutes before beginning to count. Blot off excess liquid.

8. View slide on microscope with 100× magnification.

   A 10× ocular with a 10× objective = 100× magnification.

   Position slide to view the large central area of the grid (section 3 in Fig. A.3B.1); this area is bordered by a set of three parallel lines. The central area of the grid should almost fill the microscope field. Subdivisions within the large central area are also bordered by three parallel lines and each subdivision is divided into sixteen smaller squares by single lines. Cells within this area should be evenly distributed without clumping. If cells are not evenly distributed, wash and reload hemacytometer.

9. Use a hand-held counter to count cells in each of the four corner and central squares (Fig. A.3B.1, squares numbered 1 to 5). Repeat counts for other counting chamber.

   Five squares (four corner and one center) are counted from each of the two counting chambers for a total of ten squares counted.

   Count cells touching the middle line of the triple line on the top and left of the squares. Do not count cells touching the middle line of the triple lines on the bottom or right side of the square.

Calculate cell number

10. Determine number of suspension cells per milliliter by the following calculations:

    cells/ml = average count per square × dilution factor × 10^4
    total cells = cells/ml × total original volume of cell suspension from which sample was taken.

    10^4 is the volume correction factor for the hemacytometer: each square is 1 × 1 mm and the depth is 0.1 mm.

Stain cells with trypan blue to determine cell viability

11. Determine number of viable cells by adding 0.5 ml of 0.4% trypan blue, 0.3 ml HBSS, and 0.1 ml cell suspension to a small tube. Mix thoroughly and let stand 5 min before loading hemacytometer.

    Either 0.4% trypan blue or 0.4% nigrosin can be used to determine the viable cell number. Nonviable cells will take up the dye, whereas live cells will be impermeable to it.

12. Count total number of cells and total number of viable (unstained) cells. Calculate percent viable cells as follows:

$$\%\ \text{viable cells} = \frac{\text{number of unstained cells}}{\text{total number of cells}} \times 100$$

13. Decontaminate coverslip and hemacytometer by rinsing with 70% ethanol and then deionized water. Air dry and store for future use.

PREPARING CELLS FOR TRANSPORT

SUPPORT PROTOCOL 5

Both monolayer and suspension cultures can easily be shipped in 25-cm^2 tissue culture flasks. Cells are grown to near confluency in a monolayer or to desired density in suspension. Medium is removed from monolayer cultures and the flask is filled with fresh medium. Fresh medium is added to suspension cultures to fill the flask. *It is essential that the flasks be completely filled with medium to protect cells from drying if flasks are*

inverted during transport. The cap is tightened and taped securely in place. The flask is sealed in a leak-proof plastic bag or other leak-proof container designed to prevent spillage in the event that the flask should become damaged. The primary container is then placed in a secondary insulated container to protect it from extreme temperatures during transport. A biohazard label is affixed to the outside of the package. Generally, cultures are transported by same-day or overnight courier.

Cells can also be shipped frozen. The vial containing frozen cells is removed from the liquid nitrogen freezer and placed immediately on dry ice in an insulated container to prevent thawing during transport.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete DMEM

Dulbecco's modified Eagle medium, high-glucose formulation (e.g., Life Technologies), containing:
5%, 10%, or 20% (v/v) FBS, heat inactivated (optional; see recipe below)
1% (v/v) nonessential amino acids
2 mM L-glutamine (see recipe below)
100 U/ml penicillin
100 µg/ml streptomycin sulfate
Filter sterilize if anything nonsterile has been added
Store up to 1 month at 4°C

DMEM containing this set of additives is sometimes called "complete DMEM." The percentage of serum used is indicated after the medium name—e.g., "DMEM/5% FBS." Absence of a number indicates no serum is used. DMEM is also known as Dulbecco's minimum essential medium.

Ham's F-12 nutrient mixture (e.g., Life Technologies) is sometimes added to DMEM; the resulting medium is known as DMEM/F-12.

Because of the higher bicarbonate content, DMEM requires ~10% CO_2 to maintain pH 7.4.

Culture media containing glutamine and penicillin should be warmed to 37°C as few times as possible since components, especially glutamine, degrade rapidly at 37°C.

Complete RPMI

RPMI 1640 medium (e.g., Life Technologies) containing:
2%, 5%, 10%, 15%, or 20% FBS, heat-inactivated (optional; *APPENDIX 2A*)
2 mM L-glutamine (see recipe)
100 U/ml penicillin
100 µg/ml streptomycin sulfate
Filter sterilize and store ≤1 month at 4°C

FBS (fetal bovine serum)

Thaw purchased fetal bovine serum (shipped on dry ice and kept frozen until needed). Store 3 to 4 weeks at 4°C. If FBS is not to be used within this time, aseptically divide into smaller aliquots and refreeze until used. Store ≤1 year at −20°C. To heat inactivate FBS, heat serum 30 min to 1 hr in a 56°C water bath with periodic gentle swirling during the first 10 to 15 min to ensure uniform heating.

Repeated thawing and refreezing should be avoided, as it may cause denaturation of the serum.

Heat-inactivated FBS (FBS that has been treated with heat to inactivate complement protein and thus prevent an immunological reaction against cultured cells) is useful for a variety of purposes. It can be purchased commercially or made in the lab as described above.

L-Glutamine, 0.2 M (100×)

Thaw commercially prepared frozen L-glutamine or prepare an 0.2 M solution in water, aliquot aseptically into usable portions, then refreeze. For convenience, L-glutamine can be stored in 1-ml aliquots if 100-ml bottles of medium are used and in 5-ml aliquots if 500-ml bottles are used. Store ≤1 year at −20°C.

Many laboratories supplement medium with 2 mM L-glutamine—1% (v/v) of 100× stock—just prior to use.

Trypsin/EDTA solution

Prepare in sterile HBSS (APPENDIX 2A) or 0.9% (w/v) NaCl:
0.25% (w/v) trypsin
0.2% (w/v) EDTA
Store ≤1 year (until needed) at −20°C

Specific applications may require different concentrations of trypsin.

Trypsin/EDTA solution is commercially available in various concentrations including 10×, 1×, and 0.25% (w/v). It is received frozen from the manufacturer and can be thawed and aseptically divided into smaller volumes. Preparing trypsin/EDTA from powdered stocks may reduce its cost; however, most laboratories prefer commercially prepared solutions for convenience.

EDTA (disodium ethylenediamine tetraacetic acid) is added as a chelating agent to bind Ca^{2+} and Mg^{2+} ions that can interfere with the action of trypsin.

COMMENTARY

Background Information

At its inception in the early twentieth century, tissue culture was applied to the study of tissue fragments in culture. New growth in culture was limited to cells that migrated out from the initial tissue fragment. Tissue culture techniques evolved rapidly, and since the 1950s culture methods have allowed the growth and study of dispersed cells in culture (Freshney, 1993). Cells dispersed from the original tissue can be grown in monolayers and passaged repeatedly to give rise to a relatively stable cell line.

Four distinct growth stages have been described for primary cells maintained in culture. First, cells adapt to the in vitro environment. Second, cells undergo an exponential growth phase lasting through ~30 passages. Third, the growth rate of cells slows, leading to a progressively longer generation time. Finally, after 40 or 50 passages, cells begin to senesce and die (Lee, 1991). It may be desirable to study a particular cell line over several months or years, so cultures can be preserved to retain the integrity of the cell line. Aliquots of early passage cell suspensions are frozen, then thawed, and cultures reestablished as needed. Freezing cultures prevents changes due to genetic drift and avoids loss of cultures due to senescence or accidental contamination (Freshney, 1993).

Cell lines are commercially available from a number of sources, including the American Type Culture Collection (ATCC) and the Human Genetic Mutant Cell Repository at the Coriell Cell Repository (CCR). These cell repositories are a valuable resource for researchers who do not have access to suitable patient populations.

Critical Parameters

Use of aseptic technique is essential for successful tissue culture. Cell cultures can be contaminated at any time during handling, so precautions must be taken to minimize the chance of contamination. All supplies and reagents that come into contact with cultures must be sterile and all work surfaces should be kept clean and free from clutter.

Cultures should be 75% to 100% confluent when selected for subculture. Growth in monolayer cultures will be adversely affected if cells are allowed to become overgrown. Passaging cells too early will result in a longer lag time before subcultures are established. Following dissociation of the monolayer by trypsinization, serum or medium containing serum should be added to the cell suspension to stop further action by trypsin that might be harmful to cells.

When subculturing cells, add a sufficient number of cells to give a final concentration of ~5×10^4 cells/ml in each new culture. Cells plated at too low a density may be inhibited or

delayed in entry into growth stage. Cells plated at too high a density may reach confluency before the next scheduled subculturing; this could lead to cell loss and/or cessation of proliferation. The growth characteristics for different cell lines vary. A lower cell concentration (10^4 cells/ml) may be used to initiate subcultures of rapidly growing cells, and a higher cell concentration (10^5 cells/ml) may be used to initiate subcultures of more slowly growing cells. Adjusting the initial cell concentration permits establishment of a regular, convenient schedule for subculturing—e.g., once or twice a week (Freshney, 1993).

Exposure of culture medium to light should be minimized to avoid photooxidation of tyrosine.

Cells in culture will undergo changes in growth, morphology, and genetic characteristics over time. Such changes can adversely affect reproducibility of laboratory results. Nontransformed cells will undergo senescence and eventual death if passaged indefinitely. The time of senescence will vary with cell line, but generally at between 40 and 50 population doublings fibroblast cell lines begin to senesce. Cryopreservation of cell lines will protect against these adverse changes and will avoid potential contamination.

Cultures selected for cryopreservation should be in log-phase growth and free from contamination. Cells should be frozen at a concentration of 10^6 to 10^7 cells/ml. Cells should be frozen gradually and thawed rapidly to prevent formation of ice crystals that may cause cells to lyse. Cell lines can be thawed and recovered after long-term storage in liquid nitrogen. The top of the freezing vial should be cleaned with 70% alcohol before opening to prevent introduction of contaminants. To aid in recovery of cultures, thawed cells should be reseeded at a higher concentration than that used for initiating primary cultures. Careful records regarding identity and characteristics of frozen cells as well as their location in the freezer should be maintained to allow for easy retrieval.

For accurate cell counting, the hemacytometer slide should be clean, dry, and free from lint, scratches, fingerprints, and watermarks. The coverslip supplied with the hemacytometer should always be used because it has an even surface and is specially designed for use with the counting chamber. Use of an ordinary coverslip may introduce errors in cell counting. If the cell suspension is too dense or the cells are clumped, inaccurate counts will be obtained. If the cell suspension is not evenly distributed over the counting chamber, the hemacytometer should be washed and reloaded.

Anticipated Results

Confluent cell lines can be successfully subcultured in the vast majority of cases. The yield of cells derived from monolayer culture is directly dependent on the available surface area of the culture vessel (Freshney, 1993). Overly confluent cultures or senescent cells may be difficult to trypsinize, but increasing the time of trypsin exposure will help dissociate resistant cells. Cell lines can be propagated to get sufficient cell populations for cytogenetic, biochemical, and molecular analyses.

It is well accepted that anyone can successfully freeze cultured cells; it is thawing and recovering the cultures that presents the challenge. Cultures that are healthy and free from contamination can be frozen and stored indefinitely. Cells stored in liquid nitrogen can be successfully thawed and recovered in over 95% of cases. Several aliquots of each cell line should be stored to increase the chance of recovery. Cells should be frozen gradually, with a temperature drop of ~1°C per minute, but thawed rapidly. Gradual freezing and rapid thawing prevents formation of ice crystals that might cause cell lysis.

Accurate cell counts can be obtained using the hemacytometer if cells are evenly dispersed in suspension and free from clumps. Determining the proportion of viable cells in a population will aid in standardization of experimental conditions.

Time Considerations

Establishment and maintenance of mammalian cell cultures require a regular routine for preparing media and feeding and passaging cells. Cultures should be inspected regularly for signs of contamination and to determine if the culture needs feeding or passaging.

Enzymatic Amplification of DNA by PCR: Standard Procedures and Optimization

BASIC PROTOCOL

This unit describes a method for amplifying DNA enzymatically by the polymerase chain reaction (PCR), including procedures to quickly determine conditions for successful amplification of the sequence and primer sets of interest, and to optimize for specificity, sensitivity, and yield. The first step of PCR simply entails mixing template DNA, two appropriate oligonucleotide primers, *Taq* or other thermostable DNA polymerases, deoxyribonucleoside triphosphates (dNTPs), and a buffer. Once assembled, the mixture is cycled many times (usually 30) through temperatures that permit denaturation, annealing, and synthesis to exponentially amplify a product of specific size and sequence. The PCR products are then displayed on an appropriate gel and examined for yield and specificity.

Many important variables can influence the outcome of PCR. Careful titration of the $MgCl_2$ concentration is critical. Additives that promote polymerase stability and processivity or increase hybridization stringency, and strategies that reduce nonspecific primer-template interactions, especially prior to the critical first cycle, generally improve amplification efficiency. This protocol, using *Taq* DNA polymerase, is designed to optimize the reaction components and conditions in one or two stages. The first stage (steps 1 to 7) determines the optimal $MgCl_2$ concentration and screens several enhancing additives. Most suppliers of *Taq* and other thermostable DNA polymerases provide a unique optimized $MgCl_2$-free buffer with $MgCl_2$ in a separate vial for user titration. The second stage (steps 8 to 13) compares methods for preventing pre-PCR low-stringency primer extension, which can generate nonspecific products. This has come to be known as "hot start," whether one omits an essential reaction component prior to the first denaturing-temperature step or adds a reversible inhibitor of polymerase. Hot-start methods can greatly improve specificity, sensitivity, and yield. Use of any one of the hot-start approaches is strongly recommended if primer-dimers or other nonspecific products are generated or if relatively rare template DNA is contained in a complex mixture, such as viral nucleic acids in cell or tissue preparations. This protocol suggests some relatively inexpensive methods to achieve hot start, and lists several commercial hot-start options which may be more convenient, but of course more expensive.

Materials

Sterile H_2O
15 mM (L), 30 mM (M), and 45 mM (H) $MgCl_2$
10× $MgCl_2$-free PCR amplification buffer (see recipe)
25 mM 4dNTP mix (see recipe)
50 µM oligonucleotide primer 1: 50 pmol/µl in sterile H_2O (store at −20°C)
50 µM oligonucleotide primer 2: 50 pmol/µl in sterile H_2O (store at −20°C)
Template DNA: 1 µg mammalian genomic DNA or 1.0 to 100.0 pg plasmid DNA
5 U/µl *Taq* DNA polymerase (native or recombinant; many suppliers)
Enhancer agents (optional; see recipe)
TaqStart Antibody (Clontech)
Mineral oil
Ficoll 400 (optional)
Tartrazine dye (optional)

Thin-walled PCR tubes
Automated thermal cycler

Current Protocols in Toxicology (2000) A.3C.1-A.3C.14

Table A.3C.1 Master Mixes for Optimizing Reaction Components

Components	Final concentration	Per reaction	Master mix[a] (µl)			
			I	II	III	IV
10× PCR buffer	1×	10 µl	40.0	40.0	40.0	40.0
Primer 1	0.5 µM	1 µl	4.0	4.0	4.0	4.0
Primer 2	0.5 µM	1 µl	4.0	4.0	4.0	4.0
Template DNA	Undiluted	1 vol[b]	4 vol[b]	4 vol[b]	4 vol[b]	4 vol[b]
25 mM 4dNTP mix[c]	0.2 mM	0.8 µl	3.2	3.2	3.2	3.2
Taq polymerase	2.5 U	0.5 µl	2.0	2.0	2.0	2.0
DMSO[d] (20×)	5%	5 µl	—	20.0	—	—
Glycerol[d] (10×)	10%	10 µl	—	—	40.0	—
PMPE[d] (100×)	1%	1 µl	—	—	—	4.0
H_2O	—	To 90 µl	To 360	To 360	To 360	To 360

[a]Total volume = 360 µl (enough for $n + 1$ reactions).

[b]Template DNA volume ("vol") is generally 1 to 10 µl.

[c]If 2 mM 4dNTP mix is preferred, use 10 µl per reaction, or 40 µl for each master mix; adjust the volume of water accordingly.

[d]Substitute with other enhancer agents (see recipe in Reagents and Solutions) as available.

Additional reagents and equipment for DNA preparation, agarose gel electrophoresis, nondenaturing PAGE, or sieving agarose gel electrophoresis, restriction endonuclease digestion, and Southern blotting and hybridization (*APPENDIX 3*)

NOTE: Do not use DEPC to treat water, reagents, or glassware.

NOTE: Reagents should be prepared in sterile, disposable labware, taken directly from its packaging, or in glassware that has been soaked in 10% bleach, thoroughly rinsed in tap water followed by distilled water, and if available, exposed to UV irradiation for ~10 min. Multiple small volumes of each reagent should be stored in screw-cap tubes. This will then serve as the user's own optimization "kit." Thin-walled PCR tubes are recommended.

Optimize reaction components

1. Prepare four reaction master mixes according to the recipes given in Table A.3C.1.

   Enhancing agents probably work by different mechanisms, such as protecting enzyme activity and decreasing nonspecific primer binding. However, their effects cannot be readily predicted—what improves amplification efficiency for one primer pair may decrease the amplification efficiency for another. Thus it is best to check a panel of enhancers during development of a new assay.

2. Aliquot 90 µl master mix I into each of three 0.5-ml thin-walled PCR tubes labeled I-L, I-M, and I-H. Similarly, aliquot mixes II through IV into appropriately labeled tubes. Add 10 µl of 15 mM $MgCl_2$ into one tube of each master mix (labeled L; 1.5 mM final). Similarly, aliquot 10 µl of 30 mM and 45 mM $MgCl_2$ to separate tubes of each master mix (labeled M and H, respectively; 3.0 and 4.5 mM final concentrations respectively).

It is helpful to set the tubes up in a three-by-four array to simplify aliquotting. Each of the three Mg^{2+} concentrations is combined with each of the four master mixes.

3. Overlay the reaction mixture with 50 to 100 µl mineral oil (2 to 3 drops).

   To include hot start in the first step, overlay reaction mixes with oil before adding the $MgCl_2$, heat the samples to 95°C in the thermal cycler or other heating block, and add the $MgCl_2$ once the elevated temperature is reached. Once the $MgCl_2$ has been added, do not allow the samples to cool below the optimum annealing temperature prior to performing PCR.

Choose cycling parameters

4. Using the following guidelines, program the automated thermal cycler according to the manufacturers' instructions.

30 cycles:	30 sec	94°C	(denaturation)
	30 sec	55° (GC content ≤50%) *or* 60°C (GC content >50%)	(annealing)
	~60 sec/kb product sequence	72°C	(extension)

   Cycling parameters are dependent upon the sequence and length of the template DNA, the sequence and percent complementarity of the primers, and the ramp times of the thermal cycler used. Thoughtful primer design will reduce potential problems (see Commentary). Denaturation, annealing, and extension are each quite rapid at the optimal temperatures. The time it takes to achieve the desired temperature inside the reaction tube, i.e., the ramp time, is usually longer than either denaturation or primer annealing. Thus, ramp time is a crucial cycling parameter. Manufacturers of the various thermal cyclers on the market provide ramp time specifications for their instruments. Ramp times are lower with thin-walled reaction tubes. The optimal extension time also depends on the length of the target sequence. Allow ~1 min/kb for this step for target sequences >1 kb, and as little as a 2-sec pause for targets <100 bases in length.

   The number of cycles depends on both the efficiency of the reaction and the amount of template DNA in the reaction. Starting with as little as 100 ng of mammalian genomic DNA (~10^4 cell equivalents), after 30 cycles, 10% of the reaction should produce a band that is readily visible on an ethidium bromide–stained gel as a single predominant band. With more template, fewer cycles may suffice. With much less template, further optimization is recommended rather than increasing the cycle number. Greater cycle numbers (e.g., >40) can reduce the polymerase specific activity, increase nonspecific amplification, and deplete substrate (nucleotides). Many investigators lengthen the time for the last extension step—to 7 min, for example—to try to ensure that all the PCR products are full length.

   These guidelines are appropriate for most commercially available thermal cyclers. For rapid cyclers, consult the manufacturers' protocols.

Analyze the product

5. Electrophorese 10 µl from each reaction on an agarose, nondenaturing polyacrylamide, or sieving agarose gel appropriate for the PCR product size expected. Stain with ethidium bromide.

   For resolution of PCR products between 100 and 1000 bp, an alternative to nondenaturing polyacrylamide gels or sieving agarose is a composite 3% (w/v) NuSieve (FMC Bioproducts) agarose/1% (w/v) SeaKem (FMC Bioproducts) agarose gel. SeaKem increases the mechanical strength of the gel without decreasing resolution.

   An alternative to ethidium bromide, SYBR Gold Nucleic Acid Gel Stain (Molecular Probes), is 25 to 100 times more sensitive than ethidium bromide, is more convenient to use, and permits optimization of 10- to 100-fold lower starting template copy number.

6. Examine the stained gel to determine which condition resulted in the greatest amount of product.

   Minor, nonspecific products may be present even under optimal conditions.

Table A.3C.2 Master Mixes for Optimizing First-Cycle Reactions

Components	Final concentration	Master mix (µl)			
		A	B	C	D
10× PCR buffer	1×	10	10	10	10
$MgCl_2$ (L, M, or H)	Optimal	10	10	10	10
Primer 1	0.5 µM	1.0	1.0	1.0	1.0
Primer 2	0.5 µM	1.0	1.0	1.0	1.0
Additive	Optimal	V[a]	V[a]	V[a]	V[a]
Template DNA	—[b]	V[a]	V[a]	V[a]	V[a]
25 mM 4dNTP mix[b]	0.2 mM	0.8	0.8	0.8	0.8
Taq polymerase	2.5 U	0.5	0.5	—	—
Taq pol + TaqStart	2.5 U	—	—	—	1.0
H_2O	To 100 µl	V[a]	V[a]	V[a]	V[a]
Preparation temperature		Room temperature	Ice slurry	Room temperature	Room temperature

[a]V, variable amount (total volume should be 100 µl).

[b]Use undiluted or diluted template DNA based on results obtained in step 6.

7. To ensure that the major product is the correct one, digest an aliquot of the reaction with a restriction endonuclease known to cut within the PCR product. Check buffer compatibility for the restriction endonuclease of choice. If necessary, add Na^+ or precipitate in ethanol (*APPENDIX 3*), then resuspend in the appropriate buffer. Electrophorese the digestion product on a gel to verify that the resulting fragments have the expected sizes.

   Alternatively, transfer the PCR products to a nitrocellulose or nylon filter and hybridize with an oligonucleotide derived from the sequence internal to the primers. With appropriately stringent hybridization and washing conditions, only the correct product (and possibly some minor related products) should hybridize.

Optimize the first cycle

These optional steps optimize initial hybridization and may improve efficiency and yield. They are used when primer-dimers and other nonspecific products are detected, when there is only a very small amount of starting template, or when a rare sequence is to be amplified from a complex mixture. For an optimal reaction, polymerization during the initial denaturation and annealing steps should be prevented. *Taq* DNA polymerase activity can be inhibited by temperature (reaction B), physical separation (reaction C), or reversible antibody binding (reaction D). PCR without hot start is performed for comparison (reaction A).

8. Prepare four reaction mixtures using the optimal $MgCl_2$ concentration and additive requirement determined in step 6. Prepare the mixes according to the recipes in Table A.3C.2. Use the following variations for addition of *Taq* polymerase.

   a. Prepare reactions A and C at room temperature.

   b. Chill all components of reaction B in an ice slurry before they are combined.

   c. For reaction D, combine 1.0 µl TaqStart antibody with 4.0 µl of the dilution buffer provided with the antibody, add 1.0 µl *Taq* DNA polymerase (for 1:4:1 mixture of these components), mix, and incubate 5 to 10 min at room temperature before adding to reaction mixture D (glycerol and PMPE are compatible with TaqStart antibody but DMSO will interfere with antibody binding).

To ensure that the reaction does not plateau and thereby obfuscate the results, use the smallest amount of template DNA necessary for visualization of the PCR product by ethidium bromide staining. Use the results from step 6 to decide how much template to use. If the desired product stains intensely, dilute the starting material as much as 1/100. If only a faint signal is apparent, use undiluted sample.

9. Overlay each reaction mixture with 50 to 100 µl mineral oil.
10. Heat all reactions 5 min at 94°C.

    It is most convenient to use the automated thermal cycler for this step and then initiate the cycling program directly.

11. Cool the reactions to the appropriate annealing temperature as determined in step 4. Add 0.5 µl *Taq* DNA polymerase to reaction C, making sure the pipet tip is inserted through the layer of mineral oil into the reaction mix.

    Time is also an important factor in this step. If the temperature drops below the annealing temperature and is allowed to remain low, nonspecific annealing will occur. Taq DNA polymerase retains some activity even at room temperature.

12. Begin amplification of all four reactions at once, using the same cycling parameters as before.
13. Analyze the PCR products on an agarose gel and evaluate the results as in steps 5 and 6.
14. Prepare a batch of the optimized reaction mixture, but omit *Taq* DNA polymerase, TaqStart antibody, PMPE, and 4dNTP mix—these ingredients should be added fresh just prior to use. If desired, add Ficoll 400 to a final concentration of 0.5% to 1% (v/v) and tartrazine to a final concentration of 1 mM.

    Adding Ficoll 400 and tartrazine dye to the reaction mix precludes the need for a gel loading buffer and permits direct application of PCR products to agarose or acrylamide gels. At these concentrations, Ficoll 400 and tartrazine do not decrease PCR efficiency and do not interfere with PMPE or TaqStart antibodies. Other dyes, such as bromphenol blue and xylene cyanol, do inhibit PCR. Tartrazine is a yellow dye and is not as easily visualized as other dyes; this may make gel loading more difficult.

    Ficoll 400 and tartrazine dye may be prepared as 10× stocks and stored indefinitely at room temperature.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Enhancer agents

For a discussion of how to select enhancer agents, see Commentary.

5× stocks:
25% acetamide (20 µl/reaction; 5% final)
5 M *N,N,N*-trimethylglycine (betaine; 20 µl/reaction; 1 M final)
40% polyethylene glycol (PEG) 8000 (20 µl/reaction; 8% final)

10× stocks:
Glycerol (concentrated; 10 µl/reaction; 10% final)

20× stocks:
Dimethylsulfoxide (DMSO; concentrated 5 µl/reaction; 5% final)
Formamide (concentrated; 5 µl/reaction; 5% final)

100× stocks:

1 U/µl Perfect Match Polymerase Enhancer [Strategene; 1 µl (1 U) per reaction, final]

10 mg/ml acetylated bovine serum albumin (BSA) or gelatin (1 µl/reaction; 10 µg/ml final)

1 to 5 U/µl thermostable pyrophosphatase [PPase; Boehringer Mannheim; 1 µl (1 to 5 U) per reaction, final]

5 M tetramethylammonium chloride (TMAC; betaine hydrochloride; 1 µl/reaction; 50 mM final)

0.5 mg/ml *E. coli* single-stranded DNA-binding protein (SSB; Sigma; 1 µl/reaction; 5 µg/ml final)

0.5 mg/ml Gene 32 protein (Amersham Pharmacia Biotech; 1 µl/reaction; 5 µg/ml final)

10% Tween 20, Triton X-100, or Nonidet P-40 (1 µl/reaction; 0.1% final)

1 M $(NH_4)_2SO_4$ (1 µl/reaction; 10 mM final; use with thermostable DNA polymerases other than *Taq*)

$MgCl_2$-free PCR amplification buffer, 10×

500 mM KCl
100 mM Tris·Cl, pH 9.0 (at 25°C)
0.1% Triton X-100
Store indefinitely at –20°C

This buffer can be obtained from Promega; it is supplied with Taq DNA polymerase.

4dNTP mix

For 2 mM 4dNTP mix: Prepare 2 mM each dNTP in TE buffer, pH 7.5 (see recipe). Store up to 1 year at –20°C in 1-ml aliquots.

For 25 mM 4dNTP mix: Combine equal volumes of 100 mM dNTPs (Promega). Store indefinitely at –20°C in 1-ml aliquots.

TE (Tris/EDTA) buffer, pH 7.5

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Store up to 6 months at room temperature

COMMENTARY

Background Information

The theoretical basis of the polymerase chain reaction (PCR) was probably first described in a paper by Kleppe et al. (1971). However, this technique did not excite general interest until the mid-1980s, when Kary Mullis and co-workers at Cetus developed PCR into a technique that could be used to generate large amounts of single-copy genes from genomic DNA (Saiki et al., 1985, 1986; Mullis et al., 1986; Embury et al., 1987).

The initial procedure entailed adding a fresh aliquot of the Klenow fragment of *E. coli* DNA polymerase I during each cycle because this enzyme was inactivated during the subsequent denaturation step. The introduction of thermostable *Taq* DNA polymerase from *Thermus aquaticus* (Saiki et al., 1988) alleviated this tedium and facilitated automation of the thermal cycling portion of the procedure. *Taq* DNA polymerase also permitted the use of higher temperatures for annealing and extension, which improved the stringency of primer–template hybridization and thus the specificity of the products. This also served to increase the yield of the desired product.

All applications for PCR depend upon an optimized PCR. The basic protocol in this unit optimizes PCR for several variables, including $MgCl_2$ concentration, enhancing additives—dimethyl sulfoxide (DMSO), glycerol, or Perfect Match Polymerase Enchancer (PMPE)—and prevention of pre-PCR mispriming. These and other parameters can be extremely important, as every element of PCR can affect the outcome; see Critical Parameters and Trou-

bleshooting for discussion of individual parameters.

There are several PCR optimization kits and proprietary enhancers on the market (Table A.3C.3). Optimization kits generally provide a panel of buffers in which the pH, buffer, nonionic detergents, and addition of $(NH_4)_2SO_4$ are varied, $MgCl_2$ may be added at several concentrations, and enhancers (e.g., DMSO, glycerol, formamide, betaine, and/or proprietary compounds) may be chosen. The protocol presented here is aimed at keeping the costs low and the options broad.

Critical Parameters and Troubleshooting

$MgCl_2$ concentration

Determining the optimum $MgCl_2$ concentration, which can vary even for different primers from the same region of a given template (Saiki, 1989), can have an enormous influence on PCR success. In this protocol three test concentrations are suggested—1.5 mM (L), 3.0 mM (M), and 4.5 mM (H). If further optimization is necessary, the $MgCl_2$ range can be extended or narrowed around the most successful concentration.

A 10× buffer optimized for a given enzyme and a separate vial of $MgCl_2$ are typically provided with the polymerase, so that the user may titrate the $MgCl_2$ concentration for their unique primer-template set. Note that some enhancers may broaden the $MgCl_2$ optimal range.

Reagent purity

For applications that amplify rare templates, reagent purity is the most important parameter, and avoiding contamination at every step is critical.

To maintain purity, store multiple small volumes of each reagent in screw-cap tubes.

For many applications, simply using high-quality reagents and avoiding nuclease contamination is sufficient. However, avoid one common reagent used to inactivate nucleases—diethylpyrocarbonate (DEPC). Even the tiny amounts of chemical left after treatment of water and autoclaving are enough to ruin a PCR.

Primer selection

This is the factor that is least predictable and most difficult to troubleshoot. Simply put, some primers just do not work. To maximize the probability that a given primer pair will work, pay attention to the following parameters.

General considerations. An optimal primer set should hybridize efficiently to the sequence of interest with negligible hybridization to other sequences present in the sample. If there are reasonable amounts of template available, hybridization specificity can be tested by performing oligonucleotide hybridization. The distance between the primers is rather flexible, ranging up to 10 kb. There is, however, a considerable drop-off in synthesis efficiency with distances >3 kb (Jeffreys et al., 1988). Small distances between primers, however, lessen the ability to obtain much sequence information or to reamplify with nested internal oligonucleotides, should that be necessary.

Design primers to allow demonstration of the specificity of the PCR product. Be sure that there are diagnostic restriction endonuclease sites between the primers or that an oligonucleotide can detect the PCR product specifically by hybridization.

Several computer programs can assist in primer design. These are most useful for avoiding primer sets with intra- and intermolecular complementarity, which can dramatically raise the effective melting temperature (T_m). Given the abundance of primers relative to template, this can preclude template priming. Computer primer design is not foolproof. If possible, start with a primer or primer set known to efficiently prime extensions. In addition, manufacturers' Web sites offer technical help with primer design.

Complementarity to template. For many applications, primers are designed to be exactly complementary to the template. For others, however, such as engineering of mutations or new restriction endonuclease sites (*UNIT 8.5*), or for efforts to clone or detect gene homologs where sequence information is lacking, base-pair mismatches will be intentionally or unavoidably created. It is best to have mismatches (e.g., in a restriction endonuclease linker) at the 5′ end of the primer. The closer a mismatch is to the 3′ end of the primer, the more likely it is to prevent extension. If cloned template is available, primers can be checked for suitability by using them in a sequencing reaction with *Taq* DNA polymerase.

The use of degenerate oligonucleotide primers to clone genes where only protein sequence is available, or to fish out gene homologs in other species, has sometimes been successful—but it has also failed an untold (and unpublished) number of times. When the reaction works it can be extremely valuable, but it can

Optimization support	PE Biosystems	Technical information in appendix to catalog
Optimization support	Promega	PCR troubleshooting program on the Internet: *http://www.promega.com/amplification/assistant*
Optimization kits	Boehringer Mannheim, Invitrogen, Stratagene, Sigma, Epicentre Technologies, Life Technologies	Several buffers, Mg^{2+}, and enhancers which may include DMSO, glycerol, formamide, $(NH_4)_2SO_4$, and other unspecified or proprietary agents
Quick startup	Amersham Pharmacia Biotech	Ready-To-Go Beads "optimized for standard PCR" and Ready-To-Go RAPD Analysis Beads (buffer, nucleotides, *Taq* DNA polymerase)
Quick startup	Fisher	EasyStart PCR Mix-in-a-Tube—tubes prepackaged with wax beads containing buffer, $MgCl_2$, nucleotides, *Taq* DNA polymerase
Quick startup	Life Technologies	PCR SuperMix—1.1× conc.—premix containing buffer, $MgCl_2$, nucleotides, *Taq* DNA polymerase
Quick startup	Marsh Biomedical	Advanced Biochemicals Red Hot DNA Polymerase—a new rival for *Taq* polymerase with convenience features
Hot-start/physical barrier	Fisher, Life Technologies	Molecular Bio-Products HotStart Storage and Reaction Tubes—preadhered wax bead in each tube; requires manual addition of one component at high temperature
Hot-start/separate $MgCl_2$	Invitrogen	HotWax Mg^{2+} beads—wax beads contain preformulated $MgCl_2$ which is released at first elevated-temperature step
Hot-start/separate $MgCl_2$	Stratagene	StrataSphere Magnesium Wax Beads—wax beads containing preformulated Mg^{2+}
Hot Start/separate polymerase	Promega	TaqBead Hot Start Polymerase—wax beads encapsulating *Taq* DNA polymerase which is released at first elevated-temperature step
Hot-start/reversible inactivation of polymerase by antibody binding	Clontech	TaqStart Antibody, TthStart Antibody—reversibly inactivate *Taq* and *Tth* DNA polymerases until first denaturation at 95°C
Hot-start/antibody binding	Life Technologies	PlatinumTaq—contains PlatinumTaq antibody
Hot-start/antibody binding	Sigma	JumpStart Taq—contains TaqStart antibody
Hot-start/reversible chemical modification	PE Biosystems	AmpliTaq Gold—activated at high temperature
Hot-start/reversible chemical modification	Qiagen	HotStarTaq DNA Polymerase—activated at high temperature
Enhancer	Boehringer Mannheim, New England Biolabs	*Tth* pyrophosphatase, thermostable
Enhancer	Clontech	GC-Melt (in Advantage-GC Kits)—proprietary
Enhancer	CPG	Taq-FORCE Amplification System and MIGHTY Buffer—proprietary
Enhancer	Fisher	Eppendorf MasterTaq Kit with TaqMaster Enhancer—proprietary
Enhancer	Life Technologies	PCRx Enhancer System—proprietary
Enhancer	Promega	*E.coli* Single Stranded Binding Protein (SSB)
Enhancer	Qiagen	Q-Solution—proprietary
Enhancer	Stratagene	Perfect Match Polymerase Enhancer—proprietary
Enhancer	Stratagene	TaqExtender PCR Additive—proprietary

also generate seemingly specific products that require much labor to identify and yield no useful information. The less degenerate the oligonucleotides, especially at the 3′ end, the better. Caveat emptor.

Primer length. A primer should be 20 to 30 bases in length. It is unlikely that longer primers will help increase specificity significantly.

Primer sequence. Design primers with a GC content similar to that of the template. Avoid primers with unusual sequence distributions, such as stretches of polypurines or polypyrimidines as their secondary structure can be disastrous. It is worthwhile to check for potential secondary structure using one of the appropriate computer programs that are available.

"Primer-dimers." Primer-dimers are a common artifact most frequently observed when small amounts of template are taken through many amplification cycles. They form when the 3′ end of one primer anneals to the 3′ end of the other primer, and polymerase then extends each primer to the end of the other. The ensuing product can compete very effectively against the PCR product of interest. Primer-dimers can best be avoided by using primers without complementarity, especially in their 3′ ends. Should they occur, optimizing the $MgCl_2$ concentration may minimize their abundance relative to that of the product of interest.

Template

Aside from standard methods for preparing DNA (*APPENDIX 3*), a number of simple and rapid procedures have been developed for particular tissues (Higuchi, 1989). Even relatively degraded DNA preparations can serve as useful templates for generation of moderate-sized PCR products. The two main concerns regarding template are purity and amount.

A number of contaminants found in DNA preparations can decrease the efficiency of PCR. These include urea, the detergent SDS (whose inhibitory action can be reversed by nonionic detergents), sodium acetate, and, sometimes, components carried over in purifying DNA from agarose gels (Gelfand, 1989; Gyllensten, 1989; K. Hicks and D. Coen, unpub. observ.). Additional organic extractions, ethanol precipitation from 2.5 M ammonium acetate, and/or gel purification on polyacrylamide rather than agarose, can all be beneficial in minimizing such contamination if the simplest method (precipitating the sample with ethanol and repeatedly washing the pellet with 70% ethanol) is not sufficient.

Clearly the amount of template must be sufficient to be able to visualize PCR products using ethidium bromide. Usually 100 ng of genomic DNA is sufficient to detect a PCR product from a single-copy mammalian gene. Using too much template is not advisable when optimizing for $MgCl_2$ or other parameters, as it may obscure differences in amplification efficiency. Moreover, too much template may decrease efficiency due to contaminants in the DNA preparation.

Amount of template, especially in terms of the amount of target sequence versus nonspecific sequences, can have a major effect on the yield of nonspecific products. With less target sequence, it is more likely that nonspecific products will be seen. For some applications, such as certain DNA sequencing protocols where it is important to have a single product, gel purification of the specific PCR product and reamplification are advisable.

Taq and other thermostable DNA polymerases

Among the advantages conferred by the thermostability of *Taq* DNA polymerase is its ability to withstand the repeated heating and cooling inherent in PCR and to synthesize DNA at high temperatures that melt out mismatched primers and regions of local secondary structure. The enzyme, however, is not infinitely resistant to heat, and for greatest efficiency it should not be put through unnecessary denaturation steps. Indeed, some protocols (e.g., the "hot start" method described here) recommend adding it after the first denaturation step.

Increasing the amount of *Taq* DNA polymerase beyond 2.5 U/reaction can sometimes increase PCR efficiency, but only up to a point. Adding more enzyme can sometimes increase the yield of nonspecific PCR products at the expense of the product of interest. Moreover, *Taq* DNA polymerase is not inexpensive.

A very important property of *Taq* DNA polymerase is its error rate, which was initially estimated at 2×10^{-4} nucleotides/cycle (Saiki et al., 1988). The purified enzyme supplied by manufacturers lacks a proofreading 3′→5′ exonuclease activity, which lowers error rates of other polymerases such as the Klenow fragment of *E. coli* DNA polymerase I. For many applications, this does not present any difficulties. However, for sequencing clones derived from PCR, or when starting with very few templates, this can lead to major problems. Direct sequencing of PCR products, sequencing numerous PCR-generated clones, and/or

the use of appropriate negative controls can help overcome these problems. Alternatively, changing reaction conditions (Eckert and Kunkel, 1990) or changing to a non–*Taq* DNA polymerase (with greater fidelity) may be useful.

Another important property of *Taq* DNA polymerase is its propensity for adding nontemplated nucleotides to the 3′ ends of DNA chains. This can be especially problematic in cloning PCR products. It is frequently necessary to "polish" PCR products with enzymes such as other DNA polymerases before adding linkers or proceeding to blunt-end cloning. Conversely, addition of a nontemplated A by *Taq* DNA polymerase can be advantageous in cloning.

Table A.3C.4 lists currently available thermostable DNA polymerases by generic and trade names, the original source of native and recombinant enzymes, the supplier, the end generated (3′A addition versus blunt), and associated exonuclease activities. A 3′ to 5′ exonuclease activity is proofreading. Removal of the 5′ to 3′ exonuclease activity of *Taq* DNA polymerase (N-terminal deletion) is reported to produce a higher yield. A 5′ to 3′ exonuclease activity may degrade the primers somewhat. Proofreading enzymes synthesize DNA with higher fidelity and can generate longer products than *Taq*, but tend to generate low yields. Enzyme blends (Table A.3C.5) have been optimized for increased fidelity and length along with sensitivity and yield.

Hot start

What happens prior to thermal cycling is critical to the success of PCR. *Taq* DNA polymerase retains some activity even at room temperature. Therefore, under nonstringent annealing conditions, such as at room temperature, products can be generated from annealing of primers to target DNA at locations of low complementarity or having complementarity of just a few nucleotides at the 3′ ends. The latter would in effect create new templates "tagged" with the primer sequences. Subsequent cycles amplify these tagged sequences in abundance, both generating nonspecific products and possibly reducing amplification efficiency of specific products by competition for substrates or polymerase. Thus conditions preventing polymerization prior to the first temperature-controlled steps are desirable. In this protocol, three methods of inhibiting polymerization prior to the temperature-controlled step are compared. These include physical separation of an essential reaction component prior to the first denaturation step, cooling reagents to 0°C, and reversibly blocking enzymatic activity with an antibody.

Denaturation of the template before *Taq* polymerase or $MgCl_2$ is added to the reaction provides a dramatic improvement in specificity and sensitivity in many cases (Chou et al., 1992). The main drawback of this method is that it requires opening the reaction tubes a second time to add the essential missing component. This creates both an inconvenience and an increase in the risk of contamination, an important consideration when testing for the presence of a given sequence in experimental or clinical samples.

Cooling all components of the reaction mixture to 0°C prior to mixing is more convenient and the least expensive method but is also the least reliable. Transferring the PCR reaction tubes from the ice slurry to a 95°C preheated thermocycler block may improve the chance of success.

Reversible inhibition of *Taq* DNA polymerase by TaqStart antibody (Clontech) is the most convenient and is very effective (Kellogg et al., 1994). Complete reactions can be set up, overlaid with oil, and stored at 4°C for up to several hours prior to thermal cycling with no loss of sensitivity or specificity compared to the other hot-start methods (M.F.K. and D.M.C., unpub. observ.). Cycling is initiated immediately following 5-min denaturation of the antibody at 94°C. DMSO inhibits antibody binding and should not be used with TaqStart.

Several hot-start products are now commercially available (Table A.3C.3). Success with each may depend on strict adherence to the manufacturer's protocols, even on a specific thermocycler. Wax barrier and reversible antibody binding methods are more forgiving, while chemical modifications have more stringent activation temperature requirements.

Deoxyribonucleoside triphosphates

In an effort to increase efficiency of PCR, it may be tempting to increase the concentration of dNTPs. Don't. When each dNTP is 200 μM, there is enough to synthesize 12.5 μg of DNA when half the dNTPs are incorporated. dNTPs chelate magnesium and thereby change the effective optimal magnesium concentration. Moreover, dNTP concentrations >200 μM each increase the error rate of the polymerase. Millimolar concentrations of dNTPs actually inhibit *Taq* DNA polymerase (Gelfand, 1989).

Table A.3C.4 Thermostable DNA Polymerases

DNA polymerase		Biological source	Supplier	Product ends	Exonuclease activity
Generic name	Trade name				
Pfu	—	*Pyrococcus furiosus*	Stratagene, Promega	Blunt	3′-5′ (proofreading)
Pfu (exo-)	—	*Pyrococcus furiosus*	Stratagene	Blunt	No
Psp	Deep Vent	*Pyrococcus* sp.GB-D	New England Biolabs	Blunt	3′-5′ (proofreading)
Psp (exo-)	Deep Vent (exo-)	*Pyrococcus* sp.GB-D	New England Biolabs	Blunt	No
Pwo		*Pyrococcus woesei*	Boehringer Mannheim	Blunt	3′-5′ (proofreading)
Taq (native and/or recombinant)	—	*Thermus aquaticus*	Ambion, Amersham Pharmacia Biotech, Boehringer Mannheim, Clontech, Fisher, Life Technologies, Marsh Biomedical, PE Biosystems, Promega, Qiagen, Sigma, Stratagene	3′A	5′-3′
Taq, N-terminal deletion	Stoffel fragment Klen-Taq	*Thermus aquaticus*	PE Biosystems, Sigma	3′A	No
Tbr	DyNAzyme	*Thermus brocianus*	MJ Research	—[a]	5′-3′
Tfl		*Thermus flavus*	Promega, Epicentre Technologies	Blunt	—[a]

Tli (exo-)	Vent (exo-)	*Thermococcus litoralis*	New England Biolabs	Blunt	No
Tma	UlTma	*Thermotoga maritima*	PE Biosystems	Blunt	3′-5′ (proofreading)
Tth	—	*Thermus thermophilus*	Amersham Pharmacia Biotech, Boehringer Mannheim, Epicentre Technologies, PE Biosystems, Promega	3′ A	5′-3′

[a]No information at this time.

The protocol in this unit calls for preparing 4dNTPs in 10 mM Tris·Cl/1 mM EDTA (TE buffer), pH 7.4 to 7.5. This is easier and less prone to disaster than neutralization with sodium hydroxide. However, EDTA also chelates magnesium, and this should be taken into account if stocks of dNTPs are changed. Alternatively, to lower the risk of contamination, a 4dNTP mix can be made by combining equal volumes of commercially prepared stocks.

Enhancers

Enhancers are used to increase yield and specificity and to overcome difficulties encountered with high GC content or long templates. Nonionic detergents (Triton X-100, Tween 20, or Nonidet P-40) neutralize charges of ionic detergents often used in template preparation, and should be used in the basic reaction mixture, rather than as optional enhancers. Higher yields can be achieved by stabilizing/enhancing the polymerase activity with enzyme-stabilizing proteins (BSA or gelatin), enzyme-stabilizing solutes such as betaine or betaine·HCl (TMAC), enzyme-stabilizing solvents (glycerol), solubility-enhancing solvents (DMSO or acetamide), molecular crowding solvents (PEG), and polymerase salt preferences [$(NH_4)SO_4$ is recommended for polymerases other than *Taq*]. Greater specificity can be achieved by lowering the T_M of dsDNA (using formamide), destabilizing mismatched-primer annealing (using PMPE or hot-start strategies), and stabilizing ssDNA (using *E.*

Table A.3C.5 Thermostable DNA Polymerase Blends

Product (trade name)	Supplier	Thermostable DNA polymerases and other components
Expand High Fidelity, Expand Long Template, and Expand 20kb PCR Systems	Boehringer Mannheim	*Taq* + *Pwo*
KlenTaq LA Polymerase Mix	Clontech, Sigma	KlenTaq-1 (5′-exonuclease deficient *Taq*) + unspecified proofreading polymerase
Advantage-HF PCR Kit	Clontech	KlenTaq-1 + unspecified proofreading polymerase + TaqStart Antibody
Advantage-cDNA and Advantage-GC cDNA Polymerase Mixes and Kits	Clontech	KlenTaq-1 + unspecified proofreading polymerase + TaqStart Antibody; GC Kit contains GC Melt
Advantage Genomic and Advantage-GC Genomic Polymerase Mixes and Kits	Clontech	*Tth* + unspecified proofreading polymerase + TthStart Antibody; GC Kit contains GC Melt
eLONGase Enzyme Mix	Life Technologies	*Taq* + *Psp* + unspecified proofreading polymerase(s) + eLONGase Buffer
Platinum Taq DNA Polymerase	Life Technologies	*Taq* + *Psp* + Platinum *Taq* Antibody
Platinum High Fidelity DNA Polymerase	Life Technologies	*Taq* + *Psp* + *Taq* Antibody
DyNAzyme EXT Polymerase	MJ Research	*Tbr* with unspecified enhancer

OmniBase Sequencing Enzyme Mix	Promega	Unspecified proofreading polymerase(s) with thermostable pyrophosphatase
AccuTaq LA DNA Polymerase Mix	Sigma	*Taq* + unspecified proofreading polymerase
TaqPlus Long and TaqPlus Precision PCR Systems	Stratagene	*Pfu* + *Taq*; TaqPlus Precision Reaction Buffer (proprietary)
Accurase Fidelity PCR Enzyme Mix; Calypso High Fidelity Single Tube RT-PCR System	Tetralink	*Thermus sp*. + *Thermococcus sp*.; Calypso also contains AMV-RT

coli SSB or Gene 32 Protein). Amplification of high-GC-content templates can be improved by decreasing the base pair composition dependence of the T_M of dsDNA (with betaine; Rees et al., 1993). Betaine is an osmolyte widely distributed in plants and animals and is nontoxic, a feature that recommends it for convenience in handling, storage, and disposal. Betaine may be the proprietary ingredient in various commercial formulations. For long templates, a higher pH is recommended (pH 9.0). The pH of Tris buffer decreases at high temperatures, long-template PCR requires more time at high temperatures, and increased time at lower pH may cause some depurination of the template, resulting in reduced yield of specific product. Inorganic phosphate (PPi), a product of DNA synthesis, may accumulate with amplification of long products to levels that may favor reversal of polymerization. Accumulation of PPi may be prevented by addition of thermostable PPase. When large numbers of samples are being analyzed, the convenience of adding PCR products directly to a gel represents a significant time savings. Some companies combine their thermostable polymerase with a red dye and a high density component to facilitate loading of reaction products onto gels without further addition of loading buffer.

Thermal cycling parameters

Each step in the cycle requires a minimal amount of time to be effective, while too much time can be both wasteful and deleterious to the DNA polymerase. If the amount of time in each step can be reduced, so much the better.

Denaturation. It is critical that complete strand separation occur during the denaturation step. This is a unimolecular reaction which, in itself, is very fast. The suggested 30-sec denaturation used in the protocol ensures that the tube

contents reach 94°C. If PCR is not working, it is well worth checking the temperature inside a control tube containing 100 µl water. If GC content is extremely high, higher denaturation temperatures may be necessary; however, *Taq* DNA polymerase activity falls off quickly at higher temperatures (Gelfand, 1989). To amplify a long sequence (>3 kb), minimize the denaturation time to protect the target DNA from possible effects, such as depurination, of lowered pH of the Tris buffer at elevated temperatures.

Annealing. It is critical that the primers anneal stably to the template. Primers with relatively low GC content (<50%) may require temperatures lower than 55°C for full annealing. On the other hand, this may also increase the quantity of nonspecific products. For primers with high GC content, higher annealing temperatures may be necessary. It can be worthwhile, although time-consuming, to experiment with this parameter. Two manufacturers have thermal cyclers on the market which are capable of forming a temperature gradient across the heating units, thus permitting annealing temperature optimization in one run. These are Stratagene's Robocyclers, and Eppendorf's Master Cycler. As with denaturation, the time for this step is based mainly on the time it takes to reach the proper temperature, because the primers are in such excess that the annealing reaction occurs very quickly.

Extension. The extension temperature of 72°C is close to the optimal temperature for *Taq* DNA polymerase (~75°C), yet prevents the primers from falling off. Indeed, primer extension begins during annealing, because *Taq* DNA polymerase is partially active at 55°C and even lower temperatures (Gelfand, 1989).

The duration of extension depends mainly on the length of the sequence to be amplified. A duration of 1 min per kb product length is usually sufficient.

Certain protocols end the PCR with a long final extension time in an attempt to try to make products as complete as possible.

Ramp time. Ramp time refers to the time it takes to change from one temperature to another. Using water baths and moving samples manually from temperature to temperature probably gives the shortest ramp times, which are mainly the time required for the tube's contents to change temperature. Different thermal cyclers have different ramp times; basically, the shorter the better.

The Stratagene Robocycler uses a robotic arm to move samples from one constant-temperature block to another, virtually eliminating ramp time. Rapid cyclers utilize positive-displacement pipet tips or capillary tubes for the PCR reactions, dramatically reducing the ramp times.

Generally, the more "high-performance" thermal cyclers with short ramp times are proportionally more costly. There are many new thermal cyclers on the market priced below $5000, which perform quite well (Beck, 1998).

Anticipated Results

Starting with ≥100 ng mammalian DNA (≥10^4 molecules), the basic protocol can be used to determine which $MgCl_2$ concentration, enhancing additive, and initial conditions will yield a predominant PCR product from a single-copy sequence that is readily visible on an ethidium bromide–stained gel. It is possible that other minor products will also be visible.

Time Considerations

The basic protocol can be completed in a single day. Assembly of the reaction mixtures should take ~1 hr. Cycling should take less than 3 hr. Preparing, running, and staining the gel should take another few hours. Further checks on specificity of the product such as restriction endonuclease digestion or Southern blot hybridization will take another few hours or days, respectively.

Detection and Quantitation of Radiolabeled Proteins in Gels and Blots

This unit presents procedures for visualizing and quantitating radiolabeled proteins separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis or affixed to filter membranes. Autoradiography (see Basic Protocol) is the most common method by which this is accomplished, and X-ray film is the traditional recording medium. The use of autoradiography with gels requires that the gel be dried prior to being placed in contact with the film (see Support Protocol 1). The decay of radioactive materials within the dried gel or filter leaves an image on the film that reflects its distribution in the sample. Film images can be quantified by densitometry (see Support Protocol 4) to obtain a relative measure of the amount of radioactivity in the sample.

The use of X-ray films for autoradiography, however, suffers from two drawbacks: lack of sensitivity and a limited linear range over which the image density reflects the amount of radioactivity. Lack of sensitivity can be overcome by fluorography (see Alternate Protocol 1) or by the use of intensifying screens (see Support Protocol 2), both of which enhance the radioactive signal. Ensuring that the exposure is within a linear range requires careful controls; film is often preflashed (see Support Protocol 3) to increase the linear measurement range for weakly radioactive samples, and it is important to ensure that the film not be saturated to attain strong radioactive signals. Sensitivity and linear ranges of measurement can be greatly extended by using a phosphor imaging system (see Alternate Protocol 2). Phosphor imaging also makes it much faster and easier to quantify radioactive samples.

To enhance radioactive signals, solid-state scintillation is frequently employed to convert the energy released by radioactive molecules to visible light. This is accomplished in several different ways. In fluorography (see Alternate Protocol 1) organic scintillants are incorporated into the sample to increase the proportion of emitted energy detected from low-energy β particles (e.g., from ^{3}H, ^{14}C, and ^{35}S). Another method uses high-density, fluorescent "intensifying screens" (see Support Protocol 2), which are placed next to the sample and used to capture the excess energy of γ rays (e.g., those produced by ^{125}I) and high-energy β particles (e.g., from ^{32}P).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

AUTORADIOGRAPHY

BASIC PROTOCOL

Autoradiography uses X-ray film to visualize and quantitate radioactive molecules that have been electrophoresed through agarose or polyacrylamide gels, hybridized to filters, or chromatographed through paper or thin-layer plates. A photon of light or the β particles and γ rays released from radioactive molecules "activate" silver bromide crystals on the film emulsion. This renders them capable of being reduced through the developing process to form silver metal (a "grain"). The silver grains on the film form the image.

The choice of film is critical for autoradiography. Double-coated films (e.g., Kodak X-Omat AR and Fuji RX) contain two emulsion layers on either side of a polyester support and are most commonly used for autoradiography (Laskey and Mills, 1977). Double-coated films are ideal for detecting the high-energy β particles emitted by ^{32}P and ^{125}I, since they can penetrate the polyester support and expose both emulsion layers. These

Contributed by Daniel Voytas and Ning Ke
Current Protocols in Toxicology (2001) A.3D.1-A.3D.10

films are normally used with calcium tungstate ($CaWO_4$) intensifying screens at reduced temperature (−70°C); they are highly sensitive to the blue light emitted by these screens. The green-light-sensitive BioMax MS film (Kodak) is a double-coated film spectrally matched to the blue- and green-light-emitting BioMax MS intensifying screen. The BioMax MS film/BioMax MS intensifying screen system normally gives greatest sensitivity to ^{32}P (four times greater than that of X-Omat AR film with $CaWO_4$ screens).

Single-coated films, containing one emulsion layer (e.g., Kodak BioMax MR), are optimized for direct-exposure techniques with medium-energy radioisotopes (e.g., ^{14}C, ^{35}S, and ^{33}P, but not ^{3}H). The majority of the β particles emitted by these isotopes cannot pass through the polyester support of double-coated films, and therefore the emulsion layer on the other side of the film is useless. Even though direct exposure with single-coated films gives better clarity for medium-energy isotopes, single-coated films often require longer exposure times. Fluorography, therefore, is often used to enhance sensitivity. The blue-light-sensitive double-coated X-Omat AR film is generally used for fluorography with 2,5-diphenyloxazole (PPO; which emits at 388 nm), sodium salicylate (which emits at 420 nm), and commercial fluorographic solutions and sprays (e.g., from Amersham and DuPont NEN; which emit light in the blue end of the spectrum).

Materials

Fixed and dried gel (see Support Protocol 1) or filter
Developer: Kodak developer and replenisher, prepared according to the manufacturer's instructions, 18° to 20°C
Fixer: Kodak fixer and replenisher, prepared according to the manufacturer's instructions, 18° to 20°C

Metal film cassette or paper film cassette with particle-board supports and metal binder clips
Plastic wrap (e.g., Saran Wrap)
X-ray film
Trays to hold film processing solutions
Clips for hanging film

1. In a darkroom illuminated with a safelight, place the sample (e.g., dried gel or filter) in the film cassette. Cover the sample with plastic wrap to prevent it from sticking to the film and contaminating the cassette with radioactivity.

   The safelight should be a bulb of <15 W that is equipped with a Kodak GBX-2 red filter (or equivalent).

   Fluorescent glow-in-the-dark ink (available at craft stores) is a convenient way to mark samples exposed to film. The ink can be spread on adhesive labels, which in turn are placed on the plastic wrap around the edge of the sample. If exposed to light prior to autoradiography, the ink will fluoresce and expose the film, making it possible to orient the film image on the dried gel after developing.

2. Place a sheet of X-ray film on top of the sample, then close and secure the film cassette (see Fig. A.3D.1).

   If preflashed film is used for direct exposure (see Support Protocol 3), the exposed side should face the sample. Preflashed film should be used if sample is weakly radioactive or if quantitation of the radioactivity is desired. For single-coated film, the emulsion layer should face the sample.

   If a paper cassette is used, particle-board supports the same size as the cassette should be placed on either side and secured with the metal binder clips. This will ensure that the sample and film are held in contact and do not shift during exposure.

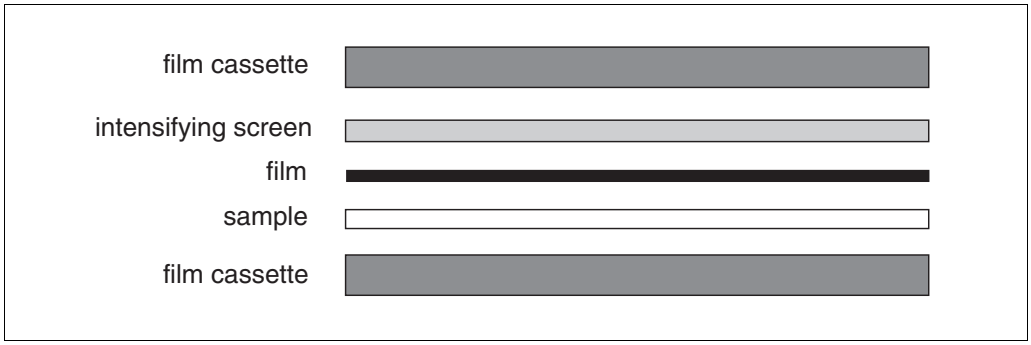

Figure A.3D.1 Autoradiography setup: intensifying screen, film, and sample in film cassette.

3. Expose the film for the desired length of time and at the appropriate temperature.

   Time of exposure will depend on the strength of the radioactivity in the sample and, in most cases, will have to be determined empirically by making multiple exposures for different lengths of time. To help estimate exposure time, a Geiger counter can often be used to detect the relative amount of radioactivity in the sample. With experience, this can help alleviate the trial and error often associated with obtaining the optimum exposure. Time of exposure and use of internal controls are particularly important if quantitative comparisons between experiments are desired.

4. After exposure, return cassette to the darkroom and remove film for developing.

   If the film was exposed at −70°C, allow the cassette to come to room temperature before developing. This will avoid static discharge, which can cause black dots or stripes on the autoradiogram.

   Automated film developers are also available and can be used to develop the film.

5. Immerse the film for 5 min in 18° to 20°C developer, then wash 1 min in running water at room temperature.

   Shorter periods of time in developer will yield a lighter image. The amount of time in developer, therefore, can be used to roughly control intensity of the image.

6. Immerse the film for 5 min in 18° to 20°C fixer, then wash for 15 min in running water.

7. Hang the film to dry.

   The orientation of the film with respect to the gel can be determined by the images of the fluorescent markers.

FIXING AND DRYING GELS FOR AUTORADIOGRAPHY

SUPPORT PROTOCOL 1

SDS-PAGE gels containing radiolabeled proteins should be fixed and dried before exposure to film. This will prevent the gel from sticking to the film, improve the sharpness of the image, and increase sensitivity slightly. However, if the specific activity of the sample is high or the detection method is sensitive (e.g., where a phosphor imager is used; see Alternate Protocol 2), then fixing and drying the gel may not be necessary. Gel dryers are available from a number of manufacturers (e.g., Bio-Rad), most of which use heat and a vacuum to accelerate the drying process.

Materials

Gel from SDS-PAGE
Fixing solution: 10% (v/v) glacial acetic acid/20% (v/v) methanol in H_2O
Alternative fixing solution (for gels with ≥15% acrylamide or thicker than 1.5 mm): 3% (v/v) glycerol/10% (v/v) glacial acetic acid/20% (v/v) methanol in H_2O

Glass dish
Rotary shaker
Filter paper (Whatman 3MM) in sheets at least 1 to 2 cm larger than gel
Plastic wrap (e.g., Saran Wrap)
Gel dryer with vacuum pump

1. After electrophoresis, remove the gel and the supporting glass plates from the electrophoresis apparatus and place in a glass dish. Carefully remove the upper glass plate by gently prying apart the corners with a metal spatula. Make a notch in the upper right hand corner of the gel for orientation.

   Since the gel contains radiolabeled proteins, be sure to follow the necessary guidelines for handling radioactivity. Everything that comes in contact with the gel is potentially radioactive.

2a. *For gels with <15% acrylamide and <1.5 mm thick:* Place the glass dish in a fume hood and pour enough fixing solution into the dish to cover the gel. Place the dish on a rotary shaker and gently rotate until 5 min after all of the blue color from the bromphenol blue in the sample buffer (if used) has disappeared (~30 min total).

   The bromphenol blue typically used in SDS-PAGE sample buffer will turn yellow as the acidic fixing solution diffuses into the gel.

   During fixing, the gel will typically slide off the lower glass plate, which can be removed.

2b. *For gels with ≥15% acrylamide or >1.5 mm thick:* Fix gel as in step 2a, but soak 1 hr in alternative fixing solution.

   The glycerol in the alternative fixing solution should help prevent cracking during drying.

3. Pour off the fixing solution and rinse the gel for a few minutes with deionized water.

   CAUTION: *Remember that solutions that come in contact with the gel are potentially radioactive.*

4. Carefully pour off the water and position the gel in the center of the glass dish. Be sure that any excess water is drained. Place a sheet of Whatman 3MM filter paper, at least 1 to 2 cm larger than the gel, over the gel.

   The gel will stick to the filter paper, which will allow it to be lifted and turned over with the gel side facing up.

5. Cover gel with plastic wrap. Smooth the wrap with a piece of tissue paper to remove any air bubbles or wrinkles.

6. Place a piece of filter paper on the gel support of the gel dryer to prevent contamination of the dryer by radioactivity.

7. Place the filter paper/gel/plastic wrap sandwich on the filter paper in the gel dryer with the plastic sheet facing up.

8. Position the rubber sealing gasket of the gel dryer over the gel. Set the appropriate heat setting on the gel dryer (normally 80°C; 60°C if the gel contains a fluor). Apply the vacuum and allow the gel to dry (typically 2 hr for a gel of 1 mm thickness).

   Removing the gel before it is completely dry can lead to cracking; it is therefore not a good idea to rush the drying process. A rough indication of whether the gel is dry can be obtained by feeling the gel under the sealing gasket. If the gel is dry, it should be warm over the entire surface.

9. Remove gel from dryer and proceed with autoradiography (see Basic Protocol).

USE OF INTENSIFYING SCREENS

SUPPORT PROTOCOL 2

Intensifying screens are used to enhance the film image generated by radioactive molecules (Laskey and Mills, 1977; Laskey, 1980). They are used strictly in conjunction with strong β-emitting isotopes such as ^{32}P or γ-emitting isotopes such as ^{125}I. Emissions from these forms of radiation will frequently pass completely through a film, but they can be absorbed by an intensifying screen which fluoresces and exposes the film with multiple photons of light. While an intensifying screen will substantially enhance the film image as compared with direct exposure (Table A.3D.1), some loss of image resolution will occur due to light scatter. Intensifying screens are distributed by most laboratory supply companies (e.g., Fisher, Sigma, and Kodak).

As shown in Figure A.3D.1, the film should be placed between the sample and the intensifying screen. Preflashed film (see Support Protocol 3) should be used if the sample is weakly radioactive or if quantitation of the radioactivity is desired. The preflashed side of the film should be placed adjacent to the intensifying screen. For very weakly radioactive samples, a second screen can be placed on the other side of the radioactive sample (i.e., screen, then sample, then film, then screen), but this causes further loss in resolution due to light scatter. Also, the sample and sample support must be sufficiently transparent to allow light from the second screen to reach the film. The film should be exposed at −70°C to stabilize the silver bromide crystals activated by the radioactivity or the light emitted from the screen.

Table A.3D.1 Different Methods for Isotope Detection and Their Sensitivities[a]

Isotope	Method[b]	Sensitivity[c]	Enhancement over direct autoradiography[d]
^{125}I	S	100	16
^{32}P	S	50	10.5
^{14}C	F	400	15
^{35}S	F	400	15
^{3}H	F	8000	>100

[a]Exposures conducted at −70°C using preexposed film.

[b]S, intensifying screen; F, fluorography using PPO.

[c]Defined as dpm/cm^2 required for detectable image (A_{540} = 0.02) in 24 hr.

[d]Direct autoradiography for comparison was performed on Kodirex film (Laskey, 1980).

PREFLASHING (PRE-EXPOSING) FILM

SUPPORT PROTOCOL 3

Silver bromide crystals that are activated by light, β particles, or γ rays are highly unstable and quickly revert back to their stable form. The absorption of several photons increases their stability but does not ensure development; approximately five photons of light are required to obtain a 50% probability that any single silver bromide crystal will be developed during film processing. This inefficiency means that film images produced by very low levels of exposure will be disproportionately faint. However, two measures can be taken to maximize efficiency and linearity of exposure at the low levels commonly encountered in ordinary use. First, the film should be pre-exposed to a hypersensitizing flash of light, which provides several photons per silver bromide crystal and stably activates them without providing enough exposure to cause them to become developed. This allows a linear relationship to be drawn between the film image and the amount of radioactivity in the sample. Second, film exposure should be conducted at low tempera-

tures (−70°C) to slow the reversal of activated silver bromide crystals to their stable form (Laskey and Mills, 1975).

Film can be hypersensitized by exposure to a flash of light (<1 msec) provided by a photographic flash unit or a stroboscope before being placed onto the radioactive sample for exposure of the autoradiogram (Laskey and Mills, 1975, 1977). As the optimal light intensity required for pre-exposure varies with the type of film and the flash unit being used, the ideal exposure is best determined empirically as described below.

Materials

Stroboscope or flash unit (e.g., Auto 22 Electronic Flash from Vivitar or Sensitize Pre-Flash from Amersham Pharmacia Biotech)
Neutral-density filter (Kodak)
Orange filter (Wratten 22; Kodak)
X-ray film
Spectrophotometer

1. Cover the stroboscope or flash unit with the neutral-density and orange filters.

   This serves to decrease the intensity of emitted light, particularly the blue wavelengths to which X-ray films are most sensitive. Filters are not required for the Amersham flash unit.

2. Place the film perpendicular to the light source at a distance of ≥50 cm to ensure uniform illumination.

3. Expose a series of test films for different flash lengths, then develop them (see Basic Protocol).

   An uneven fog level on film can be remedied by placing a porous paper diffuser, such as Whatman no. 1 filter paper, between the film and the light source.

4. Cut the films into pieces that fit into a cuvette holder of a spectrophotometer and measure the absorbance at 540 nm.

   Choose an exposure time that causes the absorbance of the pre-exposed film to increase by 0.15 with respect to film that was not pre-exposed.

ALTERNATE PROTOCOL 1

FLUOROGRAPHY

Organic scintillants can be included in radioactive samples to obtain autoradiograms of weak β-emitting isotopes such as ^{3}H, ^{14}C, and ^{35}S. The scintillant fluoresces upon absorption of β particles from these isotopes, facilitating film exposure. Fluorographs of radioactive molecules in polyacrylamide gels have traditionally used the scintillant PPO (2,5-diphenyloxazole; Laskey and Mills, 1975). PPO, however, has largely been replaced with commercial scintillation formulations that reduce the amount of preparation time and are considerably safer to use. These scintillants (e.g., Enhance from NEN Life Science) come with complete instructions for their use. In addition, spray applicators are also available that can be used on filters or thin-layer plates. The expected levels of image enhancement obtained through fluorography are listed in Table A.3D.1. Sodium salicylate can also be used for fluorography as described below (Chamberlain, 1979). It yields levels of image enhancement comparable to organic scintillants, although it sometimes causes a more diffuse film image. The conditions should work for most standard sizes and thicknesses of gels.

CAUTION: Gloves should be worn at all times; sodium salicylate can elicit allergic reactions and is readily absorbed through the skin.

Materials

Polyacrylamide gel
1 M sodium salicylate, pH 5 to 7, freshly prepared

Additional reagents and equipment for fixing and drying gels (see Support Protocol 1)

1. If gel is acid-fixed, soak for 1 to 5 hr in ~20 vol water to prevent precipitation of salicylic acid from the sodium salicylate.
2. Soak gel 30 min in 10 vol of 1 M sodium salicylate, pH 5 to 7.

   To prevent cracking of gels with >15% acrylamide or thicker than 1.5 mm, 2% (v/v) glycerol can be added to the 1 M sodium salicylate.
3. Dry the gel (see Support Protocol 1) and proceed with autoradiography (see Basic Protocol).

DENSITOMETRY

SUPPORT PROTOCOL 4

Film images obtained by autoradiographic methods can be quantified by densitometry. Densitometers work by comparing the intensity of light transmitted through a sample with the intensity of the incident light. The amount of light transmitted will be proportional to the amount of radioactivity in the gel, provided that the film has been properly pre-exposed (see Support Protocol 3). The linear range of correctly pre-exposed film is 0.1 to 1.0 absorbance units. However, if the pre-exposure is excessive—i.e., an increase of >0.2 absorbance units (A_{540}) treated film/untreated film—smaller amounts of radioactivity will produce disproportionately dense images. Autoradiograms that exceed an absorbance of 1.4 absorbance units (A_{540}) have saturated all available silver bromide crystals and also cannot be evaluated quantitatively.

Densitometers are available from several manufacturers (e.g., Molecular Dynamics, Bio-Rad, and UVP). Most models come with software that facilitates calculations and allows the user to define the region of the film to be measured. Procedures for the use of these machines vary and instructions are provided by the manufacturer. Densitometers are also available that measure light reflected from a sample. Reflectance densitometers are useful in instances where the sample medium is completely opaque—e.g., filters that have been probed using nonradioactive colorimetric detection assays.

PHOSPHOR IMAGING

ALTERNATE PROTOCOL 2

Phosphor imaging screens can be used as an alternative to film for recording and quantifying autoradiographic images (Johnston et al., 1990). They can detect radioisotopes such as ^{32}P, ^{125}I, ^{14}C, ^{35}S, and ^{3}H. There are several advantages of phosphor imaging over film: (1) linear dynamic ranges are 5 orders of magnitude, compared to ~1.5 orders of magnitude for film (Fig. A.3D.2); (2) exposure times are 10 to 250 times faster than with film; (3) quantification is much easier and faster, and most imagers come with software to directly analyze data; (4) fluorography and gel drying are often unnecessary because of the sensitivity of phosphor imaging; and (5) phosphor screens can be reused indefinitely if handled carefully.

Phosphor imaging screens are composed of crystals of $BaFBr:Eu^{+2}$. When the screen is exposed to ionizing radiation such as α, β, or γ radiation, or wavelengths of light shorter than 380 nm, the electrons from Eu^{+2} are excited and then trapped in an "F-center" of the $BaFBr^{-}$ complex; this results in the oxidation of Eu^{+2} to Eu^{+3}, which forms the latent image on the screen. After exposure, the latent image is released by scanning the screen with a

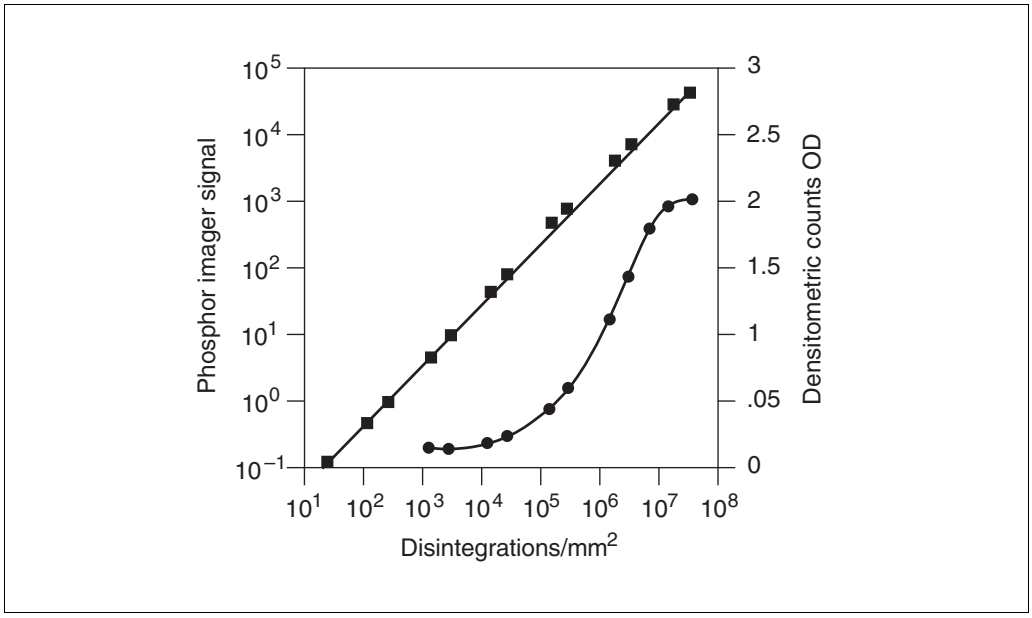

Figure A.3D.2 ^{32}P dilution series quantified on Model GS-525 phosphor imager (squares), compared to film (circles). Image courtesy of Bio-Rad, Hercules, Calif.

laser (633 nm). During scanning, Eu^{3+} reverts back to Eu^{+2}, releasing a photon at 390 nm. The luminescence can then be collected and measured in relation to the position of the scanning laser beam. The result is a representation of the latent image on the storage phosphor imaging plates. The image can then be viewed on a video monitor and analyzed with the aid of appropriate software.

Some companies (e.g., Bio-Rad) offer different screens for use with different isotopes. They vary principally in the protective coating on the screen, which is optimized for low- or high-energy β particles or γ rays. No coating is typically used for weak β emitters such as tritium. More recently, screens have also been developed that measure chemiluminescence. Such screens are particularly valuable for use with many nonradioactive labeling protocols.

The protocol below is for the PhosphorImager system from Molecular Dynamics; other phosphor imaging systems are available from Bio-Rad, Imaging Research, and National Diagnostics.

Materials

Gel or filter
PhosphorImager system (Molecular Dynamics) including:
ImageEraser light box
Exposure cassette with phosphor screen
Scanning software

1. Erase any latent image on the phosphor screen left by a previous user, or caused by background radiation, by exposure to visible light.

   The PhosphorImager system comes with an extra-bright light box (ImageEraser) for this purpose. Standard laboratory light boxes may also be used.

2. Cover gel or filter with plastic wrap to protect the exposure cassette. Place wrapped gel or filter in the PhosphorImager cassette and close to begin exposure.

   The gel does not have to be dried for this procedure. The phosphor screen is affixed to the lid of the cassette. Exposure times are typically one-tenth of the time required for film exposure.

3. After exposure, slide the screen face down into the PhosphorImager system.
4. Select the scanning area using the software supplied with the PhosphorImager and start scanning.

   The blue light emitted during scanning is collected to produce the latent image.

5. Analyze and quantitate the image using the software provided.
6. Erase the phosphor screen by exposing it to visible light as in step 1.

COMMENTARY

Background Information

The ability to detect radiolabeled proteins is critical to many studies in biology. A variety of labeling methods are described throughout this manual. More often than not, detection of radiolabeled proteins is coupled with the resolving power of SDS polyacrylamide gel electrophoresis (SDS-PAGE). Radiolabeled proteins separated on gels can be used directly to obtain an autoradiographic image. Alternatively, proteins separated by SDS-PAGE are frequently transferred to membranes and detected using radiolabeled probes such as antibodies and ^{125}I-labeled protein A. The autoradiographic image, whether generated on film or a phosphor screen, reflects the distribution of the radioactive proteins on the two-dimensional surface of the gel or filter. Molecular sizes of radiolabeled proteins, therefore, can be determined by correlating their positions with molecular markers. Also, the density of the band images can be used to determine the relative quantities of the radiolabeled proteins in the sample.

Critical Parameters

The sensitivity of the detection device and the strength of the radioactive signal are the two most important parameters for autoradiography. Sensitivity can be enhanced by treating samples with fluors or by using intensifying screens (Table A.3D.2). Because phosphor imaging is 10 to 250 times more sensitive than film (Johnston et al., 1990), this technology makes it possible to monitor radioactive samples that would previously have gone undetected with film.

A second important parameter is the range over which the measurement device is linear. Film requires preflashing in order for the intensity of the image to be linear with respect to the amount of radioactivity, particularly for weakly radioactive samples (Laskey and Mills, 1975, 1977). Phosphor imaging offers a much wider linear range of measurement (5 orders of magnitude compared to 1.5 for film; Johnston et al., 1990). This makes it possible to accurately quantitate very weak or very strong radioactive samples.

Troubleshooting

Cracking is one of the most common problems encountered when drying gels. This often occurs if the gel is removed from the dryer before it has adequately dried or if drying temperatures are too high. To overcome this problem, drying times should be extended and the performance of the vacuum pump and heater unit should be checked. For many gels, particularly for those with high percentages of polyacrylamide or >1.5 mm thick, cracking can be reduced by using an alternative fixing solution containing glycerol (3% glycerol/10% glacial acetic acid/20% methanol; see Support Protocol 1).

Among the biggest problems encountered in autoradiography are images that are either too weak or too intense. Such problems can be solved by varying the exposure time. Estimating initial exposure time is difficult, since the

Table A.3D.2 Film Choice and Exposure Temperature for Autoradiography

Isotope	Enhancement method	Film	Exposure temperature
^{3}H	Fluorography	Double-coated	–70°C
^{35}S, ^{14}C, ^{32}P	None	Single-coated	Room temperature
^{35}S, ^{14}C, ^{32}P	Fluorography	Double-coated	–70°C
^{32}P, ^{125}I	$CaWO_4$ intensifying screens	Double-coated	–70°C

amount of radioactivity in the sample is often unknown. A Geiger counter can offer some guidance with certain isotopes. For highly exposed film, the length of time in developer can be reduced to produce a lighter image. It is particularly important to remember that if accurate quantification of the film image is desired, film must be preflashed so that there is a linear relationship between the amount of radioactivity in the sample and the image intensity.

Artifacts, such as black spots and stripes, can be avoided during developing by making sure that no moisture comes in contact with the film and that films exposed at −70°C are brought to room temperature before developing. Also, it must be noted that β particles from weak isotopes such as ^{3}H cannot penetrate plastic wrap, and plastic wraps can attenuate signals from ^{35}S and ^{14}C up to two-fold.

Anticipated Results

The protocols described here should yield a film image of a gel that can be quantified, stored, and photographed for publication.

Time Considerations

Fixing a gel will require ~45 min. Drying will take an additional 2 hr for a gel 1 mm in thickness. Incorporation of a fluor will add ~45 min to the processing time.

For gels >1.5 mm thick or with >15% acrylamide, an additional 30 min will be required for fixing and ~30 additional minutes will be required for drying.

The length of exposure for films in autoradiography can range from a few minutes to a few weeks, depending on the strength of the radioactivity in the sample. Most exposures last from several hours to a few days. Exposure time can be reduced more than 10-fold with a phosphor imager.

Northern Blot Analysis of RNA

Northern blot hybridization is used to determine quantitatively the presence of specific mRNA transcripts in cell or tissue lysates and to evaluate the specificity of a select oligonucleotide probe. First the RNA is extracted from a tissue or cell culture (see Support Protocol 1). Following agarose gel separation, the RNA is transferred by capillary action to a nylon membrane (see Basic Protocol). The RNA is then UV-crosslinked to the membrane and stained with methylene blue to verify RNA integrity and equal RNA loading and transfer and then used for hybridization. After prehybridization, which blocks the nonspecific binding sites, the membrane is probed with a specific cDNA oligonucleotide, which is labeled with ^{32}P using terminal deoxynucleotidyl transferase (TdT; see Support Protocol 2). Following successive washes of increasing stringency, the membrane is exposed to an autoradiographic film. The presence of a band on the film emulsion indicates RNA hybridization with the radioactive probe. The probe can then be removed from the membrane, and subsequent probes rehybridized for further analysis (see Support Protocol 3).

In general, it is preferable to isolate mRNA instead of total RNA, as mRNA represents only 1% to 5% of the total cellular RNA; therefore, mRNA samples give a substantially higher signal than total RNA. For mRNA isolation, use commercially available kits (e.g., Invitrogen's Fastrack 2), which allow mRNA isolation directly from tissues or cells without prior total RNA extraction. Although extraction of total RNA is simpler and faster, and verification of RNA integrity is easier (the prominent bands corresponding to the 18 S and 28 S ribosomal subunits, which are 1.8 to 2 kb and 4 to 5 kb, respectively, can be used as an indication that the RNA has not been degraded during the extraction protocol), total RNA should be used for northern blots only if there is preliminary information of abundant expression of the transcript. If total RNA has to be used because of a limited amount of cells or tissues and no signal can be detected by northern blot analysis, reverse transcriptase amplification (RT-PCR) may be used.

The major problem in the analysis of RNA is contamination with ribonucleases (RNase), which are very stable enzymes that do not require any cofactors for activity. Avoid RNase contamination by wearing clean powder-free gloves for all procedures and by using RNase-free reagents, plasticware, and glassware. Autoclaving solutions, glassware, and plasticware is usually not enough to inactivate all RNases. Instead, all heat-resistant glassware and plasticware should be baked at 140° to 150°C overnight. Equipment such as the electrophoresis tank should be rinsed in RNase-free water for 30 min prior to use. All solutions (except Tris-containing solutions) can be made from water treated with the RNase inhibitor diethylpyrocarbonate (DEPC; see *UNIT 2.9*). The use of RNase-free solutions (made up with DEPC-treated water, unless otherwise stated) is recommended for the preparation of all solutions before and during the hybridization steps. Because DEPC-treated water from commercial sources is quite expensive, the use of low-cost, DEPC-treated water made in the lab is recommended. The use of RNase-free solutions is not required in post-hybridization procedures because of the resistance of RNA:RNA hybrids to RNase degradation. Because even the smallest contaminants of DEPC may affect many subsequent enzymatic steps such as labeling or amplification, purified RNA should be solubilized in water from a known RNase/DNase-free source (not DEPC-treated and pyrogen-free). RNA samples should be kept on ice when they are not protected by RNase inhibitors.

NOTE: For commentary concerning northern blot analysis, see *UNIT 2.9*.

BASIC PROTOCOL

NORTHERN BLOT HYBRIDIZATION

Isolated RNA (see Support Protocol 1) is size fractionated by gel electrophoresis using a 1% (w/v) agarose gel to separate RNA in the 1- to 10-kb range prior to transfer. If ethidium bromide is incorporated into the gel, bands can be visualized using a transilluminator.

After size fractionation, the RNA is transferred to a membrane. Capillary flow is the most common and inexpensive method to transfer nucleic acids (RNA and DNA) from an agarose gel to a membrane. The nucleic acid is washed out of the gel onto the membrane using a stack of dry paper towels, which draws the transfer solution from the reservoir through a wick of Whatman 3 MM blotting paper, then through the gel, the membrane, and into the dry paper towels. Two variants of the capillary flow transfer method currently exist: upward and downward transfer (Figs. A.3E.1A and A.3E.1B, respectively). In both systems, the gel is closest to the reservoir. The membrane is in direct contact with the surface of the gel followed by some blotter paper and a stack of dry paper towels. Although both setups work very well, downward transfer (e.g., using the TurboBlotter, Schleicher and Shuell) is recommended since it results in somewhat sharper bands as no extra weight is applied on the gel.

Once the materials are prepared, the nylon membrane bearing size-fractionated RNA is incubated with the radiolabeled oligonucleotide probe to allow hybridization between the single-stranded DNA and the single-stranded RNA. After hybridization the membrane is washed with a series of solutions of increasing stringency and then exposed to autoradiographic film to visualize the hybridized bands. This protocol is adapted for the use of short oligonucleotides (30- to 45-mer) in northern blot hybridization. Any variations in temperature, salts or denaturing conditions may greatly affect the probe hybridization.

Materials

Ultrapure agarose, low-melting temperature (e.g., Life Technologies, Bio-Rad, Sigma, or Fisher)
DEPC-treated H_2O (*UNIT 2.9*)
10× and 1× MOPS (see recipe)
37% formaldehyde (Sigma)
Purified RNA (20 to 40 µg total or 4 to 10 µg mRNA; see Support Protocol 1)
≥99.5% formamide, deionized (Sigma)
RNA loading dye (see recipe)
10 mg/ml ethidium bromide (optional; see recipe)
Nylon membrane, positively charged (Hybond from Amersham Pharmacia Biotech or Nytran SuPerCharge from Schleicher & Schuell)

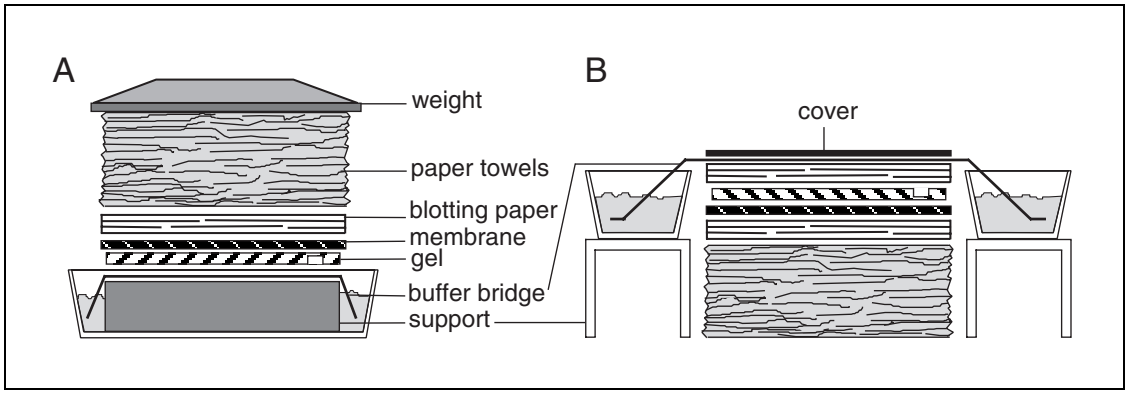

Figure A.3E.1 Capillary flow transfer of RNA from agarose gels to a membrane. (**A**) Upward capillary transfer. (**B**) Downward capillary transfer.

20× and 2× SSC (*UNIT 2.9*)
0.02% (w/v) methylene blue RNA staining solution (*UNIT 2.9*)
20× SSPE (*UNIT 2.9*)
20% (w/v) SDS (*APPENDIX 2A*)
100× Denhardt's solution (*UNIT 2.9*)
10 mg/ml heat-denatured salmon sperm DNA (Life Technologies)
50% (w/v) dextran sulfate (*UNIT 2.9*)
100 cpm/μg [α-^{32}P]dATP-labeled oligonucleotide probe (see Support Protocol 2)
1× and 2× SSPE/0.1% SDS
1× STE buffer (see recipe)

Horizontal gel electrophoresis system with casting box and Teflon combs with 3- to 4-mm teeth (e.g., Bio-Rad, Amersham Pharmacia Biotech, Owl, Shadel) and appropriate power supply
Microcentrifuge tubes, RNase-free
UV transilluminator, ruler, and camera (optional)
Elevated support (e.g., empty pipet tip box)
Whatman 3 MM papers
10- to 15-cm stack of paper towels
Small weight (~500 g) or light-weight cover
UV Cross-linker (Stratagene)
Pencil or fluorescent pen (optional)
Hybridization oven with glass hybridization bottle (Hybaid) or
42°C water bath and sealable bag
Geiger counter
Autoradiographic cassette, light-tight with intensifying screen
X-ray film (e.g., X-Omat AR5 or BioMax MS from Kodak)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CAUTION: Radiolabeled probes are hazardous; see *APPENDIX 1A* for guidelines on handling, storage, and disposal. To protect from radioactivity and RNase contamination as well as finger smudges, always wear clean, powder-free gloves when working with RNA and radioactive substances. Do not reuse gloves.

Prepare agarose gel

1. Set up the casting box (mold) following the manufacturer's instructions.
2. In a flask, mix 1.0 g ultrapure low-melting-temperature agarose with 85 ml DEPC-treated water. Heat on a heating/stirring plate (or in a microwave oven) until all crystals are dissolved.

   NOTE: *Do not boil the agarose solution.*

   The volume of agarose solution needed depends on the size of the electrophoresis chamber used. Keep the gel thickness between 4 and 6 mm to obtain sharper bands and to allow efficient RNA transfer.

   Transcripts of 1 to 10 kb are easily separated by 1% agarose gels, whereas transcripts shorter than 0.5 to 4 kb are better separated by 1.6% to 1.8% agarose gels. Gels with <1% agarose are extremely fragile and hard to handle, while gels with ≥2% agarose do not transfer RNA well.

3. Let the solution cool to ~60°C to avoid excess evaporation of the formaldehyde to be added. Add 10 ml 10× MOPS and 5 ml 37% formaldehyde in a fume hood. Swirl gently without creating air bubbles.

   CAUTION: *Formaldehyde is a denaturing agent that protects RNA from degradation. It is toxic if inhaled or absorbed through the skin. All procedures involving formaldehyde should be carried out in a fume hood. Wear gloves at all times.*

4. Place the gel casting apparatus on a leveled surface, pour the molten agarose gel mixture into the mold, and insert the Teflon comb immediately.

   To obtain sharp bands, use a gel thickness of no more than 3 to 4 mm and a comb tooth width of 6 to 8 mm. Narrower teeth or wells may result in smeared bands.

5. When the gel has set (15 to 20 min), remove the comb gently. Place the gel in the horizontal electrophoresis tank with the wells towards the anode (RNA migrates towards the cathode) and add enough 1× MOPS solution to cover up to 1 mm over the gel surface.

Prepare RNA

6. Prepare the RNA sample by combining the following in an RNase-free microcentrifuge tube:

   6 µl purified RNA (20 to 40 µg total RNA or 4 to 10 µg mRNA)
   12.5 µl ≥99.5% deionized formamide
   2.5 µl 10× MOPS
   4.0 µl 37% formaldehyde

   Mix and incubate 10 min at 65°C.

   If RNA size markers are used, treat in the same fashion as the RNA samples.

7. Place the denatured samples on ice and add 2.5 µl RNA loading dye. If desired, add 1 µl 10 mg/ml ethidium bromide. Vortex briefly and microcentrifuge for 5 sec.

   The use of ethidium bromide to stain the RNA in gels is not recommended since it is highly toxic and can interfere with RNA transfer. If necessary, the gel can be stained after the transfer to verify that all the RNA was transferred from the gel. Staining the membrane instead is generally enough to verify that the electrophoresis was successful.

Run the gel

8. Load the RNA samples into each well. Run the gel at 5 to 8 V/cm until the bromophenol blue dye has migrated two-thirds the length of the gel.

   CAUTION: *To avoid electrocution, connect the electrode leads one at a time with one hand only and then turn on the power supply.*

   The amount of RNA needed for each lane depends on the abundance of the transcript of interest and the type of RNA used. For mRNA, 4 µg is usually enough, but up to 10 µg can be loaded on the gel. For total RNA, 20 µg is typically used, but up to 40 µg can be loaded on a gel.

9. Turn off the power supply and remove the connections with one hand.

10. Remove the gel from the mold and rinse briefly in deionized water.

    If ethidium bromide is used in the samples, place the gel on a UV-transilluminator to visualize the RNA and photograph the gel along with a ruler on its side so that band positions can be transposed to the membrane after transfer.

Prepare gel for transfer

11. To save solutions and materials, cut off excess agarose from the gel (e.g., the empty lanes on the sides).

12. Cut the positively charged nylon membrane slightly larger than the gel.

    NOTE: *Keep the protective paper on both side of the membrane while cutting and handling to prevent fingerprints and high background signal.*

13. Prewet the membrane in DEPC-treated water and then soak in 20× SSC (transfer buffer) for 1 min each at room temperature.

Translocate RNA to membrane by upward transfer

NOTE: The following steps describe how to assemble the upward transfer apparatus depicted in Figure A.3E.1A.

14a. Using a clean flat dish as a reservoir, place an elevated support (island) in the middle of the dish.

    Use a support slightly larger than the gel (an empty plastic pipet tip box works well).

15a. Pour 20× SSC in the reservoir to a depth of ~2 to 3 cm.

16a. Construct a buffer bridge with a clean piece of Whatman 3 MM paper (see Fig. A.3E.1A). Wet the bridge with 20× SSC and place on top of the elevated support with the ends of the bridge hanging in the transfer solution.

17a. Place the gel (face down) directly on top of the elevated support and cover the exposed blotter paper (from the bridge) around the edge of the gel with strips of parafilm or cellophane to prevent wicking of buffer through the paper rather than the gel.

18a. Place the wet membrane (step 13) directly on top of the gel, making sure to eliminate all air bubbles between the membrane and the gel.

    To minimize the distance the nucleic acid has to migrate out from the gel to the membrane, it is important to place the side of the gel corresponding to the bottom of the wells directly against the membrane.

19a. Presoak 2 to 3 Whatman 3 MM papers cut the same size as the gel (or slightly bigger) in 20× SSC and apply to the membrane.

20a. Top with a 10- to 15-cm stack of dry paper towels cut the same size as the gel. Put a small weight (~500 g) on top of the system and transfer overnight at room temperature.

Translocate RNA to membrane by downward transfer

NOTE: The following steps describe how to assemble the downward transfer apparatus depicted in Figure A.3E.1B, which is inverted compared with the upward system.

14b. Form the island with a ~5- to 8-cm stack of dry towels or blotter paper. Place two clean buffer reservoirs (e.g., two clean pipet tip box lids, slightly wider than the height of the gel) on both sides of the blotter stack. Pour 65 ml (for gels up to 11 × 14 cm) or 100 ml (for gels up to 20 × 25 cm) of 20× SSC in each reservoirs.

    Blotter papers, paper towels, and the membrane are all cut the size of the gel (or slightly bigger).

15b. Add 4 or 5 dry Whatman 3 MM papers on top of the island.

16b. Add 2 to 3 Whatman 3 MM papers presoaked in 20× SSC.

17b. Add the wet membrane (step 13).

18b. Place the gel face up on top of the membrane, making sure to eliminate all air bubbles between the membrane and the gel..

See step 18a for specific instructions on gel placement.

19b. Place 3 sheets of Whatman 3MM blotter paper, presoaked in 20× SSC on top of the gel. Construct a transfer buffer bridge with a clean piece of Whatman 3MM paper (see Figure A.3E.1B). Presoak the bridge in 20× SSC and carefully apply on top of the blotter stack so that the short dimension of the wick completely covers the blotting stack, leaving the ends of the bridge hanging at the bottom of the transfer reservoirs. Place a light wick-cover on top to prevent evaporation.

20b. Transfer overnight at room temperature.

A TurboBlotter System (Schleicher and Shuell) can also be used according to the manufacturer's instructions. Depending on the thickness of the gel and the size of the RNA of interest, transfer time with this system can be as short as 4 hr.

Crosslink RNA

21. After transfer is complete, remove the membrane from the transfer system. Place it face up on a wet Whatman 3MM paper and crosslink the RNA using a UV-crosslinker (Stratagene) according to the manufacturer's instructions.

At this point, the wet membrane can be stored sealed in a plastic wrap at 4°C for up to 2 weeks before analysis.

Stain the membrane

22. Stain the membrane with 0.02% (w/v) methylene blue RNA staining solution until the lanes become visible (~15 min). Delineate the RNA marker bands on the side of the membrane with a pencil, fluorescent pen, or dye.

Methylene blue RNA staining solution is 0.02% methylene blue in 0.3 M sodium acetate solution, pH 5.5 (see UNIT 2.9).

23. Destain with 2× SSC. Cut one corner away to establish the orientation of the lanes.

Prehybridize membrane

24. Transfer the UV-crosslinked membrane with RNA to a sealable bag or a glass hybridization bottle.

25. Prepare the prehybridization solution by mixing the following in order, in a sterile tube (8 ml total volume):

4.4 ml DEPC-treated H_2O
2.5 ml 20× SSPE
0.5 ml 20% SDS
0.5 ml 100× Denhardt's solution
0.1 ml 10 mg/ml heat-denatured salmon sperm DNA.

When made at room temperature, the solution may cloud up after addition of SDS. This can be corrected by heating the water and the 20× SSPE mixture to 42°C before adding the other ingredients to the solution.

Use ~8 to 10 ml solution per 10 cm^2 of membrane.

26. Add the prehybridization solution to the membrane and prehybridize at least 2 hr at 42°C using either a hybridization oven or a sealed bag submerged in a shaker water bath.

Add label

27. Add 2 ml 50% dextran sulfate to the prehybridization solution and mix well.

    The total hybridization volume is 10 ml.

28. Add 10^6 to 10^7 cpm labeled probe for each 1 ml prehybridization solution. Mix well.

29. Hybridize overnight at 42°C as described above (step 26).

Wash the hybridized membrane

30. The next day, wash the membrane twice with 2× SSPE/0.1% SDS, 42°C for 15 min each and once with 1× SSPE/0.1% SDS, 42°C for 15 min. Check the activity of the membrane after each wash by holding a Geiger counter 2 to 3 cm above the membrane surface. At the first sign of significantly decreased signal intensity, stop the washing procedures.

    The signal should be very intense after the first washes. With increasing wash stringency, the signal should decrease.

    Dilutions of SSPE from the 20× SSPE stock should preferably be made with DEPC-treated water but high-quality deionized sterile water can also be used.

31. *Optional:* If necessary (i.e., too much noise), wash four times with 1× SSPE/0.1% SDS, increasing the temperature by 5°C each time from 45° to 60°C.

    If the membrane is still too radioactive after washing at 60°C, decrease the SSPE concentration to 0.5×, 0.2× and then 0.1× SSPE/0.1% SDS.

    Increasing the temperature and decreasing the SSC concentration provide more stringent conditions that facilitate the elimination of mismatched probe, thus decreasing nonspecific background.

Perform autoradiography

32. Drain the excess solution from the membrane and seal it in plastic wrap.

    Do not allow the membrane to dry between washes or during autoradiographic exposure.

33. Tape the membrane against the lid (inner surface) of a light-tight autoradiography cassette. Place an intensifying screen in the bottom of the cassette. In a dark room, place an X-ray film directly on top of the screen and then close the lid.

    The membrane attached to the inside of the lid should be in direct contact with the film emulsion.

34. Place the autoradiography cassette at −70°C for the appropriate length of time, depending on the specific activity of each sample and the abundance of mRNA.

    To save time in trying to determine which exposure time is adequate, three films can be exposed at the same time. The film closest to the intensifying screen usually gives the strongest signal whereas the one closest to the membrane (farthest from the screen) gives the lowest signal.

35. Develop the film according to the manufacturer's instructions.

TOTAL RNA EXTRACTION

SUPPORT PROTOCOL 1

This protocol describes a method to isolate undegraded, DNA-free, total RNA using Trizol Reagent (Life Technologies) followed by extractions with acidic phenol/chloroform (Ambion). This method uses a mixture of guanidine isothiocyanate and phenol, which inactivates the RNases and yields excellent quality RNA for all downstream experiments.

Additional Materials *(also see Basic Protocol)*

Tissue
Trizol Reagent (Life Technologies) or TriReagent (Sigma) or RNA STAT-60 (Tel-Test) or Ultraspec (Biotech Labs)
Chloroform
5:1 (v/v) acid phenol/chloroform, pH 4.7 (Ambion)
Isopropyl alcohol
75% and 100% ethanol
dH_2O, sterile, non-DEPC treated, RNase/DNase- and pyrogen-free (Ambion or Life Technologies)
40 U/µl RNasin (Promega)
1 M Tris·Cl, pH 7.5, RNase-free (Sigma, Ambion, Life Technologies)
50 mM $MgCl_2$, RNase-free (Sigma, Ambion, Life Technologies)
10 U/µl DNase, RNase free (Life Technologies, Roche Molecular Biochemical, Ambion)
3 M sodium acetate solution, pH 5.2, RNase-free (Sigma, Ambion)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

Polytron or Dounce homogenizer
Pipet tips, RNase-free (Fischer, Ambion, Promega)

NOTE: Because Tris·Cl, $MgCl_2$, and sodium acetate solution listed here are added directly to the RNA preparation, we recommend that they be absolutely RNase-free. Because of the small volumes used in this protocol, we recommend a commercial supplier as the source for these solutions.

CAUTION: Guanidine isothiocyanate and phenol are highly toxic. The use of gloves, adequate ventilation, and special disposal methods are required.

Collect tissue

1. Excise the tissue and freeze immediately in sterile tubes on powdered dry ice. Store at −70°C until analysis.
2. Take the tissue sample out of the freezer and place in an RNase-free microcentrifuge tube. Do not thaw.

Extract RNA

3. Immediately add 1 ml Trizol Reagent per 100 mg tissue and homogenize with a Polytron (for larger tissue samples) or Dounce homogenizer (for small tissue samples). Transfer to an RNase-free microcentrifuge tube.

   For monolayer cell culture, first rinse quickly with ice-cold sterile PBS and then add 1 ml Trizol Reagent directly to the 150-mm dish (10^2 to 10^6 cells). Scrape cells from the dish with a sterile cell scraper and transfer the lysate to an RNase-free microcentrifuge tube. Homogenize up and down through a 1000-µl pipet tip.

   Trizol reagent is equivalent to TriReagent from Sigma, RNA STAT-60 from Tel-Test, or Ultraspec from Biotech Labs.

4. Incubate 5 min at room temperature.
5. Add 0.2 ml chloroform per 1 ml Trizol Reagent and vortex the tubes vigorously for 15 sec.
6. Incubate at room temperature for 2 to 3 min.
7. Microcentrifuge 15 min at 14,000 rpm, 4°C.

8. Carefully remove the upper aqueous phase (which contains the RNA) with a pipet and transfer to an RNase-free microcentrifuge tube. Do not pipet the white protein interphase, which will result in contamination of the RNA.

Extract and precipitate RNA

9. *Optional*: Mix the supernatant with an equal amount of 5:1 acid phenol/chloroform, vortex, and microcentrifuge 15 min at 14,000 rpm, 4°C.

10. *Optional*: Transfer the upper aqueous phase to an RNase-free microcentrifuge tube. Repeat step 9 until no white interphase is visible.

    NOTE: *Steps 9 and 10 will yield higher quality RNA, free of protein contamination. This is no absolutely required for northern blot analysis but can be advantageous in RT-PCR reactions and other reactions requiring high-quality RNA.*

11. Mix the resulting upper phase with 0.5 ml isopropyl alcohol per 1 ml Trizol Reagent used. Incubate for 30 min at −20°C or overnight in order to precipitate the RNA.

12. Microcentrifuge 30 min at 14,000 rpm, 4°C.

13. Carefully remove the supernatant and keep the RNA pellet. Keep the tubes on ice after this step.

    The RNA pellet is transparent and easy to lose.

Wash RNA pellet

14. Wash pellet with 1 ml 75% ethanol.

    The pellet will turn white and will be easier to see.

15. Microcentrifuge 15 min at 14,000 rpm, 4°C and then carefully remove the supernatant.

16. Wash the pellet with 1 ml 100% ethanol.

17. Microcentrifuge 15 min at 12,000 × *g*, 4°C and then carefully remove the supernatant.

18. Dry the RNA pellet at room temperature.

    The RNA pellet becomes whiter as it dries.

    It is essential to remove all ethanol since trace contamination may affect all subsequent enzymatic reactions; however, do not overdry and absolutely never vacuum dry (SpeedVac), since this procedure will make the RNA pellet almost impossible to resolubilize.

19. Resuspend the pellet in 35 µl deionized, sterile, non-DEPC treated, RNase/DNase- and pyrogen-free water.

    NOTE: *At this stage, the pellet can also be resuspended in 10 to 25 µl of water (step 26), quantitated (step 27), and then used directly in northern blot analysis.*

    Do not use DEPC-treated H_2O since it may interfere with subsequent enzymatic reactions.

Remove DNA

20. *Optional*: To the 35 µl RNA sample, add in the following order (50 ml final volume):

    0.5 µl 40 U/µl RNasin
    2.5 µl 1 M Tris·Cl, pH 7.5
    10 µl 50 mM RNase-free $MgCl_2$
    2 µl 10 U/µl DNase (RNase-free).

    Incubate 30 min at 37°C.

21. *Optional*: Add 200 µl 5:1 acid phenol/chloroform and mix vigorously.

22. *Optional*: Centrifuge 15 min at 14,000 rpm, then transfer the upper phase to an RNase-free microcentrifuge tube. Repeat extraction (steps 21 and 22) until no white interphase can be seen.

23. *Optional*: Estimate the volume of the resulting RNA solution and add 2.5 vol 100% ethanol and 1/20 vol 3 M sodium acetate, pH 5.2.

24. *Optional*: Precipitate RNA at −20°C for 30 to 60 min or overnight.

25. *Optional*: Repeat steps 12 to 18.

26. *Optional*: Dissolve the RNA pellet in 10 to 25 µl sterile RNase/DNase- and pyrogen-free water.

    Do not use DEPC-treated water.

27. Determine the concentrations by measuring the absorbance at 260 and 280 nm. Dilute to the desired concentration (e.g., 1 µg/µl) and store in small aliquots of about 10 to 20 µg in each tube.

    The A_{260}/A_{280} ratio should be 1.8 to 2.1. Note that an A_{260} of 1 AU for single-stranded RNA = 40 µg/ml.

    If the RNA is to be used within 3 or 4 months, and the tubes are not frozen and thawed more than about 5 times, storing the RNA in sterile RNase/DNase-and pyrogen free water at −70°C is acceptable. For long-term storage, add 1/10 vol of 3 M sodium acetate, pH 5.2, and 2.5 vol of 100% ethanol to the RNA solution and freeze at −70°C. Before analysis, microcentrifuge and wash as described above (steps 25 to 26) and determine the RNA concentration in the final solution.

SUPPORT PROTOCOL 2

RADIOLABELING AN OLIGONUCLEOTIDE PROBE

The oligonucleotide probe for northern blot hybridization is labeled at the 3′ end using [α-^{32}P]dATP and terminal deoxynucleotidyl transferase (TdT).

Additional Materials *(also see Support Protocol 1)*

25 to 30 U/µl terminal deoxynucleotidyl transferase (TdT) and 5× TdT buffer (e.g., Life Technologies, Roche Molecular Biochemicals)
100 ng/µl antisense single-stranded oligonucleotide probe in H_2O
6000 Ci/mmol [α-^{32}P]dATP (20 mCi/ml; 3.33 nmol/ml)
Scintillant solution for aqueous samples (ReadySafe from Beckman or Aquasol from Packard)
1× STE (see recipe), sterile

37°C heating block
Sephadex columns: DNase/RNase-free STE Mirco Select-D G-25 Spin Column (5 Prime → 3 Prime) or NucTrap Push Column (Stratagene)
Scintillation counter and appropriate vials
β-shield column holder (Stratogene)
10- to 20-ml syringes

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CAUTION: When working with a radioactive isotope such as ^{32}P, strict radiation safety precautions should be taken to avoid exposure to harmful radioactivity and to prevent contamination of nonradioactive instruments and laboratory areas (also see *APPENDIX 1A*). Always wear powder-free gloves when working with RNA and radioactivity. Do not reuse gloves.

Prepare labeling-reaction mixture

1. Label the oligonucleotide by mixing the following reagents in an RNase-free sterile microcentrifuge tube in order (20 µl total volume):

   1.5 µl sterile RNase/DNase- and pyrogen-free H_2O (no DEPC)
   4 µl 5× TdT buffer
   2.5 µl 100 ng/µl antisense single-stranded oligonucleotide probe in H_2O
   10 µl [α-^{32}P]dATP (200 µCi)
   2 µl terminal deoxynucleotidyl transferase (TdT)

   Mix gently and incubate 1 to 1.5 hr in a heating block at 37°C.

   TdT labels the oligonucleotide by adding a radioactive poly(A) tail to the 3′ end.

Purify the probe by spin column

2a. At the end of the labeling incubation, elute the buffer from a DNase/RNase-free STE Micro-Select-D G-25 Spin Column by microcentrifuging 90 sec at 14,000 rpm. Transfer the spin column to a new RNase-free sterile microcentrifuge tube and set aside.

3a. Remove 1 µl (5% of total volume) from the labeling reaction mixture (step 1) and add to a scintillation vial containing 5 to 10 ml scintillant solution. Keep the vial for determination of percentage incorporation (step 6).

4a. Apply the rest of labeling reaction mixture from step 1 (now 19 µl) to the top of the column and let stand 2 to 3 min at room temperature. Microcentrifuge 60 sec at 14,000 rpm.

The resulting solution in the tube contains the purified oligonucleotide probe.

5a. Measure the volume of the eluate by drawing into a 20-µl pipetman. Remove an aliquot equivalent to 5% of the measured volume and add to a scintillation vial containing 5 to 10 ml scintillant solution to determine the counts after purification (see step 6).

CAUTION: *The column, which contains the unincorporated radioactive nucleotides, should be discarded strictly according to the institution's radiation safety guidelines.*

Purify the probe by Nuc Trap Push columns

2b. Put one column in the β-shield column holder and prime by adding 70 µl sterile 1× STE on top of the resin. Using a 10- to 20-ml syringe, push the buffer down the column slowly until the first drop appears at the tip end.

3b. Stop the labeling reaction (step 1) by adding 50 µl sterile 1× STE buffer to the microcentrifuge tube (total volume 70 µl). Take 2.8 µl (4% of total volume) from the final reaction mixture and add to a scintillation vial containing 5 to 10 ml scintillant solution. Keep the vial for determination of percent incorporation (step 6).

4b. Apply the rest of the final reaction mixture (now 67.3 µl) to the top of the primed Nuc Trap column and slowly push the sample down the column, using a 10- to 20-ml syringe, until most of the original volume has been eluted.

To avoid cross-contamination, use a different syringe for each sample.

5b. Measure the volume of the eluate by drawing into a 200-µl pipetman. Take out an aliquot equivalent to 4% of the measured volume and add to a scintillation vial containing 5 to 10 ml of scintillant solution to determine the counts after purification (see step 6).

CAUTION: *The column, which contains the unincorporated radioactive nucleotides, should be discarded strictly according to the radiation safety guidelines of the institution.*

In general, the total volume recovered is ~90 to 120 µl. The resulting solution contains the purified oligonucleotide probe.

6. Count the aliquots taken before and after column purification of the probe in a scintillation counter.

The first aliquot taken right before column purification gives the total counts (100%). The second aliquot taken after column purification gives the amount incorporated in the probe (final counts). Thus % incorporation = (final counts/total counts) × 100. The percent incorporation should be 20% to 60%. If the incorporation <10%, do not use the probe. The specific activity should be at least 100 cpm/µg [i.e., total final counts in cpm (after purification)/total amount of oligonucleotide probe labeled (assuming 100% recovery = 250 ng)].

SUPPORT PROTOCOL 3

STRIPPING AND REPROBING THE MEMBRANE

Bound radioactive oligonucleotides are stripped from a membrane before probing with another labeled oligonucleotide. This procedure saves considerable time by avoiding the RNA extraction and agarose gel separation steps for individual probes. Depending on the quality of the initial RNA and the type of probe used, membranes can be probed several times. By hybridizing with a probe detecting one of several housekeeping genes (e.g., cyclophilin, actin, ribosomal RNA subunit 18 S), which are known to be unaffected by stressful stimuli, the level of stress gene mRNA can be quantitatively normalized.

Additional Materials *(see Basic Protocol)*

Radioactive membrane to be stripped (see Basic Protocol)
0.01× SSPE (*UNIT 2.9*) containing 0.1% (w/v) SDS (*APPENDIX 2A*)
Formamide, deionized, minimum 99.5% (Sigma)
Secondary radioactive probe (see Support Protocol 2)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

CAUTION: To protect from radioactivity and RNase contamination as well as fingerprint smudges, always wear clean, powder-free gloves when working with RNA and radioisotopes. Do not reuse gloves.

1. After autoradiographic exposure (Basic Protocol, steps 34 and 35), incubate the radioactive membrane in 0.01× SSPE/0.1% SDS/50% formamide (final concentration), at 65°C for 0.5 to 1 min.
2. At the end of the incubation, check the activity of the membrane by holding a Geiger counter 2 to 3 cm above its surface.

After the stripping treatment, there should be no or a very minimal signal.

3. *Optional:* Expose the membrane to an X-ray film in an autoradiography cassette for 4 to 8 hr to determine the magnitude of the residual radioactive signal.

4. Hybridize with another radioactive probe or store membrane wrapped in plastic up to 2 to 3 weeks at 4°C.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ethidium bromide, 10 mg/ml

0.01 g ethidium bromide
1 ml DEPC-treated H_2O (*UNIT 2.9*)
Mix well and store several months at 4°C in the dark (i.e., wrap with foil)

CAUTION: *Ethidium bromide is a mutagen. Wear gloves and make only a small volume at a time as needed.*

MOPS, 10×, 1×

Combine 400 ml DEPC-treated water and 20.9 g MOPS. Adjust pH to 7.0 with 10 M NaOH (*APPENDIX 2A*). Add 8.3 ml 3 M sodium acetate, pH 6.0 (*APPENDIX 2A*) and 10 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*). Adjust volume to 500 ml with water. Filter sterilize. Store in the dark at room temperature. Discard if it turns yellow. Dilute to 1× with DEPC-treated water.

RNA loading dye

0.5 ml glycerol
2 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
2.5 mg bromophenol blue
2.5 mg xylene cyanol FF
DEPC-treated H_2O (*UNIT 2.9*) to 1 ml
Store several months at 4°C

STE, 1×

2 ml 1 M Tris·Cl, pH 7.5 (20 mM final; *APPENDIX 2A*)
0.4 g $Na_4EDTA{\cdot}4\ H_2O$ (10 mM final)
0.6 g NaCl (100 mM final)
H_2O to 100 ml
Store up to 1 month above 4°C

One-Dimensional SDS Gel Electrophoresis of Proteins

Electrophoresis is used to separate complex mixtures of proteins, (e.g., from cells, subcellular fractions, column fractions, or immunoprecipitates) to investigate subunit compositions, and to verify homogeneity of protein samples. It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis, proteins migrate in response to an electrical field through pores in the gel matrix; pore size decreases with higher acrylamide concentrations. The combination of gel pore size and protein charge, size, and shape determines the migration rate of the protein.

The standard Laemmli method (see Basic Protocol 1) is used for discontinuous gel electrophoresis under denaturing conditions, that is, in the presence of sodium dodecyl sulfate (SDS). The standard method for full-size gels (e.g., 14 × 14 cm) can be adapted for the minigel format (e.g., 7.3 × 8.3 cm; see Basic Protocol 2). Minigels provide rapid separation but give lower resolution.

Several alternate protocols are provided for specific applications. The first two alternate protocols cover electrophoresis of peptides and small proteins, separations that require modification of standard buffers: either a Tris-tricine buffer system (see Alternate Protocol 1), or modified Tris buffer in the absence of urea (see Alternate Protocol 2). Continuous SDS-PAGE is a simplified method in which the same buffer is used for both gel and electrode solutions and the stacking gel is omitted (see Alternate Protocol 3). Other protocols cover the preparation and electrophoresis of various types of gels: ultrathin gels (see Alternate Protocol 4), multiple single-concentration gels (see Support Protocol 1), gradient gels (see Alternate Protocol 5), multiple gradient gels (see Support Protocol 2), and multiple gradient minigels (see Support Protocol 3). Proteins separated on gels can be subsequently analyzed by immunoblotting, autoradiography, or phosphor imaging (*APPENDIX 3D*), or staining with protein dyes.

CAUTION: Before any protocols are used, it is extremely important to read the following section about electricity and electrophoresis.

ELECTRICITY AND ELECTROPHORESIS

Many researchers are poorly informed concerning the electrical parameters of running a gel. It is important to note that the voltages and currents used during electrophoresis are dangerous and potentially lethal. Thus, safety should be an overriding concern. A working knowledge of electricity is an asset in determining what conditions to use and in troubleshooting the electrophoretic separation, if necessary. For example, an unusually high or low voltage for a given current (milliampere) might indicate an improperly made buffer or an electrical leak in the chamber.

Safety Considerations

1. Never remove or insert high-voltage leads unless the power supply voltage is turned down to zero and the power supply is turned off. Always grasp high-voltage leads one at a time with one hand only. Never insert or remove high-voltage leads with both hands. This can shunt potentially lethal electricity through the chest and heart should electrical contact be made between a hand and a bare wire. On older or homemade instruments, the banana plugs may not be shielded and can still be connected to the

Contributed by Sean R. Gallagher
Current Protocols in Toxicology (2001) A.3F.1-A.3F.34

power supply at the same time they make contact with a hand. Carefully inspect all cables and connections and replace frayed or exposed wires immediately.

2. Always start with the power supply turned off. Have the power supply controls turned all the way down to zero. Then hook up the gel apparatus: generally, connect the red high-voltage lead to the red outlet and the black high-voltage lead to the black outlet. Turn the power supply on with the controls set at zero and the high-voltage leads connected. Then, turn up the voltage, current, or power to the desired level. Reverse the process when the power supply is turned off: i.e., to disconnect the gel, turn the power supply down to zero, wait for the meters to read zero, turn off the power supply, and then disconnect the gel apparatus one lead at a time.

   CAUTION: *If the gel is first disconnected and then the power supply turned off, a considerable amount of electrical charge is stored internally. The charge will stay in the power supply over a long time. This will discharge through the outlets even though the power supply is turned off and can deliver an electrical shock.*

Ohm's Law and Electrophoresis

Understanding how a gel apparatus is connected to the power supply requires a basic understanding of Ohm's law: voltage = current × resistance, or $V = IR$. A gel can be viewed as a resistor and the power supply as the voltage and current source. Most power supplies deliver constant current or constant voltage. Some will also deliver constant power: power = voltage × current, or $VI = I^2R$. The discussion below focuses on constant current because this is the most common mode in vertical SDS-PAGE.

Most modern commercial equipment is color-coded so that the red or positive terminal of the power supply can simply be connected to the red lead of the gel apparatus, which goes to the lower buffer chamber. The black lead is connected to the black or negative terminal and goes to the upper buffer chamber. This configuration is designed to work with vertical slab gel electrophoreses in which negatively charged proteins or nucleic acids move to the positive electrode in the lower buffer chamber (an anionic system).

When a single gel is attached to a power supply, the negative charges flow from the negative cathode (black) terminal into the upper buffer chamber, through the gel, and into the lower buffer chamber. The lower buffer chamber is connected to the positive anode (red) terminal to complete the circuit. Thus, negatively charged molecules, such as SDS-coated proteins and nucleic acids, move from the negative cathode attached to the upper buffer chamber toward the positive anode attached to the lower chamber. SDS-PAGE is an anionic system because of the negatively charged SDS.

Occasionally, proteins are separated in cationic systems. In these gels, the proteins are positively charged because of the very low pH of the gel buffers (e.g., acetic acid/urea gels for histone separations) or the presence of a cationic detergent (e.g., cetyltrimethyl-ammonium bromide, CTAB). Proteins move toward the negative electrode (cathode) in cationic gel systems, and the polarity is reversed compared to SDS-PAGE: the red lead from the lower buffer chamber is attached to the black outlet of the power supply, and the black lead from the upper buffer chamber is attached to the red outlet of the power supply.

Most SDS-PAGE separations are performed under constant current (consult instructions from the manufacturer to set the power supply for constant current operation). The resistance of the gel will increase during SDS-PAGE in the standard Laemmli system. If the current is constant, then the voltage will increase during the run as the resistance goes up.

Power supplies usually have more than one pair of outlets. The pairs are connected in parallel with one another internally. If more than one gel is connected directly to the outlets

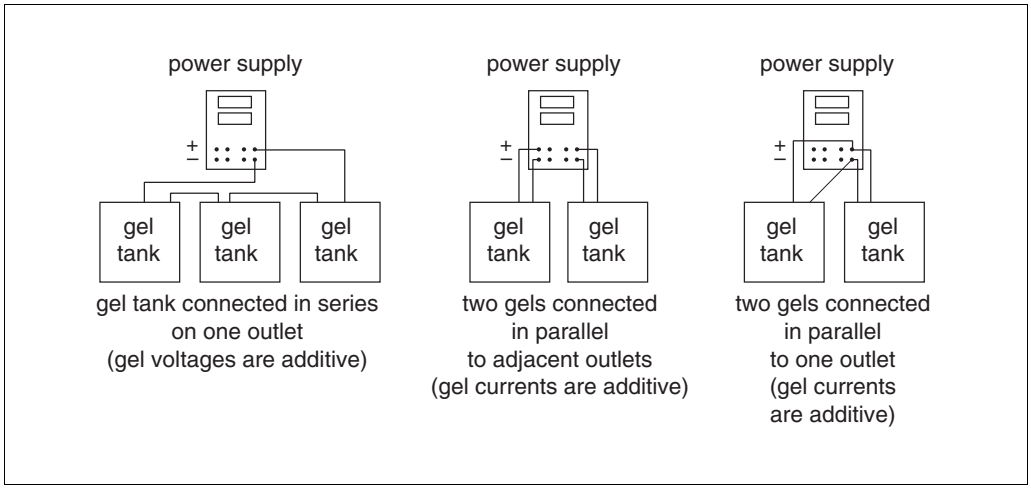

Figure A.3F.1 Series and parallel connections of gel tanks to power supply.

of a power supply, then these gels are connected in parallel. In a parallel circuit, the voltage is the same across each gel. In other words, if the power supply reads 100 V, then each gel has 100 V across its electrodes. The total current, however, is the sum of the individual currents going through each gel. Therefore, under constant current it is necessary to increase the current for each additional gel that is connected to the power supply. Two identical gels require double the current to achieve the same starting voltages and electrophoresis separation times.

Multiple gel apparatuses can also be connected to one pair of outlets on a power supply. This is useful with older power supplies that have a limited number of outlets. When connecting several gel units to one outlet, make certain the connections between the units are shielded and protected from moisture. The gels can be connected in parallel or in series (Fig. A.3F.1). In the case of two or more gels running off the same outlet in series, the current is the same for every gel. If 10 mA is displayed by the power supply meter, for example, each gel in series will experience 10 mA. The voltage, however, is additive for each gel. If one gel at a constant 10 mA produces 100 V, then two identical gels in series will produce 200 V (100 V each) and so on. Thus, the voltage can limit the number of units connected in series on low-voltage power supplies.

Gel thickness affects the above relationships. A 1.5-mm gel can be thought of as consisting of two 0.75-mm-thick gels run in parallel. Because currents are additive in parallel circuits, a 0.75-mm gel will require half the current of the 1.5-mm gel to achieve the same starting voltage and separation time. If a gel thickness is doubled, then the current must also be doubled. There are limits to the amount of current that can be applied. Thicker gels require more current, generating more heat that must be dissipated. Unless temperature control is available in the gel unit, a thick gel should be run more slowly than a thin gel.

NOTE: Milli-Q-purified water or equivalent should be used throughout the protocols.

BASIC PROTOCOL 1

DENATURING (SDS) DISCONTINUOUS GEL ELECTROPHORESIS: LAEMMLI GEL METHOD

One-dimensional gel electrophoresis under denaturing conditions (i.e., in the presence of 0.1% SDS) separates proteins based on molecular size as they move through a polyacrylamide gel matrix toward the anode. The polyacrylamide gel is cast as a separating gel (sometimes called resolving or running gel) topped by a stacking gel and secured in an electrophoresis apparatus. After sample proteins are solubilized by boiling in the presence of SDS, an aliquot of the protein solution is applied to a gel lane, and the individual proteins are separated electrophoretically. 2-Mercaptoethanol (2-ME) or dithiothreitol (DTT) is added during solubilization to reduce disulfide bonds.

This protocol is designed for a vertical slab gel with a maximum size of 0.75 mm × 14 cm × 14 cm. For thicker gels, or minigels (see Basic Protocol 2 and Support Protocol 3), the volumes of stacking and separating gels and the operating current must be adjusted. Additional protocols describe the preparation of ultrathin gels (see Alternate Protocol 4) and gradient gels (see Alternate Protocol 5), as well as the use of gel casters to make multiple gels, both single-concentration gels (see Support Protocol 1) and gradient gels (see Support Protocol 2).

Materials

Separating and stacking gel solutions (Table A.3F.1)
H_2O-saturated isobutyl alcohol
1× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table A.3F.1)
Protein sample to be analyzed
2× and 1× SDS sample buffer (see recipe for 2×)
Protein molecular-weight-standards mixture (Table A.3F.2)
6× SDS sample buffer (see recipe; optional)
1× SDS electrophoresis buffer (see recipe for 5×)

Electrophoresis apparatus: Protean II 16-cm cell (Bio-Rad) or SE 600/400 16-cm unit (Amersham Pharmacia Biotech) with clamps, glass plates, casting stand, and buffer chambers
0.75-mm spacers
0.45-µm filters (used in stock solution preparation)
25-ml Erlenmeyer side-arm flask
Vacuum pump with cold trap
0.75-mm Teflon comb with 1, 3, 5, 10, 15, or 20 teeth
25- or 100-µl syringe with flat-tipped needle
Constant-current power supply (see introduction)

Pour the separating gel

1. Assemble the glass-plate sandwich of the electrophoresis apparatus according to manufacturer's instructions using two clean glass plates and two 0.75-mm spacers.

   If needed, clean the glass plates in liquid Alconox or RBS-35 (Pierce). These aqueous-based solutions are compatible with silver and Coomassie blue staining procedures.

2. Lock the sandwich to the casting stand.

3. Prepare the separating gel solution as directed in Table A.3F.1, degassing using a rubber-stoppered 25-ml Erlenmeyer side-arm flask connected with vacuum tubing to a vacuum pump with a cold trap. After adding the specified amount of 10% ammonium persulfate and TEMED to the degassed solution, stir gently to mix.

   Table A.3F.1 was prepared as a convenient summary to aid in the preparation of separating and stacking gels. The stacking gel is the same regardless of the separating gel used.

The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. Generally, use 5% gels for SDS-denatured proteins of 60 to 200 kDa, 10% gels for SDS-denatured proteins of 16 to 70 kDa, and 15% gels for SDS-denatured proteins of 12 to 45 kDa (Table A.3F.1).

4. Using a Pasteur pipet, apply the separating gel solution to the sandwich along an edge of one of the spacers until the height of the solution between the glass plates is ~11 cm.

   Use the solution immediately; otherwise it will polymerize in the flask.

   Sample volumes <10 µl do not require a stacking gel. In this case, cast the resolving gel as you normally would, but extend the resolving gel into the comb to form the well. The proteins are then separated under the same conditions as used when a stacking gel is present. Although this protocol works well with single-concentration gels, a gradient gel is recommended for maximum resolution (see Alternate Protocol 5).

5. Using another Pasteur pipet, slowly cover the top of the gel with a layer (~1 cm thick) of H_2O-saturated isobutyl alcohol, by gently layering the isobutyl alcohol against the edge of one and then the other of the spacers.

   Be careful not to disturb the gel surface. The overlay provides a barrier to oxygen, which inhibits polymerization, and allows a flat interface to form during gel formation.

   The H_2O-saturated isobutyl alcohol is prepared by shaking isobutyl alcohol and H_2O in a separatory funnel. The aqueous (lower) phase is removed. This procedure is repeated several times. The final upper phase is H_2O-saturated isobutyl alcohol.

6. Allow the gel to polymerize 30 to 60 min at room temperature.

   A sharp optical discontinuity at the overlay/gel interface will be visible on polymerization. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED (N, N, N′, N′-tetramethylethylenediamine), or both. Ammonium persulfate solution should be made fresh before use. Ammonium persulfate should "crackle" when added to the water. If not, fresh ammonium persulfate should be purchased. Purchase TEMED in small bottles so, if necessary, a new previously unopened source can be tried.

Pour the stacking gel

7. Pour off the layer of H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

   Residual isobutyl alcohol can reduce resolution of the protein bands; therefore, it must be completely removed. The isobutyl alcohol overlay should not be left on the gel longer than 2 hr.

8. Prepare the stacking gel solution as directed in Table A.3F.1.

   Use the solution immediately to keep it from polymerizing in the flask.

9. Using a Pasteur pipet, slowly allow the stacking gel solution to trickle into the center of the sandwich along an edge of one of the spacers until the height of the solution in the sandwich is ~1 cm from the top of the plates.

   Be careful not to introduce air bubbles into the stacking gel.

10. Insert a 0.75-mm Teflon comb into the layer of stacking gel solution. If necessary, add additional stacking gel to fill the spaces in the comb completely.

    Again, be careful not to trap air bubbles in the tooth edges of the comb; they will cause small circular depressions in the well after polymerization that will lead to distortion in the protein bands during separation.

11. Allow the stacking gel solution to polymerize 30 to 45 min at room temperature.

    A sharp optical discontinuity will be visible around wells on polymerization.

Table A.3F.1 Recipes for Polyacrylamide Separating and Stacking Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]									
	5	6	7	7.5	8	9	10	12	13	15
30% acrylamide/ 0.8% bisacrylamide	2.50	3.00	3.50	3.75	4.00	4.50	5.00	6.00	6.50	7.50
4× Tris·Cl/SDS, pH 8.8	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.50	7.25	6.75	6.25	5.25	4.75	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for a gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See annotation to step 3, Basic Protocol 1.
[d]Best to prepare fresh.

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution, 4× Tris·Cl/SDS, pH 8.8 (see reagents, below), and H_2O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

STACKING GEL (*3.9% acrylamide*)

In a 25-ml side-arm flask, mix 0.65 ml of 30% acrylamide/0.8% bisacrylamide, 1.25 ml of 4× Tris·Cl/SDS, pH 6.8 (see reagents, below), and 3.05 ml H_2O. Degas under vacuum 10 to 15 min. Add 25 µl of 10% ammonium persulfate and 5 µl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

REAGENTS USED IN GELS

30% acrylamide/0.8% bisacrylamide

Mix 30.0 g acrylamide and 0.8 g *N,N′*-methylenebisacrylamide with H_2O in a total volume of 100 ml. Filter the solution through a 0.45-µm filter and store at 4°C in the dark. The 2× crystallized grades of acrylamide and bisacrylamide are recommended. Discard after 30 days, as acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: *Acrylamide monomer is neurotoxic. A mask should be worn when weighing acrylamide powder. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth.*

4× Tris·Cl/SDS, pH 6.8 *(0.5 M Tris·Cl containing 0.4% SDS)*

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter, add 0.4 g SDS, and store at 4°C up to 1 month.

4× Tris·Cl/SDS, pH 8.8 *(1.5 M Tris·Cl containing 0.4% SDS)*

Dissolve 91 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 2 g SDS, and store at 4°C up to 1 month.

Prepare the sample and load the gel

12. Dilute a portion of the protein sample to be analyzed 1:1 (v/v) with 2× SDS sample buffer and heat 3 to 5 min at 100°C in a sealed screw-cap microcentrifuge tube. If the sample is a precipitated protein pellet, dissolve the protein in 50 to 100 µl of 1× SDS sample buffer and boil 3 to 5 min at 100°C. Dissolve protein-molecular-weight standards mixture in 1× SDS sample buffer according to supplier's instructions; use these standards as a control (Table A.3F.2).

For dilute protein solutions, consider adding 5:1 protein solution/6× SDS sample buffer to increase the amount of protein loaded. Proteins can also be concentrated by precipitation in acetone, ethanol, or trichloroacetic acid (TCA), but losses will occur.

For a 0.8-cm-wide well, 25 to 50 µg total protein in <20 µl is recommended for a complex mixture when staining with Coomassie blue, and 1 to 10 µg total protein is needed for samples containing one or a few proteins. If silver staining is used, 10- to 100-fold less protein can be applied (0.01 to 5 µg in <20 µl depending on sample complexity).

To achieve the highest resolution possible, the following precautions are recommended. Prior to adding the sample buffer, keep samples at 0°C. Add the SDS sample buffer (room temperature) directly to the 0°C sample (still on ice) in a screw-top microcentrifuge tube. Cap the tube to prevent evaporation, vortex, and transfer directly to a 100°C water bath for 3 to 5 min. Let immunoprecipitates dissolve for 1 hr at 56°C in 1× SDS sample buffer prior to boiling. DO NOT leave the sample in SDS sample buffer at room temperature without first heating to 100°C to inactivate proteases (see Critical Parameters and Troubleshooting). Endogenous proteases are very active in SDS sample buffer and will cause severe degradation of the sample proteins after even a few minutes at room temperature. To test for possible proteases, mix the sample with SDS sample buffer without heating and leave at room temperature for 1 to 3 hr. A loss of high-molecular-weight bands

Table A.3F.2 Molecular Weights of Protein Standards for Polyacrylamide Gel Electrophoresis[a]

Protein	Molecular weight
Cytochrome *c*	11,700
α-Lactalbumin	14,200
Lysozyme (hen egg white)	14,300
Myoglobin (sperm whale)	16,800
β-Lactoglobulin	18,400
Trypsin inhibitor (soybean)	20,100
Trypsinogen, PMSF treated	24,000
Carbonic anhydrase (bovine erythrocytes)	29,000
Glyceraldehyde-3-phosphate dehydrogenase (rabbit muscle)	36,000
Lactate dehydrogenase (porcine heart)	36,000
Aldolase	40,000
Ovalbumin	45,000
Catalase	57,000
Bovine serum albumin	66,000
Phosphorylase *b* (rabbit muscle)	97,400
β-Galactosidase	116,000
RNA polymerase, *E. coli*	160,000
Myosin, heavy chain (rabbit muscle)	205,000

[a]Protein standards are commercially available in kits (e.g., Amersham Pharmacia Biotech, Life Technologies, Bio-Rad, or Sigma).

and a general smearing of the banding pattern indicate a protease problem. Once heated, the samples can sit at room temperature for the time it takes to load samples.

13. Carefully remove the Teflon comb without tearing the edges of the polyacrylamide wells. After the comb is removed, rinse wells with 1× SDS electrophoresis buffer.

    The rinse removes unpolymerized monomer; otherwise, the monomer will continue to polymerize after the comb is removed, creating uneven wells that will interfere with sample loading and subsequent separation.

14. Using a Pasteur pipet, fill the wells with 1× SDS electrophoresis buffer.

    If well walls are not upright, they can be manipulated with a flat-tipped needle attached to a syringe.

15. Attach gel sandwich to upper buffer chamber following manufacturer's instructions.

16. Fill lower buffer chamber with the recommended amount of 1× SDS electrophoresis buffer.

17. Place sandwich attached to upper buffer chamber into lower buffer chamber.

18. Partially fill the upper buffer chamber with 1× SDS electrophoresis buffer so that the sample wells of the stacking gel are filled with buffer.

    Monitor the upper buffer chamber for leaks and if necessary, reassemble the unit. A slow leak in the upper buffer chamber may cause arcing around the upper electrode and damage the upper buffer chamber.

19. Using a 25- or 100-µl syringe with a flat-tipped needle, load the protein sample(s) into one or more wells by carefully applying the sample as a thin layer at the bottom of the wells. Load control wells with molecular weight standards. Add an equal volume of 1× SDS sample buffer to any empty wells to prevent spreading of adjoining lanes.

    Preparing the samples at approximately the same concentration and loading an equal volume to each well will ensure that all lanes are the same width and that the proteins run evenly. If unequal volumes of sample buffer are added to wells, the lane with the larger volume will spread during electrophoresis and constrict the adjacent lanes, causing distortions.

    The samples will layer on the bottom of the wells because the glycerol added to the sample buffer gives the solution a greater density than the electrophoresis buffer. The bromphenol blue in the sample buffer makes sample application easy to follow visually.

20. Fill the remainder of the upper buffer chamber with additional 1× SDS electrophoresis buffer so that the upper platinum electrode is completely covered. Do this slowly so that samples are not swept into adjacent wells.

Run the gel

21. Connect the power supply to the cell and run at 10 mA of constant current for a slab gel 0.75 mm thick, until the bromphenol blue tracking dye enters the separating gel. Then increase the current to 15 mA.

    For a standard 16-cm gel sandwich, 4 mA per 0.75-mm-thick gel will run ~15 hr (i.e., overnight); 15 mA per 0.75-mm gel will take 4 to 5 hr. To run two gels or a 1.5-mm-thick gel, simply double the current. When running a 1.5-mm gel at 30 mA, the temperature must be controlled (10° to 20°C) with a circulating constant-temperature water bath to prevent "smiling" (curvature in the migratory band). Temperatures <5°C should not be used because SDS in the running buffer will precipitate. If the level of buffer in the upper chamber decreases, a leak has occurred.

22. After the bromphenol blue tracking dye has reached the bottom of the separating gel, disconnect the power supply.

    Refer to Safety Considerations under Electricity and Electrophoresis.

Disassemble the gel

23. Discard electrode buffer and remove the upper buffer chamber with the attached gel sandwich.

24. Orient the gel so that the order of the sample wells is known, remove the sandwich from the upper buffer chamber, and lay the sandwich on a sheet of absorbent paper or paper towels.

25. Carefully slide one of the spacers halfway from the edge of the sandwich along its entire length. Use the exposed spacer as a lever to pry open the glass plate, exposing the gel.

26. Carefully remove the gel from the lower plate. Cut a small triangle off one corner of the gel so the lane orientation is not lost during staining and drying. Proceed with protein detection.

    The gel can be stained with Coomassie blue or silver (APPENDIX 3), or proteins can be electroeluted, electroblotted onto a polyvinylidene difluoride (PVDF) membrane for subsequent staining or sequence analysis, or transferred to a membrane for immunoblotting. If the proteins are radiolabeled, they can be detected by autoradiography (APPENDIX 3D).

ELECTROPHORESIS IN TRIS-TRICINE BUFFER SYSTEMS

ALTERNATE PROTOCOL 1

Separation of peptides and proteins under 10 to 15 kDa is not possible in the traditional Laemmli discontinuous gel system (see Basic Protocol 1). This is due to the comigration of SDS and smaller proteins, obscuring the resolution. Two approaches to obtain the separation of small proteins and peptides in the range of 5 to 20 kDa are presented: the following Tris-tricine method and a system using increased buffer concentrations (see Alternate Protocol 2). The Tris-tricine system uses a modified buffer to separate the SDS and peptides, thus improving resolution. Several precast gels are available for use with the tricine formulations (Table A.3F.3).

Table A.3F.3 Vertical Format Precast Gel Compatibility

Gel type and compatibility	Gel supplier			
	Bio-Rad	ISS/Daiichi	Jule	Novex
SDS-PAGE gel type offered				
Peptide (tricine)	×	×	×	×
Single concentration	×	×	×	×

Novex		×		×
ISS/Daiichi		×	×	

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gel solutions (Table A.3F.4)
2× tricine sample buffer (see recipe)
Peptide molecular-weight-standards mixture (Table A.3F.5)
Cathode buffer (see recipe)
Anode buffer (see recipe)
Coomassie blue G-250 staining solution (see recipe)
10% (v/v) acetic acid

1. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 1 to 11), using Table A.3F.4 in place of Table A.3F.1.
2. Prepare the sample (see Basic Protocol 1, step 12), but make the following changes for tricine gels. Substitute 2× tricine sample buffer for the 2× SDS sample buffer. Dilute an aliquot of the protein or peptide sample to be analyzed 1:1 (v/v) with 2× tricine sample buffer. Treat the sample at 40°C for 30 to 60 min prior to loading.

   If proteolytic activity is a problem, heating samples to 100°C for 3 to 5 min before loading the wells may be required (see Basic Protocol 1, annotation to step 12). Use the peptide molecular-weight-standards mixture for peptide separations (Table A.3F.5).

3. Load the gel and set up the electrophoresis apparatus (see Basic Protocol 1, steps 13 to 20) with the following alterations. Remove comb and, using the tricine-containing

Table A.3F.4 Recipes for Tricine Peptide Separating and Stacking Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	9.80 ml	1.62 ml
Tris·Cl/SDS, pH 8.45	10.00 ml	3.10 ml
H_2O	7.03 ml	7.78 ml
Glycerol	4.00 g (3.17 ml)	—
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

[a]The recipes produce 30 ml of separating gel and 12.5 ml of stacking gel, which are adequate for two gels of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the Tris-tricine buffer system of Schagger and von Jagow (1987).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Best to prepare fresh.

Prepare separating and stacking gel solutions separately.

In a 50-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (Table A.3F.1), Tris·Cl/SDS, pH 8.45 (see reagents, below), and H_2O. Add glycerol to separating gel only. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix, use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

Tris·Cl/SDS, pH 8.45 (3.0 M Tris·Cl containing 0.3% SDS)

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.45 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 1.5 g SDS, and store at 4°C up to 1 month.

Table A.3F.5 Molecular Weights of Peptide Standards for Polyacrylamide Gel Electrophoresis[a]

Peptide	Molecular weight (Da)
Myoglobin (polypeptide backbone)	16,950
Myoglobin 1-131	14,440
Myoglobin 56-153	10,600
Myoglobin 56-131	8,160
Myoglobin 1-55	6,210
Glucagon	3,480
Myoglobin 132-153	2,510

[a]Peptide standards are commercially available from Sigma.

cathode buffer, or water, rinse once and fill wells. Fill the lower buffer chamber with anode buffer, assemble the unit, and attach the upper buffer chamber. Fill the upper buffer chamber with cathode buffer and load the samples.

4. Connect the power supply to the cell and run 1 hr at 30 V (constant voltage) followed by 4 to 5 hr at 150 V (constant voltage). Use heat exchanger to keep the electrophoresis chamber at room temperature.

5. After the tracking dye has reached the bottom of the separating gel, disconnect the power supply.

   Refer to Safety Considerations in the introduction.

   Coomassie blue G-250 is used as a tracking dye instead of bromphenol blue because it moves ahead of the smallest peptides.

6. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Stain proteins in the gel for 1 to 2 hr in Coomassie blue G-250 staining solution. Follow by destaining with 10% acetic acid, changing the solution every 30 min until background is clear (3 to 5 changes). For higher sensitivity, use silver staining as a recommended alternative.

   Prolonged staining and destaining will result in the loss of resolution of the smaller proteins (<10 kDa). Proteins diffuse within the gel and out of the gel, resulting in a loss of staining intensity and resolution.

NONUREA PEPTIDE SEPARATIONS WITH TRIS BUFFERS

ALTERNATE PROTOCOL 2

A simple modification of the traditional Laemmli buffer system presented in Basic Protocol 1, in which the increased concentration of buffers provides better separation between the stacked peptides and the SDS micelles, permits reasonable separation of peptides as small as 5 kDa.

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gel solutions (Table A.3F.6)
2× SDS electrophoresis buffer (see recipe)
2× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table A.3F.1)

1. Prepare and pour the separating gel (see Basic Protocol 1, steps 1 to 6) using Table A.3F.6 in place of Table A.3F.1.

2. Prepare and pour the stacking gel (see Basic Protocol 1, steps 7 to 11), using 2× Tris·Cl/SDS, pH 8.8, rather than 1× Tris·Cl/SDS buffer, for rinsing the gel after removing the isobutyl alcohol overlay.

3. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20) and substitute 2× SDS electrophoresis buffer for the 1× SDS electrophoresis buffer.

   Table A.3F.5 lists the standards for small protein separations.

4. Run the gel (see Basic Protocol 1, steps 21 and 22).

   Note that the separations will take ~25% longer than those using Basic Protocol 1. The increased buffer concentrations lead to faster transit through the stacking gel but lower mobility in the resolving gel.

5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

   Proteins in the gel may now be stained.

Table A.3F.6 Recipes for Modified Laemmli Peptide Separating and Stacking Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	10.00 ml	0.65 ml
8× Tris·Cl, pH 8.8	3.75 ml	—
4× Tris·Cl, pH 6.8	—	1.25 ml
10% (w/v) SDS	0.15 ml	50 µl
H_2O	1.00 ml	3.00 ml
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the modified Laemmli peptide separation system of Okajima et al. (1993).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Best to prepare fresh.

Prepare separating and stacking gel solutions separately

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table A.3F.1), 8× Tris·Cl, pH 8.8 (separating gel) or 4× Tris·Cl, pH 6.8 (stacking gel), 10% SDS (see reagents, below), and H_2O. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

4× Tris·Cl, pH 6.8 *(0.5 M Tris·Cl)*

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter and store up to 1 month at 4°C.

8× Tris·Cl, pH 8.8 *(3.0 M Tris·Cl)*

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter and store up to 1 month at 4°C.

10% (w/v) SDS

Mix 1 g SDS in 10 ml of H_2O. Use immediately.

CONTINUOUS SDS-PAGE

With continuous SDS-PAGE, the same buffer is used for both the gel and electrode solutions. Although continuous gels lack the resolution of the discontinuous systems, they are extremely versatile, less prone to mobility artifacts, and much easier to prepare. The stacking gel is omitted.

Additional Materials *(also see Basic Protocol 1)*

Separating gel solution (Table A.3F.7)
2× and 1× phosphate/SDS sample buffer (see recipe)
1× phosphate/SDS electrophoresis buffer (see recipe)

1. Prepare and pour a single separating gel (see Basic Protocol 1, steps 1 to 4), except use solutions in Table A.3F.7 in place of those in Table A.3F.1 and fill the gel sandwich to the top. Omit the stacking gel. Insert the comb (see Basic Protocol 1, step 10) and allow the gel to polymerize 30 to 60 min at room temperature.
2. Mix the protein sample 1:1 with 2× phosphate/SDS sample buffer and heat to 100°C for 2 min.

   For large sample volumes or samples suspended in high ionic strength buffers (>50 mM), dialyze against 1× sample buffer prior to electrophoresis. Note that the precautions about proteases (see Basic Protocol 1, step 12) apply here.

Table A.3F.7 Recipes for Separating Gels for Continuous SDS-PAGE[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide/ 0.8% bisacrylamide	2.5	3.00	3.50	4.00	4.50	5.00	5.50	6.00	6.50	7.00	7.50
4× phosphate/SDS, pH 7.2	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

[a]The recipes produce 15 ml of separating gel, which is adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the original continuous phosphate buffer system of Weber et al. (1972). The stacking gel is omitted.
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.
[d]Best to prepare fresh.

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table A.3F.1), 4× phosphate/SDS, pH 7.2, and H_2O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

ADDITIONAL REAGENTS USED IN GELS

4× phosphate/SDS, pH 7.2 *(0.4 M sodium phosphate/0.4% SDS)*

Mix 46.8 g $NaH_2PO_4 \cdot H_2O$, 231.6 g $Na_2HPO_4 \cdot 7\ H_2O$, and 12 g SDS in 3 liters H_2O.

Store at 4°C for up to 3 months.

3. Assemble the electrophoresis apparatus and load the sample (see Basic Protocol 1, steps 13 to 20), using the phosphate/SDS electrophoresis buffer and loading empty wells with 1× phosphate/SDS sample buffer.

4. Connect the power supply and start the run with 15 mA per 0.75-mm-thick gel until the tracking dye has entered the gel. Continue electrophoresis at 30 mA for 3 hr (5% gel), 5 hr (10% gel), 8 hr (15% gel), or until the dye reaches the bottom of the gel.

   Use temperature control if available to maintain the gel at 15° to 20°C. SDS will precipitate below 15°C in this system.

5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

   Refer to Safety Considerations in introduction. Proteins in the gel may now be stained.

ALTERNATE PROTOCOL 4

CASTING AND RUNNING ULTRATHIN GELS

Ultrathin gels provide superb resolution but are difficult to handle. In this application, gels are cast on Gel Bond, a Mylar support material. Silver staining is recommended for the best resolution. Combs and spacers for gels <0.5 mm thick are not readily available for most protein electrophoresis units. However, by adapting combs and spacers used for DNA sequencing, casting gels from 0.2 to 0.5 mm thick is straightforward.

Additional Materials *(also see Basic Protocol 1)*

95% (v/v) ethanol
Gel Bond (FMC BioProducts) cut to a size slightly smaller than the gel plate dimensions
Glue stick
Ink roller (available from art supply stores)
Combs and spacers (0.19 to 0.5 mm; sequencing gel spacers and combs can be cut to fit)

1. Wash gel plates with water-based laboratory detergent followed by successive rinses with hot tap water, deionized water, and finally 95% ethanol. Allow to air dry.

   Gel plates must be extremely clean for casting thin gels.

   Gloves are needed throughout these procedures to prevent contamination by proteins on the surface of skin.

2. Apply a streak of adhesive from a glue stick to the bottom edge of the glass plate. Quickly position the Gel Bond with the hydrophobic side down (a drop of water will bead up on the hydrophobic surface). Apply pressure with Kimwipe tissue to attach the Gel Bond firmly to the plate. Finally, pull the top portion of the Gel Bond back, place a few drops of water underneath, and roll flat with an ink roller.

   Make sure the Gel Bond does not extend beyond the edges of the upper and lower sealing surface of the plate. This will cause it to buckle on sealing. Reposition the Gel Bond if needed to prevent it from extending beyond the glass plate. Material may also be trimmed to fit flush with the plate edge.

3. Assemble the gel cassette according to the manufacturer's instructions (also see Basic Protocol 1, steps 1 and 2). Just prior to assembly, blow air over the surface of both the Gel Bond and the opposing glass surface to remove any particulate material (e.g., dust).

   Sequencing gel spacers can be easily adapted. First, cut the spacers slightly longer than the length of the gel plate. Position a spacer along each edge of the glass plate and assemble the gel sandwich, clamping in place. With a razor blade, trim the excess spacer at top and bottom to get a reusable spacer exactly the size of the plate.

4. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 3 to 9). In place of the Teflon comb, insert a square well sequencing comb cut to fit within the gel sandwich. Allow the stacking gel to polymerize 30 to 45 min at room temperature.

   Less solution is needed for ultrathin gels. For example, a 0.5-mm-thick gel requires 33% less gel solution than a 0.75-mm gel.

5. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20).

   When preparing protein samples for ultrathin gels, 3 to 4 µl at 5 µg protein/µl is required for Coomassie blue R-250 staining, whereas 10-fold less is needed for silver staining.

6. Run the gel (see Basic Protocol 1, steps 21 and 22), except conduct the electrophoresis at 7 mA/gel (0.25-mm-thick gels) or 14 mA/gel (0.5-mm-thick gels) for 4 to 5 hr.

7. When the separation is complete, disassemble the unit and remove the gel (see Basic Protocol 1, steps 23 to 26) with the Gel Bond still attached. With a gloved hand, wash away the adhesive material from the back of the Gel Bond under a stream of water before proceeding to protein detection.

   Either Coomassie blue or silver staining may be used, but silver staining produces particularly fine resolution with thin Gel Bond–backed gels. Compared to staining thicker (>0.75 mm) gels, thin (<0.75 mm) gels stain and destain more quickly. Although the optimum staining times must be empirically determined, all steps in Coomassie blue and silver staining procedures are generally reduced by half.

CASTING MULTIPLE SINGLE-CONCENTRATION GELS

SUPPORT PROTOCOL 1

Casting multiple gels at one time has several advantages. All the gels are identical, so sample separation is not affected by gel-to-gel variation. Furthermore, casting ten gels is only slightly more difficult than casting two gels. Once cast, gels can be stored for several days in a refrigerator.

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gels for single-concentration gels (Table A.3F.8)
H_2O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Amersham Pharmacia Biotech)
100-ml disposable syringe and flat-tipped needle
Extra plates and spacers
14 × 14–cm acrylic blocks or polycarbonate sheets
250- and 500-ml side-arm flasks (used in gel preparation)
Long razor blade *or* plastic wedge (Wonder Wedge, Amersham Pharmacia Biotech)
Resealable plastic bags

Pour the separating gel

1. Assemble the multiple gel caster according to the manufacturer's instructions.

   With the Amersham Pharmacia Biotech unit make sure to insert the large triangular space filler plug in the base of the caster. The plug is removed when casting gradient gels (see Support Protocol 2).

2. Assemble glass sandwiches and stack them in the casting chamber. Stack up to ten 1.5-mm gels and fill in extra space with acrylic blocks or polycarbonate sheets to hold the sandwiches tightly in place. Make sure the spacers are straight along the top, right, and left edges of the glass plates and that all edges of the stack are flush.

   The presence of loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis. Polycarbonate inhibits gel polymerization.

Table A.3F.8 Recipes for Multiple Single-Concentration Polyacrylamide Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide/0.8% bisacrylamide	52	62	72	83	93	103	114	124	134	145	155
4× Tris·Cl/SDS, pH 8.8	78	78	78	78	78	78	78	78	78	78	78
H_2O	181	171	160	150	140	129	119	109	98	88	78
10% (w/v) ammonium persulfate[d]	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
TEMED	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21

[a]The recipes produce about 300 ml of separating gel and 100 ml of stacking gel, which are adequate for ten gels of dimensions 1.5 mm × 14 cm × 14 cm. Volumes were measured using 1.5-mm spacers. For thinner spacers or fewer gels, calculate volumes using the equation in the annotation to step 4. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.

[d]Best to prepare fresh.

Preparation of separating gel

In a 500-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table A.3F.1), 4× Tris·Cl/SDS, pH 8.8 (Table A.3F.1), and H_2O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately.

STACKING GEL

In a 250-ml side-arm flask, mix 13.0 ml 30% acrylamide/0.8% bisacrylamide solution, 25 ml 4× Tris·Cl/SDS, pH 6.8 (Table A.3F.1), and 61 ml H_2O. Degas under vacuum ~5 min. Add 0.25 ml 10% ammonium persulfate and 50 µl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

Therefore, if polycarbonate sheets are placed in the caster before and after the set of glass sandwiches, the entire set will slide out as one block after polymerization. Placing polycarbonate sheets between each gel sandwich makes them easier to separate from one another after polymerization.

3. Place the front sealing plate on the casting chamber, making sure the stack fits snugly. Secure the plate with four spring clamps and tighten the bottom thumb screws.

4. Prepare the separating (resolving) gel solution (Table A.3F.8).

   A 12-cm separating gel with a 4-cm stacking gel is recommended.

   If fewer than ten gels are prepared (Table A.3F.8), use the following formula to estimate the amount of separating gel volume needed:

   Volume = gel number × height (cm) × width (cm) × thickness (cm) + 4 × gel number + 10 ml.

5. Using a 100-ml disposable syringe with flat-tipped needle, inject the resolving gel solution down the side of one spacer into the multiple caster. A channel in the silicone plug distributes the solution throughout the whole caster. Avoid introducing bubbles by giving the caster a quick tap on the benchtop once the caster is filled.

6. Overlay the center of each gel with 100 µl H_2O-saturated isobutyl alcohol and let polymerize for 1 to 2 hr.
7. Drain off the overlay and rinse the surface with 1× Tris·Cl/SDS, pH 8.8. If the gels will not be used immediately, skip to step 12.

Pour the stacking gel

8. Prepare the stacking gel solution either singly (see Basic Protocol 1, step 8) or for all the gels at once (Table A.3F.8).

   The stacking gel solution should be prepared just before pouring the gel.

9. Fill each sandwich in the caster with stacking gel solution.
10. Insert a comb into each sandwich and let the gel polymerize for 2 hr.

    Insert the combs at a 45° angle to avoid trapping air underneath the comb teeth. Air bubbles will inhibit polymerization and cause dents in the wells and a distorted pattern of protein bands.

11. Remove the combs and rinse wells with 1× SDS electrophoresis buffer.

Remove the gels from the caster

12. Remove the gels from the caster and separate by carefully inserting a long razor blade or knife between each gel sandwich.

    A plastic wedge (Amersham Pharmacia Biotech's Wonder Wedge) also works well.

13. Clean the outside of each gel plate with running water to remove the residual polymerized and unpolymerized acrylamide.
14. Overlay gels to be stored with 1× Tris·Cl/SDS, pH 8.8, place in a resealable plastic bag, and store at 4°C until needed (up to 1 week).

SEPARATION OF PROTEINS ON GRADIENT GELS

ALTERNATE PROTOCOL 5

Gels that consist of a gradient of increasing polyacrylamide concentration resolve a much wider size range of proteins than standard uniform-concentration gels (see Critical Parameters and Troubleshooting). The protein bands, particularly in the low-molecular-weight range, are also much sharper. Unlike single-concentration gels, gradient gels separate proteins in a way that can be represented easily to give a linear plot from 10 to 200 kDa. This facilitates molecular weight estimations.

The quantities given below provide separating gel solution sufficient for two 0.75-mm gels (~7 ml of each concentration) or one 1.5-mm gel (~14 ml of each concentration). Volumes can be adjusted to accommodate gel sandwiches of different dimensions.

Additional Materials *(also see Basic Protocol 1)*

Light and heavy acrylamide gel solutions (Table A.3F.9 and Table A.3F.10)
Bromphenol blue (optional; for checking practice gradient)
TEMED

Gradient maker (30 to 50 ml, Amersham Pharmacia Biotech SG30 or SG50; *or* 30 to 100 ml, Bio-Rad 385)
Tygon tubing with micropipet tip
Peristaltic pump (optional; e.g., Markson A-13002, A-34040, or A-34105 minipump)
Whatman 3MM filter paper

Set up the gradient maker and prepare the gel solutions

1. Assemble the magnetic stirrer and gradient maker on a ring stand as shown in Figure A.3F.2. Connect the outlet valve of the gradient maker to Tygon tubing attached to a micropipet tip that is placed over the vertical gel sandwich. If desired, place a peristaltic pump in line between the gradient maker and the gel sandwich.

   A peristaltic pump will simplify casting by providing a smooth flow rate.

2. Place a small stir-bar into the mixing chamber of the gradient maker (i.e., the chamber connected to the outlet).

3. Using the recipes in Table A.3F.9 and Table A.3F.10, prepare light and heavy acrylamide gel solutions. Do not add ammonium persulfate until just before use (step 7).

4. With the outlet port and interconnecting valve between the two chambers closed, pipet 7 ml of light (low-concentration) acrylamide gel solution into the reservoir chamber for one 0.75-mm-thick gradient gel.

   Recommended gradient ranges are 5% to 20% for most applications (to separate proteins of 10 to several hundred kilodaltons).

   A practice run with heavy and light solutions is recommended. Bromphenol blue should be added to the heavy solution to demonstrate linearity of the practice gradient.

5. Open the interconnecting valve briefly to allow a small amount (~200 µl) of light solution to flow through the valve and into the mixing chamber.

   The presence of air bubbles in the interconnecting valve may obstruct the flow between chambers during casting.

   Deaeration is not recommended for either the light or heavy solution. Omitting the deaeration will allow polymerization to proceed more slowly, letting the gradient establish itself in the gel sandwich before polymerization takes place.

6. Add 7 ml of heavy (high-concentration) acrylamide gel solution to the mixing chamber.

   Keep the heavy solution on ice until use. Once the ammonium persulfate is added to the heavy solution, it will polymerize without TEMED, albeit more slowly; keeping the solution on ice prevents this. The gel solution will come to room temperature during casting. The higher the percentage of acrylamide, the more severe the problem of premature polymerization is.

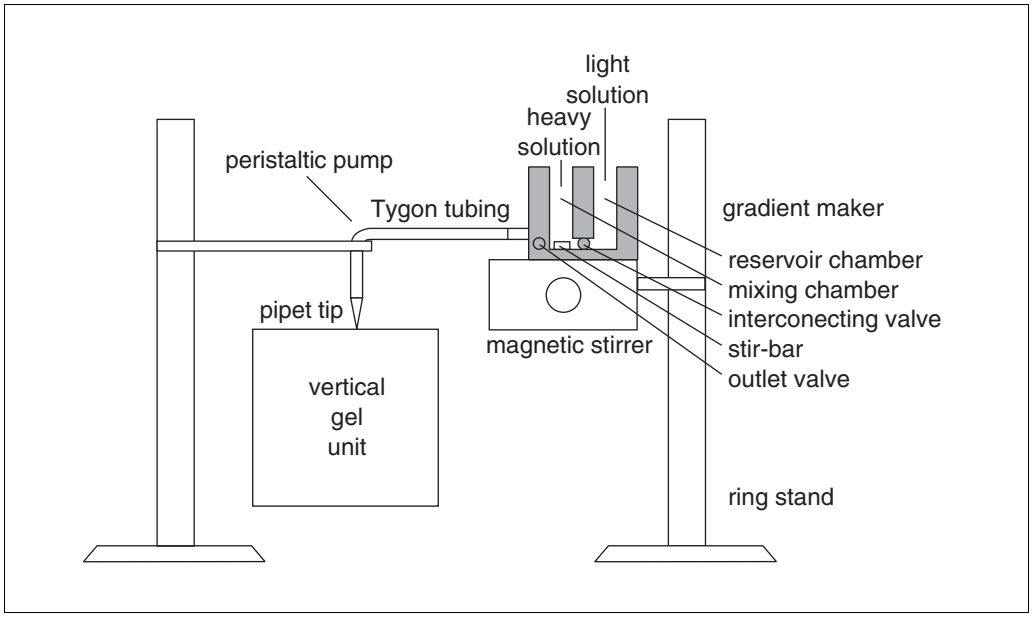

Figure A.3F.2 Gradient gel setup. A peristaltic pump, though not required, will provide better control.

Table A.3F.9 Light Acrylamide Gel Solutions for Gradient Gels[a]

Stock solution	Acrylamide concentration of light gel solution (%)[b]									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/ 0.8% bisacrylamide[c]	2.5	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05

[a]To survey proteins ≥10 kDa, 5%-20% gradient gels are recommended. To expand the range between 10 and 200 kD, a 10%-20% gel is recommended.

[b]Numbers in body of table are milliliters of stock solution. Deaeration is not required. Keep solution at room temperature prior to adding TEMED no longer than 1 hr.

[c]See Table A.3F.1 for preparation.

[d]Best to prepare fresh.

Table A.3F.10 Heavy Acrylamide Gel Solutions for Gradient Gels[a]

Stock solution	Acrylamide concentration of heavy gel solution (%)[b]										
	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/ 0.8% bisacrylamide[c]	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5	9.0	9.5	10.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	5.0	4.5	4.0	3.5	3.0	2.5	2.0	1.5	1.0	0.5	0
Sucrose (g)	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05

[a]Deaeration is not recommended for gradient gels.

[b]Numbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

[c]See Table A.3F.1 for preparation.

[d]Best to prepare fresh.

7. Add the specified amount of 10% ammonium persulfate and ~2.3 µl TEMED per 7 ml acrylamide solution to each chamber. Mix the solutions in each chamber with a disposable pipet.

Form the gradient and cast the gel

8. Open the interconnecting valve completely.

   Some of the heavy solution will flow back into the reservoir chamber containing light solution as the two chambers equilibrate. This will not affect the formation of the gradient.

9. Turn on the magnetic stirrer and adjust the rate to produce a slight vortex in the mixing chamber.

10. Open the outlet of the gradient maker slowly. Adjust the outlet valve to a flow rate of 2 ml/min. If using a peristaltic pump, calibrate the flow rate with a graduated cylinder prior to casting the gel.

    Some adjustment of the flow rate may be necessary during casting. If the light solution is not flowing into the mixing chamber, a bubble may be caught in the interconnecting valve.

Quickly close the outlet and cover the top of the reservoir chamber with a gloved thumb. Push down with the thumb to increase the pressure in the chamber and force the air bubble out of the center valve.

11. Fill the gel sandwich from the top. Place the pipet tip against one side of the sandwich so the solution flows down one plate only. The heavy solution will flow into the sandwich first, followed by progressively lighter solution.

12. Watch as the last of the light solution drains into the outlet tube and adjust the flow rate to ensure that the last few milliliters of solution do not flow quickly into the gel sandwich and disturb the gradient.

13. Overlay the gradient gel with H_2O-saturated isobutyl alcohol. Allow the gel to polymerize ~1 hr.

    In this gel system, the gel will polymerize from the bottom (i.e., heavy solution) up. Because polymerization is an exothermic reaction, heat can be felt evolving from the bottom of the gel sandwich during polymerization. A sharp optical discontinuity at the gel-overlay interface indicates that polymerization has occurred. In general, 1 hr is adequate for polymerization.

14. Remove the H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8. Cast the stacking gel (see Basic Protocol 1, steps 8 to 11).

    The gel can be covered with 1× Tris·Cl/SDS, pH 8.8, sealed in a plastic bag, and stored for up to 1 week.

Load and run the gel

15. Prepare the protein sample and protein molecular-weight-standards mixture. Load and run the gel (see Basic Protocol 1, steps 13 to 26).

    The gel can be stained with Coomassie blue or silver (APPENDIX 3).

16. After staining, dry the gels onto Whatman 3MM or equivalent filter paper.

    Gradient gels >0.75 mm thick require special handling during drying to prevent cracking. The simplest approach to drying gradient gels is to use thin gels; ≤0.75-mm gradient gels with ≤20% acrylamide solutions will dry without cracking as long as the vacuum pump is working properly and the cold trap is dry at the onset of drying. For gradient gels >0.75 mm thick, add 3% (w/v) glycerol to the final destaining solution to help prevent cracking. Another method is to dehydrate and shrink the gel in 30% methanol for up to 3 hr prior to drying. Then place the gel in distilled water for 5 min before drying.

SUPPORT PROTOCOL 2

CASTING MULTIPLE GRADIENT GELS

Casting gradient gels in a multiple gel caster has several advantages. In addition to the time savings, batch casting gives gels that are essentially identical. This is particularly important for gradient gels, where slight variations in casting technique can cause variations in protein mobility. The gels may be stored for up to 1 week after casting to ensure internal consistency from run to run during the week. Furthermore, gels with several ranges of concentrations (e.g., 5% to 20% and 10% to 20% acrylamide) can be cast and stored, giving much more flexibility to optimize separations.

Additional Materials *(also see Alternate Protocol 5)*

Plug solution (see recipe)
Light and heavy acrylamide gel solutions for multiple gradient gels (Table A.3F.11 and Table A.3F.12)
TEMED
H_2O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Amersham Pharmacia Biotech)
Peristaltic pump (25 ml/min)
500- or 1000-ml gradient maker (Bio-Rad, Amersham Pharmacia Biotech)
Tygon tubing

Set up system and pour separating gel

1. Assemble the multiple caster as in casting multiple single-concentration gels (see Support Protocol 1, steps 1 to 3), making sure to remove the triangular space filler plugs in the bottom of the caster.

   The plug is used only when casting single-concentration gels.

2. Set up the peristaltic pump (Fig. A.3F.3). Using a graduated cylinder and water, adjust the flow rate so that the volume of the gradient solution plus volume of plug solution is poured in ~15 to 18 min (~25 ml/min).

3. Set up the gradient maker. Close all valves and place a stir-bar in the mixing chamber, which is the one with the outlet port. Attach one end of a piece of Tygon tubing to the outlet of the gradient maker. Run the other end of the tubing through the peristaltic pump and attach it to the red inlet port at the bottom of the caster.

   Choose a gradient maker that holds no more than four times the total volume of the gradient solution to be poured (i.e., a 1000- or 500-ml gradient maker).

4. Prepare solutions for the gradient maker (Table A.3F.11 and Table A.3F.12).

5. Add the TEMED to both heavy and light solutions (54 µl/165 ml) and immediately pour the light (low-concentration) solution into the mixing chamber (the one with the port). Open the mixing valve slightly to allow the tunnel to fill and to avoid air bubbles. Close the valve again and pour the heavy (high-concentration) acrylamide solution into the reservoir chamber.

6. Start the magnetic stirrer and open the outlet valve; then start the pump and open the mixing valve.

   In units for casting multiple gels, acrylamide solution flows in from the bottom. To use a multiple casting unit, the light solution is placed in the mixing chamber and the heavy solution in the reservoir. This is the reverse of casting a single gel (see Alternate Protocol 5).

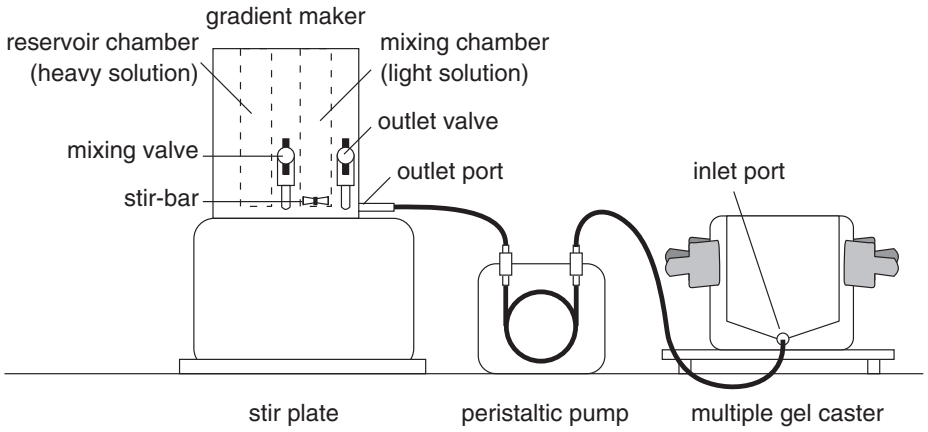

Figure A.3F.3 Setup for casting multiple gradient gels. Casting multiple gradient gels requires a peristaltic pump and a multiple gel caster. Gel solution is introduced through the bottom of the multiple caster.

Table A.3F.11 Light Acrylamide Gel Solutions for Multiple Gradient Gels[a,b]

Stock solution	Acrylamide concentration of light separating gel solution (%)[c]									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/ 0.8% bisacrylamide[d]	28	33	39	44	50	55	61	66	72	77
4× Tris·Cl/SDS, pH 8.8[d]	41	41	41	41	41	41	41	41	41	41
H_2O	96	91	85	80	74	69	63	58	52	47
10% (w/v) ammonium persulfate[e]	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55

[a]To survey proteins ≥10 kDa, 5%-20% gradient gels are recommended. To expand the range between 10 and 200 kDa, a 10%-20% gel is recommended.

[b]Recipes produce ten 1.5-mm-thick gradient gels with 10 ml extra solution to account for losses in tubing.

[c]Numbers in body of table are milliliters of stock solution. Deaeration is not required. Keep solution at room temperature prior to adding TEMED no longer than 1 hr.

[d]See Table A.3F.1 for preparation.

[e]Best to prepare fresh.

Table A.3F.12 Heavy Acrylamide Gel Solutions for Multiple Gradient Gels[a,b]

Stock solution	Acrylamide concentration of heavy gel solution (%)[c]										
	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/ 0.8% bisacrylamide[d]	55	61	66	72	77	83	88	94	99	105	110
4× Tris·Cl/SDS, pH 8.8[d]	41	41	41	41	41	41	41	41	41	41	41
H_2O	55	50	44	39	33	28	22	17	11	5.5	0
Sucrose (g)	25	25	25	25	25	25	25	25	25	25	25
10% (w/v) ammonium persulfate[e]	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55

[a]Deaeration is not recommended for gradient gels.

[b]Recipes produce 10 ml extra solution to account for losses in tubing.

[c]Numbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

[d]See Table A.3F.1 for preparation.

[e]Best to prepare fresh.

Thus, light solution enters the multiple caster first, followed by progressively heavier solution. Finally, the acrylamide solution is stabilized in the multiple caster with a heavy plug solution and allowed to polymerize (see step 8 and manufacturer's instructions).

7. When almost all the acrylamide solution is gone from the gradient maker, stop the pump and close the mixing valve. Tilt the gradient maker toward the outlet side and remove the last milliliters of the mix. Do not allow air bubbles to enter the tubing.
8. Add the plug solution to the mixing chamber and start the pump. Make sure that no bubbles are introduced. Continue pumping until the bottom of the caster is filled with plug solution to just below the glass plates; then turn off the pump. Clamp the tubing close to the red port of the casting chamber.
9. Quickly overlay each separate gel sandwich with 100 µl H_2O-saturated isobutyl alcohol. Use the same amount on each sandwich.

Failure to use the same amount of overlay solution will cause the gel sandwiches to polymerize at different heights.

10. Drain off the overlay and rinse the surface of the gels with 1× Tris·Cl/SDS, pH 8.8.

Pour stacking gel and remove gels from caster

11. Prepare and cast the stacking gel as in casting multiple single-concentration gels (see Support Protocol 1, steps 8 to 11).

12. Remove gels from the caster and clean the gel sandwiches (see Support Protocol 1, steps 12 and 13). Store gels, if necessary, according to the instructions for multiple single-concentration gels (see Support Protocol 1, step 14).

ELECTROPHORESIS IN SINGLE-CONCENTRATION MINIGELS

BASIC PROTOCOL 2

Separation of proteins in a small-gel format is becoming increasingly popular for applications that range from isolating material for peptide sequencing to performing routine protein separations. The unique combination of speed and high resolution is the foremost advantage of small gels. Additionally, small gels are easily adapted to single-concentration, gradient, and two-dimensional SDS-PAGE procedures. The minigel procedures described are adaptations of larger gel systems.

This protocol describes the use of a multiple gel caster. The caster is simple to use, and up to five gels can be prepared at one time with this procedure. Single gels can be prepared using adaptations in the manufacturer's instructions. A multiple gel caster is the only practical way to produce small linear polyacrylamide gradient gels (see Support Protocol 3).

Materials

Minigel vertical gel unit (Amersham Pharmacia Biotech Mighty Small SE 250/280 *or* Bio-Rad Mini-Protean II) with glass plates, clamps, and buffer chambers
0.75-mm spacers
Multiple gel caster (Amersham Pharmacia Biotech SE-275/295 *or* Bio-Rad Mini-Protean II multicasting chamber)
Acrylic plate (Amersham Pharmacia Biotech SE-217 *or* Bio-Rad 165-1957) or polycarbonate separation sheet (Amersham Pharmacia Biotech SE-213 *or* Bio-Rad 165-1958)
10- and 50-ml syringes
Combs (Teflon, Amersham Pharmacia Biotech SE-211A series or Bio-Rad Mini-Protean II)
Long razor blade
Micropipet

Additional reagents and equipment for standard denaturing SDS-PAGE (see Basic Protocol 1)

Pour the separating gel

1. Assemble each gel sandwich by stacking, in order, the notched (Amersham Pharmacia Biotech) or small rectangular (Bio-Rad) plate, 0.75-mm spacers, and the larger rectangular plate. Be sure to align the spacers properly, with the ends flush with the top and bottom edge of the two plates, when positioning the sandwiches in the multiple gel caster (Fig. A.3F.4).

   The protocol described is basically for the Amersham Pharmacia Biotech system. For other systems, make adjustments according to the manufacturer's instructions. Alternatively, precast minigels can be purchased from a number of suppliers (see Table A.3F.3).

   The multiple casters from Amersham Pharmacia Biotech have a notch in the base designed for casting gradient gels. A silicone rubber insert fills up this space when casting

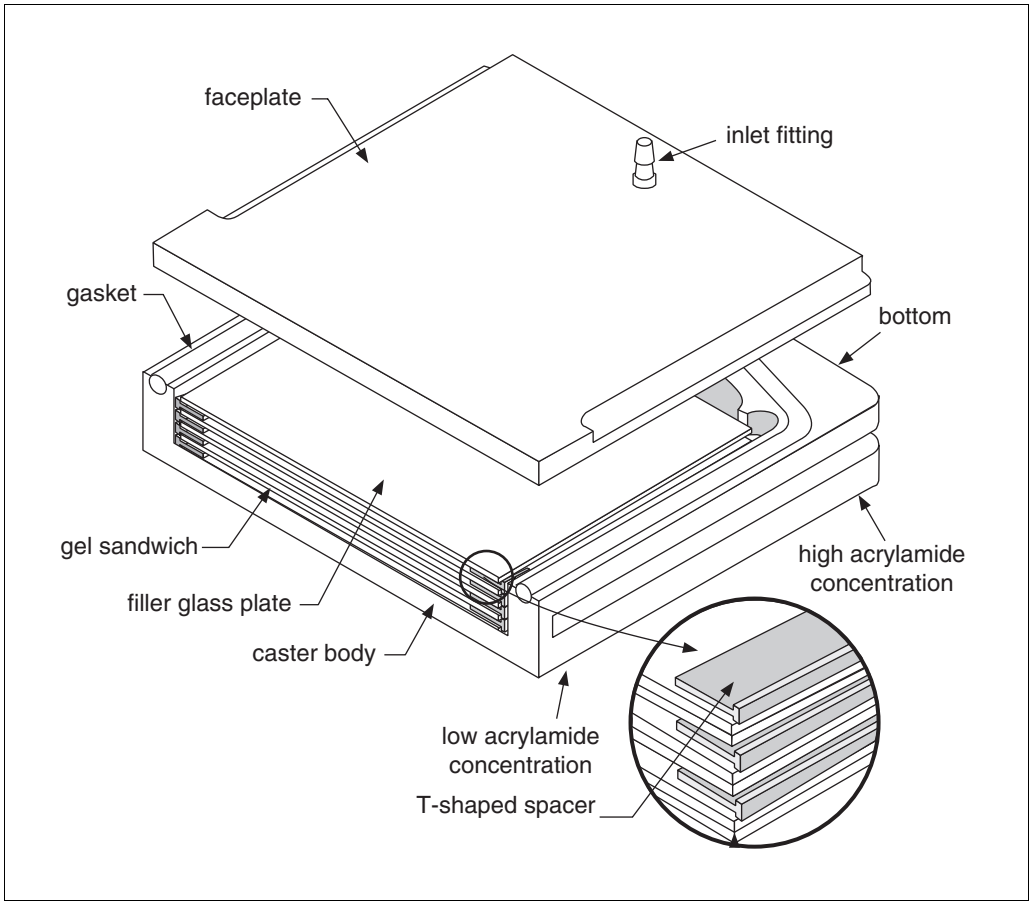

Figure A.3F.4 Minigel sandwiches positioned in the multiple gel caster. Extra glass or acrylic plates or polycarbonate sheets are used to fill any free space in the caster and to ensure that the gel sandwiches are held firmly in place.

single-concentration gels. The Amersham Pharmacia Biotech spacers are T-shaped to prevent slipping. The flanged edge of the spacer must be positioned against the outside edge of the glass plate. Placing a sheet of wax paper between the gel sandwiches will help separate the sandwiches after polymerization.

2. Fit the gel sandwiches tightly in the multiple gel caster. Use an acrylic plate or polycarbonate separation sheet to eliminate any slack in the chamber.

   Loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis.

3. Place the front faceplate on the caster, clamp it in place against the silicone gasket, and verify alignment of the glass plates and spacers.

4. Prepare the separating gel solution as directed in Table A.3F.1. For five 0.75-mm-thick gels, prepare ~30 ml solution (i.e., double the volumes listed).

   To compute the total gel volume needed, multiply the area of the gel (e.g., 7.3 × 8.3 cm) by the thickness of the gel (e.g., 0.75 mm) and then by the number of gels in the caster. If needed, add ~4 to 5 ml of extra gel solution to account for the space around the outside of the gel sandwiches.

   Do not add TEMED and ammonium persulfate until just before use.

5. Fill a 50-ml syringe with the separating gel solution and slowly inject it into the caster until the gels are 6 cm high, allowing 1.5 cm for the stacking gel.

6. Overlay each gel with 100 µl H_2O-saturated isobutyl alcohol. Allow the gels to polymerize for ~1 hr.

Pour the stacking gel

7. Remove the isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

   Stacking gels can be cast one at a time with the gel mounted on the electrophoresis unit, or all at once in the multiple caster.

8. Practice placing a comb in the gel sandwiches before preparing the stacking gel solution. Press the comb against the rectangular or taller plate so that all teeth of the comb are aligned with the opening in the gel sandwich, then insert into the sandwich. Remove combs after practicing.

9. Prepare the stacking gel solution (2 ml per gel) as directed in Table A.3F.1. Fill a 10-ml syringe with stacking gel solution and inject the solution into each gel sandwich.

10. Insert combs, taking care not to trap bubbles. Allow gels to polymerize 1 hr.

11. Remove the front faceplate. Carefully pull the gels out of the caster, using a long razor blade to separate the sandwiches.

    If the gels are left to polymerize for prolonged periods, they will be difficult to remove from the caster.

    The gels can be stored tightly wrapped in plastic wrap with the combs left in place inside a sealable bag to prevent drying for ~1 week. Without the stacking gel, the separating gel can be stored for 2 to 3 weeks. Keep gels moist with 1× Tris·Cl/SDS, pH 8.8, at 4°C. Do not store gels in the multiple caster.

Prepare the sample, load the gel, and conduct electrophoresis

12. Remove the combs and rinse the sample wells with 1× SDS electrophoresis buffer. Place a line indicating the bottom of each well on the front glass plate with a marker.

13. Fill the upper and lower buffer chambers with 1× SDS electrophoresis buffer. The upper chamber should be filled to 1 to 2 cm over the notched plate.

14. Prepare the protein sample and protein-standards mixture (see Basic Protocol 1, step 12).

15. Load the sample using a micropipet. Insert the pipet tip through the upper buffer and into the well. The mark on the glass plate will act as a guide. Dispense the sample into the well.

    For a complex mixture, 20 to 25 µg protein in 10 µl SDS sample buffer will give a strongly stained Coomassie blue pattern. Much smaller amounts (1 to 5 µg) are required for highly purified proteins, and a 10- to 100-fold smaller amount of protein in the same volume (e.g., 10 µl) is required for silver staining.

16. Electrophorese samples at 10 to 15 mA per 0.75-mm gel until the dye front reaches the bottom of the gel (~1 to 1.5 hr).

17. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Proceed with detection of proteins.

SUPPORT PROTOCOL 3

PREPARING MULTIPLE GRADIENT MINIGELS

Polyacrylamide gradients not only enhance the resolution of larger-format gels but also greatly improve protein separation in the small format. Casting gradient minigels one at a time is not generally feasible because of the small volumes used, but multiple gel casters make it easy to cast several small gradient gels at one time. The gels are cast from the bottom in multiple casters, with the light acrylamide solution entering first. This is the opposite of casting one gel at a time, in which the heavy solution enters from the top of the gel sandwich and flows down to the bottom.

Additional Materials *(also see Basic Protocol 2)*

Plug solution (see recipe)

Additional reagents and equipment for preparing gradient gels (see Alternate Protocol 5)

Set up the system and prepare the gel solutions

1. Assemble minigel sandwiches in the multiple gel caster as described for single-concentration minigels (see Basic Protocol 2, steps 1 to 3).
2. Set up the 30-ml gradient maker, magnetic stirrer, peristaltic pump (optional), and Tygon tubing as in Figure A.3F.3. Connect the outlet of the 30-ml gradient maker to the inlet at the base of the front faceplate of the caster.

   The monomer solution will be introduced through the inlet at the bottom of the front faceplate of the caster first, followed by progressively heavier solution.
3. Prepare light (Table A.3F.9) and heavy (Table A.3F.10) acrylamide gel solutions. Use ~12 ml of each solution for five 0.75-mm-thick minigels.

   Adjust volumes if a different thickness or number of gels is needed. Do not add ammonium persulfate until just before use. Deaeration is not recommended for gradient gels.
4. With the outlet and interconnecting valve closed, add the heavy solution to the reservoir chamber. Briefly open the interconnecting valve to let a small amount of heavy solution through to the mixing chamber, clearing the valve of air.
5. Fill the mixing chamber with light solution. Add 4 µl TEMED per 12 ml acrylamide solution to each chamber and mix with a disposable pipet.

Form the gradient and cast the gels

6. Turn on the magnetic stirrer. Open the interconnecting valve and allow the chambers to equilibrate. Then slowly open the outlet port to allow the solution to flow from the gradient maker to the multiple caster by gravity (a peristaltic pump may be used for better control). Adjust the flow rate to 3 to 4 ml/min.

   Faster flow rates are possible and will also produce good gradients. However, a fast flow increases the potential for introduction of bubbles into the caster.
7. Close the outlet port as the last of the gradient solution leaves the mixing chamber, just before air enters the outlet tube. Fill the two chambers with plug solution and slowly open the outlet once again.
8. Allow the plug solution to push the acrylamide in the caster up into the plates. Close the outlet when the plug solution reaches the bottom of the plates.

   A discontinuity between the bottom of the gels and the plug solution will be obvious.
9. Quickly add 100 µl H_2O-saturated isobutyl alcohol to each gel sandwich. Let the gels polymerize undisturbed for ~1 hr.
10. Prepare and pour the stacking gel (see Basic Protocol 2, steps 9 and 10).

Disassemble the system

11. Disconnect the gradient maker, place the caster in a sink, and remove the front faceplate. The plug solution will drain out from the bottom of the caster.

12. Remove the gels (see Basic Protocol 2, step 11).

Gradient minigels can be stored as described for single-concentration minigels (see Basic Protocol 2, step 11 annotation). For instructions on preparing, loading, and running the gels, see Basic Protocol 2, steps 12 to 17.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anode buffer

121.1 g Tris base (0.2 M final)
500 ml H_2O
Adjust to pH 8.9 with concentrated HCl
Dilute to 5 liters with H_2O
Store at 4°C up to 1 month

Final concentration is 0.2 M Tris·Cl, pH 8.9.

Cathode buffer

12.11 g Tris base (0.1 M final)
17.92 g tricine (0.1 M final)
1 g SDS (0.1% final)
Dilute to 1 liter with H_2O
Do not adjust pH
Store at 4°C up to 1 month

Coomassie blue G-250 staining solution

200 ml acetic acid (20% final)
1800 ml H_2O
0.5 g Coomassie blue G-250 (0.025% final)
Mix 1 hr and filter (Whatman no. 1 paper)
Store at room temperature indefinitely

Phosphate/SDS electrophoresis buffer

Dilute 500 ml of 4× phosphate/SDS, pH 7.2 (Table A.3F.7) with H_2O to 2 liters.
Store at 4°C up to 1 month.

Final concentrations are 0.1 M sodium phosphate (pH 7.2)/0.1% (w/v) SDS.

Phosphate/SDS sample buffer, 2*× (for continuous systems)*

0.5 ml 4× phosphate/SDS, pH 7.2 (Table A.3F.7; 20 mM sodium phosphate final)
0.2 g SDS (2% final)
0.1 mg bromphenol blue (0.001% final)
0.31 g DTT (0.2 M final)
2.0 ml glycerol (2% final)
Add H_2O to 10 ml and mix

Plug solution

0.125 M Tris·Cl, pH 8.8 (*APPENDIX 2A*)
50% (w/v) sucrose
0.001% (w/v) bromphenol blue
Store at 4°C up to 1 month

Recrystallized SDS *(optional)*

High-purity SDS is available from several suppliers, but for some sensitive applications (e.g., protein sequencing) recrystallization is useful. Commercially available electrophoresis-grade SDS is usually of sufficient purity for most applications.

Add 100 g SDS to 450 ml ethanol and heat to 55°C. While stirring, gradually add 50 to 75 ml hot H_2O until all SDS dissolves. Add 10 g activated charcoal (Norit 1, Sigma) to solution. After 10 min, filter solution through Whatman no. 5 paper on a Buchner funnel to remove charcoal. Chill filtrate 24 hr at 4°C and 24 hr at −20°C. Collect crystalline SDS on a coarse-frit (porosity A) sintered-glass funnel and wash with 800 ml −20°C ethanol (reagent grade). Repeat crystallization without adding activated charcoal. Dry recrystallized SDS under vacuum overnight at room temperature. Store in a desiccator over phosphorous pentoxide (P_2O_5) in a dark bottle.

If proteins will be electroeluted or electroblotted for protein sequence analysis, it may be desirable to crystallize the SDS twice from ethanol/H_2O (Hunkapiller et al., 1983).

SDS electrophoresis buffer, 5×

15.1 g Tris base (0.125 M final)
72.0 g glycine (0.96 M final)
5.0 g SDS (0.5% final)
H_2O to 1000 ml
Dilute to 1× or 2× for working solution, as appropriate

Do not adjust the pH of the stock solution, as the solution is pH 8.3 when diluted. Store at 0° to 4°C until use (up to 1 month).

SDS sample buffer, 2× *(for discontinuous systems)*

25 ml 4× Tris·Cl/SDS, pH 6.8 (Table A.3F.1)
20 ml glycerol (20% final)
4 g SDS (4% final)
2 ml 2-ME *or* 3.1 g DTT (0.2% 2-ME or 0.2 M DTT final)
1 mg bromphenol blue (0.001% final)
Add H_2O to 100 ml and mix
Store in 1-ml aliquots at −70°C

To avoid reducing proteins to subunits (if desired), omit 2-ME or DTT (reducing agent) and add 10 mM iodoacetamide to prevent disulfide interchange.

SDS sample buffer, 6× *(for discontinuous systems)*

7 ml 4× Tris·Cl/SDS, pH 6.8 (Table A.3F.1)
3.0 ml glycerol (30% final)
1 g SDS (10% final)
0.93 g DTT (0.6 M final)
1.2 mg bromphenol blue (0.012% final)
Add H_2O to 10 ml (if needed)
Store in 0.5-ml aliquots at −70°C

Tricine sample buffer, 2×

2 ml 4× Tris·Cl/SDS, pH 6.8 (Table A.3F.1; 0.1 M)
2.4 ml (3.0 g) glycerol (24% final)
0.8 g SDS (8% final)
0.31 g DTT (0.2 M final)
2 mg Coomassie blue G-250 (0.02% final)
Add H_2O to 10 ml and mix

COMMENTARY

Background Information

Polyacrylamide gels form after polymerization of monomeric acrylamide into polymeric polyacrylamide chains and cross-linking of the chains by *N,N′*-methylenebisacrylamide. The polymerization reaction is initiated by the addition of ammonium persulfate, and the reaction is accelerated by TEMED, which catalyzes the formation of free radicals from ammonium persulfate. Because oxygen inhibits the polymerization process, deaerating the gel solution before the polymerization catalysts are added will speed up polymerization; deaeration is not recommended for the gradient gel protocols because slower polymerization facilitates casting of gradient gels.

Precast gels for commonly used vertical minigel and standard-sized SDS-PAGE apparatuses are available from several manufacturers (Table A.3F.3). Flatbed (horizontal) isoelectric focusing (IEF) and SDS-PAGE gels are not listed. Amersham Pharmacia Biotech supplies a range of horizontal gels for a variety of applications and should be consulted for further information. When using precast gels, pay strict attention to shelf life. In general, manufacturers overrate the shelf life, and the sooner the gels are used, the better. When reasonably fresh, precast gels provide excellent resolution that is as good or better than a typical gel cast in the laboratory.

The most widely used method for discontinuous gel electrophoresis is the system described by Laemmli (1970). This is the denaturing (SDS) discontinuous method used in Basic Protocol 1. A discontinuous buffer system uses buffers of different pH and composition to generate a discontinuous pH and voltage gradient in the gel. Because the discontinuous gel system concentrates the proteins in each sample into narrow bands, the applied sample may be more dilute than that used for continuous electrophoresis.

In the discontinuous system the sample first passes through a stacking gel, which has large pores. The stacking gel buffer contains chloride ions (called the leading ions) whose electrophoretic mobility is greater than the mobility of the proteins in the sample. The electrophoresis buffer contains glycine ions (called the trailing ions) whose electrophoretic mobility is less than the mobility of the proteins in the sample. The net result is that the faster migrating ions leave a zone of lower conductivity between themselves and the migrating protein. The higher voltage gradient in this zone allows the proteins to move faster and to "stack" in the zone between the leading and trailing ions. After leaving the stacking gel, the protein enters the separating gel. The separating gel has a smaller pore size, a higher salt concentration, and higher pH compared to the stacking gel. In the separating gel, the glycine ions migrate past the proteins, and the proteins are separated according to either molecular size in a denaturing gel (containing SDS) or molecular shape, size, and charge in a nondenaturing gel.

Proteins are denatured by heating in the presence of a low-molecular-weight thiol (2-ME or DTT) and SDS. Most proteins bind SDS in a constant-weight ratio, leading to identical charge densities for the denatured proteins. Thus, the SDS-protein complexes migrate in the polyacrylamide gel according to size, not charge. Most proteins are resolved on polyacrylamide gels containing from 5% to 15% acrylamide and 0.2% to 0.5% bisacrylamide (see Table A.3F.1). The relationship between the relative mobility and log molecular weight is linear over these ranges (Fig. A.3F.5). With the use of plots like those shown in Figure A.3F.5, the molecular weight of an unknown protein (or its subunits) may be determined by comparison with known protein standards (Table A.3F.2). In general, all of the procedures in this unit are suitable for radiolabeled and biotinylated proteins without modification.

Basic Protocol 1 relies on denaturing proteins in the presence of SDS and 2-ME or DTT. Under these conditions, the subunits of proteins are dissociated and their biological activities are lost. A true estimate of a protein's molecular size can be made by comparing the relative mobility of the unknown protein to proteins in a calibration mixture (Fig. A.3F.5). Gradient gels (see Alternate Protocol 5) simplify molecular-weight determinations by producing a linear relationship between log molecular weight of the protein and log % T over a much wider size range than single-concentration gels. Although percent acrylamide monomer is a more common measure of gel concentration, % T, the percentage of total monomer (acrylamide plus bisacrylamide) in the solution or gel, is used for molecular weight calculations in gradient gels. The % T of a stained protein is estimated assuming the acrylamide gradient is linear. For example, proteins in the gel shown in Figure A.3F.6 were separated in a 5.1% to 20.5% T acrylamide gradient. The % T of the

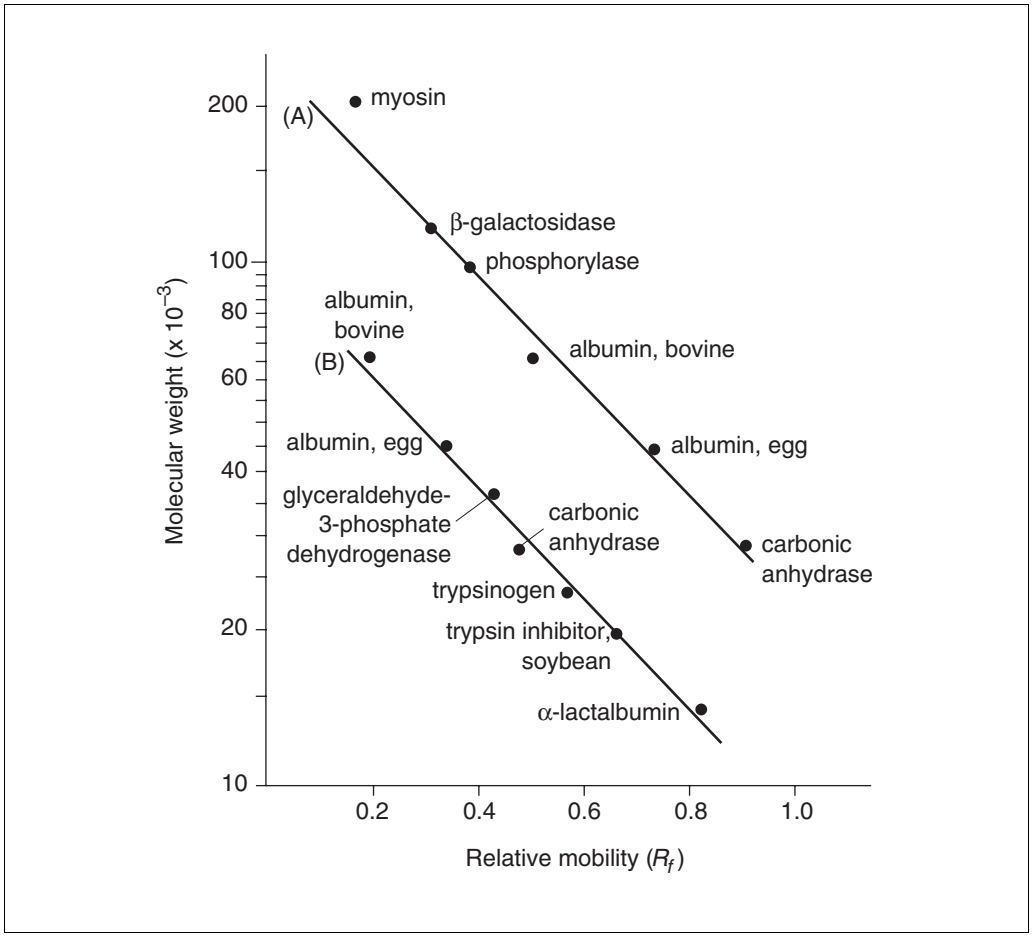

Figure A.3F.5 Typical calibration curves obtained with standard proteins separated by nongradient denaturing (SDS) discontinuous gel electrophoresis based on the method of Laemmli (1970). (**A**) Gel with 7% polyacrylamide. (**B**) Gel with 11% polyacrylamide. (Redrawn with permission from Sigma.)

point halfway through the resolving gel is 12.5% T. Simply plotting log molecular mass versus distance moved into the gel (or R_f) also produces a relatively linear standard curve over a fairly wide size range.

If two proteins have identical molecular sizes, they more than likely will not be resolved with one-dimensional SDS-PAGE, and two-dimensional SDS-PAGE should be considered. Unusual protein compositions can cause anomalous mobilities during electrophoresis (see Critical Parameters and Troubleshooting), but similar-sized proteins of widely different amino acid composition or structure may still be resolved from one another using one-dimensional SDS-PAGE. Purified protein complexes or multimeric proteins consisting of subunits of different molecular size will be resolved into constituent polypeptides. Comparison of the protein bands obtained under nonreducing and reducing conditions provides information about the molecular size of disulfide cross-linked component subunits. The individual polypeptides can be isolated by electroelution or electroblotting, and the amino acid sequences can be determined.

Both the tricine (Schagger and von Jagow, 1987) and the modified Laemmli (Okajima et al., 1993) peptide separation procedures presented here (see Alternate Protocols 1 and 2) are simple to set up and provide resolution down to 5 kDa. To separate peptides below 5 kDa, the tricine procedure must be modified by preparing a 16.5% T, 2.7% C resolving gel that uses a 10% T spacer gel between the stacking and resolving gel (Schagger and von Jagow, 1987). % C is the percentage of cross-linker (bisacrylamide) in the total monomer (acrylamide plus bisacrylamide).

Continuous electrophoresis, where the same buffer is used throughout the tank and gel, is popular because of its versatility and simplicity. The phosphate system described in Alternate Protocol 3 is based on that of Weber et al.

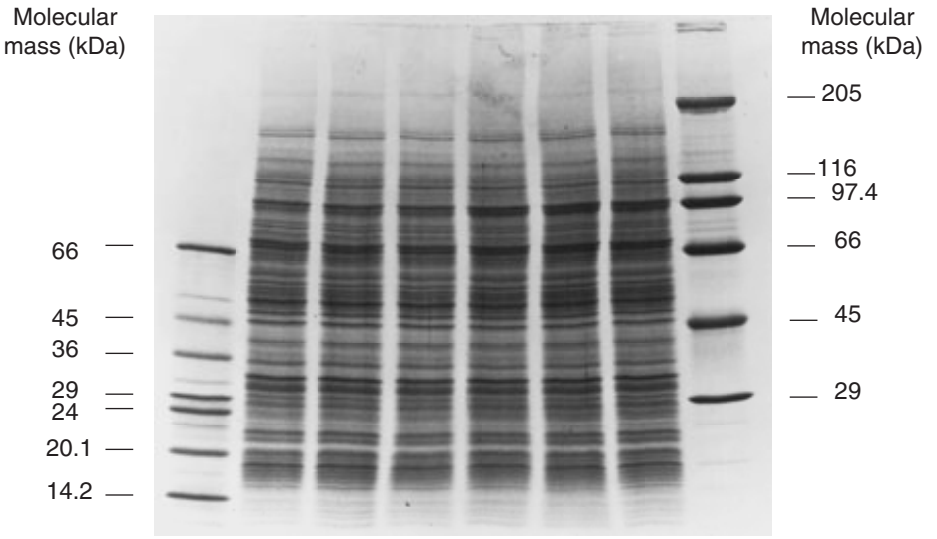

Figure A.3F.6 Separation of membrane proteins by 5.1% to 20.5% T polyacrylamide gradient SDS-PAGE. Approximately 30 μl of 1× SDS sample buffer containing 30 μg of Alaskan pea (*Pisum sativum*) membrane proteins was loaded in wells of a 14 × 14–cm, 0.75-mm-thick gel. Standard proteins were included in the outside lanes. The gel was run at 4 mA for ~15 hr.

(1972). Although unable to produce the high-resolution separations of the discontinuous SDS-PAGE procedures, continuous SDS-PAGE uses fewer solutions with one basic buffer and no stacking gel. Artifacts are also less likely to occur in continuous systems. Pepsin, for example, migrates anomalously on Laemmli-based discontinuous SDS-PAGE but has the expected mobility after electrophoresis in the phosphate-based continuous system described here. This is also true of cross-linked proteins.

Multiple gel casting (see Support Protocols 1 to 3) is appropriate when gel-to-gel consistency is paramount or when the number of gels processed exceeds five a week. The variety of multiple gel casters, gradient makers, and inexpensive pumps available from major suppliers simplifies the process of casting gels in the laboratory. Alternatively, precast gradient gels are available for most major brands of gel apparatuses (Table A.3F.3).

Minigels (see Basic Protocol 2) are generally considered to be in the 8 × 10–cm size range, although there is considerable variation in exact size. Every technique that is used on larger systems can be translated with little difficulty into the minigel format. This includes standard and gradient SDS-PAGE and separations for immunoblotting and peptide sequencing. Two-dimensional SDS-PAGE electrophoresis also adapts well, but here the limitation of separation area becomes apparent; for high-resolution separations, large-format gels are required. Gradient minigels (see Support Protocol 3) are popular due to the combination of separation range and resolution (Matsudaira and Burgess, 1978). They are particularly useful for separation of proteins prior to peptide sequencing.

Mylar support (Gel Bond) provides a practical way of casting, running, and, staining extremely thin gels. When gels <0.75 mm thick are used, reagents have much better access both into and out of the gel, reducing staining time in both Coomassie blue and silver staining. Double and broadened images caused by differential migration of the protein across the thickness of the gel are minimized, improving resolution.

Critical Parameters and Troubleshooting

If an electrophoretically separated protein will be electroeluted or electroblotted for sequence analysis, the highest-purity reagents available should be used. If necessary, SDS can be purified by recrystallization following the procedure given in Reagents and Solutions.

If the gels polymerize too fast, the amount of ammonium persulfate should be reduced by

one-third to one-half. If the gels polymerize too slowly or fail to polymerize all the way to the top, use fresh ammonium persulfate or increase the amount of ammonium persulfate by one-third to one-half. The overlay should be added slowly down the spacer edge to prevent the overlay solution from crashing down and disturbing the gel interface.

After a separating gel is poured, it may be stored with an overlay of the same buffer used in the gel. Immediately prior to use, the stacking gel should be poured; otherwise, there will be a gradual diffusion-driven mixing of buffers between the two gels, which will cause a loss of resolution.

The protein of interest should be present in 0.2- to 1-μg amounts in a complex mixture of proteins if the gel will be stained by Coomassie blue. Typically, 30 to 50 μg of a complex protein mixture in a total volume of <20 μl is loaded on a 0.75-mm-thick slab gel (16 cm, 10 wells).

When casting multiple gradient gels, eliminate all bubbles in the outlet tubing of the gradient maker. If air bubbles get into the outlet tube, they may flow into the caster and then up through the gradient being poured, causing an area of distortion in the polymerized gel. Air bubbles are not so great a problem when casting single gradient gels from the top. As the gels are cast, the stirrer must be slowed so that the vortex in the mixing chamber does not allow air to enter the outlet.

Uneven heating of the gel causes differential migration of proteins, with the outer lanes moving more slowly than the center lanes (called smiling). Increased heat transfer eliminates smiling and can be achieved by filling the lower buffer chamber with buffer all the way to the level of the sample wells, by maintaining a constant temperature between 10° to 20°C, and by stirring the lower buffer with a magnetic stirrer. Alternatively, decrease the heat load by running at a lower current.

If the tracking dye band is diffuse, prepare fresh buffer and acrylamide monomer stocks. If the protein bands are diffuse, increase the current by 25% to 50% to complete the run more quickly and minimize band diffusion, use a higher percentage of acrylamide, or try a gradient gel. Lengthy separations using gradient gels generally produce good results (Fig. A.3F.6). Check for possible proteolytic degradation that may cause loss of high-molecular-weight bands and create a smeared banding pattern.

If there is vertical streaking of protein bands, decrease the amount of sample loaded on the gel, further purify the protein of interest to reduce the amount of contaminating protein applied to the gel, or reduce the current by 25%. Another cause of vertical streaking of protein bands is precipitation, which can sometimes be eliminated by centrifuging the sample or by reducing the percentage of acrylamide in the gel.

Proteins can migrate faster or slower than their actual molecular weight would indicate. Abnormal migration is usually associated with a high proportion of basic or charged amino acids (Takano et al., 1988). Other problems can occur during isolation and preparation of the protein sample for electrophoresis. Proteolysis of proteins during cell fractionation by endogenous proteases can cause subtle band splitting and smearing in the resulting electrophoretogram (electrophoresis pattern). Many endogenous proteases are very active in SDS sample buffers and will rapidly degrade the sample; thus, first heating the samples to 70° to 100°C for 3 min is recommended.

In some cases, heating to 100°C in sample buffer will cause selective aggregation of proteins, creating a smeared layer of Coomassie blue–stained material at the top of the gel (Gallagher and Leonard, 1987). To avoid heating artifacts and also prevent proteolysis, the use of specific protease inhibitors during protein isolation and/or lower heating temperatures (70° to 80°C) have been effective (Dhugga et al., 1988).

Although continuous gels suffer from poor band sharpness, they are less prone to artifacts caused by aggregation and protein cross-linking. If streaking or aggregation appear to be a problem with the Laemmli system, then the same sample should be subjected to continuous SDS-PAGE to see if the problem is intrinsic to the Laemmli gel or the sample.

If the protein bands spread laterally from gel lanes, the time between applying the sample and running the gel should be reduced in order to decrease the diffusion of sample out of the wells. Alternatively, the acrylamide percentage should be increased in the stacking gels from 4% to 4.5% or 5% acrylamide, or the operating current should be increased by 25% to decrease diffusion in the stacking gel. Use caution when adding 1× SDS electrophoresis buffer to the upper buffer chamber. Samples can get swept into adjacent wells and onto the top of the well arm.

If the protein bands are uneven, the stacking gel may not have been adequately polymerized. This can be corrected by deaerating the stacking

gel solution thoroughly or by increasing the ammonium persulfate and TEMED concentrations by one-third to one-half. Another cause of distorted bands is salt in the protein sample, which can be removed by dialysis, gel filtration, or precipitation. Skewed protein bands can be caused by an uneven interface between the stacking and separating gels, which can be corrected by starting over and being careful not to disturb the separating gel while overlaying with isobutyl alcohol.

If a run takes too long, the buffers may be too concentrated or the operating current too low. If the run is too short, the buffers may be too dilute or the operating current too high.

If double bands are observed, the protein may be partially oxidized or partially degraded. Oxidation can be minimized by increasing the 2-ME concentration in the sample buffer or by preparing a fresh protein sample. If fewer bands than expected are observed and there is a heavy protein band at the dye front, increase the acrylamide percentage in the gel.

Anticipated Results

Polyacrylamide gel electrophoresis done under denaturing and reducing conditions should resolve any two proteins, except two of identical size. Resolution of proteins in the presence of SDS is a function of gel concentration and the size of the proteins being separated. Under nondenaturing conditions, the biological activity of a protein will be maintained.

Comparison of reducing and nonreducing denaturing gels can also provide valuable information about the number of disulfide cross-linked subunits in a protein complex. If the subunits are held together by disulfide linkages, the protein will separate in denaturing gels as a complex or as smaller-sized subunits under nonreducing or reducing conditions, respectively. However, proteins separated on nonreducing denaturing gels appear more diffuse and exhibit less overall resolution than those separated on reducing gels.

Gradient gels provide superior protein-band sharpness and resolve a larger size range of proteins, making them ideal for most types of experiments in spite of being more difficult to prepare. Molecular-weight calculations are simplified because of the extended linear relationship between size and protein position in the gel. Increased band sharpness of both high- and low-molecular-weight proteins on the same gel greatly simplifies survey experiments, such as gene expression studies where the characteristics of the responsive protein are not known. Furthermore, the increased resolution dramatically improves autoradiographic analysis. Preparation of gradient gels is straightforward, although practice with gradient solutions containing dye is recommended. The gradient gels can be stored for several days at 0° to 4°C before casting the stacking gel.

Time Considerations

Preparation of separating and stacking gels requires 2 to 3 hr. Gradient gels generally take 5 min to cast singly. Casting multiple single-concentration gels requires an additional 10 min for assembly. Casting multiple gradient gels takes 15 to 20 min plus assembly time. It takes 4 to 5 hr to run a 14 × 14–cm, 0.75-mm gel at 15 mA (70 to 150 V), and 3 to 4 hr to run a 0.75-mm gel at 20 mA (80 to 200 V). Overnight separations of ~12 hr require 4 mA per 0.75-mm gel. It takes 4 to 5 hr to run a 1.5-mm gel at 30 mA. Electrophoresis is normally performed at 15° to 20°C, with the temperature held constant using a circulating water bath. For air-cooled electrophoresis units, lower currents and thus longer run times are recommended.

It takes ~1 hr to run a 0.75-mm minigel at 20 mA (100 to 120 V). Separation times are not significantly different for gradient minigels.

Spectrophotometric Determination of Protein Concentration

This unit describes spectrophotometric methods for measuring the concentration of a sample protein in solution. In Basic Protocol 1, absorbance measured at 280 nm (A_{280}) is used to calculate protein concentration by comparison with a standard curve or published absorptivity values for that protein (a_{280}). In the Alternate Protocol, absorbance measured at 205 nm (A_{205}) is used to calculate the protein concentration. The A_{280} and A_{205} methods can be used to quantitate total protein in crude lysates and purified or partially purified protein. Both of these methods are simple and can be completed quickly. The A_{280} method is the most commonly used. The A_{205} method can detect lower concentrations of protein and is useful for dilute protein samples, but it is more susceptible to interference by reagents in the protein sample than the A_{280} method. Basic Protocol 2 uses a spectrofluorometer or a filter fluorometer to measure the intrinsic fluorescence emission of a sample solution; this value is compared with the emissions from standard solutions to determine the sample concentration. The fluorescence emission method is used to quantitate purified protein. This simple method is useful for dilute protein samples and can be completed in a short amount of time.

USING A_{280} TO DETERMINE PROTEIN CONCENTRATION

BASIC PROTOCOL 1

Determination of protein concentration by measuring absorbance at 280 nm (A_{280}) is based on the absorbance of UV light by the aromatic amino acids, tryptophan and tyrosine, and by cystine, disulfide-bonded cysteine residues, in protein solutions. The measured absorbance of a protein sample solution is used to calculate the concentration either from its published absorptivity at 280 nm (a_{280}) or by comparison with a calibration curve prepared from measurements with standard protein solutions. This assay can be used to quantitate solutions with protein concentrations of 20 to 3000 μg/ml.

Materials

3 mg/ml standard protein solution (see recipe; optional)
Sample protein
Spectrophotometer with UV lamp

1. For calibrating with standards, use the 3 mg/ml standard protein solution to prepare dilutions of 20, 50, 100, 250, 500, 1000, 2000, and 3000 μg/ml in the same solvent as used to prepare the sample protein. Prepare a blank consisting of solvent alone.

   Ideally, for purified or partially purified protein, the protein standard should have an aromatic amino acid content similar to that of the sample protein. For the total protein of a crude lysate, bovine serum albumin (BSA) is a commonly used standard for spectrophotometric quantitation of protein concentration. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 280 nm. Allow the instrument to warm up 30 min before taking measurements.

3. Zero the spectrophotometer with the solvent blank.

4. Measure the absorbance of the protein standard and unknown solutions.

   If the A_{280} of the sample protein is >2.0, dilute the sample further in the same solvent and measure the A_{280} again.

Contributed by Michael H. Simonian
Current Protocols in Toxicology (2004) A.3G.1-A.3G.7

5a. *If the a_{280} of the protein is known:* Calculate the unknown sample concentration from its absorbance value using Equation A.3G.1.

In this equation a_{280} has units of ml/mg cm and b is the path length in cm.

$$\text{concentration (mg/ml)} = \frac{A_{280}}{a_{280} \times b}$$

Equation A.3G.1

5b. *If standard solutions are used for quantitation:* Create a calibration curve by either plotting or performing regression analysis of the A_{280} versus concentration of the standards. Use the absorbance of the sample protein to determine the concentration from the calibration curve.

ALTERNATE PROTOCOL

USING A_{205} TO DETERMINE PROTEIN CONCENTRATION

Determination of protein concentration by measurement of absorbance at 205 nm (A_{205}) is based on absorbance by the peptide bond. The concentration of a protein sample is determined from the measured absorbance and the absorptivity at 205 nm (a_{205}). This assay can be used to quantitate protein solutions with concentrations of 1 to 100 μg/ml protein.

Additional Materials *(also see Basic Protocol 1)*

Brij 35 solution: 0.01% (v/v) Brij 35 (Sigma) in an aqueous solution appropriate for dissolving or diluting the sample protein

1. Dissolve or dilute the protein sample in Brij 35 solution.
2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 205 nm. Allow the instrument to warm up 30 min before taking measurements.
3. Zero the spectrophotometer with the Brij 35 solution alone.
4. Measure the absorbance of the sample protein.

5a. *If the a_{205} of the protein is known:* Use Equation A.3G.1 to calculate the concentration of the sample protein *except* substitute the appropriate values for A_{205} and a_{205}.

5b. *If the a_{205} is not known:* Estimate the concentration of the sample protein from its measured absorbance using Equation A.3G.2.

$$\text{concentration (mg/ml)} = \frac{A_{205}}{31 \times b}$$

Equation A.3G.2

In this equation, the absorptivity value, 31, has units of ml/mg cm and b is the path length in cm.

USING FLUORESCENCE EMISSION TO DETERMINE PROTEIN CONCENTRATION

Protein concentration can also be determined by measuring the intrinsic fluorescence based on fluorescence emission by the aromatic amino acids tryptophan, tyrosine, and/or phenylalanine. Usually tryptophan fluorescence is measured. The fluorescence intensity of the protein sample solution is measured and the concentration calculated from a calibration curve based on the fluorescence emission of standard solutions prepared from the purified protein. This assay can be used to quantitate protein solutions with concentrations of 5 to 50 μg/ml.

Materials

Standard protein solution prepared using the purified protein (see recipe)
Sample protein
Spectrofluorometer *or* filter fluorometer with an excitation cutoff filter ≤285 nm and an emission filter >320 nm

1. Prepare dilutions of the purified protein at 5, 7.5, 10, 25, and 50 μg/ml in the same solvent as the sample protein. Prepare a blank consisting of solvent alone.
2. Turn on the lamp of the instrument and allow it to warm up 30 min before taking measurements.

   If a spectrofluorometer is used, set the excitation wavelength to 280 nm and the emission wavelength to between 320 and 350 nm. If the exact emission wavelength is not known, determine it empirically by scanning the standard solution with the excitation wavelength set to 280 nm. If the instrument is a filter fluorometer, use an excitation cutoff filter ≤285 nm and an emission filter >320 nm.
3. Zero the instrument with the solvent blank.
4. Measure the fluorescence of the protein standard and sample protein solutions.
5. Create a calibration curve by either plotting or performing regression analysis of the fluorescence intensity versus concentration of the standards. Using the fluorescence intensity of the sample protein, determine the concentration from the calibration curve.

   Fluorescence emission is a linear function of concentration only over a limited range.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent for the preparation of all recipes and in all steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Standard protein solution, 3 mg/ml

Weigh out dry protein and prepare a stock solution at a concentration of 3 mg/ml in the same solvent as used for the sample protein. Store up to 3 months at −20°C.
To prepare calibration standard solutions, dilute the stock solution in solvent to give the desired final concentrations for the standard curve.

Bovine serum albumin (BSA, fraction V; Sigma) is frequently used for a protein standard solution. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

For quantitation of a purified or partially purified protein, if possible, the protein standard should have an aromatic amino acid content similar to that of the sample protein.

COMMENTARY

Background Information

Measuring absorbance at 280 nm (A_{280}) is one of the oldest methods for determining protein concentration (Warburg and Christian, 1942; Layne, 1957). This method is still widely used because it is simple and does not require incubating the sample with exogenous chromophores. However, the detection limit is higher than colorimetric methods and therefore higher concentrations of protein are necessary. The A_{280} method requires that the protein being quantitated have aromatic amino acids, primarily tryptophan. Because of the variability in aromatic amino acid content among different proteins, their absorptivity at 280 nm (a_{280}) also varies. Therefore, if calibration standards are used for quantitation, the aromatic amino acid content of the standard must be similar to that of the sample protein for accurate results. For many previously studied proteins, the a_{280} is known and can be obtained from the literature (Fasman, 1989).

If the absorptivity is not known but the amino acid composition is known, the molar absorptivity at 280 nm (ε_{280}) can be predicted from Equation A.3G.3 (Pace et al., 1995):

$$\varepsilon_{280} = (\text{no. of Trp})(5500) + (\text{no. of Tyr})(1490) + (\text{no. of cystine})(125)$$

Equation A.3G.3

In this equation, the number of tryptophan (Trp), tyrosine (Tyr), and cystine residues are each multiplied by an estimated ε_{280} value for each residue. This equation was derived for folded proteins in water. With the DNA sequence for many proteins now available, the predicted ε_{280} can be derived for newer proteins where this value is not published. However, there are caveats that should be considered if the predicted ε_{280} in Equation A.3G.3 is used. First, the predicted ε_{280} is most reliable if the protein contains tryptophan residues and less so if there are no tryptophan residues. Second, the number of cystine residues must be accurately known and one cannot presume that all cysteine residues, to an even number, are involved in disulfide bonds. Alternatively, there are methods for measuring the ε_{280} value that are reliable (Pace et al., 1995).

Accordingly, the quantitation of proteins by peptide bond absorption at 205 nm (A_{205}) is more universally applicable among proteins. Furthermore, the absorptivity for a given protein at 205 nm is several-fold greater than that at 280 nm (Scopes, 1974; Stoscheck, 1990). Thus lower concentrations of protein can be quantitated with the A_{205} method. The disadvantage of this method is that some buffers and other components absorb at 205 nm (Stoscheck, 1990).

In addition to the aromatic amino acids, several others have absorption maxima in the UV range. Table A.3G.1 shows the wavelengths of absorption maxima and corresponding molar absorptivity (ε) for the amino acids with appreciable absorbance in the UV range. Only

Table A.3G.1 Absorption Maxima and Molar Absorptivity (ε) of Amino Acids[a]

Amino acid	Wavelength maxima (nm)	$\varepsilon \times 10^{-3}$ (l/mol cm)
Cysteine	250	0.3
Histidine	211	5.9
Phenylalanine	188	60.0
	206	9.3
	257	0.2
Tryptophan	219	47.0
	279	5.6
Tyrosine	193	48.0
	222	8.0
	275	1.4

[a]Values are for aqueous solutions at pH 7.1 (Freifelder, 1982; Fasman, 1989).

Table A.3G.2 Molar Absorptivity (ε) of Amino Acids at 280 nm[a]

Amino acid	$\varepsilon \times 10^{-3}$ (l/mol cm)
Cystine	0.110
Phenylalanine	0.0007
Tryptophan	5.559
Tyrosine	1.197

[a]Values are for aqueous solutions at pH 7.1 except for cystine, which is for water (Fasman, 1989).

Table A.3G.3 Fluorescence Properties of Aromatic Amino Acids[a]

Amino acid	Excitation wavelength	Emission wavelength	Quantum yield
Phenylalanine	260 nm	283 nm	0.04
Tryptophan	285 nm	360 nm	0.20
Tyrosine	275 nm	310 nm	0.21

[a]Values are for aqueous solutions at pH 7 and 25°C (Hawkins and Honigs, 1987; Fasman, 1989).

tryptophan has an absorption maximum at 280 nm, although, tyrosine and cystine will also slightly absorb. The ε_{280} for tryptophan is nearly five-fold greater than that for tyrosine and 50-fold greater than that for cystine (Table A.3G.2). The contribution to the absorbance at 280 nm of the third aromatic amino acid, phenylalanine, and cysteine are negligible. Several amino acids other than those in Table A.3G.1 absorb light below 205 nm (Fasman, 1989), but either the molar absorptivities are too low to be significant or the wavelengths are too short for practical absorbance measurements.

The aromatic amino acids also have fluorescence emissions when excited by light in the UV range. Table A.3G.3 gives the excitation wavelength, fluorescence emission wavelength, and quantum yield (Q) for tryptophan, tyrosine, and phenylalanine. The quantum yield is the ratio of photons emitted to photons absorbed. Typically, phenylalanine fluorescence is not detected in the presence of tyrosine and tryptophan due to low Q. Furthermore, tyrosine fluorescence is nearly completely quenched if the tyrosine residue is ionized or near an amino group, a carboxyl group, or a tryptophan residue (Teale, 1960; Freifelder, 1982). Therefore, tryptophan fluorescence is what is customarily measured.

Measurement of intrinsic fluorescence by aromatic amino acids is primarily used to obtain qualitative information (Freifelder, 1982). However, with a protein standard whose aromatic amino acid content is similar to that of the sample, intrinsic fluorescence can be used for quantitation (Hawkins and Honigs, 1987). An additional consideration is that the tertiary structure of a protein will influence the fluorescence, e.g., adjacent protonated acidic groups in a protein molecule will quench tryptophan fluorescence (Freifelder, 1982).

Critical Parameters and Troubleshooting

A 1-cm path length quartz cuvette is most often used to make absorbance measurements. However, quartz cuvettes with shorter path lengths, 0.01 to 0.5 cm, are available (e.g., from Hellma Cells or Beckman); these shorter path length cuvettes allow higher concentrations of protein solutions to be measured. Equation A.3G.1 and Equation A.3G.2 assume the cuvette has a path length of 1 cm; when cuvettes of shorter path length are used, the correct value for b must be substituted in the equation.

The solvent pH and polarity will affect the absorbance and fluorescence properties of a protein. A notable example of pH effects on absorbance is seen with tyrosine residues, where a change in pH from neutral to alkaline results in a shift of the absorbance maximum to a longer wavelength and an increase in absorptivity due to dissociation of the tyrosine phenolic hydroxyl group (Freifelder, 1982; Fasman, 1989). An example of solvent polarity effects on fluorescence is observed with tryptophan,

Table A.3G.4 Concentration Limits of Interfering Reagents for A_{205} and A_{280} Protein Assays[a]

Reagent[b]	A_{205}	A_{280}
Ammonium sulfate	9% (w/v)	>50% (w/v)
Brij 35	1% (v/v)	1% (v/v)
DTT	0.1 mM	3 mM
EDTA	0.2 mM	30 mM
Glycerol	5% (v/v)	40% (v/v)
KCl	50 mM	100 mM
2-ME	<10 mM	10 mM
NaCl	0.6 M	>1 M
NaOH	25 mM	>1 M
Phosphate buffer	50 mM	1 M
SDS	0.10% (w/v)	0.10% (w/v)
Sucrose	0.5 M	2 M
Tris buffer	40 mM	0.5 M
Triton X-100	<0.01% (v/v)	0.02% (v/v)
TCA	<1% (w/v)	10% (w/v)
Urea	<0.1 M	>1 M

[a]Values from Stoscheck (1990).
[b]Abbreviations: DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; 2-ME, 2-mercaptoethanol; SDS, sodium dodecyl sulfate; TCA, trichloroacetic acid.

where a decrease in solvent polarity results in a shift in fluorescence emission to shorter wavelengths and an increase in intensity (Freifelder, 1982). Because of these effects, the following precautions should be taken for accurate results: (1) when calibration curves are used for quantitation by absorbance or fluorescence, standards must be in the same solvent as the samples; and (2) when a published absorptivity at a given wavelength is used for quantitation, the solvent composition of the sample must be the same as that used in obtaining the published data.

Many buffers and other reagents can interfere with A_{280} and A_{205} spectrophotometric measurements. Stoscheck (1990) lists the concentration limits for many such reagents used in these spectrophotometric methods. The more commonly used reagents that absorb at 280 and 205 nm are listed in Table A.3G.4. In addition, reagents that contain carbon-carbon or carbon-oxygen double bonds can interfere with the A_{205} method.

Because stray light can affect the linearity of absorbance versus concentration, absorbance values >2.0 should not be used for sample proteins measured by the A_{280} or A_{205} method. Samples with absorbance >2.0 should be diluted further in the appropriate buffer to obtain absorbances <2.0.

Nucleic acids have substantial absorbance at 280 nm and can interfere with A_{280} quantitation of protein in crude samples. To resolve the protein concentration in such samples, measure the absorbance at 260 nm and 280 nm and calculate the protein concentration as follows (Warburg and Christian, 1942; Layne, 1957): protein concentration (mg/ml) = $1.55 \times A_{280} - 0.76 \times A_{260}$.

This estimation of protein concentration is valid up to 20% (w/v) nucleic acid or an A_{280}/A_{260} ratio <0.6.

Anticipated Results

Depending on the protein, the concentration range for the A_{280} method is 20 to 3000 μg/ml, for the A_{205} method is 1 to 100 μg/ml, and for the fluorescence emission method is 5 to 50 μg/ml.

Published absorptivities of proteins at 280 nm are usually given as the absorbance for a 1% (w/v) protein solution per cm, $A^{1\%}$, or as the molar absorptivity, ε, which has units of l/mol cm. To convert these published

coefficients to units of mg/ml, use either Equation A.3G.4 or Equation A.3G.5.

$$\text{concentration (mg/ml)} = \frac{A_{280} \times 10}{A^{1\%} \times b}$$

Equation A.3G.4

Molecular weight in Equation A.3G.5 is the molecular weight of the protein.

$$\text{concentration (mg/ml)} = \frac{A_{280} \times \text{molecular weight}}{\varepsilon_{280} \times b}$$

Equation A.3G.5

Time Considerations

When the absorptivity for a protein is known, the A_{280} and A_{205} measurements require <30 min depending on the number of samples. When standards are used for quantitation with these assays or for intrinsic fluorescence quantitation, 1 hr is required.

Dialysis and Concentration of Protein Solutions

DIALYSIS

Conventional dialysis separates small molecules from large molecules by allowing diffusion of only the small molecules through selectively permeable membranes. Dialysis is usually used to change the salt (small-molecule) composition of a macromolecule-containing solution. The solution to be dialyzed is placed in a sealed dialysis membrane and immersed in a selected buffer; small solute molecules then equilibrate between the sample and the dialysate. Concomitant with the movement of small solutes across the membrane, however, is the movement of solvent in the opposite direction. This can result in some sample dilution (usually <50%).

This unit describes dialysis of large- and small-volume samples using cellulose membranes with pore sizes designed to exclude molecules above a selected molecular weight (see Basic Protocol 1 and Alternate Protocol). The Support Protocol describes preparation of membranes for dialysis and discusses issues related to the selection of membranes including commercial kits. Solutions of proteins or peptides can be concentrated using commercially available reagents (see Basic Protocol 2).

Large-Volume Dialysis

BASIC PROTOCOL 1

This protocol describes the use of membranes, prepared using the Support Protocol, for dialysis of samples in large, easily handled volumes, typically 0.1 to 500 ml.

Materials

Dialysis membrane (see Support Protocol)
Clamps (Spectra/Por Closures, Spectrum, or equivalent)
Macromolecule-containing sample to be dialyzed
Appropriate dialysis buffer

1. Remove dialysis membrane from ethanol storage solution and rinse with distilled water. Secure clamp to one end of the membrane or knot one end with double-knots.

   Always use gloves to handle the dialysis membrane because the membrane is susceptible to cellulolytic microorganisms.

   See Support Protocol for a discussion of commercially available membranes and preparation and storage procedures.

   Clamps are less likely to leak than knots, but either type of closure should be carefully tested as described in steps 2 and 3.

2. Fill membrane with water or buffer, hold the unclamped end closed, and squeeze membrane. A fine spray of liquid indicates a pinhole in the membrane; discard and try a new membrane.

   Pinholes are rare but cause traumatic sample loss. Hard squeezing will cause some liquid to seep from the bag; this is normal.

3. Replace the water or buffer in dialysis membrane with the macromolecule-containing sample and clamp the open end. Again, squeeze to check the integrity of the membrane and clamps.

   If dialyzing a concentrated or high-salt sample, leave some space in the clamped membrane; there will be a net flow of water into the sample, and if sufficient pressure builds up the membrane can burst.

Contributed by Sarah M. Andrew, Julie A. Titus, and Louis Zumstein
Current Protocols in Toxicology (2001) A.3H.1-A.3H.5

4. Immerse dialysis membrane in a beaker or flask containing a large volume (relative to the sample) of the desired buffer. Dialyze at least 3 hr at the desired temperature with gentle stirring of the buffer.

   Dialysis rates are dependent on membrane pore size, sample viscosity, and ratio of membrane surface to sample volume. Temperature has little effect on dialysis rate, but low temperatures (i.e., 4°C) are usually chosen to enhance macromolecule stability. Common salts will equilibrate across a 15,000-MWCO membrane (see Support Protocol) in ~3 hr with stirring.

   Some compounds, especially detergents above their critical micelle concentration (CMC), dialyze very slowly.

5. Change dialysis buffer as necessary.

   Usually two to three dialysis buffer changes are sufficient. For example, when 100 mM Tris·Cl is removed from a protein for sequence analysis or other amino-reactive chemistry, two equilibrations against a 1000-fold volume excess of buffer will decrease the Tris concentration 10^6-fold, to 100 nM; three dialyses will decrease the concentration to 100 pM.

6. Remove dialysis membrane from the buffer. Hold the membrane vertically and remove excess buffer trapped in end of membrane outside upper clamp. Release upper clamp and remove the sample with a Pasteur pipet.

ALTERNATE PROTOCOL

Small-Volume Dialysis

For solution volumes less than ~100 µl, the use of dialysis membrane as described above can result in unacceptable sample loss. The method described below can easily dialyze volumes as small as 10 µl. The sample is held in a 0.5-ml microcentrifuge tube, with dialysis membrane covering the open end of the tube.

Additional Materials *(also see Basic Protocol 1)*

0.5-ml microcentrifuge tube
Pasteur pipet
Cork borer

1. Puncture the lid of each microcentrifuge tube using a heated glass Pasteur pipet (wide end heated) or cork borer to completely remove the center part of the lid (see Fig. A.3H.1). Open lid and place a single layer of dialysis tubing over top of tube, then close lid to hold dialysis tubing in place.

   The success of this protocol is dependent on a tight-fitting cap, so make sure the cap is well-seated. On the other hand, an excessively tight-fitting cap can rip the membrane when it is inserted.

   Alternatively, some researchers use a microcentrifuge tube without a cap. The sample is placed in the microcentrifuge tube, a dialysis membrane is placed over the top of the tube, and the membrane is secured with a rubber band. With this method, however, there is a risk that a small sample—e.g., 10 to 20 µl—may be lost around the edge of the tube.

2. Turn tube upside down and shake reaction mixture onto the membrane surface. Tape each tube, dialysis surface down, to the side of a beaker, then fill the beaker with PBS or buffer of choice. Dialyze 2 hr at 4°C with stirring.

   Alternatively, place the tube in a styrofoam or foam sheet (e.g., foam microcentrifuge rack, Fisher) then place, with the tube inverted, on the surface of the dialysis buffer.

   Make sure the dialysis surface is in contact with the buffer and that no bubbles exist. This can be accomplished by gently centrifuging the tube in an inverted position in a tabletop centrifuge.

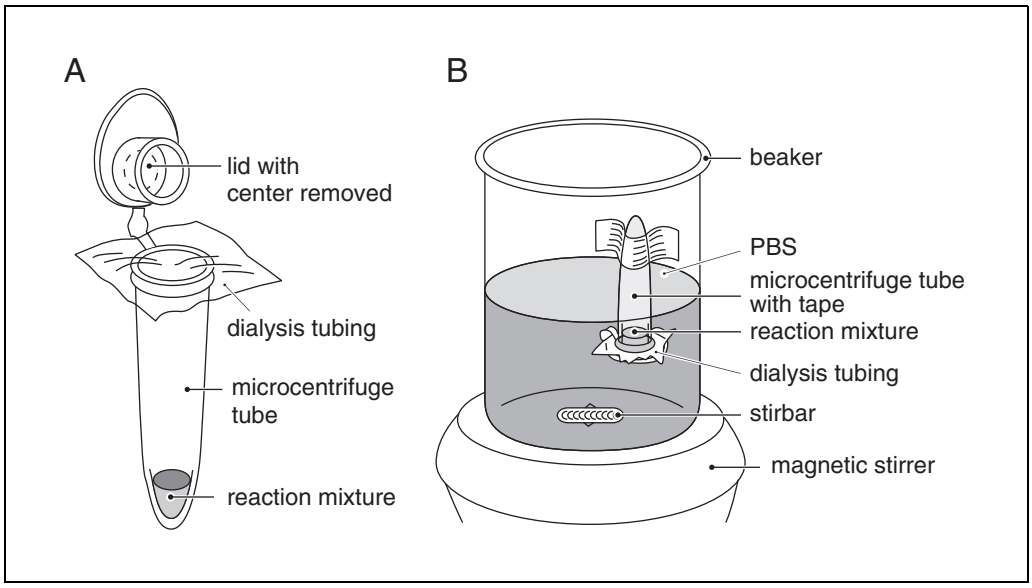

Figure A.3H.1 Making a microdialysis chamber. (**A**) Remove the center of the cap of a microcentrifuge tube with a heated Pasteur pipet (wide end). Place reaction mixture to be dialyzed into the tube. Place a piece of softened dialysis membrane loosely over top of tube. (**B**) Invert tube, shake sample down onto dialysis membrane (or centrifuge the tube inverted, if the sample is small), and tape tube into a beaker of buffer. Check that no bubbles are caught under the membrane.

The microdialysis method can be used for volumes of 50 to 500 µl (larger volumes can be dialyzed using a 1.5-ml microcentrifuge tube). The protein concentration is not important but should be 0.1 to 10 mg/ml. Most dialysis is complete after 2 hr but because proteins have a high buffering capacity, use 4 hr for a high protein concentration.

3. To recover the sample, remove microcentrifuge tube from the buffer and centrifuge briefly right-side-up.

Commercially available alternatives to this method include use of individual hollow-fiber filters from Spectrum (with sample capacities of 1 to 140 µl), and many different microdialysis machines, both single-sample and multisample (Spectrum, Cole-Parmer, Amersham Pharmacia Biotech, and others).

Selection and Preparation of Dialysis Membrane

SUPPORT PROTOCOL

Dialysis membranes are available in a number of thicknesses and pore sizes. Thicker membranes are tougher, but restrict solute flow; thus equilibrium is reached more slowly. Pore size is defined by "molecular weight cutoff" (MWCO)—i.e., the size of the smallest particle that cannot penetrate the membrane. The MWCO designation should be used only as a very rough guide; if accurate MWCO information is required, it should be determined empirically (see Craig, 1967, for a discussion of parameters affecting MWCO). Knowledge of the precise MWCO is usually not required; it is necessary only to use a membrane with a pore size that is much smaller than the macromolecule of interest. For most plasmid and protein dialyses, a MWCO of 12,000 to 14,000 is appropriate, whereas a MWCO of 3500, 2000, or even 1000 is appropriate for peptides.

Most dialysis membranes are made of derivatives of cellulose. They come in a wide variety of MWCO values, ranging from 500 to 500,000, and also vary in cleanliness, sterility, and cost. Spectrum has the most impressive inventory. The least expensive membranes come dry on rolls; these contain glycerol to keep them flexible as well as residual sulfides and traces of heavy metals from their manufacture. If glycerol, sulfur compounds, or small amounts of heavy metals are problematic, cleaner membranes should be purchased or

membranes should be prepared as described below. Protein dialysis should only be done with clean membranes.

It should be noted that several commercial kits for performing either large-scale or microdialysis are also available. For example, use of microdialysis cassettes (Slide-A-Lyzer, Pierce; or Dispo-Dialyzer, Spectrum) eliminates the need for boiling or presoaking dialysis tubing as well as the cumbersome task of clamping the dialysis tubing. Other vendors provide vessels for dialyzing multiple samples simultaneously. Selection of the best dialysis approach to be used will depend on a number of factors including the volumes to be dialyzed, the MWCO appropriate for the sample, and, of course, costs when considering the use of kits.

Materials

Dialysis membrane
10 mM sodium bicarbonate
10 mM Na_2EDTA, pH 8.0
20% to 50% (v/v) ethanol

1. Remove membrane from the roll and cut into usable lengths (usually 8 to 12 in.).

   Always use gloves to handle dialysis membrane as it is susceptible to a number of cellulolytic microorganisms. Membrane is available as sheets or preformed tubing.

2. Wet membrane and boil it for several minutes in a large excess of 10 mM sodium bicarbonate.
3. Boil several minutes in 10 mM Na_2EDTA. Repeat.

   Boiling speeds up the treatment process but is not necessary. A 30-min soak with some agitation can substitute for the boiling step.

4. Wash several times in distilled water.
5. Store at 4°C in 20% to 50% ethanol to prevent growth of cellulolytic microorganisms.

   Alternatively, bacteriostatic agents (e.g., sodium azide or sodium cacodylate) may be used for storage; however, ethanol is preferred for ease and convenience.

BASIC PROTOCOL 2

CONCENTRATION

Because it is usually more convenient to store antibodies or other proteins at >1 mg/ml, it may be necessary to concentrate the solution. In addition, concentration of protein solutions is often necessary to decrease the volume of a sample; e.g., to load onto a size-exclusion column when the volume must be ≤5 ml.

There are several simple and relatively inexpensive methods for concentrating protein solutions. Dialysis against Aquacide 11A (Calbiochem), which removes water through the dialysis tubing, may be used. After concentration, the solution must be redialyzed into the appropriate buffer. Another method is to use Immersible-CX Ultrafilters (Millipore) which, when connected to a vacuum, remove everything below their molecular weight cutoff (MWCO).

Alternatively, centrifugal concentrators which are operated with the aid of ordinary laboratory centrifuges may be used. Centricon microconcentrators (Amicon), which are available in different MWCO sizes, are very useful for concentrating small amounts of material in small volumes. Follow the instructions from the manufacturer when using these devices. Centriprep Centrifugal Filter Devices (Millipore) are disposable ultrafiltration devices used for purifying, concentrating, and desalting biological samples in the 2 to 15 ml volume range and are designed for use with most centrifuges that can accommodate 50-ml centrifuge tubes. Further description of these devices and instructions for their use are available at *http://www.millipore.com*.

The Colorimetric Detection and Quantitation of Total Protein

Protein quantification is an important step for handling protein samples for isolation and characterization, and is a prerequisite step before submitting proteins for chromatographic, electrophoretic, or immunochemical analysis and separation. The methods included in this appendix are colorimetric measurements, whose procedures are fast and simple.

This appendix describes four of the most commonly used total protein assay methods. Three of the four are copper-based assays to quantitate total protein: the Lowry method (see Basic Protocol 1 and Alternate Protocols 1 and 2), the bicinchoninic acid assay (BCA; see Basic Protocol 2 and Alternate Protocols 3 and 4), and the biuret method (see Basic Protocol 3 and Alternate Protocol 5). The fourth is the Coomassie dye binding or Bradford assay (see Basic Protocol 4 and Alternate Prortocols 6 and 7), which is included as a simple and sensitive assay, although it sometimes gives a variable response depending on how well or how poorly the protein binds the dye in acidic pH. A protein assay method should be chosen based on the sensitivity and accuracy of method as well as the condition of the sample to be analyzed.

STRATEGIC PLANNING

Colorimetric Protein Assays

The four colorimetric methods for the detection and quantitation presented in this appendix have withstood the test of time. They are all well-characterized robust assays that consistently work well. The methods were introduced over the past 15 to 50 years. They collectively represent the state of the art for colorimetric detection and quantitation of total proteins in the microgram to milligram range.

When confronted with the need to determine the total protein concentration of a sample, one of the first issues to consider is selection of a protein assay method. The choice among the available protein assays usually is made based upon consideration of the compatibility of the method with the samples to be assayed. The objective is to select a method that requires the least manipulation or pretreatment of the samples due to the presence of substances that may interfere. If the total protein concentration in the samples is high (i.e., in the range of 5 to 160 mg/ml), the biuret total protein reagent is the best choice. If the total protein concentration in the samples is low (i.e., in the range of 1 to 2000 μg/ml), then any one of the other three (i.e., the Lowry, the Coomassie Plus, or the BCA method) would be suitable. If the sample contains reducing agents or copper-chelating reagents, the Coomassie Plus Protein Assay Reagent (Pierce) would be the best choice. If the sample contains one or more detergents (at concentrations up to 5%), the BCA Protein Assay Reagent is the best choice.

Sometimes the sample contains substances that make it incompatible with any of the protein assay methods. In those cases, some pretreatment of the sample is necessary.

Each method has its advantages and disadvantages. No one method can be considered to be the ideal or best protein assay method. Because of this, most researchers keep more than one type of protein assay reagent available in their laboratory.

Contributed by Randall I. Krohn
Current Protocols in Toxicology (2005) A.3I.1-A.3I.28

Selection of the Protein Standard

The selection of a protein standard is potentially *the* greatest source of error in any protein assay. Of course, the best choice for a standard is a highly purified version of the predominant protein found in the samples. This is not always possible nor always necessary. In some cases, all that is needed is a rough estimate of the total protein concentration in the sample. For example, in the early stages of purifying a protein, identifying which fractions contain the most protein may be all that is required. If a highly purified version of the protein of interest is not available or it is too expensive to use as the standard, the alternative is to choose a protein that will produce a very similar color response curve with the selected protein assay method.

For general protein assay work, bovine serum albumin (BSA) works well as the choice for a protein standard, because it is widely available in high purity and relatively inexpensive. Although it is a mixture containing several immunoglobulins, bovine gamma globulin (BGG) is also a good choice for a standard when determining the concentration of antibodies, since BGG produces a color response curve that is very similar to that of immunoglobulin G (IgG).

For greatest accuracy of the estimates of the total protein concentration in unknown samples, it is essential to include a standard curve in each run. This is particularly true for the protein assay methods that produce nonlinear standard curves (e.g., Lowry method, Coomassie dye–binding method). The decision about the number of standards used to define the standard curve and the number of replicates to be done on each standard depends upon the degree of nonlinearity in the standard curve and the degree of accuracy required of the results. In general, fewer points are needed to construct a standard curve if the color response curve is linear. For assays done in test tubes, duplicates are sufficient; however, triplicates are recommended for assays performed in microtiter plates due to the increased error associated with microtiter plates and microtiter plate readers.

Preparation of the Samples

Before a sample can be analyzed for total protein content, it must be solubilized, usually in a buffered aqueous solution. The entire process is usually done in the cold, with additional precautions taken to inhibit microbial growth or to avoid casual contamination of the sample by foreign debris such as hair, skin, or body oils. When working with tissues, cells, or solids, the first step of the solubilization process is usually disruption of the sample's cellular structure by grinding and/or sonication, or by the use of specially designed reagents containing surfactants to lyse the cells (i.e., the POPPERS line of products, available from Pierce). This is done in a cold aqueous buffer containing one or more surfactants (to aid the solubilization of the membrane-bound proteins), one or more biocides (to prevent microbial growth), and protease inhibitors (to minimize or prevent digestion of the proteins into peptide fragments by endogenous proteases). After filtration or centrifugation (to remove the cellular debris), additional steps such as sterile filtration, removal of lipids, or further purification of the protein of interest from the other sample components may be necessary.

Calculation of the Results

If calculating the protein concentrations manually, it is best to use point-to-point interpolation. This is especially true if the standard curve is nonlinear. Point-to-point interpolation refers to a method of calculating the results for each sample using the equation for a linear regression line obtained from just two points on the standard curve. The first point is the standard that has an absorbance just below that of the sample and the second point is the standard that has an absorbance just above that of the sample. In this way, the

concentration of each sample is calculated from the most appropriate section of the whole standard curve. The average total protein concentration for each sample is determined from the average of its replicates. If multiple dilutions of each sample have been run, the results for the dilutions that fall within the most linear portion of the working range are averaged.

If using a computer program, use a quadratic curve fit for the nonlinear standard curve to calculate the protein concentration of the samples. If the standard curve is linear or if the absorbance readings for the samples fall within the linear portion of the standard curve, the total protein concentrations of the samples can be estimated using the linear regression equation.

Most software programs will allow the experimenter to construct and print a graph of the standard curve as well as calculate the protein concentration for each sample and display statistics for the replicates. Typically, the statistics displayed will include the average of the absorbance readings (or the average of the calculated protein concentrations), the standard deviation (SD), and the coefficient of variation (CV) for each standard or sample. If multiple dilutions of each sample have been run, average the results for the dilutions that fall in the most linear portion of the working range.

THE LOWRY PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEINS

BASIC PROTOCOL 1

In 1951, Oliver H. Lowry introduced this colorimetric total protein assay method. It offered a significant improvement over previous protein assays, and his paper became one of the most cited references in the life-science literature (Lowry et al., 1951). The Lowry assay is easy to perform since the incubations are done at room temperature and the assay is sensitive enough to allow the detection of total protein in the low microgram per milliliter range. It is one of three copper chelation chemistry–based methods presented in this appendix. Essentially, the Lowry protein assay is an enhanced biuret assay (see Basic Protocol 3). After a short incubation, Lowry's reagent C (Folin phenol) is added for enhanced color development (Fig. A.3I.1). The Lowry assay requires fresh (daily) preparation of two reagents and a meticulously timed incubation step. The two reagents are combined just before use to make a buffered alkaline cupric sulfate working solution. The addition of sodium dodecyl sulfate (SDS) to Lowry's reagent D (i.e., Lowry's reagent D′) allows the method to be used with samples that contain detergents.

Materials

Standard protein: 2 mg/ml BSA (see recipe)
Sample buffer or solvent
Protein sample(s)
Lowry's Reagents C and D or D′ (see recipes)

1. Dispense 0 to 100 µl standard protein to appropriately labeled tubes and bring the total volume to 100 µl with sample buffer or solvent to prepare a dilution series from 10 to 100 µg.

   These concentrations of albumin should produce A_{750} readings from ~0.10 to 1.0 AU in 1-cm cuvettes.

2. Dispense ≤100 µl protein sample(s) to separate labeled tubes and adjust the final volume to 100 µl using the same buffer or solvent used to prepare the sample.

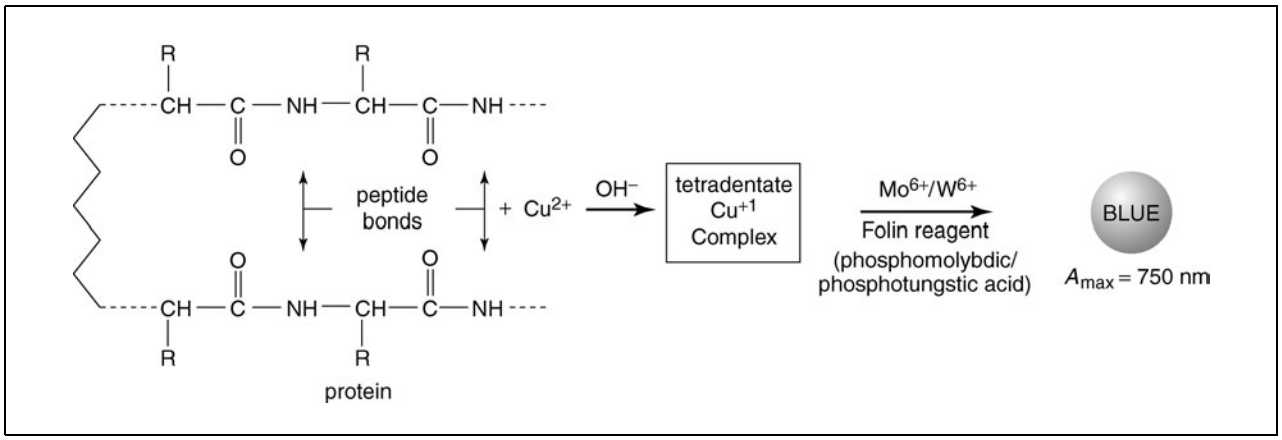

Figure A.3I.1 The reaction schematic for the Lowry Protein Assay.

3. Add 1 ml reagent D (or reagent D′) to each of the standards and unknown samples. Vortex the tubes immediately to develop optimum color. Incubate for precisely 10 min at room temperature.

   If samples contain detergent, use reagent D′ to eliminate the interference associated with up to 1% of various detergents. If a precipitate forms in reagent D′, warm the reagent and vortex before addition.

4. While mixing, add 0.1 ml reagent C. Vortex the tubes immediately. Incubate for 30 min at room temperature.

5. Measure the color at 750 nm (A_{750}) on a spectrophotometer zeroed with deionized water.

   Read samples within 10 min, as samples continue to develop color. Samples incubated >60 min should be discarded.

   If the absorbance reading of the sample is higher than that of the highest concentration of standard, dilute the sample with buffer and repeat the procedure on the diluted sample.

6. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each standard versus its protein concentration in milligrams per milliliter.

7. Determine sample protein concentration by interpolating from the standard curve (see Strategic Planning).

ALTERNATE PROTOCOL 1

MODIFIED LOWRY PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEINS

Preformulated, stabilized, modified versions of the Lowry reagent are now commercially available from Pierce (the Modified Lowry Protein Assay Reagent) or from Bio-Rad (the DC Protein Assay). The assay can be performed in test tubes or a microtiter plate (see Alternate Protocol 2). The working range of this assay is 1 to 1500 μg/ml if the Pierce reagent is used, or 200 to 1400 μg/ml if the Bio-Rad reagent is used. Table A.3I.1 is a brief troubleshooting guide for this technique.

Additional Materials *(also see Basic Protocol 1)*

Modified Lowry Protein Assay Kit (Pierce) containing:
2 mg/ml BSA in 0.9% (w/v) NaCl/0.05% (w/v) sodium azide
2 N Folin-Ciocalteu reagent: dilute fresh to 1 N
Modified Lowry's Reagent

Table A.3I.1 Troubleshooting Guide for the Modified Lowry Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains a chelating agent (e.g., EDTA, EGTA)	Dialyze or dilute the sample
		Precipitate the protein with TCA and dissolve the pellet in modified Lowry reagent
Blank A_{750} is normal, but standards show less color than expected	Sample changed the pH of the reagent	Dialyze or dilute the sample
	Color measured at the wrong wavelength	Measure the color at 750 nm
Precipitate forms in all tubes	Sample contains a surfactant (detergent)	Dialyze or dilute the sample
	Sample contains potassium ions	Precipitate the protein with TCA, dissolve the pellet in Modified Lowry Reagent
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample
	Sample contains a thiol	Precipitate the protein with TCA, dissolve pellet in Modified Lowry Reagent
Need to read color at a different wavelength	Colorimeter does not have 750-nm filter	Color may be read at any wavelength between 650 nm and 750 nm

1. Prepare a dilution series of 2 mg/ml BSA (e.g., the standard provided in the Modified Lowry Protein Assay Kit) in buffer to cover the range 2.0 to 1500 μg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. In duplicate, add 200 μl diluted standard, sample, or buffer (blank) into appropriately labeled test tubes.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

3. At 15-sec intervals, add 1.0 ml Modified Lowry Protein Assay Reagent to each of the tubes. Vortex 2 to 3 sec to mix the contents of the tube and incubate at room temperature for *exactly* 10 min.

4. At the end of the first tube's 10-min incubation, add 100 μl freshly diluted 1 N Folin-Ciocalteu reagent (freshly diluted from a 2 N stock). Immediately vortex the tube for 2 to 3 sec. Continue to maintain the 15-sec intervals from step 3 for addition of the reagent to the remaining tubes.

5. Allow each of the tubes to incubate for 30 min at room temperature.

6. Measure the color at 750 nm (A_{750}) on a spectrophotometer zeroed with deionized water.

7. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each BSA standard versus its concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3I.2.

8. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Determine the average total protein concentration for each sample from the average of its replicates.

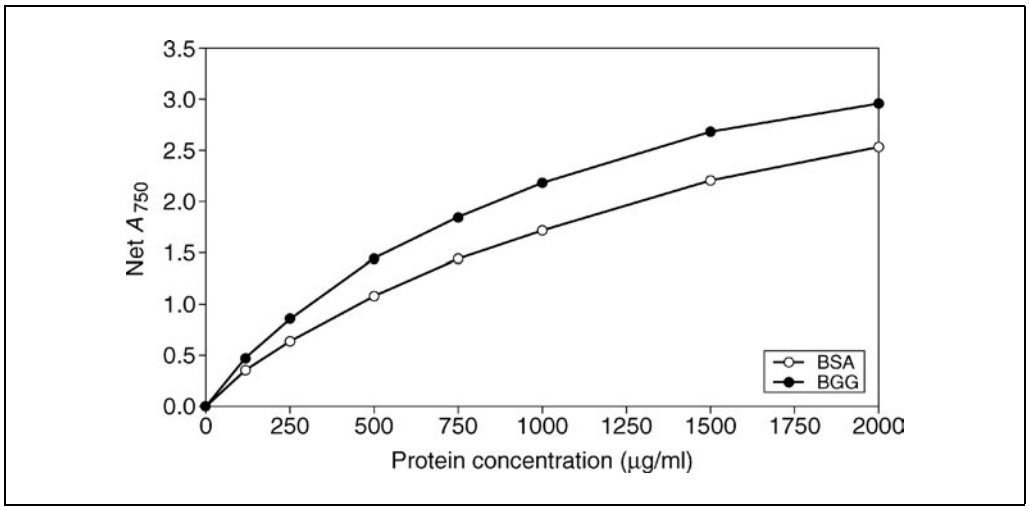

Figure A.3I.2 Graph of the color response curves obtained with Pierce's Modified Lowry Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 750 nm in a Hitachi U-2000 spectrophotometer.

ALTERNATE PROTOCOL 2

MICROTITER PLATE MODIFIED LOWRY ASSAY FOR TOTAL PROTEIN

The modified Lowry assay can also be done in a 96-well microtiter plate format. The assay has a working range of 1 to 1500 µg/ml.

Additional Materials *(also see Alternate Protocol 1)*

Microtiter plate and cover or tape seals
200-µl multichannel pipettor
Microtiter plate reader for 750 nm

1. Draw a template for placement of samples and standards on the microtiter plate.

   Blanks, standards, and samples should be prepared in triplicate.

2. Add 40 µl of each diluted BSA standard (see Alternate Protocol 1, step 1), sample, or diluent (blank) to the appropriate wells of a 96-well plate.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

3. Using a multichannel pipettor, quickly add 200 µl Modified Lowry Protein Assay Reagent to each of the wells. Mix immediately on a plate mixer for 30 sec.

4. Allow the plate to incubate at room temperature for *exactly* 10 min.

5. Using a multichannel pipettor, quickly add 20 µl freshly diluted 1 N Folin-Ciocalteu reagent to each well. Immediately mix on a plate mixer for 30 sec.

6. Cover the plate (to prevent evaporation) and incubate 30 min at room temperature.

7. Mix the plate again and measure the color (absorbance) of each well in a microtiter plate reader at 750 nm.

8. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each standard versus its protein concentration in micrograms per milliliter.

9. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average total protein concentration for each sample from the average of its replicates.

THE BICINCHONINIC ACID (BCA) ASSAY FOR DETERMINATION OF TOTAL PROTEIN

BASIC PROTOCOL 2

Smith et al. (1985) introduced the bicinchoninic acid (BCA) protein assay reagent. In one sense, it is a modification of the Lowry protein assay reagent. The mechanism of color formation with protein for the BCA protein assay reagent is similar to that of the Lowry reagent, but there are several significant differences. The BCA protein assay reagent combines the reduction of Cu^{2+} to Cu^{+} by protein in an alkaline medium (i.e., the biuret reaction; see Basic Protocol 3) with the highly sensitive and selective colorimetric detection of the cuprous cation (Cu^{+}) by bicinchoninic acid.The purple-colored reaction product of this method is formed by the chelation of two molecules of BCA with one cuprous ion (Fig. A.3I.3). The BCA/copper complex is water-soluble and exhibits a strong linear absorbance at 562 nm with increasing protein concentrations. The primary advantage of the BCA protein assay reagent is that most surfactants, even if present in the sample at concentrations up to 5% (v/v), are compatible with this method. Table A.3I.2 is a brief troubleshooting guide for this technique.

Materials

Protein standard: 2 mg/ml BSA (see recipe)
Sample buffer or solvent
Protein sample
BCA working reagent: mix 100 parts BCA reagent A with 2 parts reagent B (see recipes for each reagent)

1. Prepare a dilution series of 2 mg/ml BSA in sample buffer or diluent to cover a range from 125 to 2000 μg/ml.
2. Add 100 μl sample, diluted standard, or buffer (blank) into appropriately labeled tubes.
3. Add 2 ml BCA working reagent mix to each tube. Vortex immediately.

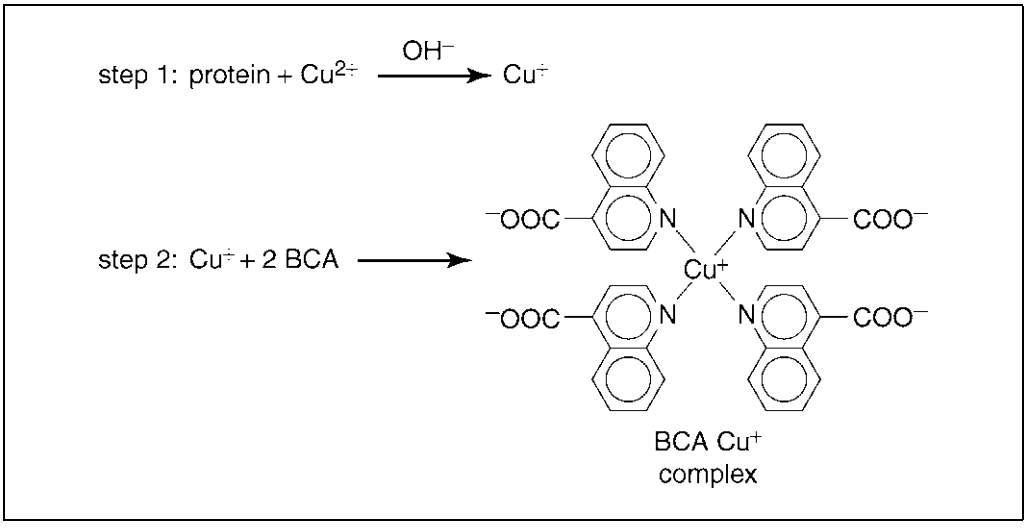

Figure A.3I.3 The reaction schematic for the BCA Protein Assay.

Table A.3I.2 Troubleshooting Guide for BCA Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains a copper chelating agent	Dialyze or dilute the sample
		Increase the copper concentration in the working reagent (use 48 parts reagent A and 2 parts reagent B)
Blank A_{562} is normal, but standards and samples show less color than expected	Strong acid or alkaline buffer, alters working reagent pH	Dialyze or dilute the sample
	Color measured at the wrong wavelength	Measure the color at 562 nm
Color of samples appear darker than expected	Protein concentration is too high	Dilute the sample
	Sample contains lipids or lipoproteins	Add 2% (w/v) SDS to the sample to eliminate interference from lipids
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample
	Sample contains a thiol	Precipitate the protein with trichloroacetic acid (TCA) and deoxycholate (DOC), dissolve pellet in BCA working reagent
	Sample contains biogenic amines (catecholamines)	Treat the sample with iodoacetamide (for thiols)
Need to read color at a different wavelength	Colorimeter does not have 562-nm filter	Color may be read at any wavelength between 550 nm and 570 nm

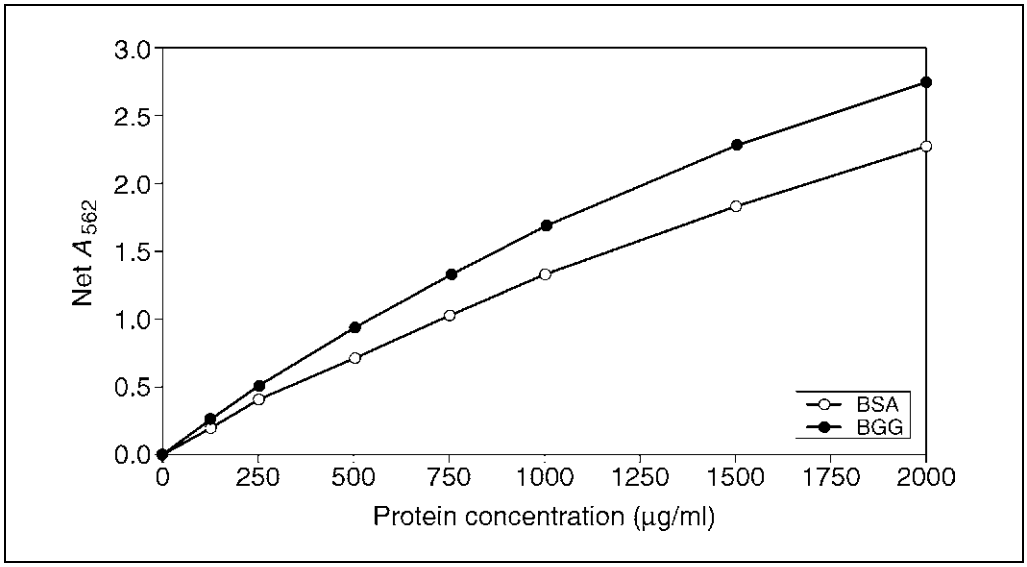

Figure A.3I.4 Graph of the color response curves obtained with Pierce's BCA Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 562 nm in a Hitachi U-2000 spectrophotometer.

4. Incubate samples and standards for 30 min at 37°C, then cool to room temperature.
5. Measure the color at 562 nm (A_{562}) on a spectrophotometer zeroed with deionized water.
6. Plot a standard curve by graphing the average net or blank-corrected A_{562} values for the standards versus protein concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Fig. A.3I.4.

7. Determine the protein concentration of the sample by interpolation from the plot (see Strategic Planning).

USING KITS FOR BCA MEASUREMENTS OF TOTAL PROTEIN

ALTERNATE PROTOCOL 3

Preformulated versions of the BCA reagent are now commercially available from Pierce (BCA Protein Assay Reagent) or Sigma (Bicinchoninic Acid Kit for Protein Determination). This assay can be performed in test tubes or microtiter plates (see Alternate Protocol 4), and has a working range of 20 to 2000 μg/ml.

Additional Materials

BCA Protein Assay Reagent Kit (Pierce) or Bicinchoninic Acid Kit (Sigma) containing:
2 mg/ml BSA in 0.9% NaCl/0.05% sodium azide (also see recipe)
BCA reagent A (also see recipe)
BCA reagent B (also see recipe)
37°C water bath

1. Prepare a dilution series of BSA standard in buffer to cover the range 125 to 2000 μg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. Prepare sufficient BCA working reagent (a minimum of 2 ml/tube or 20 ml/96-well microtiter plate) by adding 2 parts BCA reagent B to 100 parts of BCA reagent A.

   After mixing, the BCA working reagent is clear and apple green in color.

3. In duplicate, add 100 μl standard, sample, or buffer (blank) into appropriately labeled test tubes.
4. Add 2.0 ml BCA working reagent to each tube. Mix well by vortexing each tube 2 to 3 sec.

5a. *Standard tube protocol:* Incubate all tubes in a 37°C water bath for 30 min.

5b. *Enhanced assay protocol:* Alternatively, incubate all tubes in a 60°C water bath for 30 min.

   Increasing the incubation temperature to 60°C lowers the minimum detection level to 5 μg/ml and narrows the working range of the assay to a maximum of 250 μg/ml. This is known as the enhanced BCA assay.

6. After incubation, cool all tubes to room temperature.

   Since the BCA reagent does not reach a true end point, color development will continue even after cooling to room temperature; however, the rate of color development is very slow after cooling to room temperature, so no significant error is introduced if the A_{562} readings of all the tubes can be read within ~10 min.

7. Before reading, mix each tube again and measure the amount of color produced in each tube with a spectrophotometer at 562 nm (A_{562}) versus deionized water.
8. Plot a standard curve by graphing the average net or blank-corrected A_{562} values for the standards versus protein concentration in micrograms per milliliter.
9. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average sample concentration from its replicates.

ALTERNATE PROTOCOL 4

MICROTITER PLATE ASSAY FOR BCA MEASUREMENT OF TOTAL PROTEIN

BCA assays can be run in 96-well microtiter plates. The assay has a working range of 125 to 2000 μg/ml.

Additional Materials *(also see Alternate Protocol 3)*

96-well microtiter plate with cover or tape seal
200-μl multichannel pipettor
Microtiter plate shaker
37°C dry-heat incubator
Microtiter plate reader

1. Draw a template for the placement of samples and standards on a microtiter plate.

   Blanks, standards, and samples should be prepared in triplicate.

2. Add 10 μl of each diluted BSA standard (see Alternate Protocol 3, step 1), sample, or diluent (blank) to the appropriate wells.
3. Using a multichannel pipettor, add 200 μl BCA working reagent (see Alternate Protocol 3, step 2) to each well. Mix well on a microtiter plate shaker for 30 sec.
4. Cover the plate and incubate in a 37°C dry-heat incubator for 30 min.
5. After incubation, allow the plate to cool to room temperature.
6. Mix the plate again, remove the plate cover and measure the color in each well of the plate at 562 nm (A_{562}) in a microtiter plate reader.
7. Plot a standard curve by graphing the average net or blank-corrected A_{562} values for each BSA standard versus its concentration in micrograms per milliliter.
8. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average total protein concentration for each sample from the average of its replicates.

BASIC PROTOCOL 3

THE BIURET ASSAY FOR DETERMINING TOTAL PROTEIN

All proteins are composed of amino acids joined by peptide bonds in a linear sequence. There are ~20 naturally occurring amino acids found in proteins. The amino acids are joined to each other by peptide bonds formed by a condensation reaction that occurs between the terminal amine of one amino acid and the carboxyl end of the next. Peptides containing three or more amino acid residues will form a colored chelate complex with cupric ions in an alkaline environment containing sodium potassium tartrate. A similar colored chelate complex forms with the organic compound biuret (NH_2–CO–NH–CO–NH_2) and the cupric ion. The reaction in which a colored chelation complex is formed with peptide bonds in the presence of an alkaline cupric sulfate solution became known as the biuret reaction (Fig. A.3I.5). Thus, the biuret protein assay reagent gets its name

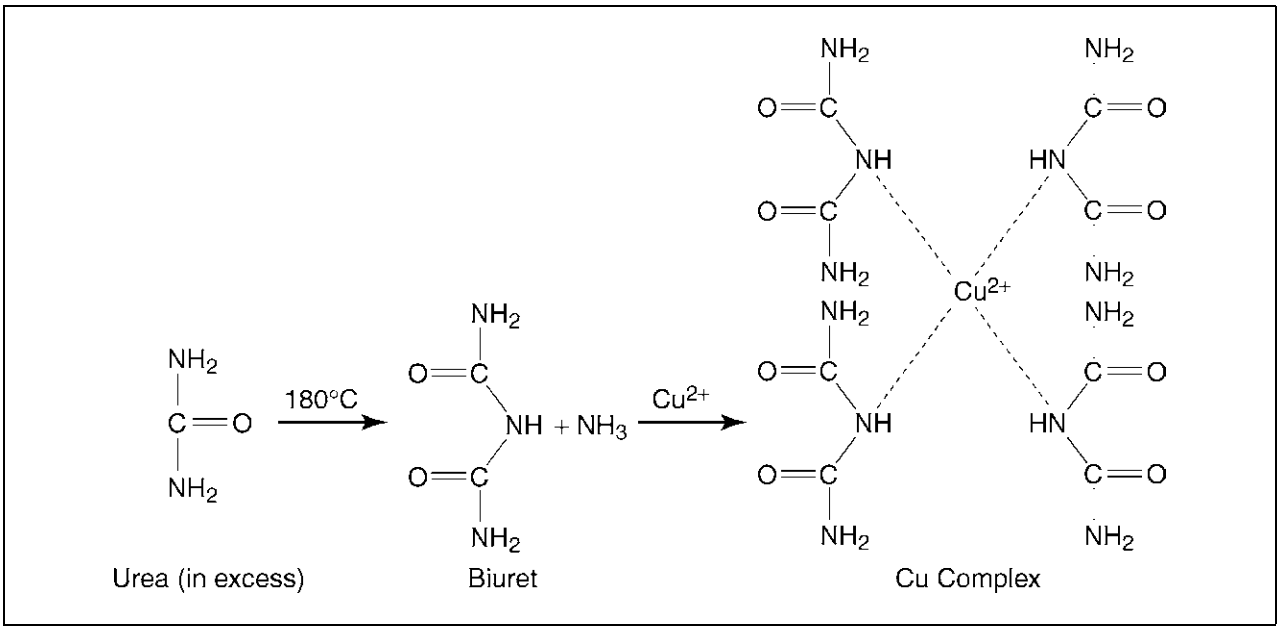

Figure A.3I.5 The schematic of the biuret reaction.

Table A.3I.3 Troubleshooting Guide for Biuret Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains copper chelating agent	Dialyze or dilute the sample
Blank A_{540} is normal, but standards show less color than expected	Color measured at the wrong wavelength	Measure the color at 540 nm
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample

from the above reaction even though it does not actually contain the organic compound biuret. Single amino acids or dipeptides do not give the biuret reaction, but tripeptides and larger polypeptides or proteins will react to produce the light-blue to violet complex that absorbs light at 540 nm. One cupric ion forms the colored coordinate complex with 4 to 6 nearby peptides bonds. The intensity of the color produced is proportional to the number of peptide bonds participating in the reaction. Thus, the biuret reaction is the basis for a simple and rapid colorimetric method of quantitatively determining total protein concentration.

Because the working range for the biuret assay is from 5 to 160 mg/ml, the biuret reagent has found utility in the clinical laboratories for the quantitation of total protein in serum. The formulation employed in the biuret total protein reagent (Sigma Diagnostics) was developed by Doumas et al. (1981) as a candidate reference method for the determination of serum total protein in the clinical lab. Using Sigma's biuret reagent, the expected range for total protein in serum is from 63 to 83 mg/ml. Bilirubin, lipids, hemoglobin, and dextran are known to interfere in the biuret assay for total serum protein. Outside of this application, other copper chelating agents such as EDTA, EGTA, citrate,

Tris, iminodiacetic acid, and nitrilotriacetic acid will interfere. The working range of this assay is 5 to 160 mg/ml. Table A.3I.3 is a brief troubleshooting guide for this technique.

Materials

Standard protein (also see Commentary)
Sample (unknown) protein
Biuret total protein reagent (Sigma Diagnostics; also see recipe)

1. Select a protein to use as the standard (see Strategic Planning) and prepare a dilution series with buffer to cover the range 10 to 160 mg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the standard that was used with the samples.

2. In duplicate, add 20 µl standard, sample, or diluent (blank) to appropriately labeled test tubes.
3. Add 1.0 ml biuret reagent to each tube. Mix well by vortexing 2 to 3 sec.
4. Incubate tubes at ambient room temperature (18° to 26°C) for 10 min.
5. Measure the color of each tube with a spectrophotometer at 540 nm (A_{540}). Compare to the blank.
6. Plot a standard curve by graphing the blank-corrected A_{540} values for the standards versus protein concentration in milligrams per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3I.6.

7. Determine the sample concentration by interpolation from the standard curve (see Strategic Planning).

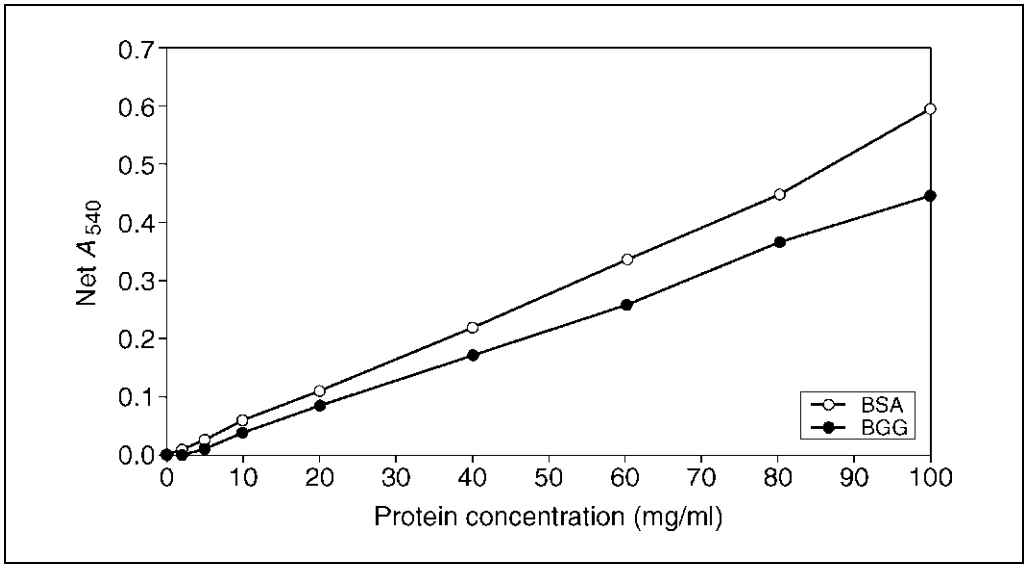

Figure A.3I.6 Graph of the color response curves obtained with Sigma's biuret Total Protein Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 540 nm in a Hitachi U-2000 spectrophotometer.

MICROTITER PLATE BIURET ASSAY FOR TOTAL PROTEIN

ALTERNATE PROTOCOL 5

The biuret assay can be performed in a 96-well microtiter plate and has a working concentration of 10 to 160 mg/ml.

Additional Materials *(also see Basic Protocol 3)*

96-well microtiter plate and cover or tape sealer
250-µl multichannel pipettor and appropriate tips
Microtiter plate mixer
Microtiter plate reader

1. Draw a template for placement of samples and standards on the microtiter plate.
2. Select a protein to use as the standard (see Strategic Planning). Prepare a dilution series with the same buffer used to dilute the samples to cover the range of 10 to 160 mg/ml.
3. In triplicate, add 5.0 µl of each diluted standard or sample into the appropriate microtiter plate wells. Use the buffer or diluent that was used to dilute the standard and samples for the blank wells.
4. Using a multichannel pipettor, add 250 µl biuret reagent to each well. Mix well on a plate shaker for 30 sec.
5. Cover the plate and incubate at room temperature for 10 min.
6. Mix again. Remove the plate cover and measure the color in each well of the plate at 540 nm (A_{540}) in a microtiter plate reader.
7. Prepare a standard curve by graphing the average net or blank-corrected A_{540} values for each standard versus its concentration in milligrams per milliliter.
8. Determine the sample concentration by interpolating from the plot (see Strategic Planning).

THE COOMASSIE DYE–BINDING (BRADFORD) ASSAY FOR DETERMINING TOTAL PROTEIN

BASIC PROTOCOL 4

The Coomassie dye–based protein-binding assays have the advantage of being the fastest and the easiest to perform (Fig. A.3I.7). In addition, the assay is performed at room temperature and no special equipment, other than a spectrophotometer, is required. Briefly, the sample is added to the ready-to-use reagent and, following a short incubation, the resultant blue color is measured at 595 nm versus deionized water.

In 1976, Marion Bradford introduced the first Coomassie dye–based reagent for the rapid colorimetric detection and quantitation of total protein. The Coomassie dye (Bradford) protein assay reagents have the advantage of being compatible with most salts, solvents, buffers, thiols, reducing substances, and metal chelating agents encountered in protein samples.

Materials

Sample buffer or solvent
Protein standard (e.g., 2 mg/ml BSA; see recipe)
Protein sample
Coomassie dye reagent (Pierce or Bio-Rad; also see recipe)

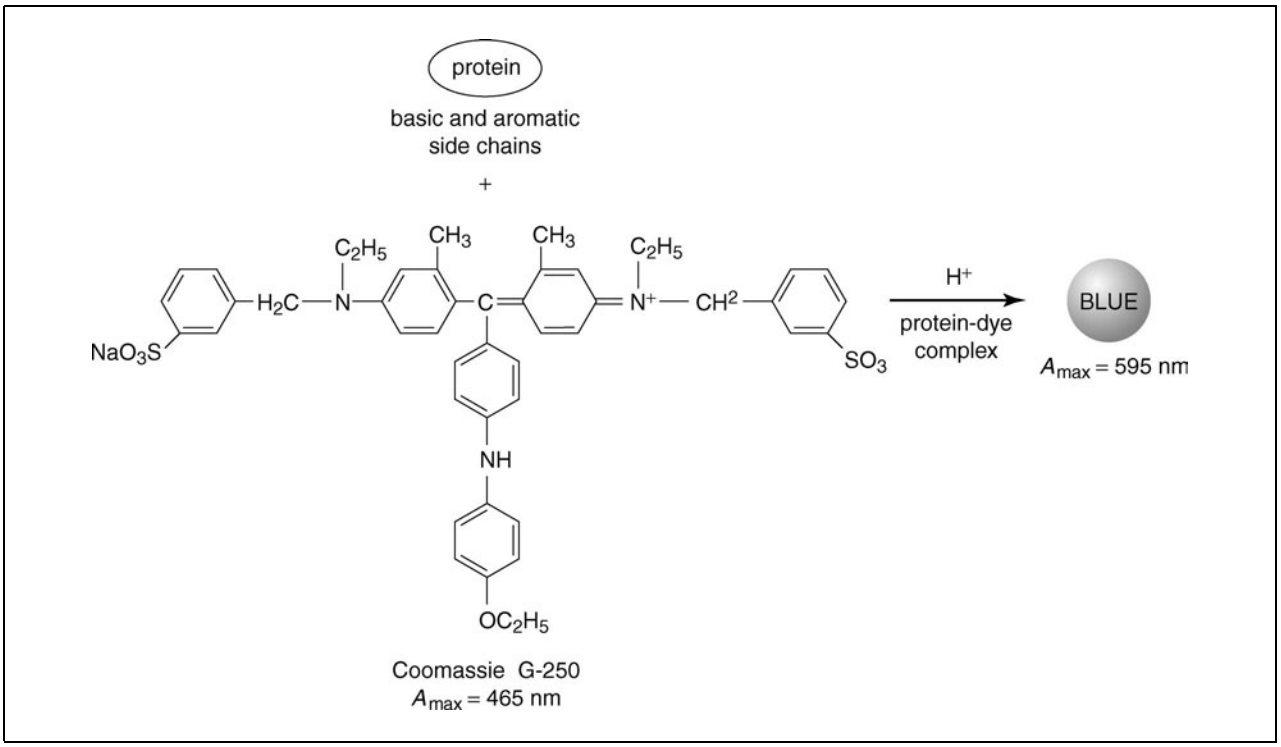

Figure A.3I.7 The reaction schematic for the Coomassie Protein Assay.

1. Prepare a dilution series from protein standard (e.g., 2 mg/ml BSA) and sample buffer to cover the range 100 to 1000 μg/ml.

   Bovine serum albumin (BSA) is often used as a calibration standard, but it has greater general dye-binding capacity than most proteins (Bradford, 1976).

2. Dispense 0.1 ml standard, sample, or buffer to appropriately labeled tubes.

   If commercially prepared Coomassie reagent is used, follow the manufacturer's instructions. Commercial reagents tend to produce less turbidity and more consistent results.

3. Add 5 ml Coomassie dye reagent. Vortex immediately.
4. Incubate 10 min at room temperature.
5. Vortex each tube just before measuring the absorbance at 595 nm (A_{595}).
6. Plot a standard curve by graphing the average net or blank-corrected A_{595} values for the standard versus its protein concentration in micrograms per milliliter.
7. Determine the sample concentration by interpolation from the standard curve (see Strategic Planning).

ALTERNATE PROTOCOL 6

THE COOMASSIE PLUS PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEIN

Several companies offer modified Bradford Coomassie dye–based protein assay reagents. Perhaps the most popular such reagent is the Protein Assay Reagent available from Bio-Rad. The Coomassie Plus Protein Assay Reagent available from Pierce is another modification of the Bradford formulation. In addition to the attributes cited above, the Coomassie Plus Protein Assay Reagent has the unique advantage of producing a linear response curve within a portion of its working range. For BSA, the response curve is linear from 125 to 1000 μg/ml and for bovine gamma globulin (BGG), the response curve is linear from 125 to 1500 μg/ml. The complete working range of the assay covers

Table A.3I.4 Troubleshooting Guide for Coomassie Plus Protein Assay

Problem	Possible cause	Solution
Blank A_{595} is normal, but standards show less color than expected	Improper reagent storage	Store reagent refrigerated
	Reagent still cold	Warm to room temperature before use
	Color measured at the wrong wavelength	Measure the color at 595 nm
Blank and standards are normal, but samples show little color	Low molecular weight of sample protein (<3000 kDa)	Use the BCA (see Basic Protocol 2) or Lowry protein assay (see Basic Protocol 1)
A precipitate forms in all tubes	Sample contains a surfactant (detergent)	Dialyze or dilute the sample
		Precipitate the protein with TCA, dissolve pellet in 50 mM NaOH
All tubes (including the blank) are dark blue	Strong alkaline buffer or reagent raises reagent's pH	Dialyze or dilute the sample
	Sample volume too large, reagent pH raised	Maximum of 1 part sample and 1 part reagent
Need to read color at a different wavelength	Colorimeter does not have 595 nm filter	Color may be read at any wavelength between 575 nm and 615 nm

the concentration range from 100 to 2000 μg/ml for the tube protocol and from 1 to 25 μg/ml for the microtiter protocol (see Alternate Protocol 7).

The main disadvantage of all Bradford-type protein assay reagents is that they are not compatible with surfactants at concentrations routinely used to solubilize membrane proteins. With some exceptions, the presence of a surfactant in the sample, even at low concentrations, causes precipitation of the reagent. Table A.3I.4 is a brief troubleshooting guide for this technique.

Additional Materials *(also see Basic Protocol 4)*

Coomassie Plus Protein Assay Reagent Kit (Pierce) containing Coomassie Plus Protein Assay Reagent

1. Prepare a dilution series with 2 mg/ml BSA and buffer to cover a range from 100 to 2000 μg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. Allow the Coomassie Plus Protein Assay Reagent to come to room temperature. Mix the assay reagent well by gentle inversion before use.

3. In duplicate, dispense 50 μl standard, sample, or diluent (blank) into appropriately labeled test tubes.

4. Add 1.5 ml Coomassie Plus Protein Assay Reagent to each tube. Mix each tube well by vortexing 2 to 3 sec.

5. Let the tubes stand 10 min at room temperature.

6. Mix each tube again just before measuring the absorbance at 595 nm (A_{595}).

   Disposable polystyrene cuvettes eliminate the job of cleaning dye-stained quartz or glass cuvettes.

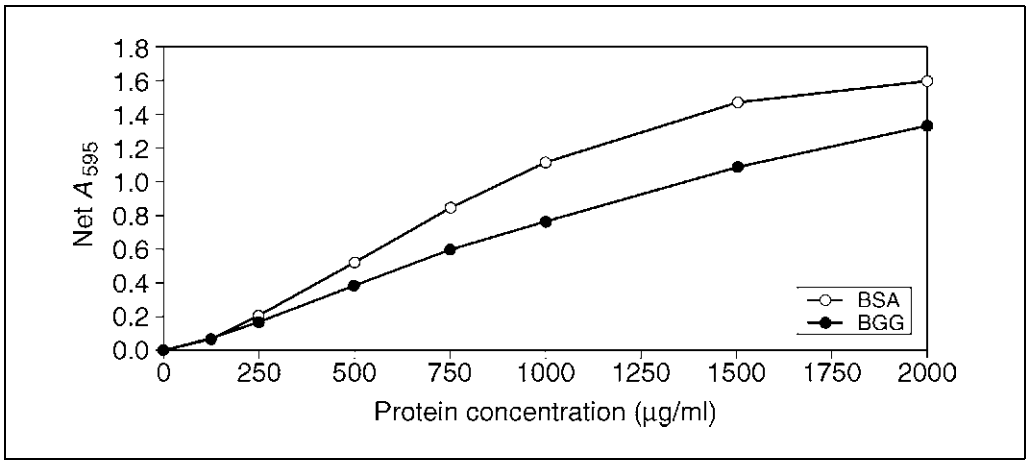

Figure A.3I.8 Graph of the color response curves obtained with Pierce's Coomassie Plus Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 595 nm in a Hitachi U-2000 spectrophotometer.

7. Plot a standard curve by graphing the average net or blank-corrected A_{595} reading for each standard versus its concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3I.8.

8. Determine the protein concentration for each sample by interpolating from the standard curve (see Strategic Planning). Calculate the average total protein concentration for each sample from the replicates.

ALTERNATE PROTOCOL 7

MICROTITER PLATE COOMASSIE ASSAY FOR TOTAL PROTEIN

This microtiter plate assay has a working range of 1 to 25 μg/ml.

Additional Materials *(see Basic Protocol 4)*

Coomassie Plus Protein Assay Reagent Kit (Pierce) containing Coomassie Plus Protein Assay reagent
96-well microtiter plate
300-μl multichannel pipettor
Microtiter plate mixer
Microtiter plate reader

1. Allow the Coomassie Plus Protein Assay Reagent to come to room temperature. Once the reagent is at room temperature, mix the reagent well by gentle inversion of the bottle.
2. Draw a template for placement of samples and standards on a 96-well microtiter plate.
3. In triplicate, dispense 10 μl of each diluted BSA standard, sample, or diluent (blank) into the appropriate wells of a 96-well microtiter plate.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock standard that was used with the samples.

4. Dispense 300 μl Coomassie Plus Protein Assay reagent into each well with a multichannel pipettor. Mix the plate well on a plate shaker for 30 sec.
5. Let the plate incubate 10 min at room temperature.
6. Just before reading, mix the plate again, then measure the absorbance at 595 nm (A_{595}) on a plate reader.

7. Prepare a standard curve by graphing the average net or blank-corrected A_{595} values for each standard versus its concentration in micrograms per milliliter.

8. Determine the sample concentration by interpolating from the standard curve (see Strategic Planning). Calculate the average total protein concentration for each sample from the replicates.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BCA reagent A

1 g 4,4′-dicarboxy-2,2′-biquinoline, disodium salt (Na_2BCA; Pierce or Sigma; 1% w/v final)
2 g $Na_2CO_3 \cdot H_2O$ (2% w/v final)
160 mg sodium tartrate dihydrate (0.16% w/v final)
0.4 g NaOH (0.4% w/v final)
0.95 g $NaHCO_3$ (0.95% w/v final)
Dissolve all of the above chemicals except the sodium bicarbonate in water and adjust the final volume to 100 ml. Adjust the pH to 11.25 by adding the sodium bicarbonate a little at a time. Store this alkaline reagent in a plastic container 1 to 3 weeks at room temperature, longer at 4°C.

Only the disodium salt of BCA is soluble at neutral pH; the free acid is not readily soluble.

BCA reagent B

4 g $CuSO_4 \cdot 5H_2O$ (4% w/v final)
100 ml H_2O
Store up to 6 months at room temperature

Biuret total protein reagent

0.6 mol/liter sodium hydroxide
12.0 mmol/liter copper sulfate
31.9 mmol/liter sodium potassium tartrate
30.1 mmol/liter potassium iodide
Store up to 6 months at room temperature

This reagent is based upon the candidate reference method for the determination of total protein in serum developed by Doumas et al. (1981). It is available from Sigma Diagnostics.

BSA, 2 mg/ml (w/v)

200 mg BSA (crystallized or lyophilized or one of the Cohn Fraction V preparations which are 96% to 98% protein and 3% to 4% water) in 100 ml of 0.9% (w/v) saline containing 0.05% (w/v) sodium azide. Store up to 6 months at 4°C.

Coomassie dye reagent

100 mg Coomassie Brilliant Blue G-250 (0.01% w/v final)
50 ml 95% ethanol (4.7% w/v final)
100 ml 85% (w/v) phosphoric acid (8.5% w/v final)

In a small container, dissolve the dye in ~25 ml ethanol, add the dye/ethanol solution to 800 ml water. Use the remaining ethanol to rinse the dye/ethanol container and add the rinses to the formulation. While mixing, slowly add the acid to the formulation and adjust the final volume to 1000 ml with water. Filter the reagent through a single pad of Whatman no. 2 filter paper. Store up to 1 month at room temperature in a glass container.

continued

Coomassie Brilliant Blue G-250 (color index 42655) is available from a number of different suppliers (e.g., ACROS, Aldrich, AMRESCO, Bio-Rad, Fisher Biotech, Fluka, ICN Biomedicals, J.T. Baker, Research Organics, Serva, Sigma, or USB).

Lowry's reagent A

21.2 g sodium carbonate (2% w/v)
40 ml 1 N NaOH (or 4.0 g NaOH; 0.1 N final)
Add water to 1 liter
Make fresh daily

Lowry's reagent B

0.5 g $CuSO_4 \cdot 5H_2O$ (0.5% w/v final)
1 g sodium tartrate (1% w/v final)
Make fresh daily
H_2O to 100 ml

Sodium tartrate may be replaced with disodium tartrate, potassium sodium tartrate, or sodium citrate for better solubility.

Lowry's reagent C (1 N Folin phenol reagent)

Dilute 2 N Folin phenol (Sigma, Fisher, or VWR) with an equal volume water. Prepare immediately before use.

Lowry's reagent D (reagent A and B mix)

Mix 1 vol Lowry's reagent B and 50 vol Lowry's reagent A (see recipes). Prepare immediately before use.

Lowry's reagent D′

Add 2 ml of 10% (w/v) sodium dodecyl sulfate (SDS; *APPENDIX 2A* for 20% solution) in water to each 100 ml Lowry's reagent D (see recipe). Prepare immediately before use.

COMMENTARY

Background Information

The modified Lowry protein assay

Although the exact mechanism of color formation reaction in the Lowry protein assay remains poorly understood, it is known that the color producing reaction with protein occurs in two distinct steps. As seen in Figure A.3I.1, protein is first reacted with alkaline cupric sulfate in the presence of tartrate during a 10-min incubation at room temperature. During this incubation, a tetradentate copper complex forms from four peptide bonds and one atom of copper. The tetradentate copper complex is light blue in color (this is the "biuret reaction"). Following the 10-min incubation, Folin phenol reagent is added. It is believed that color enhancement occurs when the tetradentate copper complex transfers electrons to the phospho-molybdic/phosphotungstic acid complex (i.e., the Folin phenol reagent).

The reduced phosphomolybdic/phosphotungstic acid complex produced by this reaction is intensely blue in color. The Folin phenol reagent loses its reactivity almost immediately upon addition to the alkaline working reagent/sample solution. The blue color continues to intensify during a 30-min room temperature incubation. It has been suggested by Lowry et al. (1951) and by Legler et al. (1985) that during the 30-min incubation, a rearrangement of the initial unstable blue complex leads to the stable final blue colored complex, which has higher absorbance.

For small peptides, the amount of color increases with the size of the peptide. The presence of any of five amino acid residues (tyrosine, tryptophan, cysteine, histidine, and asparagine) in the peptide or protein backbone further enhances the amount of color produced, because they contribute additional reducing equivalents for further reduction of the phosphomolybdic/phosphotungstic acid complex. With the exception of tyrosine and tryptophan, free amino acids will not produce a

colored product with the Lowry reagent; however, most dipeptides can be detected. In the absence of any of the five amino acids listed above, proteins containing proline residues have a lower color response with the Lowry reagent because it interferes with complex formation.

The final blue color is optimally measured at 750 nm, but it can be measured at any wavelength between 650 nm and 750 nm with little loss of color intensity. Lowry (1951) recommended reading the color at 750 nm because few other substances absorb light at that wavelength. The amount of light absorbed at 750 nm is directly proportional to the amount of protein in the sample, but the color response curve produced is nonlinear.

The sensitivity of the Modified Lowry Protein Assay Reagent is greatly enhanced over that of the biuret total protein reagent. The working range of the method covers the total protein range from 1 to 1500 μg/ml. In comparison, the working range for the biuret assay is from 5 to 160 mg/ml.

The Modified Lowry Protein Assay Reagent will form precipitates in the presence of surfactants or potassium ions. The problem of precipitation that is caused by the presence of potassium ions in the sample can sometimes be overcome by centrifuging the tube and reading the color in the supernatant. Most surfactants will cause precipitation of the reagent even at very low concentrations. One exception is sodium dodecyl sulfate (SDS), which is compatible with the reagent at concentrations up to 1% (w/v) in the sample. Chelating agents interfere because they bind copper and thus prevent formation of the copper-peptide bond complex. Reducing agents and free thiols interfere, as they reduce the phosphotungstate-phosphomolybdate complex, immediately forming an intensely blue colored product upon their addition to the Modified Lowry Protein Assay Reagent.

The Coomassie Plus protein assay

The primary advantage of the Coomassie Plus Protein Assay is that it is generally compatible with most of the buffers and reagents found in samples and is unaffected by the presence of chelating agents, reducing agents, or free sulfhydryls in the sample.

The development of color in the Coomassie dye–binding methods has been associated with the presence of certain basic amino acids (primarily arginine, lysine, and histidine) in the protein. Van der Waals forces and hydrophobic interactions also participate in the binding of the dye by protein. The number of Coomassie dye ligands bound to each protein molecule is approximately proportional to the number of positive charges found on the protein. In the acidic environment of the Coomassie Plus Protein Assay Reagent, protein binds to the Coomassie dye. This results in a spectral shift of the reagent from the reddish/brown form of the dye, with an absorbance maximum at 465 nm, to the blue form of the dye, with an absorbance maximum at 610 nm (see Fig. A.3I.7).

The difference between the two forms is greatest at 595 nm; therefore, this is the optimal wavelength to measure the blue color from the Coomassie dye–protein complex. If desired, the blue color can be read at any wavelength between 575 and 615 nm. At the two extremes (575 and 615 nm) there is a loss of ~10% in the measured amount of color (absorbance) compared to the value obtained at 595 nm.

Free amino acids, peptides, and low-molecular-weight proteins do not produce color with the Coomassie Plus Protein Assay Reagent. In general the molecular weight of the peptide or protein must be at least 3000 Da to be assayed with this reagent. In some applications this can be an advantage. The reagent has been used to measure "high-molecular-weight proteins" during fermentation in the beer brewing industry.

One disadvantage of any Coomassie dye–based protein assay is that surfactants in the sample will cause precipitation of the reagent. Another disadvantage is that the Coomassie Plus Protein Assay Reagent shows almost twice as much protein-to-protein variation as that obtained with the protein-copper chelation–based assay reagents (the Lowry Protein Assay Reagent or the BCA Protein Assay Reagent). While this is true, the reagent exhibits the least protein-to-protein variation of all Coomassie dye–based (Bradford) reagents. Since the Coomassie dye reagent is highly acidic, a small number of proteins cannot be assayed with this reagent due to poor solubility. In addition, the glass or quartz cuvettes routinely used to hold the solution in the spectrophotometer while the color intensity is being measured are stained by Coomassie dye–based reagents.

The BCA protein assay

The BCA Protein Assay is a modification of the Lowry protein assay in which enhanced color production is due to the reaction of reduced copper with bicinchoninic acid (BCA). This reagent has a unique advantage

over the Lowry Protein Assay Reagent and the Coomassie Plus Protein Assay Reagent because it is compatible with samples that contain up to 5% (v/v) surfactants (detergents). Unlike the Lowry protein assay, all reactants needed are present in the BCA working reagent. Large numbers of tubes can be run without regard to the limits imposed in the Lowry assay by the need to add a second reagent at a precise time interval.

The working range of the BCA Protein Assay Reagent is from 20 to 2000 μg/ml for both the standard tube and the standard microtiter plate protocols. Since the color reaction is not a true end-point reaction, this allows more protocol flexibility. By increasing the incubation temperature, the sensitivity of the reagent can be increased. When using the enhanced tube protocol (incubating at 60°C for 30 min), the working range for the assay shifts to 5 to 250 μg/ml and the minimum detection level becomes 5 μg/ml.

Although the mechanism of color formation with protein for the BCA Protein Assay Reagent is similar to that of the Lowry reagent, there are several significant differences. The BCA Protein Assay combines the well-known reduction of Cu^{2+} to Cu^{+} by protein in an alkaline medium (the so-called biuret reaction) with the highly sensitive and selective colorimetric detection of the cuprous cation (Cu^{+}) by bicinchoninic acid.The purple-colored reaction product of this assay is formed by the chelation of two molecules of BCA with one cuprous ion (see Fig. A.3I.3). The resultant BCA/Cu^{+} complex is water-soluble and exhibits a strong linear absorbance maximum at 562 nm with increasing protein concentrations. If desired, the purple color may be measured at any wavelength between 550 nm and 570 nm with minimum (<10%) loss of signal.

The reaction that leads to BCA color formation as a result of the reduction of Cu^{2+} is also strongly influenced by the presence of any of four amino acid residues (tyrosine, tryptophan, cysteine, or cystine) in the amino acid sequence of the protein. Unlike the Coomassie dye–binding (Bradford) methods, which require a minimum mass of protein to be present for the dye to bind, the presence of only a single amino acid residue in the sample may result in the formation of a colored BCA-Cu^{+} chelate. This is true for any of the four amino acids cited above. Studies done with di- and tripeptides indicate that the total amount of color produced is greater than can be accounted for by the simple addition of the color produced with each BCA-reactive amino acid, so the peptide backbone must contribute to the reduction of copper as well.

The rate of color formation is dependent on the incubation temperature, the types of protein present in the sample, and the relative amounts of reactive amino acids contained in the proteins. The recommended protocols do not result in end-point determinations, so the incubation periods were chosen to yield maximal color response in a reasonable time frame.

The protein-to-protein variation in the amount of color produced with the BCA Protein Assay Reagent (CV = 15% for the group of 14 proteins at 1000 μg/ml in the standard tube protocol) is similar to that observed for the Modified Lowry Protein Assay Reagent.

The biuret total protein assay

Riegler (1914) introduced the biuret reaction as a method for the estimation of albumin in urine in 1914. Modifications and improvements to the biuret method were made by Autenrieth and Mink (1915), Hiller (1926), and Fine (1935). All of these early methods required the separate addition of a sodium hydroxide solution and the separate addition of a copper sulfate solution to the sample. The methods suffered from poor precision due to ineffective mixing and variation in reaction time during mixing. The first "one solution" biuret reagent was introduced by Kingsley (1942) for use in measuring total protein, albumin, and globulin in human serum. Weichselbaum (1946) and Gornall et al. (1949) modified Kingsley's biuret reagent by decreasing the sodium hydroxide concentration to prevent the formation of precipitates and by adding sodium potassium tartrate to stabilize the reagent. Potassium iodide was added to prevent the autoreduction of Cu^{2+}. Goa (1953) published on the use of the biuret reagent for determining total protein in human cerebrospinal fluid.

Sigma Diagnostic's biuret total protein reagent is based upon the candidate reference method formulation used for the determination of total protein in serum developed by Doumas et al. (1981). Because the primary application for this reagent is the determination of total protein in serum, most of the studies regarding assay precision, assay linearity, and interfering substances have been done on clinical samples. On samples with total protein concentrations in the range of 26 to 121 mg/ml, within-run and between-run precision was found to be excellent (CV's ranged from 4.2% to 1.4%). Lipids, bilirubin, hemoglobin, dextran, and certain drugs have been shown to interfere with

the total protein results obtained with the biuret Total Protein Reagent. Interference caused by the presence of lipid in the sample is due to turbidity. Interference caused by the presence of bilirubin or hemoglobin is small, almost negligible. Dextran causes precipitation in the reaction mixture during color development; however, centrifuging the reaction mixture before reading the color can minimize this. The biuret Total Protein Reagent contains 0.6 mol/liter sodium hydroxide, 12.0 mmol/liter copper sulfate, 31.9 mmol/liter sodium potassium tartrate, and 30.1 mmol/liter potassium iodide. It should be stored at ambient room temperature until the expiration date shown on the label. Certain drugs and other substances are known to influence circulating levels of total protein (Young, 1990).

Critical Parameters

The modified Lowry protein assay reagent

The Modified Lowry Protein Assay Reagent must be refrigerated for long-term storage. If the entire bottle of reagent will be used within a reasonable time, the reagent may be stored at ambient room temperature (18° to 26°C) for up to 1 month. Reagent that has been left at room temperature for more than a month may show lower color response with protein, especially at the higher end of the working range. If the reagent has been stored refrigerated, it must be warmed to room temperature before use. The use of cold Modified Lowry Protein Assay Reagent will result in low A_{750} values.

The protocol requires that the Folin phenol reagent be added to each tube precisely at the end of the 10-min incubation. At the alkaline pH of the Lowry reagent, the Folin phenol reagent is almost immediately inactivated; therefore, it is best to add the Folin phenol reagent at the precise time while simultaneously mixing each tube. Because it is somewhat cumbersome, it requires some practice to do the assay well. From a practical point of view, it also limits the total number of tubes that can be done in a single run. If a 10-sec interval between tubes is used, the maximum number of tubes that can be done within 10 min is 60 (10 sec/tube × 60 tubes = 600 sec or 10 min).

The Coomassie Plus protein assay reagent

The Coomassie Plus Protein Assay Reagent must be refrigerated for long-term storage. If the entire bottle of reagent will be used within a reasonable time, the reagent may be stored at ambient room temperature (18° to 26°C) for up to 1 month. Reagent that has been left at room temperature for more than a month may show lower color response with protein, especially at the higher end of the working range. If the reagent has been stored refrigerated, it must be warmed to room temperature before use. The use of cold Coomassie Plus Protein Assay Reagent will result in low A_{595} values.

The Coomassie Plus Protein Assay Reagent must be mixed gently by inversion just before use. The Coomassie dye in the reagent spontaneously forms loosely associated dye-dye aggregates upon standing. These aggregates may become visible after the reagent has been standing for as little as 60 min. Gentle mixing of the reagent by inversion of the bottle will uniformly disperse the dye-dye aggregates. After binding to protein, the dye also forms protein-dye-protein-dye aggregates. Fortunately, these aggregates can be dispersed easily by mixing the reaction tube. This is common to all Coomassie dye–based (Bradford) protein assay reagents. Since these aggregates form relatively quickly, it is a good idea to routinely mix (vortex for 2 to 3 sec) each sample just before measuring the color.

Bradford-type reagents containing Coomassie dye will leave a blue stain on glass or quartz cuvettes. The stain can be removed by washing the cuvettes in a dilute detergent solution in hot tap water, rinsing with water, then washing with methanol or ethanol, and finally rinsing with deionized water. Disposable plastic (polystyrene) cuvettes are strongly recommended because they eliminate the need to clean; however, these cuvettes are not compatible with samples containing organic solvents (e.g., acetone, DMF, acetonitrile).

The BCA protein assay reagent

Since the BCA Protein Assay is not a true end-point assay, the amount of color produced varies with the incubation time and the incubation temperature. While this allows considerable flexibility in optimizing the BCA assay for each application, it also requires that the optimized procedure be followed exactly every time the assay is done.

At room temperature, following an initial lag phase, the rate of color formation remains relatively constant for hours. If the incubation time alone is increased, the total amount of color produced by a given mass of protein increases.

If the incubation temperature is increased, the rate of color formation increases and the

total amount of color produced by a given mass of protein increases. After cooling the reaction mixture back to room temperature, the rate of color development slows from its initial rate. As both time and temperature are increased, the total amount of color produced by a given mass of protein approaches a maximum. This is apparent from the dramatic decrease in the rate of color formation upon cooling to room temperature following incubation at 60°C for 30 min.

Above 75°C, a black precipitate forms in the BCA reaction mixture and the absorbance at 562 nm of the blank increases dramatically. This appears to be caused by the formation of copper oxide at high temperature.

For greatest accuracy and precision when comparing sets of data from multiple runs, a set of standards must be included with each run, and the standards and the samples must be treated exactly the same.

The biuret total protein reagent

The biuret total protein reagent is considerably less sensitive to total protein than the other three protein assay reagents discussed in this appendix. This limits the applications in which the biuret reagent can be used. Since the primary use of the biuret reagent has been for serum total protein in the clinical laboratory, there is little published information about its compatibility with substances and reagents common to nonclinical samples.

Anticipated Results

Standard curves

Typical standard curves are shown in Figures A.3I.2, A.3I.4, A.3I.6, and A.3I.8 for each of the four assay methods. In each case, the tube protocols were performed in duplicate on diluted BSA or BGG standard. The color in each tube was measured at the appropriate wavelength in a dual-beam spectrophotometer. The net absorbance for each sample was plotted versus its protein concentration.

Figure A.3I.2 shows the color response curves obtained with the Modified Lowry Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 750 nm versus the protein concentration at seven concentrations from 125 to 2000 μg/ml for each protein. Note that the response curve for BGG is higher than the response curve for BSA.

Figure A.3I.4 shows the color response curves obtained with the BCA Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 562 nm versus the protein concentration at seven concentrations from 125 to 2000 μg/ml for each protein. Note that the response curve for BGG is higher than the response curve for BSA.

Figure A.3I.6 shows the color response curves obtained with the biuret total protein reagent using BSA and BGG. The graph shows the net absorbance at 540 nm versus the protein at eight concentrations from 5 to 100 mg/ml.

Figure A.3I.8 shows the color response curves obtained with the Coomassie Plus Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 595 nm versus the protein concentration at seven concentrations from 125 to 2000 μg/ml for each protein. Note that the color response curve for BGG is lower than the response curve for BSA.

Protein-to-protein variation

Each protein in a sample is unique and can demonstrate that individuality in protein assays as variation in the color response. Such protein-to-protein variation refers to differences in the amount of color (absorbance) that are obtained when the same mass (microgram or milligram) of various proteins are assayed concurrently (i.e., in the same run) by the same method. These differences in color response relate to differences among proteins due to amino acid sequence, isoelectric point (pI), secondary structure, and the presence of certain side chains or prosthetic groups.

To analyze protein-to-protein variation for each method, a group of fourteen proteins was assayed in duplicate using the standard tube protocol in a single run. The net (blank-corrected) average absorbance for each protein was calculated. To make it easier to interpret, the net absorbance for each protein was expressed as a ratio to the net absorbance for BSA. If a protein has a ratio of 0.80, it means that the protein produces ~80% of the color that is obtained for an equivalent mass of BSA.

Table A.3I.5 demonstrates the relative degree of protein-to-protein variation that can be expected with the different protein assay methods. This differential may be a consideration in selecting a protein assay method, especially if the relative color response ratio of the protein in the samples is unknown. As expected, the protein assay methods that share the same basic chemistry show similar protein-to-protein variation.

The protein-to-protein variation observed with the various protein assay methods makes it obvious why the largest source of error for protein assays is the choice of protein for the standard curve. If the sample contained IgG

Table A.3I.5 Protein-to-Protein Variation[a]

Protein tested	Ratios obtained with the BCA method	Ratios obtained with the Coomassie plus method	Ratios obtained with the modified Lowry method
Albumin, bovine (BSA)	1.00	1.00	1.00
Aldolase, rabbit	0.85	0.74	0.94
α-Chymotrypsinogen, bovine	1.14	0.52	1.17
Cytochrome C, horse	0.83	1.03	0.94
Gamma globulin, bovine	1.11	0.58	1.14
IgG, bovine	1.21	0.63	1.29
IgG, human	1.09	0.66	1.13
IgG, mouse	1.18	0.62	1.20
IgG, rabbit	1.12	0.43	1.19
IgG, sheep	1.17	0.57	1.28
Insulin, bovine pancreas	1.08	0.67	1.12
Myoglobin	0.74	1.15	0.90
Ovalbumin	0.93	0.68	1.02
Transferrin, human	0.89	0.90	0.92
Average ratio	1.02	0.73	1.09
Standard Deviation (SD)	0.15	0.12	0.13
Coefficient of Variation	0.15	0.29	0.12

[a]The protein-to-protein variation in color response was measured at 1000 μg/ml for each protein in duplicate using the standard tube protocol. Within each assay, the average net or blank-corrected absorbance was determined for each protein. The average net absorbance for each protein was divided by the average net absorbance obtained with BSA and expressed as a ratio. The standard deviation (SD) and the coefficient of variation (CV) is presented for the fourteen proteins assayed on the three methods. By comparing the CV's, the relative degree of protein-to-protein variation to be expected with the three methods can be assessed.

as the major protein and BSA was used for the standard curve, the estimated total protein concentration of the sample will be inaccurate. Whether the concentration was underestimated or overestimated depends upon which total protein assay method was used. If the Coomassie Plus Protein Assay Reagent was used, the total protein (IgG) concentration in the sample would be underestimated by ~40%. (From Table A.3I.5, the response ratio for IgG is ~0.58 for IgG compared to 1.00 for BSA.) If the BCA Protein Assay Reagent was used, the total protein (IgG) concentration in the sample would be overestimated by ~15%. (From Table A.3I.5, the response ratio for IgG is ~1.15 for IgG compared to 1.00 for BSA.) On the other hand, if BGG had been used for both standard curves, the total protein estimates for the sample would have been in much greater agreement between the two methods.

While Table A.3I.5 is useful because it provides an estimate of the protein-to-protein variation in color response that can be expected with each method, it does not tell the whole story. Because the comparisons were done at a single protein concentration, it is not apparent that the color response ratio also varies with changes in protein concentration.

Compatible and incompatible substances

An extensive list of substances that have been found to be compatible with each of the reagents is shown in Table A.3I.6 Each substance was assayed in duplicate using the standard tube protocol for each reagent. In addition to adding the substance to a sample containing 1000 μg/ml BSA, a blank sample containing only the substance was tested. When added to the sample, a substance was deemed to be compatible with a reagent if the blank-corrected absorbance for the sample containing the substance was within 10% of the blank-corrected absorbance for the sample containing only BSA (also at 1000 μg/ml).

Time Considerations

The amount of time required to complete a total protein assay will vary for the four colorimetric total protein assay methods described. For the purpose of providing an estimate of the amount of time required to perform a run by each method, it was assumed that the run

Table A.3I.7 Estimated Time Requirements

Method	Incubation time(s)	Estimated total assay time
Modified Lowry Reagent	10 and 30 min	110 min (1 hr, 50 min)
Coomassie Plus Reagent	10 min	80 min (1 hr, 20 min)
BCA Reagent	30 min	100 min (1 hr, 40 min)
Biuret Reagent	10 min	80 min (1 hr, 20 min)

included twenty samples and eight standards (including the blank) and that each sample or standard was assayed in duplicate using the standard tube protocol. The estimates do not include the time spent obtaining the samples or the time it takes to prepare the samples for analysis, but they do include the incubation time(s) plus an estimate of the time it takes to do the following:

1. Prepare (dilute) the standard protein in the diluent buffer (10 min).
2. Organize the run and label the tubes (5 min).
3. Pipet the samples and reagents into the tubes (10 min).
4. Mix or incubate the tubes or plates (varies).
5. Measure the color produced in the tubes (15 min).
6. Graph the standard curve, calculate, record, and report the results (30 min).

For each of the four methods, a run of 20 samples (unknowns) and the standard curve (each done in duplicate) can be completed in the time estimated in Table A.3I.7

Found that the anionic form of the Coomassie dye reacts primarily with arginine residues within the macromolecular protein. Coomassie dye reacts to a lesser extent with other basic amino acid residues (His, Lys) and aromatic residues (Trp, Tyr, Phe) present in macromolecular proteins but not with the free amino acids. Dye binding is attributed to van der Waals forces and hydrophobic interactions. The interference seen with bases, detergents, and other compounds can be explained by their effects upon the equilibrium between the three dye forms (cationic, neutral, anionic).

A deoxycholate-trichloroacetic acid protein precipitation technique that provides for rapid recovery of soluble and membrane-bound proteins from interfering substances. Interference by lipids and nonionic or cationic detergents is alleviated by adding SDS.

Peterson, G.L. 1979. Review of the Folin phenol protein quantitation method of Lowry, Rosebrough, Farr and Randall. *Anal. Biochem.* 100:201-220.

A thorough review article that examines the reaction mechanism involved when protein reacts with the Lowry reagent. An extensive list of possibly interfering substances is presented along with methods of coping with those interfering substances. Finally, the method of Lowry is compared to other methods. There is an extensive list of references.

Sorenson, K. and Brodbeck, U. 1986. A sensitive protein assay method using micro-titer plates. *Experientia* 42:161-162.

A direct scale-down of the BCA method for test tubes that is suitable for microtiter plates.

Tal, M., Silberstein, A., and Nusser, D. 1980. Why does Coomassie Brilliant Blue interact differently with different proteins? *J. Biol. Chem.* 260:9976-9980.

Analysis of Scatchard plots showed that the number of Coomassie dye ligands bound to each protein is approximately proportional to the number of positive charges on the protein. About 1.5 to 3 dye molecules are bound to each positive charge on the protein.

Watters, C. 1978. A one-step biuret assay for protein in the presence of detergent. *Anal. Biochem.* 88:695-698.

A modified biuret reagent was formulated (sodium tartrate replaces sodium potassium tartrate, the sodium hydroxide concentration is reduced, and potassium iodide was deleted). When the modified biuret reagent was mixed with samples containing 2% detergent (SDS or sodium cholate or Triton X-100), it resulted in less protein-to-protein variation among six proteins.

Weichselbaum, 1946. See above.

Used sodium potassium tartrate as a stabilizer and added potassium iodide to prevent autoreduction of the biuret reagent; however, this reagent was found to be unstable after long storage.

Wiechelman, K., Braun, R., and Fitzpatrick, J. 1988. Investigation of the bicinchoninic acid protein assay: Identification of the groups responsible for color formation. *Anal. Biochem.* 175:231-237.

Cysteine, cystine, tryptophan, tyrosine, and the peptide bond are capable of reducing Cu^{2+} to Cu^{+}, but the extent of color formation is not simply the sum of the contributions from the various color producing functional groups. At 60°C, tryptophan, tyrosine, and the peptide bond are more completely oxidized than they are at 37°C, which is observed by the much greater extent of color developed at the higher temperature.

Internet Resources

http://www.piercenet.com

This site allows access to Pierce's on-line product catalog and special notice of all new products and other Pierce publications. If specific information on a product is needed, the instruction booklet can be downloaded. If additional help is needed, the technical assistance department can be reached by e-mail.

http://www.sigma-aldrich.com

This site allows access to the Sigma Diagnostics product line and applications or other technical information on their products. Questions can be sent by e-mail to the technical assistance department.

SELECTED SUPPLIERS OF REAGENTS AND EQUIPMENT

Listed below are addresses and phone numbers of commercial suppliers who have been recommended for particular items used in our manuals because: (1) the particular brand has actually been found to be of superior quality, or (2) the item is difficult to find in the marketplace. Consequently, this compilation may not include some important vendors of biological supplies. For comprehensive listings, see *Linscott's Directory of Immunological and Biological Reagents* (Santa Rosa, CA), *The Biotechnology Directory* (Stockton Press, New York), the annual Buyers' Guide supplement to the journal *Bio/Technology*, as well as various sites on the Internet.
