Current Protocols in Toxicology

ISBN: 0-471-24106-7

Last time updated: September 2005

Current Protocols in Toxicology is a "best-practices" collection of lab protocols for accurate, efficient assessments of toxicity in whole organisms, organs and tissues, cells, and biochemical pathways. Continuously updated since its initial publication in May 1999, this quarterly-updated two-volume set...
- provides the latest models and methods from molecular biology, cell biology, biochemistry, and genetics, plus sophisticated toxicological procedures from leading laboratories.
- offers expert guidelines for evaluating the effects of substances on human physiology and metabolism.
- provides valuable reference information in three appendices, including stock solutions and equipment, commonly used techniques, and using information.

FOREWORD

Toxicological research is driven by the need to understand and assess the human and ecological risks of exposure to chemicals and other toxicants as well as by interest in using toxic agents to elucidate basic biological and pathobiological processes. The level of research activity in this field is higher, the rate of change in knowledge more rapid, and interest in applying scientific information to societally important issues is greater than ever before. These are exciting and challenging times to be working in toxicology. The ongoing ferment builds on the extraordinary advances being made in the understanding of biological systems at the molecular level. This fundamental knowledge provides the opportunity for greatly enhanced insight into how chemicals and other stressors may damage biological structures and processes, influence the rate of biological repair, and lead to reversible or irreversible diseases or to a return to health.

Society increasingly calls on the scientific community for the knowledge needed both to reevaluate the health hazards of existing products and technologies and to evaluate the prospective hazards of new ones. Such information is used to develop guidelines and regulations designed to ensure that these new products and technologies do not harm people or the environment.

Acquiring sound, reproducible scientific data that can be integrated with existing information to advance the knowledge of toxicants and living systems requires rigorous adherence to the scientific method. This means intelligent, thoughtful individuals identifying important needs, formulating testable hypotheses, designing experiments to test them, meticulously conducting these experiments, carefully reviewing and interpreting data, and ultimately presenting this information to scientific peers, including publishing it in the peer-reviewed literature. *Current Protocols in Toxicology* is a clear and well-documented compendium of the most important methods in the field—proven approaches developed by leading researchers—for the benefit of other experimentalists, from students to seasoned investigators. Since toxicology by its nature is multidisciplinary, other titles in the Current Protocols series may also provide relevant methods. Although review of the literature cited for each procedure can give added insight into the underlying theory and breadth of applications, the protocols have been carefully designed to provide clear, step-by-step descriptions that can easily be followed even by the relatively inexperienced.

Regular updates to *Current Protocols in Toxicology* manual will help ensure an awareness of changes in previously documented methods and of methods newly developed. Use of these protocols will avoid unnecessary duplication of effort in development and validation when the methods are applied without modification, and will speed up the development of more refined methods that will further advance the field of toxicology and, in turn, may have a place in future updates.

Current Protocols in Toxicology (1999)

PREFACE

The span of research in toxicology has been expanding and diversifying precipitously in recent years. One cause for this is the ongoing increase in industrial activity and in the generation of toxic compounds that then find their way into the environment. Another is the intensifying public awareness of the health effects of chemical exposure. The expansion of the field can be observed by attending any major scientific event dedicated to toxicology—such as the annual meetings of the Society of Toxicology, whose attendance has tripled in the course of the 1990s.

Examining the meeting program for one of these events provides a very good feel for the broad scope of toxicology. For those who have attended such meetings periodically over the past few years, the dynamic nature of the field and its explosive growth is obvious: there is simply more in-depth research going on every year. This is in contrast to toxicology's early years, when the field was dominated by research involving gross assessment of organisms' responses to toxic chemicals. More recent times have witnessed the emergence of applications of state-of-the-art technology to the study of toxicity responses in organisms and living cells, along with phenomenal advancement in molecular and biochemical techniques, which increasingly are finding their way into toxicology research laboratories. A growing number of presentations at toxicology meetings constitute bridges between basic toxicology research and approaches to improving human health and environmental quality. It is this changing and expanding face of toxicology and its methodologies that represented the greatest challenge in assembling *Current Protocols in Toxicology*. We have attempted to include those methods that are presently central to modern toxicology and that we expect will remain valuable tomorrow. Like the field of toxicology, with its quarterly supplements this book will continue to expand in scope, to include more topics and methods as the field advances.

Because toxicological questions may be addressed using methods deriving from a wide variety of disciplines, other titles in the Current Protocols series may also provide methods that can be applied in your research. Molecular biology techniques, in particular, are integral to toxicological investigation. Such techniques are included where appropriate within units in this book; however, where these protocols are located may not be readily apparent from the table of contents. To help you find them, Table A.3A.1 in *APPENDIX 3A* provides a listing of specific techniques and where they can be found, either in this book or in related Current Protocols manuals. In addition, protocols for a number of basic techniques will be added to *APPENDIX 3* in future supplements.

Although mastery of the techniques in this manual will enable readers to pursue research in toxicology, the manual is not intended to be a substitute for graduate-level courses or a comprehensive textbook in the field. An inevitable hazard of manual writing is that protocols may become obsolete as the field expands and new techniques are developed. To safeguard this manual from inexorable obsolescence (and perhaps pleasantly surprise the users of the manual!), we provide quarterly supplements to provide protocols that utilize new innovations and technologies in the field. The updatable formats—looseleaf binder, CD-ROM, Intranet, and online Internet—easily accommodate the addition of this new material.

Current Protocols in Toxicology (1999) iii-vi

HOW TO USE THIS MANUAL

Format and Organization

This publication is available in both looseleaf and CD-ROM format. For looseleaf purchasers, a binder is provided to accommodate the growth of the manual via the quarterly update service. This format allows easy insertion of new pages, units, and chapters that are added. The index and table of contents are updated with each supplement. CD-ROM purchasers receive a completely new disc every quarter and should dispose of their outdated discs. The material covered in the two versions is identical.

Subjects in this manual are organized by chapters, and protocols are contained in units. Protocol units, which constitute the bulk of the book, generally describe a method and include one or more protocols with listings of materials, steps and annotations, recipes for unique reagents and solutions, and commentaries on the "hows" and "whys" of the method. Other units present more general information in the form of explanatory text with no protocols. Overview units contain theoretical discussions that lay the foundation for subsequent protocols. Other discussion units present more general information.

Page numbering in the looseleaf version reflects the modular arrangement by unit; for example, page 1.2.3 refers to Chapter 1 (Toxicological Models), *UNIT 1.2* (Statistical Methods in Toxicology), page 3 of that particular unit.

Many reagents and procedures are employed repeatedly throughout the manual. Instead of duplicating this information, cross-references among units are used and recipes for common reagents are supplied in *APPENDIX 2A*. Cross-referencing helps to ensure that lengthy and complex protocols are not overburdened with steps describing auxiliary procedures needed to prepare raw materials and analyze results.

Introductory and Explanatory Information

Because this publication is first and foremost a compilation of laboratory techniques in toxicology, we have included explanatory information where required to help readers gain an intuitive grasp of the procedures. Some chapters begin with special overview units that describe the state of the art of the topic matter and provide a context for the procedures that follow. Chapter and unit introductions describe how the protocols that follow connect to one another, and annotations to the actual protocol steps describe what is happening as a procedure is carried out. Finally, the Commentary that closes each protocol unit describes background information regarding the historical and theoretical development of the method, as well as alternative approaches, critical parameters, troubleshooting guidelines, anticipated results, and time considerations. All units contain cited references and many indicate key references to inform users of particularly useful background reading, original descriptions, or applications of a technique.

Protocols

Many units in the manual contain groups of protocols, each presented with a series of steps. One or more *basic* protocols are presented first in each unit and generally cover the recommended or most universally applicable approaches. *Alternate* protocols are provided where different equipment or reagents can be employed to achieve similar ends, where the starting material requires a variation in approach, or where requirements for the end product differ from those in the basic protocol. *Support* protocols describe additional steps that are required to perform the basic or alternate protocols; these steps are separated from the core protocol because they might be applicable to other uses in the manual, or because they are performed in a time frame separate from the basic protocol steps.

Reagents and Solutions

Reagents required for a protocol are itemized in the materials list before the procedure begins. Many are common stock solutions, others are commonly used buffers or media, while others are solutions unique to a particular protocol. Recipes for the latter solutions are provided in each unit, following the protocols (and before the commentary) under the heading Reagents and Solutions. It is important to note that the *names* of some of these special solutions might be similar from unit to unit (e.g., electrophoresis buffer) while the *recipes* differ; thus, make certain that reagents are prepared from the proper recipes. On the other hand, recipes for commonly used stock solutions and buffers are provided once in *APPENDIX 2A*. These universal recipes are cross-referenced parenthetically in the materials lists rather than repeated with every usage.

Commercial Suppliers

Throughout the manual, we have recommended commercial suppliers of chemicals, biological materials, and equipment. In some cases, the noted brand has been found to be of superior quality or it is the only suitable product available in the marketplace. In other cases, the experience of the author of that protocol is limited to that brand. In the latter situation, recommendations are offered as an aid to the novice in obtaining the tools of the trade. Experienced investigators are therefore encouraged to experiment with substituting their own favorite brands.

Addresses, phone numbers, and facsimile numbers of all suppliers mentioned in this manual are provided in the *SUPPLIERS APPENDIX*.

Safety Considerations

Anyone carrying out these protocols may encounter the following hazardous or potentially hazardous materials: (1) radioactive substances, (2) toxic chemicals and carcinogenic or teratogenic reagents, and (3) pathogenic and infectious biological agents. Check the guidelines of your particular institution with regard to use and disposal of these hazardous materials. Although cautionary statements are included in the appropriate units, we emphasize that users must proceed with the prudence and precaution associated with good laboratory practice, and that all materials must be used in strict accordance with local and national regulations.

Animal Handling

Many protocols call for use of live animals (usually rats or mice) for experiments. Prior to conducting any laboratory procedures with live subjects, the experimental approach must be submitted in writing to the appropriate Institutional Animal Care and Use Committee (IACUC) or must conform to appropriate governmental regulations regarding the care and use of laboratory animals. Written approval from the IACUC (or equivalent) committee is absolutely required prior to undertaking any live-animal studies. Some specific animal care and handling guidelines are provided in the protocols where live subjects are used, but check with your IACUC or governmental guidelines to obtain more extensive information.

Reader Response

Most of the protocols included in this manual are used routinely in the authors' laboratories. These protocols work for them; to make them work for you they have annotated critical steps and included critical parameters and troubleshooting guides in the commentaries to most units. However, the successful evolution of this manual depends upon readers' observations and suggestions. Consequently, a self-mailing reader-response

survey can be found at the back of the manual (and is included with each supplement); we encourage readers to send in their comments.

ACKNOWLEDGMENTS

This manual is the product of dedicated efforts by many of our scientific colleagues who are acknowledged in each unit and by the hard work by the Current Protocols editorial staff at John Wiley and Sons. We are extremely grateful for the critical contributions by Kathy Morgan (Series Editor), who kept the editors and the contributors on track and played a key role in bringing the entire project to completion, and by Gwen Crooks and Virginia Chanda, who provided developmental support in the early stages of the project. Other skilled members of the Current Protocols staff who contributed to the project include Joseph White, Kathy Wisch, Michael Gates, Demetra Kagdis, Alice Ro, Scott Holmes, Tom Cannon, and Alda Trabucchi. The extensive copyediting required to produce an accurate protocols manual was ably handled by Rebecca Barr, Allen Ranz, Elizabeth Harkins, Ben Gutman, Karen Hopkin, Monte Kendrick, Caroline Lee, Candace Levy, and Cathy Lundmark, and electronic illustrations were prepared by Gae Xavier Studios.

CHAPTER 1
Toxicological Models

INTRODUCTION

This chapter illustrates a variety of general models and approaches that can be used in toxicological studies. As such, it is considerably broader and more diverse than other chapters in *Current Protocols in Toxicology*, presenting a broad group of methodological approaches, in vivo models, and in vitro systems. As well as established toxicological protocols, the chapter will cover both traditional and novel methods developed in other disciplines that have potential application to toxicology.

UNIT 1.1 examines the role of nonhuman primates as animal models in toxicology research. While not used extensively, for certain obvious reasons (such as cost and the necessity for special facilities), their similarity animals to humans makes nonhuman primates invaluable in certain aspects of toxicology. The unit discusses several areas of investigation (including reproductive toxicology, neurobehavioral toxicology, and immunotoxicology) where studies in nonhuman primates have provided important data relating to understanding mechanisms of toxicity and setting safe levels of exposure to toxicants.

Because the end-points of toxicity used in in vivo or in vitro studies are so diverse, use of the appropriate statistical approach is of the utmost importance. *UNIT 1.2* reviews statistical methods in toxicology, with an emphasis on the approaches that should be used with different toxicological tests.

The ability to generate transgenic animals, most often mice, that overexpress or lack a certain protein (such as an enzyme or receptor) has been one of the major achievements in life science research over the past several years. The availability of transgenic animals allows a much better understanding of the physiological functions of proteins of interest and of their potential role in chemical toxicity. *UNIT 1.3* discusses strategies and applications of transgenic animals in toxicology, as well as methods currently used to generate transgenic mice.

DNA microarrays, also known as DNA "chips," allow detection of expression of RNA for thousands of genes that can be modified by toxic chemicals. In addition, they can be used to detect DNA sequence polymorphisms, thus providing a powerful method to assess genetic variations. An overview of the technologies of DNA microarrays and their applications to toxicology is presented in *UNIT 1.4*.

UNIT 1.5 describes a series of methods for the preparation and use of fish-derived cell lines for cytotoxicity testing of environmental contaminants. Another interesting model system for toxicity testing is represented by sea urchin embryos and larvae. The model, described in *UNIT 1.6*, appears to be particularly promising for studies of the effects of developmental neurotoxicants.

UNIT 1.7 describes yet another rather novel test system—the zebrafish—which has potential for a number of applications.

Current Protocols in Toxicology (2003) 1.0.1-1.0.2

Two important in vivo models for studying Parkinson's disease are discussed in *UNIT 1.8*; they utilize treatments with MPTP in mice and non-human primates and with 6-OHDA in rats.

Upcoming units will discuss in vitro methods to assess toxicity and genotoxicity in mammalian cells among other topics.

Lucio G. Costa

Nonhuman Primates as Animal Models for Toxicology Research

The use of nonhuman primates in biomedical research has a long and distinguished history (Bennett et al., 1995). An integral part of this history is biomedical research in the area of toxicology. The purpose of this unit is to present an overview of the use of nonhuman primate models in toxicological research. The unit is organized into five sections. The first section provides an overview of the extensive work with nonhuman primate models in the areas of reproductive toxicology and teratology (birth defects). The second section focuses on neurotoxicology research, including a brief discussion of nonhuman primate models for Parkinson's disease and methanol-induced ocular toxicity. This section also offers an overview of studies that used infant nonhuman primate models to investigate the neurobehavioral toxicology of early exposure to environmental pollutants (lead, methylmercury, polychlorobiphenyls) and drugs of abuse (ethanol, cocaine). Section three focuses on immunotoxicology. Recent studies that used nonhuman primate models to examine the effects of polychlorobiphenyls (PCBs) and early ethanol exposure are provided as examples. The fourth section discusses research in respiratory or lung toxicology and highlights the use of nonhuman primate models in studies of inhaled particles. The final section provides an overview of the use of nonhuman primate models for research in chemical carcinogenesis. This section also discusses long-term National Cancer Institute studies that used nonhuman primates in tumor-incidence research. More recent uses of nonhuman primates in studies of the role of diet in the development of cancer are also presented. The unit closes with a few comments on other important uses of nonhuman primates in toxicological research.

Although this unit describes the numerous contributions of nonhuman primate models in toxicology, it is important to keep in mind that the majority of toxicology research is conducted using rodent animal models. Rodents have more diverse behavioral repertoires, are less expensive to purchase (thus allowing larger sample sizes), and are easier to care for than nonhuman primates. Rodents also develop quickly, so adult physical stature and sexual maturity are reached in months instead of years.

Mazue and Richez (1982) delineated the benefits and problems associated with using nonhuman primates in toxicological research. Issues such as phylogenetic proximity and physiologic, metabolic, and behavioral similarity were listed as benefits, whereas supply, small sample sizes, the potential for disease transmission to humans, and cost were listed as problems. In addition to the above, the ethical use and treatment of nonhuman primates is an issue of great importance in toxicology research. Although the ethical issues are not specific to nonhuman primate research or research in toxicology (Dennis, 1997), researchers in toxicology must weigh these issues—such as why nonhuman primates are necessary in the investigation of toxic effects and how many animals are required to define potential toxicity—carefully when the use of nonhuman primates is considered.

The nonhuman primates most frequently used in toxicology are members of the *Macaca* genus and include the crab-eating macaque (*M. fascicularis*), the rhesus macaque (*M. mulatta*), and the pig-tailed macaque (*M. nemestrina*). Less widely used are the baboon, squirrel monkey, and chimpanzee. The specific requirements for housing and maintenance of these animals are described in the congressional Animal Welfare Act (AWA). (To obtain a copy of the AWA, call the USDA at 916-857-6205.) Administered by the US Department of Agriculture (USDA), this act covers all warm-blooded animals, with the exception of rats, mice, and birds. The US Public Health Service (USPHS) requires that all institutions supported by the National Institutes of Health (NIH) meet or exceed the regulations published in the AWA. Briefly, the minimum space (cage size) that must be provided to nonhuman primates is based on the animal's weight, except for brachiating species (those that rely on an overhead arm swing for locomotion) and the great apes (i.e., chimpanzees, orangutans, and gorillas). The AWA contains a table for calculating appropriate cage size. Animals are typically fed twice a day to support natural foraging behavior and to minimize the potential of clinical disorders, such as bloating. Purina High Fiber Monkey Chow (#5049) provides all the basic nutritional requirements, although diets are typically supplemented with vegetables and

Contributed by Thomas M. Burbacher and Kimberly S. Grant
Current Protocols in Toxicology (1999) 1.1.1-1.1.9

fruits, such as grapes, apples, green peppers, cherry tomatoes, onions, potatoes, and yams. Water is typically available ad libitum. Recently, the AWA was amended to include environmental enrichment programs for nonhuman primates and dogs. Environmental enrichment for primates typically includes regular opportunities for social contact for grooming and play, chew toys, at least one perch in each cage, food treats, positive interaction with a caregiver or another familiar person, and daily visual and auditory contact with at least one animal of the same or a compatible species.

When working with nonhuman primates, all laboratory personnel must follow special precautions for minimizing the transmission of zoonoses. These precautions include, but are not limited to, gloves, protective eyewear, shoe covers, and laboratory coats. Many of these steps have been adopted in response to the potential lethal nature of the herpes B virus. Because small research facilities find it difficult to meet all the necessary requirements, most nonhuman primate research in the United States is carried out at one of the seven NIH-sponsored Regional Primate Research Centers (*www.ncrr.nih.gov/compmed/cmrprc.htm*).

REPRODUCTIVE TOXICOLOGY AND TERATOLOGY

Reproductive Toxicology

The value of the nonhuman primate model in reproductive toxicology is largely based on similarities of the hypothalamic-pituitary-ovarian-uterine axis in monkeys and humans. The general reproductive parameters shared between many nonhuman primates and humans include the plasma hormone patterns that support menstruation, the length of the menstrual cycle, the onset of chorionic gonadotropin secretion, placental structure, and length of gestation (Hendrickx and Cukierski, 1987). Macaque menstrual cycles are typically 28 days long with 3 to 5 days of actual menses, closely matching the human menstrual cycle. Conception rates vary among species and laboratories, ranging from 25% to 50% after a single mating. In addition, similarities in embryonic and fetal development are evident, beginning with the timing and length of organogenesis. As in humans, successful reproduction in primates requires a fertilized oocyte to implant in the endometrial lining of the uterus and complex hormonal interactions to successfully maintain the pregnancy. Once conception has taken place, both humans and macaques show similar early pregnancy plasma hormone patterns. Organogenesis begins on day 21 in the macaque and day 18 in the human, ending on day 50 in the macaque and day 60 in the human. Although human placentas are monodiscoid (single lobed) and macaque placentas are bidiscoid (double lobed), placental function is virtually identical. The gestation of a full-term infant macaque ranges from 165 to 175 days (23 to 25 weeks), whereas human gestation is, on the average, ~280 days (40 weeks).

Ovarian function and pregnancy are generally well understood in many nonhuman primate species and thus provide an opportunity to examine the relationship between toxicant exposure and reproductive dysfunction (e.g., alterations in menses and fertility). Studies can be designed to evaluate changes in the production of steroids after toxicant exposure and the role these changes may play in adverse reproductive outcomes. In addition to more immediate outcome measures, such as menses, ovulation, and pregnancy, reproductive processes at the opposite end of the reproductive continuum, such as menopause, can also be examined in lifespan studies (Sakai and Hodgen, 1988).

Within the context of reproductive toxicology, Sakai and Hodgen (1988) pointed out the importance of minimally invasive experimental procedures. Examples of such procedures are the collection of blood during the menstrual cycle for analysis of gonadotropin and steroid concentrations, the collection of urine for analysis of steroids and pregnancy gonadotropins, and minor surgical procedures (e.g., laparoscopy and laparotomy). Behavioral methods have also been developed to minimize the handling and subsequent stress of adult female monkeys used for reproductive toxicology studies. Monkeys can be trained to present their perineum to human observers so menstrual bleeding can be detected, and early pregnancies can be reliably palpated by 3 to 4 weeks postconception (Burbacher et al., 1988).

Various macaque species have been used as models in studies investigating the reproductive effects of exposure to environmental pollutants (lead, methylmercury) and of drug abuse (ethanol, cocaine). Procedures for evaluating the characteristics of the menstrual cycle (length, hormone status), breeding status (number of timed matings to conception, conception rate, live-birth delivery rate), and offspring viability (gestation length, birth size, perinatal mortality) are typically included in these studies. Results indicated that lead exposure suppresses circulating levels of luteinizing hormone (LH),

follicle-stimulating hormone (FSH), and 17-β-estradiol (E_2) during the menstrual cycle in crab-eating macaques (*M. fascicularis*). The length of the menstrual cycle, the length of menses, and the circulating levels of progesterone were unaffected (Foster, 1992). Chronic methylmercury exposure was associated with a decrease in the number of live-born offspring in crab-eating macaques, but the menstrual cycle and menses lengths were again unaffected (Burbacher et al., 1988). Reproductive effects associated with ethanol exposure in pig-tailed macaques (*M. nemestrina*) also included a significant decrease in the number of live-born offspring (Clarren and Astley, 1992). This effect was primarily the result of an increase in the number of abortions. A study of the effects of maternal cocaine exposure in rhesus monkeys (*M. mulatta*) did not reveal significant effects on reproductive parameters (Morris et al., 1996a). The number of females investigated in this study (n = 3/group) may, however, have been too small to detect such effects.

Teratology

One of the most important uses of nonhuman primate models has been in research aimed at identifying toxicants that cause birth defects. Compared to adults, embryos and fetuses exhibit an increased sensitivity to the structural and functional effects of many chemical compounds. Studies designed specifically to address the risk of birth defects are required to evaluate the health risks from exposure to certain environmental compounds or drugs. For drugs that are likely to be taken by pregnant women and for a widespread environmental pollutant, such as lead or methylmercury, studies using nonhuman primate models may be appropriate.

The antinausea drug thalidomide provides a good example of the importance of using nonhuman primate models in teratology research. Limb malformations documented in infants born to women who used this drug during pregnancy were not observed in routine teratology tests using rodent models. Parallel effects were observed in nonhuman primates, including timing (sensitive period), type of malformation (limb defects), and the dose required to produce the teratogenic response (Hendrickx, 1973). The thalidomide episode established nonhuman primates as an important animal model for specific malformation syndromes seen in human infants. However, as Hendrickx and Binkerd (1990) noted, although nonhuman primates provided an excellent model for the effects of thalidomide, this was not the case for the developmental effects after exposure to the rubella virus in early pregnancy. In a study evaluating fifteen known human teratogens, rodent models predicted a human teratogenic response ~70% of the time, but nonhuman primate models predicted such a response only ~50% of the time (Schardein et al., 1985). Although several factors may account for this—e.g., metabolic differences and the small sample size typical in nonhuman primate work—it is prudent to note that nonhuman primates do not always mimic humans in their teratogenic responses.

Nonhuman primate models have been used in a wide range of studies aimed at assessing the safety of pharmaceutical agents, environmental pollutants, physical agents (e.g., X-rays), and drugs of abuse as well as the effects of infectious diseases. Hendrickx and Binkerd (1990) provided a comprehensive listing of the compounds that have been tested using nonhuman primate models and the corresponding indices of toxicity in the offspring (e.g., fetal death, structural malformations, growth retardation, and functional deficits). In addition to thalidomide, nonhuman primate models are particularly well recognized for helping elucidate the dysmorphology associated with prenatal exposure to vitamin A and its derivatives (retinoids), the anticonvulsant valproic acid, and triamcinolone acetonide (a synthetic glucocorticoid). Nonhuman primate models have also played a contributory role in defining the genital malformations associated with diethylstilbestrol.

NEUROTOXICOLOGY

One of the best known nonhuman primate models in neurotoxicity is the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)–treated monkey (Kaakkola and Teravainen, 1990; Bezard et al., 1997). The neurotoxic effects after exposure to MPTP in human and nonhuman primates resemble those associated with Parkinson's disease: i.e., hypokinesia, rigidity, resting tremor, stooping posture, dysphagia, depletion of striatal dopamine, and loss of cells in the substantia nigra. Response to drug therapy (e.g., levodopa) is also similar in humans and nonhuman primates exhibiting these symptoms. Studies using neural grafts in MPTP-treated monkeys reported a reduction in parkinsonism. Studies using MPTP-treated monkeys will continue to provide important information regarding the pathophysiology and neurochemical effects associated with Parkinson's disease. Studies of potential innovative or

long-term drug therapies will also continue to use this animal model.

Another excellent example of an important nonhuman primate model is ocular toxicity caused by methanol exposure. Methanol (methyl alcohol or wood alcohol) poisonings have been reported since the turn of the 20th century and are characterized by severe metabolic acidosis; ocular toxicity; and, in the most serious cases, coma and death. Early studies using nonhuman primate models indicated that formate (formic acid), a metabolite of methanol, was responsible for the toxicity associated with methanol intake. Human and nonhuman primates display similar effects from high-dose methanol exposure, owing to their limited capacity, compared with rodents, to metabolize formate to carbon dioxide (Black et al., 1985). Elevated formate concentrations are believed to cause the optic disc edema and optic nerve lesions associated with methanol poisoning. As is the case with MPTP exposure and induction of a parkinsonian-like condition, treatment with formate in the monkey induces the optic nerve toxicity commonly associated with human methanol poisoning. Use of this animal model has aided the development of treatment strategies designed to mitigate the severe and frequently permanent consequences of acute high-dose methanol intake.

Neurobehavioral Toxicology

The highly evolved behavioral repertoire of nonhuman primates makes them excellent subjects for investigations of the functional effects of neurotoxicants. The nonhuman primate model is especially useful in studies of developmental exposures and effects, because monkeys, like humans, have relatively long periods of gestation, infancy, and adolescence. Studies can investigate possible critical periods in development for neurotoxicant effects. Special testing procedures are available for infant nonhuman primates that target milestones in cognitive and sensory development and physical growth.

Macaque and human infants share certain limitations and abilities, particularly during the first months of life. The emergence of reflexes like sucking, rooting, grasping, clasping, and righting can be evaluated as early as postnatal day 1. Infant rhesus macaques (*M. mulatta*) developmentally exposed to lead exhibit lower muscle tonus and increased agitation on tests of neonatal reflexes and behavioral organization compared to controls (Levin et al., 1988).

Early cognition can be studied in monkeys during the first months of life using procedures identical to those used to evaluate human infants. Tests of object permanence are generally believed to measure coordinated reaching responses and spatial memory. Studies of in utero exposure to methylmercury in crab-eating macaques (*M. fascicularis*) indicated a delay in object permanence development. On average, infant crab-eating macaques exposed in utero to methylmercury exhibited object permanence a full month after controls (90 versus 60 days; Burbacher et al., 1990a).

Visual recognition memory can be measured in both humans and monkey infants using a test in which novel visual stimuli are paired with familiar stimuli; looking times to each are recorded (Fagan, 1990). Visual preferences for novel stimuli are considered evidence for recognition memory because some aspects of the familiar stimuli must be retained in memory for the novelty response to occur. Deficits in visual recognition memory have been found in a number of monkey groups at high risk for poor developmental outcome, including those exposed to known human teratogens (methylmercury, ethanol; Burbacher et al., 1990a). Studies with human infants also reported reduced visual recognition scores in infants prenatally exposed to PCBs (Jacobson et al., 1985).

The development of primate social behavior appears relatively sensitive to neurotoxicant exposure. Infants exposed in utero to methylmercury exhibited reduced levels of social play and spent more time engaged in passive, nonsocial behaviors (Burbacher et al., 1990b). Infant monkeys fed lead acetate daily from birth to 1 year of age demonstrated disrupted social development, resulting in decreased levels of social play and increased levels of fear and self-stimulation (Laughlin et al., 1991). These effects persisted after dosing was terminated. Infants exposed in utero to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) initiated more play, retreated less frequently, and were displaced less often from preferred positions in the playroom (Schantz et al., 1992). TCDD-exposed monkeys also displayed increased levels of self-directed behaviors.

Several learning and memory assessments have been developed for older infant, juvenile, and adult nonhuman primates. Tests have been designed to study both spatial and nonspatial memory, using simple and complex learning paradigms—e.g., discrimination, alternation, reversal, and concept learning (matching and nonmatching to sample). Computer-controlled

presentation of test stimuli allows the opportunity to test both monkeys and children on identical measures of cognition. Studies using these procedures have also been used to investigate the effects of in utero cocaine exposure on learning in rhesus monkeys (Morris et al., 1996b). Rice and associates have had one of the most productive neurobehavioral toxicology programs using nonhuman primate models to study caffeine, lead, PCBs, and methylmercury. Results from their research program described learning deficits on several test procedures in monkeys exposed to lead during development (Rice, 1996). The performance of the lead-exposed monkeys was characterized by an inability to attend to relevant cues and to keep pace with changing environmental contingencies. These effects are similar to those observed in children exposed to lead (e.g., attention deficits).

The assessment of sensory functioning is a frequently overlooked area in neurobehavioral toxicology studies. Sensory tests not only are valuable tools in evaluating toxicant-related brain injury but also provide a measure of neurotoxicity that is relatively unencumbered by psychological variables, such as learning ability. Vision is probably the best studied of all sensory systems and is certainly the dominant sense in both human and nonhuman primates. Tests of this nature typically involve assessment of visual acuity and contrast sensitivity and are based on a signal-detection paradigm. Monkeys exposed to chronic low levels of methylmercury from birth exhibited impaired spatial vision relative to controls under conditions of both high and low luminance (Rice and Gilbert, 1982). Studies indicate that in utero exposure to methylmercury also impairs spatial vision in adulthood (Burbacher et al., 1999). Auditory and somatosensory functioning were also evaluated using the signal-detection paradigm. Auditory detection thresholds were studied in monkeys who were exposed to methylmercury during their first 7 years of life (Rice and Gilbert, 1992). Results showed a selective high-frequency hearing loss in treated animals. Somatosensory function was also evaluated in monkeys exposed to methylmercury or lead (Rice and Gilbert, 1995). Animals exposed to methylmercury demonstrated elevated vibration detection thresholds on this procedure, whereas results from the lead-treated monkeys were somewhat equivocal.

IMMUNOTOXICOLOGY

Studies of the anatomy and function of the immune system of nonhuman primates reported many similarities to that of humans (Bleavins and de la Iglesia, 1995). Using monoclonal antibodies raised against human antigens, researchers noted extensive cross-reactivities in several nonhuman primate species, including macaques (Tryphonas et al., 1996). For example, a study by Ozwara et al. (1997) examined the reactivity of 161 antihuman monoclonal antibodies in chimpanzees, rhesus macaques, and squirrel monkeys. Antibodies directed against T cell surface antigens and against cytokine receptors were examined for their reactivity with peripheral blood mononuclear cells. The results of the study indicated that 38 of 161 monoclonal antibodies reacted in all three nonhuman primate species; 112 monoclonal antibodies reacted in one or two of the species. Chimpanzees showed the highest cross-reactivity (65%), followed by rhesus macaques (45%) and squirrel monkeys (42%). Tryphomas et al. (1996) reported extensive cross-reactivities with antihuman monoclonal antibodies in *M. fascicularis* infants. An important finding in this study was the reported sex differences in the levels of CD4 monoclonal antibodies and for the CD4/CD8 ratio (females > males), a sex difference similar to that observed in humans. Bleavins and de la Iglesia (1995) reported the results of a study aimed at developing a delayed-type hypersensitivity procedure using crab-eating macaques (*M. fascicularis*). Delayed-type hypersensitivity was measured using the human multitest cell-mediated immunity (CMI) skin test, which includes seven antigens. Responses to the skin tests paralleled those observed in humans. The authors proposed the use of this delayed-type hypersensitivity procedure in *M. fascicularis* for preclinical safety testing.

A number of sensitive methods are available for evaluating the effects of compounds on the immune systems of humans and animals. In a series of articles, Luster et al. (1993) described a screening battery for evaluating the potential immunotoxicity of compounds in mice. Five parameters were included in the battery (immunopathology, humoral-mediated immunity, CMI, nonspecific immunity, and host resistance challenge) in a two-tier approach. Studies using nonhuman primate models of immune system toxicity have included assessments of these parameters. For example, Tryphomas (1995) published a series of reports describing the effects of PCB exposure on the immune system of adult rhesus macaques. The results of the study indicated that low-level chronic (55 months) exposure to PCBs (Aroclor 1254) was

associated with changes in several immunological parameters in the rhesus macaque (Table 1.1.1). These changes were most likely the result of altered T cell and/or macrophage function.

Pig-tailed macaques (*M. nemestrina*) have been used to study the immune effects associated with fetal alcohol exposure (Grossmann et al., 1993). Monkeys exposed to ethanol in utero were more susceptible to disease and exhibited reduced T lymphocyte proliferation and lower titers to tetanus toxoid than did nonexposed controls. The reduction in T cell proliferation was consistent with reports from studies of children with fetal alcohol syndrome (FAS) and rodent models of prenatal alcohol exposure. The authors noted that several of the effects seemed sex dependent and cautioned investigators about the need to control for sex in nonhuman primate studies of immune system effects.

RESPIRATORY TOXICOLOGY

Reports of cross-species comparisons of the anatomy and physiology of the respiratory system and the rates of deposition, clearance, and retention of inhaled particles have described many similarities between nonhuman primates and humans (Snipes, 1989, 1996; Nikula et al., 1997). For example, humans and nonhuman primates clear particles from the alveolar region more slowly, have larger alveoli and alveolar ducts, and have more complex acini than do rodents. Nonhuman primate models have been used extensively in studies of dust-induced pulmonary lesions (Snipes, 1996). In rats, chronic inhalation of poorly soluble dusts causes "lung overload," which can result in altered pulmonary clearance and pulmonary fibrosis. Humans and nonhuman primates exhibit a different pattern of dust accumulation in the lungs after chronic exposure. Whereas rats show fast pulmonary clearance of dust and retain dust predominantly in macrophages within the alveoli, human and nonhuman primates exhibit a slower pulmonary clearance of dust and retain dust burdens in the pulmonary interstitium. The rat pattern of dust accumulation may be related to the increased susceptibility of this animal to alterations in pulmonary clearance after chronic dust exposure compared to nonhuman primates. The rodent animal model may not

Table 1.1.1 Immunological Parameters Assessed in PCB-Exposed Rhesus Monkeys[a,b]

Parameter	Result[c]
Cell-mediated immunity	
Lymphocyte proliferation	D
Host-resistance challenge	
Pneumococcus titers	N
Nonspecific immunity	
Serum complement (CH_{50})	I
Natural killer cells	I
Serum thymosin	I

Total interferon	I[d]
Interleukin	D
Tumor necrosis factor	N
Humoral-mediated immunity	
CD2, CD4, CD8, CD20	N[e]
IgM and IgG titers	D

[a]Summarized from Tryphonas (1995).

[b]Serum hydrocortisone levels were normal in all exposure groups.

[c]I = increased, N = normal, D = decreased.

[d]Significant increase in low and high groups; significant decrease in moderate group.

[e]Significant decrease in percent of total T lymphocytes (CD2).

provide data relevant to the risk of pulmonary disease after chronic dust exposure in humans.

In addition to dust particles, respiratory effects have been described in nonhuman primate models after exposure to diesel exhaust (Nikula et al., 1997), ozone (Dimitriadis, 1993), marijuana smoke (Flifeil et al., 1991), and different forms of beryllium (Haley et al., 1994).

CLINICAL CARCINOGENESIS

In 1961, the National Cancer Institute began a program aimed at examining the susceptibility of nonhuman primates to chemicals that were known to cause tumors in rodents. Since then, the long-term carcinogenic activity of several therapeutic agents, food additives and compounds, environmental contaminants, N-nitroso compounds, and model rodent carcinogens have been evaluated. In addition, valuable data have been collected regarding the incidence of spontaneous tumors in several nonhuman primate species. Thorgeirsson et al. (1994) reported that the spontaneous tumor rate over a 32-year period for 181 rhesus monkeys was 2.8% for malignant tumors and 3.9% for benign tumors. For 130 crab-eating macaques and 62 African green monkeys, the corresponding rates were 1.5% and 0.8% and 8% and 0%, respectively.

Continuous dosing studies with the artificial sweeteners (cyclamate or saccharin) over a 22-year period provided no evidence of carcinogenic effects. Fungal food contaminants such as aflatoxin B1 and sterigmatocystin, however, were found to be potent hepatocarcinogens. 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ), an imidazole heterocyclic amine (HCA) present in cooked meat, was also found to be a potent hepatocarcinogen, inducing malignant liver tumors in 65% of monkeys tested during a 7-year dosing period. Snyderwine et al. (1997) reported that IQ is activated in monkeys via N-hydroxylation carried out by cytochrome P-450 CYP3A4 and/or CYP2C9/10. Human hepatic microsomes have been shown to have a greater capacity to activate HCAs compared to rodents and nonhuman primates. Current estimates of the daily intake of HCAs are on the order of 1 to 20 mg/person. Based on animal data, the estimates of the cancer risk to humans associated with this intake of HCAs are 10^{-3} to 10^{-4}.

Nonhuman primate models have also been used to examine the uptake and metabolic characteristics of suspected carcinogens when different susceptibilities are observed in rodent models. For example, studies indicated that mice are much more sensitive than rats to the carcinogenic effects of 1,3-butadiene and benzene (Henderson, 1996a,b). Studies using crab-eating macaques reported a low uptake of 1,3-butadiene after inhalation exposure. Concentrations of butadiene metabolites in the blood were 5 to 50 times lower in monkeys than in mice and 4 to 14 times lower than in rats. Studies of benzene also reported species differences in metabolism after inhalation exposure. Mice metabolize a greater fraction of a given dose of benzene than do rats and nonhuman primates. Mice also exhibit higher urinary concentrations of hydroquinone and its conjugates. Both rats and mice metabolize a higher fraction of benzene to ring-breakage metabolites than do nonhuman primates, as indicated by the levels of muconic acid in urine. Ring-breakage metabolites and hydroquinone have both been implicated in benzene carcinogenesis.

SUMMARY

This unit describes several important uses of nonhuman primate models in toxicological research. The examples provided are by no means exhaustive. Nonhuman primates continue to be used in studies of drug metabolism and of the toxicokinetics of environmental pollutants. Monkeys are also likely to be used more as new biotechnology products are discovered. In all of these areas of research, monkeys represent a unique resource, given the close evolutionary history they share with humans. The decision to use nonhuman primate models should always be made after careful consideration of all other alternatives. When nonhuman primate models are deemed necessary, researchers bear a special responsibility to ensure that procedures to minimize pain and discomfort are used and that proper environmental enrichment programs are in place (Bloomsmith et al., 1991).

Statistical Approaches to the Design of Toxicology Studies

Statistical methods provide an essential tool set for use across the field of toxicology. These methods may serve to perform any combination of three possible tasks. The most familiar is hypothesis testing—i.e., determining if two (or more) groups of data differ from each other at a predetermined level of confidence. The second function involves the construction and use of models, which is most commonly linear regression or the derivation of some form of correlation coefficient. Model fitting allows researchers to relate one variable (typically a treatment, or **independent**, variable) with other variables (usually one or more effects of **dependent** variables). The third function, reduction of dimensionality, is less commonly used than the first two and includes methods for reducing the number of variables in a system while only minimally reducing the amount of information, therefore making a problem easier to visualize and understand. Examples of such techniques are factor analysis and cluster analysis. A subset of the third function, discussed under Descriptive Statistics, is the reduction of raw data to single expressions of central tendency and variability (such as the mean and standard deviation). There is also a special subset (data transformation, which includes such things as the conversion of numbers to log or probit values) that is part of both the second and third functions of statistics. Figures 1.2.1, 1.2.2, 1.2.3, and 1.2.4 present a series of decision trees for selecting individual statistical techniques within the framework of the classification of methodologies.

This unit presents an overview of statistics. Gad (1998) presents a much more extensive discussion. Salsburg (1986) and Krewski and Franklin (1991) have also published works devoted to the field of statistical analysis in toxicology; and although these are more narrow in scope, they provide useful insights.

DESCRIPTIVE STATISTICS

Descriptive statistics is a fundamental starting place, used to convey the general nature of any set of collected data. The statistics describing any single group of data have two components. One of these describes the location of the data, and the other gives a measure of the dispersion of the data in and about this location. A fact that is often overlooked is that the choice of what parameters are used to convey these pieces of information implies a particular nature for the distribution of the data.

Most commonly, for example, location is described by giving the (arithmetic) mean, and dispersion is described by giving the standard

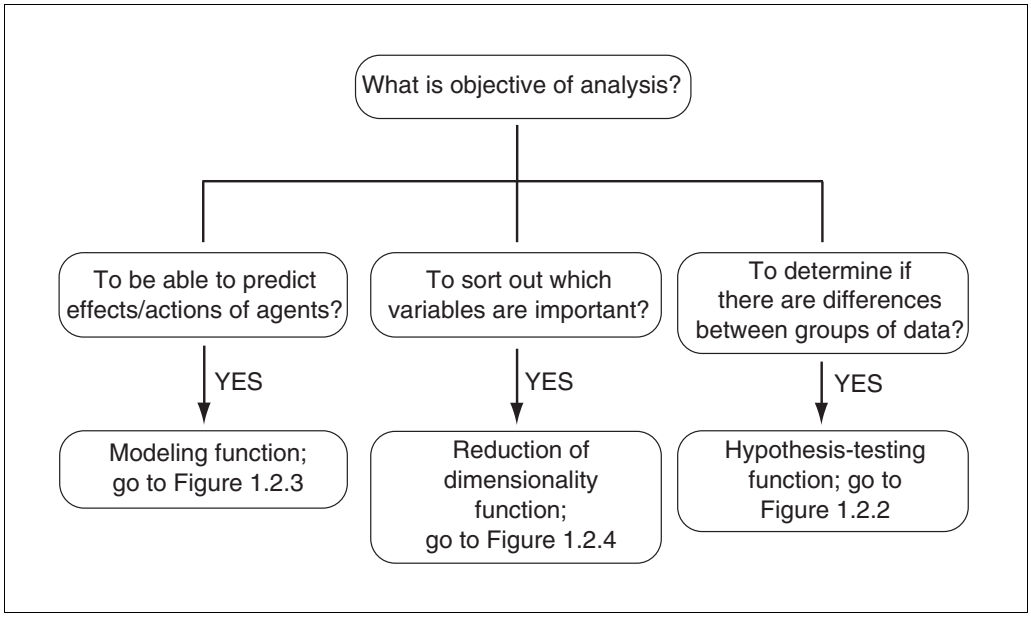

Figure 1.2.1 Overall decision tree for selecting statistical procedures. See Gad (1998) for an explanation of the statistical methods.

deviation (SD) or the standard error of the mean (SEM). For continuous variables, the character of a sample (x) may be described using the measures of central tendency and dispersion with which researchers are generally most familiar: the mean, denoted by the symbol $\overline{X}$ and also called the arithmetic average, is calculated by adding up all the values in a group then dividing by N (or n), the number of data points in a group. The SD is denoted by the symbol s for samples and σ for populations; in the former case it is calculated as

$$s = \sqrt{\frac{\sum x^2 - \frac{\left(\Sigma \overline{X}\right)^2}{N}}{N-1}}$$

where X is the individual datum. If the total number of data in the group is N, then the SEM is calculated as

$$\text{SEM} = \frac{SD}{\sqrt{N}}$$

The use of these parameters (the mean with either the SD or SEM) to describe a group implies, however, that there is reason to believe that the data being summarized are from a population that is at least approximately normally distributed. If this is not the case, then the researcher should instead use a set of terms that do not have such a rigid underpinning: commonly, the median for location and the semiquartile distance for dispersion.

When all the numbers in a group are arranged in a ranked order (i.e., from smallest to largest), the **median** is the middle value. If there is an odd number of values in a group, then the middle value is obvious (e.g., in the case of 13 values, the seventh largest is the median). When the number of values in the sample is even, the median is calculated as the midpoint between the (N/2)th and the ([N/2] + 1)th number. For example, the series of numbers 7, 12, 13, 19, the median value would be the midpoint between 12 and 13, which is 12.5.

EXPERIMENTAL DESIGN

A priori selection of statistical methodology (as opposed to the post hoc, or after the fact, approach) is as significant a portion of the process of protocol development and experimental design as any other and can measurably enhance the value of the study. The prior selection of statistical methodology is essential for the effective detailing of other parts of the protocol, such as the number of animals per group and the sampling intervals for body weight. To make such a selection, the toxicologist must have both an in-depth knowledge of the area of investigation and an understanding of the general principles of experimental design, because the analysis of any set of data is dictated to a large extent by the manner in which the data are obtained.

The four statistical principles of experimental design are replication, randomization, concurrent ("local") control, and balance.

Replication. Any treatment must be applied to more than one experimental unit (animal, plate of cells, etc.) to allow an estimate of the variability of the unit. This provides more accuracy in the measurement of a response than can be obtained from a single observation, because underlying experimental errors tend to cancel each other out. It also supplies an estimate of the experimental error derived from the variability among all the measurements taken (**replicates**).

Randomization. This is practiced to ensure that every treatment will have its fair share of extreme high and extreme low values and allows the toxicologist to proceed as if the assumption of "independence" were valid. That is, there is no avoidable/known systematic bias in how one obtains data.

Concurrent control. Comparisons between treatments should be made, to the maximum extent possible, between experimental units from the same group. That is, animals used as a **control** group should come from the same source and lot as the test-group animals. And, except for the treatment being evaluated, test and control samples should be maintained and handled in exactly the same manner.

Balance. If the effect of several different factors is being evaluated simultaneously, the experiment should be laid out in such a way that the contributions of the different factors can be separately distinguished and estimated.

The goal of all these principles is good statistical efficiency and the economizing of resources. Montgomery (1997) provides a comprehensive review of the area of experimental design.

The first precise or calculable aspect of experimental design encountered is determining sufficient test- and control-group sizes to allow one to have an adequate level of confidence in the results of a study (i.e., in the ability of the study design with the statistical tests used to detect a true difference, or effect, when it is present). The statistical test contributes a level of power to such a detection. The **power** of a

statistical test is the probability that a test results in rejection of the null hypothesis, H_0, when some other hypothesis, H, is valid. This is termed the power of the test "with respect to the (alternative) hypothesis H."

If there is a set of possible alternative hypotheses, the power, regarded as a function of H, is termed the **power function** of the test. When the alternatives are indexed by a single parameter Π, simple graphical presentation is possible. If the parameter is a vector Π, one can visualize a **power surface**.

If the power function is denoted by $\vartheta(\Pi)$ and H_0 specifies $\Pi = \Pi_0$, then the value of $\vartheta(\Pi)$—the probability of rejecting H_0 when it is in fact valid—is the significance level. A test's power is greatest when the probability of a type II error, or the probability of having a false-negative result (whereas a type I error refers to a false-positive result), is the least. Specified powers can be calculated for tests in any specific or general situation.

Some general rules to keep in mind are

1. The more stringent the significance level, the greater the necessary sample size. More subjects are needed for a 1% level test than for a 5% level test.

2. Two-tailed tests require larger sample sizes than do one-tailed tests. Assessing two directions at the same time requires a greater investment in resources.

3. The smaller the critical effect size, the larger the necessary sample size. Subtle effects require greater efforts (i.e., larger sample sizes).

4. Any difference can be significant if the sample size is large enough.

5. The larger the power required, the larger the necessary sample size. Greater protection from failure requires greater effort (more precision or larger sample size). The smaller the sample size, the smaller the power—i.e., the greater the chance of failure.

6. The requirements and means of calculating necessary sample size depends on the desired (or practical) comparative sizes of test and control groups.

This number (N), or the necessary sample size, can be calculated by using the following formula:

$$N = \frac{(t_1 + t_2)^2}{d^2} s^2$$

where t_1 is the one-tailed t-value with $N - 1$ degrees of freedom (df) corresponding to the desired confidence level; t_2 is the one-tailed t-value with $N - 1$ df corresponding to the probability that the sample size will be adequate to achieve the desired precision; s is the sample standard deviation, typically derived from historical data and calculated as follows (with υ being the variable of interest):

$$s = \sqrt{\frac{1}{N-1}\sum(\upsilon_1 - \upsilon_2)^2}$$

and d is the acceptable range of variation in the variable of interest. This calculation is illustrated in Example 1.

Example 1

In a subchronic dermal study in rabbits, the principal point of concern is the extent to which the compound causes oxidative damage to erythrocytes. To quantitate this, the laboratory will measure the numbers of reticulocytes in the blood. What then would be an adequate sample size to allow the question at hand to be addressed with reasonable certitude?

To determine this, use the one-tailed t-value for an infinite number of degrees of freedom at the 95% confidence level (i.e., $P \leq 0.05$). A set of t-tables shows this number to be 1.645. From prior experience, it is known that the usual values for reticulocytes in rabbit blood are from 0.5 to 1.9 $\times 10^6$/ml. The acceptable range of variation, zero, is therefore equal to the span of this range, or 1.4 (d). Likewise, an examination of the control data from previous rabbit studies shows that the sample standard deviation is 0.825 (s). When all these numbers are inserted into the equation for sample size (presented above), the required sample size (N) is calculated to be

$$= \frac{(1.645 + 1.645)^2}{(1.4)^2}(0.825)^2$$

$$= \frac{10.824}{1.96}(0.825)^2$$

$$= 4.556$$

In other words, in this case, in which there is little natural variability, measuring the reticulocyte counts of groups of only five animals each should be sufficient.

A good approximation can be generated by substituting t-values for an infinite number of degrees of freedom.

OUTLIERS AND ROUNDING OF NUMBERS

Outliers are extreme (high or low) values that are widely divergent from the main body

of a group of data and from what is the common experience. They may arise from an instrument (such as a balance) being faulty, they may be caused by the seemingly natural urge of some animals to frustrate research, or they may be indicative of a "real" value. Outlying values can be detected by visual inspection of the data; by use of a scattergram (discussed later); or (if the data set is small enough, which is usually the case in toxicology) by a large increase in the parameter estimating the dispersion of data, such as the standard deviation.

When it is possible to solidly tie one of the above error-producing processes (such as a balance being faulty) to an outlier, it can be safely deleted from consideration. But if it is not possible to positively attribute such a cause to an outlier (even if the researcher has strong suspicions), the problem is much more complicated, for then such a value may be one of several other things. It could be a result of a particular cause that is the grounds for the entire study—i.e., the very "effect" that is being sought—or it could be because of the collection of legitimate effects that constitute sample error. As will be discussed later (see Characteristics of Screens) and as is now becoming more widely appreciated, in animal studies outliers can be an indication of a biologically significant effect that is not yet statistically significant. Variance inflation can result from such outliers and can be used to detect them. Outliers, in fact, by increasing the variability within a sample, decrease the sensitivity of the statistical tests and may actually preclude a statistically significant result.

Alternatively, the outlier may be the result of an unobserved technician error. In this case the data point should be rejected—excluded from consideration with the rest of the data. Identifying legitimate cases (based on technical—i.e., actual technique-based measurement—error) for rejection from statistical analysis is the most complicated aspect of outlier issues.

When the number of digits in a number is to be reduced (because of limitations of space or to reflect the extent of significance of a number), it is necessary to round it off. Failure to have a rule for performing this operation can lead to both confusion and embarrassment for a facility (during such times as study audits). One common rule follows.

A digit to be rounded is not changed if it is followed by a digit <5—the digits following it are simply dropped off (**truncated**). If the number is followed by a digit >5 or by a 5 followed by other nonzero digits, it is increased to the next highest number. When the digit to be rounded is followed by 5 alone or 5 followed by zeros, it is unchanged if it is even but increased by one if it is odd. Examples of this rule for a case in which the numbers must be reduced to 3 digits follows:

1374 becomes 137
1376 becomes 138
13852 becomes 139.

The rationale behind this procedure is that over a period of time the results should even out, because as many digits will be increased as are decreased.

METHODS

The brevity of this unit enforces a focus on applications at the expense of methodology. In addition to Gad (1998), the reader is urged to consult Sheskin (1997) for detailed presentations and considerations of actual statistical methodologies.

Randomization

Randomization is the act of assigning a number of items (e.g., plates of bacteria or test animals) to groups in such a manner that there is an equal chance for any one item to end up in any one group. This is a control against any possible unconscious bias in assignment of subjects to test groups. One variation on this is what is called a **censored randomization**, which ensures that the groups are equivalent in some aspect after the assignment process is complete. The most common example of a censored randomization is one in which it is ensured that the body weights of the test animals in each group are not significantly different from those in the other groups. This is done by examining weights by analysis of variance after group assignment, then rerandomizing if there is a significant difference at some nominal level, such as $P \leq 0.10$. The process is repeated until there is no difference. A second valuation is stratified (or blocked) randomization, by which members of subclasses (such as litter mates) are assigned to different groups.

There are several alternatives for actually performing the randomization process. The three most commonly employed are card assignment, use of a random number table, and use of a computerized algorithm.

In the card-based method, individual identification numbers for items (e.g., plates or animals) are placed on separate index cards. These cards are then shuffled and placed one at a time in succession into piles corresponding to

the required number of test groups. The results are the random group assignment.

The random number table method requires that one assign unique numbers to the test subjects and have access to a random number table. For example, one may simply set up a table with a column for each group to which subjects are to be assigned. Start from the head of any one column of numbers in the random number table (each time the table is used, a new starting point should be used). If there are fewer than 100 test subjects, use only the last two digits of each random number in the table. If there are more than 99 but less than 1000, use only the last three digits. To generate group assignments, read down a column of the table, one number at a time. As you come across digits that correspond to a subject number, assign that subject to a group (enter its identifying number in a column), proceeding from left to right and filling one row at a time. After an animal is assigned to a group, any duplication of its unique number is ignored. Use as many successive columns of random numbers as needed to complete the process.

The third (and now most common) method is to use a random-number generator that is built into a calculator or computer program. Instructions for the use of such programs are provided by the manufacturer or developer.

One is also occasionally required to evaluate whether a series of numbers (such as an assignment of animals to test groups) is random. This requires the use of a randomization test, of which there are a large variety. The χ^2 test (described later), can be used to evaluate the goodness of fit to a random assignment. If the result is not critical, a simple sign test will work. For the sign test, first determine the middle value in the numbers being checked for randomness. Then go through a list of the numbers assigned to each group, scoring each as a "+" (greater than the middle number) or "–" (less than the middle number). The number of pluses and minuses in each group should be approximately equal.

APPLICATIONS

Median Lethalities

The data required to calculate the median lethality (LD_{50}) or the median effective dose (ED_{50}) include several dosage (or exposure) levels, the number of animals dosed, and the number that died. If the purpose is only to establish the median effective dose in a range-finding test, then testing four or five animals per dose level, using Thompson's method of moving averages, is the most efficient methodology and will give a sufficiently accurate solution. With two dose levels, if the ratio between the high and low dose is ≤2, even total and no mortality at those two dose levels will yield an acceptable, accurate median lethal dose, although a partial mortality is desirable. If, however, the purpose is to estimate a number of toxicity levels (LD_{10}, LD_{90}) and to establish the slope of the dose/lethality curve more precisely, it is common to use at least 10 animals per dosage level and to employ the log/probit regression technique. Note that in the equation $Y_i = a + bx_i$, b is the slope of the regression line and that the method already allows one to calculate 95% confidence intervals about any point in this line. Tests of significance between two or more such sets of data (i.e., slopes of mortality curves) may readily be done by the *t*-type test (discussed earlier) at any one set of points, such as the LD_{50} values of two curves. The confidence interval at any one point will be different from the interval at other points and must be calculated separately. In addition, the nature of the probit transform is such that toward the extremes—LD_{10} and LD_{90}, for example—the confidence intervals will "balloon," i.e., become very wide. Because the slope of the fitted line in these assays has a large uncertainty in relation to the uncertainty of the LD_{50} itself (the midpoint of the distribution), much caution must be used with calculated LD_x values other than LD_{50} values.

Body and Organ Weights

Body weight and the weights of selected organs are among the sets of data normally collected in studies for which animals are repeatedly dosed with (or exposed to) a chemical. Body weight is frequently the most sensitive parameter for indicating an adverse effect. How to best analyze this and in what form to analyze the organ weight data (as absolute weights, weight changes, or percentages of body weight) have been the subjects of a number of articles (Weil and Gad, 1980). The author's experience has been that the following procedures are appropriate if the sample sizes are sufficient (≥10). With smaller sample sizes, the normality of the data becomes increasingly uncertain and nonparametric methods, such as that of Kruskal-Wallis, may be more appropriate (Zar, 1974).

1. Organ weights as percentages of total body weights are calculated.

2. Body weights are analyzed either as weights or as changes in body weight. Even if

Table 1.2.1 Association of Changes in Biochemical Parameters with Actions at Particular Target Organs

Parameter 1	Organ system								Comments
	Blood	Heart	Lung	Kidney	Liver	Bone	Intestine	Pancreas	
Albumin	—	—	—	Dec.	Dec.	—	—	—	Produced by liver; very significant reductions require extensive liver damage
ALP	—	—	—	—	Inc.	Inc.	Inc.	—	Elevations usually associated with cholestasis; bone alkaline phosphatase tends to be higher in young animals
Total bilirubin	Inc.	—	—	—	Inc.	—	—	—	Elevations usually associated with cholestasis owing to obstruction or hepatopathy
BUN	—	—	—	Inc.	Dec.	—	—	—	Estimates blood filtering capacity of the kidneys; does not become significantly elevated until kidney function is reduced 60% to 75%
Calcium	—	—	—	Inc.	—	—	—	—	Can be life-threatening and result in sudden death
Cholinesterase	—	—	—	Inc.	Dec.	—	—	—	Found in plasma, brain, and RBC
CPK	—	Inc.	—	—	—	—	—	—	Most often elevated as a result of skeletal muscle damage but can also be produced by cardiac muscle damage; can be more sensitive than histopathology
Creatinine	—	—	—	Inc.	—	—	—	—	Also estimates blood-filtering capacity of kidney, as does BUN, but is more specific

continued

the groups were randomized properly at the beginning of a study (no group significantly different in mean body weight from any other group, and all animals in all groups within two standard deviations of the overall mean body weight), there is an advantage to using the computationally slightly more cumbersome changes in body weight.

3. Bartlett's test is performed on each set of data to ensure that the variances of the sets are homogeneous.

4. As appropriate, the sequence of analysis outlined in the decision trees (see Figs. 1.2.1, 1.2.2, 1.2.3, and 1.2.4) is followed.

Clinical Pathology

A number of clinical chemistry and hematology parameters are now assessed in the blood and urine collected from animals in chronic toxicity studies. In the past (and still, in some places), the accepted practice has been to evaluate these data using univariant-parametric methods (primarily *t*-tests and/or analysis of variance, ANOVA); however, it can be shown that this is not the best approach on a number of grounds.

First, such biochemical and blood cell parameters are rarely independent of each other, and interest is not often focused on just one parameter. Rather, there are batteries of parameters associated with toxic actions at particular target organs. For example, increases in creatine phosphokinase, α-hydroxybutyrate dehydrogenase, and lactate dehydrogenase occurring together strongly indicate myocardial damage. In such cases, the interest is not in a significant increase in just one of these, but in all three. Table 1.2.1 gives a short summary of the association of various clinical chemistry parameters with known target organ toxicities. Similarly, changes in serum electrolytes (sodium, potassium, and calcium) interact with each other; a decrease in one is frequently tied to an increase in one of the others. Loeb and Quimby (1989) provide an excellent source of detailed understanding of the meaning and de-

Table 1.2.1 Association of Changes in Biochemical Parameters with Actions at Particular Target Organs, continued

Parameter 1	Organ system								Comments
	Blood	Heart	Lung	Kidney	Liver	Bone	Intestine	Pancreas	
Glucose	—	—	—	—	—	—	—	Inc.	Alterations other than those associated with stress are uncommon and reflect an effect on the pancreatic islets or anorexia
GGT	—	—	—	—	Inc.	—	—	—	Elevated in cholestasis; a microsomal enzyme, the levels of which often increase in response to microsomal enzyme induction
HBDH	—	Inc.	—	—	Inc.	—	—	—	—
LDH	—	Inc.	Inc.	Inc.	Inc.	—	—	—	Increases usually the result of skeletal muscle, cardiac muscle, and liver damage; not very specific
Total protein	—	—	—	Dec.	Dec.	—	—	—	Absolute alterations are usually associated with decreased production (liver) or increased loss (kidney); can see increases in cases of muscle "wasting" (catabolism)
SGOT	—	Inc.	—	Inc.	Inc.	—	—	Inc.	Present in skeletal muscle and heart; most commonly associated with damage to these structures
SGPT	—	—	—	—	Inc.	—	—	—	Elevations usually associated with hepatic damage or disease
SDH	—	—	—	—	Inc. or Dec.	—	—	—	Liver enzyme; can be quite sensitive but is fairly unstable; samples should be processed as soon as possible

Abbreviations: Inc., increase of chemistry values; Dec., decrease in chemistry values; ALP, alkaline phosphatase; BUN, blood urea nitrogen; RBC, red blood cells; CPK, creatinine phosphokinase; GGT, gamma glutamyl transferase; HBDH, hydroxybutyric dehydrogenase; LDH, lactic dehydrogenase; SGOT, serum glutamic oxaloacetic transaminase (also called aspartate aminotransferase; AST); SGPT, serum glutamic pyruvic transaminase (also called alanine amino transferase; ALT); SDH, sorbitol dehydrogenase.

tails of laboratory animal clinical chemistries. Furthermore, for some parameters—owing to their biological background or the measurement method—the data are frequently either not normally distributed (particularly because of being markedly skewed) or not continuous. This can be seen in some of the reference data for experimental animals in Weil (1982). Both normality (a normal distribution) and continuous data are underlying assumptions in the parametric statistical techniques most commonly used and described in this unit.

Finally, it should always be kept in mind that it is rare for a change in any single parameter to be biologically significant. Rather, because parameters are so interrelated, patterns of changes in parameters should be expected and analyzed.

Incidence of Histopathologic Lesion

In recent years, there has been as increasing emphasis on histopathologic examination of many tissues collected from animals in subchronic and chronic toxicity studies. Although it is not true that only those lesions that occur at a statistically significant increased rate in treated/exposed animals are of concern (because there are cases in which a lesion may be of such a rare type that the occurrence of only one or a few such treated animals raises a flag), it is true that, in most cases, a statistical evaluation is the only way to determine if what is seen in treated animals is significantly worse than what is seen in control animals. And although cancer is not the only concern, among the possible classes of lesion it is the one that is of greatest interest.

Typically, comparison of incidences of any one type of lesion between controls and treated animals are made using χ^2 or Fisher's exact test with a modification of the denominators. Too often, experimenters exclude from consideration all those animals (in both groups) that died before the first animals were found with a tumor at that site.

Two major controversial questions are involved in such comparisons: should they be based on one-tailed or two-tailed distribution, and what are the effects and implications of multiple comparisons?

The one- versus two-tailed distribution controversy revolves around the question of which hypothesis is being properly tested in a study such as a chronic carcinogenicity study. Is the tumor incidence different between the control and treated groups? In such cases, the hypothesis is bidirectional and therefore a two-tailed distribution is being tested against. Or is the question whether the tumor incidence is greater in the treated group than in the control group? In the latter case, the hypothesis is unidirectional, and only the right-hand tail of the distribution is under consideration. The implications of the answer to this question are more than theoretical; significance is much greater (exactly double, in fact) in the one-tailed case than in the two-tailed. For example, a set of data analyzed by Fisher's exact test, which would have a two-tailed P level of 0.098 and a one-tailed level of 0.049, would be flagged as significantly different.

The multiple comparisons problem is a much more lively one. In chronic studies, the lesion/tumor incidence on each of a number of tissues, for each sex and species, is tested, and each result is flagged if it exceeds the fiducial limit of $P \geq 0.05$.

The point to ponder here is the meaning of "$P \geq 0.05$." This is the level of the probability of making a type I error (incorrectly concluding that there is an effect when, in fact, there is not). It is necessary to accept the fact that there is a 5% chance of producing a false positive from this study. The tradeoff is a much lower chance (typically 1%) of a type II error (i.e., of passing as safe a compound that is not safe). These two error levels are connected; to achieve a lower type II level inflates the type I level. The problem in this case is that making a large number of such comparisons involves repeatedly taking the chance of "finding" a false-positive result. The set of lesions and/or tumor comparisons described above may number >70 tests for significance in a single study, which will result in a large inflation of false-positive findings.

The extent of this inflated false-positive rate (and what can best be done to reduce its effects) has been discussed and estimated with a great degree of variability. Salsburg (1977) estimated that the typical National Cancer Institute (NCI)–type cancer bioassay has a probability of type I error of between 20% and 50%. Fears et al. (1977), however, estimated it as being between 6% and 24%. Without some form of correction factor, the false-positive rate of a series of multiple tests can be calculated as being equal to $1 - 0.95^N$, where N is the number of tests and the selected alpha level (type I error rate) is 0.05.

What, then, is a proper use of such results? Or, conversely, how can the researcher control for such an inflated error rate? There are statistical methods available for dealing with this multiple comparisons problem. One is the use of Bonferroni inequalities to correct for successive multiple comparisons (Wilks, 1962). These methods have the drawback that there is some accompanying loss of power, expressed as an inability to identify true positives properly.

A second approach is to use the information in a more mature decision-making process. First, the historical control incidence rates (such as are given for the B6C3FI mouse and Fischer-344 rats in Fears et al., 1977) should be considered; some background incidences are so high that these tissues are null and void for making decisions. Second, one should not look for just a single significant incidence in a tissue but rather for a trend. For example, the following percentages of a liver tumor incidence were found for the female rats of a study: (a) control, 3%; (b) 10 mg/kg, 6%; (c) 50 mg/kg, 17%; and (d) 250 mg/kg, 54%. In this study only the incidence at the 250-mg/kg level might be statistically significant; however, the trend through the levels suggests a dose response. Looking for such a trend is an essential step in a scientific assessment of the results; and one of the available trend analysis techniques should be used.

Reproductive Toxicology

Reproductive implications of the toxic effects of chemicals have become increasingly important. Along with other types of studies that are closely related (such as teratogenesis and dominant lethal mutagenesis), reproduction studies are now common companions to chronic toxicity studies.

One point that must be keep in mind with all the reproduction-related studies is the nature of the appropriate sampling unit. Put another way: What is the appropriate *N* in such a study—the number of individual pups or the number of litters (or pregnant females)? Fortunately, it is now fairly well accepted that the first case (using the number of offspring as the *N*) is inappropriate (Weil, 1970). The real effects in such studies are actually occurring in the female that receives the dosage or exposure to the chemical or that is mated to a male that received a dosage or exposure. What happens to her, and to the development of the litter she is carrying, is biologically independent of what happens to every other female/litter in the study. This cannot be said for each offspring in each litter; the death of, or other change in, one member of a litter can and will be related to what happens to every other member in numerous fashions. Or the effect on all the offspring might be similar for all those from one female and different or lacking in another.

As defined by Oser and Oser (1956), there are four primary variables of interest in a reproduction study. First, there is the fertility index, which may be defined as the percentage of attempted matings (i.e., each female housed with a male) that resulted in pregnancy; pregnancy is determined by a method such as the presence of implantation sites in the female. Second, there is the gestation index, which is defined as the percentage of mated females, as evidenced by a dropped vaginal plug or a positive vaginal smear, that deliver viable litters (i.e., litters with at least one live pup). Two related variables that may also be studied are the mean number of pups born per litter and the percentage of total pups per litter that are stillborn. Third, there is the viability index, which is defined as the percentage of offspring born that survive at least 4 days after birth. Finally, there is the lactation index, which is the percentage of those animals per litter alive at 4 days that survive to weaning. In rats and mice, this is classically taken to be 21 days after birth. An additional variable that may reasonably be included in such a study is the mean weight gain per pup per litter.

Given that *N* is at least 10 (proper sample size is discussed in Developmental Toxicology), it is possible to test each of these variables for significance using a method such as the Wilcoxon-Mann-Whitney *U* test, or the Kruskal-Wallis nonparametric ANOVA. If *N* <10, the central limit theorem cannot be expected to be operative, and the Wilcoxon sum or ranks (for two groups) or the Kruskal-Wallis nonparametric ANOVA (for three or more groups) should be used to compare groups.

Developmental Toxicology

When the primary concern of a reproductive/developmental study is the occurrence of birth defects or deformations (terata, either structural or functional) in the offspring of exposed animals, the study is one of developmental toxicology. In the analysis of the data from such a study, several points must be considered.

First is sample size. Earlier in this unit the general concerns of this topic were reviewed and a method to estimate a sufficient sample size was presented. The difficulties with applying these methods here revolve around two points: selecting a sufficient level of sensitivity for detecting an effect and factoring in how many animals will be removed from the study (without contributing a datum) by either not becoming pregnant or not surviving to a sufficiently late stage of pregnancy. Experience generally dictates that one should attempt to have 20 pregnant animals per study group if a pilot study has provided some confidence that the pregnant test animals will survive the dose levels selected. Again, it is essential to recognize that the litter, not the fetus, is the basic independent variable.

A more basic consideration, as alluded to in the section on reproduction, is that as more animals are used, the mean of means (each variable will be such in a mathematical sense) will approach normality in its distribution. At sample size of 10 or greater, the approximation of normality is such that an aparametric test (such as a *t*-test or ANOVA) may be used to evaluate results. At sample sizes <10, a nonparametric test (Wilcoxon rank-sum or Kruskal-Wallis nonparametric ANOVA) is more appropriate. One nonparametric method that is widely used is the Wilcoxon-Mann-Whitney *U* test.

Diet and Chamber Analyses

In a feeding study, desired doses of a material are delivered to animals by mixing the material with their diet. Similarly, in an inhalation study, the material is mixed with the air the test animals breathe.

In both cases, the medium (feed or atmosphere) must be sampled and the samples analyzed to determine what levels or concentrations of material were actually present and to ensure that the test material is homogeneously

distributed. Having an accurate picture of these delivered concentrations, and how they varied over the course of time, is essential on a number of grounds:

1. The regulatory agencies and sound scientific practice require that analyzed diet and atmosphere levels be ≥10% of the target level.

2. Marked peak concentrations could, owing to the overloading of metabolic and repair systems, result in extreme acute effects that would add to apparent results in a chronic study that are not truly indicative of the chronic low-level effects of the compound, but rather of periods of metabolic and physiologic overload. Such results could be misinterpreted if the true exposure/diet were not known.

Sample strategies are not just a matter of numbers (for the statistical aspects) but of geometry—so that the contents of a container or the entire atmosphere in a chamber is truly sampled—and of time, in accordance with the stability of the test compound. The samples must be both randomly collected and *representative* of the entire mass of what is being characterized. In the special case of sampling and characterizing the physical properties of aerosols in an inhalation study, some special considerations and terminology apply. Because of the physiologic characteristics of the respiration of humans and of test animals, the concern is very largely limited to particles or droplets that are of a respirable size. Unfortunately, "respirable size" is a somewhat complexly defined characteristic, based on aerodynamic diameter, density, and physiologic characteristics. A second misfortune is that, although particles with an aerodynamic diameter of <10 μm are generally agreed to be respirable in humans (i.e., they can be drawn down to the deep portions of the lungs), in the rat this characteristic is more realistically limited to particles <3 μm in aerodynamic diameter. The one favorable factor is that there are now available a selection of instruments that accurately (and relatively easily) collect and measure aerodynamically sized particles or droplets. These measurements provide data for concentrations in a defined volume of gas, which can be expressed as either a number concentration or a mass concentration (the latter being more common). Such measurements generate categorical data—concentrations are measured in each of a series of aerodynamic size groups (such as >100 μm, 100 to 25 μm, 25 to 10 μm, 10 to 3 μm). The appropriate descriptive statistics for this class of data are the geometric mean and its standard deviation. These aspects, and the statistical interpretation of the data that are finally collected, should be considered carefully after consultation with appropriate experts. Typically, it then becomes a matter of calculating measures of central tendency and dispersion statistics, and identifying the values that are beyond acceptable limits (Bliss, 1965).

Mutagenesis

Since the early 1960s a wide variety of tests for mutagenicity have been developed and brought into use. These tests provide a quicker and cheaper (although less conclusive) way of predicting whether a material of interest is a mutagen, and possibly a carcinogen, than do longer-term whole-animal studies.

How to analyze the results of this multitude of tests—e.g., Ames (*UNIT 3.1*), DNA repair, micronucleus, host mediated, cell transformation, sister chromatid exchange, and *Drosophila*—is a new and extremely important question. Some workers in the field have held that test results can simply be judged to be positive or not positive on the basis of whether they achieve a particular degree of increase in the incidence of mutations in the test organism. Such quantitations of potency are complicated by the fact that the phenomenon is nonlinear. Although low doses of most mutagens produce a linear response curve, the curve will flatten out (and even turn into a declining curve) with increasing doses, because higher doses take the target systems into levels of acute toxicity.

Several concerns that differ from those previously discussed need to be examined, because the concern has now shifted from how a multicellular organism acts in response to one of a number of complex actions to how a mutational event is expressed, most frequently by a single cell. Given that it is possible to handle large numbers of experimental units in systems that use small test organisms, it is possible to detect both weak and strong mutagens.

What are the background mutation level and the variability in the technique? As any good genetic or general toxicologist will acknowledge, matched concurrent control groups are essential. Fortunately, with these test systems large *N*'s are readily attainable.

Instrumentation and Technique Factors

Most if not all toxicology studies depend on at least some instrumentation. Very frequently overlooked here (and, indeed, in most research) is that instrumentation, by its operating characteristics and limitations, goes a long way toward

determining the nature of the data it generates. An activity monitor measures motor activity in discrete segments. If it is a jiggle-cage type monitor, the segments are constricted so that only a distinctly limited number of counts can be achieved in a given period of time and then only if they are of the appropriate magnitude. Likewise, technique can readily determine the nature of the data. When measuring response to pain, for example, the technician could record it as a quantal measure (present or absent), as a rank score (on a scale of 1 to 5 from decreased to increased responsiveness, with 3 being normal), or as scalar data (by using an analgesia meter, which determines how much pressure or heat is required to evoke a response).

Study Design Factors

Study design is probably the most widely recognized of the factors that influence the type of data generated. Number of animals used, frequency of measures, and length of observation period are three obvious design factors that are readily under the control of the researcher and that directly help determine the nature of the data.

SCREENING STUDIES

Perhaps the major set of activities in toxicology is screening for the presence of an effect. Screening for nervous system, immune system, and other involvement, in particular for the effects of chemicals, has been a long-standing enterprise that has taken on new importance with both the advent of the Toxic Substance Control Act (TSCA) and the growing concern over new chemicals, drugs, and food additives coming to market with significant human exposure (Zbinden et al., 1984). Perhaps ironically, despite this level of awareness and activity, screening tests have not to any great extent undergone standardization or validation, and the relationships between the observed systemic effects and underlying causes remain largely unknown. The result is less information on more structures but an overall increase in the efficiency with which compounds of concern are discovered (assuming that truly active compounds are entering at a steady rate).

It should be noted that the methods described here are better suited to analyzing screening data when the interest is truly in detecting the absence of an effect with little chance of false negatives. Anderson et al. (1980) should be consulted for a more thorough discussion of considerations involved in cases in which the desire is to have few false positives (i.e., when the direction of the hypothesis test has been reversed).

The design of each assay and the choice of the activity criterion should, therefore, be adjusted, bearing in mind the relative costs of retaining false positives and rejecting false negatives. Decreasing the group sizes in the early assays reduces the chance of obtaining significance at any particular level (such as 5%) so that the activity criterion must be relaxed, in a statistical sense, to allow more compounds through. At some stage, however, it becomes too expensive to continue screening many false positives; and the criteria must be tightened up accordingly. Where the criteria are set depends on the acceptable noise levels in a screening system.

Screening systems may be approached by one of at least three different formats: single stage, sequential, and tier. For the purposes of this discussion, only the single-stage case is considered in depth, although the other forms are described.

Characteristics of Screens

The basic assumptions underlying screening are that a compound is either active or inactive and that the proportion of actives can be estimated from past experience. After testing, a compound is classified as positive or negative. It is then possible to design the assay to optimize the following characteristics: **sensitivity**, the ratio of true positives to total actives; **specificity**, the ratio of true negatives to total inactives; **positive accuracy**, the ratio of true to observed positives; **negative accuracy**, the ratio of true to observed negatives; **capacity**, the number of compounds evaluated per unit time, and **reproducibility**, the ability to have operational characteristics replicated.

An advantage of testing more compounds is that it gives the opportunity to average activity evidence over structural classes or to study quantitative structure-activity relationships (QSARs). QSARs can be used to predict the composite activities of new compounds and thus reduce the chance of actual testing on compounds of interest passing through the system.

Screens may thus truly be considered the biologic equivalent of exploratory data analysis (EDA). EDA methods, in fact, provide a number of useful possibilities for less rigid and yet quite effective approaches to the statistical analysis of the data from screens, and are one of the alternative approaches presented here.

Such screens are almost always focused on detecting a single end point of effect (e.g., mutagenicity, lethality, neurotoxicity, developmental toxicity) and have a particular set of operating characteristics in common.

1. A large number of compounds must be evaluated; therefore, ease and speed of performance (which may also be considered efficiency) are major desirable characteristics.

2. The screen must be very sensitive in its detection of potential effective agents. An absolute minimum of effective agents should escape detection—i.e., there should be very few false negatives (in other words, the type II error rate, or beta level, should be low). Stated another way, the signal gain should be significantly elevated.

3. It is desirable that the number of false positives be small (i.e., that there be a low type I error rate, or alpha level). The exact level selected depends on test characteristics and what kind of separation of screened compounds is desired. Less than 0.10 is usually inappropriate for a screen, however.

4. Items 1 to 3 are all to some degree contradictory, requiring the researchers involved to agree on a set of compromises. These typically start with acceptance of a relatively high noise level (0.10 or more).

5. In an effort to better serve item 1, such screens are frequently performed in batteries, so that multiple end points are measured in the same operation. In addition, such measurements may be repeated over a period of time in each model as a means of supporting item 2.

NEW APPROACHES TO STATISTICAL ANALYSIS

Trend Analysis

A variation on the theme of regression testing that has gained popularity in toxicology over the last 15 years is trend analysis. In the broadest sense, this is determining whether a sequence of observations taken over a period of time (e.g., the cumulative proportions of a group of animals that have tumors of a particular sort) exhibit some sort of pattern of change: an increase (upward trend) or decrease (downward trend). There are a number of tests that can be used to evaluate data to determine if a trend exists. The most popular test in toxicology is currently the one presented by Tarone (1975), because it is the one used by the NCI in the analysis of carcinogenicity data. A simple but efficient alternative is the Cox and Stuart test (1955), which is a modification of the sign test. For each point at which there is a measure (e.g., the incidence of animals observed with tumors), a pair of observations is formed, one from each of the groups being compared. In a traditional NCI bioassay, this would mean pairing control with low dose and low dose with control (to explore a dose-related trend) or each time period observation in a dose group (except the first) with its predecessor (to evaluate a time-related trend). When the second observation in a pair exceeds the first observation, record a plus sign for that pair. When the first observation is greater than the second, record a minus sign for that pair. A preponderance of plus signs suggests a downward trend, whereas an excess of minus signs suggests an upward trend. A formal test of the hypothesis at a preselected confidence level can then be performed.

Expressed more formally, first (having defined what trend is to be tested for) match pairs as $(X_1 + X_{1+c}), (X_2, X_{2+c}), \ldots, (X_{n'-c}, X_{n-})$, where $c = n'/2$ when n' is even and $c = (n' + \frac{1}{2})$ when n' is odd (where n' is the number of observations in a set). The hypothesis is then tested by comparing the resulting number of excess positive or negative signs against a sign test table (Beyer, 1976).

It is possible, of course, to combine a number of observations to actively test for a set of trends, such as the existence of a trend of increasing difference between two groups of animals over a period of time. This is demonstrated in Example 2.

Example 2

A chronic feeding study in rats is set up to test, in the second year of the study, the hypothesis that there is a dose-responsive increase in tumor incidence over time associated with receiving the test compound. A Cox-Stuart test for trend to address this question is used. All groups start the second year with an equal number of animals. The data are presented in Table 1.2.2.

Control Charts

The control-chart approach (Montgomery, 1985), commonly used in clinical laboratories for quality control, used as a form of screening offers some desirable characteristics. By keeping records of cumulative results during the development of the screen methodology, for example, the researcher can make an initial estimate of the variability (such as standard deviation) of each assay, which is available when full-scale use of the screen starts. The

initial estimates can then be revised as more data are generated (i.e., as familiarity with the screen increases).

The example below shows the usefulness of control charts for control measurements in a screening procedure. The example test for screening potential muscle strength–suppressive agents measures reduction of grip strength by test compounds compared to a control treatment. A control chart was established to monitor the performance of the control agent to establish the mean and variability of the control and to ensure that the results of the control for a given experiment are within reasonable limits (a validation of the assay procedure). The average grip strengths and the average range of a series of experiments are presented in Tables 1.2.3 and 1.2.4; Example 3 shows the construction and use of the resulting control chart.

As in control charts for quality control, the mean and average range of the assay were determined from previous experiments. In this

Table 1.2.2 Data for Example 2

Month of study	Control		Low dose			High dose		
	Total X animals with tumors	Change $[X_{A-B}]$	Total Y animals with tumors	Change $[Y_{A-B}]$	Compared with control $(Y - X)$	Total Z animals with tumors	Change $[Z_{A-B}]$	Compared with control $(Z - X)$
12(A)	1	NA	0	NA	NA	5	NA	NA
13(B)	1	0	0	0	0	7	2	(+)2
14(C)	3	2	1	1	(−)1	11	4	(+)2
15(D)	3	0	1	0	0	11	0	0
16(E)	4	1	1	0	(−)1	13	2	(+)1
17(F)	5	1	3	2	(+)1	14	1	0
18(G)	5	0	3	0	0	15	1	(+)1
19(H)	5	0	5	2	(+)2	18	3	(3)
20(I)	6	1	6	1	0	19	1	0
21(J)	8	2	7	1	(−)1	22	3	(+)1
22(K)	12	4	9	2	(−)2	26	4	0
23(L)	14	2	12	3	(+)1	28	2	0
24(M)	18	4	17	5	(+)1	31	3	(−)1
Sum of signs[a]								
+					4+			6+
−					4−			1−
$N = 12$					$Y - X = 0$ (no trend)			$Z - X = 5$

[a]Reference to a sign table is not necessary for the low dose comparison (where there is no trend) but clearly shows the high dose to be significant at the $P \leq 0.05$ level.

Table 1.2.3 Average Grip Strengths and Ranges for Screening Procedures

Test number	Mean	Range	Test number	Mean	Range
1	380	40	11	280	120
2	430	30	12	410	100
3	340	30	13	400	220
4	480	60	14	340	50
5	380	240	15	370	40
6	450	40	16	430	140
7	490	50	17	370	60
8	320	90	18	450	80
9	480	50	19	320	70
10	340	80	21	420	130

example, the screen had been run 20 times previous to the data shown. The initial data showed a mean grip strength of 400 g and a mean range R of 90 g. These values were used for the control chart. The size of the subgroups is 5. The action limits for the $\overline{X}$ and range charts were calculated as follows:

$$\overline{X} \pm 0.58R = 400 \pm 0.58 \times 90$$
$$= 348 - 452$$
$$= (X \text{ chart})$$

$$2.11R = 2.11 \times 90$$
$$= 190, \text{ the upper limit for the range}$$

Note that the range limit actually established a limit for the variability of the data, that it is in fact a "detector" for the presence of outliers (extreme values). This data set in a control-chart format is shown in Figure 1.2.5.

Such charts may also be constructed and used for proportion or count types of data. Charts constructed for the range of control data can be used as rapid and efficient tools for

Table 1.2.4 Values for Determining Upper and Lower Limits for Mean (X) and Range Charts

Sample size of subgroup (N)	A: factor for X chart	Range chart factors lower limit (DL)	
2	1.88	0	3.27
3	1.02	0	2.57
4	0.73	0	2.28
5	0.58	0	2.11
6	0.48	10	2.00
7	0.42	0.08	1.92
8	0.37	0.14	1.86
9	0.34	0.18	1.82
10	0.31	0.22	1.78
20	0.18	0.41	1.59

detecting effects in groups being assessed for that same screen end point.

Graphical Methods

The use of innovative visual displays of data as a means of both analysis and communication of relationships has been developed extensively since the 1980s. These methods should be of particular interest to practicing toxicologists, because detecting, understanding, and communicating relationships in more than two dimensions is a constant challenge. Figure 1.2.6 provides one simple example of such an approach.

The reader's attention is particularly directed to the work of Tufte (1997) as an excellent source for this field.

Transgenic Animals in Toxicology

STRATEGIES AND APPLICATIONS

A transgenic (Tg) animal is defined as an animal in which genetic material has been experimentally introduced into, or deleted from, the germ cells. The altered DNA need not be genetically active, but should be heritable. Tg mice can be generated to express two distinct generalized phenotypes, gain of function and loss of function. Gain of function is usually associated with an overexpressing, randomly integrated transgene. Loss of function is created by targeting the deletion of a specific gene using embryonic stem (ES) cell technology. However, randomly integrated transgenes can result in functional inactivity of a gene product, and, vice versa, transgenes can be targeted for overexpression using ES cell technology (see discussion of Production of Tg Mice by Gene Targeting). Tg mice are a unique tool for understanding how interactions between individual genes and the environment affect human health. Tg animal models in the area of toxicology can be useful for a number of applications, including mutagenesis, carcinogenesis, risk assessment, and stress response (see Table 1.3.1). Transgenic technology is rapidly evolving, and future developments will allow scientists the opportunity to address difficult questions in toxicology where no specific targets have been identified. It must be remembered that animal systems are not passive, and along with technical advancements intensive studies must be undertaken to understand how specific gene expression is controlled.

Understanding toxic mechanisms is difficult because of the complexity of animal systems, and extrapolation between species is generally speculative. The anticipated promise of transgenic technology is to provide sets of Tg animals with individual but related characteristics, using human genes, and subject them to standard toxicology protocols. The end result will be a delineation of the relationship between biochemical and metabolic pathways and chemical toxicity. Several Tg mouse models have been developed and characterized for mutagenesis and carcinogenesis testing. The mutagenesis systems in Tg mice incorporate well understood bacterial genes into the murine genome. Genes from chemically treated mice are then extracted and tested for mutagenic effect in simple bacterial assays. Two systems that are gradually gaining acceptance are commercially available and use a bacteriophage lambda shuttle vector from the *E coli* β-galactosidase *lac*Z gene (Tinwell et al., 1994; Douglas et al., 1997). The Hazelton Mutamouse (Hazelton Research) and the Stratagene Big Blue systems use the structural *lac*Z gene and repressor *lac*I gene, respectively. The two systems use similar testing procedures. Briefly, Tg mice are exposed to a mutagen for a period of time and then euthanized. DNA is then isolated from various organs and treated with a commercial lambda packaging system. The resultant bacteriophages are plated on an appropriate bacterial *E. coli* background, and mutants are counted according to their ability to express β-galactosidase. This enzyme is easily detected in bacteriophage plaques using an indicator dye, 5-bromo-4-chloro-3-indolyl-β-D-galactoside (Xgal), which produces a blue color on the plate.

Tg mice used in chemical carcinogenesis assays carry an activated oncogene, or lack a tumor-suppressor gene, which can result in increased sensitivity to tumor development (Brown et al., 1995). The concept in this case is based on the increased probability of a cell accumulating the full complement of events required for malignancy if an oncogene has already been activated, or if the lack of suppressor gene allows it to become activated. A number of Tg mice carrying activated oncogenes have been reported and studied, as shown in Table 1.3.1. Expression of the oncogene is usually determined by the type of promoter/enhancer sequence associated with the transgene, thus making it possible to target specific organs or tissues. For example, the *TG:AC* Tg mouse exhibits the unique phenotype of chemical papillogenesis, which provides a model for identifying potential carcinogens (Spaulding et al., 1993).

The *p53* tumor-suppressor gene knockout mouse is an example of a Tg mouse that has more broad-spectrum utility in determining compound-induced carcinogenesis (Donehower et al., 1992). The *p53* gene has been shown to control the entry of damaged cells into specific stages of the cell cycle and appears to be an essential component of the pathway by which malignancies develop in several tissues. Homozygous *p53* knockout mice, which lack the *p53* gene on both alleles, develop a high incidence of predominantly hematopoietic tu-

mors within the first 6 months of life, and thus are of no value for potential carcinogenic evaluations. However, the *p53* heterozygotes, which lack the *p53* gene on one allele, remain tumor-free for up to 1 year, but the mutation renders the mice more sensitive to the effects of at least some carcinogens. Studies have shown that *p53* heterozygotes exposed to dimethylnitrosamine have an increased sensitivity to the induction of hemangiosarcomas (Harvey et al., 1993). Kemp et al. (1993) showed that *p53* heterozygotes had an earlier onset and increased frequency of malignancy than the wild-type background strain when both groups were exposed to chemical carcinogens.

The application of transgenic technology has provided important information on the roles of various enzyme systems in the developing organism. For example, the cytochrome P-450 enzyme system is involved in metabolic oxidation of a number of endogenous and exogenous materials, including fatty acids, steroids, drugs, and environmental toxicants. The system has been well characterized in adults but little is known about its role during development. Tg knockout mice have been generated for cytochrome P-450 1a2 and shown to express a neonatal lethal phenotype (Pineau et al., 1995). However, another Tg knockout line for cytochrome P-450 1a2 did not have developmental abnormalities, but exhibited deficient drug metabolism (Liang et al., 1996). A second example of the value of transgenic technology in developmental biology is the homeobox gene system, which influences embryonic development by determining the order of expression of various regulators of embryonic development. A number of laboratories have developed Tg knockout mice that lack expression of specific *Hox* genes, thus allowing identification of the associated area required for development (developmental domain). These Tg mouse studies may be useful in defining functional periods of toxic exposure during gestation.

A collective family of genes, which produces stress proteins in response to toxic exposure, comprises a generalized repair system for protecting cells from a wide variety of nongenotoxic environmental exposures. Heavy metals, pesticides, and other reagents, including free radicals, induce stress proteins (Hightower, 1991). Elucidation of the genes in this family could lead to the generation of new Tg models capable of screening for toxic agents. For example, Tg nematodes were generated by inserting a *lac*Z reporter gene fused to a heat-shock protein gene (Stringham et al., 1992). When the organism was subjected to stress, heat-shock proteins were induced. Tg mice carrying a stress-inducible gene associated with a common reporter gene could provide an easily detectable and sensitive biological assay for toxicological exposure.

Techniques used to generate Tg mice have frequently been described in the literature. The remainder of this unit provides an overview of commonly accepted procedures for producing overexpression, point mutation, and null

Table 1.3.2 Comparison of Steps for Generating Overexpression and Gene-Targeted Transgenic Mice

Step	Pronuclear transgenesis (overexpression)	Gene targeting
1	Prepare construct	Prepare construct
2	Select mouse strain as embryo donor	Transfect ES cells, clone, and analyze
3	Microinject DNA into pronuclei	Microinject targeted ES cells into blastocysts
4	Transfer embryo to oviduct	Transfer embryo to uterus
5	Test pups for transgene DNA	Identify male chimeras by coat color
6	Breed positive mice	Breed chimeric mice
7	Test pups for DNA expression	Test pups for targeted mutation
8	Expand colony	Expand colony

ES, embryonic stem cells.

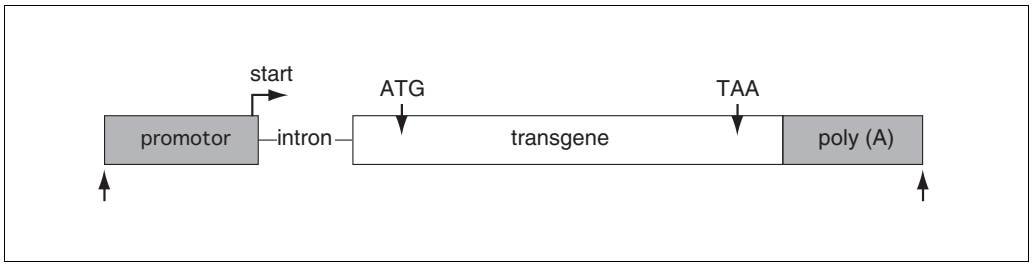

Figure 1.3.1 An example of a construct design for random integration via pronuclear microinjection. The transcription start site is depicted as an arrow rising from the promoter point right. The initiation (ATG) and stop (TAA) codons are represented by arrows pointing into the transgene. The two arrows pointing upward represent the restriction sites used to remove the bacterial plasmid sequences. The polyadenylation site is designated as poly(A).

(knockout) Tg mice. Transgenic technology consists of two basic avenues: pronuclear microinjection of one-cell embryos, and blastocyst microinjection (or aggregation) of gene-targeted ES cells with the formation of chimeras. A flow chart comparing the steps involved in both procedures is presented in Table 1.3.2. This unit focuses exclusively on the mouse. The rat is used extensively in toxicology studies, but unfortunately the understanding of preimplantation embryology and transgenesis lags behind that of the mouse. However, several recent articles have been published on generation of Tg rats (Sullivan and Ouhibi, 1995; Charreau et al., 1996).

DNA CONSTRUCT CONSIDERATIONS

Constructs for Overexpression Tg Mice

Construct design for producing overexpression Tg mice is fairly straightforward. The construct should contain a functional promoter, initiation codon (ATG), and polyadenylation site (Fig. 1.3.1). The 3′ poly(A) site, consisting of a polyadenylation signal, cleavage site, and cleavage binding factor, ensures that mRNA will be correctly processed to produce a polyadenylated transcript. Transgenes are constructed to consist of a full-length cDNA or genomic DNA for a specific gene fused to the enhancer/promoter sequence. Entire genes, containing endogenous introns, exons, and the 5′-flanking promoter sequences, have been used. However, the larger the DNA fragment, the lower the efficiency of producing Tg mice. The use of intact genes also does not allow the flexibility of promoter choice and external temporal control of transgene expression. Many vectors used in cloning can interfere with expression of the transgene. Consequently, unique restriction sites at the 5′ and 3′ ends of the transgene should be available to remove plasmid sequences. Sequencing of junction fragments to confirm that the transgene contains all the elements in the correct orientation, as well as testing for expression in a tissue culture system, are useful steps to ensure that the best possible conditions are available for transgene integration. Transgenes should be constructed to be easily identified subsequent to integration. It is important that a screening scheme to detect DNA in potential founder mice be devised before starting pronuclear microinjections.

PCR is the most frequently used method for analyzing transgene integration, although both Southern and dot blot analyses are often used.

The choice of promoter depends on the target tissue of interest, or the desire to direct the ubiquitous expression of a transgene. There is limited information on promoters that can focus the expression of genes to a broad array of tissues. The chick β-actin promoter has broad-spectrum activity, inducing high levels of transgenic expression in heart, muscle, lung, and brain; however, expression in liver, kidney, spleen, and intestine is low or undetectable (Oberly et al., 1993; Kagan et al., 1994). Another promoter, human cytomegalovirus (CMV), directs high expression of transgenes in a number of tissues including muscle, heart, kidney, spleen, testis, and brain, but expression is low or undetectable in liver (Furth et al., 1991). Examples of specific-tissue promoters that have been successful in Tg mice used as models in toxicology are shown in Table 1.3.1.

Inducible promoters are preferable in a number of situations in order to obtain maximum quantity of the gene product and to regulate its expression. The human metallothionein promoter is activated by heavy metals, but appears to lack desired specificity (Palmiter et al., 1983). A tetracycline-inducible system has been developed and demonstrated to be effective in several studies (Shockett and Schatz, 1996). The latter is referred to as a binary system since it requires two sets of transgenes. The expression of a specific transgene in one mouse (Tg line 2) depends on a tetracycline-sensitive transactivator transgene from another mouse (Tg line 1) for the promoter region of the transgene of interest. When offspring from a cross of the two lines are treated with tetracycline, the transactivator gene remains inactive. When the tetracycline is removed, the transactivator gene is activated and triggers the promoter and subsequent expression of the specific DNA inserted in Tg line 2. Two new binary systems that have recently been introduced are the estrogen-inducible (Braselmann et al., 1993) and ecdysone-inducible (No et al., 1996) systems. Studies to confirm their applications in Tg mice used for toxicology models are forthcoming.

Frequently, transgenes fail to be expressed, spatial or temporal patterns are not followed, or expression cannot be distinguished from endogenous gene levels. The size limitation of standard transgenic constructs, set by the cloning capacity of plasmid, phage, or cosmid vectors, may prevent the inclusion of necessary but distinct regulatory elements. Yeast artificial chromosomes (YACs) have proven to be a powerful tool in transgenic technology because they provide a means of cloning and stably maintaining DNA >1 Mb in size (Montoliu et al., 1993). YAC-borne DNA can be microinjected into one-cell embryos in an efficient manner, provided steps are taken to prevent shearing (W.C. Ladiges, unpub. observ.). The ability to introduce such large segments of DNA into laboratory mice provides the opportunity to study the functional analysis of genes too large to clone by conventional methods, and allows a practical means of evaluating regulatory activity in large clusters such as *Hox* and globin genes.

A recent approach in construct design which has extended the usefulness of randomly integrated transgenes is the creation of a dominant negative mutation so that endogenous gene function will be blocked with subsequent creation of a functional null mutation. For example, dominant negative retinoic acid receptor (RAR) transgenes have been used to generate Tg mice in order to address the effects of blocking specific functional domains of these receptors in various organ systems (Damm et al., 1993; Saitou et al., 1995). The use of dominant negative mutations requires a detailed characterization of functional domains of the protein(s) involved.

Constructs for Gene Targeting

In contrast to random integration, homologous recombination allows targeted alterations of the murine genome. These can be as defined as specifically as a point mutation or as broadly as gene function ablation (null mutation). The components of a vector destined for homologous recombination in ES cells include sequences that are homologous to the desired site of integration, a selection marker, and a plasmid backbone. There are two basic approaches: replacement and insertion vectors (Fig. 1.3.2). Subtle mutations require further selection, following vector insertion, for naturally occurring recombination events that result in the desired gene configuration. The entire process of vector insertion followed by loss of target-site sequences is termed hit and run (Fig. 1.3.3). Hasty and Bradley (1993) and Bronson and Smithies (1994) provide lucid explanations of overall vector design.

Replacement vectors are most commonly used to make null mutations. The positive selection cassette is inserted in an area of homology that ablates the ability to encode a functional RNA. Therefore, some understanding of exon correlation to protein function prior to

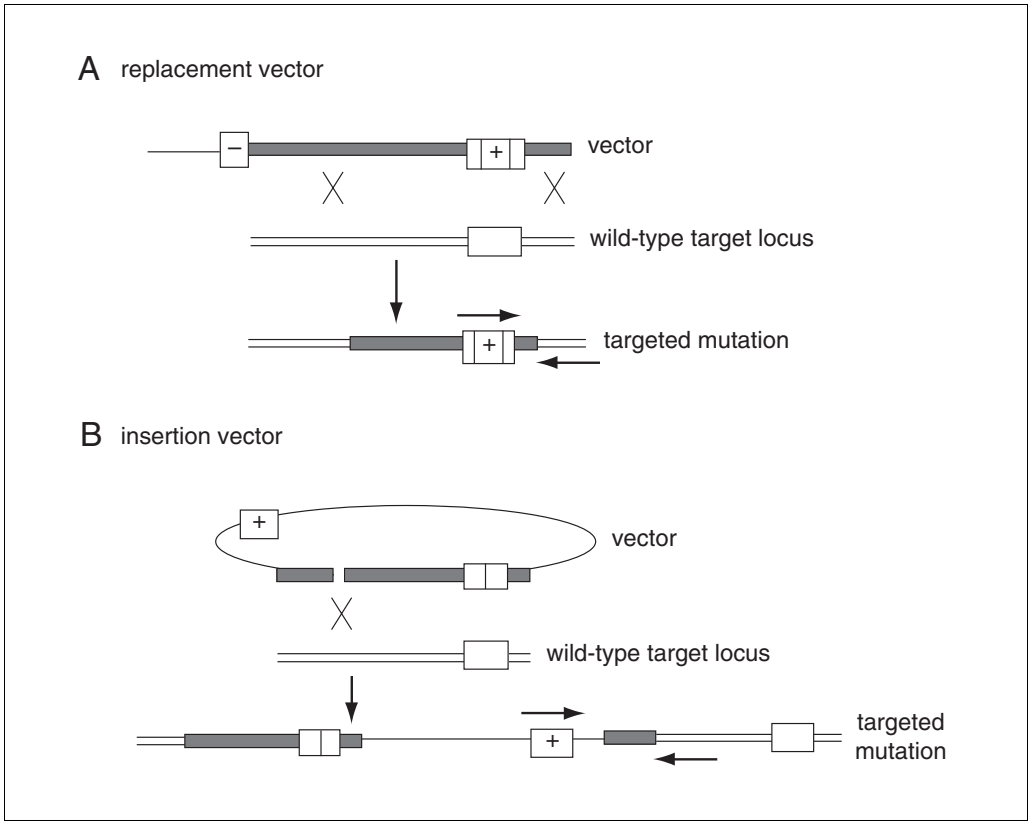

Figure 1.3.2 Replacement and insertion vector integration patterns. A thick line represents vector homology with the target locus and the thin, single line represents the plasmid backbone. The box containing a minus sign is the negative selection marker. The double line represents wild-type homology with the vector. The exon targeted for mutation is represented as an open box. Arrows pointing horizontally represent PCR primer locations. The X's are crossover points for vector integration. (**A**) The box containing a plus is the sequence homologous to the targeted exon disrupted by the positive selection marker. (**B**) The box containing a single line in the middle represents a subtle mutation engineered into the homologous sequences for the target exon. The break in the thick line on the vector represents the vector linearization site.

vector design is advantageous. Other vector considerations include the provision of a unique restriction site outside the area of homology to linearize the construct. There should be ≥5 kb of homology overall (Hasty et al., 1991a). Acentric homology such that the short arm contains 0.5 to 2 kb of homologous sequences is desired if PCR analysis of targeted events is to be pursued (Hasty and Bradley, 1993). Otherwise, Southern analysis to determine successful targeting can incorporate any length of homology on the individual 5′ and 3′ ends, with overall length of homology the primary consideration (Hasty et al., 1991a). PCR analysis requires that one primer be located outside the area of homology, while the other primer should be located within the vector, often utilizing sequences within the positive selection marker (Fig. 1.3.2A). The resulting PCR product should be short enough to allow efficient amplification (≤2 kb). Replacement recombination products may be the result of single-copy or multicopy vector insertion, thus containing the plasmid backbone. Inclusion of a negative selection marker in the vector design may eliminate these undesirable events through drug (antibiotic) selection. Diagnostic Southern blot analysis is used to verify that one set of vector sequences is integrated within the target site in the correct orientation. A unique probe which hybridizes to a sequence outside one or both regions of homology is used to detect restriction-fragment size. Often a restriction site is engineered into the vector to assist in analysis.

Insertion vectors are used to generate either subtle or null gene mutations. Targeted integration can occur more frequently by insertion than replacement (Hasty et al., 1991b). Insertion events result in duplication of the area of homology (Fig. 1.3.2B) which can lead to null mutation. A primary difference in vector requirements between insertion and replacement

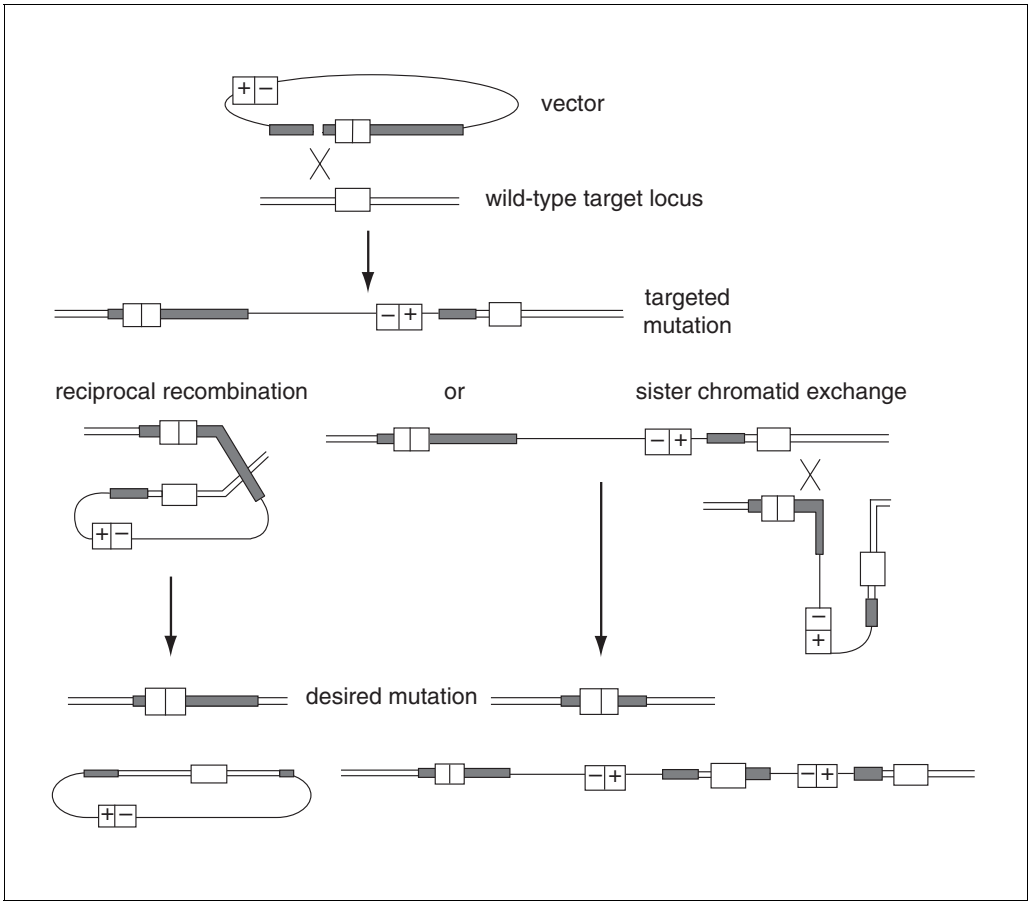

Figure 1.3.3 Hit and run vector insertion and intrachromosomal recombination patterns. The thick line represents vector homology with the target locus and the single line represents the plasmid backbone. The box containing a plus sign is the positive selection marker. The box containing a minus sign is the negative selection marker. The exon targeted for mutation is represented as an open box. The box containing a single line in the middle represents a subtle mutation engineered into the homologous sequences for the target exon. The break in the thick line on the vector represents the linearization site. The double line represents wild-type homology with the vector. The X's are the crossover points for vector integration and sister chromatid exchange. Intrachromosomal recombination of the insertion product can occur by single reciprocal recombination (left) or uneven sister chromatid exchange (right) to result in the desired targeted mutation. The diagram at the bottom shows how undesirable recombination products are lost through excision and degradation (left) or sensitivity to negative selection (right).

vectors is that location of the restriction site for vector linearization is incorporated within the area of homology rather than the plasmid backbone. The recommended level of overall homology is the same (≥5 kb). A positive selection marker can be included either within an exon or, more commonly, in the plasmid backbone, depending on the ultimate goal. Analysis of insertion events by PCR takes advantage of repair of DNA deleted from the insertion vector at the linearization site, such that one primer is within the area of repair and one within the vector, often utilizing sequences within the positive selection marker (Fig. 1.3.2B). As with replacement, the Southern analysis strategy for insertion relies on the use of an external probe.

Hit and run strategy involves the loss of vector sequences following vector insertion to generate either a subtle or a null mutation. The unwanted sequences (plasmid backbone, selection markers, and one complement of the target locus duplication) are lost through spontaneous intrachromosomal recombination (Fig. 1.3.3). Inclusion of a negative selection marker fused to the positive selection cassette is utilized to detect successful loss of sequences through recombination.

It is desirable to optimize the frequency of site-specific homologous recombination to reduce the eventual clone-analysis workload. Vectors containing homologous sequences cloned from isogenic DNA are generally more effi-

cient at targeting (Deng and Capecchi, 1992). A commonly used approach involves inclusion of a negative selection marker, such as thymidine kinase, on one end of the replacement vector. This is called positive negative selection (PNS) and allows a higher frequency of detection of targeted events by sensitizing clones,—derived by random, concatemer, or vector circle integration—to the presence of a negative selection drug (Mansour et al., 1988). A similar approach—using an antisense cassette of the positive selection marker containing a strong promoter in reverse orientation located outside the area of homology—allows positive and negative selection to occur simultaneously in response to addition of only one selection drug (Skryabin and Schmauss, 1997). Targeting frequency can be improved by driving a positive selection marker using the endogenous promoter or enhancer at the site of integration, as long as neither promoter nor enhancer is included within the area of sequence homology on the positive selection marker (Schwartzberg et al., 1990).

Temporal and cell-type-specific control of gene targeting provide a means to more accurately assess the physiological role of the gene of interest. The Cre-*lox*P system is used in gene targeting to remove vector sequences by flanking the sequences to be removed with *lox*P sites. The vector sequences are then excised using Cre recombinase (Lakso et al., 1992; Orban et al., 1992), either by in vitro exposure to Cre recombinase or in vivo by introducing a Cre recombinase transgene. The Cre-*lox*P system not only duplicates one goal of hit and run vector design by removing the selection marker, but can be utilized for tissue-specific targeted gene mutation (Gu et al., 1994) and temporal control of targeted gene mutation (Kühn et al., 1995; Feil et al., 1996). Any portion of a gene can be excised by predetermining the *lox*P site location within a vector. Through the choice of promoter to drive the Cre recombinase gene, tissue and site-specific gene alteration can be controlled. Finally, the administration of a drug to switch on Cre recombinase activity allows temporal expression of the site-specific gene alteration. Prior to Cre recombinase induction, the animal must be homozygous for the targeting event and hemizygous (heterozygous for the transgene) for Cre recombinase overexpression in order to look at temporally targeted mutations. This represents a significant investment in time prior to biological assessment of gene function. It is important to be aware that with each level of control of transgenic production, the burden on the investigator to make wise choices in experimental aim and vector design increases.

Overall, the concerns that drive vector design are: (1) size of the desired mutation; (2) exon location of the targeting event; (3) sequence homology length; (4) location of selection marker(s); (5) incorporation and location of a unique restriction site to linearize the vector; (6) PCR and/or Southern blot analysis strategy to detect and clarify targeted events; (7) whether to incorporate strategies to improve targeting frequency; and (8) whether to include refinements, such as incorporation of a reporter gene as an expression marker (see Bonnert and Nicolas, 1993; Vernet et al., 1993), or inclusion of *lox*P sites.

Overexpression of a transgene can be achieved following introduction of a vector into embryonic stem (ES) cells. This is a relatively efficient means of producing random-insertion Tg mice, and is useful when the transgene may profoundly affect development (Jaffe et al., 1992; Kitsukawa et al., 1995), when stable integration of a large piece of unrearranged DNA is needed (Jakobovits et al., 1993; Lamb et al., 1993; Strauss et al., 1993), or when a genetically defined inbred background is required in cases where a suitable ES line is available (C. Ware, unpub. observ.). This method has the added advantage that clones can be characterized for integration copy number and, depending on the promoter used, determination of the level of transgene expression before introduction into mouse embryos. Often, a selection marker that incorporates a promoter that is expressed in ES cells is included in the electroporation mix in a ratio of 1 part selection marker to 10 parts desired gene vector. Following this scheme, the gene construct is identical to that described for pronuclear injection. Otherwise, the selection marker can be incorporated directly within the vector construct. It is important to be aware that overexpression using ES cells will require the production of chimeras to introduce the mutation into the germ line. This effectively adds one generation to the time frame, relative to standard pronuclear microinjection.

MOUSE HUSBANDRY

A number of different inbred, outbred, and hybrid strains of mice have been used to produce Tg mice. F2 hybrid embryos, generated from matings between F1 hybrid mice are most commonly used for DNA microinjection. Hybrids that are commonly used include (C57BL/6XSJL)F1, (C57BL/6XC3H/He)F1, (C57BL/

6XDBA/2)F1, and (BALB/ cXC57BL/6)F1. Inbred strains, such as C57BL/6, FVB, BALB/c, and C3H are also used, but the efficiency of generating Tg mice is less than with hybrid strains. However, the problems of genetic variation between F2 animals, genetic drift in subsequent generations, and the extensive backcrossing onto an inbred background required to regain genetic definition are greatly minimized by using an inbred embryo strain. Inbred strains are routinely used as blastocyst donors to provide a constant genetic background for the production of chimeras. Outbred Swiss albino strains, such as CD1, ICR, and SW, are frequently used as embryo donors because they are relatively inexpensive. However, they do not respond to superovulation as well as hybrid strains, and their embryos develop more slowly. Table 1.3.3 provides an overview of criteria for selecting a donor mouse strain based on physiological and biological characteristics.

There may also be scientific considerations for selecting a genetically defined background strain. Historically, inbred strains have been phenotypically characterized in a wide variety of biological studies. Thus, many toxicology studies are based on data using inbred strains. The ease and efficiency of generating Tg mice using hybrid strains must be weighed against the relatively lower efficiency, but scientific validity, of generating Tg mice on defined genetic backgrounds of commonly used inbred strains.

Embryo Collection

Natural ovulation in the mouse occurs 2 to 3 hr prior to the onset of estrus, producing 10 to 12 ova, depending on the mouse strain. Figure 1.3.4 schematically shows the time course of embryos as they are released from the ovary and travel through the oviduct and into the uterus. The administration of exogenous hormones to sexually immature female mice (<5 weeks of age) is usually thought to increase the quantity of viable ova to 15 to 30 per mouse and synchronize the release of ova from females within the same group. Superovulation consists of injecting two hormones in sequence—pregnant mare's serum gonadotrophin (PMSG) followed by human chorionic gonadotrophin (hCG) 42 to 48 hr later—into 3- to 4-week-old sexually immature female mice. However, adult females as old as 9 weeks of age have been found to respond favorably to superovulation (W.C. Ladiges, unpub. observ.). PMSG contains a relatively higher ratio of follicle-stimulating hormone to luteinizing hormone than does hCG, and will increase the number of developing ova that will mature just before ovulation. On the other hand, hCG contains a relatively higher ratio of luteinizing hormone to follicle-stimulating hormone, and stimulates the synchronous ovulation of almost all of the PMSG-stimulated follicles within 6 to 8 hr following injection. Both hormones are given intraperitoneally in sterile saline at a dose of 3 to 8 IU per mouse. Inbred strains typically require lower doses (3 to 5 IU per mouse), while hybrid strains often need slightly higher doses (5 to 7 IU per mouse). In actual practice, it is acceptable to administer 5 IU per mouse, regardless of the strain. The timing of administration is also of importance, depending on the light cycle of the room where mice are housed. If a standard 6 a.m. to 6 p.m. light cycle is used, PMSG should be given later in the day, between 12 noon and 4 p.m. A specific time should be

Table 1.3.3 Suggestions for Selecting a Mouse Strain for Transgenic Manipulation

Strain	Genetic status	Superovulation[a]	Embryo quality[b]	Litter size[c]	Cost[d]
C57BL/6	Inbred	Medium	Acceptable	Average	High
FVB	Inbred	Medium	Outstanding	High	Medium
BALB/c	Inbred	Low	Acceptable	Average	High

selected and used consistently. The authors routinely use 12 noon, so that 47 hr later hCG can be given and females placed with fertile male studs, on a one female to one male basis. The following morning, plugged females are euthanized and embryos collected for microinjection. For blastocyst collection, plugged females are held for three days and then euthanized for the collection procedure. It is advisable to use ten females for each microinjection. From this group, expect between 200 and 300 ova, and 20 to 60 blastocysts, depending on the strain and season.

Pseudopregnant Recipients

The female mouse is a spontaneously ovulating animal, with an estrus cycle of 4 to 5 days and an estrus period lasting from 9 to 20 hr. The standard procedure for generating Tg mice calls for transferring microinjected embryos into the reproductive tract of a recipient female within a few hours following microinjection. These

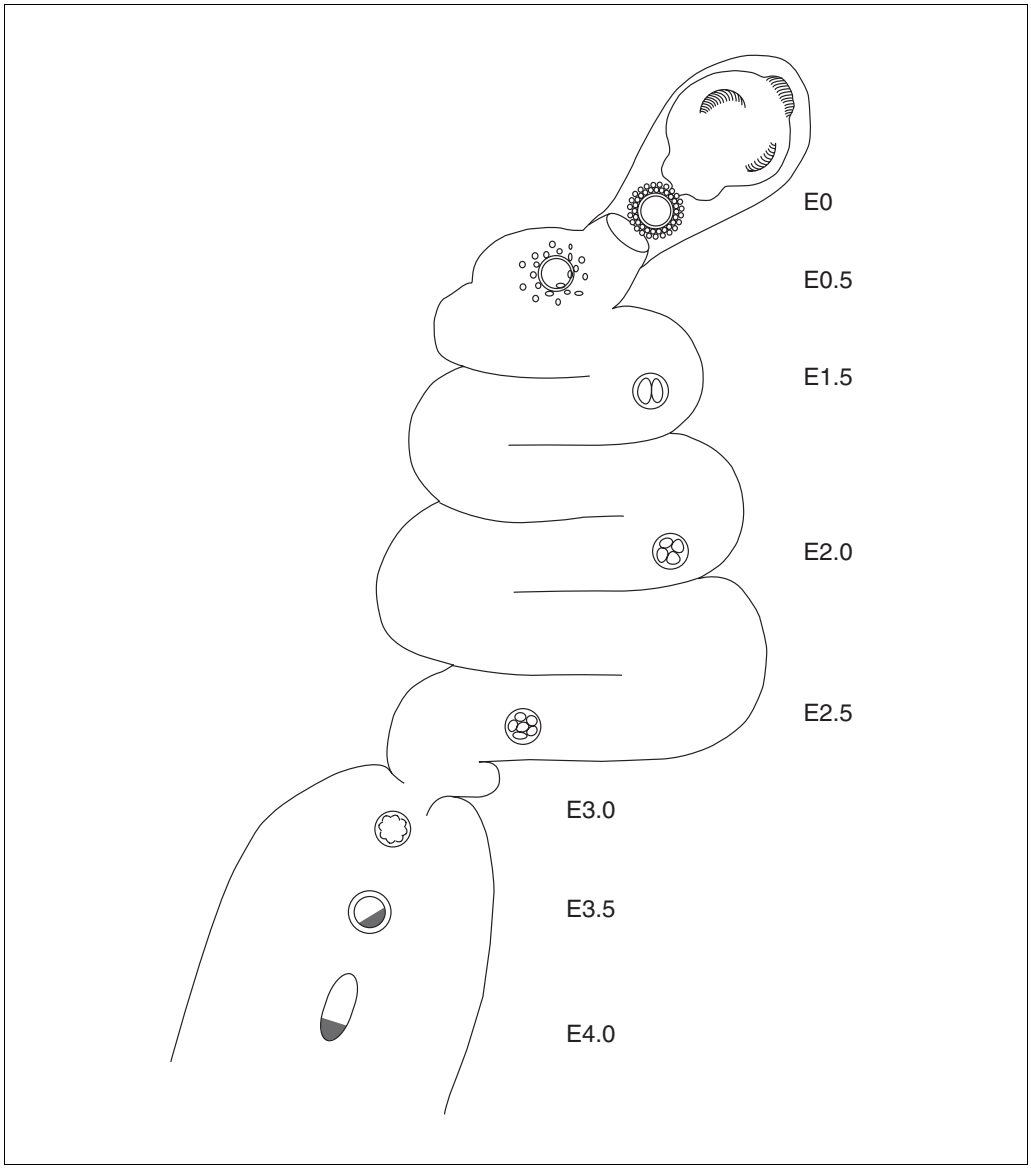

Figure 1.3.4 Diagram of the location of developing embryos within the murine reproductive tract. The days of embryonic development are designated by E followed by a number. An unfertilized one-cell oocyte (shown surrounded in cumulus oophorus) is released from an ovarian follicle on E0, when it enters the oviduct. Fertilized one-cell embryos (shown with the cumulus expanding) are collected on E0.5 for pronuclear injection. On E1.5, a two-cell embryo has formed and the cumulus has been shed. On E.2.0, this has grown to a four-cell embryo. On E2.5, eight-cell embryos (uncompacted or compacting) are still within the oviduct near the utero-tubal junction. Embryos enter the uterus by E3.0 (morula stage), become blastocysts by E3.5, and become hatched blastocyst by E4.0. Embryos for ES cell injection or aggregation can be used from E2.5 to E3.5.

recipient females must be synchronized to receive the embryos at the proper developmental time, without interference by endogenous fertilized ova. This is accomplished by the natural mating of females, generally of a reproductively vigorous outbred strain, with vasectomized males (duds) of any reproductively aggressive background, to induce pseudopregnancy. Females to be used as pseudopregnant recipients are selected for their hardiness, ability to withstand the surgical implantation procedure, and mothering ability. A common practice is to use strains expressing a different coat color than that expected for the Tg litter. Outbred CD1-type mice are routinely used, but FVB females also make good recipients under some conditions (W.C. Ladiges, unpub. observ.). The females are mated to the vasectomized males the day before DNA microinjection of embryos if they are to be transferred as one-cell embryos. If they are to be transferred as two-cell embryos, the recipient females are mated with the duds the same day as embryo microinjection. The following morning, plugged females are collected for surgical implantation. If recipients are needed for uterine transfer of ES cell–injected blastocysts, females are held for 2 days after first detection of plugs. Regardless of how the recipients will be used, approximately four times the number of females that are actually needed will have to be mated with duds, since natural mating will result in only ~25% of the females having detectable vaginal plugs (a vaginal plug is evidence of copulation). Plugged females that are not used can be placed back in the breeding rotation after a 14-day holding period. Females beyond the stage of good reproductive performance (generally 12 weeks, depending on the strain) should be culled from the recipient pool. Vasectomized males should be at least 8 weeks of age and can remain sexually active for up to 1 year, but it is advisable to replace them at ~9 months of age.

PRODUCTION OF Tg MICE BY PRONUCLEAR MICROINJECTION

DNA should be linearized before microinjection since linearized DNA is more efficiently integrated than circular DNA. DNA <10 kb in length is commonly used, since large-molecular-weight DNA becomes highly viscous, making it difficult to load and inject through the 1- to 2-μm opening of a microinjection needle. The gene unit should be cut from its plasmid vector sequences and isolated by gel electrophoresis. Purification is necessary to remove contaminants, and this is a major factor in determining successful or unsuccessful integration of the transgene. Injection buffer consists of 10 mM Tris·Cl/0.25 mM EDTA, pH 7.6. The optimum concentration for injection is 2 to 5 ng/μl (Brinster et al., 1985).

Good microinjection needles and holding pipets are essential for successful transfer of DNA into pronuclei of E0.5 embryos (see Fig. 1.3.4 for an explanation of E terminology). A detailed description of the pros and cons of micropipet size and shape and the techniques for making them have been published (DePamphilis et al., 1988; Mann and McMahon, 1993). The injection equipment consists of an inverted microscope with a movable stage and Nomarski differential interference contrast optics, micromanipulators to support the holding and injection pipets and reduce hand movements, and a vibration-free table to hold the microinjection apparatus. In addition, the flow of DNA into and out of the microinjection pipet, as well as the suction needed for the holding pipet, can easily be controlled by oil or air lines hooked up to airtight microsyringes or a micro-injector (described by Hogan et al., 1994). Before microinjection, the DNA preparation is centrifuged to sediment precipitates that may clog the injection needle. It is often necessary to remove obstructing contaminants from the construct using an ultrapure 0.45-μm spin filter. The actual technique of microinjection has been described (Gordon, 1993; see Fig 1.3.5). An experienced operator can inject between 100 and 200 embryos, in an injection chamber containing HEPES-buffered medium under oil, in 1 to 2 hr.

The standard medium for E0.5 embryo collection and pronuclear injection is M2 (available from Sigma; Quinn et al., 1982). This is buffered for use in air and is suboptimal for embryo culture of more than several hours. If embryos are to be transferred immediately after microinjection, at the one-cell stage, they can be transferred directly in M2. Often, embryos are cultured overnight in a medium buffered with bicarbonate in a 5% CO_2/air atmosphere, for transfer at the two-cell stage. A number of media have been used successfully for the culture of one-cell mouse embryos. The plethora of medium options and the continuing improvement of medium choices is due to a great body of work on various mammalian species that has been given a recent boost by the economic importance of early human embryo culture. The most commonly used medium for overnight culture of mouse embryos to the two-cell stage

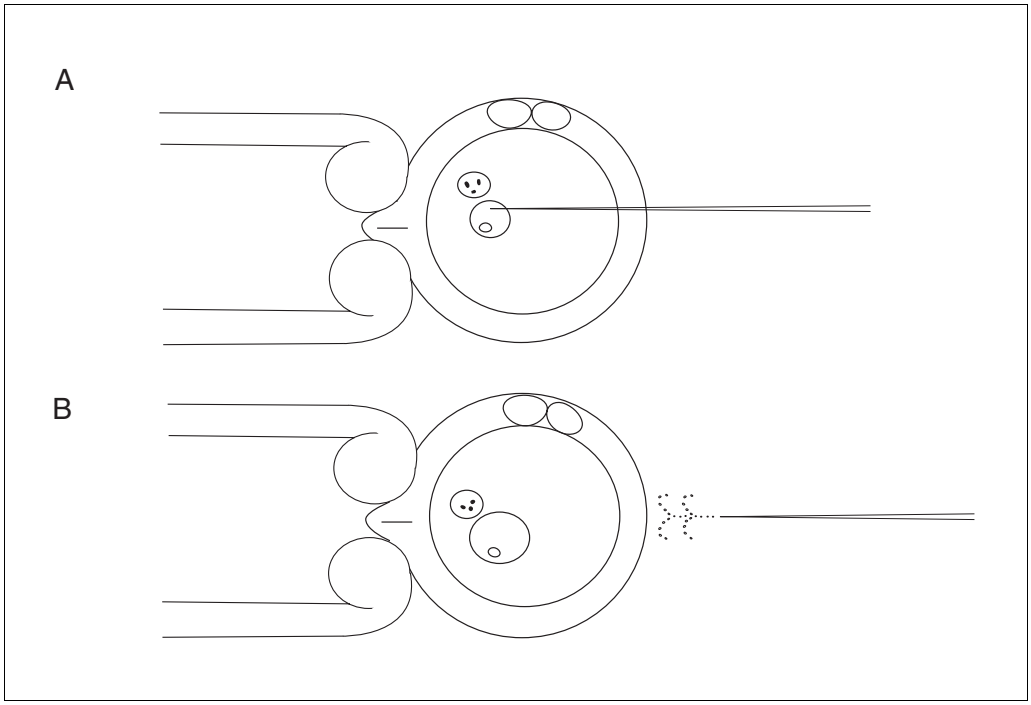

Figure 1.3.5 Pronuclear microinjection. The one-cell embryo is being held by the zona pellucida with an embryo holder on the left. The microinjection needle is on the right. Two polar bodies are in view beneath the zona pellucida. The small female pronucleus is above the male pronucleus. (**A**) The microinjection needle containing DNA has entered the male pronucleus, which will swell when DNA is injected into it. (**B**) The injected pronucleus is swollen and the microinjection needle has been withdrawn from the embryo. Note the steady flow of DNA from the needle.

is M16 (available from Sigma; Whittingham, 1971).

The surgical transfer of microinjected embryos to E0.5 pseudopregnant recipients is technically demanding but straightforward, and must be performed aseptically and rapidly, but gently. Mice are administered a general anesthetic, such as Avertin (Hogan et al., 1994) or ketamine/xylazine combination (0.35 ml per 20 g mouse mouse weight of a mixture of 1 part 20 mg/ml xylazine and 3 parts 100 mg/ml ketamine, diluted 1 to 10), which, when given intraperitoneally, generally provides quick, safe, and adequate levels of anesthesia for short periods of time. The surgical procedure is best performed under a dissecting microscope. It consists of exteriorizing one oviduct through a laparotomy incision, and placing the embryos through a puncture incision in the oviduct just anterior to the ampulla, using a glass transfer pipet (Fig. 1.3.6). An optional port of entry for the embryos is the ostium of the infundibulum. More embryos per recipient are transferred at the one-cell compared to the two-cell stage (typically 20 one-cell or 15 two-cell embryos per recipient). The aim is to have comfortably sized litters of 5 to 8 pups. Results do not differ using either stage of embryo, so the choice depends more on individual preference and laboratory schedules. An optional method yielding similar success rates is to transfer embryos to oviducts on both sides. In this case, the oviducts are exteriorized via bilateral dorsal incisions, and 4 to 12 embryos are transferred into each oviduct as already described. Following recovery from anesthesia, females should be housed no more than two per cage in relative isolation for the duration of their anticipated pregnancy.

Tail- or ear-punch biopsies are obtained from 2- to 4-week-old potential founder pups as a source of DNA for testing transgene integration. Pups are individually identified so transgene-positive animals can be retained for breeding. Approximately 1.0 to 1.5 cm of the distal tip of the tail is snipped for DNA extraction. Identification of Tg mice by PCR analysis of saliva has recently been described (Irwin et al., 1996). Cells from the oral cavity of weanling or adult mice are obtained by flushing with a small amount of sterile water using a plastic pipet tip. No surgical procedure is required and sampling can be repeated as often as needed. The DNA obtained from tissue biopsies can be analyzed by PCR, Southern blot analysis, or other hybridization techniques. PCR is rapid and efficient for detecting the presence of the transgene DNA. Southern blot analysis, while

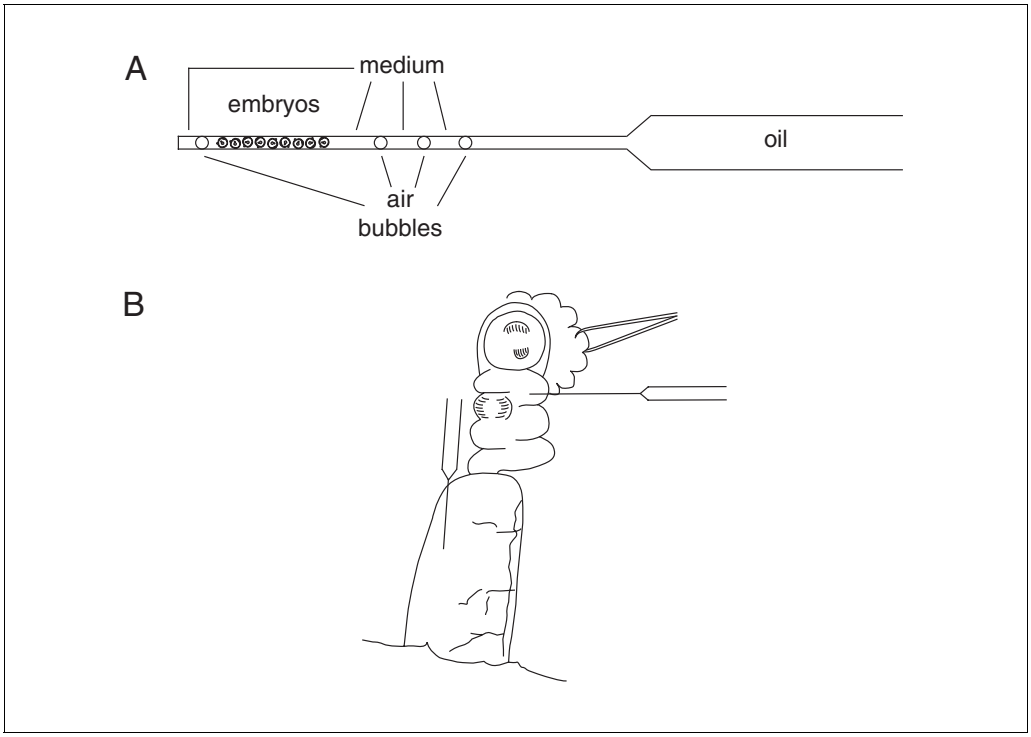

Figure 1.3.6 Embryo transfer. (**A**) Embryos are transferred with a glass pipet pulled so that the interior diameter can hold embryos in single file (~150 mm). Oil is loaded into the capillary, followed by two short columns of embryo-holding medium (M2), separated by air bubbles. Embryos are loaded in a minimum amount of medium separated by an air bubble from a tiny column of medium at the tip. (**B**) Transfer into the oviduct or uterus. For oviductal transfer (on the right), the ovary and oviduct are exteriorized under a dissecting microscope to place the ampulla in view. A 30-G needle is used to make a small opening in the oviduct just anterior to the ampulla on the infundibulum side. The tip of the transfer pipet is inserted into the opening and the embryos are transferred into the oviduct. Visualization of the first air bubble in the oviduct is evidence that the tip of the pipet is in the oviduct, while visualization of the second air bubble confirms that embryos were placed in the oviduct and the pipet can then be withdrawn. For uterine transfer (on the left), the tip of the uterus is exteriorized and held in place using the ovarian fat pad. The ovary is checked for corpora lutea. The uterine wall is punctured into the lumen with a 25-G needle, while avoiding capillaries. The transfer capillary is inserted into the puncture and embryos expelled using the air bubbles as markers so that oil is not placed in the uterus.

technically more cumbersome, will provide an estimate of transgene copy number, and is used by many to confirm PCR results. Once potential founders are identified, they are raised to sexual maturity and mated to non-Tg mice of the desired background strain. The offspring are tested for transmission of the transgene using the same assay as used for the parents. Mice that test positive for expression of the transgene can then be legitimately designated as founders for that specific line.

Interpretation of transgene expression can at times be a daunting task. The integration site can have a major influence on expression because a transgene may be incorporated into a "silent" region of the genome, so expression of the transgene will not be detected, or detected only at very low levels. Of more concern is whether active integration of the transgene disturbs the expression of endogenous host genes, resulting in an inadvertent phenotype. Therefore, it is essential to demonstrate that overexpression of a transgene is responsible for a specific phenotype by observing at least two and preferably three Tg lines from different founders. Evidence that the phenotype was due to the overexpression of the transgene in question would be conclusive if similar phenotypes were observed in separate founder lines.

There are several patterns of transgene transmission in founder mice. Most founders will transmit their transgene to 50% of their offspring. If 30% or less of the offspring are positive for the transgene, the founder is probably mosaic. Founder mice with 80% or more positive offspring may have more than one integration site. Southern blotting will help verify insertion sites. Offspring of founders

should transmit the transgene in a Mendelian fashion. However, loss of the transgene in subsequent generations has been observed (Gorden, 1993). The goals of breeding the founder mice are: (1) to observe the inheritance and expression patterns of Tg lines through several generations; (2) to expand the colony to provide mice for experimental study; and (3) to produce transgene homozygosity for comparison with the heterozygous state.

Mice can be mated when they are sexually mature, at 6 to 8 weeks of age. Tg founders are mated to the inbred strain of choice, but one of the most commonly used strains is C57BL/6. It takes six generations of mating onto the C57BL/6 background to obtain at least 99% of the Tg background as C57BL/6. It will then be possible to control for the influence of genetic background on gene expression by comparing Tg mice with normal C57BL/6 mice. Sexually mature female mice cycle every 3 to 4 days and have a gestation time of 19 to 21 days, so pups should be born within a month of breeder setup. If no pups are produced within 1 month, mice caged with a potential Tg founder should be replaced. It is possible that Tg founders may be infertile as a result of Tg expression or other unknown causes.

The production of homozygous Tg lines entails additional analysis to identify the first homozygotes. This is done by Southern blotting and genetic testing (Gorden, 1993). A potential homozygous Tg mouse is mated to several naive mice, and if all offspring are DNA-positive (assuming a minimum of 14 offspring tested), there is reasonable assurance the founder is homozygous. Additional test breeding will be necessary to ensure that homozygosity is maintained. There is also the risk that Tg expansion of a homozygous Tg line may result in a phenotype unassociated with the transgene, since ~10% of transgene integration events interrupt an endogenous gene involved in normal development. If homozygosity provides no scientific advantages, Tg lines should be maintained in the hemizygous (heterozygous for the transgene) state—i.e., in which the transgene is on only one chromosome.

PRODUCTION OF Tg MICE BY GENE TARGETING

Embryonic Stem Cell Culture

ES cell lines are derived from the inner cell mass of mouse embryos at embryonic day 3.5 (E3.5, where E0.5 is the day of plug; Fig. 1.3.4). ES cells can give rise to teratocarcinomas and teratomas when placed in an extrauterine site within a host mouse. They are not contact-inhibited in vitro and are able to grow in suspension, which are hallmarks of transformed cells. Thus, they form an interesting link between tumor formation and normal development. The aim of successful ES cell culture is to retain developmental capability so that when the cells are reintroduced into an embryo host, they can participate in development of an individual to make a chimera, i.e., an animal comprising cells from both the host embryo and the ES cells. Under most circumstances, it is desirable that among the tissue contributions, ES cells participate in the germ-cell lineage and thus transmit genetic changes introduced into ES cells into the germ line of chimeras. The doubling time (18 to 24 hr) of ES cells and the ability to retain germ-line potential (totipotency) in culture allow rare, induced genetic mutation events to be detected and the cells containing the desired mutation to be clonally grown and analyzed for reintroduction into embryos.

ES cells in culture have a remarkable ability to differentiate. Growth factors that interact with the leukemia inhibitory factor receptor (LIFR) subunit suppress ES-cell differentiation (Gearing et al., 1991; Rose et al., 1994; Pennica et al., 1995). Because ES cells are not contact-inhibited and lack the architectural elements that facilitate movement on a tissue culture plate, they tend to pile up as they divide (Fig. 1.3.7A). If cells are trapped within a cell cluster and lose direct exposure to growth factors bound to the feeder layer and/or in soluble form in the medium, the internal cells of the cluster influence the outer layer to differentiate into endoderm cells, which then gain contact inhibition and grow in a characteristic fashion (Fig. 1.3.7B and C). ES cell culture to eventually generate mutations in the germ line is primarily an effort to keep the cells in small, undifferentiated colonies, and so requires frequent passage accompanied by thorough dispersion of colonies using trypsin-EDTA. Passaging the cells every 2 days at three densities is useful for routine maintenance. Ideally, the culture medium should be changed daily. In general, ES cells thrive best in the presence of other ES cells, but are extremely fragile under pH conditions fluctuating too far from 7.2. Consequently, successful maintenance is a balance between keeping the cell density high enough without overly acidifying the medium by crowding. It is better to err on the side of lighter cell density as acid (yellow) medium can destroy the ES culture germ line potential overnight.

Isolation of ES lines from various murine strains has met with varying success

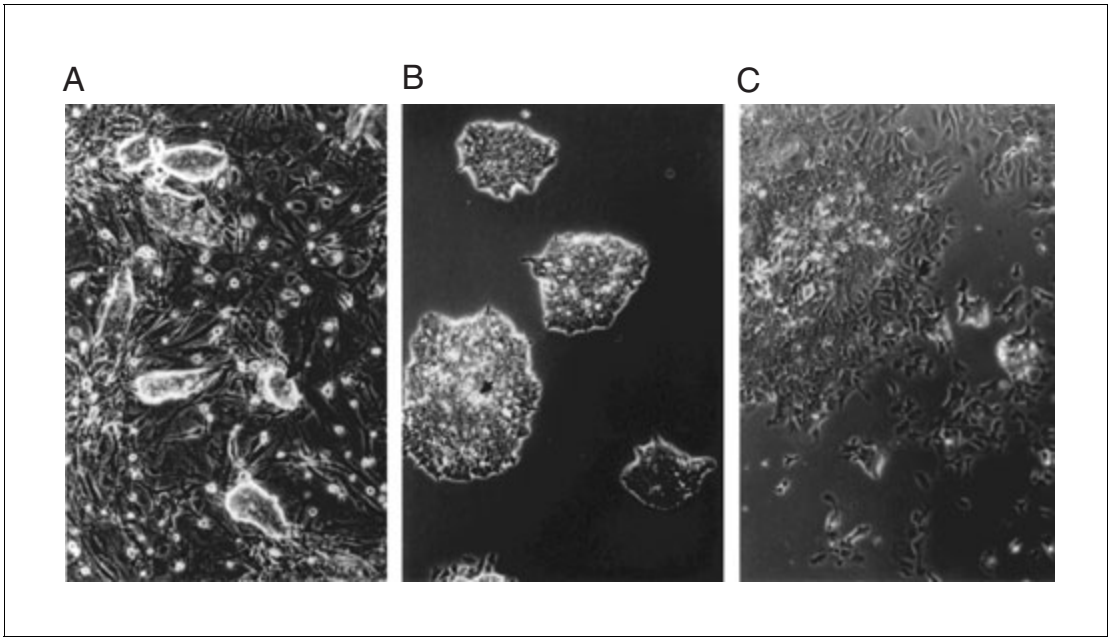

Figure 1.3.7 ES cells growing in vitro. (**A**) Small colonies of ES cells growing on a fibroblast feeder. The large arrow points toward an undifferentiated colony. Note the bright edge indicating that the colony is mounding as the cells divide. The small arrow points toward a flattened colony. Normal cultures contain both colony morphologies. Whether a flattened morphology is an indicator of early differentiation has not been determined. When passaging ES cells for injection into embryos, the aim is to have approximately three-fold more colonies of either morphology within this size range per unit area on the day of injection. (**B**) Undifferentiated ES cells growing for 4 days in the absence of a feeder, with added LIF. The arrow points to an area of vacuole formation that indicates stress due to crowding. (**C**) Differentiating ES cells growing for 4 days in the absence of a feeder layer,without added LIF. The arrow points to the leading edge of an ES colony that has differentiated into endoderm. Note the presence of cells that remain undifferentiated.

(Doetschmann et al., 1985; Ledermann and Bürki, 1991; Roche et al., 1995). If it is important to have specific strain backgrounds other than 129, it may be most effective to chose an ES line of that particular strain, if available. ES cell culture conditions have become fairly standardized; however, it is beneficial to obtain and follow the culture conditions used to isolate and establish the ES line. Lines that are transferred between laboratories,such as R1 (Nagy et al., 1993) and D3 (Doetschmann et al., 1985), are coming into common use, as are the culture conditions to maintain them. Abbondanzo et al. (1993) and Wurst and Joyner (1993) provide excellent protocols for ES culture techniques.

ES cells are routinely grown on a gelatinized plate in medium supplemented with 10^3 U/ml leukemia inhibitory factor (LIF) and/or on a growth-inactivated feeder layer plated on a gelatinized plate. When ES cells were first derived, they were grown on fibroblast feeder layers (Evans and Kaufman, 1981; Martin, 1981). Subsequently, it was determined that LIF suppresses differentiation in ES cells and that fibroblast feeder cells commonly used to support ES cells make LIF (Smith et al., 1988; Williams et al., 1988). However, all fibroblast feeders are not equal in their ability to maintain undifferentiated cultures (Suemori and Nakatsuji, 1987) nor is LIF alone as a medium supplement as good as a fibroblast feeder layer in maintaining an undifferentiated culture (Nichols et al., 1990). Consequently, it is recommended that a feeder layer be used for ES growth and that the feeder layer be derived from mid-gestation mouse fetuses (primary murine embryonic fibroblasts or PMEFs) and carried as a nonestablished line for only eight passages. PMEFs can be successfully frozen; therefore, low-passage PMEFs can be stockpiled. The use of feeders in conjunction with positive selection drugs requires that the feeder cells contain a gene that confers resistance to selection. This can be accomplished by deriving PMEFs from pregnancies in transgenic mice carrying the selection marker. If selection-resistant PMEFs are unavailable, some ES lines can endure culture in the absence of feeders on a gelatinized plate in medium supplemented with LIF for the time it takes to select resistant clones.

PMEFs, either proliferating or growth-arrested, as well as ES cells, are routinely held in liquid nitrogen frozen storage using standard tissue culture protocols. Bulk freezing of ES parent stocks is recommended because ES cells can drift rapidly in culture. A routine of thawing a new batch of parent cells prior to vector introduction helps to keep the transgenic lines at as low a passage number as possible. Following DNA transfection, ES cells should be stored frozen for the duration of analysis so that the cells destined for injection into embryos for chimera production are at as low a passage number as possible Figure 1.3.8 illustrates the passaging routine.

Abnormal variants continue to arise even under the best of culture conditions and are especially problematic if the ES culture has become contaminated by mycoplasma. Unfortunately, variants that no longer retain germ-

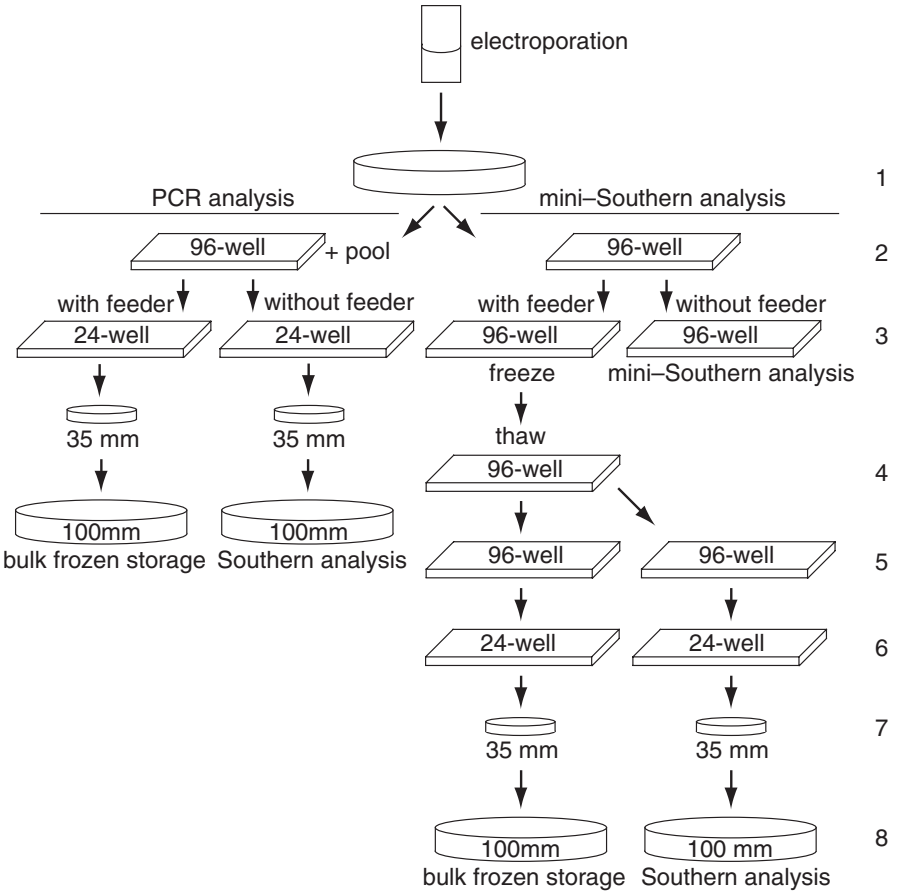

Figure 1.3.8 Comparison of number of passages of ES cells required following PCR versus Southern analysis of targeted events. Beginning with electroporation, represented by the rectangle in the upper center, passage numbers, on the right, are shown. During passage 1 the cells are grown clonally in the presence of selection drug(s). Picking colonies for growth in individual wells on a 96-well plate is passage 2. Half of each colony is pooled with other colonies for PCR analysis, represented on the left, while the entire colony goes into the well for mini-Southern analysis, represented on the right. Further divergence between culture methods occurs upon handling passage 3 plates. In the case of PCR analysis, on the left, the cells are passaged onto individual wells of a 24-well plate containing a feeder layer for eventual frozen storage of positive clones at passage 5 and without a feeder layer for Southern analysis of positive clones, also at passage 5. Mini-Southern analysis (on the right) requires freezing of the cells on the passage-3 96-well plate, while the sister plate is used for mini–Southern analysis. When successfully targeted colonies are identified, those colonies are thawed and passaged for bulk frozen storage and standard Southern analysis, as with the PCR scheme on the left. These represent ideal passage conditions. One passage should be added if initial isolated colony growth (passage 2) is poor.

line potential are not readily obvious by gross phenotype. Karyotypic analysis for chromosome number, or more finely by G or C banding (e.g., Abbondanzo et al., 1993), is helpful in analyzing colony drift and clonal loss of germ-line potential. Parent ES cell cultures that have drifted from the norm can be rescued by cloning.

Homologous recombination vectors are commonly transfected into ES cells via electroporation. The vector stock should be at a concentration of ~1 mg/ml, linearized (Ramirez-Solis et al., 1993), and free of toxic contaminants such as ethanol, ethidium bromide, and excess salt. ES cells, passaged 1 day prior to electroporation, should be growing densely in small colonies. Reports of the number of cells and amount of vector used for electroporation vary. Median amounts are 2×10^7 ES cells in PBS (without Ca^{2+} and Mg^{2+}) containing 25 µg vector. Electroporater settings vary from unit to unit. A short, high-voltage electrical pulse is applied to the ES-vector mixture. Pores form in the ES cell membrane that allow entry of the vector. Ideally, an immediate upshot of successful electroporation is 50% killing of the ES cells, as assessed by the trypan blue exclusion test of cell viability. This is a useful method to predetermine effective electroporater settings. DNA can also be injected directly into the nucleus by monolayer microinjection (Zimmer and Gruss, 1989). Although homologous recombination is efficient enough following microinjection so that no selection marker is required, the technique requires expertise and expensive equipment and is not commonly reported.

Following electroporation, the cells are plated either directly onto gelatinized plates in medium containing LIF or onto selection-resistant feeders. Reported cell densities vary; however, the aim is to plate the cells sparsely enough so that overgrowth prior to selection taking effect does not occur, and so that the cells are not plated so sparsely as to be wasteful of medium. Positive selection drugs, such as neomycin, vary in effectiveness from batch to batch and should be tested for complete killing of parent ES cells prior to use for selection of integration. One day after electroporation, the selection drug or drugs are added to the plates. Negative selection with ganciclovir may be responsible for lowered germ-line potential of resulting clones, so it is present for only 4 days, while the positive selection drug is present for the duration of selection, or 7 to 12 days. Cultures require frequent fluid changes prior to and during the death of nonresistant cells.

When colonies of resistant cells can be detected they are picked and dispersed. Colonies destined for PCR analysis are divided in half between cells designated for further culture on a feeder (individual wells on a 96-well plate) and pools with a few other clones to be immediately analyzed by PCR (Fig. 1.3.8). Colonies destined for initial analysis by mini–Southern blot analysis (Ramirez-Solis et al., 1992, 1993) are placed individually in one well of a 96-well plate. At this point, the aim is to grow the cells sufficiently to complete analysis by PCR, and to do this rapidly enough to passage only candidate clones for further analysis and bulk frozen storage. Alternatively, if analysis is by a mini-Southern approach, the aim is to grow only enough cells for frozen storage so as to be able to retrieve interesting clones during analysis. Again, it is important to freeze the cells at sufficient density and at the lowest passage number possible for successful thawing and chimera production. See Ramirez-Solis et al. (1993) and Wurst and Joyner (1993) for standard electroporation and selection protocols.

Production of Chimeras

Early mouse embryos are able to incorporate ES cells into the inner cell mass, which allows functional contribution of the introduced cells to all tissues of the resulting pup. Because there is no intracellular mixing of genetic material between host embryo and ES cell, the resulting mice are chimeras. The entire effort of ES cell culture in regard to production of transgenic mice is to maintain the potential of ES cells to participate in the murine germ line so that induced genetic alterations will be inherited. Consequently, it is important to verify that ES culture conditions are sufficient to achieve this, by directly testing parental ES cell lines prior to genetic manipulation for germ-line potential.

The most frequently used ES lines are male (XY) for several reasons. Male ES cells contribute functional gametes to a male host embryo, resulting in a gamete mix derived from ES cells and host embryo. Female ES lines tend to lose one X chromosome upon culture to become XO. The female ES cells containing an XO or XX chromosome complement are viable in the resulting germ line of female host embryos; thus only female chimeras will transmit the ES genotype (Robertson, 1986). A strong male ES contribution can switch the phenotype of a female embryo to male. When this happens, the host embryo can no longer contribute cells to the germ line, and resulting functional gametes are completely ES derived (Robertson,

1986). Thus, a good male ES line will skew the offspring sex ratio to predominately male. However, this also means that many of the phenotypic males may be sterile due to incomplete sex conversion. Some male ES lines do not skew the sex ratio of resulting chimeras and can transmit through a female chimera, presumably due to partial or total loss of the Y chromosome, resulting in XO ES cells (Kuehn et al., 1987). Establishment of a mutation proceeds more quickly through founder male chimeras; however, it can proceed through female chimeras when the ES line is an XO or XX female.

ES cells should be passaged 1 to 2 days prior to injection, at different densities to ensure that on the day of injection there will be one plate that is seeded relatively densely with small colonies (Fig. 1.3.7A). Cells from plates older than 2 days do not trypsinize well, resulting in poorly dispersed ES cell aggregates containing cells that have begun to differentiate.

Sparse plates result in a high feeder-to-ES cell ratio, making ES cell selection under the microscope tedious. Feeder cells can be partially removed by preplating; however, this technique can increase the incidence of cell aggregates. Disaggregated ES cells are resuspended in injection medium and held at 4°C until use.

Choice of host mouse strain will depend on the strain origin of the ES cells. Initial studies on interstrain chimeras (Mintz, 1965, 1969) were suggestive as to useful, commonly available strain mixtures for successful chimerism. Most ES lines are derived from various substrains of 129 and contribute efficiently within C57BL/6 host embryos. ES cells from the 129 strain can carry white, chinchilla, or black agouti coat colors. All potential 129 coat colors contrast sufficiently with black to identify extent of coat chimerism. C57BL/6 ES cells contribute well within white BALB/c host embryos. ES cells, particularly of 129 origin, can be so efficient at populating the C57BL/6 host embryo that there has been no need to identify a more suitable host. Optimization of embryo host strain for non-129 ES lines remains to be elucidated.

Chimera production can be divided into three basic tasks: embryo production, microinjection (or aggregation), and transfer. Superovulation of immature females for embryo production is identical to methods used to obtain pronuclear-stage embryos. The use of naturally mated adult females results in lower numbers, but higher quality embryos. See Hogan et al. (1994) for a natural mating protocol. Flow in the murine reproductive system is unidirectional, so that nothing can flow retrograde from the uterus into the oviduct. Embryo recovery method is determined by the stage and method chosen to place ES cells into the embryo. Eight-cell (E2.5) embryos are collected from within the oviduct at the utero-tubal junction (Fig. 1.3.9A) while morulae and blastocysts (E3.5) are collected from the uterus (Fig. 1.3.9B). See Nagy and Rossant (1993) for eight-cell embryo collection methods; see Papaioannou and Johnson (1993) for blastocyst collection methods.

There is no consensus on the best medium for either embryo holding, injection, or culture.

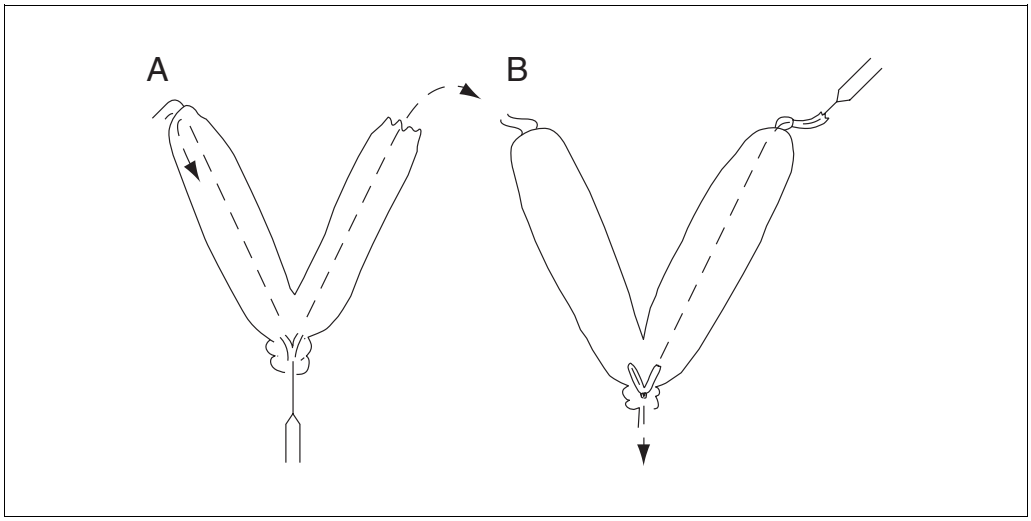

Figure 1.3.9 Direction of uterine flush. (**A**) Retrograde flush requires that the tip of the uterine horn be removed so that flush medium can flow out. (**B**) Flush through the oviduct through the utero-tubal junction allows flush collection through the cervix.

Medium for holding embryos in an air atmosphere needs to be buffered for air, using either a phosphate buffer or a bicarbonate-buffered medium containing HEPES. Culture requirements for mouse embryos from the eight-cell stage onward are less demanding than for earlier stages. However, limiting metabolic activity by reducing the temperature below 37°C and limiting time under substandard culture conditions are aims when working with morula and blastocyst stages. With this in mind, embryos can be successfully flushed, held, injected, and transfered in M2 medium (Quinn et al., 1982). Other medium options are described by Hogan et al. (1994), Stewart (1993), and Papaioannou and Johnson (1993).

Microinjection is the most common route for placing ES cells into embryos. Eight-cell (E2.5) to blastocyst (E3.5) stages can be used for microinjection, while embryo aggregation relies on the use of precompacted eight-cell embryos. Micromanipulation equipment is similar to that described for pronuclear injection. However, microscope optics need not be as refined nor as powerful because the cell interior does not need to be visualized, as is the case for pronuclear injection. Therefore, phase contrast at 100× magnification is sufficient to select healthy looking ES cells with clear, round morphology, and to determine the location of trophoblast cell junctions. Insertion of the injection needle at the junction between trophoblast cells will allow successful entry into the blastocoel without occlusion of the needle tip with cytoplasm, which could occur as a result of cell lysis (Fig. 1.3.10). Because phase contrast is sufficient to visualize the microinjection process, the injection chamber can be plastic. The lid of a 35-or 100-mm petri dish is sufficient to contain the injection droplets covered in oil. Use of a cooled chamber is optional. Holding ES cells at 4°C until they are placed in the injection chamber increases the time they can be held in suspension for injection. ES cells aggregate into unworkable clumps after 30 to 60 min at room temperature. Cells in the chamber need to be replaced with cooled cells when the existing cells become difficult to aspirate.

Microinjection of ES cells into embryos using micromanipulation requires the use of two specific tools, an embryo holder and an injection needle (Fig. 1.3.10). These require the use of specialized equipment to pull and bend the capillary tubing and generate the required tips. Embryo holders are the same as those used for pronuclear injection. Control of pressure on the injection needle ought to be fine enough to allow slow, easy ES cell aspiration and expulsion. Cleaning the interior of the needle using acid or sonication is useful to improve flow. The forces required for DNA microinjection may make the injection apparatus used for pronuclear injection too insensitive for ES cell injection. This is easily remedied by using a larger-diameter oil line. Fluorinert (Sigma) as a buffer between the oil in the line and the injection medium helps to increase control. ES cells are injected into the space between the uncompacted eight-cell embryo and the zona pellucida, into the center of a compacted eight-cell embryo or morula or into the blastocoel of a blastocyst, whether unhatched or hatched. The most difficult stage to inject is the hatched blastocyst, because trophoblast junctions are extremely tight while the embryo is difficult to hold firmly without a zona pellucida to prevent inadvertent collapse of the blastocyst. Glass pipets used for moving embryos from dish to dish are similar to the embryo transfer pipet and are made without using specialized instruments. See Papaioannou and Johnson (1993) and Stewart (1993) for overall manipulation setups and injection protocols. Another method of ES cell introduction into embryos is via aggregation to eight-cell embryos. This avoids the use of expensive toolmaking and microinjection equipment and can be as successful as microinjection (Nagy and Rossant, 1993).

Embryos can be transferred into either the oviduct or uterine lumen of E2.5 pseudopregnant recipients (Fig. 1.3.6). Suitable recipient mice are obtained as described for transfer of pronuclear-injected embryos. Uterine transfer is convenient due to its simplicity, but care should be taken to avoid introducing blood into the lumen or causing uterine contractions through rough handling. Pups are born ~18 days after transfer. Detection of chimerism is possible as early as 3 days later, but cannot be quantified until hair grows in, 5 to 7 days after birth. See Papaioannou and Johnson (1993) and Stewart (1993) for embryo-transfer techniques.

Extent of ES coat color contribution is used as a measure of potential germ-line contribution. However, coat color is not directly correlated with the germ-cell lineage in that the extent of chimerism in all tissues within the chimeric pup may not be uniform (Lallemand and Brulet, 1990; C.B. Ware, unpub. observ.).

A rule of thumb is to use only male chimeras where ≥50% of the coat color is from the ES contribution for testing germ line transmission of the induced mutation. This rule can be bent under circumstances where strong male chime-

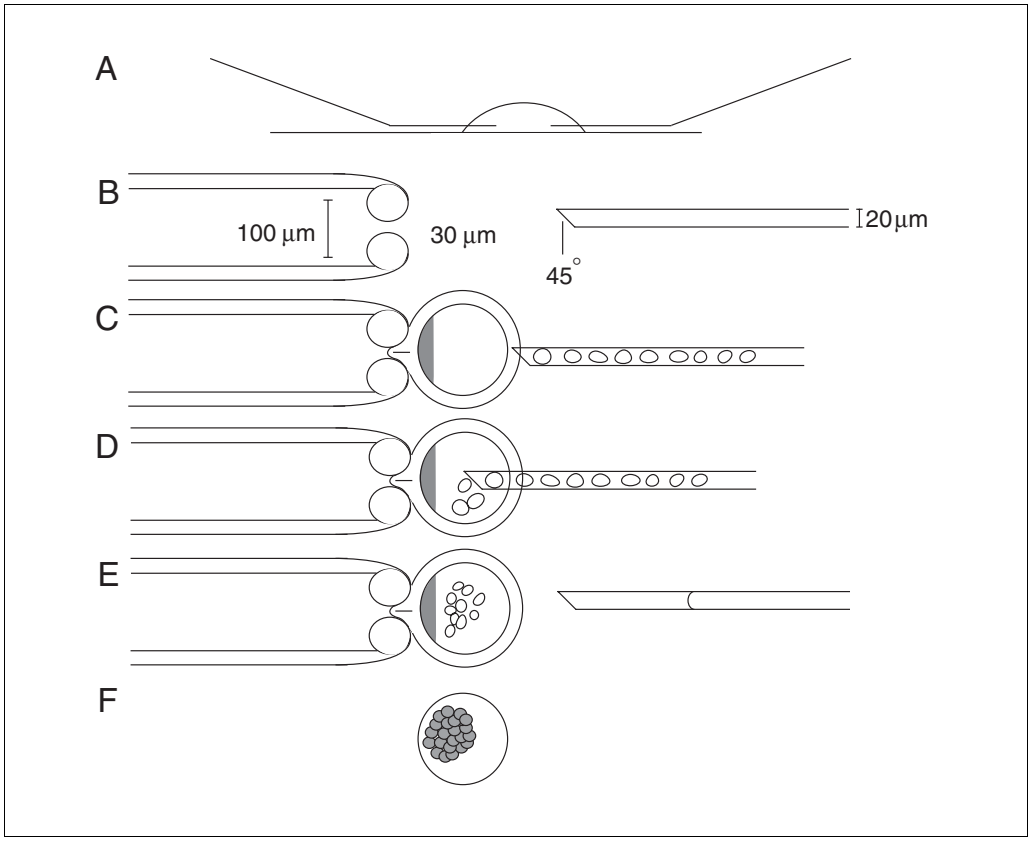

Figure 1.3.10 Embryo microinjection of ES cells. (**A**) Side view of the injection-droplet arrangement. Embryos and ES cells are placed in the droplet, which is overlaid with mineral oil. The two injection tools enter from opposite sides of the droplet and have an elbow bend that allows the tools to rest almost parallel with the plate bottom. (**B**) Tools used for injection. An embryo holder (left) should be about the size of an embryo, including zona pellucida, 80 to 100 µm, with an opening of 25 to 50 µm. Sizing is determined by individual preference. The injection needle is on the right. It has an internal diameter equivalent to the diameter of an ES cell (~18 to 20 µm). The tip has a 45° bevel and is sharpened. The orientation of the bevel when looking under the microscope is such that the tip is either on the bottom or on the top of the bevel (as shown). (**C**) The embryo is held with the holder. The inner cell mass is represented by a darkened semicircle on the left of the embryo. The injection needle is filled with ES cells and is approaching a trophoblast cell junction. (**D**) The needle is pushed through the cell junction and 10 to 15 cells dropped within the blastocoel. (**E**) The injection needle is withdrawn. A meniscus is seen between the medium and Fluorinert. (**F**) The embryo collapses around the ES cells.

ras are rare and the low frequency of targeted mutation events does not allow testing of alternate clones.

The genetic background of the 129 mouse strain is questionable (Threadgill et al., 1997). Chimeras generated from a 129 ES background are usually mated onto a better characterized strain with superior breeding performance. If kept on a 129 background, coat color frequently will not indicate germ line transmission, so offspring would have to be genotyped for the targeted mutation. Many mutations have been successfully analyzed on several generations of an F2 background. For example, test mating of chimeras is often accomplished with C57BL/6 females. The resulting black offspring are derived only from the host embryo background. Black agouti offspring are derived from ES cell contribution, due to coat color genetics of all the ES 129 substrains. These pups are further tested, using tail or ear biopsies, to determine whether the wild-type or the targeted allele was transmitted. Pups determined to be heterozygous (+/–) for the mutation are retained for breeding. At this point, a decision must be made whether to breed closer to an inbred background and/or to breed to homozygosity. In this example, mating the +/–animal to wild-type C57BL/6 will bring the resulting pups closer to C57BL/6 at a rate of 50% C57BL/6 contribution per generation. Each generation must be genotyped and only +/–animals must be bred

to C57BL/6. Three generations of crosses to C57BL/6, including the initial chimera mating, will bring the line to 87.5% C57BL/6. Seven to eight generations and more than 1.5 years later, the line is >99% C57BL/6, though drifted somewhat from C57BL/6 (Green, 1966). It is particularly unfortunate that genes in proximity to the targeted mutation are the least likely to be brought onto the C57BL/6 background. Once the line is predominantly C57BL/6, brother-sister matings will be the most rapid way to bring loci linked with the induced mutation to homozygosity (Green, 1966).

Breeding directly to homozygosity means +/– brother to +/– sister mating of offspring from chimera matings. If the chimera was not mated to a female of the ES strain, the background will be a random mix of ES cell and maternal strain backgrounds. Consequently, controls cannot be considered identical, nor might the resulting phenotype be as consistent among individuals as desired. In this situation, within-litter controls are the best available; however, independent wild-type or +/–brother-sister matings of the same generation can serve as useful controls. Depending on the target mutation, this may not be critical for successful biological analysis. However, the importance of having a genetically defined background for analysis may not be apparent during conceptualization of experimental design. Relevant to previously existing data, use of ES cells that are derived from an inbred background, such as C57BL/6, can overcome these difficulties (Fig. 1.3.11 and Fig. 1.3.12).

Tissue biopsy is usually taken from the tail as described for overexpression transgenics (see Production of Tg Mice by Pronuclear Microinjection). Frequently, the various targeted mutation genotypes can be easily identified using PCR for the positive selection marker in combination with primers to amplify the wild-type gene. Less tissue is required for PCR, so ear-biopsy tissue is sufficient for analysis. DNA extraction and analysis follow standard protocols. If PCR analysis is efficient, it may be convenient to use a quick DNA extraction, without cleaning away contaminating protein. It is advisable to look at the mutation in +/– pups from chimera matings using the same restriction digests used when selecting ES clones for chimera production, followed by Southern analysis. This will verify that no confounding rearrangements have occurred when the mutation passed through the chimera germ line.

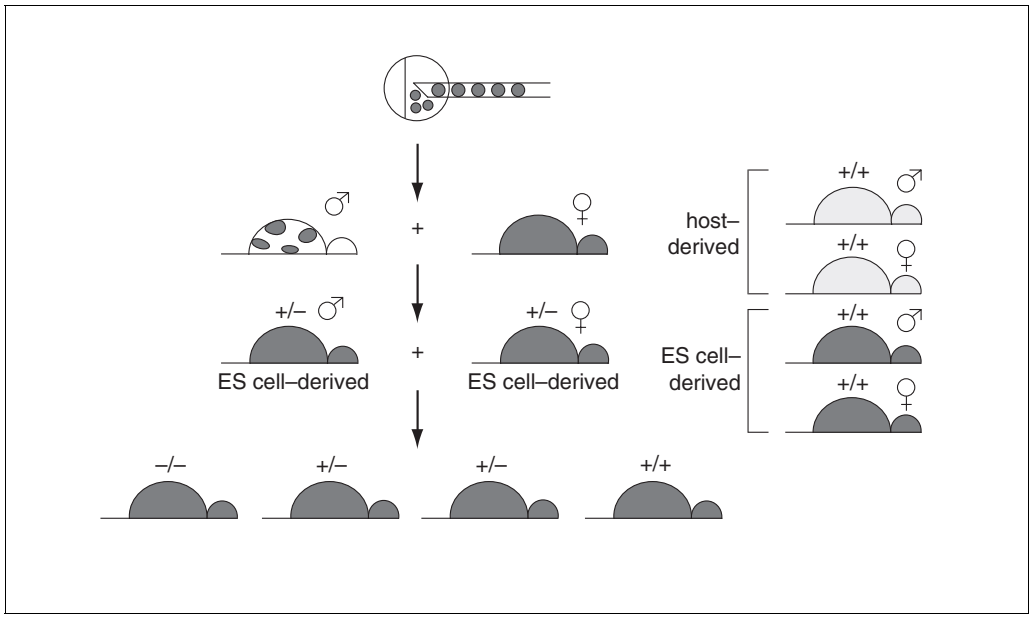

Figure 1.3.11 Breeding scheme to derive homozygous mutant animals from injection of targeted C57BL/6 ES cells into Balb/c blastocysts. The diagram at the top represents a BALB/c embryo being injected with C57BL/6 ES cells. The strain coat colors are represented by a white inner cell mass and black ES cells. The injected embryo results in a chimeric male (spotted animal on the left). It is mated with a C57BL/6 wild-type female. Paternal inheritance of the offspring is from either the host embryo (light gray animals, F1 between C57BL/6 ×BALB/c, on the right) or from the ES cells (inbred C57BL/6 animals). ES cell contribution is either from the wild-type allele (+/+, black animals on the right) or the targeted allele (+/–, black animals on the left). Heterozygous brother-sister matings result in inbred C57BL/6 homozygous targeted (–/–), +/–targeted and +/+ animals.

Figure 1.3.12 C57BL/6 ES ×BALB/c embryo chimeric mouse mated with wild-type BALB/c female, with their offspring. Pups are all derived solely by germ-line transmission of the C57BL/6 ES genome from the father. Consequently, all the pups have a brown coat color (C57Bl/6 from the chimeric father and BALB/c from the mother). If the targeted mutation is transmitted in a Mendelian fashion, half of these pups carry the targeted allele (+/–). Had the host embryo contributed to the germ line of the chimera, pups would be white (BALB/c from the chimeric father and BALB/c from the mother).

The resulting phenotype of targeted mutations is unpredictable, and may lead to developmental lethality. In this case, if +/– animals are viable and fertile, the mutation can be carried in this state and the offspring of +/– matings can used for phenotype analysis. Study of +/– animals prior to mutation-induced death is required if the mutation is dominant lethal or if the +/– animals are infertile. If the gene is critical in the heterozygous state for gamete or vital-system function, chimeras and in vitro differentiation may be the only route for phenotype analysis. See Papaioannou and Johnson (1993) for a description of animal husbandry.

COLONY MANAGEMENT

An ideal record-keeping system should allow the recording of data of all activities within the breeding colony, including individually identifying each mouse and its ancestry, breeders set up and pups born, and experimental phenotypes unique to each mouse. All mice born within a Tg colony should be individually identified. Ear tags are commonly used because they are relatively permanent, inexpensive, and easy to apply starting at 3 weeks of age. Other methods include toe and ear clipping and tattoo application. All data for lines within a Tg colony should be recorded so that phenotype patterns can be accurately evaluated on a retrospective basis. Records should be maintained in a format that allows for rapid and clear determination of the relationships between colony components. This can be done by simple hand entry of data into a breeding notebook, or by more elaborate maintenance on a computer spreadsheet. The authors use a standard Excel spreadsheet to maintain a Master List of every mouse that is ear tagged. Ear tag numbers consist of a two-digit letter code and a numerical code of up to four digits. The Master List contains birth date, transgene name, generation, line, sex, parents, phenotype and genotype, and information about the specific project. A pedigree should be established for each founder mouse that is mated. Customized cage cards can be printed for breeder cages to provide a summary of the breeding activity for each cage. Customized weaning cards can be used to record the line and ear tag numbers so weanlings can be readily located and tracked. A separate spreadsheet file should be used for breeding records, containing birthdates of litters, number of pups born and weaned per litter, ear tag numbers for pups, breeder setup date, breeder retirement date, strain, generation, line, and comments. Computer software packages specifically for mouse colony record keeping have been developed and are commercially available (Silver, 1993).

Because it requires a considerable effort to generate a Tg line, it is prudent to be sensitive to the health status of the mice and also of the environment where they are housed. Many researchers opt to maintain Tg lines in specific-pathogen-free housing facilities where the mice and the environment are diligently monitored for mouse pathogens. It generally costs more to maintain mice under these conditions, but complicating disease factors and loss of a Tg line will be greatly minimized. This is particularly appropriate where underlying disease states compromise biological analysis, or where analysis requires investigation in an uninfected background. Another way to help in the preservation of infection-free lines is to store embryos under cryopreservation in liquid nitrogen.

A registry of Tg strains and their characteristics is essential to prevent duplication of existing strains, to promote comparison among related strains, and to maintain valuable Tg models. The Oak Ridge National Laboratory (Oak Ridge, Tennessee) has developed a database for cataloging Tg animals, referred to as TBASE, which is currently administered by the Jackson Laboratory. To this end, an acceptable standardized nomenclature for Tg animals is necessary. Tg nomenclature must incorporate information related to both the methods used to produce Tg mice and the diversity of genetic elements that are inserted into their germ line. The actual format has been standardized (Standard Nomenclature for Transgenic Animals, 1992) and starts with the symbol "Tg" followed by a letter code for the mode of trangenesis where "N" stands for nonhomologous recombination by pronuclear microinjection or electroporation, "H" stands for homologous recombination, usually via targeted ES cells, and "R" stands for retroviral transfection. Following the letter for the mode of transgenesis is a set of parentheses enclosing relevant information about the transgene, which generally should not exceed eight characters. Finally, letter codes designating the laboratory of origin complete the nomenclature designed for Tg mice. Designation of the founder strain precedes the nomenclature if the background strain is maintained throughout the breeding. An example of a typical lineage nomenclature would be designated as follows: FVB-TgN(pkrGe)551Wcl, where FVB stands for the inbred strain, N for pronuclear microinjection, pkrGe for a genomic clone of the PKR gene, and 551Wcl for the Tg founder mouse number 551 in the laboratory of Warren C. Ladiges.

DNA Microarrays: An Overview of Technologies and Applications to Toxicology

AIMS AND OBJECTIVES

The Genome Project and the technological innovations that it spawned have dramatically altered the future course of all biological research, including toxicology. The GenBank database already harbors billions of base pairs of DNA sequences derived from millions of individual sequence entries (*http://www.ncbi.nlm.nih.gov/Genbank/index.html*). The first complete genomic sequence to be completed almost 5 years ago was that of *Heamophilus influenzae.* Since then, the genomes of more than two dozen additional organisms have been completed and made available to the research community (*http://www.ncbi.nlm.nih.gov/Entrez/Genome/org.html*). Continued improvement in high throughput DNA sequence technology has made it possible to complete the reference human genome sequence by the year 2001, several years ahead of schedule. Exploiting the enormous potential of genome-wide sequence information will require the development of a battery of new tools for high throughput and highly parallel molecular analyses and commensurate bioinformatics tools to analyze data sets of unprecedented depth and complexity.

An increasing number of molecular techniques continue to be developed for high throughput analyses of gene expression and genetic polymorphisms. Included among these methodologies are automated DNA sequencing, serial analysis of gene expression (Velculescu et al., 1995), denaturing high performance liquid chromatography (Underhill et al., 1996), differential display (Liang and Pardee, 1992), high-density filter hybridization (Zhao et al., 1995), and highly sensitive mutation assays coupled with iterative sample repooling strategies (Zarbl et al., 1998). While each of these approaches has advantages and limitations, none possess the versatility or potential of DNA microarrays, also known as DNA "chips". The unprecedented capacity of chips for highly parallel detection of RNA expression and/or DNA variation at the genomic level suggests that microarrays will play a major role in functional genomics, the study of how genome-wide genetic variation and patterns of gene expression interact to produce complex biological responses.

The response of cells or organisms to toxic stimuli is an example of such a complex response, which ranges all the way from the induction of a specific xenobiotic metabolizing enzyme to the induction of cellular suicide or apoptosis. Except in the case where a toxicant induces immediate cellular destruction, toxicants invariably induce an altered pattern of gene expression in exposed cells. Moreover, it is now well understood that polymorphisms in genes comprising the toxic response pathways can have a major effect on toxicity, while also effecting the pattern of gene expression in cells with the variant genotypes. The availability of DNA sequence data and DNA microarray technologies provides toxicologists with the unique opportunity to study these complex cellular responses to environmental toxicants or stimuli on a genomic scale, simultaneously observing effects on all cellular components and the effect of genetic polymorphisms. This combination of genomics and toxicology has been deemed toxicogenomics (Nuwaysir et al., 1999) and is expected to impact all areas of environmental research. The purpose of this unit is to provide an overview of the currently available, state-of-the-art DNA microarray technologies. Specific protocols are not presented because they are evolving at a very rapid pace and some remain proprietary. Instead, potential applications to the science of toxicology are discussed with emphasis on present limitations and potential pitfalls associated with use of these technologies, and whenever applicable suggest possible mitigating experimental approaches.

DEVELOPMENT OF DNA "CHIPS": A QUANTUM LEAP IN MOLECULAR DETECTION TECHNOLOGY

Oligonucleotide Arrays

Allele-specific oligonucleotide (ASO) hybridization for detection of specific DNA sequence changes was developed in the early 1980s (Conner et al., 1983). The availability of ASO technology prompted several groups to independently propose the use of oligonucleotide hybridization on a large scale as a method for sequencing DNA. The first strategy proposed involved the arraying of individual sequences of interest (targets) onto membrane filters, which would then be sequentially hybridized with a large number of individual oli-

Contributed by Helmut Zarbl
Current Protocols in Toxicology (2001) 1.4.1-1.4.16

gonucleotide probes (Drmanac et al., 1989). Since each labeled target molecule hybridizes specifically to its complementary oligonucleotide probe, this approach allows for highly parallel extraction of sequence information from a single hybridization. If many thousands of clones were arrayed on a single membrane, ASO hybridization with even a single oligonucleotide could yield hundreds of base pairs of sequence information. However, this strategy required the synthesis of a large number of oligonucleotide probes, each of which would then be individually labeled and sequentially hybridized to each array.

The alternative approach was to array a large number of oligonucleotide probes on a solid support, and then hybridize the array with labeled DNA (target) from the cells of interest (Fodor et al., 1991; Khrapko et al., 1991; Southern et al., 1992). Several methodologies, including micro-injection of synthesized oligomers into patches of activated polyacrylamide (Khrapko et al., 1991) and the coupling of synthesized oligomers to surface-modified glass or polypropylene, were independently developed in a number of laboratories (Maskos and Southern, 1993; Matson et al., 1995). However, arraying a large number of individual oligonucleotides to a solid support represents a formidable technical challenge as the number of probes increases. The limitations imposed by arraying individual probes could only be overcome by in situ synthesis of the individual oligonucleotides at spatially addressable sites on the solid support. The latter approach requires the precise and sequential delivery of chemical reagents to individual positions on the solid support. These prerequisites were satisfied by using "masks" that allow the sequential protection and deprotection of specific areas of the surface from reaction synthetic reagents (Fodor et al., 1991; Southern et al., 1992). By using combinatorial methods of chemical synthesis and sequential masking of the reactive surface, it is possible to synthesize large numbers of oligonucleotide sequences using a limited number of nucleotide coupling reactions. Given that there are 4 possible nucleotides at any position in an oligonucleotide, the number of sequences that can be generated increases as a function of 4^n, where n is the length of the sequence. It is theoretically possible to synthesize 4^n sequences using n coupling reactions.

Among the procedures developed for in situ synthesis of oligonucleotides is the use of channels formed by sealing the surface with a chemical mask, guiding the precursor molecules to the appropriate areas on the surface (Southern et al., 1992). Channel plates can apply the reagents in strips with a resolution of 1 cm. An alternative approach being developed is the use of modified inkjet printer heads to, in effect, spray the reagents onto a designated address on the surface (Marshall and Hodgson, 1998). In this technology, the "masks" are defined by the two-dimensional displacement of the printer head. Using the inkjet technology, reagents can be applied with a much higher spatial precision, making it possible to synthesize thousands of oligonucleotides per cm^2. The inkjet technology has the further advantage of flexibility, in that the pattern of reagents applied to the surface can be easily adapted to a new application.

The most sophisticated technology for the synthesis of oligonucleotide arrays is an adaptation of the photolithography methods that are used by the semiconductor industry to produce computer chips (Fodor et al., 1991). A comprehensive description of the technology for production of these arrays can be viewed at the Affymetrix website (*http://www.Affymetrix.com/technology/index.html*). The key innovation that made this approach feasible was the development of novel nucleotide precursors with protecting groups that can be cleaved by exposure to light of a specific wavelength. These precursors make it possible to deprotect specific regions of the chip by shining high-intensity light through openings in a light-impermeable, chromium mask. As a result, only regions of the surface not protected by the mask are chemically reactive to the next nucleotide precursor washed across the entire surface of the chip. By using a series of masks, it is possible to synthesize any nucleotide sequence at a given site on the chip. With this technology, it is presently possible to produce high-density arrays comprised of tiles or addresses that are 20 to 50 μm^2 in size, each consisting of a specific oligonucleotide sequence ≥25 nucleotides in length. It is therefore possible to synthesize 65,536 separate probes using 50-μm^2 tiles, or as many as 409,605 different probes using 20-μm^2 tiles, on a single 1.28-cm^2 chip. The density of the probe on each tile is between 10^7 and 10^8 molecules.

Oligonucleotide arrays represent a momentous leap forward in the capacity to analyze DNA sequences present in biological specimens. Microarrays are useful in a variety of DNA sequence-based assays including but not limited to the detection of single nucleotide polymorphisms (SNPs), loss of heterozygosity (LOH), constitutive and somatic allelotyping, genetic linkage analysis, mRNA expression

analysis, gene mapping, and methylation mapping.

cDNA Microarrays

The simplest expression arrays consist of individual cDNA clones spotted onto nitrocellulose or nylon filters. These arrays are then hybridized sequentially or in parallel with different radioactively labeled target cDNAs, and data is collected by phosphoimager analysis (Drmanac and Drmanac, 1999). Filters with thousands of arrayed human or murine genes and the requisite analysis software are available from several commercial suppliers (see Internet Resources for Web addresses of commercial suppliers).

A limitation of these spotted arrays remains the variability in the amount of probe that is applied to each spot, which increases the variance in the data and limits the sensitivity in comparing results among experiments. A second limitation derives from the use of radioactively labeled target cDNA. Scattering of the signal resulting from radioactive decay of the radionucleides and the tendency of filters to warp during experimental manipulation limits the density at which probes can be arrayed and still retain the ability to resolve individual signals. The former limitation can be mitigated with ^{33}P-labeled hybridization probes.

A significant step forward resulted from the availability of methods for generating fluorescently labeled target DNA (Schena et al., 1995; Shalon et al., 1996). When combined with confocal imaging of the fluorescence signal emitted following hybridization with labeled target, these approaches provide a significant increase in the performance of parallel assays. Detection by fluorescence does not suffer from the spatial restraints encountered using radioactive probes. However, the inherent fluorescence of nitrocellulose and nylon filters spurred the development of novel solid supports on which to array the cDNAs. Techniques for automated transfer of cDNAs by spotting onto derivatized glass supports were pioneered by Pat Brown and his colleagues and the complete plans for the inexpensive assembly of the robotic arrayer are available at the following website: *http://cmgm.stanford.edu/pbrown/mguide/index.html.* Robotic arrayers are also commercially available from numerous suppliers in a range of prices. The lower costs of hardware and chips make cDNA microarrays more attractive and accessible to most researchers than the commercially fabricated oligonucleotide arrays. Nonetheless, it is important to remember that cDNA arrays still require the production, purification, and handling of the individual cDNAs to be spotted onto the matrix. Typically, the cDNA clones or genomic DNAs of interest are obtained and amplified using the polymerase chain reaction (PCR). The advantage of using clones from cDNA libraries is that one pair of vector primers can be used to amplify coding sequences from all of the clones, whereas multiple primer pairs are required for each exon to be amplified from genomic DNA. In either case, the amplifications are performed in a multi-well format that can be automated (Fig. 1.4.1). The amplified probes, which should ideally be between 500 and 2500 nucleotides in length, are then arrayed onto the matrix with or without further purification. Printing chips with more than a few hundred probes will therefore require a substantial investment of effort and resources to produce and amplify the individual cDNAs.

Microarrays can then be used to compare expression levels of each represented gene under two sets of experimental conditions, such as before and after exposure to toxicants. Messenger RNA is extracted from the cell types and cDNA is produced by reverse transcription in the presence of a different fluorescence-labeled dNTP precursors for each mRNA, typically Cye3-dUTP for the reference sample and Cye5-dUTP for the test sample. The labeled cDNAs are then co-hybridized to the microarray such that each target molecule will form a stable duplex with its corresponding probe on the array. The amount of each labeled target molecule hybridized to the probe spot is a function of how much of each target was present in each cell type. Each spot on the array is then scanned for fluorescence at the optimal wavelength for the Cye3 and Cye5 fluors using lasers, or high-intensity light and monochromatic filters as in the case of Array Worx Scanner shown (Applied Precision). Expression data for each gene represented on the array is expressed as a ratio of flurescence intensities normalized to the reference sample (i.e., Cye3/Cye5). Shown in the figure is an array with the entire set of yeast genes printed and hybridized in the facility at the Fred Hutchinson Cancer Research Center. If the expression of a gene is unchanged, the ratio will remain close to unity (yellow color on computer-generated false image). Any significant deviation from unity indicates either an increase (>1, image becomes more red) or a decrease (<1, image becomes more green) in the level of expression between the test and the reference sample, and the magnitude of the

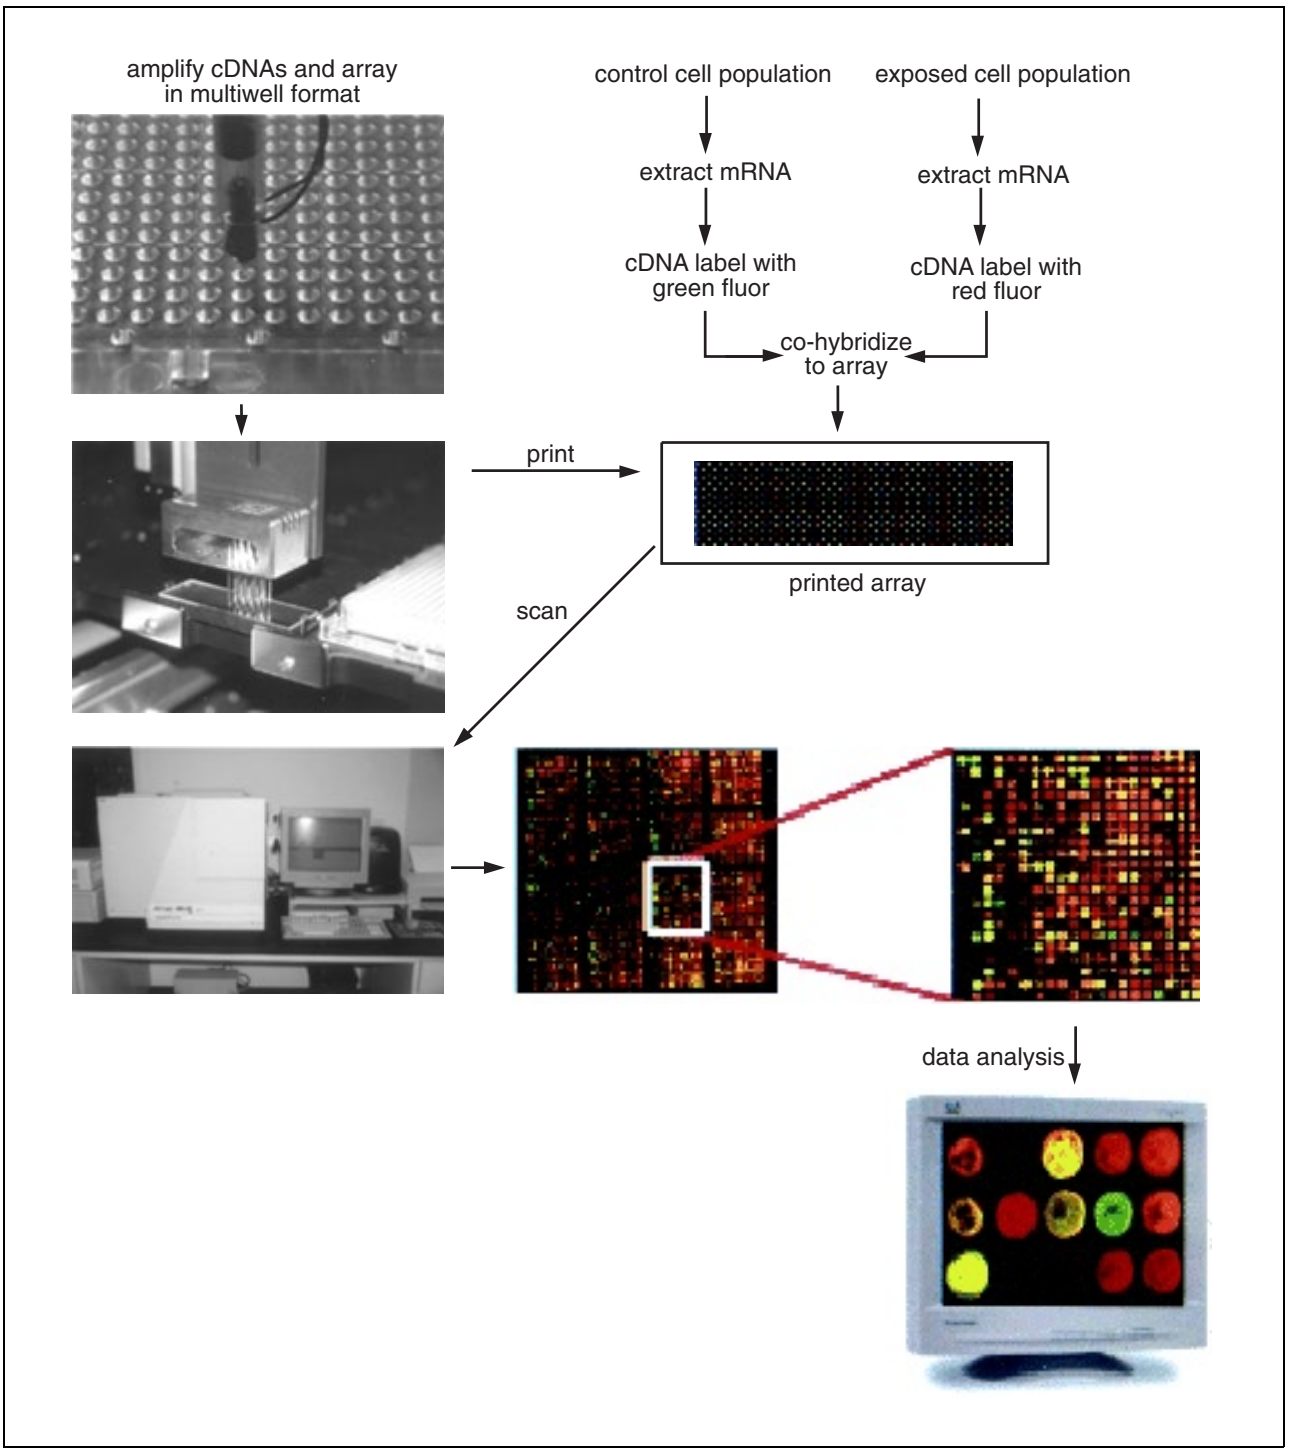

Figure 1.4.1 Expression analysis using cDNA microarrays. To produce cDNA microarrays, individual cDNA clones are amplified by PCR and arrayed in a multiwell format with or without purification. The upper left panel shows samples being arrayed with a piezoceramic fluid dispensing system (Engineering Arts). The multiwell plates with cDNA clones are then placed on a robotic printer such as the Gene Machines system shown in the second panel. The software that drives the robot is used to assign each clone to a specific address on the surface of a polylysine-coated or chemically derivatized microscope slide. Spotting of individual clones is accomplished using a series of pins or quills that are dipped into each well to take up a sufficient volume of the cDNA solution to spot or print each clone onto all of the slides. Printing is accomplished by rapid displacement of the robot head and the microscope stage using precision micromanipulation technologies. After each round of printing, the pins are washed and the process repeated until all clones have been printed on each slide to produce a microarray. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures*

change is indicative of the fold difference in the expression levels. Fluorescence intensity data are collected in the form of a spread sheet, which is merged with a database that contains the identity of the gene at each position on the array. The complete set of specific alterations defines the expression signature for the given experimental condition relative to the reference condition (e.g., a toxicant signature for a given exposure condition). Expression signatures can be compared using a variety of statistical and visual tools. Data from multiple experiments can also be compared using appropriate "data mining" software.

Most available methods utilize finely machined pins or quills to mechanically spot the probes onto polylysine-coated or chemically derivatized microscope slides. The pins, which function much like a fountain pen, are dipped into individual wells of multi-well plates, and a sufficient volume of probe is retained to spot multiple slides at the same relative position. The pins are then washed and dried, and the next cDNA probe is printed onto all of the slides. Most high-speed robots using a multiple-pin format can print 100 or so slides with thousands of probes each in a single day. The density of spots is defined by the size and quality of the pins, by the arrangements of the pins within the robotic head, and by the software used to drive the robotics. Currently, it is possible to print >18,000 cDNA clones onto a single microscope slide.

ANALYSIS OF GENE EXPRESSION PATTERNS USING NUCLEIC ACID ARRAYS

The fundamental determinant of cell growth, differentiation, and phenotype is the pattern of gene expression. The amounts of each gene expressed in a cell at any given time are a function of the genetic and epigenetic constitution of the cell, and how the cells integrate responses to environmental stimuli. The pattern of gene expression, thus, provides a signature of the cell's physiological state. By hybridizing arrays (the probe) with labeled cDNA or in vitro transcribed cRNA from cells (the target) one can simultaneously compare the levels of thousands of mRNAs between cells under different exposure conditions. The ability to detect and understand the meaning of these altered patterns of gene expression may lead to a better understanding of the biochemical mechanisms and hence, predictions of cellular responses associated with exposure to toxicants.

Analysis of gene expression patterns can be performed using either printed cDNA arrays (Fig. 1.4.1) or oligonucleotide arrays (Fig. 1.4.2). Typically, hybridizations to a single cDNA microarray require 5 µg of labeled cDNA. Production of such quantities of labeled cDNA using methods that do not involve amplification typically requires 50 to 200 µg of total RNA or 2 to 5 µg of poly(A)$^+$ RNA. To prepare cDNA or cRNA targets for hydridization and fluorescently labeled nucleotides that can be directly incorporated into the cDNA by reverse transcriptase. Typically, Cy3-dUTP and Cy5-dUTP are used to label target RNA from each of the two cell types being compared for expression profiles (De Risi et al., 1997). A more efficient labeling protocol involves the incorporation of amino-allyl derivatives of dNTPs, followed by chemical coupling of amino-allyl groups by reaction with NHS-esters of Cy3 or Cy5 (*http://cmgm.stanford.edu/pbrown/protocols/aadUTPCoupling Procedure.htm*). In either labeling protocol, the amount of label associated with each target mRNA is a function of the amount of each in the cell from which the mRNA was extracted. The differentially labeled targets are then co-hybridized to the array under conditions that allow each target mRNA to hybridize with its corresponding probe. Hence, the ratio Cy3 to Cy5 of fluorescence associated with each probe is a measure of the fold change in the level of expression of each gene represented on the probe array (Fig. 1.4.1).

However, for most experiments involving clinical specimens, the amounts of tissue available for mRNA extraction will be limiting. Thus, a number of techniques have been developed to amplify the starting poly(A)$^+$ RNA or the cDNA (Lockhart et al., 1996; Phillips and Eberwine, 1996; Trenkle et al., 1998). Many of these increase detection by orders of magnitude and are now widely used in experiments involving human samples (Lockhart and Winzler, 2000; Wang et al., 2000). In the author's experience, most of these allow one to generate enough labeled target from 5 µg of total mRNA. Wang et al. (2000) recently reported a method of amplification that combined antisense RNA amplification with the strand-switching effect (Clontech). The latter protocol may be applicable when using significantly smaller quantities of target mRNA.

In contrast to oligonucleotide arrays that are hybridized to a single target, cDNA microarrays require the co-hybridization of each target cDNA or cRNA to a reference sample. The latter

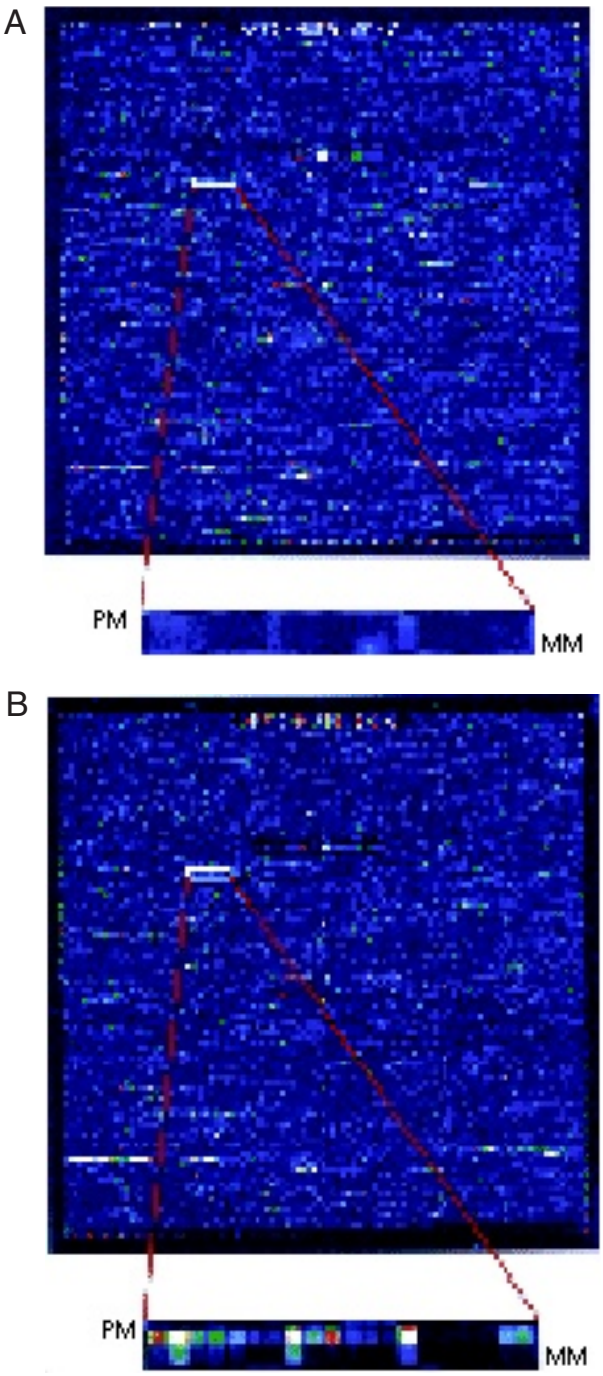

Figure 1.4.2 Expression analysis using oligonucleotide arrays. The figure shows expression patterns for (**A**) normal human squamous epithelial cells and (**B**) chronically exposed cells (M.T. Barrett, K.Y. Yueng, P.L. Blount, R.C. Sullivan, H. Zarbl, J. Delrow, and B.J. Reid, unpub. observ.) using oligonucleotide GeneChip Expression arrays produced by light-directed chemical synthesis (Affymetrix). Each array comprises tens of thousands of probes that interrogate the expression levels of ~1700 genes. Messenger RNA extracted from each cell type is reverse transcribed into cDNA and is subjected to linear amplification by in vitro transcription in the presence of biotinylated oligonucleotides. The amplified cRNA targets from each cell are hybridized to a separate microarray. The amount of each target sequence hybridized to a probe is quantified by binding of strepavidin phycoerythrin, excitation with laser light, and collection of fluorescence intensity data using a Hewlett-Packard scanner. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures*

can consist of target generated from a cell line or tissue to which all experimental samples are then compared. For example, one could compare bronchioepithelium from smokers to normal lung epithelium or a bronchioepithelial cell line. There are several disadvantages to using such reference samples. A tissue sample is not a renewable resource and the variability in gene expression profiles among tissue samples from different donors is subject to variability due to differences in genotype and environmental exposures. These limitations can be partially mitigated by preparing large cultures of a cell line under reproducible growth conditions. However, any given cell line will only express a limited number of genes. For example, genes induced during malignant progression of initiated cells may not be expressed at detectable levels in the normal cells. Thus, in half of the replicate experiments the denominator in Cy3:Cy5 fluorescence ratio will be zero (background), and vice versa, thereby complicating statistical analyses of the data. A more type-useful reference mRNA, initially proposed by Perou et al. (2000) and now available commercially (Stratagene), is comprised of mRNAs pooled from ≥10 cell lines representing different tissue types. Such a reference set is a renewable resource that expresses the majority of the genes detectable on the probe array at levels that are statistically significantly above background. In addition to the benefits alluded to above, use of a common reference allows the standardization of the data and permits all samples to be compared to one another relative to the reference set.

A significant limitation of chips produced by mechanical spotting is the variability in the volume of probe solution and hence the amount of probe deposited in each spot. The volume deposited is affected by surface characteristics, speed of the robot, time and pressure of the pin on the slide surface, viscosity, and other factors. Even when comparable volumes are deposited, evaporation from the pins or the sample wells during the printing process can change the concentration of the probes on the pin or in the wells. Although evaporation of the probe solution can be minimized by increased humidity in the printing area, the amount of probe deposited can still vary several-fold among spots. Thus, a variety of alternative technologies such as inkjet printers and piezoelectric dispensers, are being evaluated in a number of laboratories including the author's own.

Variability on printed arrays can, to a large extent, be overcome by simultaneously hybridizing a given array with the target cDNA from the two cell types or states being compared, each of which is labeled with a different fluorescent molecule. The relative amount of a specific mRNA expressed in the two cells can then be determined by measuring the amount of fluorescence from each fluor. For molecules with similar emission spectra but different absorption spectra, one can use different wavelengths of incident light. For molecules with different emission spectra but similar absorption spectra, one can use a single source of incident light and monochromatic filters to measure fluorescence at individual wavelengths. A variety of array scanners with different capabilities are commercially available and usually include software for spot detection and identification, data capture, and quantitative analysis. Once fluorescence intensity data are collected, they can be expressed as a ratio, such that the relative signals from each spot are internally controlled for variance in probe density on the array. By expressing the data as ratios, it is possible to compare relative changes in expression among arrays despite a high level of inter-array variability. To further reduce variance within the data, the same probe can be replicated on a single array or the same hybridization repeated, usually with reversal of the dyes used to label the target cDNA. Nonetheless, variance remains the significant consideration when comparing the expression of low-abundance genes, which generate weak fluorescence signals, such that even the ratios of intensities are subject to large fluctuations.

Another limitation of cDNA arrays is that it may not be possible to discern signals that are generated by the cross hybridization of a labeled target sequence derived from one member of a gene family with the probe for another family member. The latter limitation could in theory be addressed using shorter oligonucleotide probes for each transcript and by selecting probes from regions of the cDNA where gene family members show little sequence identity. Despite these limitations, the relatively lower cost and the flexibility to alter the probes on the chips makes cDNA arrays the preferred method in most research settings.

The use of arrays produced by chemical synthesis of oligonucleotide probes directly on a solid support to monitor gene expression patterns at the transcriptional level (Lockhart et al., 1996) has several advantages over printed arrays. First and foremost is that the amount of each probe synthesized on the chip surface using photolithographic techniques is highly repro-

ducible (Fodor et al., 1991, 1993). This reproducibility allows for direct comparison of expression data obtained among chips. In practice, this means the target nucleic acid from each cell studied is hybridized to a separate chip, an important consideration when multiple comparisons are to be made using samples with limited cell numbers.

Another advantage is that the higher probe density makes it possible to include multiple probes representing different regions of each transcript. The GeneChip Expression analysis system produced by Affymetrix is comprised of a set of four chips that collectively can compare the levels of up to ~40,000 separate human transcripts. The design of the arrays is such that the level of each transcript is interrogated by at least ten separate perfectly matched probes (PM). In addition, a probe with a mismatched base (MM) relative to each PM probe is included on the chip. By comparing the amount of hybridization between the PM and the MM probes, it is possible to differentiate signal from noise and to distinguish among signals from hybridization with transcripts from gene family members (Fig. 1.4.2). Real signals will show preferentail hybridization to the PM probes with little hybridization to the MM probes, while noise will be comparable among both probe sets. GeneChip Software applies statistical parameters to compare the fold change in expression of all genes for a given test sample relative to the baseline sample (e.g., untreated controls). On the two panels the PM and MM hybridization signals for the probes representing a single gene are highlighted and magnified as an example of the data that are obtained using this type of microarray (computer generated images). These arrays can reproducibly detect changes in mRNA levels that are as low as two- to three-fold. Moreover, the fluorescent signal generated by hybridization with the fluorescent target yields linear data over four orders of magnitude. These parameters endow the high-density microarrays with an unprecedented level of sensitivity and specificity. Studies indicate that the arrays can detect transcripts that are present at a frequency of 1:300,000 in the mRNA of the target cells.

To monitor gene expression using the GeneChip Expression arrays, mRNA extracted from cells is reverse transcribed using a primer comprised of a T7 polymerase start site at its 5′-end and an oligo dT sequence at its 3′-end. Following second-strand synthesis, the purified double-stranded cDNA is used as a template for in vitro transcription using T7 polymerase. Biotinylated ribonucleotides are incorporated into the cRNA during the in vitro transcription reaction. After purification and fragmentation to an optimal size, the labeled target cRNA is hybridized to the appropriate DNA chips. In order to yield high-quality data, the hybridization requires ~10 μg of labeled, in vitro transcribed cRNA. Typically, this amount of labeled target cRNA can be generated when starting with as little as 0.1 μg of poly(A)$^+$ mRNA, or $\geq 5 \times 10^5$ cells. Following hybridization, the target molecules are stained with strepavidin-phycoerythrin or fluorescently labeled antibodies using proprietary protocols. Fluorescence associated with each tile is then analyzed using a Hewlett-Packard Gene Array Scanner. Since the amount of each target cRNA molecule synthesized depends on the original number of mRNA molecules present in the poly(A)$^+$ mRNA preparation, the signal emitted by each tile should reflect the relative amounts of each target mRNA. Fluorescence intensity data are collected automatically by the GeneChip software and an image of the probe array is displayed in real time (Fig. 1.4.2). Following the image acquisition, the software algorithms compute the average fluorescence intensity for each PM and MM probe. Statistical analyses are then used to estimate fold changes in the expression of each gene in a test sample relative to the levels in a baseline array, such as untreated control cells in a toxicology experiment.

APPLICATION OF DNA CHIP TECHNOLOGY TO DETECT DNA SEQUENCE POLYMORPHISMS (SNPs)

Another important advantage of oligonucleotide arrays is the possibility of performing DNA sequencing by allele-specific hybridization. While the primary result of a toxic exposure is an altered pattern of gene expression, the ultimate biological effect of the toxicant is also dependent on the genotype of the exposed cell. Thus, genetic polymorphisms within key toxic response genes may abrogate the potential benefit of altered gene expression in the exposed cell.

A method for sequencing based on hybridization with an arrayed set of all possible oligonucleotides of a fixed size was proposed first in 1991 (Khrapko et al., 1991). The capacity for highly parallel, in situ synthesis of high-density oligonucleotide arrays has made this approach practical. Using the combinatorial approach and series of appropriate chromium masks, it is possible to synthesize all possible octomers (4^8 = 65,536) using as few as 32 rounds of synthesis

on a single chip with 50-μm^2 tiles, a level of resolution which has already been reduced to practice. Similarly, the set of all of the ~10^{12} possible 20-mers, or a subset thereof could be synthesized in just 80 nucleotide coupling reactions. Although such an approach is feasible, it is not practical for sequencing since analysis of the data would be complex and multiple rounds of hybridization would be required to obtain complete sequence information.

Oligonucleotide arrays can, however, be used for high throughput resequencing of genes in multiple individuals. The simplest format of the high-density DNA arrays for use in DNA resequencing is the so-called 4*L* tiled array (Chee et al., 1996). In this format, the complete set of overlapping oligonucleotides of a given length (usually 25-mers) that comprise the complete sequence of interest are synthesized on a chip. Also included are the sets of overlapping probes representing all possible single base pair substitutions at each position in the sequence interrogated by the array. Thus, all possible sequences can be interrogated by 4*L* oligonucleotides, where *L* is the number of bases in the target sequence. When the labeled target DNA is hybridized to the array, labeled DNA fragments will hybridize most efficiently with the oligonucleotides to which the sequence is perfectly complementary. By the same token, the target will show reduced hybridization with probes that contain a single base mismatch. By comparing the strength of the hybridization among the set of four probes that define each position, it is possible to directly read the sequence of the target DNA from the fluorescence image. Since each probe will have its own T_m, the maximal fluorescence intensity observed when the target hybridizes with its complementary probe can vary over four orders of magnitude. However, since comparisons are only made among the four probes that interrogate the given oligomer, these differences have no effect on the analysis of the data. The 4*L* array is the basis of the sequencing GeneChips, including those designed to sequence portions of the BRCA1 tumor suppressor gene, the p53 tumor suppressor gene, and the HIV viral genome (Hacia, 1999).

Using a variation on the sequencing chip design, it is possible to simultaneously detect the presence of multiple alleles that differ by a single nucleotide (SNPs; Chee et al., 1996; Wang et al., 1998). For all polymorphic sites, a series of 5 columns of probes is used to interrogate the sequence of the polymorphic base and 2 bases on either side (Fig. 1.4.3). The columns are comprised of a set of four different oligonucleotide probes (4*L*) that collectively detect all 4 possible nucleotides at each position within the 5 bp. In such an analysis, the presence of an allelic variant in the target DNA will result in a characteristic pattern of hybridization. The mutant target will show reduced hybridization with the wild-type probe and strong hybridization with the probe that carries the corresponding base substitution. The variant target DNA will also form one or more mismatches when it hybridizes to the probes that interrogate flanking sequences (Chee et al., 1996). This characteristic footprint of reduced hybridization with sequences flanking the variant specific probe provides further evidence for the presence of a variant sequence in the target DNA. Furthermore, when more than one allele is present in the target DNA, two or more tiles within a given set of four probes will show intense hybridization relative to that seen with a reference wild-type probe. This approach can be used not only to detect allelic variants of a given sequence among individuals, but it can be used also to design arrays for use in genetic linkage studies and to detect allelic losses that occur during tumor progression.

For SNP detection, genomic DNA is extracted and a region of several hundred base pairs flanking each polymorphic site is amplified by multiplexed PCR. After verifying that each region of interest was amplified, the PCR products are fragmented to a size optimal for hybridization and 3′-end labeled using fluoresceinated deoxyribonucleosides and a terminal transferase enzyme. Following hybridization and scanning, the data are analyzed by appropriate software and genotypes are assigned to each sample. The ability to detect SNPs is presently the sole dominion of oligonucleotide arrays, although the author's laboratory is developing a method that will allow simultaneous genotyping and expression analysis on printed cDNA arrays.

Potential Uses for Microarrays in Toxicology

Toxicant signatures

A central tenet of toxicology is that, with the possible exception of acute cell necrosis, every toxic exposure leads to an alteration in the pattern of gene expression. This altered pattern of gene expression reflects the cell's attempt to cope with the toxic insult and can range from induction of xenobiotic metabolism to the extreme of cell suicide or apoptosis. While numer-

ous studies have looked at changes in the expression of a limited number of genes thought to play a role in these adaptive responses, the power of array technology is the ability to obtain a comprehensive survey of thousands of genes simultaneously. This global analysis of gene expression affords researchers the ability to discern specific patterns or signatures of expression that are associated with particular classes of toxicants. These signatures are likely to include classes of genes not previously implicated in response to specific toxic insults (Jelinsky and Samson, 1999). As such the applications of array technologies to toxicology will undoubtedly enhance understanding of the cellular response to toxicants, which should by

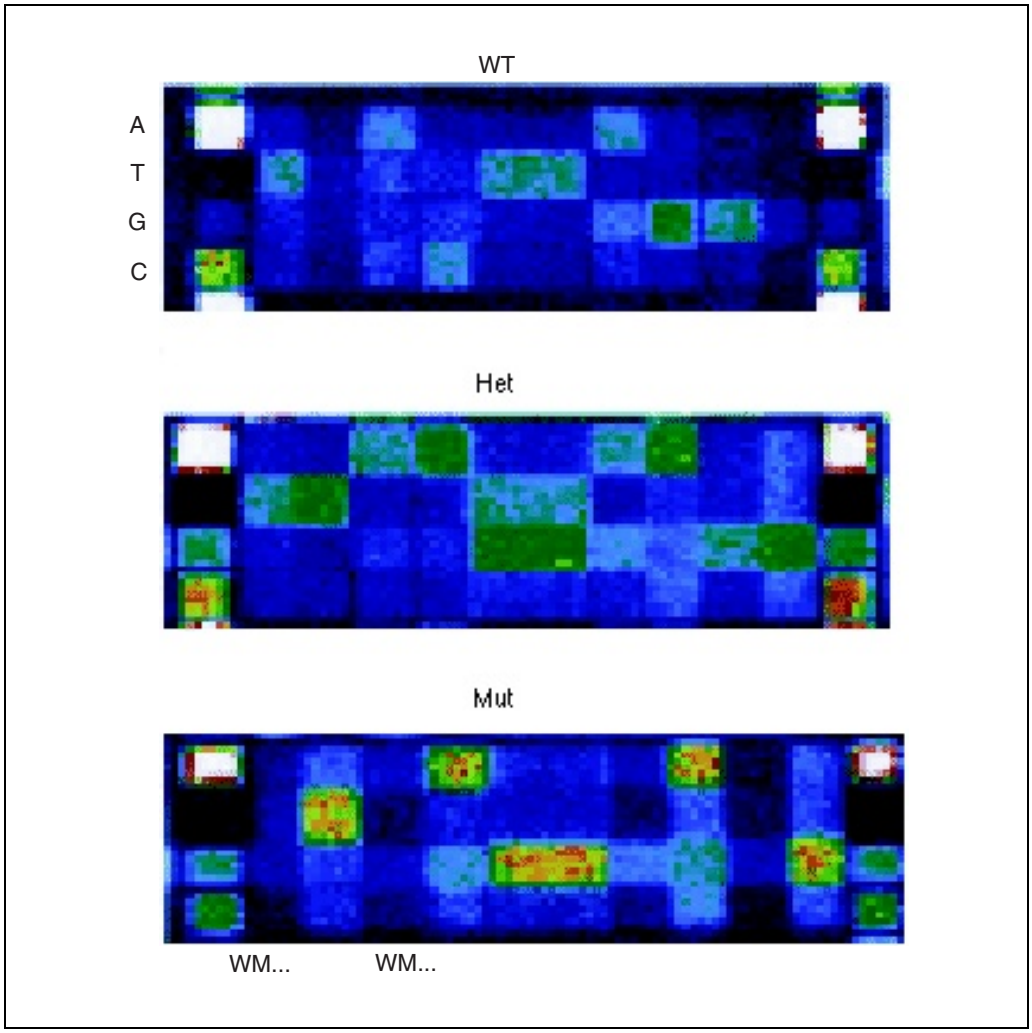

Figure 1.4.3 Detection of single nucleotide polymorphisms (SNPs) using oligonucleotide arrays. This is an example of the data obtained for individuals that are wild-type homozygous (WT), heterozygous (Het), or mutant homozygous (Mut) for a specific allele of the P450 cyp 2D16 gene. Experiments were performed using the GeneChip P450 oligonucleotide arrays produced by light-directed chemical synthesis (Affymetrix). For each polymorphic site, there is a series of five columns of probes that interrogate the polymorphic base and 2 bases on either side. Columns from left to right interrogate sequences at position –2 to +2 relative to the site interrogated and alternate from left to right between wild-type (W) and mutant (M) probes. The columns are each comprised of four probes (4*L*) that collectively detect all 4 possible nucleotides at each position within the 5-bp sequence. The presence of wild-type and mutant alleles is determined by the pattern of hybridization with probes that detect wild-type and/or mutant targets. For SNP detection, genomic DNA is extracted and a region of several hundred base pairs flanking each polymorphic site is amplified by multiplexed PCR. After verification that each region of interest was amplified, the PCR products are fragmented to a size optimal for hybridization and 3′-end labeled using fluoresceinated deoxyribonucleosides and terminal transferase enzyme. Following hybridization and scanning, the data are analyzed by appropriate software and genotypes are assigned to each sample. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures*

inference also provide insight into the mechanism of toxicity. For example, agents that induce genes involved in DNA repair almost certainly must be directly or indirectly genotoxic to the cell.

There is significant evidence to suggest that specific toxic exposures will produce discernible expression signatures. Studies in yeast and mammalian cells have demonstrated that a reproducible subset of genes will show altered expression in response to specific conditions such as anoxia, nutrient deprivation, exposure to alkylating agents, and chemotherapeutic agents (DeRisi et al., 1997; Iyer et al., 1999; Jelinsky and Samson, 1999). It is therefore reasonable to hypothesize that toxicant signatures will exist for individual classes of toxicants such as polycyclic aromatic hydrocarbons (PAH), alkylating agents, ionizing radiation, and neurotoxicants. Moreover the individual signatures will almost certainly reflect underlying mechanisms of toxicity such as oxidative stress, DNA damage, inhibition of oxidative phosphorylation, and disruption of cell membrane potentials (Marton et al., 1998; Norman et al., 1999). Since many toxicants will have multiple mechanisms of action, the signature will also reflect this complexity of mechanisms. As an example, the signature of PAHs will almost certainly include genes involved in their xenobiotic metabolism and genes that are involved in the response to oxidative stress. Also, the ability of gene expression signatures to provide insight into the underlying mechanisms would make it possible to predict the mechanism of toxicity of unknown compounds. For example, if the expression signature of an unknown compound includes a set of genes that are common to other inducers of peroxisome proliferation, then the unknown can be tentatively assigned to this class of toxicants.

Another exciting application of array technology is the possibility of defining thresholds of exposure below which there is no biological effect. In toxicology, a wide variety of biological tests are used to assess the toxicity of given compounds or exposures. In vivo animal models such as the rodent bioassays and carcinogenicity tests remain the standard in the field. These animal model systems are increasingly replaced or supplemented with an ever-increasing number of in vitro assays, such as the Ames test (*UNIT 3.1*), human cell mutation assays (*UNIT 3.3*), cell transformation assays (*UNIT 3.4*), assays for sister chromosome exchange, unscheduled DNA synthesis (*UNIT 3.7*), and micronuclei (*UNIT 3.5*). While each of these tests has its strengths and limitations, they all measure complex biological endpoints that are many steps removed from the initial exposure. Arguably, altered gene expression is the earliest measurable biological endpoint in response to a given exposure. Moreover, the signatures for doses of toxicant that do not have any biological effect are likely to be distinct from the signatures of doses that induce cellular stress and adaptation. Signatures at even higher doses will reflect more acute cellular responses such as apoptosis. Application of array technology to toxicology testing could, thus, make it possible to define biologically meaningful toxicity thresholds. The classical NOEL (no observable effect levels) is established by tests whose endpoints (e.g., mutation, transformation, unscheduled DNA synthesis) rely on the integration of complex responses at the level of the cell and in some cases at the level of the organism (teratology). By contrast, toxicant signatures measure the earliest cellular responses and provide information on the nature of the cellular response. In addition, toxicant signatures should reveal if the effects of multiple nontoxic doses are cumulative at the level of gene expression, the earliest cellular response. The ability to obtain and compare toxicant signatures of many different compounds, at different doses, and as complex mixtures is expected to herald a new chapter in toxicology research.

Factors affecting toxicant signatures

Although the application of microarray technology will have an enormous impact on the understanding of mechanisms underlying toxicity, it is important to realize that the toxicant signatures obtained will be highly sensitive to the assays' conditions and methodologies. The data obtained will be affected by numerous factors ranging from the composition of the array to the source of the target nucleic acid.

Microarrays used to define toxicant signatures can include probes from all available genes or can be designed using the subset of genes already shown or suspected to be involved in the toxic response (some housekeeping genes are included as controls). The latter type of array is exemplified by the Tox-Chips being designed by researchers at the N.I.E.H.S. (Nuwaysir et al., 1999). These arrays will detected 325 transcripts that were elevated and 76 that were decreased after exposure. Eighteen of the novel inducible additional genes were elevated to higher levels than the previously studied genes. Significantly, the data also allowed these researchers to conclude that alkylating agents activated a

previously unsuspected program of gene expression to eliminate and replace adducted proteins. Neither the novel genes nor the protein replacement pathways would have been detected if the chip contained a subset of all yeast genes, and this underscores the need to develop comprehensive signatures for toxicants. Of course comprehensive screens are not yet possible for human cells. At present, the GeneChip Expression array from Affymetrix can simultaneously examine ~40,000 transcripts *(http://www.affymetrix.com)*, and printed arrays are quickly approaching that number. It is likely that the entire gene set for humans will be arrayed within the next several years. While the cost of comprehensive screens remains a major hindrance, it would seem prudent to make screens as comprehensive as possible to derive toxicant signatures. Lower cost arrays with subsets of genes could then be designed and used for routine screening of compounds for functionally relevant signatures.

Other important considerations when using microarrays to study responses to toxicants are the experimental parameters. The expression pattern detected by a single array represents a snapshot of the cellular response in time and physiological state. As already discussed above, the response of a cell to a given exposure will be a function of the toxicant dose. However, the response at the mRNA level will also vary as a function of time after exposure. Experience in yeast experiments clearly demonstrates that the induction or repression of genes follow predictable temporal patterns, which may fall into clusters for sets of genes that define affected biochemical pathways (DeRisi et al., 1997). Moreover, the kinetics of the response could depend on dose. It is, therefore, important to examine toxicant signatures under a variety of experimental settings. Even when all experiments are carefully controlled, there will always be minor variations in conditions due to operator handling, small differences in cell density, temperature, and anoxia, each of which will contribute to the observed expression pattern in a given experiment. The impact of the interexperiment variation can be minimized either by performing replicate assays, or by pooling mRNA samples from multiple experiments prior to analysis on arrays. In the former, outliers could be eliminated statistically; while in the latter, the spuriously elevated or decreased mRNAs would be averaged with levels in other experiments. Finally the choice of cell type will affect the observed signatures. It is likely that the response at the level of gene expression will vary among cell types, since many toxicants are known to be highly tissue specific.

Application to animal models used in toxicology testing

Despite an increased emphasis on developing alternatives, animal testing persists as the mainstay of toxicology testing. Even though new in vitro methods and models systems continue to be developed and evaluated, there are, as of yet, few viable alternatives for complex biological response testing such as neurotoxicity, immunotoxicity, reproductive and developmental toxicity, carcinogenesis, and teratology. However, animal testing remains both controversial and problematic. In addition to the requirement for a large number of animals and the associated costs, these assays often require years to complete. More significantly, the results obtained cannot always be easily extrapolated to humans due to interspecies variations and the fact that the doses used are often not relevant to human exposures. The addition of microarray technologies to the arsenal of toxicology tests could significantly impact the need for animal testing. Toxicant signatures could be used to assign compounds with unknown biological activities to specific functional groups before animal testing, thereby eliminating the need for expensive global testing and simplifying cross-species extrapolations. For example, a compound that has the expression signature of a neurotoxicant without elements of genotoxicity may not require assessment via the expensive and dubious rodent cancer bioassay.

The sensitivity of gene expression patterns to low levels of toxic exposures could also make it possible to assess toxicity at dose rates more relevant to human experience. Moreover, the assay endpoint, gene expression patterns, will be altered within hours of exposure. Results can therefore be obtained and analyzed in days instead of years, while using fewer animals. In addition, expression signatures based on an underlying mechanism may simplify the results obtained with complex mixtures or environmental samples.

Although the potential advantages of combining microarray technology with animal testing are readily appreciated, there are also potential pitfalls and sources of error. If toxicant signatures are to be used to exempt unknown compounds from animal bioassays, then care must be taken to establish that the model system will permit extrapolation to human exposures. Gene expression signatures, which should be also obtained for a variety of species, organs,

and cell type can present numerous challenges. While expression signatures can be readily obtained in vitro using cell lines, the same may not be true for organs or tissues comprised of multiple cell types. A toxicant signature derived for a whole organ may belie the effect on a specific cell type or cells at specific states of differentiation within the organ (i.e., stem cells). For example, looking at the toxicant signature of a compound on the whole brain may fail to detect the effect a specific center in the brain comprised of few cells, since the resulting toxicant gene expression signature would be diluted by the vast excess of unaffected cells. Likewise, toxic effects on limited numbers of stem cells in an organ might not be detected in signatures of whole organs, even though they could have dire consequences. It may be essential to examine signatures for specific cell types in tissues and organ. Such an approach will require significant effort to develop protocols for cell enrichment, such as cell sorting and immunoaffinity separations. Even if enrichment can be achieved, it must be demonstrated that the processes of organ/tissue disruption and cell purification do not, in and of themselves, alter the pattern of gene expression in ways that will mask the intended observation.

Finally, if the cells are present in limited numbers, the amount of mRNA available may be insufficient to perform an assay on the microarrays. In this case, the cells from numerous animals may need to be pooled for each assay. Alternatively, the mRNA from individual animals would have to be amplified prior to labeling of the target. In this case care must be taken to ensure that the method of amplification does not distort the pattern of expression by preferential amplification of some targets. Exponential amplification, such as occurs during PCR, is thus inappropriate. Alternatives, such as the production of cDNA libraries from single cells, are being evaluated for this purpose.

In summary, the use of array technology in toxicology testing has enormous potential for reducing costs and efforts associated with animal testing. Since the assay endpoint is based on underlying mechanisms, the toxicant signatures obtained may simplify cross-species extrapolations, allow for assessment of doses more relevant to human exposures, and more readily permit evaluation of complex mixtures. Nonetheless, the potential for missing effects on specific cell types or differentiation states within tissues and organs warrants caution and careful design of test parameters.

Applications to exposure monitoring

The exquisite sensitivity of expression signatures could also find numerous applications in monitoring environmental exposures. Since gene expression is affected seconds to hours after exposures, toxicant signatures are most appropriate as biomarkers of recent or chronic exposures. Microarrays are thus expected to provide highly sensitive and specific toxicity data in occupational settings or in patients given specific therapeutic compounds or treatments, where a cell sample can be obtained from the same individual before and after exposure. Since gene expression patterns provide mechanistic underpinning of the response, the data obtained should provide an effective dosimeter of biological consequences to an exposed individual in the face of genetic variations in sensitivity. However, care must be taken that the cells available for these assays (e.g., blood, buccal scrapes) are appropriate surrogates for cells that are the targets of toxicity. Moreover, expression profiles will be affected by a wide range of exposures, including diet, lifestyle, other medication, nonoccupational sources, etc.; it will therefore be important to minimize the effects of these confounding factors. As discussed above, the effects of spurious alterations in gene expression can be minimized by sample pooling, but pooling may not be appropriate for defining individual exposure. The alternative is to compare multiple samples from many exposed individuals to define the toxicant-specific signature. This "mining" of data will require the establishment of large databases and the appropriate bioinformatics tools to extract commonality of patterns across individual arrays (Bassett et al., 1999).

Gene expression may also prove to be an effective tool in environment exposures. As an early response biomarker, toxicant signatures could be used to monitor biological effect of environmental accidents on invertebrate and vertebrate indicator species. By comparing patterns in the same species from areas with known or suspected exposures to those without exposure, it may also be possible to monitor the effects of long-term exposures to low doses of compounds. Expression signatures may also prove effective in detecting the effects of compounds such as endocrine disruptors, whose biological effects are difficult to monitor using traditional biomarkers.

Applications to toxicogenetics

A major issue in toxicology testing is the difficulty in understanding and predicting indi-

vidual variation in toxicant sensitivity. Toxicogenetics seeks to establish the genetic basis for these variations. A great deal of research has already identified numerous genetic polymorphisms in genes comprising biochemical pathways important for resistance to toxicants (e.g., xenobiotic metabolism and DNA repair). In some cases, a specific polymorphism has been linked to a specific phenotype of chemical susceptibility. However, sensitivity to more complex effects of toxic exposure, such as cancer and birth defects, may depend on the integrated effects of numerous polymorphisms. As a result, most attempts to find an association between genetic polymorphisms in xenobiotic metabolizing genes and cancer risk have found only minimal and often conflicting effects, and even meta-analyses of the data can yield inconclusive results (Taioli, 1999). Clearly, the ability to perform highly parallel genotyping at multiple alleles will be required to define the effects of genes showing high population prevalence but low phenotypic penetrance. DNA sequencing by allele-specific hybridization on oligonucleotide arrays has the capacity to make highly parallel analysis of single nucleotide polymorphisms (SNPs) a reality (Wang et al., 1998). From a small number of cells from an individual, it is possible to obtain genotypes at thousands of alleles.

Widespread application of this technology is still limited by the number of SNP sequenced and by the high cost of designing and producing oligonucleotide arrays. The concerted effort for SNP detection by both academic and commercial enterprises should deal with the former, while the development of alternative technologies such as the inkjet oligonucleotide synthesizers should address the latter limitation. Another limitation affecting high-throughput genotyping on arrays is the need to amplify and label each individual allele or target prior to analysis on an array. Multiplexing of PCR reactions can minimize the number of amplification reactions, but it still requires considerable effort in development and intensive quality control during implementation. Low cost, high-throughput genotyping on arrays will not really be feasible until technologies are developed to eliminate the need for target amplification prior to hybridization to the probes on the array. A final limitation of SNP detection is the fact that SNP detection is based on allele-specific hybridization. The problem arises from the fact that all of the hybridizations on a probe array are occurring at the same condition of salt, temperature, etc. Therefore, it is important to select probe sequences such that all allele-specific hybridizations will have the appropriate specificity for allelic discrimination under the given experimental condition. As the number of probes on the array increases, the possibility of finding conditions at which all probes show sufficient allele discrimination becomes more difficult. For these reasons, the author's laboratory is developing methods of SNP analysis on cDNA arrays that are independent of hybridization conditions. The latter approach also holds the promise of obtaining expression signatures and genotypes from the same array experiment.

While toxicant signatures should, in theory, include the effects of genetic variability and predict individual susceptibility, SNPs have the advantage that they can be detected without exposure and in a very small number of readily available cells. In addition, SNPs can be used for linkage analysis, disease association studies, and loss of heterozygosity studies to define other disease genes. The application of microarray technology promises to dramatically enhance understanding of variability in response to toxicants.

COMPUTATIONAL BIOLOGY

The previous section outlined available microarray technologies, their application to toxicogenomics and toxicogenetics, as well as their limitations. Implicit in the above discussion was the assumption that adequate computational and bioinformatics tools would be available for analysis of the unprecedented size and complexity of the data these studies would generate. The development of these tools remains a formidable challenge and may prove to be the rate-limiting step in the implementation of these exciting new methodologies to toxicology. A number of programs for statistical evaluation of data have already been developed in both academic (Ermolaeva et al., 1998; Bassett et al., 1999) and commercial settings. The computer software required falls into several categories. The first type deals with capture and statistical analysis of the data and may include the ability to compare expression levels between two cell types or conditions. This type of analysis software is usually provided with array scanners or can be obtained from academic investigators. Continued development in this statistical analysis software remains an area of active research. The second area for software development is for analysis of data across experimental conditions. For example, an investigator may want to find sets of genes that show common temporal pro-

files of altered expression after an exposure. Similarly, genes could be clustered on the basis of function categories, dose response, and biochemical pathways. This type of analysis typically makes use of clustering algorithms. A discussion of these methods is beyond the scope of this unit, and the reader is referred to the Key References for additional information.

The third and vastly more complex area for software development is for analysis of data across all experiments. For example, an investigator may wish to find patterns of gene expression common to all individuals that are sensitive to a complex mixture of toxicants. Such a pattern might be used to predict the risk of individuals to that exposure. This type of analysis exemplifies the complexity and issues associated with the use of array technology in any setting, including toxicology. In addition to having adequate computing power and appropriate software for the required comparisons, one also needs to have publicly accessible databases containing the information gathered by many laboratories. The databases must also be annotated with experimental parameters to facilitate comparisons. The software used must allow for exchange of information among different laboratories and different computer platforms. Moreover, the software must be compatible with data generated by different microarray platforms. It might also be important to combine expression data with genotype data.

The successful application of array technology to toxicogenetics and toxicogenomics will require continued technology development, the establishment of public databases with accepted standards for data annotation, and the development of powerful new statistical and bioinformatics tools. Clearly, many promises and challenges lie ahead.

The Use of Fish-Derived Cell Lines for Investigation of Environmental Contaminants

Fish-derived cell lines are being used for at least three basic purposes in the investigation of environmental contaminants. One is in ascertaining the mechanisms by which contaminants exert their toxicity; a second is in determining the relative toxicity of different chemical contaminants; and a third application is in evaluating the toxicity of environmental samples. These three goals are interrelated, as toxic mechanisms give insight into the basis of toxicity rankings and allow the risk of untested compounds and of environmental samples to be estimated. The endpoints that are used in these studies can be specific or general. A specific response evaluates a particular function, which might be expressed by only certain fish-derived cell lines and is caused by just some classes of chemical contaminants. General responses assess fundamental cellular activities, which would be expressed by all fish cell lines and caused by a wide range of contaminants.

In this unit, three assays for assessing a change in cell viability, a general response, are described. Each assay is done on cells in microwell cultures and uses a different fluorescent indicator dye, but the results are quantified in arbitrary fluorescent units (FU) with a common instrument—a fluorescent plate reader (O'Connor et al., 1991; Schirmer et al., 1997). Cell viability is compared in toxicant-treated cultures by expressing their FU as a percentage of the FU for control cultures. The use of these assays is illustrated with some members of an important class of environmental contaminants, the polycyclic aromatic hydrocarbons (PAHs), which can act as toxicants and as phototoxicants (Schirmer et al., 1998a,b).

This unit describes a protocol on how to culture fish cell lines, which provide a continuous supply of cells. These cells are used to initiate microwell cultures for exposure to environmental toxicants in the dark and in the presence of UV radiation, and cell viability is assessed using the fluorescent indicator dye alamar blue (see Basic Protocol). Cell viability is also assessed using other fluorescent indicator dyes, such as CFDA-AM to assess membrane integrity (see Alternate Protocol 1) and neutral red to assess lysosomal activity (see Alternate Protocol 2).

EVALUATION OF TOXICITY IN FISH-DERIVED CELL LINES USING ALAMAR BLUE TO ASSESS METABOLIC ACTIVITY

BASIC PROTOCOL

This protocol describes the routine maintenance of salmonid cell lines, although very similar procedures could likely be used for cell lines from other groups of fish. Approximately 30 different fish cell lines are available in total from the American Type Culture Collection (ATCC) and the European Collection of Animal Cell Cultures (ECACC), although many more have been described in the literature. The rainbow trout gill cell line, RTgill-W1, which is available from ATCC as CRL-2523, is used as an example in this protocol for growing fish cells.

This protocol outlines the steps for setting up confluent monolayers of cultures of fish-derived, RTgill-W1 cell lines in 48- and 96-well microwell plates (6-, 12-, 24-, and 384-well plates are also available), which will then be exposed to toxicants in the presence or absence of UV irradiation. This allows the detection of directly cytotoxic compounds, or those that need the presence of UV irradiation to become toxic, in which case the compound is called photocytotoxic (Schirmer et al., 1998a,b). Upon termination of the experiment, cell viability as measured by metabolic activity is assessed by using the fluorescent indicator dye alamar blue. Other fluorescent dyes are used to assess membrane

Current Protocols in Toxicology (2003) 1.5.1-1.5.17

integrity (CDFA-AM; see Alternate Protocol 1) and lysosomal activity (neutral red; see Alternate Protocol 2).

Alamar blue is a commercial preparation of the dye resazurin (O'Brien et al., 2000) and is increasingly being used in pharmacology to screen for compounds toxic to mammalian cells (Evans et al., 2001). Resazurin, which is not fluorescent, becomes fluorescent upon reduction by living cells.

Materials

70% ethanol solution
Confluent culture of RTgill-W1 cells (CRL-2523, ATCC) in a 75-cm^2 flask
0.53 mM versene (EDTA; Life Technologies) diluted 1:5000 (1× 0.2 g tetrasodium EDTA/liter in PBS)
Trypsin solution (see recipe)
Leibovitz's (L-15) complete medium containing FBS (see recipe)
Test compounds (toxicants) in dimethyl sulfoxide (DMSO), stock solutions
DMSO
L-15/ex solution (see recipe)
Alamar blue (Immunocorp)

Laminar flow hood, either horizontal or vertical
Inverted phase-contrast microscope
Vacuum aspirator
15-ml centrifuge tubes, sterile
Hemacytometer
48- or 96-well tissue-culture treated microwell plate
75 cm^2 tissue culture flask
Incubator (see Critical Parameters and Troubleshooting)
Catch basin (a plastic container at least slightly larger than the size of the microwell plate)
Positive displacement digital micropipet (e.g., Nichiryo model 800)
Glass pipet tips for digital micropipet (Nichiryo)
Parafilm
Radiation exposure chamber containing UV-A and/or UV-B fluorescent lamps (Southern N.E. Ultraviolet) and a fan
Spectroradiometer (e.g., InstaSpec II photodiode array spectroradiometer, Oriel)
Transformer to modulate UV intensity
Fluorometric microwell plate reader

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly. Work >6-in. from the front of the vertical laminar flow hood, as the sterile zone begins there.

Prepare fish-derived cell cultures

1. Turn on the laminar flow hood, and wipe all surfaces with 70% ethanol solution.
2. Examine the confluent culture of RTgill-W1 cell flask under an inverted phase-contrast microscope.

   Note the general appearance of the culture, checking for inadvertent microbial contamination or unexpected rounding and detachment of the fish-derived cells. Cultures to be passaged should appear normal and confluent (i.e., covering the bottom of the flask completely) or close to confluence.

3. Under the laminar flow hood, aspirate the old medium and add 1.5 ml of 0.53 mM versene to the flask. Swirl it around gently, leave for 1 min, and aspirate it off.

4. Add 1 ml versene and 1 ml trypsin solution to the flask, replace the cap, and observe under the inverted phase-contrast microscope. Do not leave the cells in trypsin for >5 min as cellular digestion and cell death may ensue.

   The cells will begin to detach from the culture surface in ~1 to 3 min. Older cultures that have not been passaged for a long period of time are difficult to detach. Ideally, the cells will detach individually, and form a single-cell suspension.

5. Add 3 ml Leibovitz's complete medium containing FBS to the flask. Pipet the medium up and down, directing the stream towards the bottom of the flask, to make sure that all cells are dislodged and resuspended in the medium.

   Trypsin inhibitors in FBS stop the action of the trypsin.

6. Transfer the cell suspension to a sterile 15-ml centrifuge tube and centrifuge 5 min at 200 × *g*, room temperature, in a tabletop centrifuge.

7. Aspirate the supernatant from the 15-ml centrifuge tube, being careful not to aspirate the cell pellet. Leave a small amount of supernatant (0.25 ml) over the cell pellet. Flick the centrifuge tube to resuspend the cells in the small volume of medium.

Plate cells to maintain cell line

8a. Add 10 ml fresh medium to the centrifuge tube and transfer 5 ml to each of two 75 cm^2 tissue culture flasks. Add 5 ml medium to each flask.

9a. Examine flasks using a phase-contrast microscope. Note whether cells have detached as single cells or as clumps and whether the suspension has been distributed equally between the two flasks.

10a. Allow the cells to grow at 18° to 22°C. When the cultures are confluent (7 to 10 days), split 1:3 or harvest to use for an experiment.

Plate cells in microwell plates

8b. Add 4 ml Leibovitz's complete medium containing FBS. Determine the cell density using a hemacytometer (*APPENDIX 3B*). Using fresh medium, adjust cell density to 1×10^5 cells/ml if using 48-well plates and to 1.5×10^5 cells/ml if using 96-well plates.

9b. If using a 48-well tissue-culture microwell plate, add 5×10^4 RTgill-W1 cells in 500 µl of Leibovitz's complete medium to 40 wells of a 48-well tissue-culture microwell plate. Use the remaining eight wells as blanks by adding Leibovitz's complete medium alone. If using a 96-well tissue-culture microwell plate, add 3×10^4 RTgill-W1 cells in 200 µl of Leibovitz's complete medium to 84 wells of a 96-well tissue culture plate. Use the remaining twelve wells as blanks by adding Leibovitz's complete medium alone.

10b. Allow the cells to grow for 3 to 4 days in the dark at 18° to 22°C to form a confluent cell monolayer for the 48-well plates and for 2 to 3 days for the 96-well plates.

   Growing cells over a 2- to 4-day period allows for a more consistent cell density and better adherence of cells than newly initiated, dense cultures.

Expose fish-derived cell lines to putative toxicants

11. Turn on the laminar flow hood, and wipe all surfaces with 70% ethanol solution.

12. Examine the plated microwell plate under the inverted phase-contrast microscope.

    Note the general appearance of the cell culture, making sure that the bottom of the wells contain a confluent monolayer and inadvertent microbial contamination is absent.

13. Make serial dilutions (working solutions) from test compound stock solutions in carrier solution (e.g., DMSO).

    If the carrier solution is an organic solvent, prepare working solutions such that the concentrations are at least 200 times the final concentrations desired in the culture wells.

    Serial dilutions are necessary to ensure that the solvent is diluted sufficiently in the culture medium in the wells in order minimize interference due to the solvent with cell viability and/or toxicant uptake. For more water-soluble compounds, a dilution series can be prepared directly in culture medium. However, many organic toxicants, including PAHs, will require the use of an organic carrier solvent.

14. Remove growth medium from plates by inverting over a catch basin. Drain plates further for a few seconds on a small stack of paper towels.

15. Rinse each culture well with 500 µl L-15/ex solution if using 48-well plates or 200 µl L-15/ex solution if using 96-well plates. Remove this rinsing medium by inverting over a catch basin. Drain plates further for a few seconds on a small stack of paper towels. Then add 500 µl L-15/ex solution to each well if using 48-well plates or 200 µl L-15/ex solution if using 96-well plates.

16. Expose cells to the test compound in a vertical laminar flow hood. For example, if working solutions were prepared in DMSO at 200 times the final concentration required, pipet 2.5 µl test compound to each well containing 500 µl/well L-15/ex solution in 48-well plates using a positive displacement digital micropipet. If using a 96-well plate, pipet 1.0 µl test compound dissolved in DMSO to each well containing 200 µl/well L-15/ex solution.

    Because cells in L-15/ex solution are particularly sensitive to DMSO, tilt the plates before adding the test compound to increase the volume of medium above the cells as a protective layer. Dispense the 2.5 µl or 1 µl test compound above the level of the medium, and then touch the droplet to the surface of the medium to aid in dispersion. In addition, reduce the light level in the flow hood to avoid irradiation of cells in the presence of the toxicant.

17. In a 48-well plate, dose six wells (five wells with confluent cell monolayers and one well without cells to serve as a blank) for each of seven concentrations of compounds and the DMSO control. In a 96-well plate, dose eight wells (seven wells with confluent cell monolayers and one without cells to serve as a blank) for each of twelve concentrations of compounds and the DMSO control. Wrap plates in Parafilm to prevent evaporation during the exposure period.

    The use of plate sealing foils, which are commercially available, e.g., Nunc or Greiner, is recommended in order to minimize well-to-well transfer and losses due to evaporation of more volatile toxicants.

For exposure of fish-derived cells to toxicants in the dark

18a. For exposures in the dark, incubate plates up to 48 hr at 18°to 22°C.

19a. If not specifically desired (see below), avoid exposure of the plates to light.

    Although L-15/ex is unlikely to be affected by irradiation, many toxicants may be altered chemically.

20a. At the end of the dark exposure, remove plates from the incubator and continue with the cytotoxicity assay for assessing metabolic activity with the fluorescent dye alamar blue, proceed to step 23 (for membrane integrity assessment, use CDFA-AM, see Alternate Protocol 1; or for lysosomal activity assessment, use neutral red, see Alternate Protocol 2).

For exposure of fish-derived cells to toxicants in the presence of irradiation

18b. Turn on the lamps of the radiation exposure chamber at least 15 min prior to use in order to allow lamps to warm up and emit a stable radiation.

The radiation chamber should contain at least two fixtures to hold lamps, e.g., one UV-A and one UV-B fluorescent lamp, and it should be shielded from any radiation outside the chamber. Ideally, lamps should be linked to a transformer in order to allow for easy manipulation of the radiation output.

19b. Place the appropriate unit of the spectroradiometer into the radiation exposure chamber in order to perform UV radiation measurements as described in the user manual of the spectroradiometer.

Ensure that the appropriate unit of the spectroradiometer is positioned the same distance from the UV lamps as the culture plate would be. Also, place the lid of the culture plate on top of the unit to measure the amount of UV irradiation passing through the lid of the plate.

20b. Using the transformer, adjust UV intensities as desired.

For example, a 10:1 ratio of UV-A to UV-B may be desirable in order to mimic the ratio of these two UV components in nature. If no transformer is available, radiation intensity may be adjusted by varying the distance between the exposure tray and the lamps but this method is somewhat cumbersome.

21b. Once the radiation exposure chamber has been set up, place tissue culture plates into the chamber in an atmosphere of air for the required exposure period. Place a second tissue culture plate into the chamber at the same time but protected from radiation.

This second plate serves as the dark control.

22b. At the end of the UV exposure, remove plates from the chamber and proceed with the cytotoxicity assay for assessing metabolic activity using alamar blue, proceed to step 23 (for membrane integrity using CDFA-AM, see Alternate Protocol 1; or for lysosomal activity using neutral red, see Alternate Protocol 2).

Assess metabolic activity using alamar blue

23. Prepare a 5% (v/v) working solution of alamar blue in L-15/ex solution.

Alamar blue is purchased as a ready-to-use solution in quantities of 25 ml and 100 ml. When stored in the dark at 2° to 8°C and kept aseptically, alamar blue can be used for at least 1 year.

24. Remove exposure medium from plates by inverting over a catch basin. Drain plates further for a few seconds on a small stack of paper towels.

25. Add 100 to 150 µl of 5% alamar blue working solution to each well of a 48-well plate, or 50 to 100 µl per well to a 96-well plate.

The general rule is to at least cover the growth surface of the wells although some plate readers may require slightly larger volumes for accurate readings.

26. Incubate the plates in the dark at 18° to 22°C for 30 min.

Although longer incubation times are also possible, the yield of fluorescent units from alamar blue can decline if the incubation period is too long (O'Brien et al., 2000).

27. Measure alamar blue on the fluorometric plate reader at excitation and emission wavelengths of 530 and 590 nm, respectively.

ALTERNATE PROTOCOL 1

EVALUATION OF TOXICITY IN FISH-DERIVED CELL LINES USING CFDA-AM TO ASSESS MEMBRANE INTEGRITY

Although esterase substrates have been used as a measure of cell membrane integrity since the 1960s (Rotman and Papermaster, 1966), 5-carboxyfluorescein diacetate acetoxymethyl ester (CFDA-AM) is an example of one developed to improve this application (Haugland, 1996). CFDA-AM diffuses into cells rapidly and is converted by non-specific esterases of living cells from a nonpolar, nonfluorescent dye into a polar, fluorescent dye, 5-carboxyfluorescein (CF), which diffuses out of cells slowly. In this protocol, fish cells in microwell cultures are exposed for a period of time to a putative toxicant, and after removal of the putative toxicant, CFDA-AM is added and the capacity of the cells to produce CF is measured.

Additional Materials *(also see Basic Protocol)*

4 mM 5-carboxyfluorescein diacetate acetoxymethyl ester (CFDA-AM, see recipe)
RTgill-W1 cells in a 48-well or 96-well plate exposed to toxicants (see Basic Protocol, steps 1 to 22)

1. Prepare a working solution of 4 µM CFDA-AM by diluting the 4 mM CFDA-AM stock solution 1:1000 in L-15/ex solution.
2. Remove exposure medium from RTgill-W1 cells in a 48-well or 96-well plate exposed to toxicants by inverting over a catch basin. Drain plates further for a few seconds on a small stack of paper towels.
3. Add 100 to 150 µl of 4 µM CFDA-AM working solution to each well of a 48-well plate or 50 to 100 µl of 4 µM CFDA-AM working solution to each well of a 96-well plate and incubate the plate in the dark for 30 to 120 min at 18°to 22°C.
4. Measure CF fluorescence on the fluorometric plate reader at respective excitation and emission wavelengths of 485 and 530 nm.

Alamar blue (see Basic Protocol, steps 23 to 27) and CFDA-AM can be added together to perform the two assays in a single step (Schirmer et al., 1997) because the fluorescent products of the two indicator dyes can be detected at different emission wavelengths without interfering with each other. The advantage of doing so is the conservation of material and time as fluorescent readings are taken on the same culture wells. Thus, in order to perform the two assays together, add the appropriate amount of alamar blue to make a 5% (v/v) working solution in L-15/ex solution and then dilute the CFDA-AM stock solution (4 mM in DMSO) 1:1000 in that same volume of L-15/ex solution. Proceed with the incubation period as described above in step 3.

Inasmuch as alamar blue and CFDA-AM do not affect the viability of cells, fluorescent dyes can be removed after fluorescent measurement and replaced by culture medium to allow the cells to recover for a period of time after which the indicator dyes can be re-applied.

ALTERNATE PROTOCOL 2

EVALUATION OF TOXICITY IN FISH-DERIVED CELL LINES USING NEUTRAL RED TO ASSESS LYSOSOMAL ACTIVITY

Although first used to evaluate cell viability in virology, neutral red (NR) has been utilized most intensively in in vitro toxicology. The principle is that viable cells accumulate NR (3-amino-7-dimethylamino-2-methylphenazine hydrochloride) in lysosomes (Borenfreund and Puerner, 1984). NR can be applied before or after the exposure of cell cultures to toxicants, so that the measured endpoint represents either the release or uptake of the dye (Borenfreund and Puerner, 1984; Reader et al., 1990). Measurements can be done either spectrophotometrically (Borenfreund and Puerner, 1984) or fluorometrically (Essig-Marcello and van Buskirk, 1990). In this protocol, the use of NR after the exposure of fish cells to toxicants and the fluorometric measurement of any subsequent changes in NR uptake are described.

Additional Materials *(also see Basic Protocol)*

Neutral red stock solution (see recipe)
RTgill-W1 cells in a 48-well or 96-well plate exposed to toxicants (see Basic Protocol, steps 1 to 22)
Neutral red fixative solution (see recipe)
Neutral red extraction solution (see recipe)
Orbital shaker

1. Prepare a working solution of 33 µg/ml neutral red by diluting the neutral red stock solution 1:100 in L-15/ex solution.
2. Remove exposure medium from RTgill-W1 cells in a 48-well or 96-well plate exposed to toxicants by inverting over a catch basin. Drain plates further for a few seconds on a small stack of paper towels.
3. Add 100 to 150 µl of 33 µg/ml neutral red working solution to each well of a 48-well plate or 50 to 100 µl of 33 µg/ml working solution to each well of a 96-well plate and incubate the plate in the dark for 60 min at 18°to 22°C.
4. Remove the neutral red working solution by inverting over a catch basin and drain a few seconds on a small stack of paper towels.

   It is critical to remove all the neutral red working solution from each well, especially in a 96-well plate.

5. Rinse wells once with 100 µl/well of neutral red fixative solution.

   The rinsing step removes any excess neutral red that has not been localized in lysosomes.

6. Add 100 µl/well of neutral red extraction solution to solubilize the lysosomal neutral red. Place plates on an orbital shaker and shake at ~40 rpm for 10 min.
7. Measure neutral red fluorescence on the fluorometric plate reader at excitation and emission wavelengths of 530 and 645 nm, respectively.

   In the interest of conserving material and for performing cell viability assays on the same set of cells, the neutral red assay can be performed on the same plate previously used to assess alamar blue (see Basic Protocol) and/or CFDA-AM fluorescence (see Alternate Protocol 1). After termination of the alamar blue and CFDA-AM exposures, remove the dye solution(s) and start by adding neutral red as described above. However, inasmuch as the neutral red assay will terminate the cell culture because cells will be fixed, a separate plate needs to be used if the alamar blue/CFDA-AM plates are to be used to study recovery.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CFDA-AM stock solution, 4 mM

Dissolve the 5-mg vial of CFDA-AM (Molecular Probes) in 2.35 ml of sterile anhydrous DMSO (final concentration 4 mM) in a laminar flow hood. Dispense into sterile 1.5-ml microcentrifuge tubes in 50-µl aliquots to prevent degradation from thawing and refreezing. Wrap each microcentrifuge tube in aluminum foil to prevent light degradation. Store dessicated up to 1 year at −20°C to avoid ester hydrolysis due to moisture.

L-15/ex solution

Development of this modified medium is outlined in Schirmer et al. (1997) and is based on the constituents of basal medium, L-15 (Leibovitz, 1963). Make up all components from cell-culture grade reagents (Sigma) and prepare in cell-culture grade, distilled water.

Salt solution A: In 600 ml water, dissolve: 80 g NaCl, 4.0 g KCl, 2.0 g $MgSO_4$, 2.0 g $MgCl_2$

Salt solution B: In 100 ml water, dissolve: 1.4 g $CaCl_2$

Salt solution C: In 300 ml water, dissolve: 1.9 g Na_2HPO_4, 0.6 g KH_2PO_4

Autoclave each solution separately and store up to 1 year at room temperature.

Sodium pyruvate solution: In 100 ml of water, dissolve 5.5 g sodium pyruvate. Filter sterilize through a 0.2-µm filter, dispense in 5.7-ml aliquots, and store up to 1 year at −20°C.

Galactose solution: In 100 ml of water, dissolve 9.0 g galactose. Filter sterilize through a 0.2-µm filter, dispense in 5.7-ml aliquots, and store up to 1 year at −20°C.

To prepare L-15/ex solution:

To 500 ml of sterile cell culture-grade, distilled water, add aseptically:
34.0 ml salt solution A
5.7 ml salt solution B
17.0 ml salt solution C
5.7 ml sodium pyruvate solution
5.7 ml galactose solution
Store L-15/ex solution up to 1 year at room temperature

Leibovitz's L-15 complete medium containing FBS

To 500 ml of Leibovitz's L-15 medium (Sigma), aseptically add 50 ml fetal bovine serum (FBS; Sigma). Final FBS concentration in culture medium is 8.9%, which is usually referred to as 10%. Aseptically add 10 ml of penicillin/streptomycin (100 IU/ml penicillin, 100 µg/ml streptomycin; Sigma). Store up to 1 year at 4°C.

Neutral red extraction solution

Prepare 1% (v/v) acetic acid and 50% (v/v) ethanol in deionized, distilled water. Store for up to 1 year at room temperature in the dark.

Neutral red fixative solution

Prepare 0.5% (v/v) formaldehyde and 1% (w/v) $CaCl_2$ in deionized, distilled water. Store for up to 1 year at room temperature in the dark.

Neutral red stock solution

Dissolve 3.3 mg of neutral red powder (Sigma) per milliliter of Dulbecco's PBS (D-PBS; Sigma or Life Technologies) in an amber vial. Store for up to 1 year at 4°C.

Alternatively, neutral red stock solution can be purchased dissolved in D-PBS at a concentration of 3.3 mg/ml (Sigma).

Trypsin solution

Dissolve 100 mg trypsin (Sigma) in 10 ml of Ca^{2+}- and Mg^{2+}-free Hank's balanced salt solution (Sigma) to make a trypsin stock solution. Dispense 0.5 ml of this solution into 9.5 ml of Ca^{2+}- and Mg^{2+}-free Hank's balanced salt solution. Store for up to 1 year at −20°C.

COMMENTARY

Background Information

The many in vitro toxicology tests can be divided into two types: general (basal) cytotoxicity tests and tests of differentiated cell function (Flint, 1990). The general type consists of tests that measure cytotoxic phenomena only, e.g., the inhibition of cell proliferation. One premise of this approach is that all toxic phenomena are fundamentally related to an impairment of some aspect of cellular activity in vivo. Therefore, toxicity in vivo should be expected if the test agent is bioavailable to a target tissue at concentrations that are observed to impair cell viability in vitro. A potential weakness of this approach is the observation that rather than being a general phenomenon of all tissues, toxicity in vivo is often limited to a small group of organs and cells within these organs. Thus, specific toxic effects might occur at concentrations well below those causing general cytotoxicity. The second class of in vitro tests attempts to overcome this weakness by monitoring a cellular function specific for the differentiated state of the cultured cell. From a risk assessment point of view, the tests for differentiated cell functions are usually more valuable (Flint, 1990). To date, general cytotoxicity tests mostly have been used in fish toxicology and are described in this unit.

Many general cytotoxicity tests have been described. They measure impairment of cellular activities by potentially toxic treatments. However, since their first introduction, assays of cytotoxicity and/or cell viability have been criticized as to their meaning and have aroused debate as to which assay is most appropriate (Schrek, 1965; Shaw, 1994). Cytotoxicity assays that monitor reproductive capacity have been described as being the most comprehensive because they integrate the soundness of the entire cellular machinery (Shaw, 1994). However, proliferation assays are not ideal for all purposes. They usually reveal little about the specific cellular events that lead to impaired proliferation and can miss subtle, transitory effects. They give little insight into the potential short-term impact of an effect on cells to the integrity of an organ or tissue. Also, colony formation and proliferation rates are impractical endpoints with most fish cell lines because the cells grow slowly. As an alternative to proliferative endpoints, assays of cell viability and cell injury can be performed (Shaw, 1994), such as the ones described here.

Although numerous assays of cell viability have been developed, those that utilize fluorometric indicator dyes are perhaps best. First, more and more dyes are becoming commercially available to evaluate distinct cellular parameters. Second, the development of fluorometric multiwell plate readers has made the use of fluorometric dyes easy and rapid, such as for the assays in this unit. The microwells conserve material resources by reducing the number of cells needed and increasing the number of replicates. The plate readers have the potential for high interlaboratory reproducibility and can be coupled to computers in order to manage data quickly and easily.

Critical Parameters and Troubleshooting

Temperature

The choice of temperature for growth, exposure, and assay of fish cell cultures is flexible and can be dictated by practical considerations or by scientific objectives. This is because fish cells can be grown over a wide temperature range, e.g., from 5° to 25°C for salmonid cells (Bols et al., 1992). The medium used in this unit is based on Leibovitz's L-15, which does not need a 5% CO_2 atmosphere in order for the pH to be buffered (Leibovitz, 1963). As a result, the "incubator" for fish cell cultures in CO_2-independent media, such as L-15, can be a desk drawer at room temperature, or a temperature-regulated chamber, such as a conventional incubator or a refrigerator. For all the protocols that are described in this unit with salmonid cells, temperatures from 18° to 22°C give consistent results, and fluctuations within this range have little or no effect on the outcome.

Toxicant preparation

The acts of dissolving compounds and of adding them to cell cultures can be the source of several problems. Unfortunately, these are difficulties that cannot really be solved, but are important to consider when interpreting results. The problems are most severe for hydrophobic environmental contaminants, such as the PAHs. Several alternative strategies for toxicant delivery have to be considered. One is whether or not to use carrier solutions to dissolve the compounds. The second is whether or not to completely remove the medium that was used to initiate the cell cultures from the microwells and to replace it with an equivalent volume of

toxicant solution. For compounds that are going to be presented without the use of a carrier, there is usually no choice, the original medium has to be replaced with the toxicant solution. Except for extremely water-soluble compounds, the highest doses in dose-response curves cannot be achieved by adding small aliquots of a concentrated solution. By contrast, high concentrations of hydrophobic compounds can be achieved in carrier solutions, allowing them to be added to cultures in small aliquots. Potential problems with carriers, exposure media, and presentation strategies for toxicants are further discussed below.

Carriers such as dimethylsulfoxide (DMSO) have nearly always been used to dissolve environmental contaminants for toxicity testing, but they potentially can influence the results. For example, fluoranthene that was dissolved in L-15/ex solution with DMSO was slightly more photocytotoxic to RTgill-W1 cells than fluoranthene dissolved in L-15/ex solution without DMSO (Schirmer et al., 1997). Differences can also be found between carriers. DDT in DMSO was more cytotoxic to tilapia brain cells than DDT in acetone (Parkinson and Agius, 1987). The induction of 7-ethoxyresorufin o-deethylase (EROD) activity in RTL-W1 cells was better after exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in DMSO than in isooctane (Clemons et al., 1994). Also, the carrier could influence the induction potency of some compounds (Yu et al., 1997).

Exposure medium

The medium in which cells are incubated during exposure to environmental contaminants is another variable that can influence results. An extremely simple one is used in this unit, which contains salts, galactose, and pyruvate at specified concentrations in the basal medium, Leibovitz's L-15 (Leibovitz, 1963), which is termed L-15 exposure or L-15/ex (Schirmer et al., 1997). L-15/ex has several advantages. For photocytotoxicity studies, the absence of vitamins and aromatic amino acids prevents the inadvertent generation of toxicants from these compounds during the UV treatment. L-15/ex is also advantageous for detecting toxicants that cause cytotoxicity through the generation of reactive oxygen species (ROS). This is because expression of their toxicity should be aided by the absence in L-15/ex of most antioxidants. The one exception might be the presence of pyruvate. For mammalian cells, pyruvate is part of an antioxidant defense (O'Donnell-Tormey et al., 1987). A limitation of L-15/ex is that exposure times are restricted to several days, as ultimately nutrient deprivation will cause cell death. The short exposure times mean that toxicants acting by inducing particular cellular processes, such as xenobiotic metabolism, and causing accumulative damage might be missed. Yet, RTgill-W1 cells survive in L-15/ex for at least 100 hr (Schirmer et al., 1997). Although addition of fetal bovine serum (FBS) to the medium extends the life of cell cultures, the antioxidants of FBS prevents the detection of fluoranthene photocytotoxicity (Schirmer et al., 1997). Also, FBS can alter the bioavailability of toxicants (Schirmer et al., 1997; Hestermann et al., 2000).

Dosing strategies

One strategy for presenting toxicants to cells is to completely remove the medium that was used to initiate the cell cultures from the microwells and add an equivalent volume of solution with the toxicant under study. Both steps present difficulties. The medium removal step has two problems. First, removal must be done quickly without damaging cells, which can be done by aspirating off the medium. But, this sometimes causes cell death. Death usually appears within minutes of aspiration and occurs in large patches over the culture surface. Routinely examining cultures with an inverted phase-contrast microscope shortly after aspiration easily identifies this problem. Alternatively, the medium can be removed by inverting the plate over a catch basin and blotting with a paper towel. This is the recommended medium removal technique because the cells are not subjected to the same force as aspiration may involve. Second, complete removal of the initiating medium over the cell cultures has the potential to change the physiology of cell cultures. An example of this is the rapid induction of 7-ethoxyresorufin o-deethylase (EROD) activity upon the removal of medium from cultures of the rainbow trout liver cell line, RTL-W1 (Segner et al., 2000). For short-term exposures (as described in this unit), this should not be a problem. Replacing the medium with toxicant solution is problematic for hydrophobic compounds. A concentrated solution of toxicant in a carrier such as DMSO must be serially diluted in an aqueous solution to prepare concentrations for dose-response curves. Hydrophobic compounds have a tendency to stick to the walls of containers and pipets used to prepare these solutions. Thus, the final toxicant concentrations that the cultures receive can be

lower than the concentrations apparently added. The problem cannot be solved by simply measuring the concentrations through analytical chemistry methods, for this approach also requires the use of containers and pipets that can lead to an underestimation of final concentrations.

The second presentation strategy is to use micropipets to add small volumes (≤10 µl) of the toxicant in carrier solvent to the medium over the cells in microwells. Dosing in this manner must be done very carefully with carriers, such as DMSO. The small volume of DMSO sometimes falls as a blob directly onto the cells, immediately killing them. Again, examining cultures with an inverted phase-contrast microscope easily identifies this problem. As mentioned, the difficulty can be avoided by keeping the pipet tip close to the medium surface and allowing the surface tension to disperse the DMSO rapidly and evenly through the culture. This second presentation strategy has at least two advantages. Changing the medium is avoided, which also avoids any possible changes in the cells caused by this act. Final culture concentrations are closer to the apparent toxicant concentration that is added. In extreme cases, a compound might appear to be toxic with this dosing method, but not by the method of preparing the toxicant in exposure medium and using this solution to replace the growth medium of cell cultures. If the results of the two different dosing strategies are profoundly different, they should be reported as such, as this will aid others in replicating the results in any future studies and will stress the subtlety of the cytotoxicant's actions.

UV irradiation

For the concurrent exposure of cultures to environmental contaminants and UV light, the radiation exposures can be expressed in different ways, sometimes causing confusion. The most important distinction is between energy units, which refer to the wave-like character of radiation, and quantum units, which reflect the corpuscular character. The conversion from energy content to photon content is defined by Planck's equation. Fluence rates are used to refer to the quantity of radiation per area per time. Thus, Wm^{-2} and Jm^{-2} sec^{-1} are expressions of energy fluence rates, whereas $moles_{(photons)}m^{-2}sec^{-1}$ is an expression of photon fluence rates. In contrast to the fluence rates, the total amount of radiation received by the cells can be expressed as fluence, that is quantity per area. Thus, the energy fluence (Jm^{-2}= $Wm^{-2}sec$) or the photon fluence ($mol_{(photons)}m^{-2}$) can be calculated by multiplying the fluence rate by the time of irradiation (in seconds). For example, a photon fluence rate of UV-B at 313 nm of 1.4 $\mu mol(m^{-2})sec^{-1}$, which has been shown to be environmentally relevant (Oris and Giesy, 1987), is equivalent to an energy fluence rate at that wavelength of 53 μWcm^{-2}(or 53 $\mu Jcm^{-2}sec^{-1}$). If irradiation is performed for 2 hr, the energy fluence that the cells are exposed to is 0.4 $Wcm^{-2}sec$ (or 0.4 Jcm^{-2}).

Inasmuch as UV radiation exposure decreases with increasing distance from the UV source, it is important to measure UV radiation at the position at which culture plates will be placed. In order to account for absorption of UV radiation by culture plate lids, place a lid between the UV source and the radiation measurement device. The irradiation of cells in the presence of tissue culture plate lids is highly recommended for two reasons. First, the lids ensure sterility during the illumination process. Second, the plate lids absorb any radiation below a wavelength of 290 nm, a filtering process which, under natural conditions, is carried out by a stratospheric ozone (Schirmer et al., 1997).

While measurements of UV irradiance should be done frequently to ensure that UV intensities of the fluorescent lamps are as required, initial measurements should confirm that the culture medium covering the cells does not detrimentally affect UV penetration. To study this, a lid-covered tissue culture plate with and without culture medium should be placed between the UV source and the spectroradiometer and the values compared. If measurements are the same, it can be concluded that the culture medium used has no discernible effect on UV penetration. In contrast, lower UV intensities measured in the presence of culture medium indicate that cells obtain less UV radiation than anticipated. For example, the authors found that UV intensities were not significantly affected upon passage through a 4.7 mm path of L-15/ex medium, which equals 500 µl L-15/ex medium in a 48-well tissue culture plate. In contrast, the same passage of UV in the presence of 10% FBS led to a reduction of UV readings of 27% for UV-B and 9% for UV-A (Schirmer et al., 1997). Another factor to consider is temperature. In the presence of a small fan and a distance of the tissue culture plates from the UV lamps of at least 15 cm, the authors did not find temperature to rise in the tissue culture medium within 2 hr of UV-irradiation at a photon fluence rate of 10 µmol m^{-2}

sec^{-1}UV-A and 1 μmol $m^{-2}sec^{-1}$UV-B (Schirmer et al., 1998b). However, longer exposures or higher UV intensity may potentially lead to an increase in temperature.

Toxicant removal

Termination of toxicant exposures prior to the addition of the fluorescent indicator dyes to cell cultures must be done carefully and consistently. Inverting plates over a catch basin is recommend over aspiration. Removal must be done rapidly but without damaging cells. Viewing control cultures with an inverted phase-contrast microscope will identify any problems. Of course, at this stage, the loss of cells from toxicant-treated cultures can be expected.

Fluorescent microwell plate readers

A number of manufacturers (e.g., Molecular Devices, Applied Biosystems) make fluorescent plate readers, and likewise, microwell plates are produced by several companies (e.g., Falcon, Costar, Nunc). Although all fluorescent plate readers are likely suitable, the crucial issue is to make sure the microwell plate correctly matches the plate reader. Under most circumstances, only the appropriate settings need to be chosen, as the plate readers have been designed to accept most plates from various manufacturers. However, sometimes the dimensions for a particular microwell plate must be obtained from the manufacturer and entered into the plate reader.

As mentioned earlier, the minimum volume of fluorescent indicator dyes needed for accurate measurement might vary for different microwell plate readers. Thus, initial experiments should determine the most suitable volume.

Anticipated Results

Data analysis: Calculation of EC_{50}

The raw fluorescent units resulting from the cell viability assays are used to evaluate the toxicity of the chemical being tested. Cell viability is expressed as a percent of non-toxicant exposed cells (% of control). For each concentration of toxicant, there is one well that contains no cells (no cell control). Both the well with no cells and the wells with cells are exposed to the toxicant. Prior to calculating percent of control, subtract the fluorescent units (FU) for wells without cells from the experimental (ex) and control (con) values with cells. To calculate the cell viability (% of control) use the following formula:

$$\%\ \text{of control} = (FU_{\text{ex cells}} - FU_{\text{ex no cells}}) \times 100/(\text{average}\ [FU_{\text{con}} - FU_{\text{con no cells}}])$$

Data for each well of each concentration are expressed as a percent of control. Then, the average and standard deviation for each concentration are calculated. These values are used to calculate the EC_{50} for the toxicant.

Dose-response data typically follow a sigmoidal relationship and can be analyzed by nonlinear regression in most graphing software such as SigmaPlot (Jandel Scientific). The data is fitted to the four-parameter logistic function for continuous response data. The logistic function is:

$$y(d) = Y_{\min} + (Y_{\max} - Y_{\min})\backslash\{1 + \exp[-g(\ln(d) - \ln(EC50))]\}^{-1}$$

where $y(d)$ is the % cell viability at the dose d, $Y_{\min}$ is the minimum percent cell viability, $Y_{\max}$is the maximum percent cell viability, $g$is a slope parameter, $EC_{50}$is the dose that produces 50% of cell viability.

Inasmuch as cell viability data are expressed on a 0% to 100% basis, the four-parameter equation is simplified to a two-parameter equation because $Y_{\max}$ and $Y_{\min}$ are constants of 100% and 0%, respectively:

$$y(d) = 0\% + (100\% - 0\%)\ \{1 + \exp[-g(\ln(d) - \ln(EC_{50}))]\}^{-1}$$

Interpretation of results

With each fluorescent indicator dye (alamar blue, CFDA-AM, and NR), a reduction in fluorescent unit readings in experimentally treated cultures relative to the readings in control cultures indicates cytotoxicity or a loss of cell viability. The use of multiple dyes has the potential of revealing the mechanism(s) behind the cytotoxicity. However, the results and the interpretation can be straightforward or complicated, depending on the toxicant under study. Both a simple (Fig. 1.5.1) and a complex example (Fig. 1.5.2) are presented.

When the dose-response curves for the three indicator dyes are identical or very similar for cell cultures after short exposures to toxicants, e.g., illustrated in Figure 1.5.1 for 1,4-dimethyl naphthalene, this indicates that the toxic mechanism is general membrane damage, which includes impairment of organelle membranes, such as those for mitochondria and lysosomes, as well as the plasma membrane. Because this loss of cell viability occurs quickly, it has come to be known as direct cytotoxicity to indicate that cellular metabolism of the toxicant is unlikely to be involved

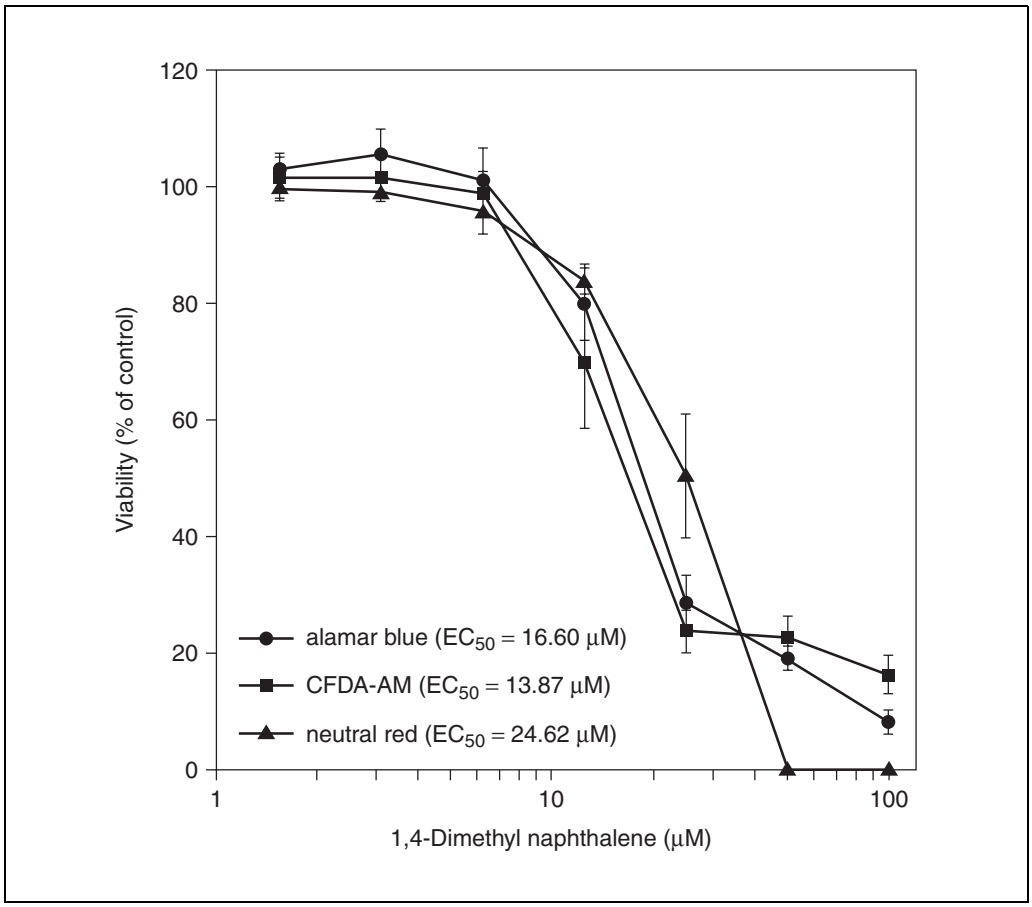

Figure 1.5.1 Effect of 1,4-dimethyl naphthalene on viability of RTgill-W1 cultures. After the cultures had been exposed for 2 hr, cell viability was assessed with alamar blue (circles), CFDA-AM (squares), and neutral red (triangles). Results were expressed as a percentage of the readings in control wells exposed to L-15/ex solution with DMSO.

(Schirmer et al., 1998a). The terms ultra-fast cell death, or less preferably, necrosis, have been suggested for cell death that occurs quickly in mammalian cell cultures in response to strong stimuli (Blagosklonny, 2000). Ultra-fast cell death appears before the activation of caspase, which is a characteristic of apoptosis (Blagosklonny, 2000). For mammalian cells, Blagosklonny (2000) has suggested that a time frame for the development of a decline in cell viability can be used to distinguish ultra-fast cell death (2 to 16 hr), apoptosis (16 to 36 hr), and slow cell death (>36 hr). As cellular phenomena take longer to develop in fish cells being grown at 18° to 22°C than in mammalian cells at 37°C, the time frame for these in fish cell lines might be increased considerably.

Alternatively, the dose-response curves with the different indicator dyes can be unlike one another. Several examples already have appeared in the literature. One combination of outcomes is a decline in cell viability as measured with alamar blue being accompanied by little or no change in cell viability as measured with CFDA-AM. Such results have been seen with benzo[a]pyrene (BaP) and 6, 12-BaP quinone (Schirmer et al., 2000). As the reduction of alamar blue to a fluorescent product is now thought to indicate cellular metabolism rather than specifically mitochondrial activity (O'Brien et al., 2000), the results are interpreted as indicating that these compounds impair metabolism without impacting plasma membrane integrity. Another outcome combination is that of a greater decline in cell viability as measured with neutral red than in the cell viability monitored with alamar blue and CFDA-AM. This was seen in studies on the photocytoxicity of acenaphthylene, acenaphthene, phenanthrene, fluoranthene, pyrene, anthracene, and benzo[g,h,i]perylene (Schirmer et al., 1998b) . The interpretation of these results is that specific lysosomal damage has occurred immediately after concurrent exposure to these com-

pounds and UV radiation, with little or no impairment of plasma membranes and cellular metabolism.

The CFDA-AM assay appears to monitor impairment to plasma membranes, but Figure 1.5.2A illustrates a perplexing outcome. A decline in fluorescent readings occurs at lower concentrations of 2-ethyl phenanthrene with CFDA-AM than with alamar blue, resulting in a lower EC_{50} for this toxicant. If the CFDA-AM measures membrane integrity, then cellular metabolism evaluated with alamar blue would not be expected to continue with little or no impairment while the integrity of the plasma membrane has been lost. An explanation can be advanced for this apparent anomaly. When carried out as described here, a decrease in fluorescent readings with CFDA-AM actually measures a decline in the total esterase activity within a microwell cell culture. The decrease in esterase activity with toxicant treatment could be achieved in two general ways: the loss of plasma membrane integrity and/or specific inhibitory actions on cellular esterases. In turn, the loss of plasma membrane integrity could decrease culture esterase activity in two slightly different ways. The first of these would be the complete or partial lysis of the cells upon toxicant exposure so that the esterases are released into the medium and lost when the medium is removed and replaced with the CFDA-AM solution. Another possible cause for the diminution of esterase activity is a change in plasma membrane integrity so that cytoplasmic constituents are lost to the medium but the esterases remain contained within the cells, which are still attached to the surface of the microwells. This change in the cytoplasmic milieu would be less able to support maximal esterase activity. Alternatively, the toxicant treatment could leave membrane integrity unimpaired but specifically interfere with cellular esterases, causing activity to decline. Examples of this would be a toxicant interfering with the uptake of the substrate, CFDA-AM, across the plasma membrane or inhibiting the catalytic activity of the esterases. The results in Figure 1.5.2A in which increasing 2-ethyl phenanthrene concentrations cause a more precipitous decline in CFDA-AM readings than in alamar blue readings are likely an example of a toxicant impairing esterase activity rather than the plasma membrane.

Additional information into mechanisms of toxicity can be obtained by applying the indicator dyes both immediately after terminating toxicant exposure and later after a period of potential recovery. The assays with alamar blue and CFDA-AM are non-toxic and can be applied on the same microwell cultures for both time points. For the NR assay, which requires cultures to be extracted, separate microwell cultures must be used. Differences between dose-response curves immediately and 24 hr after toxicant exposures have been found, suggesting impairments at specific cellular sites and the capacity of cells to repair them. For example, alamar blue readings decreased immediately after the end of exposures to BaP and 6, 12 BaP quinone, but recovered 24 hr later (Schirmer et al., 2000). As the CFDA-AM readings showed no changes, these results suggested that short exposures to these compounds transitorily disrupted cellular metabolism, although continuous exposure would ultimately lead to cell death. By contrast, a comparison of Figures 1.5.2A and 1.5.2B suggests that a 2-hr exposure to high concentrations of 2-ethyl phenanthrene initiates a process leading to irreparable cellular damage that is expressed as a loss of cell viability 24 hr later. As the development of this cytotoxicity occurs quickly, and for most of the time in the absence of significant amounts of test compound in the medium, the cytotoxicity is unlikely to be due to the generation of toxic metabolites by cell metabolism during the recovery period. Instead, during the 2-hr exposure period, 2-ethyl phenanthrene likely partitions into cell membranes, and in cultures with high concentrations, reaches levels that begins disrupting the plasma membrane. As a membrane-bound toxicant would not be easily removed upon termination of toxicant exposure, the process of plasma membrane impairment would continue during the recovery period, leading to cell death.

The above discussion illustrates some of the complexities that might be anticipated. Likely, all the possible scenarios for cellular responses to toxicants as measured with these three indi-

Figure 1.5.2 *(at right)* Effect of 2-ethyl phenanthrene on viability of RTgill-W1 cultures. After the cultures had been exposed for 2 hr (**A**), cell viability was assessed with alamar blue (circles), and CFDA-AM (squares). The exposure medium was replaced with complete medium and the cells were incubated for an additional 24 hr (**B**), after which viability was reassessed with alamar blue (hexagons) and CFDA-AM (diamonds). Results were expressed as a percentage of the readings in control wells exposed to medium with DMSO.

cator dyes have yet to be described. Several additional complicated scenarios will likely be revealed only by examining more compounds with these indicator dyes. For example, under some circumstances, neutral red readings might increase (Zhang et al., 1990). Overall, the methods described in this unit allow the rapid and inexpensive screening of toxicants for fish cells and at the same time give potential insight into their mechanism(s) of toxicity. In the future, understanding better the cellular function(s) being monitored with each indicator dye will improve their utility in identifying toxicity mechanisms.

Time Considerations

One must consider the time to culture the fish-derived cell lines in preparation for exposure to the toxicants. The time between subculturing of the stock culture is between 7 and 10 days if a 1 to 3 split is used routinely. Once the flask is confluent, the cells are transferred to a microwell culture plate allowing the cells to attach and become a confluent monolayer on the bottom of each well, which will take ~2 to 3 days depending on the use of 48-well or 96-well plates. The time for exposure to a toxicant can vary. Commonly, 2-hr exposures are done with toxicants that are believed to act through a necrotic process of ultra-fast cell death. Longer exposures, commonly 24- or 48-hr exposures, can be done to test toxicants that do not have a response within 2 hr. In terms of the cytotoxicity assays, all three assays can be done using one microplate. Thus, in <2 hr, results for metabolic activity, membrane function, and lysosomal activity can be assessed.

Sea Urchin Embryos and Larvae as Biosensors for Neurotoxicants

Functionally active neurotransmitter substances and neurotransmitter receptors are found in early embryos of all vertebrate and invertebrate species studied (reviewed in Buznikov et al., 1996, 2001a). These preneuronal neurotransmitter systems have been studied in detail in sea urchin embryos and larvae, where they play critical roles in morphogenesis. Because neurotransmitter molecules in sea urchin embryos may recapitulate the trophic functions that they exert in mammalian nervous system development, these invertebrates have been used as biosensors for many different neuroactive substances, including pharmaceutical compounds and pesticides (Buznikov, 1990; Falugi, 1993; Buznikov et al., 1997b, 1998, 2001a,b).

The normal features of sea urchin development are well characterized, as are typical developmental malformations caused by a variety of neuroactive compounds (reviewed in Buznikov, 1990; Buznikov et al., 2001b). Therefore, the developmental effects of new pharmaceutical compounds or suspected neurotoxicants can be compared with those previously observed for compounds possessing defined pharmacological, biochemical, or molecular characteristics. In addition, the developmental dynamics of responses can provide clues to the mechanisms underlying teratogenic alterations.

A major advantage of this animal model is the ability to test for developmental defects caused by neuroactive compounds in large, homogeneous populations of staged embryos or larvae (Basic Protocols 1 to 4). The uniform phenotypic response of entire populations allows for the rapid determination of dose-response characteristics of test compounds and the identification of critical periods of vulnerability (Buznikov et al., 2001b). The relative ease and low cost of carrying out these experiments are additional advantages. Basic Protocol 5 and Alternate Protocols 1 to 3 describe methods for analyzing neurotoxicants that affect the cholinergic and serotonergic neurotransmitter systems.

Sea urchins thus provide an inexpensive high-throughput system for determining developmental actions and dose-response characteristics of pharmacologic agents or environmental neurotoxicants in both applied and basic biologic contexts.

MAINTAINING AND HANDLING ADULT SEA URCHINS

BASIC PROTOCOL 1

Adult *Lytechinus variegatus* sea urchins are available from Duke University Marine Laboratory and from private suppliers. *Strongylocentrotus droebachiensis* sea urchins can be collected by trawling or using SCUBA. Both species should be maintained at 0° to 4°C during transportation. They can then be kept on their normal food (seaweed) in aquaria with continuously flowing natural sea water (NSW) or circulating and filtered artificial sea water (ASW; see recipe), which is also available commercially (e.g., Instant Ocean; Aquarium Systems), up to a salinity of 3.30% at the appropriate temperature for that species (8° to 10°C, *S. droebachiensis;* 20° to 22°C, *L. variegatus*). Calcium-free artificial sea water (CFASW; see recipe) is used for some experiments. If seaweed is unavailable, artificial food can be used (see Internet Resources).

NOTE: Adult sea urchins can start to spawn spontaneously or because of unfavorable conditions (such as a sharp increase in temperature). The spawning of a single specimen can evoke spawning of many adults in an aquarium, making the entire group unusable. The first sign of spontaneous spawning is the typical appearance of turbidity in the water of the aquarium. It is necessary to rinse all animals quickly with deionized water and to transfer them to another aquarium with fresh ASW (or filtered NSW). Washing with deionized water is also helpful after long-distance transportation of animals.

Current Protocols in Toxicology (2003) 1.6.1-1.6.24

BASIC PROTOCOL 2

HARVESTING SEA URCHIN GAMETES

Injection of 0.55 mM KCl is used both to determine sex and ripeness of gametes and to harvest gametes. KCl (~0.2 to 0.5 ml) is injected using a 1-ml syringe with a 22-G needle via the peristome wall or through one of the gonopores of an adult sea urchin. After injection, a ripe urchin will begin to release gametes (white sperm or yellowish eggs; other sea urchin species can have eggs of a different color) through the gonopores. Males releasing sperm are inverted with the aboral side (i.e., the upper or gonopores side) down over a Petri dish in order to collect dry sperm. Dry sperm are collected in microcentrifuge tubes and can be stored at 2° to 4°C for 2 to 3 days. Ripe females are inverted over a 50-ml glass beaker containing artificial sea water (ASW; see recipe) for 10 to 15 min with the gonopores contacting the ASW surface. The egg suspension is then filtered via a nylon net for cleaning and elimination of jelly coats. After filtration, eggs are washed twice in ASW and resuspended. Depending on the species, eggs should be fertilized immediately (*L. variegatus*) or the egg suspension can be stored for 12 to 24 hr at 2° to 4°C (*S. droebachiensis*). Adult animals can be returned to aquaria with adequate seaweed or other food and may become ripe again after 3 to 4 weeks. Animals that have undergone gamete collection should be kept in separate aquaria from ripe adults.

NOTE: It is possible to obtain up to 3 to 4 ml packed eggs, embryos, or larvae from one female of *L. variegatus* or up to 10 to 20 ml from *S. droebachiensis*. If a large volume of material is necessary, the eggs from several females must be combined. It is better, however, to work with fully homogenous material, using for corresponding experiments other sea urchin species such as *S. franciscanus* (North Pacific) or *Echinus esculentus* (North Atlantic), which each produce up to 50 to 100 ml of packed eggs from one female. For some experiments, *S. purpuratus* is recommended, as was used for the sea urchin genome project (Cameron et al., 2000).

BASIC PROTOCOL 3

FERTILIZING AND INCUBATING SEA URCHIN EGGS

Fertilization and the incubation of fertilized eggs should be carried out under optimal temperature conditions (as for adult animals of a given species). One drop (~20 µl) of dry sperm (see Basic Protocol 2) is diluted in 5 ml ASW and is mixed with eggs (0.1 to 0.2 ml sperm per 100 ml dense egg suspension; see Basic Protocol 2). After 1 to 2 min, the suspension is diluted 10- to 20-fold with ASW (see recipe), and after the eggs settle, the ASW is changed. This washing is repeated two to three times. Embryos are incubated in ASW with continuous gentle agitation using a Nutator (Fisher) or small electromotor (~60 rpm). The optimal density of embryos or larvae in this suspension should not exceed 10,000 to 40,000 specimens/ml. Sea urchins will develop under such conditions up to the larval stage mid-pluteus 2 (i.e., the onset of active feeding).

BASIC PROTOCOL 4

EMBRYONIC AND LARVAL DEVELOPMENT OF SEA URCHINS

Normal development of sea urchins has been described in many monographs, papers, and web sites (Harvey, 1956; Stephens, 1972; Czihak, 1975; also see Internet Resources). Here the authors present the original table of the stages of sea urchin development as published by Buznikov and Podmarev (1990), with some modifications (Table 1.6.1; Figs. 1.6.1-1.6.3). In Table 1.6.2, the authors present a schedule of development for both *S. droebachiensis* and *L. variegatus*, including a method of staging embryos in dimensionless units (first described by Dettlaff and Dettlaff, 1961). This allows direct developmental comparisons to be made across sea urchin species.

The first external sign of successful fertilization (see Basic Protocol 3) is the separation of the so-called fertilization envelope from the egg surface and the formation of the

[a]One dimensionless unit (τ_0; Dettlaff and Dettlaff, 1961) is equal to the duration of the second cell cycle after fertilization for a given species and temperature of incubation (in this case 2 hr 00 min for *S. droebachiensis*, 8°C and 35 min for *L.variegatus*, 21°C). NA, not applicable; ND, not determined.

perivitelline space. This process begins on the surface of the egg at the point of sperm entry and spreads over the entire surface. Separation of the fertilization envelope is completed at stage 1a (Table 1.6.2 and Fig. 1.6.1). The number of successfully fertilized eggs must be 98% to 100%. Otherwise, the original quality of the eggs or sperm, composition of the ASW, or fertilization procedure is likely to be at fault, and the batch of eggs must be discarded. Also, the percent of polyspermic eggs should not be more than 0.2% to 0.5%. Usual signs of polyspermy are formation of multinuclear, uncleaved eggs or precocious and nonregular cleavage divisions, most often with simultaneous formation of three blastomeres.

Spontaneous malformations arising immediately after the midblastula stage (i.e., before or during gastrulation) are signs of larvae that are of poor quality, ASW that has not been properly made, hypoxia, or other problems. The most common malformations are exogastrulation, total inhibition of gastrulation (with embryos remaining as blastulae, often with multilayer walls), and underdevelopment of the archenteron during gastrulation.

Dimensionless units of sea urchin development

Theoretically, embryos and larvae of all sea urchin species can be used for testing of neurochemicals. However, some species (*Arbacia lixula* and possibly *A. punctulata*) are much more sensitive than other species to certain neurotransmitter receptor antagonists (and are therefore not discussed in our protocols). All information about sea urchin development is applicable not only to *S. droebachiensis* and *L. variegatus* but also to other sea urchin species that are grown at optimal temperatures, if dimensionless units of development are calculated (Dettlaff and Dettlaff, 1961). This is done by determining the duration of the second cell cycle (cleavage division) for the optimal temperature for that species and using this value as a dimensionless (biological) unit (τ_0) for the conversion of the time schedule of development (Table 1.6.2). Using this method, the authors have found that the age of embryos and larvae from several different sea urchin species, when expressed in dimensionless units, is practically the same for a given stage of development. For example, for *S. droebachiensis* and *L. variegatus*, mid-blastula 2 stage (stage 11) occurs at 15 τ_0, early gastrula 1 stage (stage 14) occurs at 22 to 23 τ_0, and late gastrula 2 stage (stage 19) occurs at 34 to 36 τ_0.

PROTOCOLS FOR TESTING NEUROTOXICANTS

The following set of protocols uses sea urchin embryos or larvae to test the effects of various classes of neurotoxicants. They also incorporate methods for assessing potential rescue compounds.

CAUTION: All of the compounds used in these assays, but especially chlorpyrifos (cpf), nicotine, D-tubocurarine, and phorbol-12-myristate-13-acetate (PMA), are toxic and should be handled with caution. Avoid inhalation and dermal exposure. Dispose of waste materials in an appropriate approved manner.

BASIC PROTOCOL 5

Testing of Chlorpyrifos on Sea Urchin Embryos and Larvae

Chlorpyrifos (*O*,*O*-diethyl *O*-3,5,6-trichloro-2-pyridyl phosphorothioate; cpf) is one of the most widely used organophosphate pesticides. It can be an environmental pollutant because of its stability and persistence. Cpf acts as a developmental toxin in embryos and larvae of sea urchins and similarly has adverse effects on mammalian neurodevelopment (Slotkin, 1999; Buznikov et al., 2001b). Its specific actions depend on the stage of development, which corresponds to the expression of particular genes of the embryonic genome, and the consequent participation of acetylcholine as a trophic modulator. The sea urchin model system is suitable for both detailed investigations of stage-dependent actions of cpf and the isolation of its underlying mechanisms (e.g., intracellular signaling cascades), as well as the search for compounds capable of rescuing the developmental phenotype. The cpf protocol also provides a method for step-by-step testing of developmental effects of other neurochemicals and suspected environmental neurotoxicants.

Materials

Sea urchin embryos and larvae, stages 1a or 1b, 3 or 4, 10, 11, 13 (Tables 1.6.1 and 1.6.2; Figs. 1.6.1 and 1.6.2; see Basic Protocol 4)

ASW (see recipe) or commercially available artificial sea water (e.g., Instant Ocean; Aquarium Systems)

20 mM chlorpyrifos (cpf; Chem Service) in 100% (v/v) methanol, store up to 1 to 2 weeks at −20°C

Potential rescue compound, such as the polyenoic fatty acid derivatives (see recipe) dimethylaminoethyl arachidonate (AA-DMAE) and dimethylaminoethyl docosahexaenoate (DHA-DMAE), or other substance of interest

Digital imaging system, including microscope (e.g., Leica), digital color videocamera (e.g., Spot RT; Diagnostic Instruments), and computer with appropriate software

12- or 24-well tissue culture plates

1. Prepare a homogeneous suspension of ~1000 sea urchin embryos or larvae/ml ASW and determine their quality and stage of development using a digital imaging system.

   Alternatively, filtered natural sea water (NSW) can be used to prepare the suspension of embryos or larvae.

2. Place 200 or 100 µl suspension into each well of a 12- or 24-well tissue culture plate, respectively, and add ASW to a final volume of 2 or 1 ml.

   The suspension must be mixed continuously prior to plating, otherwise the final density of specimens (which should be ~100 specimens/ml) will differ between wells, and the effects of test compounds will be variable. The sensitivity of embryos or larvae to cpf, as well as to other neurotransmitter-related substances, decreases sharply when the density is too high (≥250 to 500 specimens/ml).

   For each test compound concentration to be tested, one to three wells of specimens should be prepared. Sufficient wells should also be prepared for controls (step 4).

3. Dilute 20 mM cpf in ASW to the necessary concentrations. Prepare dilutions of a potential rescue compound or other substance in ASW.

   Standard cpf concentrations are 50, 100, 200, and 400 µM. Higher or lower concentrations may be needed depending on the goals of the experiment. Useful concentrations for potential rescue compounds or other substances must be determined empirically; 200 or 400 µM is generally an appropriate starting point.

   Other substances may be used in the assay that can strengthen the effects of cpf or that may prove to have no effect.

4. Transfer 0.2 ml or 0.1 ml dilute neurotoxicant solution (with and without the potential rescue compound or other substance) to the appropriate wells of the 12- or 24-well plate, respectively. Carefully agitate the plates to distribute the neurotoxicant and incubate at the appropriate temperature.

   To reveal possible side effects, the following controls should be included: ASW with the corresponding concentration of methanol (i.e., the vehicle for cpf), ASW with the corresponding concentration of vehicle for the rescue compound, and rescue compound without cpf. If undesirable effects of the vehicles or rescue compound are found, concentrations should be adjusted and re-examined.

   L. variegatus embryos and larvae are incubated at room temperature; S. droebachiensis embryos and larvae are incubated at 8° to 10°C.

   Further shaking or agitation of the multiwell plate during the experiment is not necessary.

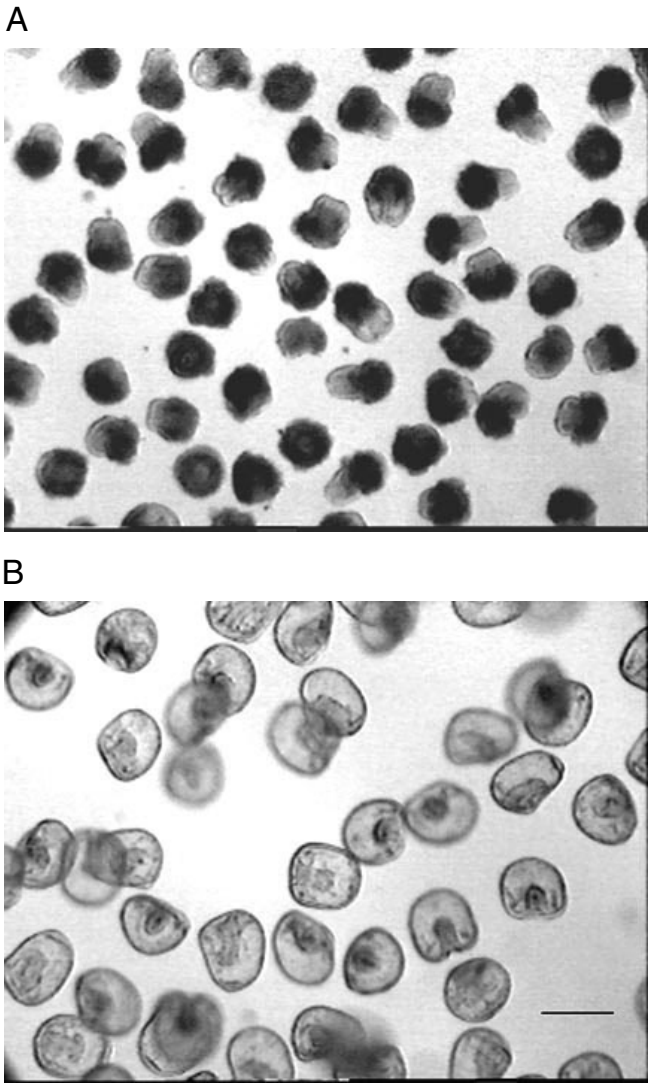

Figure 1.6.4 Effects of chlorpyrifos (cpf) introduced at stage 11 (25 hr 30 min after fertilization, 10°C or 30 hr 00 min, 8°C) on development of the sea urchin, *S. droebachiensis*. (**A**) Mushroom-like (defect III) larvae after exposure to 20 μM cpf. (**B**) Practically normal (defect 0) larvae (stage 20) after exposure to 0.5 μM cpf. They are similar to controls, but with a small retardation in development. Imaging was done 62 hr after fertilization (10°C). Scale bar, 200 μm. Modified from Buznikov et al., 2001b.

5. View and record the development of treated and control embryos and/or larvae using the digital imaging system at appropriate time intervals. Collect images until the treated embryos or larvae display maximal abnormal phenotypes or control larvae reach the mid-pluteus 1 stage.

   L. variegatus should be viewed 2 to 4 hr after the neurotoxicant has been added; S. droebachiensis should be viewed after 4 to 8 hr. Embryos and larvae should then be viewed at 2- to 4-hr intervals (or longer) until the end of the experiment.

   Each well should be imaged at low (40×) magnification; only after this should representative specimens be selected for imaging at higher magnifications (100 or 200×). Otherwise, the final results may be biased.

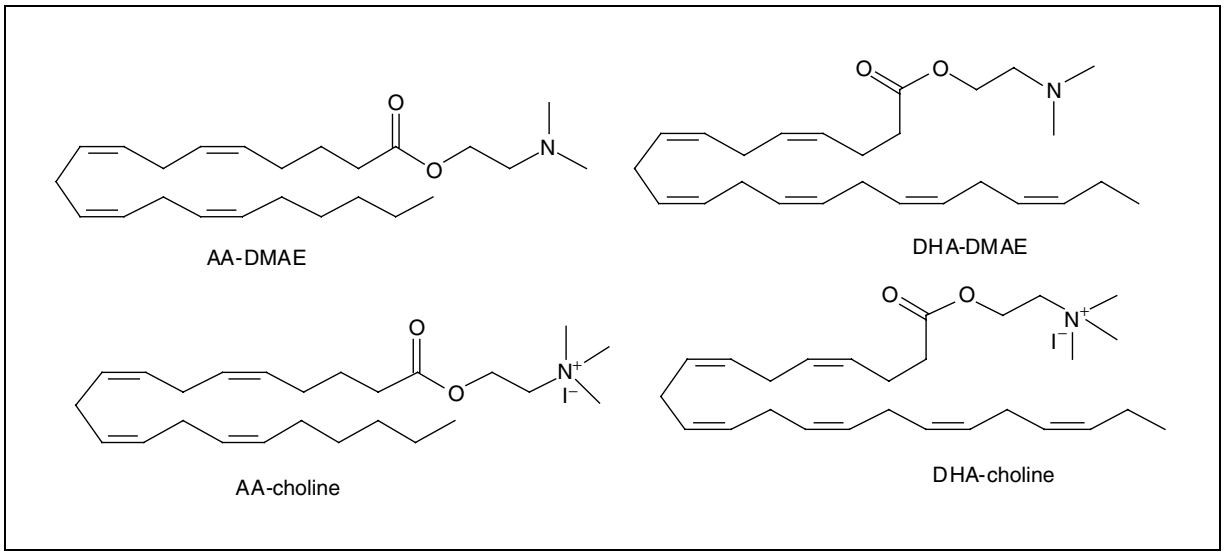

Figure 1.6.5 Structure of the choline and dimethylaminoethyl esters of polyenoic fatty acid. Abbreviations: AA-choline, arachidonoylcholine; AA-DMAE, dimethylaminoethyl arachidonate; DHA-choline, docosahexaenoylcholine; DHA-DMAE, dimethylaminoethyl docosahexaenoate.

For routine work, cpf concentrations that produce a given phenotype for 100% of treated embryos or larvae in experimental wells should be used (Fig. 1.6.5).

6. Compare images of treated and control embryos and/or larvae (Figs. 1.6.1-1.6.4; Table 1.6.1). Determine from which developmental stage cpf started to disturb development. Characterize malformations and protective actions, if any, of the rescue compound.

   The recorded images must be comparable. If it is necessary to digitize many different variants simultaneously, development can be stopped by adding a few drops of 1% (v/v) formaldehyde in ASW to the wells.

Testing of L-Nicotine on Sea Urchin Embryos and Larvae

ALTERNATE PROTOCOL 1

L-nicotine, the addictive substance in tobacco, acts as a cholinergic neurotoxicant affecting mammalian brain development (Slotkin, 1998, 1999) and similarly affects morphogenesis in sea urchin larvae (Buznikov et al., 1998, 2001c). The comparison of its action with the effects of chlorpyrifos (cpf) is interesting and demonstrates some additional peculiarities of the biosensor under consideration. This action presumably occurs through activation of nicotinic acetylcholine receptors, nAChRs (Falugi, 1993; Buznikov et al., 1997b; Ivonnet and Chambers, 1997). The sensitivity of sea urchin embryos and larvae to L-nicotine is moderate but may be enhanced or altered by manipulating intracellular signaling cascades downstream from nAChR activation, with such compounds as phorbol 12-myristate 13-acetate (PMA), a protein kinase C activator. The search for compounds capable of rescuing the developmental phenotype after L-nicotine treatment is similar to that used for cpf, although the spectrum of effects for L-nicotine is not identical for the two compounds, which probably reflects noncholinergic effects of cpf that are not shared by nicotine, a direct cholinergic agonist (Slotkin, 1998, 1999). Experiments with L-nicotine provide some additional information related to nAChRs of sea urchin embryos and larvae and, therefore, the role of preneuronal and/or non-neuronal cholinergic systems in regulating events of early development.

Additional Materials *(also see Basic Protocol 5)*

20 mM L-nicotine bitartrate in 100% (v/v) methanol, store in dark up to 1 to 2 weeks at 4°C

Potential rescue compound, such as:

20 mM D-tubocurarine chloride (Sigma), store up to 1 week at −20°C

20 mM imechine (Latoxan), store up to 1 to 2 weeks at 4°C

20 mM QX-222 (Astra Pharmaceuticals), store up to 1 to 2 weeks at 4°C

20 mM 1-(5-isoquinolinesulfonyl)-2-methylpiperazine) (H-7; Sigma), store for several days at −20°C

CFASW (see recipe)

2 mM PMA (see recipe)

1. Set up sea urchin embryos or larvae in appropriate tissue culture plates as described (see Basic Protocol 5, steps 1 and 2).

2. Dilute 20 mM L-nicotine and a potential rescue compound in CFASW or ASW. Prepare a 0.01 to 0.2 µM PMA solution (Buznikov et al., 1998) in CFASW or ASW.

   Standard L-nicotine concentrations are 500, 1000, and 2000 µM. Higher or lower concentrations may be needed depending on the goals of the experiment. Nicotine solutions should be stored in the refrigerator with aluminum foil around the bottle, because the compound is subject to oxidation that is promoted by light and heat. Useful concentrations for potential rescue compounds or other substances must be determined empirically; 200 or 400 µM is generally an appropriate starting point.

   Other substances may be used in the assay that can strengthen the effects of nicotine or that may prove to have no effect.

   Phorbol 12-myristate 13-acetate (PMA), an activator of protein kinase C, enhances and alters the developmental effects of L-nicotine. Cleaving sea urchin embryos completely or partly lose their sensitivity to L-nicotine with PMA when incubated in CFASW (Buznikov et al., 1997b, 1998).

   When CFASW is used as the incubation medium, the eggs must be fertilized in ASW, as usual, and washed with CFASW three to four times before their transfer to CFASW. Such incubation is possible during cleavage divisions and blastulation only; it disturbs later development.

3. Expose the specimens to L-nicotine (with and without PMA) and the potential rescue compound and analyze the effects as described (see Basic Protocol 5, steps 4 to 6).

   When the embryos or larvae are treated with the mixture L-nicotine in the presence of PMA, developmental malformations occur and reach a maximum very quickly. Therefore, viewing and digitization must be started earlier (1 to 2 hr after compound exposure for L. variegatus or 2 to 4 hr for S. droebachiensis) and must be carried out more often (every 1 to 2 hr up to the end of the experiment).

ALTERNATE PROTOCOL 2

Testing of Arachidonoylcholine and Docosahexaenoylcholine on Sea Urchin Embryos and Larvae

Arachidonoylcholine (AA-choline) and docosahexaenoylcholine (DHA-choline; Fig. 1.6.5) act on embryonic and larval development of sea urchins as lipophilic agonists of nAChRs (i.e., they can penetrate cells to stimulate intracellular receptors). In addition, they have a noncholinergic component of teratogenic activity that may reflect actions on intracellular signaling cascades rather than on the nAChRs themselves (Bezuglov et al., 2001).

Additional Materials *(also see Basic Protocol 5)*

Polyenoic fatty acid derivatives (see recipe), including:
Arachidonoylcholine (AA-choline)
Docosahexaenoylcholine (DHA-choline)

1. Set up sea urchin embryos or larvae in appropriate tissue culture plates as described (see Basic Protocol 5, steps 1 and 2).
2. Dilute AA-choline and DHA-choline and a potential rescue compound (e.g., AA-DMAE and DHA-DMAE) in CFASW or ASW.

   Standard AA-choline and DHA-choline concentrations are 50, 100, 200, and 400 μM. Higher or lower concentrations may be needed depending on the goals of the experiment.

   The polyenoic fatty acid derivatives dimethylaminoethyl arachidonate (AA-DMAE) and dimethylaminoethyl docosahexaenoate (DHA-DMAE) rescue the effects of AA-choline. Useful concentrations for potential rescue compounds must be determined empirically; 200 or 400 μM is generally an appropriate starting point.

   Cleaving sea urchin embryos completely or partly lose their sensitivity to AA-choline and DHA-choline when incubated in CFASW. When CFASW is used as the incubation medium, the eggs must be fertilized in ASW, as usual, and washed with CFASW three to four times before their transfer to CFASW. Such incubation is possible during cleavage divisions and blastulation only; it disturbs later development.
3. Expose the specimens to AA-choline and DHA-choline and the potential rescue compound and analyze the effects as described (see Basic Protocol 5, steps 4 to 6).

Testing of Ritanserin on Sea Urchin Embryos and Larvae

ALTERNATE PROTOCOL 3

Acetylcholine is by no means the only neurotransmitter that modulates development of sea urchin embryos and larvae. For instance, the biogenic amines (serotonin [5-HT] and catecholamines) all play critical roles in proper morphogenesis (Buznikov, 1990; Buznikov et al., 2001a). Accordingly, the sea urchin model system is suitable for testing and studying different neurochemicals, including many ligands for biogenic amine receptors (Buznikov, 1990). Ritanserin, a pan-5-HT_2 receptor antagonist, was selected for this protocol because of its ability to cause very typical and reproducible concentration-dependent malformations.

Additional Materials *(also see Basic Protocol 5)*

20 mM ritanserin (Sigma) in methanol, store up to 2 days at 20°C
20 mM serotonin hydrochloride (5-HT), store in dark up to 24 hr at 4°C
Polyenoic fatty acid derivatives (see recipe), such as the following serotonin agonists:
Serotonamide of arachidonic acid (arachidonoyl serotonin; AA-5-HT)
Serotonamide of docosahexaenoic acid (DHA-5-HT)
Serotonamide of eicosapentaenoic acid (EPA-5-HT)

1. Set up sea urchin embryos or larvae in appropriate tissue culture plates as described (see Basic Protocol 5, steps 1 and 2).
2. Dilute 20 mM ritanserin in ASW. Prepare 400-μM solutions of 5-HT and other serotonin agonists in ASW.

   Standard ritanserin concentrations are 25, 50, 100, and 200 μM. Higher or lower concentrations may be needed depending on the goals of the experiment.

   In this experiment, serotonin agonists function to rescue ritanserin's effects.
3. Expose the specimens to ritanserin (with and without serotonin agonists) and analyze the effects as described (see Basic Protocol 5, steps 4 to 6).

REAGENTS AND SOLUTIONS

Use distilled or deionized water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Artificial sea water (ASW)

To 0.3 to 0.4 liter H_2O add:
26.05 g NaCl (445 mM final)
5 g $MgCl_2 \cdot 6H_2O$ (24.6 mM final)
4.46 g $MgSO_4 \cdot 7H_2O$ (18.1 mM final)
0.67 g KCl (9.2 mM final)
0.198 g $NaHCO_3$ (2.36 mM final)
1.27 g $CaCl_2$ (11.5 mM final)
Add H_2O to 1 liter
Adjust pH to 7.5 with 1 N NaOH
Store indefinitely at room temperature

There are other ASW recipes, but the authors have used this composition for many years with good results. The authors use ASW for fertilization and incubation of fertilized eggs, embryos, and larvae, whereas Instant Ocean (Aquarium Systems) is routinely used to maintain adults in aquaria.

Depending on the sea urchin species that is used, the ASW should be prewarmed or precooled if necessary.

A second method for preparing ASW from stock solutions follows. Stock solutions can be stored indefinitely at room temperature. The pH adjustment and storage conditions are as described above.

Stock solutions	*For 1 liter ASW*
776 g/liter $MgCl_2 \cdot 6H_2O$	6.5 ml
446 g/liter $MgSO_4 \cdot 7H_2O$	10 ml
276 g/liter KCl	5 ml
39.7 g/liter $NaHCO_3$	5 ml
285.2 g/liter $CaCl_2$	5 ml
	26.05 g NaCl

Calcium-free artificial sea water (CFASW)

Dissolve 380.1 mg ethylene glycol bis(β-aminoethylether)-*N*,*N*,*N′*,*N′*-tetraacetic acid (EGTA) in 12.5 ml distilled or deionized water (1 mM final) and add this solution to 300 to 400 ml water. Dissolve 26.05 g NaCl (445 mM final) in this mixture. Add stock solution volumes for remaining compounds except $CaCl_2$ as described for ASW (see recipe). Add water to 1 liter. Adjust the pH to 7.5 with 1 N HCl. Store indefinitely at room temperature.

There are other CFASW recipes in which the elimination of $CaCl_2$ is compensated for by a corresponding increase in the concentration of magnesium salts.

Depending on the sea urchin species that is used, the CFASW should be prewarmed or precooled if necessary.

Phorbol 12-myristate 13-acetate (PMA), 2 mM

Add 0.81 ml dimethyl sulfoxide or 100% (v/v) ethanol to 1 mg PMA and vortex. Store protected from light up to 1 to 2 months at −20°C.

Polyenoic fatty acid derivatives

These compounds are synthesized by V.V. Bezuglov and his collaborators at the Laboratory of Oxylipins, Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry, Russian Academy of Sciences (117997, Moscow, Russia) as solutions in 100% (v/v) ethanol (10, 20, or 50 mg/ml [w/v]). Store up to 1 to 2 years protected from

continued

light in ampules under argon at −20°C. If the solutions are not colorless and transparent, they are degraded. Make fresh intermediate solutions in ASW (see recipe) or CFASW (see recipe) daily. Arachidonyl serotonin (AA-5-HT) is now commercially available from Cayman Chemical.

COMMENTARY

Background Information

Sea urchin embryos and larvae can be used as cost-effective biosensors for rapid, high-throughput screening of environmental neurotoxicants and other neurodevelopmental disruptors as well as heavy metals, detergents, metabolic poisons, cytotoxic and tumorigenic compounds, and disruptors of the cytoskeleton (Dinnel et al., 1989; Buznikov et al., 1997a; Bottger and McClintock, 2001). They can be used to study the mechanisms underlying the effects of these compounds as well as critical periods of vulnerability (reviewed in Buznikov, 1990). Stage-dependent morphological malformations evoked by given doses of a test compound can be contrasted with the known effects of previously studied compounds targeting specific neurotransmitter systems, thereby providing a comparative framework for prospective identification of parallel, vulnerable pathways in the developing mammalian nervous system. The investigation of corresponding substances that provide protection or rescue from adverse effects is equally important for two reasons. First, this information can be useful to corroborate conclusions about specific mechanisms, receptors, or signaling pathways involved in the adverse developmental effects. Second, it can indicate directions for potential therapeutic interventions that might avoid adverse effects after exposure or provide guidance for strategies that can reverse the effects so as to normalize developmental parameters. In addition, identification of the effects of neurotoxicants on defined receptor or signaling targets can also be used to identify the processes underlying neurotrophic control of embryonic development, which may then be translated to study equivalent neurotrophic processes in the mammalian brain. In that way, studies in sea urchins can point the way to acquiring new information about mammalian brain development as well as its vulnerability to neurotoxicants.

Experiments with chlorpyrifos (cpf), L-nicotine, arachidonoylcholine (AA-choline), docosahexaenoylcholine (DHA-choline), and ritanserin provide good examples of studies of the effects of different neurotoxicants (including those with an environmental context) using the sea urchin model. These studies demonstrate that cpf and nicotine, when introduced immediately after fertilization, and even at high concentrations (≤200 μM), do not disturb early embryonic development (blastulation; see Anticipated Results and Fig. 1.6.7). Later, from the midblastula 1 to early gastrula 1 stages (Figs. 1.6.4, 1.6.6, and 1.6.8; stages 10 to 14 of Table 1.6.1), cpf at 1 to 40 μM or L-nicotine at 50 to 200 μM causes dose-dependent developmental malformations. In the case of cpf, many cells of different origin (up to ~90% of all embryonic cells) are apparently transformed into an abnormal phenotype and accumulate in the blastocoel. (These disruptions occur with no accompanying increase in cell proliferation.) These transformed cells are extruded from the blastocoel at the animal pole and form an extralarval cluster. In the case of L-nicotine, cells are extruded from the blastocoel at the vegetal pole (i.e., in the opposite direction; Fig. 1.6.8). It is remarkable that moderate concentrations of cpf (2.5 to 5.0 μM) do not evoke the extrusion of transformed cells but can cause outward growth of the primary gut or archenteron (known as exogastrulation) at later stages. In some cases, formation of the extralarval cluster of transformed cells is also followed by exogastrulation (i.e., the normal oriented cell movements towards the animal pole can be changed into movements in the opposite direction; Fig. 1.6.6).

The sensitivity of larvae to cpf decreases during gastrulation and the first postgastrulation stages of development. Although the late developmental dynamics of sensitivity to L-nicotine have not yet been studied, it is clear that the period of maximal sensitivity for both cpf and L-nicotine extends from the end of blastulation to the beginning of gastrulation. This period corresponds to the so-called midblastula transition (MBT) when genomic activity changes significantly (Buznikov et al., 2001b).

Lipophilic cholinergic receptor ligands (AA-choline, DHA-choline) also disturb cleavage divisions (as indicated by formation of multinuclear one-cell embryos followed by cell

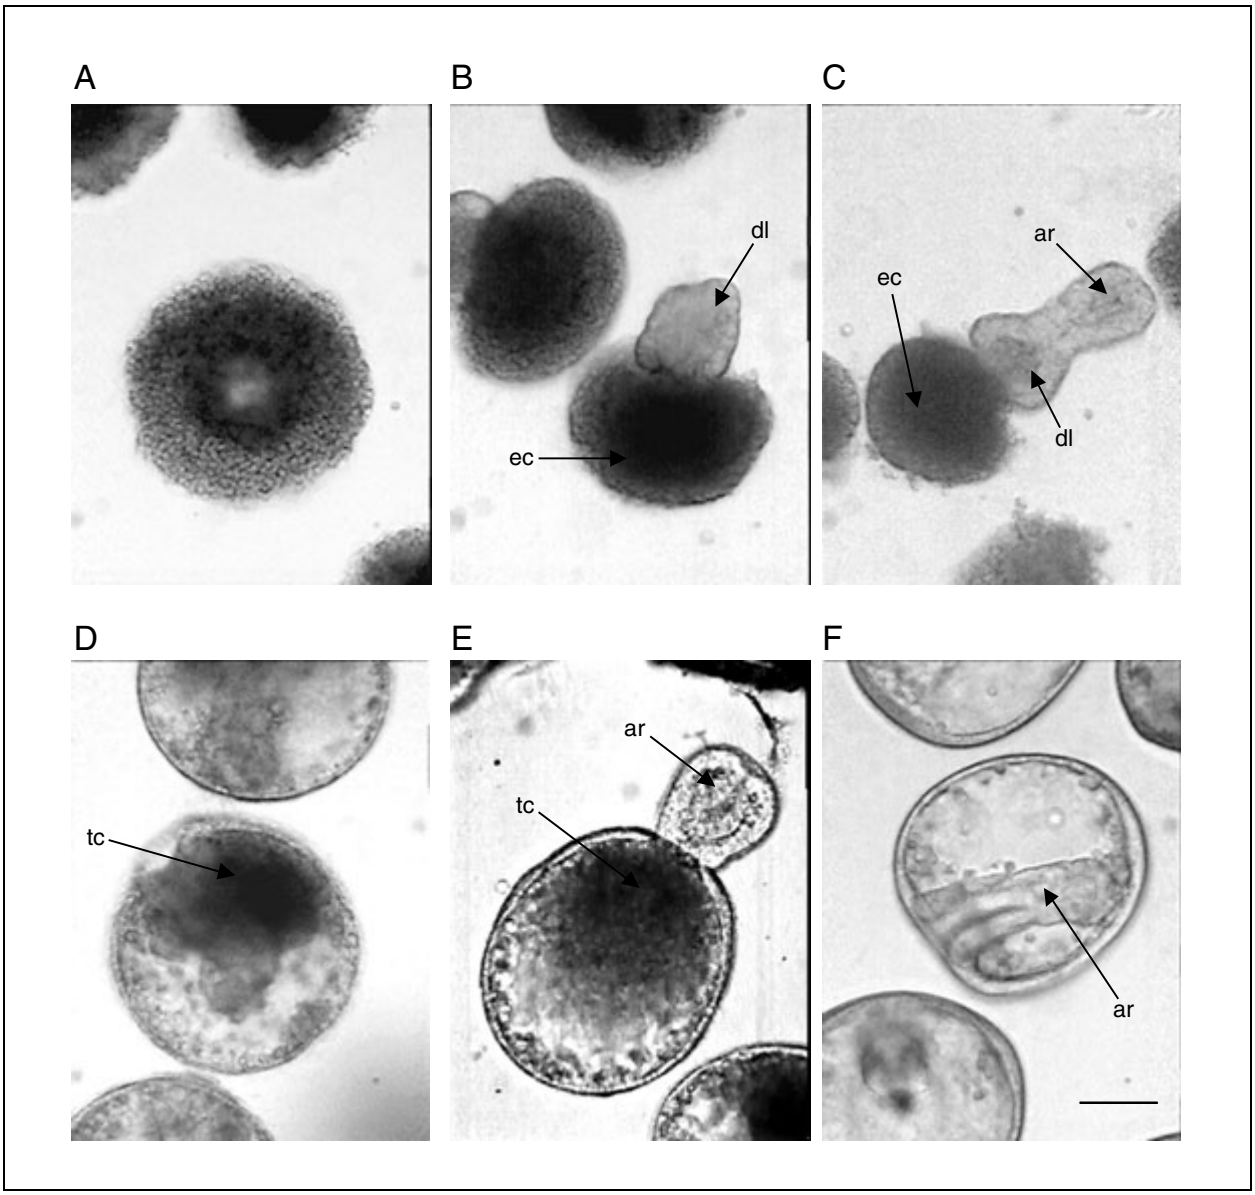

Figure 1.6.6 Effects of chlorpyrifos (cpf) introduced at stage 11 (25 hr 30 min after fertilization, 10°C) on the development of the sea urchin, *S. droebachiensis*. (**A**) Extruded, transformed (pigmented) cells cover the entire surface of larvae (defect IV) after exposure to 40 μM cpf. (**B**) Transformed cells (>50% of all larval cells) form an extralarval cluster (defect III, first phase) after exposure to 20 μM cpf. (**C**) Exogastrulation (defect II, second phase) after exposure to 40 μM cpf. (**D**) Transformed cells accumulate in the blastocoel without extruding (defect I) after exposure to 5 μM cpf. (**E**) Exogastrulation (defect I, second phase) after exposure to 5 μM cpf. (**F**) At stage 19, larvae appear normal after exposure to 40 μM cpf with 40 μM dimethylaminoethyl arachidonate (AA-DMAE). Imaging was done 62 hr after fertilization (A,B,D,F) or 10 hr later (C,E). Abbreviations: dl, dwarf larva; ec, extralarval cell cluster; tr, transformed (pigmented) cells. Scale bar, 50 μm.

(**B**) Control stage 8 (8 hr 45 min after fertilization) specimen. (**C**) Exposure to 40 μM cpf. (**D**) Control stage 10 (22 hr 25 min after fertilization) specimen. (**E**) Mushroom-like larvae after exposure to 40 μM cpf. (**F**) Control stage 20 (64 hr 30 min after fertilization) specimen. Abbreviations: dl, dwarf larva; ec, extralarval cell cluster; tr, transformed (pigmented) cells. Scale bar, 50 μm. Modified from Buznikov et al., 2001b.

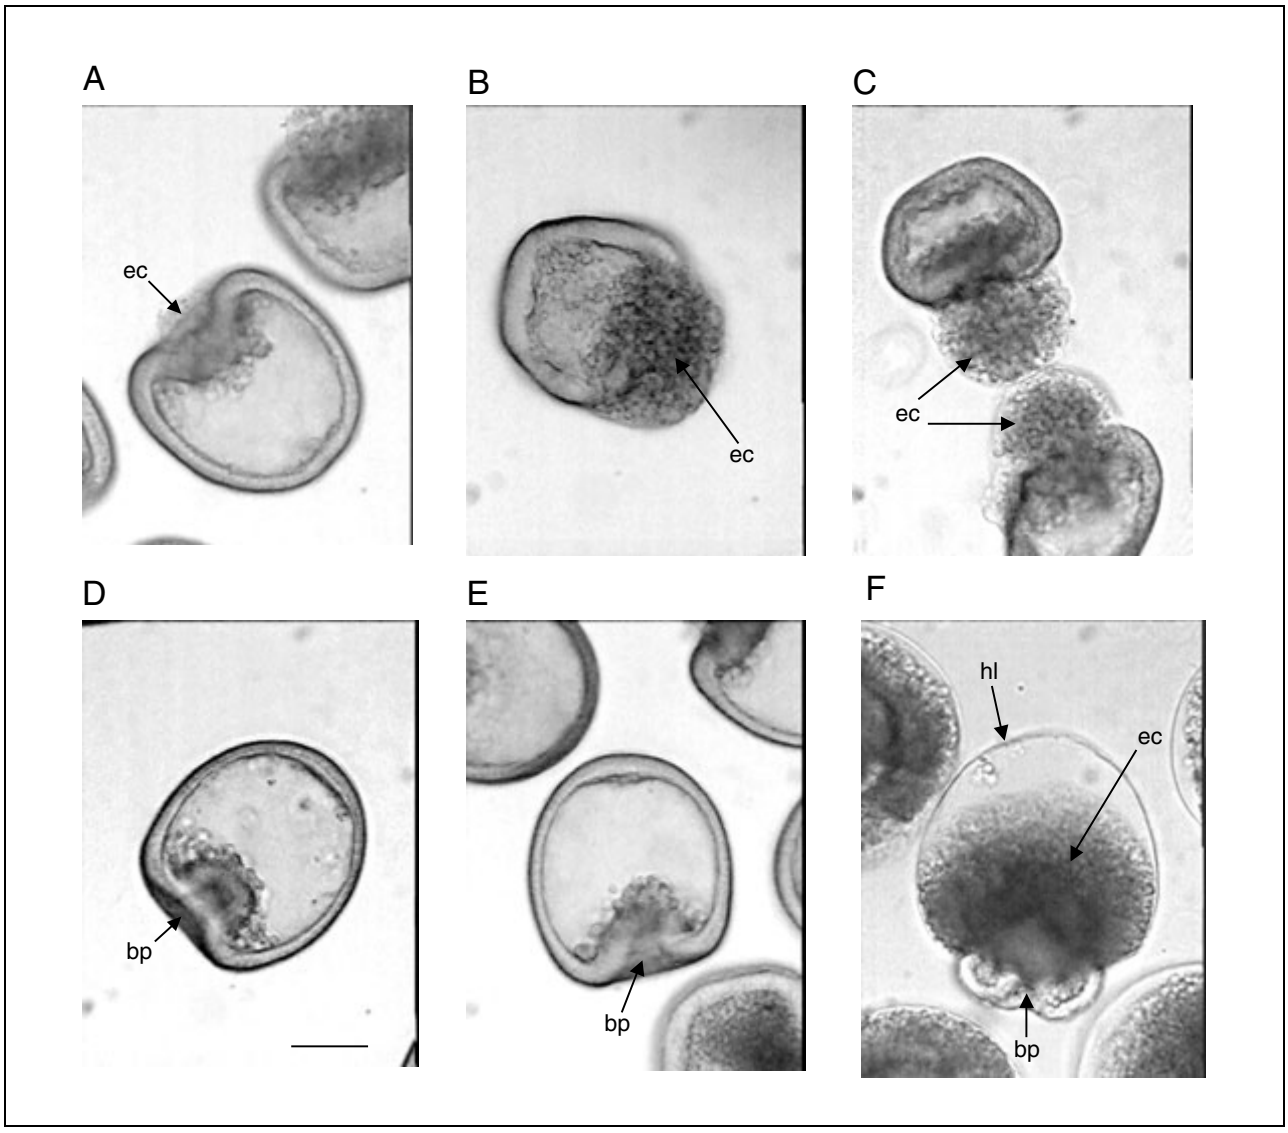

Figure 1.6.8 Effect of L-nicotine introduced at stage 12 (35 hr after fertilization, 8°C) on development of the sea urchin, *S. droebachiensis. (***A**-**C**) Development of extralarval cell cluster near the vegetal pole of larvae after exposure to 200 μM L-nicotine. Imaging was done (A) 47, (B) 51, and (C) 60 hr after fertilization. (**D**) Normal larva at stage 15 (51 hr after fertilization) after exposure to 200 μM L-nicotine and 50 μM imechine. (**E**) Nearly normal larva at stage 15 after exposure to 200 μM L-nicotine and 40 μM dimethylaminoethyl docosahexaenoate (DHA-DMAE). (**F**) Extralarval cell cluster near the animal pole of a larva 60 hr after fertilization following exposure to 50 μM L-nicotine and 0.2 μM phorbol 12-myristate 13-acetate (PMA). Abbreviations: bp, blastopore; ec, extralarval cell cluster; hl, hyaline layer (enfoliated). Scale bar, 50 μm.

lysis; Fig. 1.6.9), but, like nicotine and cpf, the period of maximal sensitivity is the MBT. When these lipophilic choline derivatives are introduced during the MBT, they, like cpf, evoke extrusion of transformed cells and formation of extralarval cell clusters at the animal pole (Fig. 1.6.9).

In keeping with the fact that it acts on a different neurotransmitter, ritanserin, an antagonist of 5-HT_2 receptors, has very different pharmacological characteristics and does not evoke extrusion of transformed cells. Instead, it causes the formation of a multilayered embryonic or larval wall (Fig. 1.6.10). The period of maximal sensitivity to ritanserin does, however, coincide with the MBT, reflecting the fact that different neuromodulators participate together in assembly of the embryo at a critical developmental period.

Developmental malformations evoked by cholinergic ligands can be prevented by antagonists of nicotinic acetylcholine receptors (nAChRs) but not by atropine, an antagonist of muscarinic cholinergic receptors. The most effective antidotes for L-nicotine are D-tubocurarine, imechine, QX-222, and some

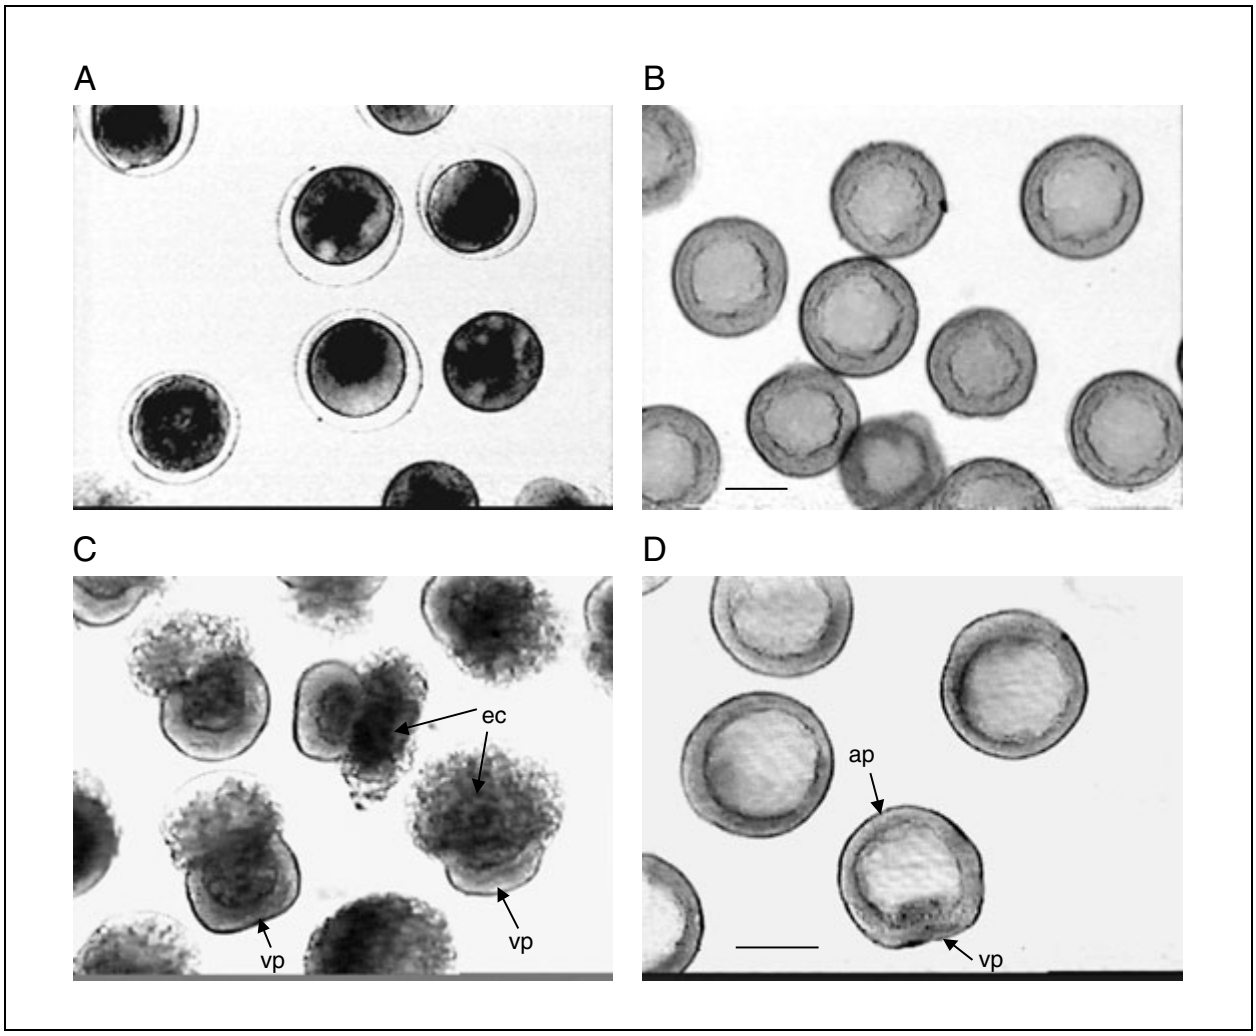

Figure 1.6.9 Effects of 40 μM arachidonoylcholine (AA-choline) on development of the sea urchin, *S. droebachiensis* and protective action of 40 μM dimethylaminoethyl arachidonate (AA-DMAE). (**A**) AA-choline produces one-cell multinuclear embryos, which are beginning to undergo cell lysis. (**B**) AA-choline with AA-DMAE produces normal hatched larvae (stage 11). (**C**) AA-choline produces typical mushroom-like larvae at later stages. (**D**) AA-choline with AA-DMAE produces normal larvae (stages 12 to 13). Substances were introduced at stage 1b (15 min after fertilization; A, B) or at stage 10 (28 hr after fertilization; C,D). Specimens were imaged 3 hr (A) or 27 hr (B) later or 40 hr after fertilization (C,D). Abbreviations: ap, animal pole; ec, extralarval cell cluster; vp, vegetal pole. Scale bars, 50 μm.

other competitive and noncompetitive drugs, especially hydrophilic (quaternary and bisquaternary) compounds. Lipophilic nAChR antagonists such as dimethylaminoethyl arachidonate (AA-DMAE) and dimethylaminoethyl docosahexaenoate (DHA-DMAE) are less effective or ineffective (Buznikov et al., 2001c). Quite the opposite situation exists for cpf and AA-choline, for which AA-DMAE or DHA-DMAE provides full protection (Fig. 1.6.9), compared with only partial or even insignificant protection by hydrophilic nAChR antagonists.

None of the cholinergic antagonists tested prevents the developmental malformations evoked by ritanserin, which acts on 5-HT_2 receptors. All rescue compounds for ritanserin are 5-HT receptor agonists, especially very lipophilic compounds such as serotonamide of arachidonic acid (AA-5-HT), serotonamide of docosahexaenoic acid (DHA-5-HT), and serotonamide of eicosapentaenoic acid (EPA-5-HT; Fig. 1.6.11), which completely rescue the ritanserin phenotype. 5-HT itself (which is hydrophilic) provides only partial protection, however, and the very hydrophilic compound *N,N,N*-trimethylserotonin iodide (5-HTQ) does not protect at all (Fig. 1.6.10). This suggests that putative intracellular 5-HT receptors (or more precisely, functional equivalents of 5-HT receptors) are the targets for all of the substances that rescue the ritanserin phenotype (and apparently for endogenous 5-HT also).

Neurotransmitter receptors ultimately affect gene expression, and hence cell replication and

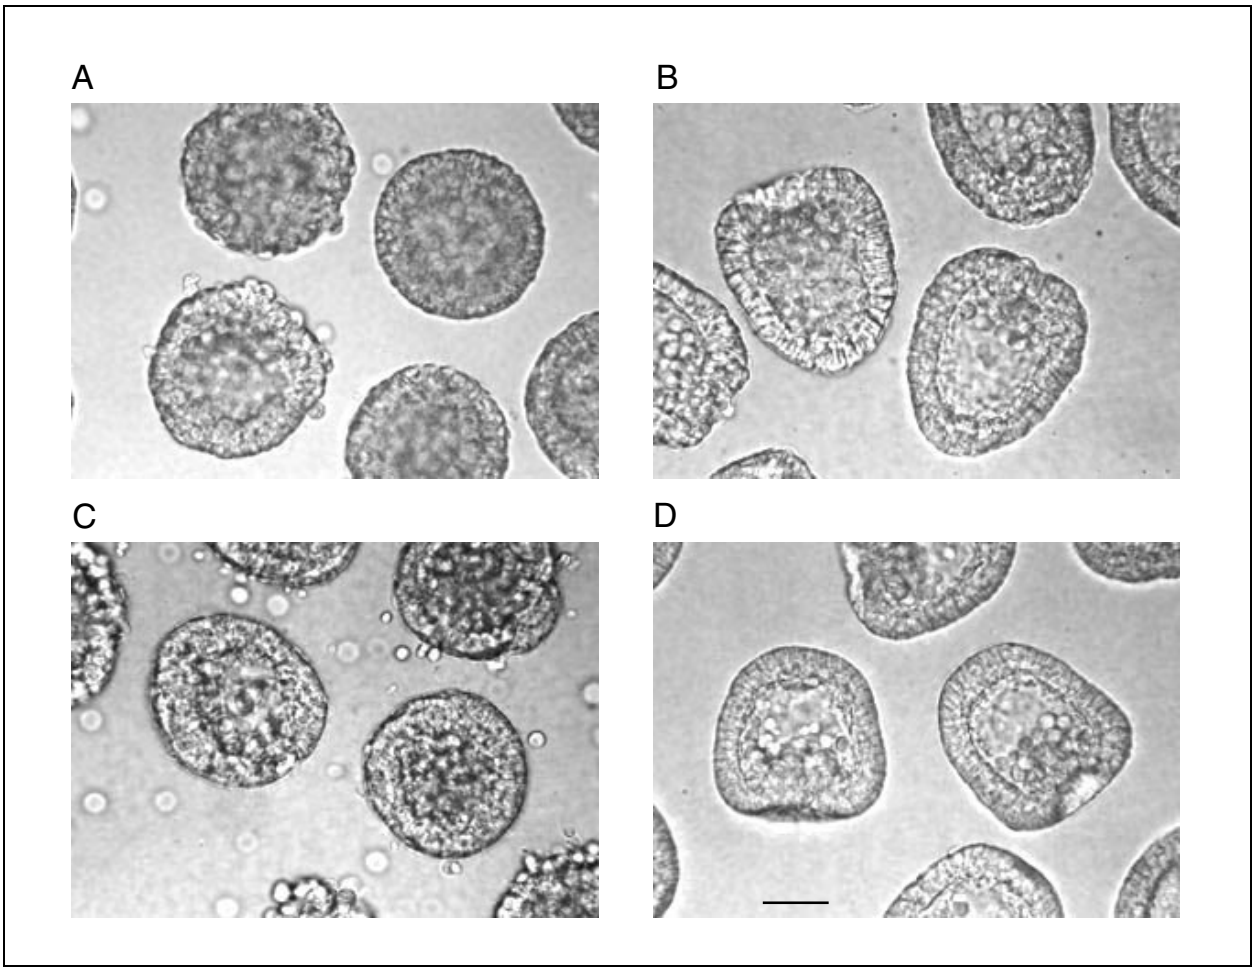

Figure 1.6.10 Effect of ritanserin introduced at stage 11 (9 hr 15 min after fertilization, 21°C) on development of the sea urchin, *L. variegatus*. (**A**) Exposure to 10 μM ritanserin produces blastulae with multilayered cell walls. (**B**) Exposure to 10 μM ritanserin with 40 μM serotonamide of arachidonic acid (AA-5-HT) produces almost normal larvae at stage 15. (**C**) Exposure to 10 μM ritanserin with 40 μM *N,N,N*-trimethylserotonin iodide (5-HTQ) provides no protection. (**D**) Control larvae, stage 15. Imaging was done 15 hr after fertilization. Scale bar, 50 μm.

differentiation, by stimulating or inhibiting the activity of intracellular signaling pathways. Phorbol 12-myristate 13-acetate (PMA; 0.01 to 0.2 μM), an activator of protein kinase C, when introduced together with L-nicotine during the MBT, enhances and alters the reaction of sea urchin larvae to nicotine. The relative number of transformed cells increases sharply, and they are extruded at the animal pole (Fig. 1.6.8) rather than the vegetal pole. In the presence of PMA, cleaving embryos become sensitive to L-nicotine (as seen by the formation of multinuclear one-cell embryos and their quick lysis). The developmental effects of L-nicotine with PMA are very similar to the those of AA-choline, not just morphologically but also pharmacologically (as shown by the complete protective action of AA-DMAE and DHA-DMAE and the incomplete or insignificant protection by D-tubocurarine, imechine, or QX-222). These malformations can be prevented or reduced by 1-(5-isoquinolinesulfonyl)-2-methylpiperazine) (H-7), whereas similar effects of cpf are potentiated by this protein kinase C inhibitor. HA-1004, an inhibitor of protein kinase A, does not affect the sensitivity to any cholinergic neurotoxicants studied. In addition, cleaving sea urchin embryos completely or partly lose their sensitivity to both L-nicotine with PMA and AA-choline when incubated in calcium-free artificial sea water (CFASW). These results provide cogent examples of how the sea urchin model can be used to dissect the intracellular events underlying the mechanisms by which neurotoxicants perturb development. The obvious next step is to pursue the parallel signaling events in the mammalian brain so as to determine if they too reflect actions on these signaling intermediates.

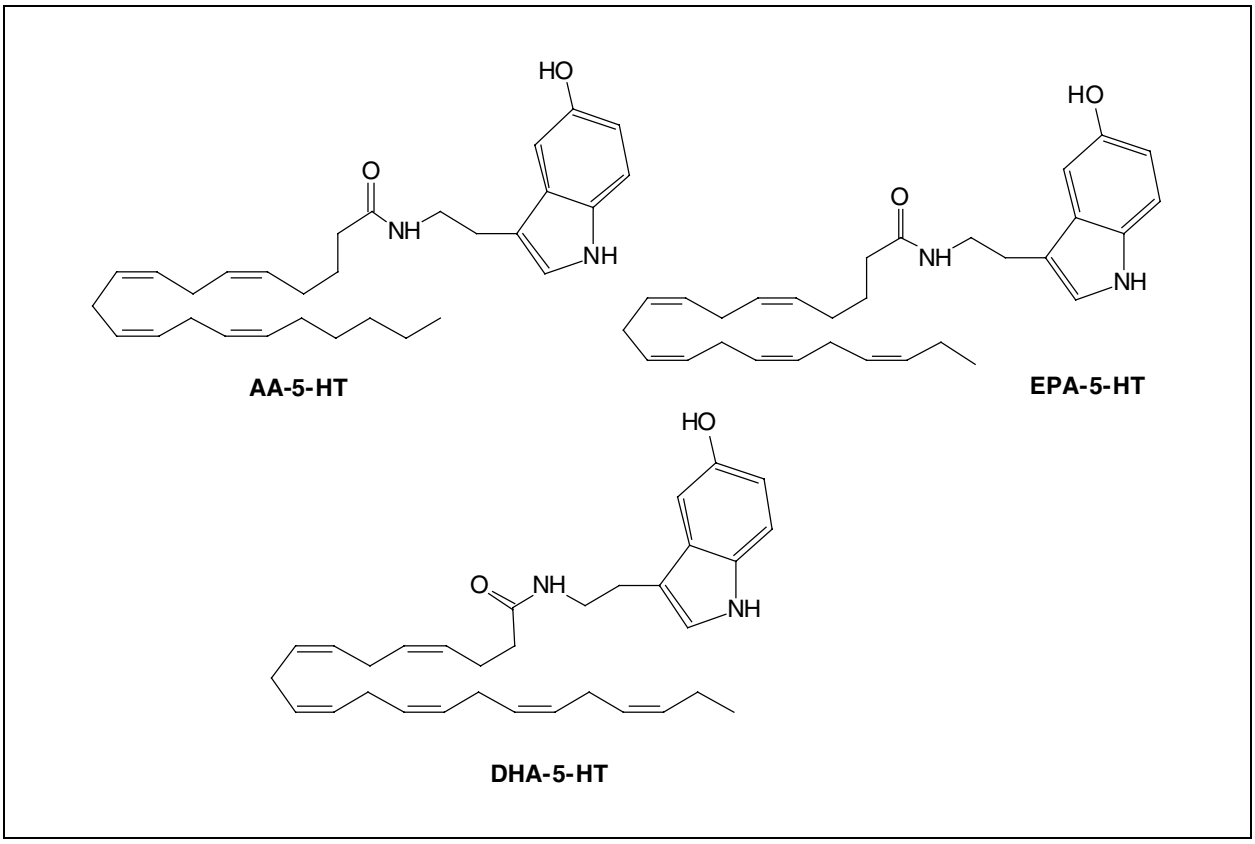

Figure 1.6.11 Structure of serotonamides of polyenoic fatty acid. Abbreviations: AA-5-HT, serotonamide of arachidonic acid; DHA-5-HT, serotonamide of docosahexanoic acid; EPA-5-HT, serotonamide of eicosapentanoic acid.

As another example of how this model helps to explore mechanisms of developmental toxicity, the authors have evaluated the effects of chlorpyrifos-oxon (a metabolite of cpf known to be the active inhibitor of cholinesterase). Unlike cpf itself, cpf-oxon does not perturb sea urchin development (Buznikov et al., 2001b). Therefore, the developmental effects of cpf are not associated with inhibition of cholinesterase activity, and the underlying cholinergic component reflects the actions of cpf itself directed towards nAChRs and their associated signaling pathways. In contrast to the ease with which these conclusions were reached with the sea urchin model, comparable mechanistic conclusions in mammalian models would require extensive evaluations of placental transfer, maternal effects, and systemic toxicity of cpf-oxon, all of which are avoided with the invertebrate model.

Based on these studies, the authors hypothesize that cpf, AA-choline, and DHA-choline have dual (cholinergic and noncholinergic) actions on sea urchin development. In other words, they can act as agonists of nAChRs coupled to L-type Ca^{2+} channels together with signal transduction cascades involving PKC and intracellular Ca^{2+}. Such actions are consistent with the dual effects of cpf on mammalian central nervous system (CNS) development (Slotkin, 1999). nAChRs located at the cell surface are already present at the one-cell stage of sea urchin development and during blastulation (Buznikov et al., 1997b, 1998; Ivonnet and Chambers, 1997); they can be available to some cholinergic ligands that evoke malformations during cleavage divisions (e.g., lipophilic cholines and L-nicotine with PMA). The typical changes in morphogenetic cell movements that occur during the MBT, however, appear to be coincident with rapid changes in expression or function of nAChRs that take place immediately prior to gastrulation. Judging by these morphological and pharmacological data, it appears that cholinergic neurotoxicants may disturb genomic regulatory signals mediated by endogenous acetylcholine during the MBT. Other regulatory signals may be mediated by endogenous 5-HT acting on 5-HT_2 receptors, which are disturbed by ritanserin (Buznikov et al., 2001a). Future studies to test this hypothesis should be very informative.

Invertebrate models such as sea urchin embryos and larvae may ultimately provide us with tools for rapid, high-throughput screening of neurotoxicants that affect mammalian brain development. They may also provide a framework for characterizing the cellular events underlying the neuroteratogenesis of a wide variety of compounds and environmental agents that converge on neurotrophic signals or their downstream signaling cascades. There are, of course, limitations to this model. The sea urchin, like culture-based models, cannot elucidate the importance of maternal-fetal pharmacokinetics and metabolism in determining the concentration of neuroteratogens that reach the fetus. Accordingly, the thresholds necessary to elicit effects in sea urchins cannot provide an absolute guide to the appropriate calculation of exposure limits for regulatory purposes, although they can be used for physiologically based pharmacokinetic models that provide a measure of exposure level of the fetal mammalian brain. On the other hand, the sensitivity of sea urchin embryos and larvae seen with the compounds used in these protocols is quite comparable to that of in vitro mammalian models, such as whole embryos, neuronal cell lines, or CNS cultures (Slotkin, 1999). The authors' results indicate the potential utility of this model system (or of similar invertebrate model systems) to screen compounds for potential neuroteratogenic activity in a comparative manner and to assist in the identification of heretofore unsuspected cellular targets underlying neuroteratogenesis.

Critical Parameters and Troubleshooting

There are three main critical parameters of experiments with sea urchin embryos. (1) The specimens in the embryo suspensions must be maintained at an optimal density. (2) The optimal temperature for the particular species must be constantly maintained. (3) The eggs, embryos, and larvae must be protected from mechanical injuries, evaporation of water from wells of culture plates, and direct bright light. These are the main reasons that embryos or larvae are of an unsatisfactory quality. Sometimes specimens develop relatively normally up to the beginning of gastrulation, but then their subsequent development can be disturbed. If the relative number of abnormal larvae is 5% to 10% or more in controls, then the experiment needs to be aborted. It is then necessary to assess which conditions (e.g., transportation and maintenance of adult sea urchins) contributed to the disturbances.

Developmental dynamics are one of the main peculiarities of developing embryos as biosensors. Some neurotoxicants tested on sea urchin embryos inhibit, disturb, or block cleavage divisions, whereas others start to evoke developmental malformations at the midblastula stage or later. It is possible to determine the critical periods of vulnerability for different neurotoxicants and to use this information for subsequent analysis of results. Therefore, the timing of experiments is a critical parameter that is worth special attention.

Anticipated Results

Cpf (40 μM or greater) added at stages 10 to 12 should evoke the maximal effect (Buznikov et al., 2001b; defect IV), where ~90% of embryonic or larval cells are transformed, extruded from the blastocoel at the animal pole, and are observed to cover the surface of the larvae (Fig. 1.6.6A). Lower cpf concentrations (20 to 30 μM) should produce an effect that is strong but less than maximal (defect III), where 50% to 75% of all extruded embryonic or larval cells form a mushroom-like cap (Fig. 1.6.6B). Defects III and IV are incompatible with further development. Cpf at 10 to 15 μM should produce a moderate effect (defect II), where the extralarval cap includes ~20% to 40% of larval cells (Fig. 1.6.6C) and can be lost, resulting in dwarf larvae that are motile but incapable of further normal development. Defect II is often accompanied by exogastrulation. Cpf at 2.5 to 5 μM should evoke the accumulation of transformed cells in the vegetal half of the blastocoel followed by exogastrulation, but not the extrusion of transformed cells (Fig. 1.6.6D,E and Buznikov et al., 2001b; defect I). These exogastrulated larvae can develop as far as stages 20 to 22. Cpf at 0.5 to 1 μM should not disturb development up to at least stage 25 (Fig. 1.6.4). If cpf is introduced at the one-cell stage or during the first cleavage divisions, embryos should develop quite normally up to stage 10 to 11. In this case, typical developmental malformations may become noticeable when control larvae begin gastrulation (Fig. 1.6.7).

AA-choline and DHA-choline (10 to 40 μM) or L-nicotine (25 to 100 μM) with PMA (0.05 to 0.2 μM) added at the one-cell stage evoke the formation of multinuclear embryos followed by rapid cell lysis (Fig. 1.6.9). If the embryos are incubated in CFASW, they are

more or less insensitive to these effects. The same substances added at stages 10 to 12 should evoke malformations (Fig. 1.6.8) very similar to those caused by cpf. In the case of choline derivatives, the dependence of developmental malformations on the concentration of ligand is clear: 20 to 40 μM AA-choline or DHA-choline produces maximal effects, whereas 2.5 to 5 μM are near-threshold concentrations.

All developmental malformations described above can be fully prevented by lipophilic cholinergic compounds (e.g., 40 μM AA-DMAE or DHA-DMAE) introduced simultaneously with cpf or 1 to 2 hr earlier (Fig. 1.6.6F). Nonlipophilic cholinergic compounds such as D-tubocurarine, imechine, or QX-222, however, only partially protect against cpf.

L-nicotine alone (50 to 100 μM and even 200 μM) should not disturb the cleavage divisions but evokes the extrusion of cells near the vegetal pole of larvae during gastrulation (Fig. 1.6.8). This effect is prevented by different nonlipophilic nAChR antagonists (D-tubocurarine, imechine, QX-222) but not by atropine; the protective action of lipophilic cholines is incomplete or even insignificant.

Ritanserin (2.5 to 10 μM), added during the MBT, blocks gastrulation and evokes the formation of additional cell layers in the larval wall. AA-5-HT, DHA-5-HT, or EPA-5-HT used in equimolar or higher concentrations completely prevents this typical malformation, whereas the protective action of 5-HT is incomplete but observable. 5-HTQ provides no protection against ritanserin.

Time Considerations

If cpf, lipophilic choline, or ritanserin are introduced at stage 10 (24 hr after fertilization for *S. droebachiensis*, 8°C or 7 hr after fertilization for *L. variegatus*, 21°C), anomalies become evident by 20 hr or 5 to 6 hr later, respectively, with maximal effects occurring after the next 8 to 10 hr (*S. droebachiensis*) or 2 to 3 hr (*L. variegatus*).

Zebrafish: An Animal Model for Toxicological Studies

During the last century, teleosts (bony fish) have been widely used as sentinels for assessing environmental hazards including aquatic pollutants. Species used for assessing environmental toxicity include small fish such as fathead minnow, medaka, and zebrafish, as well as large fish such as trout, salmon, and catfish. The underlying biology of environmental toxicity in teleosts has been extensively studied and well described. Molecular biology and genetics have recently been used to elucidate the underlying mechanisms of toxicity in zebrafish and medaka and to predict effects in mammals. The versatile zebrafish is now incorporated in biopharmaceutical programs for elucidating human disease and for preclinical drug discovery and screening.

ZEBRAFISH AS AN ANIMAL MODEL

Zebrafish (*Danio rerio*), a member of the Cyprinidae family, originate in South Asia. Zebrafish prefer warm water, but they thrive in many environments. Zebrafish have been used as a model organism for biological research since the 1930s. The zebrafish embryo has been extensively studied and described (Kimmel et al., 1995) since then and has become a popular model for developmental biology, toxicology, and recently for drug discovery (Peterson et al., 2000; Parng et al., 2002a). In addition, embryogenesis has been investigated using several large-scale genetic screens (Driever et al., 1996; Haffter et al., 1996). The model is now well established in many areas of biological research.

Zebrafish are easy to breed and inexpensive to maintain. Adult fish grow to 4 to 5 cm long, and reach sexual maturity in 3 to 4 months. In addition, each female can lay 200 to 300 eggs per week. Zebrafish embryos develop rapidly; embryogenesis is complete five days after fertilization. Because the embryo is transparent, morphological structures and internal organs, including brain, eyes, heart, liver, and kidney can be easily visualized using light microscopy, without the need for surgery. Organ-specific and overall developmental toxicity can be assessed visually or quantified using dyes. Enzyme induction and gene expression can also be easily monitored. In addition, many intracellular biomarkers, such as glutathione, reactive oxygen species, and protein and DNA-adduct formation can be studied in the whole animal.

Because of its small size, a single embryo can be maintained in fluid volumes as small as 100 µl for the first six days of development and can be raised in individual wells of microtiter plates. Zebrafish embryos are remarkably permeable. Small molecules added directly to the fish water easily diffuse into the embryos, simplifying drug dispensing and assay processing (Peterson et al., 2000; Parng et al., 2002a). Large or lipophilic molecules can be injected into several hundred embryos in one hour. Because the embryo develops rapidly, compound screening can be completed in a few days. These features make the zebrafish a unique vertebrate model for high-throughput chemical screening, which is useful for preclinical drug discovery and toxicological evaluation (Fishman, 2001; Table 1.7.1).

ZEBRAFISH DEVELOPMENTAL AND GENETIC STUDIES

Developmental and genetic studies using whole animals have typically been performed with invertebrates, including fruit fly and nematode. However, these animal models are not closely related to humans and lack many vertebrate organs, hence their use for predicting human toxicity is limited. Zebrafish are more closely related to humans and share many biological traits, genes, developmental processes, anatomy, physiology, and behavior.

The size of the zebrafish genome is ~50% of the mouse genome (Matthews, 2001). In addition, there is extensive synteny between zebrafish and mammalian genomes, and zebrafish genes are ~75% homologous to human genes on average (Barbazuk et al., 2000). Zebrafish orthologs for some genes that are known to play key roles in human diseases have been identified, and results from large-scale mutant screens have demonstrated that mutations in some of these zebrafish orthologs display phenotypes similar to those present in human diseases (Dooley and Zon, 2000; Ward and Lieschke, 2002).

Developmental Stages

Compared with other vertebrates, the embryonic development of zebrafish is rapid. Cell

Table 1.7.1 Zebrafish as an Animal Model for Toxicity

Advantages	Disadvantages
Ease of maintenance	Use for toxicity testing not standardized by regulatory agencies in the U.S.
Large number of offspring: ~200 eggs per female every two weeks	Physiology less well characterized than mammals
Rapid embryogenesis (6 days)	
Rapid generation cycle (2–3 months)	
Well characterized developmental stages	
Transparent embryo: internal organs can be visualized during embryogenesis	
Embryos are permeable to small molecules, and large or lipophilic molecules can be microinjected	
Embryos can be directly used to monitor water, soil, and waste water samples	
Small test sample size required per animal	
Genetics are well studied with many mutants available and easy to generate	
Genomic sequence is nearly complete with many genes cloned	
Transgenic reporter and disease lines available and easy to generate	
Methods and guidelines for toxicity studies established in Europe	

division begins shortly after fertilization, and by 6 hr post fertilization (hpf) gastrulation has begun (Fig. 1.7.1). The body plan is established within the first 20 hpf; by 24 hpf the heart is beating and there is a rudimentary circulatory loop (Stainier and Fishman, 1994). Hatching from the chorion occurs at ~72 hpf, and the hatching rate is usually >80% (Creaser, 1934; Hisaoka and Firlit, 1960). By 96 hpf, the animal can swim and eat, although it still receives nourishment from the yolk. The majority of zebrafish morphogenesis is completed during this time; a marker for this stage is protrusion of the lower jaw and inflation of the swim bladder. By 120 hpf (5 days), all the internal organs, including heart, liver, kidney, and pancreas are fully developed and functioning. The stages of early development have been carefully described, and these stages are considered the standard for developmental biologists (Kimmel et al., 1990). The staging described by Kimmel was performed at 28°C, and this temperature is consistently used in developmental studies; however, much of the toxicity literature describes experiments performed at 26°C. Since development of the exothermic zebrafish embryo is affected by small changes in temperature, it is important to consider experimental temperature when comparing results.

Mutagenic Screens

In the late 1970s, George Streisinger at the University of Oregon recognized that zebrafish embryos have many advantages that make them superior to *C. elegans* and *Drosophila* for developmental and genetic studies (Streisinger et al., 1981). Dr. Streisinger used X rays to generate chromosomal abnormalities and developed a technique for producing homozygous diploid fish that made it possible to detect rare recessive mutations and to produce large clones of genetically identical fish. Streisinger's colleagues at the University of Oregon continued to lay the foundations for establishing zebrafish as a model for developmental genetics. Normal development has been described in considerable detail, and a number of mutations that affect embryogenesis have been described (Kimmel et al., 1995).

In the late 1980s, based on the work performed by Streisinger and his colleagues, several developmental biologists recognized that zebrafish would be an extremely useful verte-

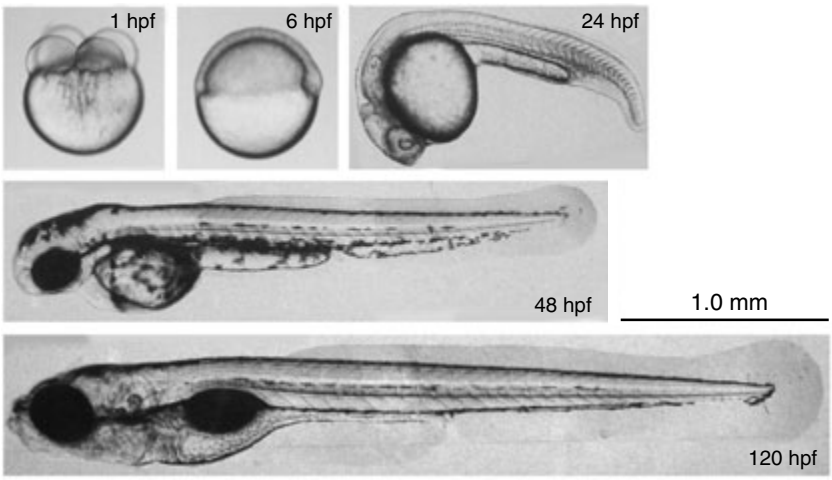

Figure 1.7.1 Zebrafish development occurs rapidly. By 1 hpf (top left), two cell divisions have occurred. Gastrulation begins at 6 hpf (top center). By 24 hpf (top right), the organ primordia have been laid down and the brain has significantly developed. The heart is beating and a rudimentary circulatory loop through the main body axis has been established. By 48 hpf (middle panel), pigment has begun to form; the body axis has elongated. By 120 hpf (bottom panel), organ morphogenesis is complete and most organs are functioning. The swim bladder has inflated and the embryo can swim and eat on its own. At this point the embryo is considered a larva.

brate for extensive genetic studies. Beginning in 1992, large-scale screens for mutations affecting embryonic development were conducted by Nüsslein-Volhard's and Driever's groups in Germany and Boston, respectively (Driever et al., 1996; Haffter et al., 1996). These experiments resulted in the identification and characterization of a large number of mutants affecting many aspects of embryonic development, and the results were jointly published in a dedicated volume of *Development* (1996, vol. 123). Since then, cell lineage, embryonic axis formation, nervous system development, heart and muscle formation, and differential regulation of gene expression have been extensively studied at various stages of development in wild-type and mutant embryos (Stainier et al., 1993; Driever et al., 1994; Lee et al., 1994; Mullins et al., 1994; Strahle and Blader, 1994; Driever, 1995; Solnica-Krezel et al., 1995; Wilson et al., 1995; Lele and Krone, 1996).

Many mutated genes have been cloned, which was an arduous process since chemical mutagenesis used in the screens typically results in point mutations (Talbot and Schier, 1999). Several cloned genes are orthologs of mammalian genes and these mutations result in similar phenotypes as those in humans. Thus, zebrafish is potentially a predictive model for human disease (Dooley and Zon, 2000; Ward and Lieschke, 2002).

In the mid-1990's, a genetic screen was performed by insertional mutagenesis (Golling et al., 2002). Since this mutagenic process is laborious compared to chemical mutagenesis, this screen yielded fewer mutants, but the mutated genes are tagged by insertions so they can be easily cloned. Several mutants were found in known genes, and several novel genes were identified (Golling et al., 2002). At least one of the mutants resembles a mutation that causes kidney disease in humans (Sun and Hopkins, 2001). Ongoing research into the development and genetics of zebrafish will further strengthen the utility of zebrafish as a model organism for biological studies, including toxicity.

Gene Inactivation by RNA Interference

Gene replacements and targeted deletions are not yet feasible in zebrafish; however, it is possible to remove a specific gene product by interfering with translation, a method called RNA interference (RNAi). In zebrafish, a type of RNAi using synthesized oligomers called morpholinos has been successfully used to knockdown expression of a number of genes (Nasevicius and Ekker, 2000; and references in *Genesis*, 2001, 30:89-200). RNAi knockdown can be used to: (1) identify the function of novel genes, (2) identify possible candidate genes when cloning a gene by position, or (3) inves-

tigate whether a gene cloned by homology is a functional ortholog of a mammalian gene.

Transgenic Reporter Lines

Transgenic fish are a powerful tool for studying gene regulation and expression, disease mechanisms and progression, and drug efficacy and toxicity. Transgenic lines can be created that express a visible marker, such as green fluorescent protein (GFP), under the regulation of specific promoters. These lines can serve as reporters to detect changes in expression of the marked gene and can serve as sentinels to detect the presence of bioactive compounds. The procedure for generating transgenic zebrafish is well established (Stuart et al., 1988, 1990; Westerfield et al., 1992; Lin et al., 1994). The use of live reporter gene markers such as GFP simplifies the screening for progeny that carry the transgene. Recently, high germline transmission rates (nearly 50%) were achieved by attaching DNA to nuclear localization signal peptides or by coinjecting I-*Sce*I meganuclease (Liang et al., 2000; Thermes et al., 2002).

Transgenic lines using organ-specific promoters expressing GFP have been created for vessels, kidney, blood, central nervous system, and lymphocytes (Jessen et al., 1999; Goldman et al., 2001; Huang et al., 2001). These lines have been used to study gene regulation, organ development, and the effect of mutations and drugs on development.

Several transgenic lines have been developed to assess toxicity. A line expressing GFP from the heat shock protein 70 promoter is currently used to study organ toxicity of heavy metals (Blechinger et al., 2002). Transgenic lines have been created that combine several response elements, such as those for aromatic hydrocarbons, electrophiles, metals, estrogen, and retinoic acid, driving the expression of luciferase or GFP, for use as sentinels of aquatic pollution (Carvan et al., 2000; Kinoshita et al., 2000). Another transgenic line has been developed for screening estrogenic activity (Legler et al., 2002; Schreurs et al., 2002). Advantages of these lines include the ability to distinguish aquatic pollutants using living biosensors and to elucidate toxicity response to various toxins in whole animals.

TOXICOLOGICAL STUDIES

Starting in the 1950s, zebrafish have been used to test the toxicity of synthetic chemicals and natural products (Battle and Hisaoka, 1952; Hisaoka and Hopper, 1953, 1957; Hisaoka, 1955). The toxic effects of some metals (e.g., zinc, selenium, mercury, and copper) and some organic solvents (e.g., phenol, aniline, and cyclohexane) were also assessed in zebrafish (Vitozzi and De Angelis, 1991). Because of the convenience and low cost of maintaining and handling zebrafish, subsequent studies in all areas of toxicology were performed in order to understand the adverse effects of chemicals and to predict results in humans. In experiments performed using zebrafish, lethality and malformation (during embryonic development) were used as general parameters for assessing toxicity. These studies demonstrated that zebrafish are amenable to chemical screens and exhibit good dose responsiveness to toxicity. In addition, the zebrafish embryo may have a predictive value similar to mammalian teratogenicity and toxicity assays (Van Leeuwen et al., 1990; Ensenbach and Nagel, 1995). However, since few compounds were tested, and effects on individual tissues and organs were not assessed, more studies are needed to further validate the correlation between the zebrafish and mammalian toxicity tests.

Ecotoxicological Studies

Ecotoxicological studies are performed to detect, manage, and monitor the presence of environmental pollutants in water, soil, and waste. Assays using zebrafish have been developed to directly monitor water, soil, and wastewater quality (Ruoppa and Nakari, 1988). Zebrafish have also been used to assess risks, predict hazards associated with petroleum products and by-products, and evaluate working conditions in the petrochemical and mining industries (Vitozzi and De Angelis, 1991; Lele and Krone, 1996). In addition, pesticides, polychlorinated biphenyls (PCBs), dioxin, and some of their derivatives have been studied in zebrafish embryos (Burkhardt-Holm et al., 1999; Wiegand et al., 2000, 2001; Anderson, 2001; Andreasen et al., 2002).

Because zebrafish develop rapidly, many toxicological endpoints can be evaluated a few days after fertilization. According to Schulte and Nagel (1994), toxicological endpoints at 72 hpf fall into two major groups. Type I endpoints are used for general morphological evaluation of development and include egg coagulation, embryo gastrulation, somite formation, tail extension, heart function, spontaneous movement, and hatching frequency. Type II endpoints are more detailed and include quantification of number of somites, blood circula-

tion, eye development, spontaneous movement at 24 hpf, cardiac function measured by heart rate, otolith development, melanocyte development, skeletal malformation, and delayed hatching (Zhu and Shi, 2002).

In Europe, zebrafish are widely accepted as an assay system for ecotoxicological studies. A number of recent guidelines from the Organisation of Economic Co-operation and Development (OECD; Guidelines 203, 210, and 212; OECD, 1992a,c, 1998) recommend zebrafish for aquatic toxicity testing. Different guidelines recommend using zebrafish at various stages, such as egg- and sac-fry-stage fish, early-life-stage fish, and juvenile fish. When testing a compound for acute toxicity (lethality), Guideline 203 (Fish Acute Toxicity Test; OECD, 1992a) recommends that medium lethal concentration (LC_{50}) be obtained using zebrafish 2.0 ± 1.0 cm long (i.e., 2- to 3-month-old juvenile to adult fish), using an incubation time of 96 hr. Guideline 210 (Fish, early-life stage toxicity test; OECD, 1992c) suggests the use of early life stage fish, from 4 hpf to day 16, for chemical testing. Briefly, 4-hpf embryos are exposed to a chemical, usually under flow-through conditions, until all the fish are free swimming and feeding exogenously. Observation continues until day 16. Lethal and sublethal effects on parameters such as growth are assessed and compared with controls. Since larval and early fry stages are the most sensitive stages for assessing developmental effects of xenobiotics, OECD Guideline 212 (Fish, short-term toxicity test on embryo and sac-fry stages; OECD, 1998) focuses on developmental toxicity in the early fish, from shortly after fertilization to 5 days post-hatching. Each guideline includes a detailed discussion of the principle of the test, a description of the method, procedures, and formats for data reporting and analysis.

Zebrafish embryos have been used to assess the toxicity of heavy metals, organic pesticides, and organic reagents (Vitozzi and De Angelis, 1991; Zhu and Shi, 2002). The no-observed-effect level (NOEL) and lowest-observed-effect level (LOEL) were determined after treatment with copper, mercury, lead, nickel, chromium, zinc, and cobalt for 16 days, starting at 4 hpf. Treatment effects included delayed hatching and developmental toxicity (Zhu and Shi, 2002). Organic pesticides, such as astrazine, malathion, carbaryl, urea, and lindane have been tested and the LC_{50} values were reported (Dave, 1987; Gorge and Napel, 1990; Dave and Xiu, 1991; Groth et al., 1993; Schulte and Nagel, 1994; Zhu and Shi, 2002). The LC_{50} of 40 organic-solvent reagents were assessed after incubating for 48 or 96 hr (Zhu and Shi, 2002). Zebrafish-derived cell lines are also used for these purposes. Toxicity studies with polychlorinated dioxin compounds, biphenyl, and antifouling compounds have also been reported (Henry, 2000; Okamura, 2002).

Results from these experiments showed that the zebrafish embryo is sensitive to environmental toxins and is a reliable and convenient model for toxicity testing. Furthermore, zebrafish can be used to monitor and elucidate the toxicological mechanisms underlying embryo development and to identify organs targeted by specific compounds.

Endocrine Disruption

There is increasing awareness that both man-made and naturally occurring chemicals may mimic or interfere with the endocrine processes in humans. Such substances have been termed endocrine disruptors (EDCs). A range of synthetic chemicals and some natural compounds have been reported to mimic estrogen effects in aquatic organisms (Pelissero and Sumpter, 1992; Sumpter and Jobling, 1995; Harries et al., 1996). Currently, there is a great demand for new assay methods, predictive endpoints, and reliable animal models for endocrine disruption testing and assessment (EDTA). EDCs interfere with homeostasis by interacting with receptors for endogenous hormones, or they can exert effects in a receptor-independent manner. Estrogens and their analogs, such as 17-β-estrodiol (E2) and 17-α-ethinylestradiol (EE2), are the most potent EDCs identified so far.

OECD recommends the use of several fish species for monitoring estrogens and estrogen analogs (OECD, 1992b,c, 2000). According to these Guidelines, teleosts such as fathead minnow, zebrafish, and medaka are the most promising models. Although fathead minnow, zebrafish, and medaka are all small fish and have similar generation cycles (3 to 4 months), zebrafish has several inherent advantages for EDTA studies, including a unique process of sexual development that differs from either the fathead minnow or medaka. Sex determination in zebrafish is not genetically determined: sex ratios are dependent on population density and food availability during development. In addition, gonadal development in zebrafish passes through a stage of juvenile hermaphroditism (Takahashi, 1977; Chan and Yenung, 1983). This means that short-term exposure may affect the genetic regulation of both female and male

Table 1.7.2 Comparison of Toxicity in Zebrafish and Mammalian Models[a]

Compound	Zebrafish		Mammalian models		
	LC_{50}/log LC_{50} (mg/liter)	Target organs	LC_{50}/log LC_{50} (mg/kg)	Model (dose route)	Target organs
Acetaminophen	252/2.4	Liver	500/2.69	Mouse (i.p.)	Liver, kidney, gastrointestinal

[c]Maximum tolerance dose.

development, resulting in a change of sex or sexual characteristics. However, sexual differentiation in medaka begins before hatching in females and at ~13 days post hatching in males (Kime and Nash, 1999). Gonad development in the fathead minnow is less well characterized. Moreover, the sex ratio has been well characterized for zebrafish under specific conditions (Fenske et al., 1999), but it is not known for either fathead minnow or medaka. Therefore, use of zebrafish for EDTA studies may produce more accurate and predictive results than other species. Furthermore, due to the small size of zebrafish compared to larger species such as rainbow trout, zebrafish assays can substantially reduce the cost, time, and space required for testing.

It has been reported that treatment with estrogen or its analogs changed the sex ratio of the siblings of exposed female zebrafish, caused necrosis in testes, and induced over-expression of vitellogenin protein (VTG; Kime, 1998; Olsson et al., 1999). VTG is an egg yolk protein synthesized in the liver and excreted into blood in the female fish. Estrogen is believed to regulate the expression of VTG. Due to the low concentration of circulating estrogen in male and juvenile fish, their blood levels of VTG are usually low. An increase in VTG in nonfemale fish indicates the presence of EDCs. Therefore, monitoring the blood levels of VTG in male fish has become a reliable endpoint for EDTA studies (Sumpter and Jobling, 1995).

Whole-fish homogenate is used in EDTA tests because it is difficult to obtain enough blood from zebrafish. Using a zebrafish-specific anti-VTG antibody, VTG at concentrations as low as 40 ng/g fish can be detected by ELISA. Other approaches include immunohistochemical studies, RT-PCR to detect VTG mRNA, histological analysis of gonad development, reproduction rates, and reproductive strength of the following generation. For histological examination after chemical exposure, the gonad is removed and sectioned. Sections are fixed on a slide and examined under a light microscope for any morphological change or necrosis. Studies related to reproduction include the ability to lay eggs, the fertilization rate, and the fertility of the subsequent generation.

It has been reported that EDCs caused developmental arrest of eggs from exposed females (Kime and Nash, 1999; Olsson et al., 1999). PCBs and their metabolites, di-2-ethylhexyl phthalate, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), and toxaphene have been tested on zebrafish (Holm et al., 1995; Orn et al., 1998; Olsson et al., 1999). It has been proposed that TCDD exerts its antiestrogenic effect by binding to the Ah-receptor, rather than by interfering with the estrogen receptor. Although the mechanism of action is not fully known, TCDD has been shown to reduce egg number and cause abnormality in offspring of mature females that ingested TCDD (Wannemacher et al., 1992; Fahraus-Van Ree and Payne, 1997; Gillesby and Zacharewski, 1998). However, which signal transduction pathway is involved in toxicity of PCBs is controversial. PCBs, like TCDD, have been reported to bind to the Ah-receptor (Cook et al., 1997). In contrast, PCB 104 was capable of mimicking the effect of E2 by inducing ER mRNA (Billsson et al., 1998). Since the mechanisms of endocrine disruption are quite complicated, additional research is needed in this area.

TOXICITY TESTING OF THERAPEUTICS: A COMPREHENSIVE APPROACH USING ZEBRAFISH

The authors have recently developed a family of assays in which chemical toxicity can be rapidly assessed in zebrafish. These methods include acute toxicity testing, target organ toxicity, developmental toxicity and teratogenicity, and an assay for apoptosis.

Using 30 chemicals which were commercially available or provided by the National Cancer Institute (NCI), the authors demonstrated the feasibility of using zebrafish embryos to study toxicity response by assessing LC_{50}, developmental teratogenicity, and specific organ toxicity (Table 1.7.2). The data show good correlation with LC_{50} values in other mammalian models (Fig. 1.7.2). In addition, as expected, >90% of the compounds showed specific tissue, organ, and behavioral toxicity. These results suggest that zebrafish is an excellent model organism for drug toxicity testing.

LC_{50} results showed that a few of the compounds (trithiophene, naproxen, ibuprofen, Col-3, DCA, PCBs, and 2,4-DNT) were more toxic in zebrafish than in mammals, perhaps because testing in zebrafish was performed on embryos, a developmental system, while the comparative mammalian toxicity was obtained using adult animals. The finding that a subset of compounds is more toxic in zebrafish than in mice or rats suggests that zebrafish may be a more sensitive model for chemical toxicity.

Zebrafish embryos exhibit responses to xenobiotic chemicals similar to those in mammals, including induction of xenobiotic enzymes and generation of oxidative stress (Wiegand et al., 2000; Dong et al., 2001). In addition to developmental defects (see below), changes in gene expression can be used for toxicogenomic studies. Although zebrafish orthologs of many genes involved in human toxicity have been identified (Table 1.7.3), expression of the cytochrome gene CYP 1A1, the first cytochrome gene cloned and characterized, is examined in most zebrafish toxicity studies. CYP 1A1 has been shown to be up-regulated in a zebrafish liver cell line treated with TCDD and β-naphthoflavone (BNF; Miranda et al., 1993). Additionally, CYP 1A1 has been shown to be functionally active in embryos in late gastrula stage, and its expression can be induced by TCDD or hexachlorobenzene (HCB; Mizell and Roming, 1997).

Recent studies designed to assess effects of several drugs on toxicity response demonstrate that CYP 1A1 expression was up-regulated in zebrafish embryos treated with 10 μM tacrine and 50 μM phenytoin, and down-regulated with 10 μM ibuprofen and 100 μM doxorubicin (Fig. 1.7.3). These results suggest that, similar to mammalian models (Sinz and Woolf, 1997; Nakamura et al., 2000), CYP P450 in zebrafish is responsive to drug treatment (Parng et al., 2002b; Semino et al., 2002). Expression of several genes has been examined in response to a number of drugs (Parng et al., 2002b; Semino et al., 2002), and currently DNA arrays are

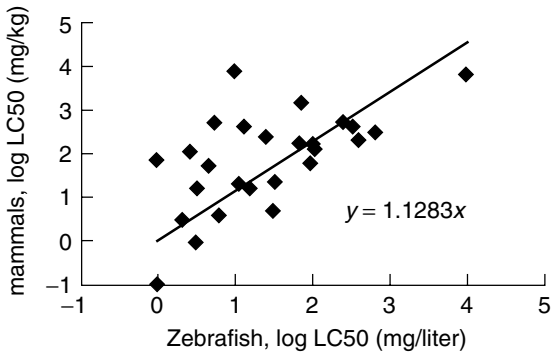

Figure 1.7.2 Comparative LC_{50} values. LC_{50} values obtained with zebrafish (expressed as mg/liter in Table 1.7.2) are compared with the corresponding LD_{50} values (mg/lg) obtained with mammals, in logarithmic scale. A graphic representation of the data was developed; the line represents the best fit between the two sets of values (slope = 1.13). LD_{50} values for mammals were obtained from the NIH TOXNET database, NCI, and others.

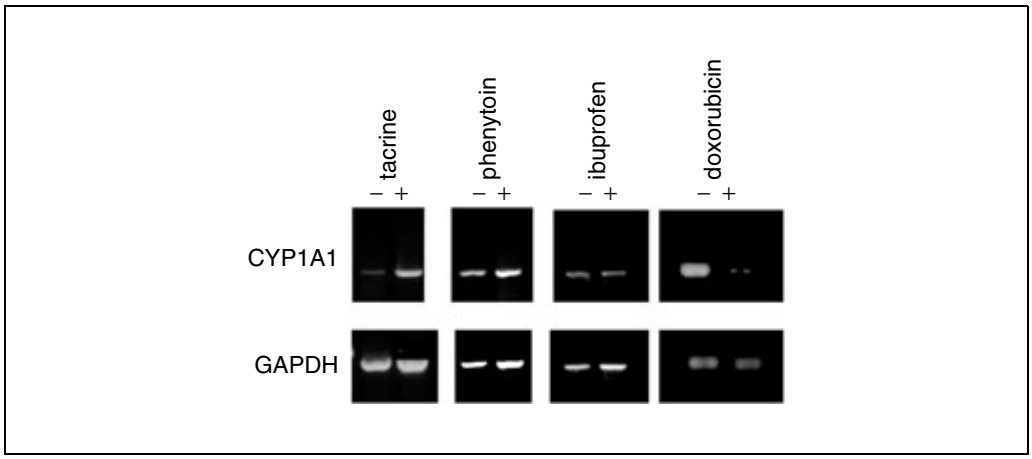

Figure 1.7.3 CYP 1A1 expression in zebrafish embryos. Zebrafish embryos (96 hpf) were treated with 0.1% DMSO (–) or 10 μM tacrine, 50 μM phenytoin, 10 μM ibuprofen, or 10 μM doxorubicin (+) for 4 hr. RNAs were isolated, and RT-PCR was used to analyze expression of both CYP 1A1 and GAPDH, a housekeeping gene. CYP 1A1 was up-regulated by tacrine and phenytoin treatment and down-regulated by ibuprofen and doxorubicin treatment.

being generated to assess patterns of gene expression and toxicity (by Phylonix, MWG Biotech, and Oakridge National Labs). Although these results suggest that P450 metabolism in zebrafish may be similar to that in mammals, the function of P450 in zebrafish has not been directly studied.

ORGAN TOXICITY

Organ toxicity studies include examining liver, gastrointestinal (GI), and kidney morphologies. Liver and GI toxicity is assessed using a staining method that relies on the presence of biotinylated proteins in the liver and gut: biotin is visualized by the application of streptavidin-peroxidase followed by a chromogenic substrate for peroxidase to specifically visualize the liver and intestine after drug treatment (Fig. 1.7.4A). The data showed that treating a 24-hpf zebrafish embryo with 100 μM dexamethasone for 5 days caused a dramatic reduction in liver size. Kidney toxicity is assessed by staining with an antibody against the mouse sodium/potassium ATPase (Fig. 1.7.4B). Antibody staining outlines the pronephric duct (black arrows) and the newly developed nephron (white arrow) at 48 hpf. Treating embryos for 24 hr with 5 μM brefeldin A had little effect on the pronephric duct, but completely inhibited nephron development.

Using the same methods described above, organ toxicity was quantified by staining with soluble substrate. The intensity of the resulting colorimetric product is proportional to the size of the organ. In addition to quantifying the toxic response, this method can be automated to process a large number of animals using a microplate reader. The results show that dexamethasone (from 1 to 100 μM) reduced liver and GI size in 144-hpf zebrafish embryos in a dose dependent manner (Fig. 1.7.5).

A functional assay for fatty acid metabolism in the gut has also been developed (Farber et al., 2001). This assay relies on the change in the fluorescence of phospholipase A2 after cleavage in the gut and can be used to identify chemicals that alter lipid metabolism.

Developmental toxicity in zebrafish embryos has been assessed after treatment with valproic acid (VPA), an anticonvulsant drug, and twelve other related substances (Herrmann, 1993). It was shown that VPA and the twelve other compounds cause retardation, developmental arrest, and malformation, including edema, brain deformation, shortened and bent tail, and bipartite axiation of the posterior trunk. These findings show that results with zebrafish embryos are similar to those observed in hydroids and in mammalian embryo culture systems. Furthermore, zebrafish development is highly synchronous and the developmental stages can be accurately determined, making zebrafish embryos a suitable model for drug toxicity testing. The authors have developed a detailed system to assess developmental toxicity in response to chemicals and therapeutics treatment (see below).

Developmental Toxicity and Teratogenicity

Developmental toxicity is a major aspect of environmental pollutants and a significant

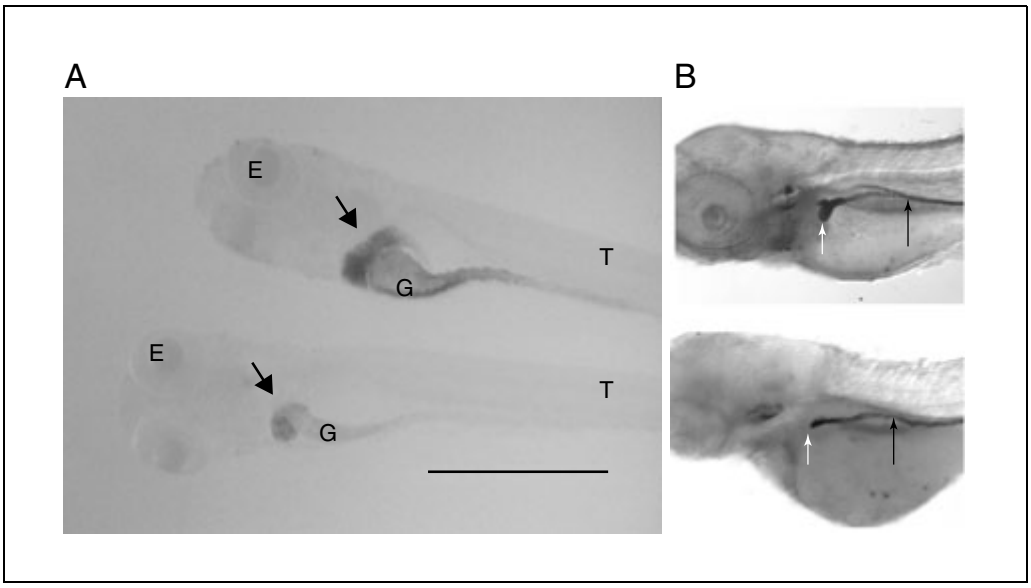

Figure 1.7.4 Visual assessment of liver and kidney organ toxicity. (**A**) Zebrafish embryos (24 hpf) treated for 5 days were used to determine the effects of dexamethasone on liver toxicity. The embryos were fixed with paraformaldehyde, incubated with streptavidin-peroxidase, and stained with a chromogenic dye to specifically label biotinylated enzymes in the liver and gut. Arrows indicate the position of the liver. Top, untreated embryo; bottom, embryo treated with 100 μM dexamethasone for 5 days. E, eye; G, gastrointestine; T, tail. Scale bar = 1 mm. (**B**) Zebrafish embryos (48 hpf) were fixed with methanol and formalin and stained with a mouse antibody against sodium/potassium ATPase. Black arrow indicates the position of the pronephric duct; white arrow indicates the nephron. Top, untreated embryo; bottom, embryo treated with 5 μM brefeldin A for 24 hr.

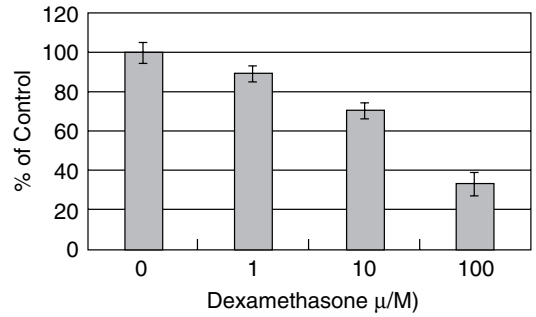

Figure 1.7.5 Quantification of liver toxicity after dexamethasone treatment: generation of dose response. Larva 144 hpf show a dose response to 1 to 100 μM dexamethasone on liver size detected and quantified by peroxidase and stained with a soluble dye. Ten zebrafish were analyzed for each concentration. The absorbance was detected at 405 nm. Values are expressed as a percentage of control (% Control) ± standard deviation.

problem with numerous pharmaceutical agents. Several mammalian models are typically used for developmental toxicity studies, including rat and mouse whole-embryo, organ, and tissue cultures (Chatot et al., 1980; Cicurel and Schmid, 1988). However, mammalian whole-embryo cultures are complicated: embryos must be explanted with the visceral yolk sac and ectoplacental cone intact for culture, and the embryo culture time is limited to 48 hr (Bechter et al., 1991). Partly due to the embryonic attributes described above, zebrafish is a much simpler model system for assessing toxicity.

The frog embryo teratogenesis assay-*Xenopus* (FETAX) is well established for evaluating developmental toxicity (Van Leeuwen et al., 1990; Dawson, 1991; Fort et al.,

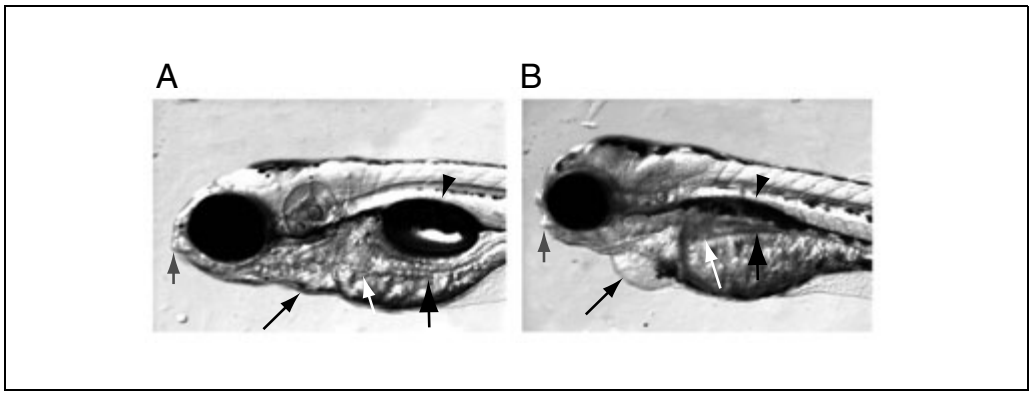

Figure 1.7.6 Morphological characteristics for developmental index assessment. Comparison of zebrafish (120 hpf) untreated (**A**) and treated (**B**) with 5 μM brefeldin A. Treated zebrafish shows heart edema (black arrow), necrotic liver (white arrow), undeveloped intestine (large arrow), underdeveloped jaw (gray arrow), and lack of swim bladder (arrowhead).

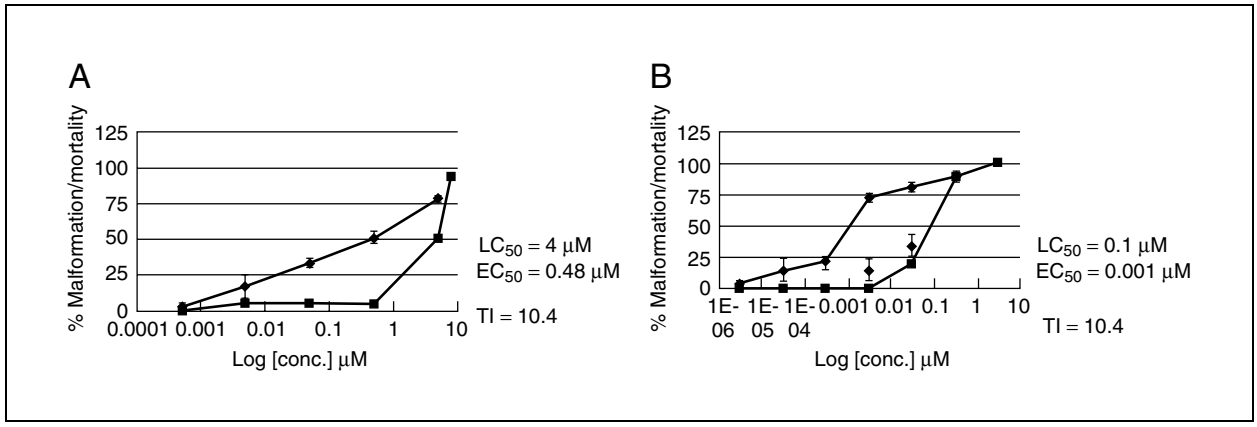

Figure 1.7.7 Dose-response curves for developmental toxicity of flavopiridol (A) and TCDD (B). Developmental malformation (diamonds) and mortality (squares) are shown.

1991; Stringer and Blankememyer, 1993). However, it appears that the frog is not responsive to halogenated aromatic hydrocarbons (HAHs), such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD; Beck and Powell, 2002), a major class of environmental toxins. Another complication of FETAX is that many compounds require activation by metabolic liver enzymes; since toxicity is evaluated before the embryonic frog liver develops, FETAX assessment of some compounds must be done in the presence of liver extract (Fort et al., 1991, 1998). Furthermore, since frog embryos are not transparent, it is difficult to inspect effects on internal organs.

The authors have developed a scoring system for evaluating developmental toxicity using zebrafish embryos. The scoring system consists of 20 toxicological endpoints, including heart shape, swim bladder inflation, jaw development, body edema, hemorrhage, several aspects of organ malformation, and necrosis (Fig. 1.7.6). The authors determine the mortality (LC_{50}), malformation (EC_{50}), no-observed-effect level for malformation (NOEL), and teratogenic index (TI) by generating dose-response curves for mortality and developmental malformation.

The authors have assessed the effects of eight chemicals, including environmental contaminants and common drugs, and more studies are ongoing. The results are shown in Fig. 1.7.7 and Table 1.7.4. Treatment by semistatic emersion (compounds replenished daily) was initiated at 24 hpf (day 1) and terminated at 120 hpf (day 5). Mortality was monitored each day and used to obtain the dose-response curve to establish the LC_{50} value—i.e, the percentage lethality was plotted against the concentration to obtain the concentration that caused 50% lethality (LC_{50}). To obtain the dose-response curve for malformation, the developmental score was plotted against the concentrations for each compound. The concentration that caused

Table 1.7.4 Comparison of Chemical Teratogenicity[a,b]

Chemicals	Zebrafish TI	Zebrafish LC_{50} (mg/liter)	FETAX (TI)	LC_{50} or MTD in other species	Teratogenicity in mammals
Col-3	3	1.0	75 mg/kg	Rat (oral)	Mouse, rat
2,4-DNT	1.7	23	24.3 mg/liter	96-hpf fathead minnow	Mouse, rat, rabbit
Epirubicin	0.75	16.3	16 mg/kg	Mouse (i.v.)	—
Flavopiridol	10.4	2.2	3 mg/kg (MTD)	Rat (oral)	Mouse, rat, hamster
Methotrexate	18.2	454[b]	504 mg/liter	FETAX	Mouse, rat, hamster
Staurosporine	1.0	0.012	Unknown	—	—
SU 5416	4.3	1.0	Unknown	—	Unknown
TCDD	100	0.98	0.81 mg/kg	*Streptopelia rioria* (oral)	Mouse, rat, rabbit

[a]Abbreviations: DNT, 2,4-dinitrotoluene; FETAX, frog embryo teratogenesis assay-*Xenopus*; MTD, maximum tolerated dose; TCDD, 2,3,7,8,-tetrachlorodibenzo-*p*-dioxin.

[b]FETAX TI value 19.3. See Bantle (1995).

50% malformation is defined as the medium effective concentration (EC_{50}). The teratogenic index (TI) is defined as the ratio of LC_{50}/ EC_{50}. The test compound is considered teratogenic if the TI value is >1.5 (Bantle et al., 1989, 1990; Bantle, 1995). Dose-response curves for EC_{50} and LC_{50} for flavopiridol (a cyclin-dependent kinase inhibitor used as an experimental anticancer compound), and TCDD, are shown in Figure 1.7.7. Developmental toxicity of the eight compounds was studied using the scoring system and compared with data for other species (Table 1.7.4). Although the authors have only assessed eight compounds to date, the data strongly suggest that zebrafish embryo is a suitable model for studying developmental toxicity and teratogenicity.

TOXICITY-RELATED CELL DEATH

Cell death often occurs in response to exposure to toxic compounds. General cell death, or necrosis, is easily scored in the developing embryo by localized opacity within an organ (Fig. 1.7.6). Apoptosis, or programmed cell death, is a mechanism of ridding the organism of unwanted or damaged cells and is involved in organ toxicity of many classes of compounds. The pathways and mechanisms of apoptosis in zebrafish appear to be similar to those in mammals. For example, specific caspase inhibitors have been shown to inhibit DNA fragmentation in zebrafish embryos, similar to mammals (Inohara and Nunez, 2000). Prevention of apoptosis in zebrafish embryos using caspase inhibitors has also been reported (Chan and Yager, 1998). Homologs of many genes in the apoptotic pathway in zebrafish have been identified and cloned, including nine Bcl-2 family genes (Mcl-1a, Mcl-1b, BLP1, Bcl-xl, Bax, Bad, Nip3, Nip3L, NR13), and seven caspase member genes (caspase 2, 3, 4, 6, 8, 9, 13; Parng et al., 2002a). Other apoptosis-related genes identified in zebrafish include four IAPs (inhibitor of apoptosis), four death receptor genes, ten apoptosis related kinases, and other related transcriptional genes and molecules (Ikegami et al., 1997). Therefore, zebrafish is a promising animal model for studying apoptosis mechanisms and gene regulation in response to environmental toxins and for evaluating the potential toxicity of therapeutics.

To detect apoptotic cells in live embryos, the authors developed apoptosis assays that rely on fluorescent reagents, including acridine orange and caspase substrates. Apoptotic cells are stained with fluorescent dyes that are easily detected in vivo with an epifluorescent microscope. In developing zebrafish embryos, naturally occurring apoptosis is consistently detected in the dorsal neural tube, hatching glands, retina, lens, cornea, inner ear, and olfactory organs (Bader et al., 1982; Yabu et al., 2001; Parng et al., 2002a); therefore, reagents that alter this developmental apoptosis pattern can be effectively screened in transparent embryos and the target organs or cells of pro-apoptotic reagents can be identified. As shown in Figure 1.7.8, increased apoptosis can be visualized in the liver of neomycin-treated embryos. In addition, these assays can be adapted for quantitative microtiter plate analysis using the same approach described for organ toxicity screens.

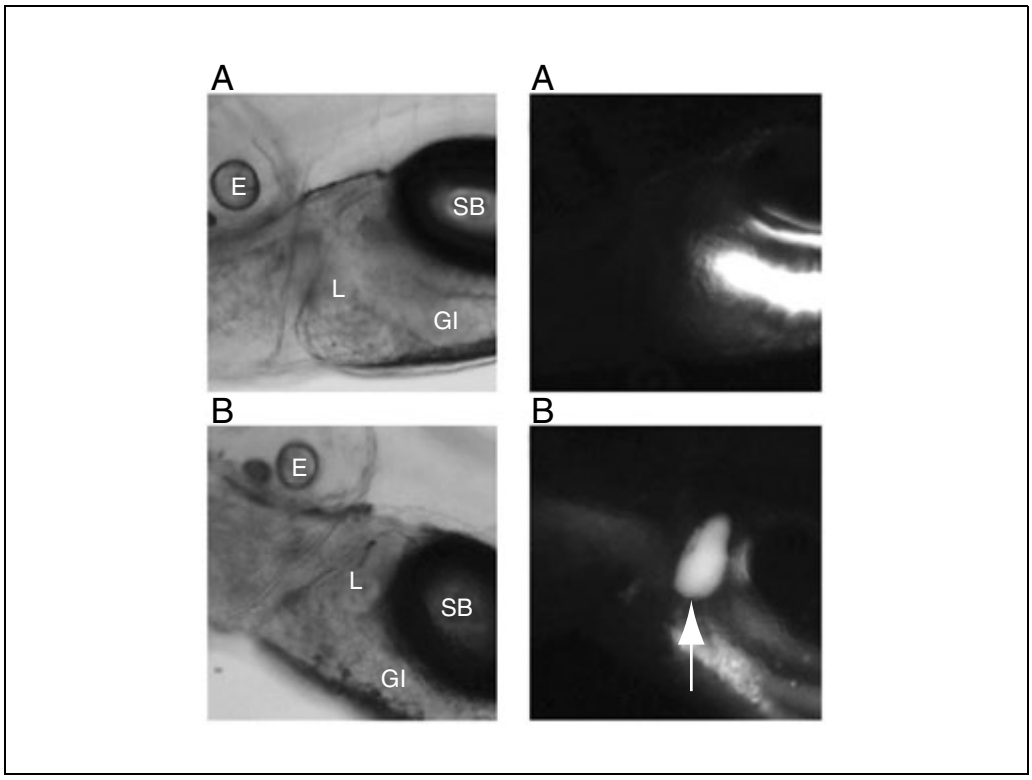

Figure 1.7.8 Neomycin-induced liver apoptosis in zebrafish. Zebrafish embryos (96 hpf) were stained with acridine orange. (**A**) Untreated zebrafish. (**B**) Zebrafish treated with 2.5 μg/ml neomycin for 24 hr. Left panels show light micrographs and right panels, fluorescent micrographs. Neomycin induced apoptosis in the liver (arrow in lower right panel). Intestine (GI) is fluorescent in both treated and untreated zebrafish due to ingestion of dye. Abbreviations: L, liver; E, ear; SB, swim bladder.

SUMMARY

Zebrafish is a unique animal model for assessing toxicity. It is a vertebrate that completes morphogenesis in 120 hpf, and embryos are transparent and develop ex utero. Since zebrafish has become a popular model for geneticists and developmental biologists, information about all aspects of zebrafish biology is rapidly accumulating. In addition, for decades zebrafish has been used to evaluate environmental toxicity, and formal protocols have been established by the OECD. Exploratory research for evaluating toxicity using many classes of compounds, from environmental toxins to therapeutics, shows that, in general, responses in zebrafish are similar to those in mammals. All of these factors indicate that this model organism will become a valuable tool for assessing environmental toxicity and for predicting drug toxicity.

Preclinical Models of Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative disorder in which pigmented midbrain neurons progressively die producing a dopamine (DA) deficit in the striatum, which manifests as an akinetic movement disorder. Experimentally induced striatal DA depletion in animals is a valid model of parkinsonism (Schultz, 1982). The capacity of certain substances to damage catecholaminergic neurons has been used extensively to produce DA deficiency in animals (Ungerstedt, 1971a,b; Burns et al., 1983; Annett et al., 1992). This unit describes methods for inducing parkinsonism in nonhuman primates and rodents using the neurotoxins 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; Basic Protocols 1 and 4 and Alternate Protocol 1) and 6-hydroxydopamine (6-OHDA; Basic Protocols 2 and 3). Additionally, procedures for evaluating the animals are presented (Support Protocols 1 to 4). Other models are briefly reviewed in the Commentary.

STRATEGIC PLANNING

Model Selection: Species

Rodent models of PD are good anatomical and biochemical models of the disease. However, they are not good functional models because the behavioral syndrome only superficially resembles some aspects of idiopathic PD, and the progressive nature of the disease is not reproduced. The complex behavioral repertoire of monkeys provides greater scope for determining the extent of functional recovery.

In nonhuman primates, administration of MPTP can induce a stable parkinsonian syndrome that is remarkably similar to the idiopathic disease (Burns et al., 1983). All primates are susceptible to MPTP toxicity. However, marmosets show considerable motor recovery despite biochemical and histological evidence for extensive damage, so that in the chronic stage only mild akinesia and incoordination of movement remain. The choice of species for specific experiments depends on the cost, availability of the animals, the type of study proposed (some species, like squirrel monkeys, are difficult to train), and the size of the brain required (for certain neuroimaging studies, such as positron emission tomography or PET scanning, the large brain of baboons is preferable). All results and specifications concerning doses and behavior in this unit refer to macaques (Rhesus and Cynomolgus) in the MPTP models and marmosets for the 6-OHDA lesions.

As in primates, MPTP and 6-OHDA are the most common toxicants used to induce DA depletion in rodents. Rats are the most commonly used experimental rodents, but they are rather insensitive to MPTP, requiring high doses and, with most strains, intracerebral administration of 1-methyl-4-phenyl-pyridinium (MPP^+; the toxic metabolite of MPTP). So far, 6-OHDA lesioning continues to be the most popular parkinsonian model in rats.

Lesion

Different lesions yield appropriate animal models to evaluate different therapeutic strategies, such as DA replacement (cell-mediated or pharmacological), neuroprotection, and neuroregeneration, as well as physiopathological mechanisms of neurodegeneration. Complete DA lesions in experimental animals are considered, at least in a neuropathological sense, analogous to end-stage PD. Data obtained from studies using this type of model are useful for the evaluation of therapeutic strategies aimed at DA replacement, as the DA-mediated positive effects will not be complicated by the potential response of remaining host DA neurons. On the other hand, experimental PD models sparing some DA terminals are analogous to less severe stages of the disease and are appropriate for investigating the potential benefit of regenerative approaches (e.g., the use of trophic

Contributed by Krys S. Bankiewicz, Rosario Sanchez-Pernaute, Yoshitsugu Oiwa, Malgorzata Kohutnicka, Alex Cummins, and Jamie Eberling

Current Protocols in Toxicology (2003) 1.8.1-1.8.31

factors) that require the presence of some residual DA neurons. In the context of tissue transplantation, the relative contributions of DA replacement or graft-induced trophic responses of a particular procedure are probably best addressed when efficacy is compared in both types of model.

Toxin

MPTP

The capacity of MPTP to induce persistent parkinsonism in humans (Davis et al., 1979) and in nonhuman primates (Burns et al., 1983) provides the opportunity to investigate both therapeutic approaches and possible pathogenic mechanisms of PD in primate models. Three models can be induced in primates by MPTP administration: (1) the unilateral model, induced by internal carotid artery (ICA) administration; (2) the bilateral model, induced by systemic (i.v., i.m., or s.c.) administration; and (3) the combined overlesioned or bilateral asymmetric model, induced by unilateral ICA plus i.v. administration. Basic Protocol 1 describes procedures for both ICA and systemic administration.

Mice exhibit characteristic neuropathological and biochemical signs of DA system damage following systemic administration of MPTP (Basic Protocol 4). Loss of tyrosine hydroxylase (TH)–positive neurons is seen in the substantia nigra pars compacta (SNc) and decreased levels of DA and its metabolites are observed in the striatum. These changes are accompanied by akinesia-depressed spontaneous motor activity (Heikkila et al., 1985; Hallman et al., 1985; Donnan et al., 1987; Sundstrom et al., 1990). Rats are very resistant to MPTP; to produce significant DA damage, the toxic metabolite MPP^+ has to be directly administered into the CNS.

6-OHDA

6-Hydroxydopamine has been used extensively to produce parkinsonism in rodents; however, few studies in primates have used this toxin (Schultz, 1982; Annett et al., 1992), most likely because it requires intracerebral administration. Basic Protocols 2 and 3 describe the respective procedures for stereotactic administration of this toxin in primates and rats.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

BASIC PROTOCOL 1

COMBINED ICA AND INTRAVENOUS ADMINISTRATION OF MPTP: THE OVERLESIONED (BILATERAL ASYMMETRIC) PRIMATE MODEL

In both humans and nonhuman primates, administration of MPTP produces a stable parkinsonian syndrome (Burns et al., 1983). MPP^+ is the toxic metabolite of MPTP (Nicklas et al., 1985), and conversion of MPTP to MPP^+ is mediated by monoamine oxidase B (MAO-B). MPP^+ accumulates selectively in neurons possessing a DA uptake system (Javitch et al., 1985) and is further concentrated in mitochondria. The basis of the toxic effects of MPP^+ is only partially understood; retrograde axonal transport, melanin binding, and damage to the mitochondrial respiratory system (Nicklas et al., 1985) have been implicated in the pathogenesis of injury to DA neurons. Replacement of DA with L-3,4-dihydroxyphenylalanine (L-DOPA) is the most common therapeutic approach in PD, and thus far the most efficacious. L-DOPA response is a diagnostic criterion and staging tool in PD and, as such, it is included in this unit with other outcome measures for parkinsonian primates. Evaluation of the response of MPTP-lesioned nonhuman primates to L-DOPA is also useful for validating the sensitivity of the specific neurobehavioral measures used to assess the effect of novel therapies and to compare the relative efficacy of such therapies, taking into account both positive and adverse effects. Moreover, the direct effect of different therapies on the response to L-DOPA can be investigated.

Materials

Sterile saline: 0.9% (w/v) NaCl
10-mg vial of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine HCl (MPTP·HCl; Sigma)
Adult macaques (Rhesus and Cynomolgus; Sierra Biomedical or Charles River)
Ketamine/xylazine
Isoflurane
Betadine
70% (v/v) ethanol
0.1 M HCl
Peroxide

10- and 60-ml sterile syringes
10- or 30-ml sterile vial
Animal balance (accurate to 0.1 g)
Intravenous (i.v.) extension set
Electric shaver
Alcohol pads
22-G i.v. catheter
Tracheal tube
Surgical table
Absorbant blue benchpads
Stretch gauze and cotton swabs
Sterile surgical tools: scalpel, large forceps, delicate curved forceps, scissors, needle holders, retractors, mosquito hemostats
27-G sterile needle
Infusion pump (fitted for a 60-ml syringe)
3-0 Vicryl with needle
Plastic, transparent millimeter-scale ruler
22-G angiocatheter
Heated water pad
Drapes
2/0 silk suture
Towel clamps

CAUTION: The most hazardous operations in conducting MPTP animal experiments are the preparation, handling, and injection of concentrated solutions of MPTP. Always use a chemical hood and skin protection (gloves, Tyvex laboratory coat) and mask. Any spilled MPTP should be degraded by spraying with 0.1 N HCl, while excess solution should be mixed 1:1 with 6 M H_2SO_4 and degraded by adding 4.7 mg potassium permanganate per 100 ml. The concentration of MPTP in the solution used for ICA administration is very low (0.03 to 0.07 mg/ml) and therefore quite safe. However, solutions for i.v. administration (even small volumes) are much more concentrated, and additional caution must be taken.

NOTE: Animals should be adults and should interact well with the investigators so clinical evaluation can be performed.

Prepare MPTP solution

1. Fit a 10-ml sterile syringe with a 20- or 23-G needle and fill with sterile saline.
2. Infuse 1 ml sterile saline into a sterile vial containing 10 mg MPTP·HCl. Aspirate the 1-ml solution back into the syringe to complete the 10-ml volume (final 1 mg/ml MPTP).
3. Transfer the entire 10-ml MPTP solution into a sterile 10- or 30-ml vial.

4. Weigh the animal (within 0.1 g) and determine the total dose, adjusting for the HCl group using a 1.2× conversion factor.

   Particular caution should be exercised when calculating the dose for intracarotid administration. MPTP is toxic during the infusion (i.e., first pass effect) only because it undergoes peripheral conversion to MPP^+, which cannot cross the blood brain barrier. For this route of administration, MPTP should be calculated according to brain size, which tends to be constant over wide body weight ranges, instead of per body weight. The latter can give the false impression that older (heavier) animals are more susceptible to MPTP, when in fact they are receiving larger doses for similar brain sizes. As a general guideline, 2 to 2.5 mg can be used for small (3 to 5 kg) animals, 3 to 3.5 mg for a 6- to 10-kg monkey, and 4 mg for large (>10 kg) animals.

5. Fill a sterile 60-ml syringe with 2 to 4 ml MPTP solution (2 to 4 mg MPTP). Fill the rest of the syringe with sterile saline and attach an i.v. extension set.

   The final concentration in the syringe is 2 to 4 mg/60 ml (0.033 to 0.067 mg/ml MPTP).

Prepare the animal

6. Anesthetize a macaque monkey with ketamine (10 mg/kg) and xylazine (1 mg/kg) in the home cage. Transfer to the procedure room.
7. Shave the calves and neck region of the animal using an electric shaver. Palpate the calf muscle and identify the saphenous vein.
8. Clean the skin with an alcohol pad. Using a 22-G i.v. catheter, cannulate the vessel and flush with saline.
9. Intubate the animal with a 3.5- to 5-mm (inside diameter) tracheal tube, according to the size of the animal.
10. Transfer the animal to a surgery room, place it on a surgical table with absorbant blue benchpads, and a heated water pad at 37°C. Maintain isoflurane anesthesia at 1.5% with an oxygen flow of ~0.3 liters/min.
11. Hyperextend the head on the surgical table by placing stretch gauze through the canines and applying gentle retraction. Secure the head in position by tying the gauze to the surgery table.
12. Cover the animal completely with a series of sterile drapes. Cut out an opening in the drape for the neck incision and secure drapes with towel clamps. Scrub the surgery site with Betadine followed by 70% ethanol.
13. Make a midline incision through the skin of the neck with a sterile scalpel.
14. Using blunt dissection technique, locate and open the carotid sheath, exposing the common carotid artery, internal jugular vein, and vagus nerve (Fig. 1.8.1). Isolate the common carotid artery below the carotid bifurcation.
15. Locate the superior thyroid artery and the external carotid artery and temporarily clamp the vessels using mosquito hemostats.

    Typically, both superior thyroid and external carotid arteries form a very short branch medially to the carotid bifurcation. Hemostats should be clamped on this branch, if possible. Another alternative is to clamp both the thyroid superior and external carotid (below the external maxillary branch) arteries using single hemostats distal to the carotid bifurcation. Use only mosquito hemostats with an adjusted clipping mechanism formed by bending handles inside.

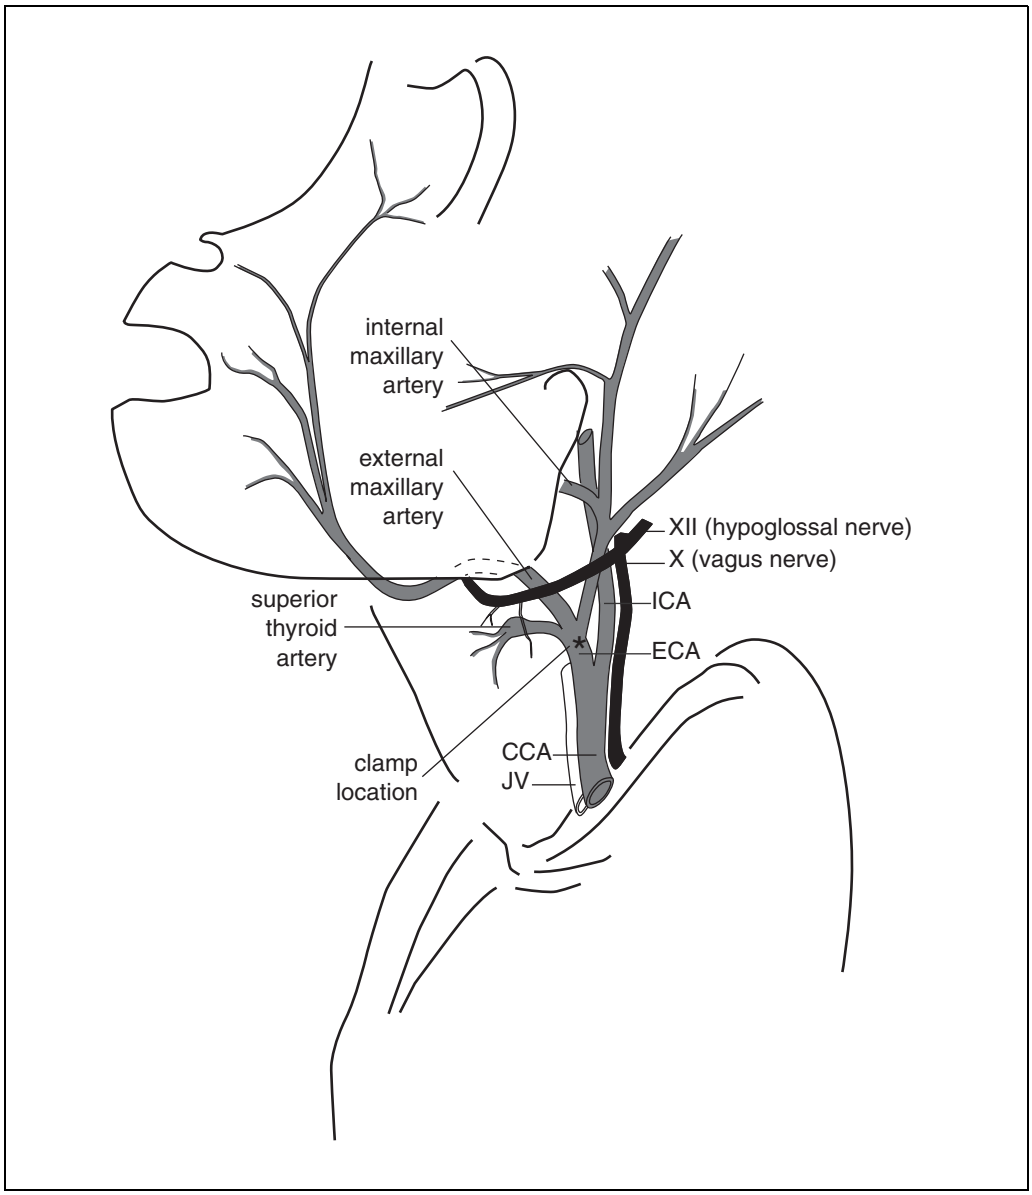

Figure 1.8.1 ICA dissection. The common carotid artery (CCA) at the level of the bifurcation showing the internal carotid artery (ICA), the X and XII cranial nerves, the external carotid artery (ECA), and its first branches: the superior thyroid artery and the external maxillary artery. An asterisk marks the recommended location of the vascular clamp, in the ECA proximal to the superior thyroid artery origin. JV, jugular vein.

16. Attach a 27-G needle to the i.v. extension tubing and drain all the air from the needle by activating an infusion pump for several seconds. Drain all excess MPTP onto a sponge soaked with 0.1 M HCl solution.

Perform ICA infusion

17. Insert the 27-G needle (with attached extension set and 60-ml MPTP syringe) into the internal carotid artery in a direction retrograde to the direction of blood flow.

18. Program the infusion pump to deliver 4 ml/min and infuse the entire volume from the syringe (2 to 4 mg MPTP).

19. Remove the vascular clamps (or mosquito hemostat) from the superior thyroid and external carotid arteries. Withdraw the needle from the common carotid artery and apply pressure for 5 min (until bleeding has stopped).

20. Clean the wound with peroxide, close the incision site at the neck with 3-0 Vicryl, and clean the sutured area.

21. Monitor the recovery of the animal and return it to the animal room. Record ipsilateral pupil mydriasis (dilation) by measuring the diameter of both pupils with a plastic transparent millimeter-scale ruler.

    In most cases, ipsilateral pupil mydriasis of 3 to 5 mm follows ICA infusion of MPTP solution. Absence of mydriasis does not indicate that lesion has not been successful, but its presence is a good indicator of unilateral damage.

    CAUTION: *Whenever possible, keep the animals in a quarantine room for 48 to 72 hr. Animal excreta may contain considerable amounts of unmetabolized MPTP; thus, precautions should be taken to minimize skin contact with animal fur and excreta and to avoid inhalation of bedding dust from MPTP-treated animals. As a general precaution, 0.1 N HCl solution should be used to spray the bedding in monkey cages during the first 48 hr after MPTP administration, and the cages should then be washed with an acidic solution. This ensures that any free MPTP is converted to its nontoxic form (for safety concerns see Yang et al., 1988).*

22. House animals for 2 weeks before i.v. administration.

Administer systemic (i.v.) MPTP

23. Weigh the animal (within 0.1 g) and determine the total dose of MPTP required, adjusting for the HCl group using a 1.2× conversion factor.

    For i.v. administration, the recommended dose is 0.3 mg/kg body weight.

24. Anesthetize the animal with ketamine (10 mg/kg) and xylazine (1 mg/kg) in the home cage. Transfer the monkey to the procedure room.

25. Shave the calves using an electric shaver. Palpate the calf muscle and identify the saphenous vein. Clean the vein with an alcohol pad.

26. Using a 22-G angiocatheter, cannulate the vessel and flush with sterile saline.

27. Fill a sterile 3- to 6-ml syringe with the appropriate volume of 1 mg/ml MPTP solution (0.3 ml/kg or 0.3 mg/kg) and infuse the MPTP into the vein over 3 min.

28. Flush the line with 3 ml sterile saline.

29. Remove the needle and apply pressure to the saphenous vein until bleeding stops.

    All safety guidelines described for ICA administration should be followed (see annotation to step 21).

Evaluate motor behavior

30. One week after i.v. administration of MPTP, assess the syndrome using a motor rating scale for primates (Table 1.8.1) based on the unified Parkinson's disease rating scale (UPDRS). Monitor response to L-DOPA (see Support Protocol 1) and activity (see Support Protocol 2).

Table 1.8.1 Rating Scale for Parkinsonian Primates[a]

Parameter	Score	Degree
Tremor (right arm/left arm)[b]	0	Absent
	1	Occasional or barely detectable (normal for aged), occurring while active
	2	Frequent or easily detectable, occurring while active or at rest
	3	Continuous or intense, occurring while active and at rest
Freezing	0	Absent
	1	Occasional episodes of short duration (<5 sec)
	2	Occasional episodes of moderate duration (6 to 10 sec)
	3	Frequent episodes or episodes of long duration (>10 sec)
Locomotion	0	Uses all four limbs smoothly and symmetrically
	1	Walks slowly (normal for aged), noticeable limp
	2	Walks very slowly and with effort, may drag limb or refuse to bear weight
	3	Unable to ambulate
Fine motor skills (right arm/left arm)[b]	0	Normal function: able to grasp/retrieve small objects, aims accurately, independent use
	1	Reduced ability in grasping/retrieving small objects, independent use, may have reduced aim
	2	Able to grasp small objects rarely, only with assistance, or with great difficulty
	3	Unable to grasp/retrieve small objects
Bradykinesia (right arm/left arm)[b]	0	Quick, precise movements
	1	Mild slowing of movements (normal for aged)
	2	Slow deliberate movements with marked impairment initiating movements
	3	No movements
Hypokinesia	0	Moves freely, alert, responsive
	1	Reduced activity (normal for aged), moves less frequently (without provocation)
	2	Minimal activity, moves with provocation, may have reduced facial expression
	3	Akinetic (essentially no movements)
Balance	0	Requires no assistance for maintaining posture
	1	Requires assistance for standing
	2	Requires assistance for walking, or falls
	3	Face down, or unable to maintain posture
Posture	0	Normal posture, stands erect
	1	Reduced posture (normal for aged), stands with feet apart, knees flexed
	2	Stooped posture, hunched, legs bent
	3	Unable to maintain posture, recumbent
Startle response	0	Immediate, robust response to provocation
	1	Slightly diminished or delayed response, open mouth threat
	2	Minimal response or longer delay, without open mouth threat
	3	No response to provocation
Gross motor skills (right arm/left arm)[b]	0	Normal function, able to grasp/retrieve large objects accurately
	1	Reduced ability/frequency of grasping/retrieving large objects
	2	Great difficulty in grasping/retrieving large objects, rarely used
	3	Unable to grasp/retrieve large objects

[a]According to mean scores in the scale, animals are classified into five stages. Stage 0: A maximum of 5 points is considered normal according to the authors' results in healthy animals. Stage 1: Total of 5-12 points; hemiparkinsonian monkeys do not show axial impairment. Stage 2: Total 12-20 points; mild to moderate bilateral symptoms. Stage 3: Total 21-30 points; moderate to severe bilateral symptoms, but without major systemic consequence. Stage 4: Total >30 points; severely damaged and can be difficult to manage due to feeding difficulties and complications of akinesia; may require DA replacement.

[b]Score each arm separately and add the total.

ALTERNATE PROTOCOL 1

SYSTEMIC MPTP LESION IN PRIMATES

The principal advantage of this approach is that the behavioral syndrome closely resembles that of Parkinson's disease in humans. The main drawbacks are that it takes a long time to produce animals with stable and uniform lesions and, if the lesion is too extensive, it produces a considerable mortality. Total dose is not predetermined, but will depend on the highly variable response of each animal to the toxin. Therefore, careful clinical evaluation is mandatory throughout the lesion progression. The toxic effect is cumulative.

Additional Materials (also see Basic Protocol 1)

3-ml syringes equipped with 26-G needles
Cage with back-squeezing mechanism

1. Prepare MPTP as described (see Basic Protocol 1, steps 1 to 3).
2. Weigh the animal and determine the appropriate dose (0.33 to 1 mg/kg), adjusting for the HCl group with a 1.2× conversion factor.
3. Fill a sterile syringe with the appropriate volume of MPTP solution.
4. With the monkey in a cage with a back-squeezing mechanism, squeeze the back of the cage to hold the animal and inject the MPTP intramuscularly or subcutaneously into the thigh or arm. For better results, inject twice a week.

   Follow safety guidelines described for ICA administration (see Basic Protocol 1, step 21).

   If the animal shows general symptoms such as feeding difficulty or profound akinesia, stop the injections and reevaluate the motor syndrome (see Table 1.8.1) 2 to 4 weeks later.
5. Assess the syndrome as described (see Basic Protocol 1, step 30).

BASIC PROTOCOL 2

UNILATERAL 6-OHDA LESION IN PRIMATES

6-OHDA uses the catecholamine uptake system to enter catecholamine neurons and kill the cells through oxidative mechanisms. Unilateral injection of 6-OHDA into the medial forebrain bundle of marmosets produces a severe loss of tyrosine hydroxylase-immunoreactive neurons in the ipsilateral SNc and DA depletion of >90% in the dorsal striatum, accumbens, and frontal cortex ipsilateral to the lesion (Annett et al., 1992). Levels of 5-hydroxytryptamine and noradrenaline (NA) are also decreased, but previous administration of NA uptake blockers (e.g., desipramine) limits the non-DA damage. The animals show ipsilateral spontaneous rotation, contralateral apomorphine-induced rotation, reduced spontaneous activity, contralateral sensorimotor neglect, and ipsilateral hand preference with variable impairment of hand skill (Annett et al., 1992). Persistent deficits are observed in animals with >95% DA depletion.

Materials

Sterile saline: 0.9% (w/v) NaCl
Adult marmosets (Sierra Biomedical or Charles River)
Ketamine/xylazine
Isoflurane
Betadine
70% (v/v) ethanol
4 mg/ml 6-hydroxydopamine (6-OHDA), HBr (Sigma) in 0.01% (w/v) ascorbate/0.9% (w/v) NaCl (protect from light)

Stereotaxic frame/tower (David Kopf Instruments)
Manipulator arm
Spinal needle

5-ml syringes
Intravenous (i.v.) line with 3-way stopcock
22-G angiocatheter
Animal balance
Electric razor
Alcohol pads
Surgical tape
Tracheal tube
Isoflurane inhalation chamber
Sterile drapes, gauze, and rubber bands
Towel clamps
Tissue forceps
Scissors
Electric cauterizer
Water heating pad
Dremel drill with carbide bur excavating tip
10-µl Hamilton syringes and needle
3-0 Vicryl
2-0 silk sutures

NOTE: Animals should be adults and should interact well with the investigators so clinical evaluation can be performed.

Calibrate stereotactic frame

1. Fix the settings on the ear bars of a stereotactic frame so the bars are ~1 mm apart.
2. Fit the manipulator arm with a 20-G spinal needle and position it on the stereotactic frame. Ensure that the mark readings on both ear bars are identical.
3. Advance the spinal needle into the space between the ear bars. Adjust the position of the needle along the anterior/posterior (A/P) scale to correlate with the plane of the ear bars.

Prepare animal

4. Flush an i.v. line with sterile saline using a 5-ml syringe, then prime a 22-G angiocatheter and 3-way stopcock with saline.
5. In the animal room, weigh a marmoset and anesthetize with 10 mg/kg ketamine/1 mg/kg xylazine. Transfer animal to the surgery room.
6. Shave the calves, arms, and head for surgical and intravenous access using an electric razor.
7. Palpate the calf muscle or flex and extend the ankle to visualize the saphenous vein. Clean the shaved area with an alcohol pad.
8. Insert the 22-G angiocatheter into the saphenous vein and flush with saline to ensure patency.
9. Attach the 3-way stopcock with i.v. line to the catheter and start a slow saline drip (1 ml/min) to maintain patency of the vessel. Secure the i.v. line onto the calf muscle using surgical tape.
10. Intubate the animal with an appropriate size tracheal tube and maintain on isoflurane anesthesia by inhalation.

Position animal in stereotactic frame

11. Place the animal in the stereotactic frame and tighten the right ear bar to the frame. Elevate the animal's head and insert the right ear bar into the ear canal.
12. Position the left ear bar in the animal's left ear. Ensure that the animal's eyes are parallel to the front plane of the frame.
13. Center the animal's head such that the same setting for both ear bars is achieved. Position the eye bars in the inferior border of the orbits. Set the incisor bar and readjust the eyebars to the inferior orbital rim. Fix the incisor bar at an adequate height.
14. Clean the entire surface of the cranium by scrubbing in an outward circular motion with Betadine scrub followed by 70% ethanol. Spray the stereotactic frame with 70% ethanol. Use sterile gloves for cranium preparation.
15. Cover the animal completely with a heating pad and then cover it with a series of sterile drapes. Cut out an opening in the drape for the craniotomy and secure drapes with towel clamps.

Administer 6-OHDA

16. Determine the target skin incision site using the baseline A/P coordinates as a guideline. Make a small sagittal incision through the skin and fascia using an electric cauterizer.
17. Using sterile gauze, retract the skin and fascia to expose the cranial surface. Secure the skin in place with towel clamps.
18. Cover a Dremel drill with sterile drapes and fix in place with sterile rubber bands. Use a carbide bur excavating tip and make a burr hole that exposes the dura.
19. Position the spinal needle over the first target site and manually advance the needle to the surface of the cranium. For marmosets, use the following coordinates with reference to stereotactic zero (Annett et al., 1992), with all five injection sites at A/P +6.5:

    one lateral (3 µl): lateral (L) ±3.2, ventral (V) 7.5
    two central (2 µl each): L ±2.2, V 6.5 and V 7
    two medial (2 µl each): L ±1.2, V 6 and V 7.

20. Insert the needle at the first target site, then touch the electric cauterizer to the needle and withdraw manually.
21. Place a 10-µl Hamilton syringe on the arm holder and infuse the selected volume of 4 mg/ml 6-OHDA at a rate of 0.5 µl/min. Leave the syringe in place for 5 min to avoid overflow.
22. Repeat steps 19 to 21 at the remaining four injection sites.
23. Suture the fascia with sterile 3-0 Vicryl. Close the incision site by subcutaneous suturing of the skin with 2-0 silk sutures. Clean and dry the incision site with sterile gauze and spray with Betadine.

Evaluate motor behavior

24. Evaluate nigral damage in vivo and post mortem using the methods described for the MPTP model (see Support Protocol 1 and Support Protocol 2). Also evaluate rotational behavior (see Support Protocol 3).

EVALUATION OF CHANGES IN MOTOR BEHAVIOR IN RESPONSE TO L-DOPA

Once the animals show a stable deficit (typically ~6 weeks), it is possible to evaluate the changes in motor behavior following an intramuscular injection of L-DOPA methyl ester (M-L-DOPA) with a peripheral inhibitor of L-aromatic amino acid decarboxylase. Dosing with Sinemet preparation does not provide predictable results due to inadequate control of intake and stomach content. M-L-DOPA injection should be used to ensure adequate brain delivery, as estimation of the effective dose is highly inaccurate with oral administration. Local complications are not observed using intramuscular (i.m.) injection.

The effect of L-DOPA can be evaluated using the activity or motor tasks shown in Table 1.8.1. For each animal, the response to saline injection should be used as control.

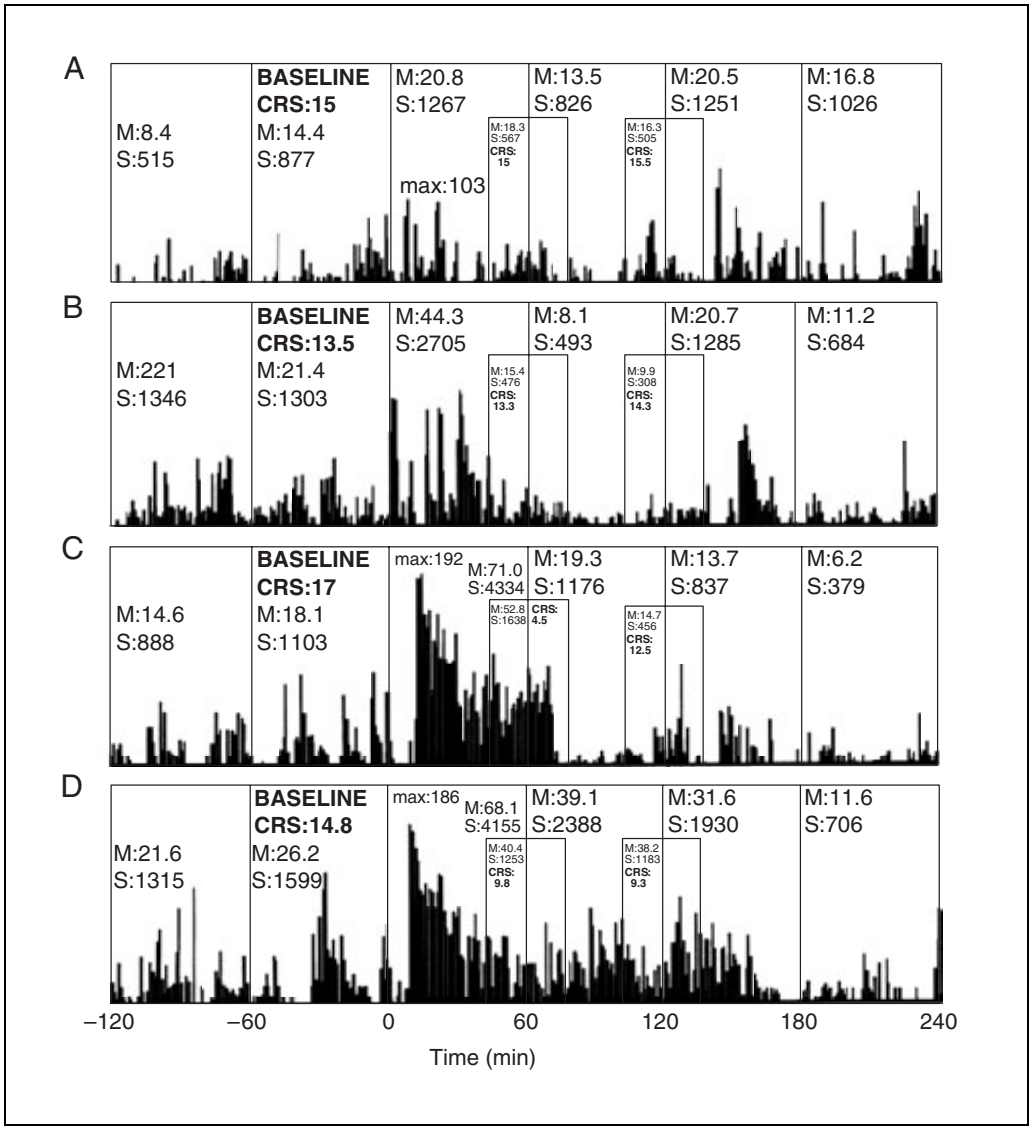

Figure 1.8.2 Activity and clinical rating scale (CRS) outcome of administration of increasing doses of M-L-DOPA in an overlesioned monkey. The drug was administered at time zero and activity is shown from 120 min before to 240 min following administration of (**A**) 5 mg, (**B**) 10 mg, (**C**) 20 mg, and (**D**) 40 mg M-L-DOPA. Mean and raw activity data for each segment is shown along with clinical score. During this experiment a shorter version of the scale was used; therefore, clinical score values are smaller than would be recorded using the scale as shown in Table 1.8.1. Increase of drug-induced activity is associated with clinical improvement in a dose-responsive manner. In panels, M, mean counts; S, sum of counts.

Materials

Lesioned animal (see Basic Protocol 1, Alternate Protocol 1, and Basic Protocol 2)
L-3,4-Dihydroxyphenylalanine methyl ester (M-L-DOPA; Sigma)
Benserazide (Sigma)
Sterile saline: 0.9% (w/v) NaCl

Cage with back-squeezing mechanism
3-ml syringes
26- to 30-G needles

1. Prepare the total dose of M-L-DOPA and add benserazide at a 1:10 benserazide/M-L-DOPA ratio. Mix and dilute in 1 to 2 ml sterile saline.

   Appropriate doses might vary for different stages and between species, but typical doses are 5 to 50 mg/kg.

2. With a lesioned monkey in a cage with a back-squeezing mechanism, squeeze the cage and inject i.m. into the thigh of the animal using a 3-ml syringe with a 26- to 30-G needle.

   It is advisable to keep the monkeys in cages with back-squeezing mechanisms so they can easily be held for i.m. injections, removal of monitors, or other quick procedures.

3. Rate the response according to the parameters described in Table 1.8.1. Evaluate the response 45 to 60 min after injection and at later time points when duration of the response is relevant.

   It is useful to videotape the animals, particularly when they display abnormal movements that might be difficult to categorize. Figure 1.8.2 shows typical results of the procedure.

SUPPORT PROTOCOL 2

MONITORING ACTIVITY TO ASSESS MPTP-TREATED MONKEYS

Whole-body activity measurement is a useful indicator of DA lesion in MPTP-treated monkeys and correlates with the global motor score (Fig. 1.8.3). This objective measure approximates akinesia, which is most pronounced in animals with moderate to severe lesions. The baseline motor activity is reduced and the normal pattern disappears after the MPTP lesion. An example of the striking MPTP effect on activity is shown in Figure 1.8.4. The personal activity monitors (PAM) contain a biaxial piezoelectric sensor that is calibrated to detect threshold activities $>0.024 \times g$ acceleration. Sensitivity and epoch length is programmable. The acceleration signal is sampled and digitally integrated to quantify all activity under the signal curve. The information is converted to a reference scale of data counts or acceleration units (G). The PAM monitor can be inserted into a vest that the animal wears during testing or into a collar around the neck. Activity data are normally acquired over four to five days that should include a weekend.

Materials

Lesioned animal (see Basic Protocol 1, Alternate Protocol 1, and Basic Protocol 2)
Ketamine/xylazine

Personal activity monitors (PAM; ActiTrac, Individual Monitoring Systems)
PAM connector cable
Computer
Nylon cable ties
Vetwrap
Nylon collars/vest

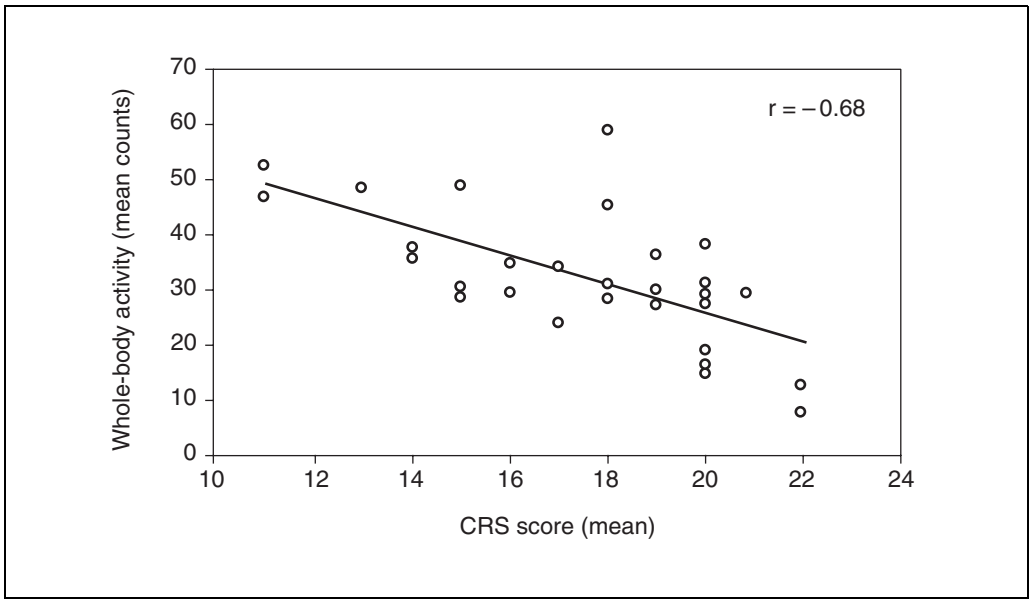

Figure 1.8.3 Correlation between clinical rating scale and whole-body activity in overlesioned hemiparkinsonian monkeys. Increased parkinsonian disability correlates well with a decrease in whole-body activity. Data from 28 overlesioned monkeys in stages 1, 2, and 3 are shown.

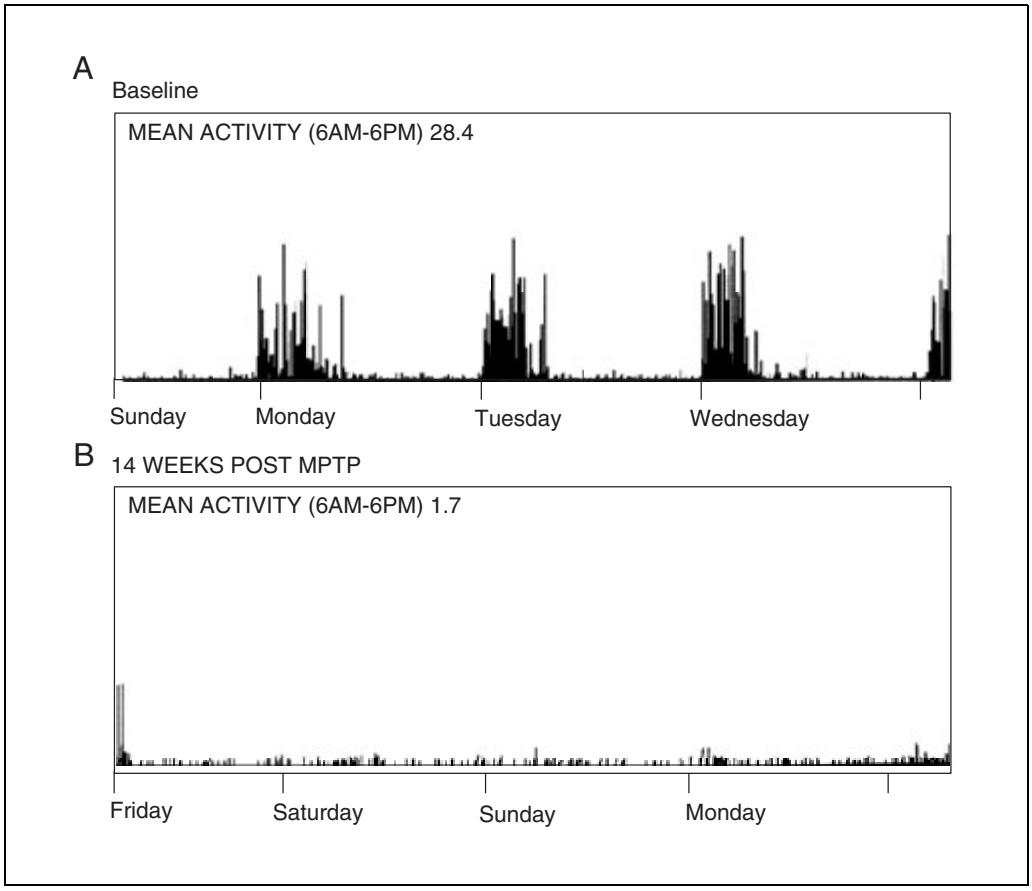

Figure 1.8.4 Whole-body activity measured by activity monitors (**A**) before and (**B**) 14 weeks after MPTP administration. Activity was recorded over 3 days.

1. Connect a PAM to a computer. Check that the battery level for the PAM is >5.25 volts, and program the sensitivity, epoch length, and start time and date. Enter the animal and test data.

   ActiTrac has a battery life of 4 years and memory allows up to 62 days of continuous recording. An epoch time of 1 min provides adequate information for time periods >60 min; to detect short-lived changes, use 30 sec.

2. Place the PAM in a horizontal position such that the PAM label faces outward. Secure the PAM to the collar using nylon cable ties. Wrap the monitor and cable ties with Vetwrap.
3. Anesthetize a lesioned animal in its home cage with 7 mg/kg ketamine and 1 mg/kg xylazine.
4. Place a nylon collar around the animal's neck and then wrap the buckle with Vetwrap.
5. Record the animal's identification number, the date and time, and the PAM identification number.
6. Begin activity data acquisition 60 min after administration of anesthesia.

   As long as data analysis is done comparing similar time periods (excluding setup and removal), the exact delay between anesthesia and activity monitoring is not critical.

7. Anesthetize the animal as in step 3 and remove the PAM.
8. Connect the PAM to the interface and download information to a data file.
9. Extract 12-hr segments (e.g., 6:00 am to 6:00 pm) and summarize them in a table (Fig. 1.8.4).

   Depending upon the study, activity is normally evaluated at the following time points: prelesion baseline, postlesion baseline, and postexperimental treatment. Mean and total counts can be used to compare animals but, as there is considerable variability between subjects, it is better to compare relative values (e.g., percentage with respect to baseline).

SUPPORT PROTOCOL 3

ROTATIONAL BEHAVIOR AS A MEASURE OF UNILATERAL NIGROSTRIATAL LESIONS

In animals with a unilateral DA lesion (see Basic Protocol 2), there is an imbalance of motor activity such that they usually display spontaneous turning toward the side of the lesion. Administration of indirect DA agonists (e.g., DA-releasing drugs such as D-amphetamine) increases the imbalance and the ipsilateral rotation. Administration of direct DA agonists (e.g., apomorphine) evokes contralateral turning, which is considered to be the result of denervation hypersensitivity of DA receptors in the lesioned side. Rotational behavior in response to DA agonists grossly correlates with the severity of the lesion (it is, in fact, better correlated with asymmetry indices). Quantification of the rotational response can be accomplished in monkeys by videotaping the animals and counting the turns, and in rats by using specific devices called rotometers (Ungerstedt, 1971a,b).

Suggested compounds and doses include 0.5 to 5 mg/kg D-amphetamine sulfate (Sigma) in saline and 0.025 to 0.25 mg/kg apomorphine·HCl (Sigma) in saline. Avoid amphetamine whenever possible, particularly if tests have to be repeated, as it might increase the mortality rate. For either compound, use the lower end of the range for primates (primates are susceptible to compound effects), the higher end for rats.

6-OHDA LESIONS IN RATS

In rats, several models can be induced by unilateral intracerebral stereotactic injection of 6-OHDA into different brain structures. Bilateral application of 6-OHDA is rarely used because of high mortality due to diencephalic damage (adipsia and aphagia); hence, only unilateral models are discussed here.

Complete DA lesion can be induced by unilateral injection of 6-OHDA in the medial forebrain bundle or in the SNc (Ungerstedt and Arbuthnott, 1970; Ungerstedt, 1971a). These animals demonstrate a characteristic asymmetric motor behavior in response to antiparkinsonian drugs (Ungerstedt, 1971b) that enables distinction between drugs with predominantly DA receptor agonist activity from those with predominantly DA-releasing activity. Systemic administration of L-DOPA or direct DA receptor agonists leads to contralateral rotation (towards the undamaged side), while administration of DA-releasing substances (amphetamine, amantadine) leads to ipsilateral rotation (in the direction of the damaged side). This model is also useful in studies of DA replacement therapy and neuroprotection factors.

Partial lesion models are induced by injection of 6-OHDA in the medial forebrain bundle (MFB) or SNc in smaller doses that leave a number of DA neurons intact (Zigmond and Strickler, 1989). These are useful models for the study of pathophysiological mechanisms and neuroregeneration.

The *selective A-9 lesion model* can be induced by injection of 6-OHDA in the SNc, leaving the ventral tegmental area (VTA or A-10 region) neurons intact (Perese et al., 1989; Thomas et al., 1994), thus reproducing the selective vulnerability of DA neurons in the SNc observed in idiopathic PD. This model is useful to study the contribution by other DA areas to the restoration of the nigrostriatal pathway and the differential effects of protective and repair mechanisms on different DA nuclei.

The *striatal lesion model* is induced by injections of 6-OHDA into the striatum, causing progressive retrograde degenerative changes of the corresponding DA neurons in the SNc (Sauer and Oertel, 1994; Lee et al., 1996). This is a useful model for pathophysiological, neuroregenerative, and neuroprotective studies.

Materials

Sprague-Dawley rats, 200 to 250 g
Isoflurane
Betadine
70% (w/v) ethanol
4 mg/ml 6-hydroxydopamine (6-OHDA, HBr; Sigma) in 0.01% (w/v) ascorbate/saline (protect from light)
Sterile saline: 0.9% (w/v) NaCl

Animal balance (accurate to 0.1 g)
Isoflurane inhalation chamber
Electric razor
Stereotactic frame
Scalpel
Tissue forceps
Scissors
10-µl Hamilton syringes and needles
Dental drill
Sutures or staples

Prepare animal

1. Weigh a Sprague-Dawley rat (within 0.1 g) and place in an isoflurane chamber until deeply anesthetized.
2. Position the animal in a stereotactic frame and fix the plastic tube connected to the anesthesia machine to the nose of the animal using surgical tape (make sure that the snout bar does not collapse the tube). Maintain isoflurane at ~1.5% with an oxygen flow of 2 to 3 liters/min.

   Alternative anesthetics such as ketamine/xylazine or chloral hydrate may also be used.
3. Shave the head with an electric razor. Clean the skin with Betadine and 70% ethanol.
4. Perform a midline incision with a scalpel and identify the bregma at the intersection of the coronal and the sagittal sutures.

Administer 6-OHDA

5. Fill a 10-µl Hamilton syringe with the appropriate 6-OHDA solution. Attach syringe to the holder on the stereotactic frame. Adjust 6-OHDA solutions according to the region of injection:

   For medial forebrain bundle lesion: 2 µg/µl 6-OHDA in saline containing 0.1% (w/v) ascorbic acid
   For SNc lesion: 4 µg/µl 6-OHDA in saline containing 0.02% (w/v) ascorbic acid
   For striatal lesion: 0.4 µg/µl 6-OHDA in saline containing 0.1% (w/v) ascorbic acid
   For A-9 selective lesion: 2 µg/µl 6-OHDA in saline containing 0.02% (w/v) ascorbic acid.
6. Calculate the stereotactic coordinates for injection (Paxinos and Watson, 1986). Some examples of possible injection sites include:

   For medial forebrain bundle lesion: Anteroposterior (A/P) −2.2 mm, mediolateral (M/L) 1.5 mm with reference to bregma; ventrodorsal (V/D) −8.0 mm with reference to dura
   For SNc: A/P −5.4 mm, M/L 2.2 mm with reference to bregma, V/D −7.5 mm with reference to dura
   For striatal lesion: A/P +0.5 mm, M/L 2.8 mm with reference to bregma, V/D −4.5 mm with reference to dura
   For A-9 selective lesion:
   1st lesion: A/P +3.5 mm, M/L 1.9 mm, V/D −7.1 mm with reference to lambda and dura with needle bevel directed rostrally
   2nd lesion: A/P +3.5 mm, M/L 2.3 mm, V/D −6.8 mm with reference to lambda and dura.
7. Adjust the incisor bar in the animal until the heights of lambda and bregma skull points are equal.
8. Drill a burr hole at the target site using a dental drill.
9. Lower the needle of the Hamilton syringe through the dura down to the selected depth and start injection at a rate of 0.5 to 1 µl/min. Adjust volumes (and doses) of 6-OHDA according to the region of injection:

   For medial forebrain bundle lesion: 4 µl solution (8 µg 6-OHDA)
   For SNc lesion: 2 µl solution (8 µg 6-OHDA)
   For striatal lesion: 20 µl solution (8 µg 6-OHDA)
   For A-9 selective lesion: 2 µl solution (4 µg 6-OHDA).

10. Leave the needle in place for 5 min and withdraw slowly (1 mm/min).
11. Close scalp margins with sutures or staples. Remove the animal from the stereotactic frame and place it in its home cage. Put food on the floor of the cage and monitor the animal's weight for 3 days after surgery. Supplement the diet (e.g., with fruit) if there is >10% weight loss.

Evaluate behavior

12. Evaluate rotational behavior (see Support Protocol 3).

MPTP LESION IN MICE

BASIC PROTOCOL 4

This model is induced by systemic administration of MPTP, which causes transient impairment of DA system function in these animals. It is a simple and useful model for studies on the pathophysiology of neurodegenerative processes as well as the effects of neurotrophic and neuroprotective agents.

Many different protocols have been used with various doses, routes of administration, and species. An example of the model induced by intraperitoneal administration of MPTP to C57Black mice, using four injections of 10 mg/kg (total 40 mg/kg), is described (Ricaurte et al., 1987).

Materials

C57Black mouse, age 8 to 12 months
1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine HCl (MPTP·HCl; Sigma)
Isotonic saline

Animal balance (accurate to 0.1 g)
1-ml syringe equipped with 26-G needle

1. Weigh a C57Black mouse (within 0.1 g).
2. Prepare a 1 mg/ml MPTP solution in isotonic saline.
3. Fill a 1-ml syringe, equipped with a 26-G needle, with MPTP solution to provide a dose of 10 mg/kg (e.g., 0.4 ml for 40-g mouse).
4. Hold mouse in dorsal recumbency with left leg immobilized. Insert the needle in the lateral aspect of the lower left abdominal quadrant through the skin and musculature, and immediately lift the needle against the abdominal wall and inject the solution.
5. Repeat the injection three times at 1-hr intervals.
6. Observe animals for any changes in general locomotion, stooped posture and piloerection (see Support Protocol 4).

MONITORING ACTIVITY IN MPTP-TREATED MICE

SUPPORT PROTOCOL 4

Open-field locomotor activity can be measured to evaluate the toxic effect of MPTP in mice and correlates with the content of dopamine in the striatum and nucleus accumbens (Leroux-Nicollet and Costentin, 1986). However, MPTP induces an acute increase in activity in some mouse strains, as the predominant effect in the early stage is inhibition of DA reuptake by MPTP. This effect can be blocked with neuroleptics. In C57 Bl/6 mice, MPTP produces a decrease in baseline activity (~60% in albino and 40% in black mice) that is prevented by administration of monoamine oxidase inhibitors. Amphetamine induces an increase in locomotor activity in normal animals that is absent in MPTP-lesioned animals. Apomorphine induces a decrease in locomotor activity that is not significantly different between normal and MPTP-injected animals.

Measurement of locomotor activity can range from simple observation to sophisticated automated procedures. In general, these instruments use an array of infrared photobeams and reveal the activity of the animal by the number and pattern of beam interruptions. The Digiscan Animal Activity Monitor (Omnitech Electronics) consists basically of a Plexiglas cage with infrared monitoring sensors at determined distances. A Digiscan analyzer collects data and transmits them to a computer for storage and further use. Several variables can be recorded, such as horizontal activity, movement time, total distance, average speed, average distance per horizontal movement, and number of movements.

Materials

MPTP-lesioned mouse (see Basic Protocol 4)
Dexamphetamine sulfate
Saline: 0.9% (w/v) NaCl

Automated open-field instrument (e.g., Digiscan Animal Activity Monitor; Omnitech Electronics)
1-ml syringe with 26- to 30-G needle

1. Place an MPTP-lesioned mouse in a Digiscan cage and record activity for the selected period of time.

   It is mandatory to perform pre-exposure habituation to get a reliable baseline.

2. Prepare dexamphetamine sulfate at 0.5 mg/ml in saline and place in a 1-ml syringe with a 26- to 30-G needle.
3. Weigh mouse and inject intraperitoneally at 1.5 mg/kg.
4. Place the animal in the Digiscan cage and record data for ≥30 min.

   It is important to perform all experiments at the same time of day as activity varies with circadian cycles.

COMMENTARY

Background Information

Evaluation of DA deficit in primates

Many different methods have been used to rate motor impairment induced in primates by MPTP and 6-OHDA. Rotational behavior and reach-and-grasp timed tasks are usually employed to quantify motor deficits in unilateral models. Marked delay in initiating movements on the side contralateral to ICA MPTP administration manifests clinically as "neglect" but, unlike cortical neglect, the animals respond when stimuli are maintained long enough, showing that the apparent inattention is really a profound hypokinesia. In these animals, this characteristic parkinsonian sign can be measured independently.

In most studies in which the functional capabilities of unilaterally lesioned monkeys have been examined, there are obvious deficits in gross motor behavior evident upon direct observation or detected by the use of automated monitoring devices or measurement of voluntary reaching movements. However, these measures provide little information about the cognitive abilities of the animal. Delayed responses and delayed alternation tests, which are measures sensitive to disruption of the frontostriatal system, are altered in monkeys treated with MPTP. These changes occur in monkeys with measurable motor deficits and also in animals treated chronically with low doses of MPTP that retain normal motor function by clinical assessment (Schneider and Kovelowski, 1990).

Neuroimaging techniques such as positron emission tomography (PET), single photon emission tomography (SPECT), and functional magnetic resonance imaging (MRI) are powerful methods that allow in vivo evaluation of DA function in parkinsonian monkeys. However, selecting the most appropriate approach depends largely on available resources. PET and the DA metabolism tracer [^{18}F]-6-fluoro-L-DOPA (FDOPA) have been used extensively to evaluate DA function in the striatum of normal

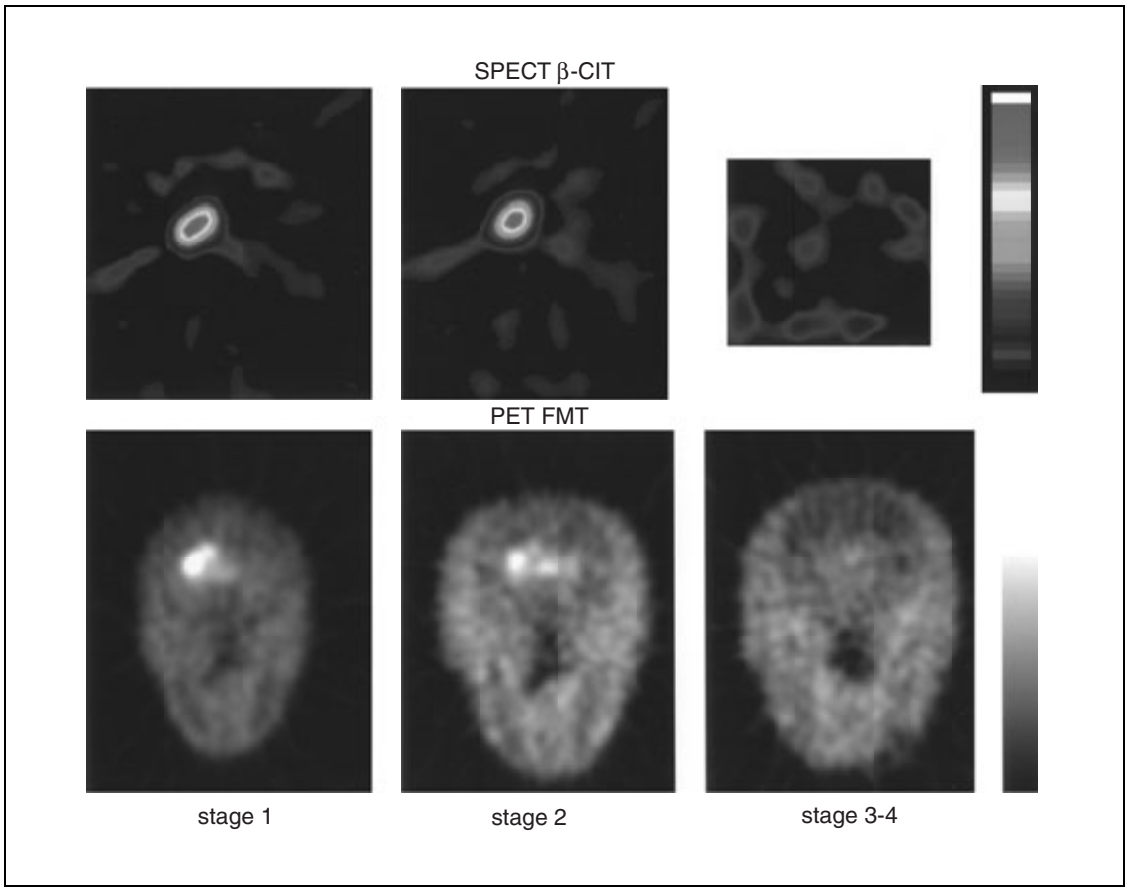

Figure 1.8.5 Neuroimaging representation of mild (stage 1), moderate (stage 2), and severe (stage 3-4) MPTP-induced DA lesion in overlesioned monkeys. Note that the side ipsilateral to the intracarotid infusion of MPTP is severely depleted at all stages. The contralateral side shows a progressive DA depletion on both (top row) SPECT β-CIT [2β-carbomethoxy-3β-(4-iodophenyl)tropane, a cocaine analogue with a high affinity for the dopamine transporter] and (bottom row) PET FMT images as the animals display more severe signs of PD. *This black-and-white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

and MPTP-treated monkeys (Doudet et al., 1989; Pate et al., 1993) but not in midbrain structures due to limitations in both tomograph resolution and quantification of FDOPA metabolism. The use of the DA tracer [^{18}F]-6-fluoro-L-*m*-tyrosine (FMT; Melega et al., 1989) provides a high level of image contrast and a high signal-to-noise ratio, reflecting its more restricted metabolism in both peripheral and central tissues, and permitting the evaluation of DA activity in the SNc and striatum (Eberling et al., 1997, 1998; Jordan et al., 1997). For examples of SPECT and PET images, see Figure 1.8.5, Figure 1.8.6, and Figure 1.8.7.

^{123}Iodine-2β-carbomethoxy-3β-(4-iodoph enyl) tropane ([^{123}I]β-CIT) has been used to measure DA transporter activity in both human and nonhuman primates using SPECT (Laruelle et al., 1993). Although [^{123}I]β-CIT has high affinity for both DA and serotonin transporters, the high density of DA transporters in the striatum makes striatal tracer uptake a relatively specific indicator of striatal DA transporter density (Laruelle et al., 1993). Postmortem studies have shown a reduction in DA transporter density in the striatum of PD patients that parallels the loss of DA, and SPECT [^{123}I]β-CIT studies have shown a reduction in striatal DA transporters in PD and an association between clinical signs and striatal uptake of [^{123}I]β-CIT. Discussing detailed neuroimaging methods is beyond the scope of this unit, but as shown in Figure 1.8.5, both PET and SPECT can be used successfully to determine the severity of a lesion in monkey striatum following MPTP administration.

ICA MPTP administration as a model of active degeneration of the nigrostriatal DA pathway

An interesting approach to study neuroprotection in MPTP-treated monkeys is based on

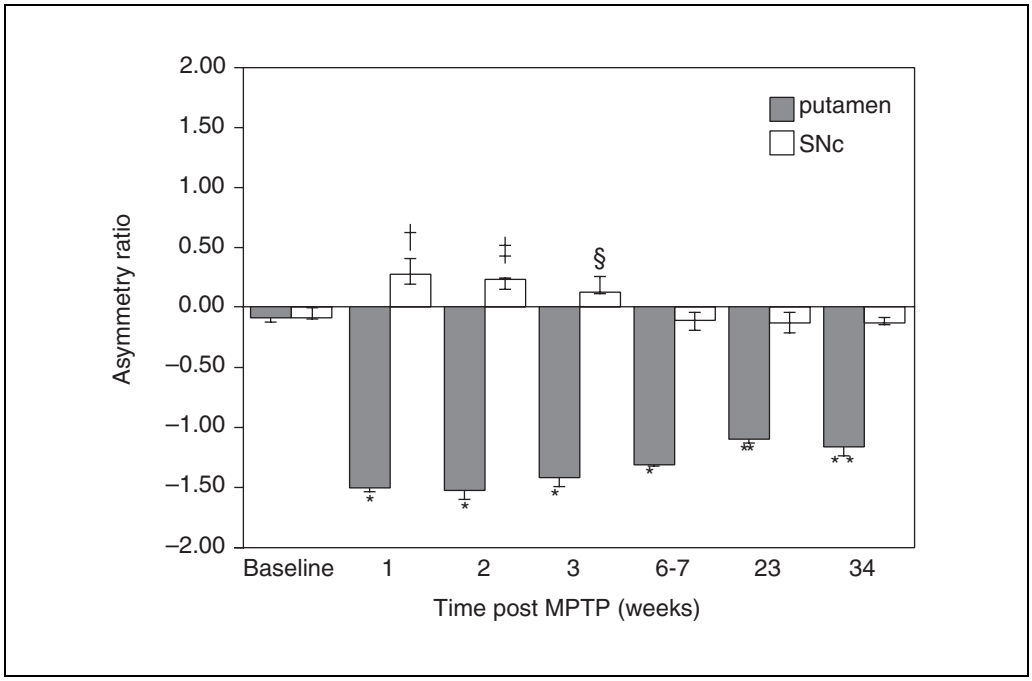

Figure 1.8.6 Following ICA administration of MPTP, DA terminals degenerate first, followed by degeneration of DA neurons in the SNc 5 weeks later. During the time period between MPTP administration and DA cell death in the SNc there is a transient upregulation of activity in the SNc that can be measured by PET. This upregulation represents the time course of cell death and can be used as an indicator of DA cell degeneration. Asymmetry ratios were constructed to evaluate differences in FMT accumulation between ipsilateral (the side of ICA MPTP infusion) and contralateral sides at eight different time points. Asymmetry ratios for the putamen and SNc were calculated as the K_i value for the ipsilateral side minus the K_i value for the contralateral side divided by the mean of the two K_i. A negative asymmetry ratio indicates that K_i was lower on the ipsilateral side, while positive ratios indicate higher K_i values on the ipsilateral side. $^*p < 0.0001$ significantly less than baseline; $\dagger p = 0.001$, $\ddagger p = 0.002$, and $\S p = 0.04$ significantly greater than baseline; $^{**}p < 0.05$) significantly greater than 1 week, 2 weeks, 3 weeks.

the finding that following ICA MPTP administration, MPP^+ is sequestered in both DA terminals and cell bodies as a result of its selective uptake by the DA transporter system. This initiates molecular changes that ultimately result in neuronal degeneration, most likely by compromising mitochondrial function. Within the first few weeks following MPTP administration, DA levels are profoundly decreased in the striatum with little or no morphological changes in the nigral cell bodies. MPTP-induced nigrostriatal degeneration begins almost immediately in the striatal terminals and results in cell body degeneration within 4 to 6 weeks (Fig. 1.8.7 and Fig. 1.8.8). The difference in the time course of degeneration in the striatum and SNc suggests that the primary mechanism of toxicity in the terminals is MPP^+, while cell body degeneration may result from both retrograde degeneration and retrograde transport of MPP^+ from the striatum (Javitch et al., 1985; Herkenham et al., 1991). Importantly, although the time course of degeneration is clearly accelerated, the MPTP model includes the key elements of idiopathic PD, including selective and progressive degeneration of the nigrostriatal DA pathway (Fig. 1.8.7). The use of FMT, along with higher resolution PET tomographs, allows direct longitudinal evaluation of DA activity in the SNc as well as in the striatum (Eberling et al., 1997; Fig. 1.8.6). Following ICA infusion of MPTP, activity of DA neurons is upregulated during degeneration of the DA pathway, which is completed within 5 weeks.

This pattern of MPTP-induced degeneration can be used to study neuroprotection. Following ICA administration of MPTP, >95% of TH-immunoreactive cells in the SNc will degenerate within 4 to 5 weeks. There is very little, if any, between-animal variation in TH-positive cell degeneration in the SNc following the successful ICA infusion of MPTP. Active neuroprotective agents should be able to protect DA neurons following ICA administration of MPTP. Such neuroprotection might be demon-

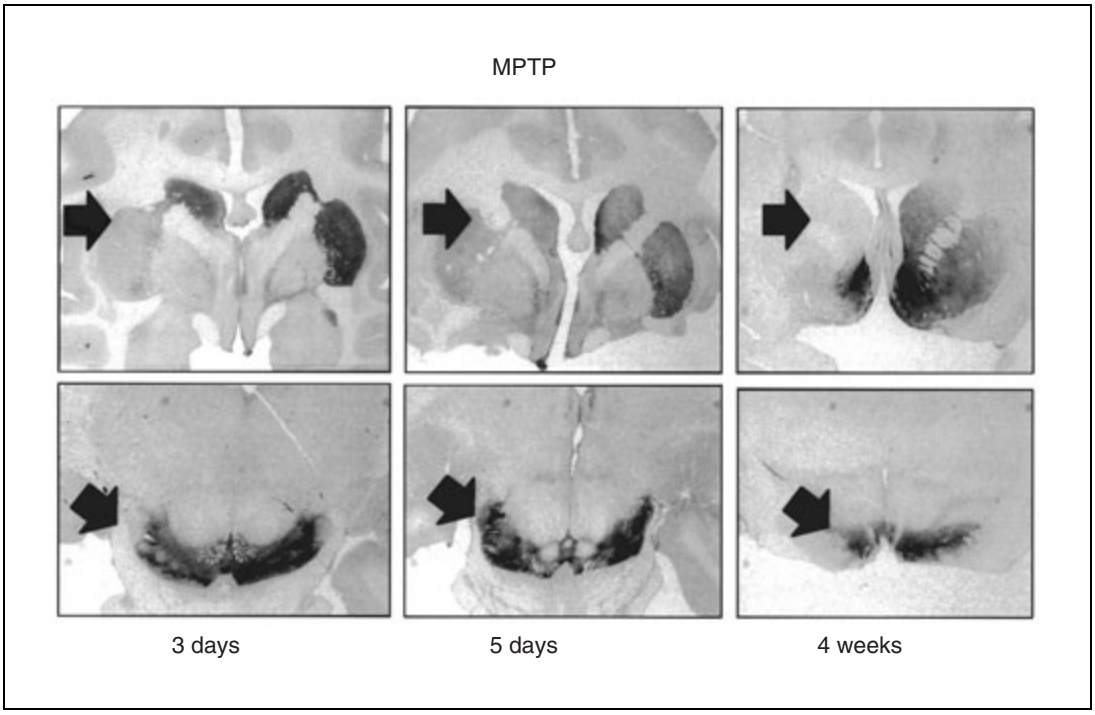

Figure 1.8.7 Low-power photomicrography showing tyrosine hydroxylase immunoreactivity in the striatum and SNc in monkeys at 3 days, 5 days, and 4 weeks following unilateral intracarotid infusion of MPTP. Terminals in the striatum degenerate first, shortly after MPTP administration, while DA cell bodies are not affected (note lack of TH staining in the striatum but not in SNc at 3 and 5 days). It takes 4 to 6 weeks for DA cells in the SNc to degenerate.

strated by preventing upregulation and/or extending survival of DA cells in the SNc on the side of MPTP infusion during the first 3 to 4 weeks following MPTP infusion.

Other models of PD in primates

Isoquinolines. For some time now there has been an active search for endogenous compounds that act like MPTP. Isoquinoline (IQ) derivatives such as tetrahydroisoquinoline (TIQ), 1-benzyl-TIQ, and (*R*)-1,2-dimethyl-5,6-dihydroxy-TIQ[(*R*)-*N*-methyl-salsolinol)] are DA-derived alkaloids that have shown potential neurotoxicity (Nagatsu and Yoshida, 1988). TIQs, like MPTP, may be activated via N-methylation by *N*-methyltransferase and via oxidation by MAO. TIQs as well as MPP^+ inhibit complex I of the electron transport system in mitochondria, thereby reducing ATP formation and producing oxygen radicals. Although the properties of TIQs are similar to those of MPTP, the neurotoxicity is weaker. Chronic administration produces parkinsonism in primates with decreased DA, biopterin, and tyrosine hydroxylase activity (Nagatsu and Yoshida, 1988). Long-term neurotoxic effects of IQs remain to be further examined in primates.

Aged monkeys. DA cells are lost during the normal course of aging at a rate of ~5% per decade in monkeys (Fearnley and Lees, 1991). Rhesus monkeys that are over 22 years of age display many Parkinson-like changes that appear to be age-related. Some, but not all, hypokinetic aged monkeys respond to L-DOPA administration as shown in Figure 1.8.9. In a recent study, motor deficits in aged monkeys were shown to correlate with decreased DA markers (Emborg et al., 1998). However, because decreased locomotion of aged monkeys can also be attributed to factors that are not DA-mediated, the response to L-DOPA might be used as a selection marker for animals that show DA-mediated hypokinesia. More work needs to be done to fully characterize aged monkeys as a potential model of PD.

Other models of PD in mice

Weaver mutant. This is a genetically induced model of cerebellum atrophy accompanied by brain DA deficiency due to abnormal development and additional degeneration of the striatal DA system. The adult weaver mutant develops striatal DA deficiency related to a reduction in the number of DA neurons in the SNc (A-9). The neuropathological and biochemical

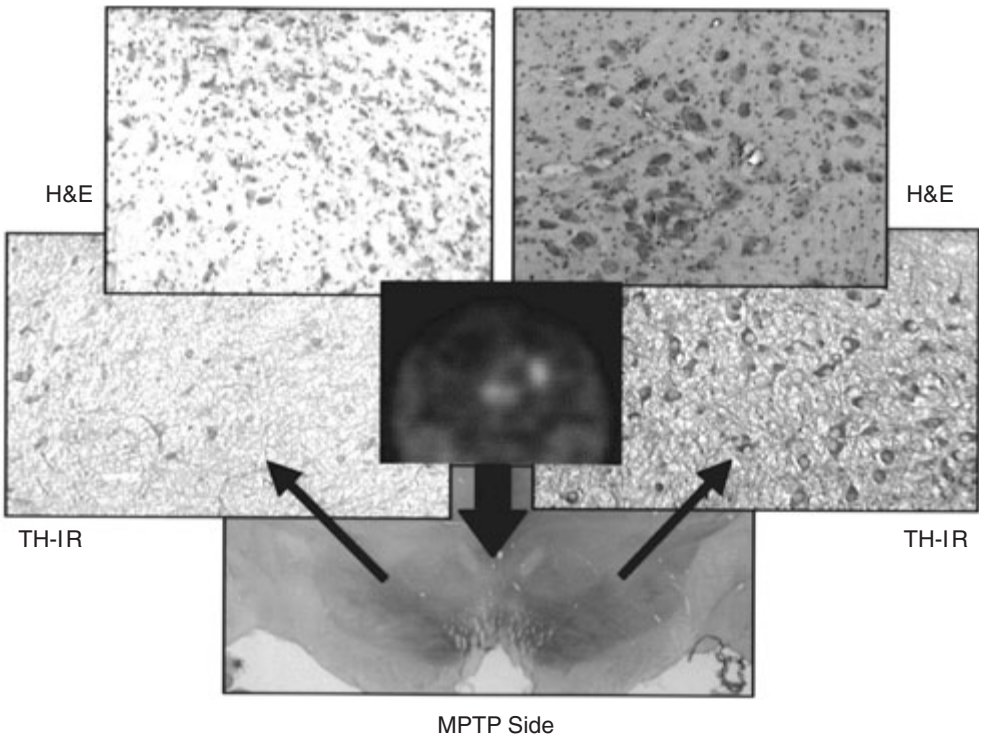

Figure 1.8.8 Three weeks following ICA administration of MPTP, this animal showed clear signs of unilateral deficit. Upon PET examination, activity in the SNC was still elevated while the signal from the putamen was absent. The animal was sacrificed one day after PET, and degenerating but still TH-positive neurons were present in the SNc. No TH staining was detected in the putamen. Abbreviations: H&E, hematoxylin and eosin staining; TH-IR, tyrosine hydroxylase immunoreactivity.

changes manifest as ataxia and fine tremor (Schmidt et al., 1982). This is a convenient model for studying potential DA trophic effects.

Homozygous weaver animals of the C57Black strain are obtained by breeding heterozygote pairs. At ~2 weeks of age, homozygous weaver animals are recognized behaviorally by poor righting response, ataxia, hypotonia, and tremor, and anatomopathologically by visible atrophy of the cerebellum.

DA-deficient mouse model. This model is created by inactivation of the TH gene resulting in an inability to synthesize DA. These mice show no TH immunoreactivity in midbrain DA neurons and their terminals have extremely low DA concentrations. Behaviorally they manifest hypoactivity, adipsia, and aphagia leading to negative growth rate and death by 4 weeks of age. L-DOPA reverses the behavioral changes, and continuous administration can lead to a nearly normal growth rate. These animals have normal development of DA midbrain neurons and nigrostriatal projections. The model is useful for DA replacement and pharmacological studies.

Critical Parameters and Troubleshooting

MPTP primate models

Handling MPTP. The experimenter should always use a chemical hood and skin protection (gloves, laboratory coat) and mask. Any spilled MPTP or excess solution should be degraded by potassium permanganate (see cautionary note in Basic Protocol 1). In case of exposure, MAO-B inhibitors block the conversion to MPP^+, thus preventing the toxic effects.

ICA administration. Selective injection in the ICA minimizes contralateral involvement. For this route, the dose should be calculated according to brain size, which is fairly stable for a wide range of body weights. In macaques there appears to be no direct correlation between the severity of the parkinsonian lesion and the dose of MPTP or the weight and age of the animal. Some monkeys are more suscepti-

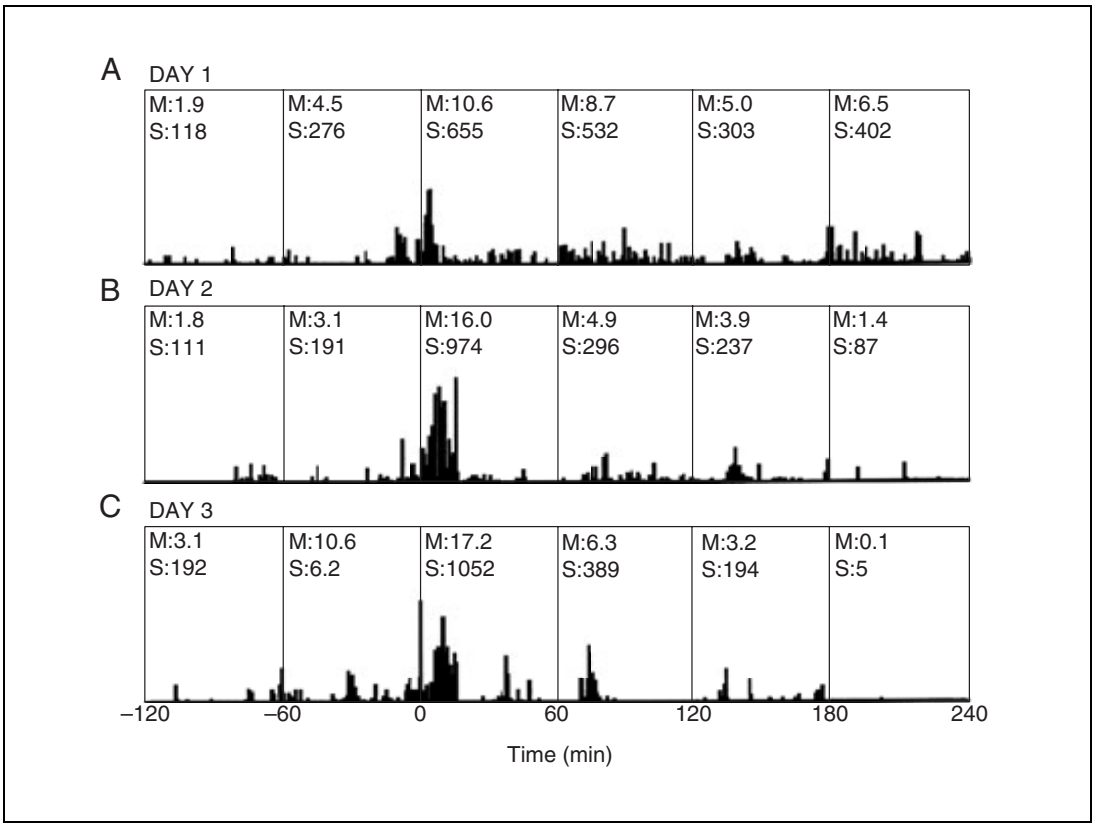

Figure 1.8.9 Activity tracing in a 24-year-old female rhesus monkey over 3 days. This animal displayed an increase of body activity 5 to 10 min following intramuscular administration of 30 mg/kg M-L-DOPA with benserazide. Only some of the hypokinetic monkeys examined showed an increase in activity in response to M-L-DOPA, suggesting that hypokinetic features in aged animals are not always due to decreased DA levels in the striatum. M, mean counts; S, sum of counts.

ble to MPTP than others and, in general, old females are more prone to MPTP toxicity than young males. The choice of anesthetics is also relevant, as the widely used ketamine inhibits DA uptake and can thus decrease MPTP toxicity by inhibiting MPP^+ uptake into the DA cells.

Acute stage. Administration of MPTP produces mydriasis, piloerection, tachycardia, and tachypnea lasting 5 to 15 min. Repeated injections produce involuntary facial (perioral) movements, facial grimacing, retrocollis, and dystonic flexion of the extremities lasting 10 to 30 min. Intake of food and water should be carefully monitored in the acute phase; some animals might require tube feeding and L-DOPA support. In the first 48 hr following ICA administration of MPTP, the animal might present partial motor seizures with occasional secondary generalization; this should be adequately treated with diazepam at 0.5 mg/kg. The degree of motor impairment is quite variable at acute stages. The severity of the motor signs increases over the first 2 weeks. This phase, which can be life threatening in severely affected animals, is followed by a period of partial improvement during the following 4 to 6 weeks, probably related to functional recovery of non-DA neurons and/or compensatory mechanisms within the nigrostriatal system. In these first weeks, dystonic posturing is frequently observed in severely lesioned animals in addition to akinesia, dyskinesia, and occasionally oculogyric crises.

L-DOPA response. Dyskinesias occur in several primate species after MPTP and chronic L-DOPA therapy (Schneider, 1989), as in the majority of patients with chronic PD who are treated with L-DOPA. In general, dyskinesias develop more rapidly in MPTP-induced parkinsonism—both in humans and nonhuman primates—than in patients with idiopathic PD, but it is exceptional when this complication appears with an acute challenge. It is nevertheless advisable to avoid the use of high doses producing significant dyskinesias as this might invalidate the test.

Model. The overlesioned bilateral model has several advantages over other models. It is a practical model in which animals are very seldom affected by MPTP to the extent that they

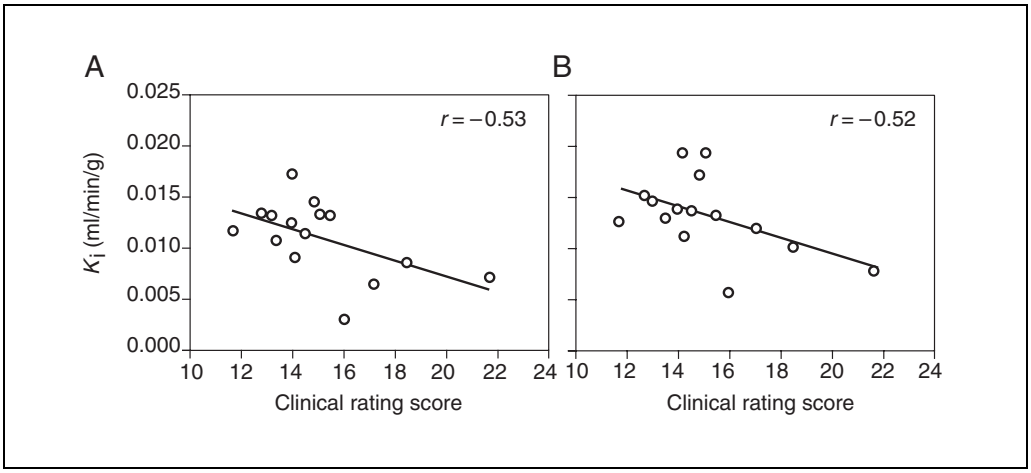

Figure 1.8.10 Relationship between K_i values for the (**A**) caudate and (**B**) putamen, and clinical rating scores for stage 2 and 3 monkeys. Monkeys with more severe clinical signs showed lower K_i values in both regions.

cannot take care of themselves. The success rate of the model is very high. Typically 80% to 90% of animals that are enrolled into the project are considered good study subjects, and the mortality rate is very low (e.g., <4%). Scientifically, this model is particularly useful because it enables approximation to several stages of PD. Monkeys defined as stage 1 and 2 are good for studies of mild stages of PD, while stage 3 animals represent a more advanced stage of the idiopathic disease. In this model, the clinical stage correlates well with biochemical markers (PET/DA punch analysis; Figs. 1.8.10, 1.8.11, and 1.8.12; Eberling et al., 1998) and with midbrain DA cell counts (Fig. 1.8.13; Oiwa et al., 2003). It is thus possible to predict the degree of the lesion on the side contralateral to ICA MPTP administration based on the clinical rating. In addition, two different types of therapeutic approaches can be addressed in the over-lesioned model:

Neuroprotection. Agents that might protect DA cells from further MPTP toxicity can be studied using monkeys in stages 1 and 2. If such agents are indeed neuroprotective, further i.v. administration will induce stage 3 parkinsonism only in a placebo control group. This is more clinically relevant than administration of a neuroprotective agent to normal animals prior to MPTP administration, because in a clinical situation neuroprotection might be used in patients with subclinical and /or mild parkinsonism.

Recovery. Therapeutic strategies aimed at improving the function of remaining DA innervation can be studied in stage 3 monkeys, as DA is only partially depleted on the side contralateral to the ICA infusion. If such an approach works, treated animals will move from stage 3 to stage 1 or 2.

6-OHDA administration in primates

6-OHDA administration in marmosets produces a persistent motor impairment in animals with extensive lesions (>97% DA depletion). In general the probability of spontaneous behavioral recovery depends on the extent of DA depletion. However, animals with a similar degree of DA denervation show different recovery profiles in behavioral tests, probably resulting from regional anatomical variation in DA content. Thus, it is necessary to obtain data from a group of animals to control for spontaneous recovery. Rotation in response to apomorphine is fairly stable over time and correlates with other motor scores. Amphetamine induces rotation, but does not increase motor activity and does not correlate with other measures.

6-OHDA rat model

The 6-OHDA rat model is rather simple and reliable, although the rotational response must be tested to select rats with severe lesions (>99% DA depletion) for use in long-term experiments. This means that it is necessary to lesion a large number of animals to produce enough well-lesioned animals. High doses (>40 μg) have a considerable mortality rate (e.g., 3% to 5%), as do bilateral lesions. The volume of the infusion is relevant, as diffusion depends directly on volume. For medial forebrain bundle (MFB) lesions, small volumes are recommended to keep the lesion limited; for striatal infusion, large volumes are necessary to cover the whole nucleus.

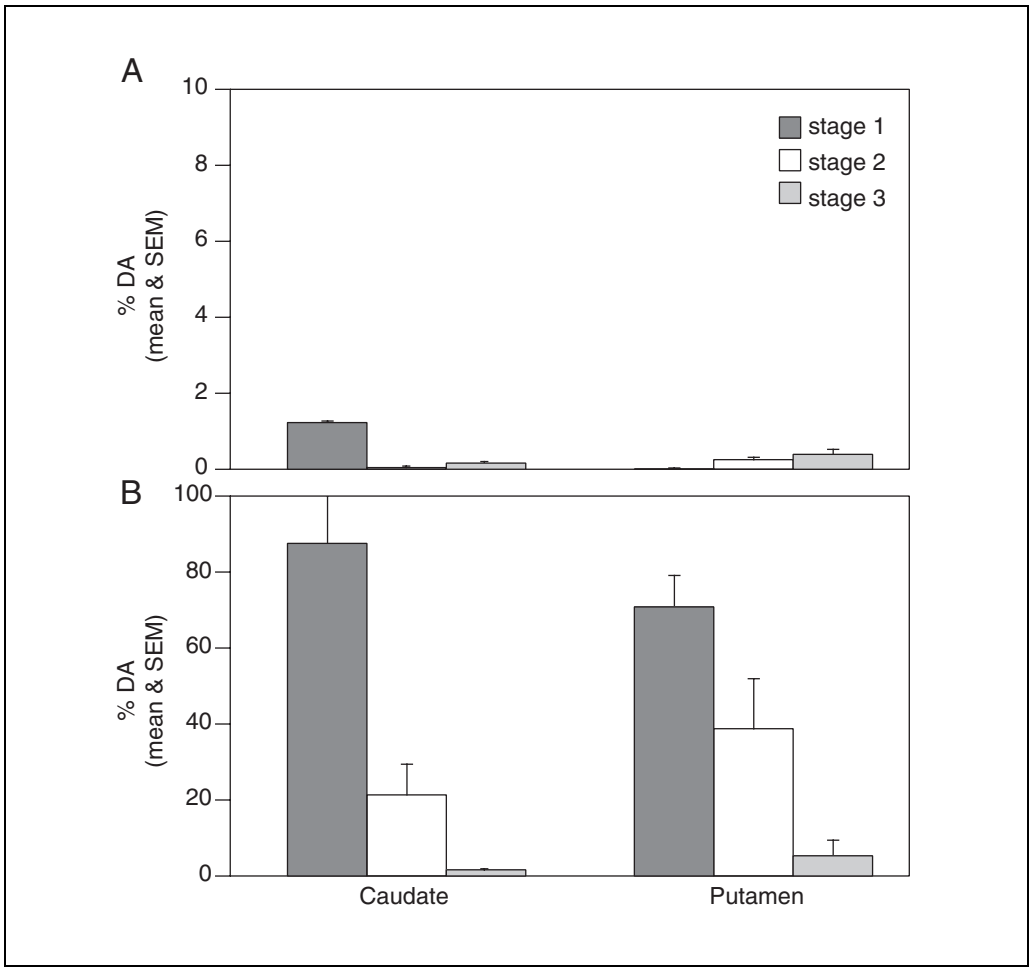

Figure 1.8.11 Tissue concentration of DA in the caudate nucleus and putamen in parkinsonian monkeys at stages 1 ($n = 3$), 2 ($n = 7$), and 3 ($n = 5$) shown as a percentage of (**A**) ipsilateral striatum and (**B**) contralateral striatum tissue concentration in normal ($n = 4$) monkeys.

MPTP administration in mice

Systemic MPTP administration in mice causes damage to the nigrostriatal rather than mesolimbic terminal areas (Donnan et al., 1987). The severity and duration of this specific damage depends on total dose, administration regimen (multiple injections are more effective than single), route of administration (subcutaneous is the most effective), strain (C57Black strain is the most sensitive), and age (older animals are more sensitive; Heikkila and Sonsalla, 1987; Date et al., 1990). The neurotoxic effect of MPTP can be augmented by coadministration of diethyldithiocarbamate, acetylaldehyde, or ethanol. Recovery of behavioral, neuropathological, and biochemical changes is observed after a variable period of time, most frequently over a period of months depending on the dose of MPTP and cotreatment regimen (Hallman et al., 1985; Donnan et al., 1987).

Anticipated Results

Motor behavior

Primates. Unilateral administration of MPTP and 6-OHDA is attended by persistent contralateral motor impairment; both upper and lower limbs show the characteristic parkinsonian signs of bradykinesia, rigidity, cogwheeling, and tremor. Spontaneous locomotor activity usually consists of continuous circling towards the lesioned side. Treatment with L-DOPA/carbidopa or the directly acting mixed D1 and D2 receptor agonist apomorphine alleviates motor deficits and reverses the direction of turning (Bankiewicz et al., 1986). The apomorphine-induced turning response in a direction away from the lesioned side is very stable over time (for ≥5 years) and can also be quantified. Assessment of drug-induced turning response and function of the contralateral arm can be used for evaluation of new experimental therapeutic strategies.

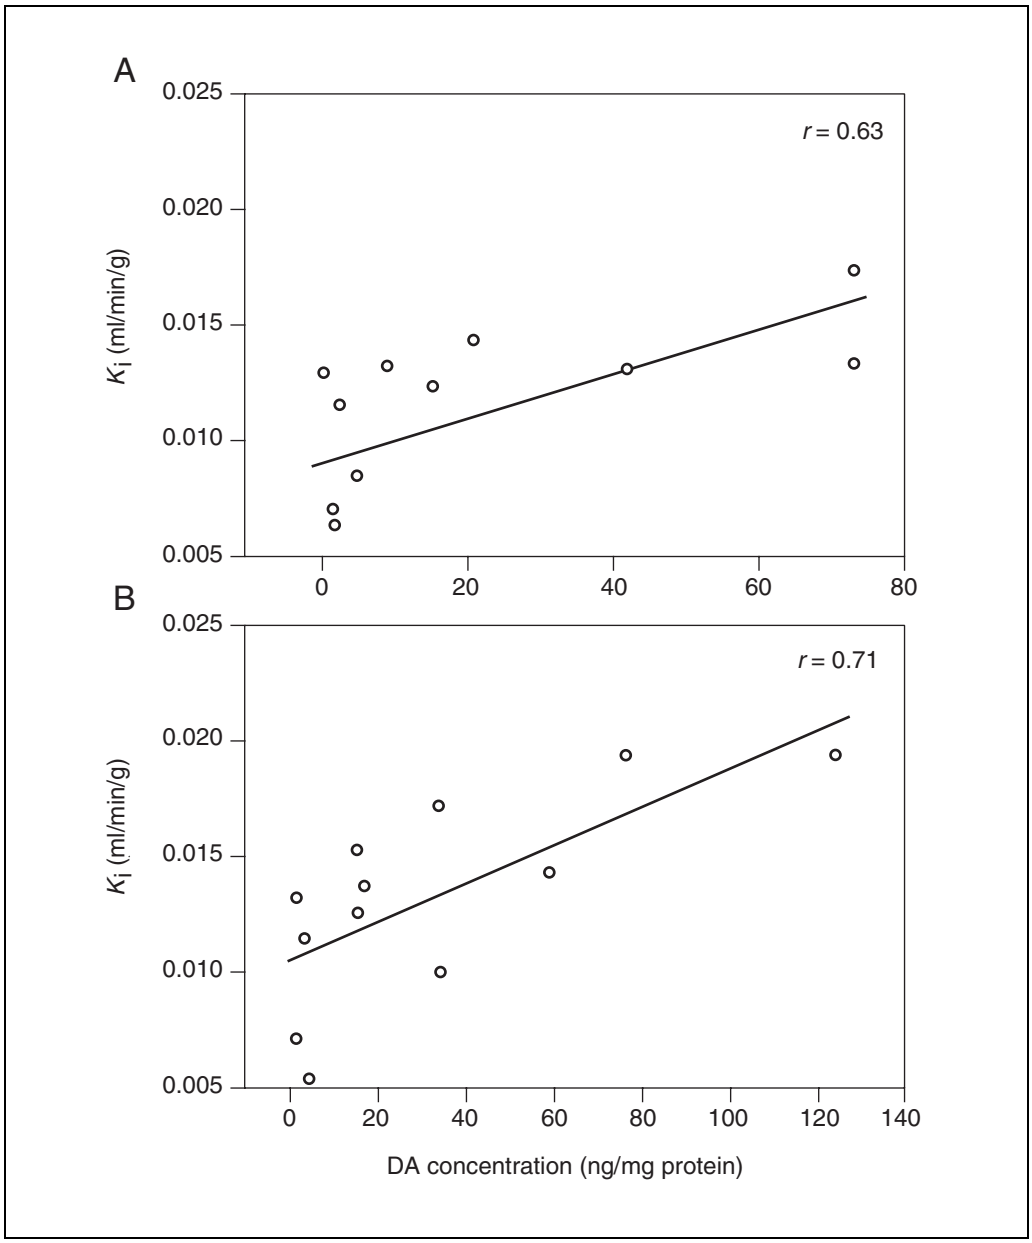

Figure 1.8.12 Correlation between levels of DA as measured by PET and HPLC in stage 2 and 3 overlesioned hemiparkinsonian monkeys in (**A**) caudate and (**B**) putamen.

Systemic and overlesioned models using MPTP produce a bilateral parkinsonian syndrome displaying axial signs, such as stooped posture and impaired balance. In these animals evaluation can be made using a specific scale similar to the UPDRS, such as the one shown in Table 1.8.1. Figure 1.8.2 shows the effect of increasing doses of L-DOPA on motor activity and scores in a stable parkinsonian primate.

Rodents. In rats, turning behavior is the easiest way to assess the degree of DA denervation. Apomorphine induces contralateral rotation in animals with >90% striatal DA depletion. In animals with partial lesions, apomorphine does not induce significant turning but amphetamine induces ipsilateral rotation demonstrating an asymmetry in DA content. In mice, a decrease of spontaneous locomotor activity and an increase in response to amphetamine can be observed.

In vivo neurochemical changes

CSF. After unilateral administration of MPTP in monkeys, the level of monoamine metabolites in cerebrospinal fluid (CSF) initially drops. However, after 3 months, only the levels of homovanillic acid remain low (Burns et al., 1983). In hemiparkinsonian monkeys, the initial decrement in CSF monoamine metabolites and DA levels is >60%; three weeks after

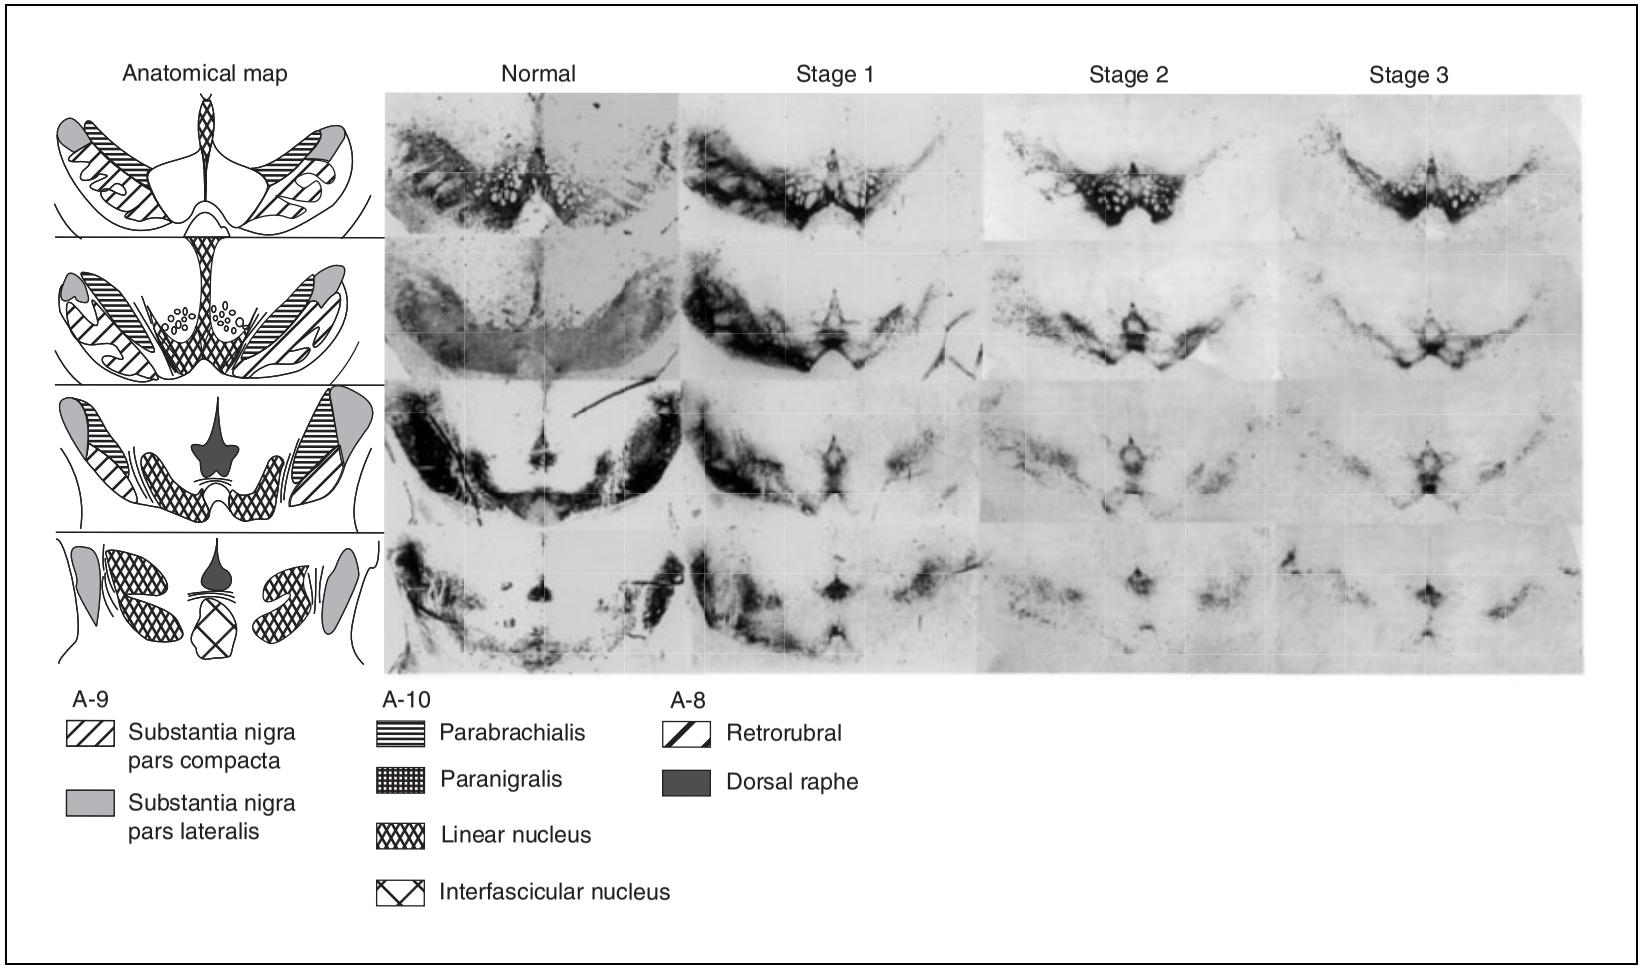

Figure 1.8.13 Anatomical representation of midbrain DA structures in normal and stage 1, 2, and 3 overlesioned hemiparkinsonian monkeys. In stage 1, DA cells in the SNc (A-9 region) are severely depleted while the contralateral side shows no significant cell death in this region. Note that TH-positive cells in the SNc are further depleted in stage 2 and 3 monkeys, which corresponds to progressive parkinsonian signs that are seen in these monkeys. Regions of the ventral tegmental area are partially spared at all stages.

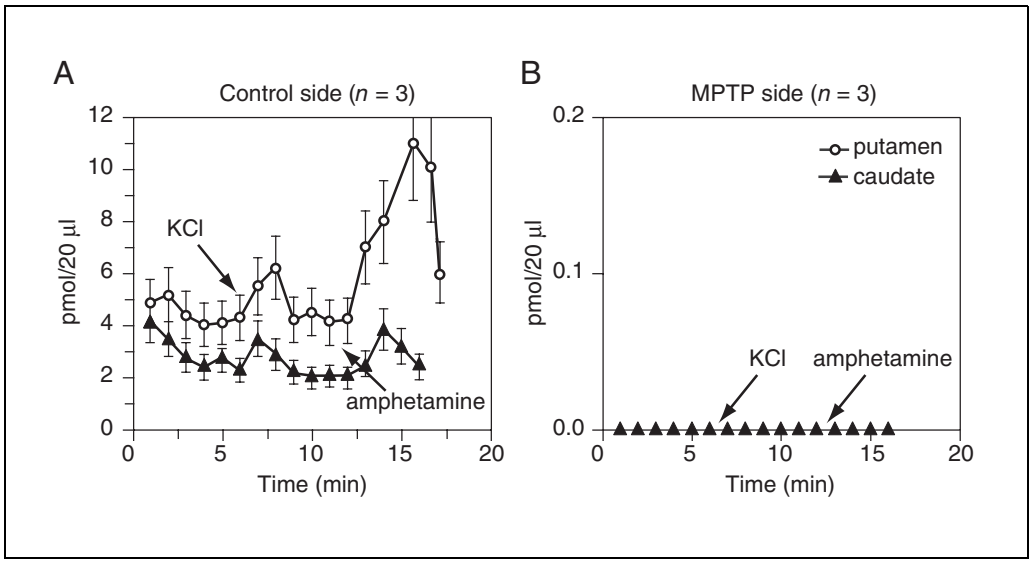

Figure 1.8.14 Results of in vivo microdialysis of three hemiparkinsonian (stage 1) monkeys. Samples were collected over 20 min from the caudate and putamen on both sides of the brain and were analyzed for levels of DA. Extracellular levels of DA were detected only on the control side (**A**), with putamen showing higher levels of DA than caudate nucleus. KCl and amphetamine induced DA release only on the control side, suggesting complete DA lesion on MPTP-treated side (**B**).

the lesion they are decreased by only 40% to 50% (Bankiewicz et al., 1990).

Microdialysis. Extracellular fluid (ECF) levels of catecholamines in brain tissue can be examined in vivo by microdialysis (Fig. 1.8.14). Using a small probe (27-G), it is possible to measure the regional distribution and concentration of DA and its metabolites in brain ECF (Wang et al., 1990). With this technique it is also possible to examine the relationship between changes in levels of different neurotransmitters in brain ECF. Methodology for performing microdialysis experiments in MPTP-treated monkeys is described elsewhere (Wang et al., 1990).

Postmortem analyses

Parkinson's disease is characterized by loss of DA neurons in the SNc leading to DA depletion in the striatum. Consequently, evaluation of nigral cell loss and striatal DA deficiency are the main post mortem outcome measures for all of these models.

Immunohistochemistry. The distribution of neuronal damage within the SNc in the MPTP-treated animal model (see Basic Protocol 1) is also of interest because histological changes in this region are exhibited in a specific pattern in PD. MPTP is selectively toxic, affecting mostly the nigrostriatal DA system while leaving the mesolimbic system relatively intact. The midline population of DA cells in the midbrain (ventral tegmental area, paranigralis nucleus, and paraventricular area), the parabrachial nucleus, and parts of nucleus lateralis are affected by MPTP (German et al., 1988). Furthermore, the damage closely resembles the histological findings in PD. TH immunoreactivity in DA midbrain nuclei and anatomic schemes of each level are shown in Figure 1.8.12 for different stages.

MPTP-treated monkeys in stage 1 (hemiparkinsonian) show a dramatic loss of DA cells (>95%) in the SNc on the MPTP-lesioned side, whereas animals at stage 2 and 3 display further loss of DA neurons on the contralateral side as they become more parkinsonian (Fig. 1.8.13). This pattern follows changes observed by neuroimaging (Figs. 1.8.5 and 1.8.6) and biochemical techniques (Fig. 1.8.11).

The decrease of TH immunoreactivity in the SNc (cell bodies) and striatum (projections) is observed in all models described here. However, it is transient in mice and, in partial lesions, a significant recovery can be observed over time.

Unilateral injection of 6-OHDA in marmosets (see Basic Protocol 2) produces a decrease in TH immunoreactivity in the SNc of 90% to 97% on the contralateral side (Annett et al., 1992).

In rats treated with 6-OHDA (see Basic Protocol 3), loss of TH-positive nigral cells depends on the type of lesion. Lesions of the

MFB and SNc at high doses should achieve a complete nigral depletion. Partial lesions should respect VTA and the medial ventral tier. Striatal lesions cause a cell loss in the ipsilateral SNc that is correlated with the dose and volume of the striatal injection.

Neurochemical changes. MPTP administration (see Basic Protocol 1) causes a profound reduction in striatal DA with no clear differences between caudate and putamen levels. After ICA MPTP administration, DA is almost completely absent in the caudate and putamen on the lesioned side. The difference in DA concentration between the normal and the MPTP-treated side is >96% (Fig. 1.8.11). This represents almost total DA denervation of the caudate and putamen on the MPTP-lesioned side. However, greater concentrations of DA are found in areas that receive innervation from remaining DA cells in the ventral tegmental area (e.g., nucleus accumbens septi, area olfactoria, septum pellucidum). In the model that combines ICA and i.v. MPTP administration, DA depletion on the side contralateral to ICA administration is much less severe than on the side of ICA administration and correlates with the severity of parkinsonian signs. DA concentration, as measured by postmortem striatal punches (Fig. 1.8.11), correlates well with in vivo PET measurements of DA activity (Fig. 1.8.12).

In marmosets lesioned with 6-OHDA (see Basic Protocol 2), the reduction of DA in the ipsilateral striatum is usually >97% (Annett et al., 1992). In rats lesioned with 6-OHDA (see Basic Protocol 3) and showing a robust rotational response to apomorphine, DA levels are decreased by >99% in the contralateral striatum.

Time Considerations

For Basic Protocol 1, ICA injection takes 30 to 60 min and i.v. injection takes 15 min. To obtain overlesioned animals, a 2-week waiting period is required between ICA and i.v. administration. It is then necessary to wait 6 to 8 weeks (acute stage and spontaneous recovery) to establish a stable parkinsonian syndrome. Clinical rating takes <10 min but is variable depending on the familiarity and cooperation of the animals. The L-DOPA test requires 5 min preparation and 60 to 120 min observation. Activity monitors require 5 min to put on and remove collars (vests take slightly longer), after which it is necessary to record for several days to account for normal variation in baseline activity.

For Basic Protocol 2, the stereotactic procedure takes 40 to 60 min and it is advisable to wait 6 to 8 weeks to ensure stable animals.

For Basic Protocol 3, the whole procedure should take 30 to 40 min, in which the infusion rate is the time-limiting factor. For long-term experiments it is necessary to test the rotational response to apomorphine/amphetamine 3 to 6 weeks later and to select only rats with a complete lesion (>99% DA depletion). These animals show a stable deficit with consistent drug-induced rotational behavior over time appropriate for such studies.

Basic Protocol 4 is a very simple and quick procedure as animals can be used right away but only for a short period of time. Animals show minimal or no behavioral symptoms after weeks to months.

CHAPTER 2
Assessment of Cell Toxicity

INTRODUCTION

Environmental agents that are injurious to cells trigger a spectrum of responses that can range from cell death to adaptation, repair, and proliferation. Cell death, in turn, can take the form of apoptosis—a programmed form of cell death that requires gene expression—or necrosis. A host of environmental agents have been implicated in toxic cell injury, among them free radicals (nitrogen, oxygen, and carbon derivatives), which are known to interact with cellular constituents including membrane lipids and chromagen materials.

There are various ways of evaluating cellular toxicity and cell death, and a number of different indices for assessing cellular response to toxic stimulus or injury. *UNIT 2.1* outlines the current understanding of what constitutes cell toxicity and how it should be defined. *UNIT 2.2* presents a number of methods that can be used to discriminate between the apoptotic and necrotic modes of cell death. Because many of the distinguishing criteria are not specific to one mode, more than one method should be used to make the determination. It is now known that the mitochondrial function is changed in apoptosis. *UNIT 2.10* provides protocols for assessment of various aspects of mitochondrial function. *UNIT 2.3* describes immunochemical methods for detecting the covalent binding of chemicals to proteins as a means to investigate the interactions of potentially cytotoxic chemicals with cellular constituents. *UNIT 2.4* describes methods for detecting lipid peroxides, free radicals formed by the interaction of oxygen derivatives with membrane proteins. Oxygen free radicals have been implicated in both apoptosis and necrosis.

UNIT 2.5 provides protocols for measuring intracellular free Ca^{2+} using fluorescence spectroscopy or digital imaging microscopy. Changes in cellular Ca^{2+} homeostasis are intimately linked to cell death, with the cascade of events that they set in motion culminating in cellular necrosis and/or apoptosis. In addition, intracellular calcium is used in signaling and as a second messenger.

UNIT 2.6 provides protocols that can be used to detect cytotoxicity, which is operationally defined as the effect toxicants have on cell growth, metabolic functions, or viability. The protocols permit detection of physiological and/or morphological changes that may have occurred as a consequence of toxicant exposure. Sixteen protocols are provided to detect cytotoxicity in vitro. These protocols can be used to screen chemicals efficiently and economically before testing in animals.

UNIT 2.7 describes in situ hybridization for analyzing specific cellular mRNA in frozen and cryostat-sectioned tissues. The method combines cell and molecular biology techniques for detection and localization of specific nucleic acid sequences within individual cell or tissue preparations. Many protocols have been developed for different types of in situ hybridization. This unit includes methods using either radiolabeled or digoxigenin-labeled probes.

Current Protocols in Toxicology (2004) 2.0.1-2.0.2

UNIT 2.8 presents a basic insight into the theoretical and practical possibilities and limitations of confocal microscopy. It also provides practical guidelines for the novice user of the technique. The method makes it possible to view a very thin optical plane in a specimen by excluding light from planes above and below the focal plane. Although there are several different types of confocal microscopes developed for specialized purposes, this unit concentrates on confocal scanning laser microscopy (CSLM).

The heat shock family of proteins (HSP) rapidly responds to chemical and environmental insults. The HSP70 family of proteins comprises a major family of stress-responsive proteins that have in common various functions in cellular defense mechanisms. *UNIT 2.9* provides procedures that allow measurement of response of different isotypes of the HSP70 family at the transcription and translation levels.

Mahin D. Maines

Current Concepts in Cell Toxicity

Toxicology is sometimes defined as the study of the adverse or harsh effects of toxic agents on living cells, tissues, or whole organisms. The term "toxic agent" is generally used to refer to both naturally occurring toxic substances (toxins) and to harmful products or byproducts (toxicants) generated from human activities, which may have diverse effects on living cells. These agents can be subclassified in various ways—for example, according to their target organ (e.g., liver, kidney, or reproductive organs), industrial use (e.g., food additives or pesticides), source (e.g., animal or plant toxins), and effects (e.g., cancer or liver injury). When a cell is exposed to toxic agents, it will undergo certain molecular or biochemical transformations. The biotransformations or alterations caused by the cell's exposure to harmful products is generally referred to as cell toxication or cell toxicity. On the other hand, the biotransformations or cellular alterations that lead to the elimination of toxicants or the prevention of toxic metabolite formation from these compounds are called "cell detoxification."

Cell toxicity can have reversible (short-lived or repairable) effects, or affect the cell irreversibly, leading to mutations, malignant transformation, or cell death. The final outcome of being in contact with toxic agents depends mainly on the nature of the toxic substance, the dose applied, and the exposure time. At low doses or short exposure times, small quantities of the toxic agent will come in contact with the cell and be delivered into its cytosol. This may lead to toxicity resulting from the mere presence of the agent in the cell, or the agent may interact with an array of target molecules. Such toxicity initiates a series of events leading to minor and potentially reversible injuries. These events can cause a temporary halt in some of the cellular functions. Similarly, the presence of toxic agents or cellular injuries caused by them may activate the cell's defenses—detoxification or repair mechanisms—to enable it to withstand such harsh environments and to repair the injuries that have been inflicted upon the cell. The cell's defense mechanisms involve rapid production or activation of specific molecules—examples of which are heat-shock proteins (HSPs), metallothioneins (MTs), superoxide dismutases (SODs), and catalase—which enable the cell to withstand or tolerate selective toxic agents. A number of xenobiotics (e.g., carbon monoxide, heavy-metal ions, and strong acids and bases) are directly toxic, whereas the toxicity of the others is largely due to production of metabolites. The mechanism of detoxification includes glutathione, cytochrome P-450, Cu, Zn-SOD, and Mn-SOD.

However, at high doses or prolonged exposure times, the toxic agents cause irreversible cellular damage, to the extent that the rate of toxication exceeds that of detoxification, leading to a general cellular dysfunction and cell death. This unit attempts to define cell toxicity that leads to cellular demise, with a strong emphasis on cell death via both apoptosis and necrosis, by summarizing some of the more recent developments in cellular, molecular, and biochemical studies of the events that govern the induction and execution of cell death.

CELL DEATH

Toxic cell death can occur via two processes, which are fundamentally different in their nature and biological significance (Kerr et al., 1972). These are termed necrosis and apoptosis and their features are summarized in Table 2.1.1.

Necrosis, or "accidental" cell death, was the classic model and was thought to be the universal mode of cell death until apoptosis was identified in 1972 as a separate mode of cell death. In general, necrosis is considered to be a passive process (Trump and Ginn, 1969) that is usually caused by extreme trauma or injury to the cell (Kerr et al., 1972). In tissues, necrosis is often seen as a lesion or patch consisting of many disintegrated cells. Typically, necrosis involves irreversible changes within the nuclei (such as karyolysis), loss of cytoplasmic structure, dysfunction in various organelles (especially mitochondria), and, finally, cytolysis as a result of high-amplitude swelling. The release of the dying cell's contents into the extracellular space can cause further injury or even death of neighboring cells, and may result in inflammation or infiltration of proinflammatory cells into the lesion, leading to further tissue damage (Haslett, 1992).

The first references to a different type of cell death came from developmental studies. The concept of a programmed physiological cell death in developmental biology or embryology refers to the type of cell death that occurs at

Current Protocols in Toxicology (1999) 2.1.1-2.1.16

Table 2.1.1 Features of Apoptosis and Necrosis

Characteristics	Apoptosis	Necrosis
Stimuli	Physiological or pathological	Pathological (injury)
Occurrence	Single cells	Groups of cells
Reversibility	Limited	Limited
Cellular level		
Cell shape	Shrinkage and formation of apoptotic bodies	Swelling and later disintegration
Adhesion between cells	Lost (early)	Lost (late)
Phagocytosis by other cells	Present	Absent
Exudative inflammation	Absent	Present
Cellular organelles		
Membranes	Blebbing	Blebbing proir to lysis
Cytoplasm	Late-stage swelling	Very early swelling
Mitochondrial permeability transition	Present	Present
Nucleus	Convolution of nuclear outline and breakdown (karyorrexis)	Disappearance (karyolysis)
Biochemical level		
Gene activation	Present[a]	Absent[a]
Requirement for protein synthesis	Present[a]	Absent[a]
Lysosomal enzyme release	Absent	Present
Activation of non-lysosomal enzymes	Present	Present
Activation of caspases	Present	Absent
Cleavage of specific proteins	Present	—[a]
Changes in cytoskeleton	Present	Present
Level of ATP required	High	Low
Bcl-2 protection	Present	Present
Nuclear chromatin	Compaction in uniformly dense masses	Clumping not sharply defined
DNA breakdown	HMW and internucleosomal	Randomized
RNA degradation	Present	—[a]
Phosphatidylserine exposure	Present	Absent

[a]This feature is not a universal event or there are conflicting reports.

specific times during the development of the organism. Glucksmann (1951) clearly emphasized the existence of this phenomenon for the first time. This was followed by a surge of interest in 1960s (for a review see Lockshin, 1981). In the 1970s, histochemical studies of lysosomal changes in hepatic ischemia provided direct evidence for the existence of two distinct types of cell death (Kerr, 1971; Kerr et al., 1972). It was observed that rounded masses that developed in dead hepatic tissue contained cells that were morphologically different from those found in necrosis. These differences initially caused some confusion: the process was mistaken for a variation of necrosis and was called "shrinkage necrosis" (Kerr, 1971). The following year, Kerr, Wyllie, and Currie proposed the term "apoptosis" to describe the distinct morphological changes associated with this form of cell death (Kerr et al., 1972). Nowadays, apoptosis commonly refers to the process of cell death leading to the appearance of the morphological changes, rather than to the morphological characteristics themselves, which set this form of cell death apart from necrosis.

Apoptosis has been described as a form of cellular suicide, since death appears to result from induction of active processes within the cell itself. Typically, apoptosis involves margi-

nation and condensation of nuclear chromatin (pyknosis), cytoplasmic shrinkage, membrane blebbing, nuclear fragmentation, and finally, formation of apoptotic bodies.

A cell that is dying, whether by apoptosis or necrosis, undergoes rapid changes which are reflected in its structure, morphology, and biochemistry. These are generally a result of various enzymes activated through elaborate signaling pathways. Since the first description of apoptosis in 1972, there has been a surge of interest in the study of apoptosis, and very little attention has been given to necrosis. This lack of parallel study of the two processes is also reflected in the degree of detail provided here describing apoptosis and necrosis.

STRUCTURAL CHANGES DURING CELL DEATH

Considerable biochemical changes occur within the apoptotic cell, which facilitate neat packaging and removal of apoptotic bodies by neighboring cells. However, as described above, necrosis is accompanied by high-amplitude cell swelling. Modifications in the cytoskeleton and cytoplasmic membrane are required for both shrinkage and swelling to occur. During apoptosis, this results in the loss of cell-cell contact, untethering of the plasma membrane, and rapid blebbing or zeiosis (Saunderson, 1982). Similarly, necrotic cells undergo membrane blebbing, but in contrast to apoptosis, the tracts of contiguous dying necrotic cells collapse without loss of contact with neighboring cells. This results in clumps of necrotic cells rather than single cells.

Tissue transglutaminase, a Ca^{2+}-dependent protein-glutamine γ-glutamyltransferase, is induced and activated in liver hyperplasia and in glucocorticoid-treated thymocytes (Fesus et al., 1987). This enzyme cross-links cytokeratin, a component of the cytoskeleton, through ε-(γ-glutamyl) lysine bonds. During apoptosis there is a significant increase in transglutaminase mRNA, as well as the the protein itself, its enzyme activity, and protein-bound (γ-glutamyl) lysine (Fesus et al., 1987). It is thought that transglutaminase activity may stabilize apoptotic cells and inhibit membrane leakage during the early stages of the process by forming a shell around the cell. Transglutaminase activity, however, does not appear to change during necrosis. For example, it was recently reported that ethanol-induced cytotoxicity in astroglial cells was due to necrotic cell death, and that it occurred in the absence of any change in transglutaminase activity (Holownia et al., 1997).

A critical part of apoptosis, in contrast to necrosis, is the efficient recognition and removal of the apoptotic cells by phagocytes (Fadok et al., 1992). This involves the rearrangement and biochemical alteration of the plasma membrane in the dying cell. There are a number of different changes that occur in the plasma membrane of apoptotic cells. One such change results in the alteration of carbohydrates on the plasma membrane, which helps preferential binding of macrophages to apoptotic cells (Duvall et al., 1985). Recognition of apoptotic cells by macrophages can also be mediated via the vitronectin receptor (CD36; Savill et al., 1990). The loss of membrane phospholipid asymmetry in the membrane of cells undergoing apoptosis is yet another significant change leading to the externalization of phosphatidylserine at the surface of the cell, thereby enabling cell recognition by macrophages (Fadok et al., 1992). Development of fluorescently labeled annexin V, which binds specifically to phosphatidylserine residues, enables detection of this externalization in apoptotic cells (Koopman et al., 1994). However, under in vitro culture conditions, where phagocytic cells are absent, apoptotic cells and their fragments lyse in a process very similar to that observed in necrosis. This phenomenon is termed secondary necrosis or post-apoptotic necrosis. Despite such systematic changes in the plasma membranes of apoptotic cells, there are no reports of any changes in the composition of the plasma membranes of necrotic cells. Necrotic cells do not undergo phagocytosis by other cells, and the spillage of their cellular contents through plasma membrane disruption into the extracellular milieu induces cellular inflammatory responses.

Cell-volume changes are another feature of cell death. Interestingly, the cell volume changes during apoptosis and necrosis go in different directions. Apoptotic cell shrinkage, which leads to a loss of 30% to 50% of the cell volume (Saunderson, 1982), is due to budding of the endoplasmic reticulum. Vesicles thus generated migrate and fuse to the plasma membrane, releasing their contents into the extracellular region. This process requires energy (ATP), since water is moved against the osmotic gradient (Saunderson, 1982). Mitochondria, which are postulated to remain structurally and functionally intact during apoptosis, provide the necessary energy. In contrast, during necrosis the cell loses control of ion flux, resulting in a reduction in concentration gradients of Na^+, K^+, Ca^{2+}, and Mg^{2+}, as well as changes in

osmotic pressure. This, in turn, leads to uptake of water, giving rise to high-amplitude swelling of the cell and its organelles. This process is energy-independent and does not require a large amount of ATP.

MACROMOLECULAR DEGRADATION DURING CELL DEATH

Cell death is associated with activation or increase in the activity of lipases, nucleases, and different classes of proteases. In apoptosis there is an efficient and neat packaging of the cell contents into apoptotic bodies. This requires the rearrangement and breakdown of lipids, proteins, and nucleic acids. Another possible reason for efficient degradation of macromolecules in apoptotic cells prior to their phagocytosis is that contents from dead cells are thus prevented from entering the phagocyte or the neighboring cells and causing the same injuries that may have cost the dying cell its life. Which enzymes and substrates are activated depends on the induction stimuli and/or the cell type. In necrosis, the types of enzymes activated appear to be different, with very little overlap, if any, with the apoptotic enzymes. These enzymes are largely lysosomal acidic enzymes with less specific substrates than the apoptotic enzymes. However, these necrotic enzymes are thought to be activated in late apoptosis and in the absence of phagocytosis, when the cells undergo secondary necrosis. Thus, there is a similarity between the features of necrotic cells and those of apoptotic cells undergoing secondary necrosis. The major macromolecules and the mode of their degradation during apoptosis and necrosis are discussed below.

DNA Degradation

Three patterns of DNA degradation are already known to occur during apoptosis. One or more of these may occur during the progression of apoptosis in a single cell (for review see Zhivotovsky et al., 1994). These are: single-strand nicks (Gorczyca et al., 1992), chromatin cleavage with the formation of large (50- to 200-kbp) fragments (Brown et al., 1993; Zhivotovsky et al., 1994), and finally formation of nucleosome-size fragments of 180 to 200 bp, which produce the ladder pattern that has long been accepted as a biochemical hallmark of apoptosis (Wyllie, 1980).

One or more nuclear endonucleases have been suggested as being responsible for these patterns of DNA fragmentation, since isolated nuclei can be induced to produce the same pattern. A number of endonucleases have been identified in different cell systems, with different ion requirements for their activity (for review see Zhivotovsky et al., 1994). For example, the endonuclease in thymocytes is Ca^{2+}/Mg^{2+}-dependent, whereas the endonuclease operating in HL-60 cells appears to function independently of these ions (Fernandes and Cotter, 1993). Endonuclease activity in cells undergoing apoptosis can be regulated by proto-oncogenes and tumor-suppressor genes, such as *c-myc*, Ha-*ras*, *bcl-2*, and *p53*, as shown by analysis of genetic control of susceptibility to apoptosis (Arends et al., 1993). The apoptotic endonuclease or endonucleases cleave DNA at the exposed linker regions, and it has been suggested that these nucleases are topologically constrained rather than sequence constrained. Results obtained from cloning and sequencing DNA fragments from apoptotic cells show that the nuclease has no preference for specific DNA sequences or for the type of DNA to cleave. This randomness may be functionally important, and reflects the known properties of the endonucleases. The finding that apoptotic endonucleases are constitutive enzymes and that their activity can be modulated by different signals in cells undergoing apoptosis underlines the important role of nucleases in both physiological and pathophysiological processes. Although the role of intracellular endonucleases is not yet understood, one may speculate that a major function is to maintain genomic stability. Unfortunately, both purpose and mechanisms of DNA fragmentation in apoptotic cells are still unclear. Such fragmentation could serve to destroy the genetic information of unwanted cells and thus act as an irreversible step in the process. On the other hand, it may be simply a mid-to-late event that reflects ion redistribution and subsequent chromatin hypersensitivity to endonuclease(s) present in apoptotic cells. Alternatively, it may facilitate cleavage of DNA before uptake of apoptotic bodies during phagocytosis. Whatever the reason, it is still important to understand the mechanisms of this intriguing step of apoptosis.

As compared to apoptosis, at least two patterns of DNA degradation are recognized as occurring during necrosis. The first is the formation of both single- and double-strand DNA breaks. The second is randomized chromatin fragmentation. It is unclear if there is a link between these two steps of chromatin disintegration, although the probability for that is

rather high. DNA fragments isolated from necrotic cells contain 5′-OH and 3′-PO_4 end groups. Among different endonucleases isolated and characterized up to now, only one is able to produce such DNA fragments—i.e., DNase II, which is localized in lysosomes. This makes sense, since the activation of lysosomal enzymes has been observed in necrotic cells. Several publications have implicated the involvement of DNase II in apoptosis as well; however a critical role for this enzyme in apoptosis appears improbable in view of at least two considerations. First, DNase II is a lysosomal enzyme and lysosomes are intact until very late stages of apoptosis. Second, DNA fragments isolated from apoptotic cells contain 3′-OH end groups, not 3′-PO_4 groups as in necrotic cells. The search for enzymes responsible for cleaving of chromatin during necrosis is still in progress in many laboratories.

RNA Degradation

Changes in ribosomal counts occurring in response to cell injury have been known for a number of years. This phenomenon may be a result of the release of ribosomes from the endoplasmic reticulum at particular stages leading to necrosis (for review see Bowen, 1981). A detailed analysis of the role of ribosomes in the pathogenesis of liver-cell necrosis was conducted by Bernelli-Zazzera (1975). He showed that ischemia resulted in a decrease in the number of ribosomes, and that stripped rough endoplasmic reticulum from ischemic cells bound fewer added ribosomes than did the reticulum from normal cells. We have concluded that there is a "loosened relationship" between endoplasmic reticulum membranes and ribosomes in ischemic livers. However, it is unknown how specific these changes are for necrosis and what relationship they bear to this type of cell death.

There are also a number of reports that RNA, as well as DNA, is susceptible to cleavage during apoptosis. The changes in ribosomal RNA (rRNA) during apoptosis are best studied. rRNA consists of conserved and divergent (or variable) domains numbered from D1 to D12 (for review see Houge and Doskeland, 1996). The cleavage of rRNA during apoptosis selectively affects the two largest divergent domains, D2 and D8, in the large 28S rRNA molecule of the 60S ribosomal subunit, while the 18S rRNA molecule in the 40S ribosomal subunit remains unaffected (Houge et al., 1993). However, the pattern of rRNA cleavage occurring during apoptosis cannot be reproduced in necrotic cells or when exposing cell lysates to random RNase activity, suggesting that it is specific to apoptotic cells.

Recently it was demonstrated that rRNA and DNA cleavages can occur independently in apoptotic cells (Samali et al., 1997). In other words, the previously observed correlation is likely to be coincidental. The absence of apoptotic rRNA cleavage in some cell types suggests that this phenomenon is tightly regulated and unrelated to DNA fragmentation. Therefore it appears that the pattern of fragmentation seen during apoptosis is not part of a scheme for general macromolecular disintegration and degradation, but rather a trait present in only some cell types.

Protein Degradation

The prerequisite for proteolysis in apoptosis is well documented. Several proteolytic activities were implicated in both the induction and execution steps of cell killing (for review see Zhivotovsky et al., 1997). Early evidence of a role for proteases in apoptosis came from studies on granule proteases (granzymes/fragmentins). These investigations identified granzymes involved in the exocytosis pathway of lymphocyte-mediated cytotoxicity, which are responsible for the lethal damage inflicted by these cells upon target cells (Shi et al., 1992). More recently, a family of aspartic acid–specific cysteine proteases have been discovered in mammalian cells, which share homology with the *Caenorhabditis elegans* death gene, *ced-3* (Yuan et al., 1993). The newly adopted nomenclature for these enzymes, caspases, refers to the aspartic acid–specific cysteine protease activity specific to this family (Alnemri et al., 1996). At least thirteen of these proteases have now been purified and their genes cloned (for review see Zhivotovsky et al., 1997). The activation of the caspase family of proteases has been detected in numerous tissues and cell types and may function as a common pathway through which apoptotic mechanisms operate. Some procaspases, following translation, become autocatalytically cleaved at specific P1 aspartic acid residues, thereby generating a tetrameric cysteine protease holoenzyme that recognizes a characteristic cleavage motif (WXXD, DEXD, or XEXD) in target proteins (Nicholson and Thornberry, 1997). The effects of caspases in apoptosis appear to be accomplished by the cleavage of numerous proteins located in the cytoskeleton, cytoplasm, and nucleus, although the significance of these cleavages to the cell-death process is still unclear.

There have been a large number of reports on caspase involvement in apoptosis; however, there is yet very little evidence for the involvement of this family of proteases in necrosis. Recent work from our own group has shown that menadione-induced necrosis of hepatoma cells is independent of caspase activation (A. Samali et al, 1999). Furthermore, Tomaselli and co-workers (Armstrong et al., 1997) observed the activation of caspase 3 (CPP32/apopain) in cerebellar granule neurons undergoing apoptosis but not necrosis. These results appear to be in line with the work carried out in our laboratory which have shown that after the acute, necrotic death of cerebellar granule neurons exposed to glutamate, the remaining neurons undergo a delayed, apoptotic death (Ankarcrona et al., 1995). However, we did not detect any caspase activation during the "necrotic" step of our experimental model (M. Ankarcrona, B. Zhivotovsky, S. Orrenius, and P. Nicotera, unpub. observ.).

Apart from the caspase family of proteases, a number of other proteolytic enzymes are also implicated in cell death. Studies from our laboratory have suggested the involvement of Ca^{2+}-dependent proteolytic activity in oxidant injury in the liver (Nicotera et al., 1986). Although the substrates for this protease activity during cell injury remain largely unidentified, it appears that cytoskeletal and membrane-integral proteins may be a major target for this proteolytic event during chemical toxicity (Mirabelli et al., 1989). Calpain, another Ca^{2+}-dependent neutral protease and member of the papain family of cysteine proteases, degrades a number of key cellular proteins including proto-oncogenes, steroid-hormone receptors, protein kinases, and cytoskeletal proteins (Croal and DeMartino, 1991, Vanags et al., 1996). Calpain, one of the degradative nonlysosomal proteases, is also implicated in necrosis (Arai et al., 1990). Enhanced calpain activity has been observed in anoxic hepatocytes and neurons. Moreover, inhibition of calpain by acidosis, calpain protease inhibitors, and glycine delays anoxic injury. Precise mechanisms responsible for the stimulation of calpain activity during either necrosis or apoptosis are still unclear. More recently, it has been shown that hepatocellular carcinoma cells resist necrosis during anoxia by preventing phospholipase-mediated calpain activation (Arora et al., 1996). However, it is unknown whether sustained calpain activity promotes necrosis as a "deathase" by degrading key cytoskeletal proteins such as spectrin or by acting as a "signaling protease." Therefore, a better understanding of the protein substrates cleaved in necrosis will be required before the role of calpains in necrosis can be elucidated.

Another example of noncaspase proteases that may be involved in apoptosis is seen in the plasminogen activator system, which is a major proteolytic complex responsible for the breakdown of the extracellular matrix. Expression of the plasminogen activator inhibitor type 2 (PAI-2) in HeLa cells, which do not synthesize PAI-2, protects them from tumor-necrosis factor– (TNF-) induced apoptosis (Dickinson et al., 1995). Interestingly PAI-2 has a high degree of structural similarity to crmA, which inhibits interleukin 1β–converting enzyme– (ICE)–induced apoptosis (Dickinson et al., 1995). PAI-2 itself is not spared during apoptosis, and it loses its activity after cleavage by other proteases (Jensen et al., 1994). There are no reports about the involvement of this protease in necrosis.

An alternative protease system, which is thought to play a role in cell death, is that of proteasomes. The contribution of proteasomal activity during apoptosis has primarily been evaluated by using inhibitors. There are several observations that show inhibition of proteasomal activity by "specific" peptide inhibitors either fails to prevent receptor-mediated apoptosis (B. Zhivotovsky, D.H. Burgess, I. Ares-Pörn, and S. Orrenius, unpub. observ.) or drives cells into apoptosis (Shinohara et al., 1996). Currently there is no evidence that these enzymes activate caspases. Thus, a conclusive role for this enzymatic system in apoptosis remains to be elucidated. The interaction between other enzyme activities, either proximal or distal to the cleavage and activation of the procaspases, and their role in apoptosis, is the subject of rapidly evolving research.

The lytic nature of lysosomal enzymes and their release by various experimental procedures suggested long ago that they might be responsible for cell necrosis in damaged cells and tissues (for review see Bowen, 1981). DeDuve had already in the 1960s developed the concept of the lysosome as a "suicide bag" (deDuve, 1963). This hypothesis states that particle-bound acid hydrolase can be released into the surrounding cytoplasm under appropriate conditions and bring about the cell's ultimate destruction. Such a response might occur during cellular injury, but lysosomes in fact are relatively stable organelles, which fragment and release their contents after cell death rather than before. Much attention was paid to acid hydrolases in the earlier publications. Hydro-

lases, however, were later shown to occur in association with the Golgi and/or Golgi–endoplasmic reticulum lysosomes, endoplasmic reticulum extracisternal spaces, and plasma membranes (for review see Bowen, 1981). In reference to inflammatory cells, it has been shown that acid hydrolases are directly transferred from the endoplasmic reticulum into foci of cytoplasmic degeneration (Van Lancker, 1975). It was later concluded that when cells die, areas of the cytoplasm become segregated for autolysis, and that these areas are supplied with hydrolases, either from primary lysosomes or directly from the endoplasmic reticulum. Furthermore, an accumulation of free acid phosphatases around ribosomes in the extracisternal space of the endoplasmic reticulum has been linked to this type of cell death (for review see Bowen, 1981). This early extracisternal buildup appears as a prelude to cell autolysis. On the other hand, histochemical studies showed that the liberation of acid phosphatases and esterases was not an early change (Kerr et al., 1972), and the authors of that study suggested that the release of lysosomal enzymes is not responsible for the initiation of necrotic cell death, but rather accompanies this type of death. There is no evidence for preferable degradation of any proteins by lysosomal proteases during necrosis. Thus, in contrast to apoptosis, the involvement of both lysosomal and nonlysosomal protease activities in necrosis was documented. However, the precise role of these protease activities in either induction or execution of necrosis, as well as the specific cleavage of cellular proteins, remain to be elucidated.

CELLULAR SIGNALING DURING CELL DEATH

Signal transduction is thought to play a key role in the onset of both apoptosis and necrosis, and this may be mediated by an increase in intracellular Ca^{2+} levels, protein kinase C (PKC), cyclic adenosine monophosphate/protein kinase A (cAMP/PKA), or phosphatases. It has been demonstrated that glucocorticoid-induced cell death involves Ca^{2+} influx in lymphocytes and that this type of cell death can be mimicked using calcium ionophores (Kaiser and Edelman, 1978). Based on these observations it appears that intracellular Ca^{2+} levels may initiate a death signal, probably through the activation of Ca^{2+}-dependent enzymes (proteases, phospholipases, and endonucleases) in this system. The evidence for a role of Ca^{2+} in necrotic cell killing is particularly strong in the central nervous system. Ca^{2+} appears to mediate the neurotoxicity of cyanide, such heavy metals as lead and mercury, and organotin compounds (for review see Nicotera and Orrenius, 1996). Furthermore, intracellular Ca^{2+} overload, resulting from excessive stimulation of excitatory amino acid receptors and enhanced Ca^{2+} influx through membrane channels, appears to play an important role in ischemic brain damage. Much recent research has focused on glutamate-induced excitotoxicity and its contribution to brain damage in various diseases (Choi, 1992; Ankarcrona et al., 1995). The calcium ion plays a critical role in this process, and intracellular Ca^{2+} overload appears to mediate the lethal effect of *N*-methyl-D-aspartate (NMDA) receptor overactivation. This mechanism is responsible not only for the brain damage induced by certain neurotoxins, but also for excitotoxicity, which is strongly implicated in neuronal death following insults such as ischemia and trauma. Thus, NMDA receptor antagonist not only blocks Ca^{2+} influx and neuronal death elicited by glutamate or NMDA in vitro, but can also reduce the volume of infarction produced by focal ischemia in vivo. As discussed above, glutamate can trigger the onset of both apoptosis and necrosis in cerebellar granule cells (Ankarcrona et al., 1995). Radical scavengers and agents that inhibit the generation of nitric oxide by nitric oxide synthase were ineffective in preventing cell death in this system, whereas NMDA receptor/channel blockers prevented both necrosis and apoptosis in glutamate-treated cerebellar granule cells. These data suggest that Ca^{2+} overload–mediated NMDA-receptor-operated channels are sufficient to induce either necrosis or apoptosis in cerebellar granule neurons in vivo. It is clear that intracellular Ca^{2+} overload is an important factor in various in vitro models, and results from clinical studies appear to support this hypothesis. The Ca^{2+} overload seems to result from increased Ca^{2+} influx through both receptor-operated and L-type Ca^{2+} channels, as indicated by the neuroprotective effects of glutamate-receptor antagonists and L-type channel blockers. Various Ca^{2+}-dependent degradative processes have been found to contribute to Ca^{2+}-mediated necrotic cell killing in in vitro studies, and, although their relative contribution is unclear, it appears that perturbation of cytoskeletal organization, impairment of mitochondrial function, and/or activation of certain proteases may be of particular importance. For example, it has been proposed that activation of phospholipase A2 by a sustained increase in

cytosolic calcium plays an important role in necrotic cell killing. Support for this hypothesis comes from several observations that necrosis in the liver and heart caused by ischemia, as well as in hepatocellular carcinoma cells in anoxic condition, is prevented by inhibitors of this enzyme or by the inhibition of calpain activation (for review see Nicotera and Orrenius, 1996). Thus, it is likely that the calcium ion may play a determinant role in the necrotic killing process.

One of the classic signaling pathways is that of PKC, which is a multifunctional serine/threonine kinase that utilizes diacylglycerol as a second messenger (Nishizuka, 1984). Twelve different isoforms of PKC have been identified to date and are classified according to their calcium dependence and phorbol ester binding activity (for review see Lavin et al., 1996). There are some reports as to the involvement of PKC in apoptosis. For example, it has been reported that treatment of mouse thymocytes with phorbol esters, which activate PKC, induces apoptosis (Kizaki et al., 1989). Similarly, apoptosis induced by the calcium ionophore A23187 can be inhibited by the PKC inhibitor H7. However, most of the evidence to date indicates that PKC activation inhibits apoptosis (McConkey et al., 1996). This paradox may be explained by the large number of isoforms, which may be differentially regulated during apoptosis (Forbes et al., 1992).

Similarly, the role of protein phosphatases during apoptosis is not clear. There are some reports that a number of cell lines react to okadaic acid by undergoing apoptosis (Boe et al., 1991), while there are other reports that the inhibition of protein phosphatase activity blocks apoptosis in some other cell lines (Baxter and Lavin, 1992). From these reports it appears that protein activation/modification, through reversible protein phosphorylation by kinases and protein phosphatases rather than by de novo protein synthesis, may play a more central role in the regulation of apoptosis in some cells.

Receptor-mediated killing involves activation of a cascade of signaling events leading to activation of caspases. For example, apoptosis induced by ligation of the CD95 (Fas/Apo-1) receptor results in association of several cytotoxicity-dependent Apo-1-associated proteins (CAPs; Trauth et al., 1989). The aggregated receptor, together with the CAP proteins (1 to 4) form the death-inducing signaling complex or DISC. DISC formation upon engagement of the receptor is essential for CD95-induced apoptosis. CAP1/2 were identified as the serine phosphorylated Fas-associated death domain (FADD) and CAP3/4 as Fas-like (FLICE) or caspase-8, pro-enzyme and activated enzyme (for review see Wallach, 1997).

ROLE OF MITOCHONDRIA DURING CELL DEATH

Work from several laboratories has indicated that mitochondrial damage may be a common event in the development of cell injury caused by various toxic agents (Nicotera and Orrenius, 1996). It was postulated that mitochondrial damage is initially manifested by a decrease in the mitochondrial membrane potential followed by ATP depletion (Zamzami et al., 1995). During necrosis, these changes occur irreversibly and usually lead to disruption of the mitochondrial structure. These changes set necrosis aside from apoptosis, during which mitochondrial structure remains morphologically intact. Mitochondria have nevertheless been implicated in apoptosis ever since the discovery that the Bcl-2 protein localizes to the outer mitochondrial membrane (Hockenbery et al., 1990). Moreover, by using different cell-free systems, it has been shown that nuclear apoptosis depends on the presence of ATP (Lazebnik et al., 1993; Newmeyer et al., 1994; Kass et al., 1996). It has been demonstrated that cytochrome *c* can induce cleavage and activation of procaspase 3 in cytochrome *c*–minus cytoplasmic extracts (Liu et al., 1996). It has also been shown that cytochrome *c* is released from the mitochondrial intermembrane space into the cytosol by cells undergoing apoptosis. In this case cytochrome *c* release is not preceded by changes in mitochondrial membrane potential (Kluck et al., 1997).

Two groups have presented evidence that a high ATP level is required during the apoptotic process and suggested that the level of intracellular ATP determines whether a cell will die by apoptosis or necrosis (Nicotera and Leist, 1997; Tsugimoto, 1997). During exposure to glutamate, both mitochondrial membrane potential and ATP levels decline in many neurons (Ankarcrona et al., 1995). In neurons with irreversibly dissipated mitochondrial potentials, necrosis rapidly ensued. The surviving population recovered both mitochondrial membrane potential and energy levels and subsequently underwent delayed apoptosis. It was postulated that the loss of energy and the onset of rapid necrosis simply prevents the activation of the default apoptotic program. This postulate was supported by the observation that treatment of

cerebellar granule cells with a combination of glutamate and the irreversible mitochondrial uncoupler carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) resulted in necrosis for most of the neuronal population, rather than in the delayed apoptosis observed with glutamate alone.

There is abundant evidence for an ATP requirement in several apoptosis models, although the critical ATP-dependent steps in the process have not been characterized in detail. They are likely to be linked to both the signaling and the execution phases of apoptosis. It was suggested (Tsugimoto, 1997) that the caspase protease cascade is regulated by ATP-dependent reactions and that the protease cascade might not proceed in an autonomous fashion. In addition, it has been shown (Yasuhara et al., 1997) that the active nuclear transport mechanism, which requires ATP hydrolysis, is involved in the apoptotic changes of the nuclei. It is likely that an another ATP-dependent step or steps downstream from caspase activation is important for perpetuation of the apoptotic process. This fact could explain the previously published data on the ATP requirement for induction of nuclear apoptosis, induced by different cytoplasmic extracts (Lazebnik et al., 1993; Newmeyer et al., 1994; Kass et al., 1996). Thus, it is not surprising that the depletion of cellular ATP blocks various events in apoptosis. The question that remains to be answered is whether, and how, ATP depletion redirects the death process towards necrosis when cells have been triggered with apoptotic stimuli, such as anti-CD95 antibodies. In addition to the possible requirement of ATP for caspase activation, redirection could also be explained by an unknown mechanism, which shortens the survival time of cells that would eventually die by necrosis resulting from energy deprivation.

The next important question that remains to be resolved is an apparent contradiction between, on the one hand, the obligatory induction of the mitochondrial permeability transition associated with a cessation of mitochondrial ATP synthesis, and, on the other hand, a need for maintenance of the intracellular ATP level during development of apoptosis, which may take many hours or days. In addition, hyperproduction of reactive oxygen species (ROS) results from the loss of mitochondrial membrane potential, yet the cell needs to maintain a reducing environment for optimal caspase activity. These controversies could be resolved if the proposed apoptosis-induced changes were restricted to a small subset of mitochondria in the cell. Maintenance of the energy level required by cells to undergo apoptosis could occur solely by glycolysis. This would be consistent with the observation by Jacobson et al. (1993) that cells lacking mitochondrial DNA and a functional respiratory chain can still undergo apoptosis. It is very likely that the mitochondrial permeability transition associated with a cessation of mitochondrial ATP plays an important role in necrotic cell death, whereas leakage of cytochrome *c* from morphologically intact mitochondria via a yet unknown and more selective pathway than outer-membrane rupture following permeability transition–induced mitochondrial swelling plays an important role in apoptotic cell death.

GENETIC MODULATION OF APOPTOTIC CELL DEATH

In recent years, enough evidence has been gathered to suggest a role for the protein products of a number of oncogenes and tumor-suppressor genes, as well as stress proteins and acute phase proteins, in the modulation cell death. These can be grouped into genes whose products are positive or negative regulators of cell death. The genes with a key role in the modulation of cell death and their effects on both apoptosis and necrosis are reviewed below.

c-myc

The *c-myc* proto-oncogene is a short-lived nuclear protein and a member of a family closely related genes that also include *v-myc*, *n-myc*, and *b-myc*. The *Myc* family plays a key role in the regulation of cell proliferation (for review see Ryan and Brinie, 1996). It has been demonstrated that *c-myc* is capable of driving apoptosis (Evan et al., 1992). For instance, when T cell hybridomas were stimulated through their CD3/T cell receptor, they rapidly underwent apoptosis that could be blocked using an antisense oligonucleotide to *c-myc* mRNA. Furthermore, in fibroblasts, *c-myc* overexpression can induce apoptosis (Evan et al., 1992). The decision to proliferate or die in cells overexpressing *c-myc* seems to depend on the presence or absence of extracellular survival factors.

p53

The p53 protein is the product of a tumor-suppressor gene whose loss of function occurs in over half of all human tumors, thus implicating p53 inactivation in tumorigenesis. Nevertheless, the main functions of p53 appear to be in mediating the cellular response to DNA dam-

age and maintaining genomic stability (Kastan et al., 1991). Many forms of genotoxic stress induce a rapid increase in p53 protein levels, through both stabilization of the protein (Kastan et al., 1991) and an increase in p53 mRNA levels (Sun et al., 1995). p53 induces growth suppression by regulating cell-cycle arrest and/or inducing apoptosis. Reintroduction and overexpression of wild-type p53 in cells that have lost endogenous p53 function may induce apoptosis (Yonish-Rouach et al., 1991). In this regard, p53 is shown to be required for both irradiation-induced G1 arrest and apoptosis in several cell systems (Lowe et al., 1993). Induction of growth arrest by p53 has been shown to be transcription activation–dependent and appears to involve induction of *p21* (*Waf1/Cip/sdi1*) and growth arrest and DNA damage-inducible gene 45 (*Gadd45*). For review see Yonish-Rouach (1996).

Although transcriptional activation appears to be involved in the induction of growth arrest, little is known about the possible downstream elements in this apoptotic pathway. p53 has been shown to induce apoptosis in the presence of transcriptional activation, in which case p53 may induce expression of Bax (Miyashita and Reed, 1995) and/or CD95 (Owen-Schaub et al., 1995). However, recent reports suggest that transcriptional activation is not essential for the induction and progression of p53-induced apoptosis (for review see Yonish-Rouach, 1996).

Bcl-2 family

This is a family of genes in which many members hold key positions in the apoptotic machinery. The proteins in this family share at least two highly conserved regions, which have been referred to as *Bcl-2* homology 1 and 2 (BH1 and BH2) domains (Oltvai et al., 1993). *Bcl-2* was the first member of this family to be identified in follicular B cell lymphomas (Bakhshi et al., 1985). Several other family members, which were discovered later, may function to inhibit apoptosis, including *Bcl-2*, *Bcl-x_L*, *Bcl-W*, *Bfl-1*, *A1*, and *MCL-1*, while others function to accelerate the rate of apoptosis once it has been induced, including *Bax*, *Bcl-x_s*, *Bag*, *Bik*, *Bim*, *Bak*, *Bar*, and *Bad*.

Bcl-2 protein is localized to the mitochondria, endoplasmic reticulum, and nuclear membrane (Hockenbery et al., 1990). Bcl-2 appears to have antioxidant properties, as it can inhibit apoptosis induced by reactive oxygen species (Hockenbery et al., 1993). However, it has also been demonstrated that Bcl-2 can inhibit cell death under conditions that preclude the formation of reactive oxygen species (Jackobson et al., 1993). Therefore, the ability of Bcl-2 to protect against the damaging effects of free radicals does not appear to completely account for the suppression of cell death by Bcl-2.

Bax is more ubiquitously expressed than Bcl-2 (Krajewski et al., 1994). The *bax* gene promoter contains four p53-binding sites, and it has been shown that the levels of its protein can be up-regulated by p53 (Miyashita and Reed, 1995). It is suggested that the ability of Bcl-2 to suppress apoptosis depends on the relative proportion of Bcl-2 homodimers and Bcl-2/Bax. In addition to Bcl-2, Bax can also heterodimerize with other Bcl-2-related proteins, including Bcl-x_L, Bcl-x_S, MCL-1, and A1, as shown by the yeast two-hybrid assay (for review see Reed, 1997). These reports suggest that Bcl-2 family members function in part through protein-protein interactions, and that susceptibility to apoptosis is determined by multiple competing dimerizations in which Bax is a common partner. However, the ultimate mechanism by which members of this family may induce or suppress apoptosis is not understood.

It has been shown recently that overexpression of Bcl-2 can also inhibit necrosis at least in neuronal cells when induced by such diverse stimuli as viruses, hypoxia, oxidative stress, or exposure to toxicants (Lezoulac'h et al., 1996; Shimizu et al., 1996). Whether this effect is cell-specific remains unclear. The mechanism of action of Bcl-2 in cells undergoing necrosis may simply involve antioxidant activity. The second possibility is that Bcl-2 prevents the consequences of mitochondrial dysfunction (collapse of the mitochondrial transmembrane potential, uncoupling of the respiratory chain, hyperproduction of superoxide anions, disruption of mitochondrial biogenesis, outflow of matrix calcium and glutathione, and release of soluble intermembrane proteins), all of which can lead to a bioenergetic catastrophe culminating in the disruption of plasma membrane integrity which is specific for necrosis (Kroemer, 1997). However, more work should be done to justify this hypothesis and to understand the mechanism of Bcl-2-induced protection from necrosis.

Ras

Members of the Ras family of proteins play an essential role in the control of normal cell growth and may induce transformation. Certain evidence has led a number of groups to advocate that Ras, in addition to inducing transformation, can also prevent cell death. Overex-

pression of the *ras* gene is shown to inhibit apoptosis in a number of cases (Wyllie et al., 1987; Arends et al., 1993). Ras appears to be a focal point for the convergence of many signaling pathways, especially during receptor/ligand interaction, such as epidermal growth factor (EGF), fibroblast growth factor (FGF) and nerve growth factor (NGF), T cell receptor–CD3 (TCR-CD3), and CD95. The question as to which protein downstream of the pathway is the key effector of the anti-apoptotic signal through Ras is unclear, but it may involve the activation of MAP kinase or phosphotidylinositol 3 kinase or both.

Stress Proteins

The stress proteins are a set of evolutionarily conserved proteins that are synthesized or activated in response to stress (for review see Lindquist and Craig, 1988). The main function of these proteins is to afford protection to cells in times of stress. When the stress element is removed, these cells continue to function normally and the levels drop back to the normal. Heat-shock proteins (HSPs), a subgroup of stress proteins, were first demonstrated to be induced as a response to elevated temperatures.

There is strong evidence suggesting that the induction of HSPs coincides with the acquisition of tolerance to higher doses of stress, which may otherwise be lethal to the cell. In this regard, it was demonstrated that a mild heat shock induces the rapid synthesis of a number of HSPs (Jaattela et al., 1992; Mosser and Martin, 1992) and that heat-shocked or thermotolerant cells demonstrated a greater degree of resistance to environmental stress (Jaattela et al., 1992), probably by resisting apoptosis (Samali and Cotter, 1996). Furthermore, it was demonstrated that thermotolerant or HSP-overexpressing cells are more resistant to cell death induced by hyperthermia or growth-factor withdrawal (Mailhos et al., 1993). This may suggest a possible role for HSPs in the resistance mechanism. Furthermore, HSPs are also implicated in drug resistance (McClean and Hill, 1992), and heat-shocked or HSP-overexpressing cells become more resistant to the cytotoxic effects of some anticancer drugs (Oesterreich et al., 1993) that are otherwise capable of inducing both apoptosis and necrosis (Martin et al., 1990).

CONCLUSIONS

Cell toxicity leading to cell death may occur via apoptosis or necrosis. The mode of cell death depends on the nature of the toxic agent, but in extreme situations the final outcome is cell disruption and disintegration. In other words, necrosis is the acute type of cell death or the cellular response to extreme toxic injury. During necrosis, chromatin adopts a highly flocculated form, and the DNA from these cells is digested randomly to give a smear when analyzed by agarose gel electrophoresis. The main feature of necrosis is an increase in cell volume. The rapid increase in cell volume results in membrane rupture and cell lysis (for review see Trump and Berezesky, 1995).

After two decades of research and development in the field of cell death, it is now universally accepted that apoptosis is an essential strategy for maintaining dynamic balance and equilibrium of living systems, and is observed to occur as a normal mechanism in development and homeostasis, as well as an altruistic mode of toxic cell death. Classification of cell death is now based on morphological and biochemical criteria, their circumstantial occurrence, or a combination of both. Although morphological characterization of apoptosis and the features distinguishing it from necrosis have been well documented, progress in our understanding of the mechanisms underlying the process has been quite slow.

There is now much evidence that classic apoptosis and necrosis represent only definitive endpoints for these two processes. However, both types of cell death can occur either simultaneously or sequentially in the same cell suspension or tissues depending on type and/or dose of toxic insult. This suggests that some early biochemical and morphological events might be similar or even identical in both types of cell death. If this is the case, different downstream events might be important in determining whether the cell will undergo apoptosis or necrosis. It could also be that after intensive toxic treatment, the cellular apoptotic machinery becomes suppressed, after which necrosis would predominate. The events summarized in Table 2.1.1 can be observed at different levels of cellular organization. Thus, both physiological or pathological stimuli can induce apoptosis, but only pathological injury leads to necrosis. Apoptosis, in contrast to necrosis, occurs in individual cells in an asynchronous fashion without damaging neighboring cells. Both processes can be protected by certain inhibitors before a point of no return is reached. Once the cascade of caspase proteolytic activities becomes active, apoptosis cannot be completely reversed. The point of no return during necrosis remains to be elucidated. Neverthe-

less, cells can be rescued from necrosis as well as from apoptosis.

Cellular shrinkage is a hallmark of apoptosis and is seen in many if not all cell types that undergo this type of death. Cell-volume regulation is a complex phenomenon, involving the homeostasis of intracellular ions such as chloride, sodium, and potassium. As the most abundant intracellular ion, K^+ has been implicated in several of the regulatory mechanisms governing cell volume, including regulatory volume decrease. It has been shown that intracellular K^+ content decreases in cells undergoing apoptosis induced either with etoposide or dexamethasone (Barbiero et al., 1995). Work in the authors' laboratory has shown a potential link between glutathione (GSH) efflux and apoptotic cell shrinkage (Nobel, 1997). Inhibitors of apoptotic GSH efflux were able to inhibit cell shrinkage in thymocytes induced to undergo apoptosis by etoposide without affecting DNA fragmentation. Moreover, the GSH efflux was accompanied by K^+ efflux in Jurkat cells treated with anti-CD95 antibody. The K^+ efflux was not blocked either by the inhibitor of GSH efflux or by any known inhibitors of K^+ channels and cotransporters tested. Concomitant with apoptotic K^+ efflux, significant inhibition of Na^+/K^+-ATPase activity was observed. Inhibition of this enzyme by ouabain caused a K^+ efflux of similar magnitude to that induced by anti-CD95 antibody, and it potentiated CD95-mediated cell shrinkage. This suggested that with Na^+/K^+-ATPase activation, K^+ and GSH effluxes facilitated apoptotic cell shrinkage, which was followed by the formation of apoptotic bodies. In contrast, necrotic cells showed extensive swelling, which resulted in subsequent disintegration of cells.

Apoptotic cells lose adhesion at the very early stages, while necrotic cells stay adherent together until very late stages. As mentioned before, individual apoptotic cells can be efficiently recognized either by neighboring cells or professional macrophages and can be removed by phagocytosis. This step of the apoptotic process involves rearrangements of and dramatic changes in the plasma membrane. Removal of the dead-cell fragments before their plasma membranes are lysed has important implications for other cells within the tissues. It is assumed that apoptosis occurs without inflammation. Lysis of plasma membranes in necrotic cells seems to precede the removal of these remnants, and exudative inflammation is a common event during necrosis.

The significance of apoptosis is based on the fact that apoptotic cells tend to be "environmentally friendly" and package their contents into membrane-bound vesicles ready for ingestion by phagocytic cells, without releasing their contents into the intercellular matrix. Hence there is no inflammatory response. Apoptosis is also an altruistic cell death, in that damaged or injured cells commit suicide to allow the neighboring cells to continue to proliferate without being affected by the death of the neighbor. In addition, sacrifice of individual abnormal cells benefits the whole organism.

Most if not all mechanisms leading to cell death involve molecular damage that is potentially reversible by cellular repair mechanisms. Therefore, if the repair mechanisms operate effectively, they may prevent cell death. It could be that in cells undergoing apoptosis, the cell-repair machinery is repressed by specific signals, which program cells to die. On the other hand, in cells undergoing necrosis this machinery might be directly suppressed by extremely strong insult (high doses of toxicants or irradiation). Since apoptosis is a gene-directed process and many genes are involved in the regulation of this multistage action, the repression of repair processes can also be regulated on this level. There is no evidence for expression of any specific genes during necrosis, which is why it is difficult to discuss the possible requirement of gene regulation for necrotic cell death. Thus, it seems that classic necrosis is a passive process. An inhibition of the activity of a number of gene products involved in apoptosis can switch the death pathway from apoptosis to necrosis. Also rapid changes in the cellular ATP levels, discussed above, and an imbalance in the ratio of nitric oxide and superoxide, can switch the form of cell death. The search on both molecular and biochemical levels for mechanisms of apoptosis and necrosis, along with attempts to understand the differences/similarities between these two types of cellular response to toxicants, are currently the hottest topics in biological research.

Determination of Apoptosis and Necrosis

Cell death may occur by two mechanisms: apoptosis, or programmed cell death, and necrosis, or cell death due to injury or trauma (see *UNIT 2.1*). Both types of cell death have their own specific and distinct morphological and biochemical hallmarks. Apoptotic cells share a number of common features, such as phosphatidylserine (PS) exposure, cell shrinkage, chromatin cleavage, nuclear condensation, and formation of pyknotic bodies of condensed chromatin. Necrotic cells exhibit nuclear swelling, chromatin flocculation, loss of nuclear basophilia, breakdown of cytoplasmic structure and organelle function, and cytolysis by swelling. Cell death can be induced by a wide variety of stimuli, such as growth factor withdrawal, heat shock, cold shock, radiation, heavy metals, genotoxic drugs, and a number of biological ligands such as Fas-L and tumor necrosis factor (TNF). Most if not all of these can induce both apoptosis and necrosis in a time- and dose-dependent manner.

A variety of techniques have been developed to assess cytotoxicity in untreated and/or toxicant-treated cells, most of which are based on the loss of plasma membrane integrity. Membrane disruption can be detected based on the uptake of vital dyes (see Basic Protocol 1) or the release of cellular contents into the extracellular milieu (see Basic Protocol 5). However, during apoptosis, the cell membrane remains intact for a relatively long time, and therefore some of these assays cannot detect the early stages of apoptosis. Alternatively, assays that detect all types of cell death do not discriminate between apoptosis and necrosis. Therefore, more specific techniques have been developed to determine cell death, and the combination of several methods is required to distinguish between the two separate types. These techniques rely on specific morphological and molecular or biochemical changes associated with these two processes.

This unit describes some of the techniques most commonly used to detect cell death. Morphological assays include trypan blue exclusion (see Basic Protocol 1), differential staining (see Basic Protocol 2), Hoechst staining (see Basic Protocol 3), flow cytometry to measure cell size and DNA content (see Basic Protocol 4), and annexin V binding to detect externalized phosphatidylserine (see BAsic Protocol 5). Methods to detect chromatin cleavage include TUNEL assays for whole cells (see Basic Protocol 6) and paraffin sections (see Alternate Protocol 1), DNA fragmentation assays using whole cells (see Basic Protocol 7), assays of total genomic DNA (see Alternate Protocol 2), analysis of DNA fragmentation by agarose gel electrophoresis (see Alternate Protocol 3), phenol extraction of DNA for analysis of fragmentation (see Alternate Protocol 4), a quantitative assay for DNA fragmentation (see Basic Protocol 8), and detection of DNA fragmentation by pulsed-field gel electrophoresis (see Basic Protocol 9). Caspase activity is assessed by detecting proteolytic cleavage of fluorescent substrates (see Basic Protocol 10) or by immunodetection (see Basic Protocol 11). Protocols are also provided for Cytospin preparations from cell suspensions (see Support Protocol 1) and preparation of SDS-polycrylamide minigels (see Support Protocol 2). Table 2.2.1 describes how these assays are used to distinguish apoptotic cells from necrotic cells.

MORPHOLOGY ASSAYS

Loss of membrane integrity, which occurs late in apoptosis and relatively early in necrosis, can be detected by cellular uptake of the vital dye trypan blue (see Basic Protocol 1). Apoptosis and necrosis also can be identified morphologically based on the criteria described elsewhere (Bowen, 1980). These include cell shrinkage, nuclear condensation, and cleavage for apoptotic cells; and nuclear swelling, chromatin flocculation, and loss

Current Protocols in Toxicology (1999) 2.2.1-2.2.34

Table 2.2.1 Methods for Determination of Apoptosis and Necrosis

Method	Protocol	Result for	
		Apoptosis	Necrosis
Morphological/cytological analysis			
Trypan blue staining	Basic Protocol 1	No staining (early apoptosis) Blue staining (late apoptosis)	Blue cells
Differential staining	Basic Protocol 2	Membrane blebbing, chromosome condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume	Nuclear swelling, chromatin flocculation, membrane blebbing and disruption, appearance of cell "ghosts"
Hoechst staining	Basic Protocol 3	Increased blue fluorescence, fragmented or condensed nuclei	Blue nucleus with diffuse staining
Flow cytometry	Basic Protocol 4	Reduced forward and side scatter	Increased forward and side scatter
Annexin V binding and PI staining	Basic Protocol 5	Positive fluorescence response for annexin V binding; exclusion of PI	Positive fluorescence; uptake of PI
Assays for chromatin cleavage			
TUNEL assay	Basic Protocol 6 and Alternate Protocol 1	Detection of strand breaks	Detection of strand breaks
Whole-cell DNA fragmentation	Basic Protocol 7	DNA ladder	DNA smear
Total genomic DNA fragmentation	Alternate Protocol 2	DNA ladder	DNA smear
Simple protocol for DNA fragmentation	Alternate Protocol 3	DNA ladder	DNA smear
Phenol extraction for DNA fragmentation	Alternate Protocol 4	DNA ladder	DNA smear
Quantitative assay of DNA fragmentation	Basic Protocol 8	Increase in the percentage of fragmented DNA	Increase in the percentage of fragmented DNA
Pulsed-field detection of high-molecular-weight DNA	Basic Protocol 9	High-molecular-weight bands	DNA smear
Assays for caspase activation			
Specific substrate cleavage assay	Basic Protocol 10	Positive detection of cleaved fluorescent substrate	No changes in fluorescence detected
Immunodetection of caspase activation	Basic Protocol 11	Positive detection of cleavage products of procaspase	No cleavage products detected

of nuclear basophilia for necrotic cells. The levels of both apoptosis and necrosis in a particular cell population can be estimated from Cytospin preparations (see Support Protocol 1) stained with RAPI-DIFF (see Basic Protocol 2 Figure 2.2.1), Hoechst stain (see Basic Protocol 3), or propidium iodide (see Basic Protocol 4).

BASIC PROTOCOL 1

Measurement of Cell Death by Trypan Blue Exclusion

This common cell viability assay is based on the ability of a cell with an intact membrane to exclude the dye trypan blue. Therefore, this assay allows one to distinguish between cells with intact and disrupted membranes. Since this method does not give an indication of the mode of cell death, it should be used only in conjuction with a more informative morphological method.

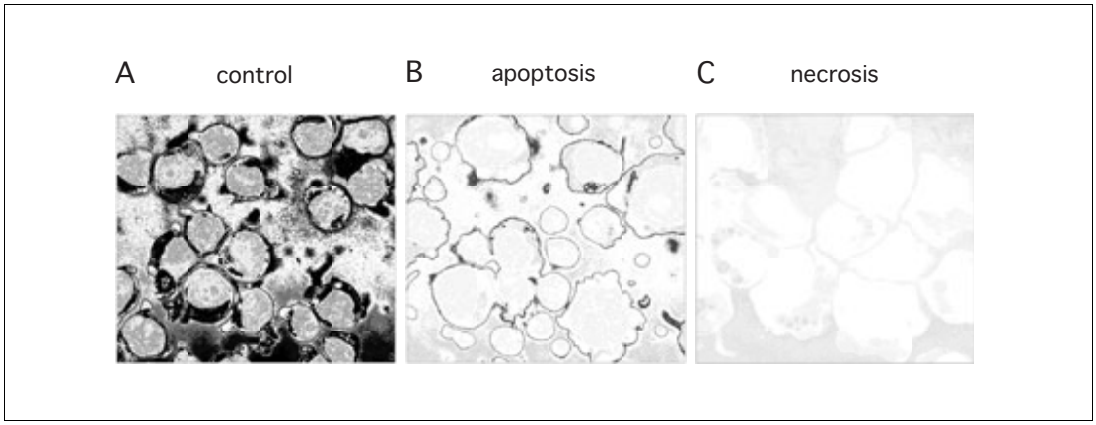

Figure 2.2.1 RAPI-DIFF staining of Cytospin preparation of HL-60 cells. Cells were treated with different concentrations of a cytotoxic drug to induce apoptosis or necrosis. (**A**) Untreated cells, (**B**) apoptotic cells, and (**C**) necrotic cells.

Materials

Cell suspension to be assessed
2× PBS tablets, pH 7.2 to 7.4 (Sigma) or 2× PBS (*APPENDIX 2A*)
0.2% (w/v) trypan blue (Sigma) in 2× PBS (store up to 1 to 2 months at 4°C)

Hemacytometer: improved Neubauer type (Karl Hecht; Baxter) or equivalent
Coverslips (e.g., Chance Propper)
Light microscope

1. Remove from the cell suspension a sample containing ~5×10^4 cells.
2. Add an equal volume of 0.2% trypan blue, mix, and incubate 1 to 2 min at room temperature to permit dye uptake.
3. Load samples onto the hemacytometer.
4. Count the total number of cells and the number of unstained cells in five of the major sections of the hemacytometer. Calculate the average number of cells per section.
5. Calculate the number of cells/ml culture medium by multiplying the average number of cells per section by the dilution factor (2 in this case) and hemacytometer index (10^4). Determine the percentage viability according to the following formula:

$$\% \text{ viability} = \frac{\text{number of unstained cells}}{\text{total number of cells}} \times 100$$

Control cells and cells in early stages of apoptosis exclude trypan blue; cells in the late stages of apoptosis and necrotic cells take up the dye and appear as blue cells.

Differential Staining of Cells

BASIC PROTOCOL 2

This staining procedure involves three steps: first cells are fixed in 100% methanol, then the nuclei are stained with an acid dye, and finally the cytoplasm is stained using a basic dye. Such three-step procedure allows differential staining and contrast between the cytoplasm and the nucleus. Apoptotic cells exhibit membrane blebbing, chromatin condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume, and formation of apoptotic bodies. Necrotic cells undergo nuclear swelling, chromatin flocculation, cell membrane blebbing and disruption, and finally cell lysis resulting in the appearance of "ghost cells" (see Figure 2.2.1). This method can also be applied to cells growing attached to coverslips or chambered culture slides.

Materials

Cytospin preparations of cells (see Support Protocol 1)
100% methanol
Acid dye: 0.1% (w/v) eosin Y/0.1% (w/v) formaldehyde/0.4% (w/v) sodium phosphate dibasic/0.5% potassium phosphate monobasic
Basic dye: 0.4% (w/v) methylene blue–polychromed/0.4% (w/v) azure/0.4% (w/v) sodium phosphate dibasic/0.5% (w/v) monobasic potassium phosphate
DPX mountant (in solution; BDH)

Coverslips (e.g., Chance Propper)
Microscope slides (e.g., Menzel-Glaser)
Light microscope

1. Fix cells after Cytospin preparation (see Support Protocol 1) by immersing the slide ten times in 100% methanol.

   The three solutions required for this procedure are available as a kit, called RAPI-DIFF Stain kit, from Diagnostic Developments. The solutions can be stored 1 to 2 months at room temperature.

2. Stain the cell nuclei by dipping the slide in the acid dye ten times.
3. Stain the cell cytoplasm by dipping the slide in basic dye ten times.
4. Rinse the slide by dipping in distilled water, let it air dry, and mount it using DPX mountant.
5. Score the cells as normal, apoptotic, condensed and/or fragmented nuclei, or necrotic swollen cells, based on their morphological appearance under a light microscope (see *UNIT 2.1* and Fig. 2.2.1).

BASIC PROTOCOL 3

Hoechst Staining of Cells

Hoechst 33342, a bisbenzimide dye, is a cell-permeant, minor group–binding DNA stain that fluoresces bright blue upon binding to DNA. It is water soluble and relatively nontoxic. Hoechst 33342 can be excited with the UV lines of the argon-ion laser and most conventional fluorescence excitation sources, and it exhibits relatively large Stokes shifts (excitation and emission maxima ~350 and 460 nm), making it suitable for multicolor labeling experiments (Pollak and Ciancio, 1990). Cells are scored as apoptotic if they have fragmented nuclei. This method can also be applied to cells growing attached to coverslips or chambered culture slides.

Materials

Cell suspension
1× and 2× PBS, pH 7.2 to 7.4 (from Sigma 2× PBS tablets, or see *APPENDIX 2A*)
4% (w/v) paraformaldehyde (see recipe)
10 μg/ml Hoechst 33342 dye (Molecular Probes) in PBS (*APPENDIX 2A*)
50/50 (v/v) PBS/glycerol

Microscope slides (e.g., Menzel-Glaser)
Coverslips (e.g., Chance Propper)
Fluorescent microscope

Additional reagents and equipment for Cytospin preparations (see Support Protocol 1)

1. Place an aliquot of cell suspension containing $0.3–0.5 \times 10^6$ cells in a microcentrifuge tube, and centrifuge 5 min at $1000 \times g$, 4°C.

2. Remove and discard supernatant. Resuspend the dry pellet in 30 to 50 µl of 4% paraformaldehyde.
3. Spin the fixed cells onto a glass slide using a Shandon/Lipshaw Cytospin centrifuge (see Support Protocol 1). Alternatively, spread the cells onto a slide with a pipet tip, and air dry slide.
4. Stain slide with 10 µg/ml Hoechst dye.

   Hoechst 33342 dye can be diluted from 100× stock kept in the dark at 4°C.
5. Leave slide in the dark for 10 min at room temperature.
6. Rinse by dipping slide five times in distilled water, and let it air dry in the dark.
7. Mount slide with coverslip using PBS/glycerol. Monitor fluorescence with a blue filter in the fluorescence microscope, and score cells with fragmented nuclei as apoptotic.

   This method is useful for discrimination of apoptotic from nonapoptotic (untreated or necrotic) cells.

Cytospin Preparation of Cells for Analysis

SUPPORT PROTOCOL 1

Cytospin preparations can be used in many protocols for cell biology. Once slides are prepared they can be stained with variety of dyes and analyzed using light, fluorescent, and confocal microscopy, depending on the dye type. Before staining, slides can be stored up to 1 year at −20°C covered with aluminum foil. Fixed and stained slides can be stored indefinitely once mounted permanently.

Materials

Cell suspension
PBS (*APPENDIX 2A*)
Cytospin centrifuge and cups (Shandon/Lipshaw)

1. Place a sample of cell suspension containing ~0.5–1 × 10^5 cells in a microcentrifuge tube, and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Resuspend pelleted cells in 100 µl PBS.
3. Add suspension to the Cytospin cup and slide setup, and centrifuge 2 min at 500 × *g*, 4°C.
4. Air dry the slide.

Flow Cytometric Analysis to Detect Apoptotic Cells

BASIC PROTOCOL 4

Many studies report that a reduction in cell size and buoyant density accompany apoptotic cell death (Yamada and Ohyama, 1980); thus, apoptotic cells appear smaller and more dense than their normal counterparts. These changes are accurately detected in a majority of cells by their light-scattering properties as measured by a flow cytometer (Darzynkiewicz et al., 1994; Robinson et al., 1999). The forward scatter (FSC), which indicates cell size, and the side scatter (SSC), which reveals the degree of granularity of the cell, are monitored in cells undergoing apoptosis. The DNA content profile, which is regularly used in studies of the cell cycle, indicates cells' positions in the cycle depending on their DNA content as measured by propidium iodide (PI) staining (fluorescence). Dead cells have a higher amount of subdiploid DNA which accumulates in the pre-G_1 position of cell cycle profiles. The protocol described here uses flow cytometry of fixed cells to simultaneously assess changes in cell size and granularity as well as differing DNA content.

Materials

Cell suspension
70% ethanol, ice cold
1× PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
50 µg/ml propidium iodide (Sigma) in 1× PBS (*APPENDIX 2A* for PBS; store up to 1 month at 4°C)
25 mg/ml RNase A (e.g., Sigma) in water
Flow cytometer (e.g., Becton Dickinson) and tubes

1. Place a sample of cell suspension containing ~1×10^5 cells in a microcentrifuge tube, and centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant.
2. Add 1 ml ice-cold 70% ethanol dropwise while vortexing (to avoid clumping) to resuspend cells. Incubate 30 min on ice to allow cell fixation.
3. Centrifuge 5 min at 1000 × *g*, 4°C, to pellet cells.
4. Decant ethanol. Add 1 ml of 50 µg/ml propidium iodide containing 20 µl of 25 mg/ml RNase A and incubate 15 min at room temperature.
5. Set up the flow cytometer for forward scatter and side scatter (FSC and SSC) to determine cell size and granularity, together with FL-2 content for DNA (560 nm excitation, 640 nm emission; see manufacturer's instructions).

   The reduction in FSC and SSC seen in apoptotic cells is due to the decrease in cell volume and increase in cellular granularity. In necrotic cells there is an increase in both FSC and SSC, reflecting an increase cell volume and loss of cell granularity.

BASIC PROTOCOL 5

Assessment of Annexin V Binding to Detect Externalized Phosphatidylserine and Propidium Iodide Exclusion

A typical feature of apoptosis is the rearrangement and loss of plasma membrane phospholipid asymmetry as a result of externalization of phosphatidylserine (PS) from the inner leaflet of the plasma membrane to the outer leaflet. It has been demonstrated that annexin V can bind to PS in a calcium-dependent manner. This property of annexin V has made it a very useful tool for detection of apoptosis at the early stages of the process (Koopman et al., 1994), especially in conjuction with propidium iodide.

Materials

Cell suspension
PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
1 to 3 µg/ml annexin V–FITC (Bender Biosystems, Nexin Research, Roche, or Pharmingen)
HEPES buffer, pH 7.4 (see recipe)
HEPES buffer (see recipe) containing 50 µg/ml propidium iodide (e.g., Sigma)
Flow cytometer (e.g., Becton Dickinson) and tubes

1. Place a sample of cell suspension containing ~2–4 × 10^5 cells in a microcentrifuge tube, and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Resuspend cells in 200 µl annexin V–FITC diluted 4:1 in HEPES buffer/propidium iodide. Incubate 5 min at room temperature in the dark.
3. Analyze cells by flow cytometer for both green (annexin V–FITC; FL-1, 515 nm excitation, 545 nm emission) and red (PI; FL-2, 560 nm excitation, 640 nm emission) fluorescence according to the manufacturer's instructions (see Figure 2.2.2).

   Cells that are apoptotic bind annexin V, display green fluorescence, and exclude propidium iodide. In contrast, necrotic cells with a disrupted plasma membrane display uptake of both annexin V (green fluorescence) and propidium iodide (red fluorescence; see fig 2.2.2).

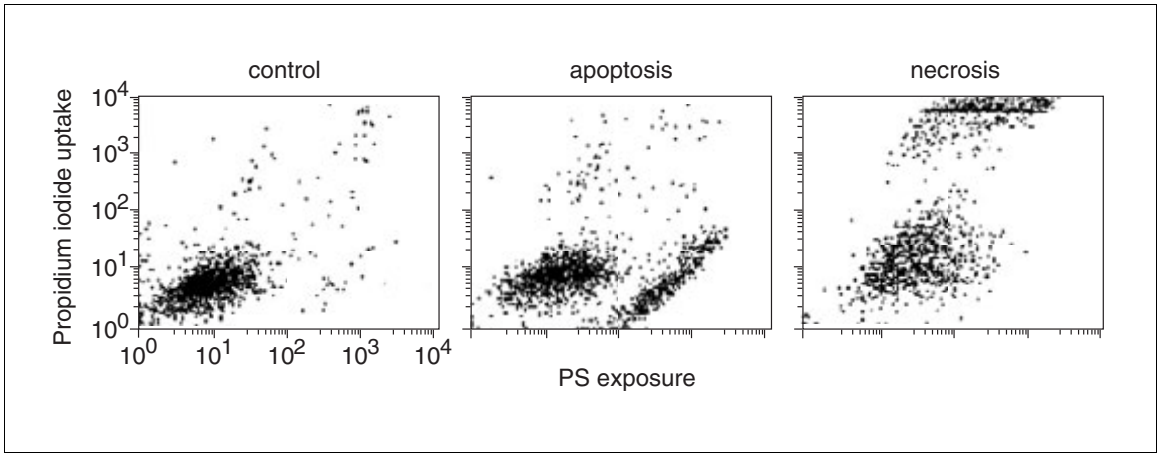

Figure 2.2.2 Flow cytometric analysis of phosphatidylserine exposure of Jurkat cells treated with different concentrations of a cytotoxic drug. Cells were double stained for annexin V and propidium iodide. Apoptotic cells are positive for annexin V only, whereas necrotic cells are positive for both annexin V and propidium iodide. (**A**) Untreated cells, (**B**) apoptotic cells, (**C**) necrotic cells. (This figure is reproduced by kind permission from Dr. M. Hampton, Institute of Environmental Medicine, Karolinska Institute, Stockholm.)

ASSAYS FOR CHROMATIN CLEAVAGE

Chromatin cleavage is a hallmark of apoptosis and involves the formation of high-molecular-weight (>50-kbp) and nucleosome-sized (200-bp) DNA fragments. The high-molecular-weight fragments can be separated by pulsed-field gel electrophoresis, and the nucleosome-sized fragments, when separated on a conventional agarose gel, demonstrate a ladder pattern. The DNA from necrotic cells, on the other hand, has a random and general cleavage pattern and produces a smear when electrophoresed on either a pulsed-field or conventional gel (see Figure 2.2.3). Prior to the formation of the cleavage products, endogenous nucleases must generate a large number of DNA strand breaks. These strand breaks in DNA can be detected by attaching biotin-conjugated nucleotides to the 3′ hydroxyl termini in a reaction catalyzed by exogenous terminal deoxynucleotidyl transferase (TdT). A number of methods can be used to identify apoptotic or necrotic DNA. All of these methods are equally successful and require the same number of cells.

TUNEL Assay for DNA Fragmentation in Cells

BASIC PROTOCOL 6

Induction of apoptosis results in the generation of single-strand DNA breaks. These can be detected using the TdT-mediated dUTP-biotin nick end-labeling (TUNEL) method (Gavrieli et al., 1992). This method requires cell fixation with cross-linking agents such as formaldehyde, which, unlike some of the alcohols (such as ethanol), prevents the extraction of degraded DNA. In other words, this fixation step prevents the loss or reduction of the cellular DNA content after the extensive washings and staining involved in this protocol. Once cells are fixed with formaldehyde, treatment with alcohols does not affect the DNA content of cells.

Materials

Cell suspension
100% methanol, –20°C
PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
1% (v/v) formaldehyde
70% ethanol, ice cold

continued

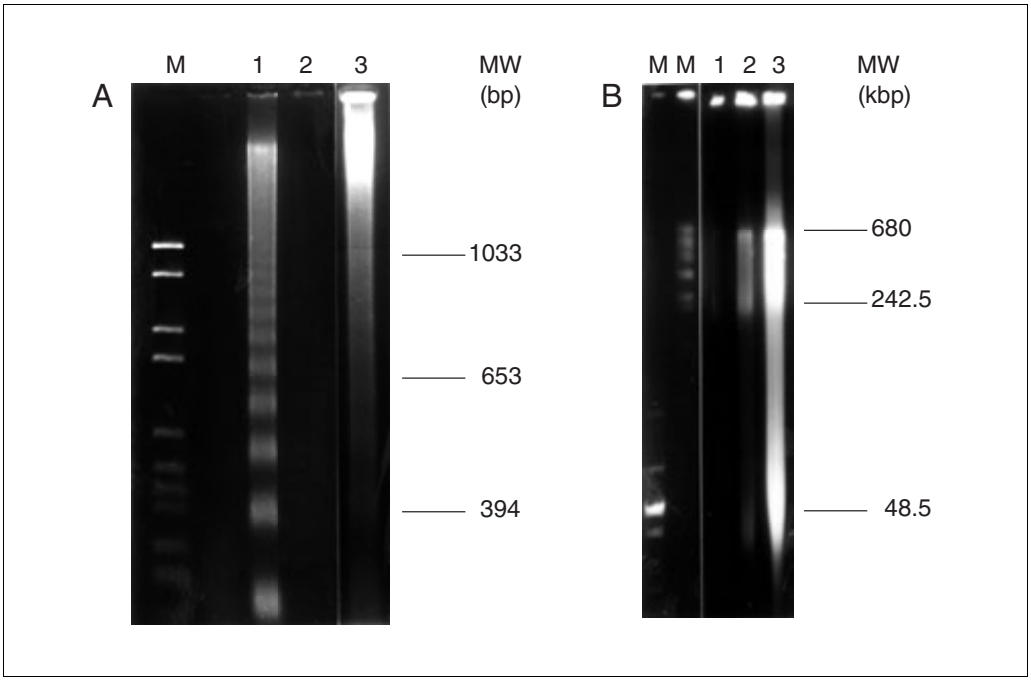

Figure 2.2.3 Gel electrophoresis of DNA from Jurkat cells treated with different concentrations of a cytotoxic drug. (**A**) Conventional gel: M, marker; lanes 1 to 3, DNA from apoptotic, untreated, and necrotic cells, respectively. The DNA ladder, when present, is a strong indicator of apoptosis. (**B**) Pulsed-field gel: MM, markers; lanes 1 to 3, DNA from untreated, apoptotic, and necrotic cells, respectively.

Terminal deoxyribonucleotidyltransferase (TdT; 25 U/µl) and 10× buffer (0.3 M Tris base/1.4 M sodium cacodylate, pH 7.2/1 mM DTT; e.g., Boehringer Mannheim)
25 mM $CoCl_2$
1 mM Bio-16-dUTP (e.g., Boehringer Mannheim)
Termination buffer: 300 mM NaCl/30 mM sodium citrate (e.g., Sigma or equivalent)
Staining buffer (e.g., Sigma; see recipe)
FACS fluid (e.g., Becton Dickinson; optional; for flow cytometry)
DPX mountant (BDH)
5 µg/ml propidium iodide in PBS (*APPENDIX 2A*)

Flow cytometer (e.g., Becton Dickinson) and tubes; *or* fluorescent microscope
Coverslips (e.g., Chance Propper)
Microscope slide (e.g., Objektträger, Menzel-Glaser)

1. Wash a sample of cell suspension containing ~10^6 cells by centrifuging 5 min at 1000 × g, 4°C, discarding supernatant, and resuspending in PBS. Transfer to microcentrifuge tube and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Resuspend cells in 1% formaldehyde and fix for 15 min on ice.
3. Centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant. Resuspend cell pellet in PBS, and repeat centrifugation. Remove and discard supernatant.
4. Resuspend cell pellet in 0.5 ml PBS and add to 5 ml ice-cold 70% ethanol.

   Cells can be stored in ethanol for several weeks at −20°C.

5. Centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard ethanol. Resuspend cells in PBS, and repeat centrifugation.

6. Prepare elongation buffer (50 µl per sample):

   41.5 µl ultrapure water
   5 µl 10× TdT buffer
   2 µl 25 mM $CoCl_2$
   1 µl 1 mM Bio-16-dUTP
   0.5 µl 25 U/µl TdT enzyme.

   Add 50 µl elongation buffer to each cell pellet and resuspend. Incubate 30 min at 37°C.

   It is recommended that more than the required amount of elongation buffer be prepared; that is, multiply the total number of samples + 1 by 50 µl (the volume of the elongation buffer per sample) when calculating how much buffer to prepare. This buffer needs to be made fresh.

7. Add 5 ml PBS and centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant.

   The reaction may first be stopped by incubating cells with termination buffer for 15 min at room temperature, though omission of this step does not appear to affect the results.

8. Resuspend cell pellet in 100 µl staining buffer, and incubate 30 min at room temperature.

   Again, it is recommended that extra buffer be prepared.

9. Add 2 ml PBS, resuspend cells, and centrifuge 5 min at 1000 × g, 4°C. Remove and discard supernatant. Repeat.

10. Add 1 ml of 5 µg/ml propidium iodide and incubate 30 min at room temperature in the dark.

11. Centrifuge 5 min at 1000 × g, 4°C, and remove supernatant.

12a. *For flow cytometry:* Resuspend cells in sufficient amount of PBS or FACS fluid and measure fluorescence (for FITC, 488 nm excitation, 520 ± 20 nm emission, FL-1 channel; for PI, 560 nm excitation, 640 nm emission, FL-2 or FL-3 channels).

12b. *For fluorescence microscopy:* Resuspend cells in 50 to 100 µl of PBS and spin them onto a slide as described under Cytospin preparations (see Support Protocol 1). Mount slides with DPX mountant and observe fluorescence with green and red filters under microscope.

   Cells for fluorescence microscopy can be counterstained with hematoxylin for ≤30 sec, and then rinsed with water, before microscopy.

   The number of single-strand breaks is increased during the early stages of apoptosis (increase in green fluorescence) without any change in the DNA content (measured by PI staining). With time the DNA content is decreased (red fluorescence) due to formation of apoptotic bodies, which also results in the reduction of TUNEL signal.

TUNEL Assay in Paraffin-Embedded Sections

ALTERNATE PROTOCOL 1

The TUNEL assay can also be performed on paraffin-embedded tissue sections.

Additional Materials *(also see Basic Protocol 6)*

Paraffin-embedded tissue sections on slides
4% (w/v) paraformaldehyde (see recipe) *or* 4% formaldehyde, in PBS (*APPENDIX 2A*)
96%, 90%, and 80% ethanol
Xylene
BSA (e.g., Sigma)

continued

10 mM Tris·Cl, pH 8 (*APPENDIX 2A*)
20 µg/ml proteinase K in 10 mM Tris·Cl (*APPENDIX 2A* for Tris·Cl)
3% (v/v) methanol
2% (w/v) BSA in PBS (*APPENDIX 2A* for PBS)
ExtrAvidin-peroxidase (Sigma) diluted 1/50 in PBS/1% BSA/0.5% Tween 20
3-Amino-9-ethylcarbazole (AEC)

Fluorescent microscope
Coverslips (e.g., Chance Propper)
Microscope slide (e.g., Objektträger, Menzel-Glaser)

1. Fix section in 4% paraformaldehyde or formaldehyde, then immerse in PBS.
2. Remove paraffin from sections by incubating slide 10 min at 70°C or 30 min at 58° to 60°C.
3. Rehydrate sections by sequential incubation in xylene (twice, 5 min each), 96% ethanol (twice, 3 min each), 90% ethanol (3 min), and 80% ethanol (3 min), followed by 3 min in water.

   Because paraffin traces might interfere with the enzymatic reaction in tissue sections, use of fresh solvents is recommended.
4. Treat sections with 10 mM Tris·Cl, pH 8, for 5 min, then incubate 15 min in 20 µg/ml proteinase K at room temperature. Wash slide four times in ultrapure water, 2 min each time.
5. Incubate sections in 3% methanol for 30 min at room temperature, and rinse by dipping five times in ultrapure water.
6. Prepare 100 µl per slide of elongation buffer (see Basic Protocol 6, step 6; the buffer needs to be fresh). Incubate the sections 60 min at 37°C in humid atmosphere.
7. Rinse the sections by dipping three times in ultrapure water, and incubate in termination buffer for 15 min at room temperature.
8. Place sections sequentially in PBS (5 min), 2% BSA (10 min), and PBS (5 min), all at room temperature.

   Addition of BSA prevents nonspecific binding of ExtrAvidin-peroxide.
9. Incubate the sections in ExtrAvidin-peroxidase for 15 min at room temperature.
10. Incubate the sections in 2% BSA, and wash four times in PBS.
11. Stain the sections with AEC for 30 min at 37°C, then rinse by dipping three times in ultrapure water.
12. Mount slides and observe for fluorescence.

    After mounting the covered slides can stored for many months at 4°C.

    Tissue sections, like cells, can be counterstained with hematoxylin for ≤30 sec, followed by rinsing in water.

BASIC PROTOCOL 7

Detection of DNA Fragmentation in Whole Cells

In 1976, Skalka et al. reported that the DNA in chromatin of irradiated lymphoid tissues degrades in vivo into oligonucleosome-length fragments. This observation was first linked to endonuclease activation in 1980 (Wyllie, 1980). Since then several methods have been developed to measure internucleosomal DNA fragmentation. This method was adopted from the protocol first described by Sorenson et al. (1990) and does not require DNA purification. Appearance of a DNA ladder will correspond to apoptosis, whereas a DNA smear will indicate necrosis. This also applies to all the alternate protocols in this section.

Materials

1× and 5× TBE buffer (see recipe), pH ~8.0 at room temperature (do not adjust pH)
SeaKem GTG agarose (FMC Bioproducts)
Cell suspension
50 mg/ml RNase A (see recipe)
4× DNA loading buffer: 4× TBE buffer (see recipe) containing 40% (w/v) sucrose and 0.25% (w/v) bromphenol blue (e.g., Sigma; store up to 2 to 3 weeks at 4°C)
Ultrapure agarose (Life Technologies)
10% (w/v) SDS (see recipe)
20 mg/ml proteinase K in water (store in aliquots up to 1 year at −20°C)
1× DNA loading buffer: 1× TBE buffer (see recipe) containing 10% (w/v) sucrose and 0.25% (w/v) bromphenol blue (e.g., Sigma)
DNA marker VI (pBR328 DNA cleaved with *Bgl*I and *Hin*fI; Boehringer Mannheim), 1 µl in 20 µl of 1× DNA loading buffer
TE buffer, pH 8.0: 10 mM Tris·Cl/1 mM EDTA
10 mg/ml ethidium bromide (see recipe)

Boiling water bath or microwave oven
Gel electrophoresis apparatus: GNA-100 (Amersham Pharmacia Biotech), Buffer Puffer (Owl Scientific), or equivalent
Power supply (Power-Pac 300, Bio-Rad, or equivalent)
Shaker at 4°C
MacroVue UV Transilluminator (Hoefer Scientific Instruments) or equivalent
Photoman Polaroid gel documentation system (Hoefer Scientific Instruments) or equivalent

Prepare agarose gel for electrophoresis

1. Prepare sufficient volume of 1× TBE to cast the gel and to fill the electrophoresis tank.

   It is important to use the same batch of electrophoresis buffer in both the electrophoresis tank and in the gel. Differences in pH or ionic strength can greatly affect the DNA mobility.

2. Weigh 0.9 g SeaKem agarose in a flask, and add 50 ml of 1× TBE (for GNA-100 gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved, then allow the agarose to cool to 60°C for 10 to 15 min.

   This is a standard 1.8% agarose gel. The volume should not occupy >40% of the volume of the flask.

   For the Buffer Puffer gel electrophoresis apparatus, use 2.7 g agarose and 150 ml TBE.

3. Pour gel into mold. Remove unwanted air bubbles. Place comb in the gel and allow gel to set 1 hr.

Prepare sample

4. Place a sample of cell suspension containing 4–5 × 10^5 cells in a microcentrifuge tube, and centrifuge 3 min at 1000 × *g*, 4°C.

   If necessary, the pellet may be stored up to 2 to 3 weeks in microcentrifuge tubes at −20°C before proceeding.

5. Carefully remove supernatant and resuspend pellet in 16 µl ultrapure water.

6. Add 4 µl of 50 mg/ml RNase A (final concentration 10 mg/ml), mix, and leave 20 min at room temperature.

7. Add 5 µl of 4× DNA loading buffer.

8. Using a scalpel, cut out a piece of gel between the comb and the upper edge of the gel (do not remove the comb), leaving the gel above the first one or two wells intact.

Prepare digestion gel

9. Prepare 5 ml of digestion gel by weighing 40 mg Ultrapure agarose, adding 2.75 ml ultrapure water, and stirring on a hot plate to dissolve.

   Do not use the SeaKem agarose in this step because it causes SDS to come out of solution.

   For the Buffer Puffer gel electrophoresis apparatus, prepare 10 ml of digestion gel.

10. When steam starts to rise from the flask, add 1 ml of 5× TBE and 1 ml of 10% SDS. When agarose has boiled and dissolved, take flask off the heat and allow gel to cool to 50°C.

11. Add 250 µl of 20 mg/ml proteinase K, mix gently, and pour into the gap above the main gel. Allow to cool, and remove the comb.

Set up for electrophoresis

12. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover it to a depth of 1 mm.

13. Add 1 µl DNA marker VI to 30 µl of 1× DNA loading buffer and load the marker into the well that is separated from the digestion gel. Load all other samples into the wells connected with the digestion gel.

    For the Buffer Puffer apparatus, use 2 µl DNA marker VI dissolved in 30 µl of 1× DNA loading buffer.

14. Run the gel overnight (~14 hr) at 20 V to facilitate digestion of the sample.

15. Turn the voltage up to 90 V and run for an additional 1.5 hr.

    For the Buffer Puffer apparatus, run gel 2 hr at 100 V after the initial 20-V overnight run.

Develop gel

16. Remove the gel from the tank and rinse with water.

17. Add 100 ml TE buffer and 40 µl of 50 mg/ml RNase A. Place gel on shaker for 3 to 4 hr.

18. Rinse the gel with distilled water. Add 100 ml TE buffer and 5 µl of 10 mg/ml ethidium bromide. Place gel on the shaker for 40 min.

19. Wash several times with fresh TE to remove ethidium bromide, and photograph under UV light.

ALTERNATE PROTOCOL 2

Detection of DNA Fragmentation in Total Genomic DNA

This method is a modified version of the protocol described by McGahon et al. (1995). The presence of ethidium bromide in the gel avoids later staining and destaining of the gel. Although Basic Protocol 7 and this alternate protocol are equally sensitive, the latter is less time consuming. In addition, the dry loading prevents the loss of material.

Additional Materials *(also see Basic Protocol 7)*

Lysis buffer: 2 mM EDTA/100 mM Tris·Cl, pH 8.0/0.8% (w/v) SDS (store at room temperature)

1. Place sample of cell suspension containing 4–6 × 10^5 cells in a 1.5-ml microcentrifuge tube. Centrifuge 5 min at 2000 × *g*, 4°C.
2. Remove and discard supernatant. Add 20 µl lysis buffer.
3. Add 2 µl of 50 mg/ml RNase A. Mix well by flicking the tip of the tube. Do not apply vigorous vortexing. Incubate at least 30 min at 37°C.
4. Add 10 µl of 20 mg/ml proteinase K, and incubate at least 1.5 hr at 50°C.
5. Add 8 µl of 4× DNA loading buffer.

   If necessary, after this step the samples can be stored for at least 1 week at 4°C.
6. Place 0.9 g SeaKem agarose (1.8%) in 50 ml of 1× TBE buffer in a flask (for GNA-100 gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved. Allow the agarose to cool to 60°C for 10 to 15 min. Add 3 µl of 10 mg/ml ethidium bromide.
7. Dry load the samples. Dissolve 1 µl DNA marker VI in 30 µl of 1 × DNA loading buffer and load into the gel. Apply low current (~35 mA) for 7 hr or higher current (~60 mA) for 4 hr.

   Samples are dry loaded and enough TBE buffer is added to the apparatus so it touches both sides of the gel but does not cover it. This is to ensure that the sample is not lost. After 10 min, when the samples have entered the gel, the current is stopped and more TBE is added so it covers the whole gel, and the current is then reapplied.
8. Photograph the gel under UV light.

Simple Protocol for Detection of DNA Fragments

ALTERNATE PROTOCOL 3

This simple protocol was developed in our laboratory. It is particularly useful for detection of chromatin cleavage in lymphoid cells (Zhivotovsky et al., 1995). It is also very useful for different lymphoid cells and less so for hepatocytes and epithelial cells. For these types of cells, see Alternate Protocol 4.

Additional Materials *(also see Basic Protocol 7)*

Lysis buffer, 4°C: 5 mM Tris·Cl, pH 8.0/20 mM EDTA/0.5% (v/v) Triton X-100
100% ethanol, –20°C
5 M NaCl (*APPENDIX 2A*)
RNase T1/A stock (see recipe)
Vacuum lyophilizer (e.g., Hetovac, Heto-Holten)

Prepare DNA sample

1. Place sample containing 1–2 × 10^6 cells in a microcentrifuge tube, and centrifuge 5 min at 2000 × *g*, 4°C. Resuspend pellet in 1 ml PBS and repeat centrifugation.
2. Resuspend pellet in 250 µl TE buffer, add 250 µl of 4°C lysis buffer, and vortex. Refrigerate 30 min.
3. Centrifuge sample 15 min at 15,000 × *g*, 4°C.
4. Transfer supernatant to a fresh microcentrifuge tube. Add 1 ml –20°C ethanol and 30 µl of 5 M NaCl. Mix and place in –20°C freezer overnight.
5. Centrifuge sample for 15 min at 15,000 × *g*, 4°C. Remove and discard supernatant.
6. Place precipitate in vacuum lyophilizer for 20 to 25 min.

7. Add 20 to 30 µl TE buffer and 1 µl RNase T1/A stock. Incubate 1 hr at 37°C.
8. Add 1 µl of 20 mg/ml proteinase K, and incubate an additional 1 hr at 37°C.
9. Add 8 µl of 4× DNA loading buffer.

Cast and run the gel

10. Dissolve 0.9 g SeaKem agarose in 50 ml TBE buffer (for GNA-100 gel electrophoresis apparatus) or 2.7 g SeaKem agarose in 150 ml TBE buffer (for Buffer Puffer gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved, then cool gel and pour into mold.
11. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover the gel to a depth of 1 mm.
12. Load DNA marker VI in the first well and samples in the rest of wells (see Basic Protocol 7, step 13).
13. Run the gel at 60 mA (for GNA-100) or 70 mA (for Buffer Puffer) until the bromphenol blue front is ~1 to 2 cm from the end of the gel.
14. Stain gel with ethidium bromide and photograph under UV light (see Basic Protocol 7, steps 18 to 19).

ALTERNATE PROTOCOL 4

Phenol Extraction of DNA Fragments for Agarose Gel Electrophoresis

This protocol is a modification of the classical method described by Wyllie (1980). This method requires DNA purification. Although it takes much more time tha other techniques and needs many more cells for preparation, it yields very clean, protein-free DNA fragments.

Additional Materials *(also see Basic Protocol 7)*

Lysis buffer (see Alternate Protocol 3), 4°C
100% ethanol, −20°C
5 M NaCl (*APPENDIX 2A*)
RNase T1/A stock (see recipe)
TE-saturated phenol (see recipe)
24:1 (v/v) chloroform/isoamyl alcohol (store mixture at room temperature in a fume hood)
0.5% (w/v) SDS

Prepare DNA sample

1. Place sample containing 2–5 × 10^6 cells in microcentrifuge tube, and centrifuge 5 min at 2000 × *g*, 4°C.
2. Resuspend pellet in 250 µl TE buffer, add 250 µl of 4°C lysis buffer, vortex, and refrigerate 30 min at 4°C.
3. Centrifuge sample 15 min at 15,000 × *g*, 4°C.
4. Transfer supernatant to fresh microcentrifuge tube. Add 1 ml −20°C 100% ethanol and 30 µl of 5 M NaCl. Mix and place in −20°C freezer overnight.
5. Centrifuge sample 15 min at 15,000 × *g*, 4°C. Remove and discard supernatant.
6. Add 500 µl TE buffer and 5 µl RNase T1/A stock to pellet. Incubate 30 min at 37°C.

7. Add 250 µl TE-saturated phenol and 250 µl of 24:1 chloroform/isoamyl alcohol. Vortex, and centrifuge for 2 to 3 min at 5000 × *g*, 4°C. Transfer upper layer to fresh 2-ml microcentrifuge tube.
8. Add 500 µl of TE buffer to lower layer; repeat step 7. Transfer upper layer to 2-ml microcentrifuge tube and mix with upper layer from step 7.
9. Extract the mixed samples from steps 7 and 8 with 1000 µl 24:1 chloroform/isoamyl alcohol and centrifuge again.
10. Transfer the upper layer to 1.5-ml microcentrifuge tubes, 500 µl per tube. Precipitate overnight with ethanol and NaCl as in step 4.
11. Repeat step 5.
12. Place precipitate in vacuum lyophilizer for 20 to 25 min.
13. Dissolve and mix precipitates from both microcentrifuge tubes in a total of 20 to 30 µl TE buffer/0.5% SDS. Add 5 µl of 4× DNA loading buffer.

Cast and run the gel

14. Mix a 1.8% agarose gel by dissolving 0.9 g agarose in 50 ml TBE buffer (for GNA-100 gel electrophoresis apparatus) or 2.7 agarose in 150 ml TBE buffer (for Buffer Puffer). Cool gel and pour into mold.
15. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover the gel to a depth of 1 mm.
16. Load DNA marker VI in the first well (see Basic Protocol 7, step 13) and samples in the rest of the wells.
17. Run the gel at 60 mA (for GNA-100) or 70 mA (for Buffer Puffer) until the bromphenol blue front is ~1 to 2 cm from the end of the gel.
18. Stain gel with ethidium bromide (see Basic Protocol 7, steps 18 to 19) and photograph under UV light.

Quantitative Assay of DNA Fragmentation

BASIC PROTOCOL 8

In addition to qualitative analysis by gel electrophoresis, DNA fragmentation can be quantitatively determined by using the diphenylamine reagent. This method, introduced by Burton (1956), cannot, however, discriminate between apoptotic and necrotic chromatin cleavage.

Materials

Cell suspension to be assessed
Lysis buffer (see Alternate Protocol 3), ice cold
10% (w/v) and 5% (w/v) trichloroacetic acid (TCA; keep at room temperature in dark flasks)
Diphenylamine reagent (see recipe)

10-ml conical glass tubes
Round-bottom glass tubes
Water bath, 100°C

1. Prepare cell suspension containing $1–10 \times 10^6$ cells in a 1-ml volume.
2. Transfer 0.8 ml of cell suspension to microcentrifuge tube. Add 0.7 ml ice-cold lysis buffer. Vortex, and allow lysis to proceed 15 to 30 min at 4°C.

3. Centrifuge 15 min at 15,000 × *g*, 4°C. Transfer supernatant to labeled conical glass tube.
4. Add 0.65 ml of 5% TCA to the pellet in microcentrifuge tube, and add 1.5 ml of 10% TCA to the sample in labeled glass tube.
5. Precipitate both samples overnight (≥4 hr) at 4°C.
6. Centrifuge conical tube 10 min at 2500 × *g*, room temperature.
7. Remove supernatant after centrifugation and add 0.65 ml of 5% TCA to the pellet. Prepare two blank tubes with 0.65 ml of 5% TCA to be treated the same for the remaining steps.
8. Make hole on the top of each microcentrifuge tube from step 5, and cover each conical tube with a marble.
9. Boil both sets of tubes for 15 min in 100°C water bath.
10. Cool to room temperature. Centrifuge samples 5 min at 2500 × *g*, room temperature.
11. Transfer 0.5 ml of each supernatant (from both glass and microcentrifuge tubes) to labeled, round-bottom glass tubes.
12. Add 1 ml diphenylamine reagent to each tube. Incubate ≥4 hr at 37°C with a marble covering each tube.
13. Read absorbance at 600 nm in spectrophotometer. Set zero with blanks from step 7. Express results as the percentage of DNA fragmented:

$$\%\ \text{fragmented DNA} = \frac{\text{absorbance of the supernatant}}{\text{absorbance of supernatant + pellet}} \times 100$$

BASIC PROTOCOL 9

Detection of High-Molecular-Weight Chromatin Fragments by Pulsed-Field Agarose Gel Electrophoresis

Not all forms of apoptosis are accompanied by internucleosomal DNA fragmentation (Oberhammer et al., 1993a). However, the formation of high-molecular-weight apoptotic DNA fragments of 50 to 700 kbp (see Figure 2.2.3B), which was first observed by Walker et al. (1991), has been reported to occur in all the cell types studied to date (see Background Information in Commentary).

One of the forms of pulse-field gel electrophoresis, field-inversion gel electrophoresis (FIGE), has been successfully used in several laboratories to identify high-molecular-weight DNA fragments in apoptotic cells and a smear in the same range of DNA size in necrotic cells. The authors have used both vertical and horizontal gel chambers; resolution of DNA fragments is the same. This protocol is an adaptation of an earlier method described by Anand and Southern (1990).

Materials

Cell suspension
Agarose buffer (for molds; see recipe)
SeaPlaque GTG low-melting-point agarose (FMC Bioproducts)
20 mg/ml proteinase K in water (store in aliquots up to 1 year at −20°C)
Proteinase buffer (for plugs; see recipe)
TE buffer, pH 8.0:10 mM Tris·Cl/1 mM EDTA

50 mM EDTA, pH 8.0 (*APPENDIX 2A*)
SeaKem GTG agarose (FMC Bioproducts)
5× TBE buffer (see recipe)
DNA size pulse markers: chromosomes from *Saccharomyces cerevisiae* (225 to 2200 kbp) and a mixture of λDNA *Hin*dIII fragments, λDNA, and λDNA concatemers (0.1 to 200 kbp; Sigma; supplied premade in syringe)

Gel leveling table
100-µl insert molds (Amersham Pharmacia Biotech), stored in 0.1 M HCl
12- or 24-well tissue culture plates
50°C incubator
100°C water bath or microwave oven
Pulsed-field gel electrophoresis system: vertical gel chamber with cooling elements (Protean II, Bio-Rad); horizontal gel chamber (HE 100B); power supply (PS 500 XT); and Switchback pulse controller (PC 500, Hoefer Scientific Instruments)
Thermostatic circulator Multi Temp III (Amersham Pharmacia Biotech)

Prepare sample plugs of agarose

1. Rinse insert molds extensively in distilled water and dry. Wrap Parafilm around the bottom of the molds and place them on ice to chill at least 10 min before pouring in the gel.

   Make sure to mark the sample wells with pencil or pen.

2. Place sample of cell suspension containing 1×10^6 cells in a microcentrifuge tube, and centrifuge 3 min at $2000 \times g$, 4°C. Remove and discard supernatant. Resuspend pellet in 100 µl of agarose buffer.

3. Prepare 1% low-melting-point agarose in agarose buffer, and place in a 60°C water bath until melted.

4. Add 100 µl of molten 1% agarose to the cell suspension, and mix with pipet. Immediately pipet mixture into two prechilled insert molds, 100 µl per mold.

5. Place the filled insert molds on ice for 10 to 15 min.

6. Remove Parafilm from the bottom of the insert molds, and dislodge each plug into separate well of a tissue culture plate.

   It is convenient to use 12- or 24-well tissue culture plates for this purpose.

7. Add 1 ml of proteinase buffer and 10 µl proteinase K (final concentration 0.2 mg/ml plug) to each well. Wrap Parafilm or clear tape around the plate, and incubate ≥24 hr on a shaker at 50°C.

8. Remove wrapping from plate, and remove buffer with pipet.

   If it is necessary to simultaneously analyze the low-molecular-weight DNA, it is possible to remove the DNA fragments that have leached out from the plugs during incubation with proteinase K by precipitating them from this buffer over 48 hr at −20°C. Add 0.2 volume of 10.5 M ammonium acetate and 2 volumes of cold absolute ethanol. This DNA can then be lyophilized, dissolved in 1× DNA loading buffer, and analyzed by conventional gel electrophoresis.

9. Wash each plug three times with 1 ml TE buffer, 2 hr per wash, on a shaker at 4°C.

10. Remove TE buffer, and add 1 ml of 50 mM EDTA.

    Plugs are now ready to put on a gel. To save samples for a long time, store the plugs in EDTA, in which DNA is stable for several months, at 4°C.

Prepare separating gel

11. Prepare 1% agarose (SeaKem GTG) gel in 0.5× TBE.

For horizontal gels

12a. Dissolve 2.5 g agarose in 250 ml 0.5× TBE in a boiling water bath or microwave oven. Allow the agarose to cool to 60°C for 10 to 15 min.

13a. Seal the edges of the gel platform with tape, and place platform on leveling table.

14a. Pour the gel into the mold, and remove unwanted air bubbles. Place the comb into the gel, and allow to set for 1 hr.

15a. Remove the comb very carefully so as not to break the gel. Remove tape.

For vertical gels

12b. Clamp two frosted glass plates together with 3-mm spacers in between. Seal the bottom with Parafilm to prevent leakage of warm agarose.

13b. Warm glass plates for 30 min in 50°C incubator.

14b. Melt agarose as in step 12a (1 g agarose in 100 ml 0.5× TBE), and pour into the prewarmed gel assembly to ~5 mm below top of plates. Insert comb into the gel, and allow to set for 1 hr.

15b. Remove the comb very carefully so as not to break the gel, and wash the wells with 0.5× TBE to remove partially polymerized agarose.

Load and run gel

16. Using a scalpel, cut out a 2-mm slab from one marker, and insert into first well of the gel with a spatula.

17. Repeat this procedure with the second marker.

    Make sure that the slab is flat on the bottom of the well. This applies to loading of samples as well.

18. To load sample, cut off 3 mm from sample plug, and insert it into individual well with a spatula. Repeat same procedure for all samples. Avoid introducing any air bubbles into the wells.

    Note and record the order of the samples!

19. Cement the slabs into wells with the remaining molten 1% agarose.

20. Transfer the loaded gel (either horizontal or vertical) into a precooled tank filled with 0.5× TBE.

    The buffer temperature should be 11° to 12°C at the beginning of the experiment.

21. Run the gel at a constant voltage with a suitable switcher program to achieve the desired resolution. The programs listed in Table 2.2.2 give good resolution of 50-, 300-, and 700-kbp fragments.

22. Remove gel carefully, and stain it in ethidium bromide for 1 hr (see Basic Protocol 7, step 18). Destain it in 0.5× TBE for 2 to 3 hr.

23. Visualize and photograph bands under UV light.

Table 2.2.2 Parameters for Running Pulsed-Field Agarose Gels

	Horizontal gel	Vertical gel
Running voltage[a]	170 V	200 V
Procedure	10 min: run the DNA into gel with continuous forward pulse	10 min: run the DNA into gel with continuous forward pulse
	6 hr: apply 20 sec forward time, 3:1 forward/back ratio, ramp factor 1.5[b]	2 hr: apply 12 sec forward time, 3:1 forward/back ratio, ramp factor 2[c]
	6 hr: apply 10 sec forward time, 3:1 forward/back ratio, ramp factor 2	3 hr: apply 2.4 sec forward time, 3:1 forward/back ratio, ramp factor 5.0
	12 hr: apply 0.8 sec forward time, 3:1 forward/back ratio, ramp factor 12.5	2.5 hr: apply 8.0 sec forward time, 3:1 forward/back ratio, ramp factor 3.0
Total running time	24 hr, 10 min	7 hr, 40 min

[a] Constant voltage

[b] This means that at the end of these 6 hr, the forward time should be 30 sec.

[c] This means that at the end of these 2 hr, the forward time should be 24 sec.

METHODS FOR ANALYSIS OF CASPASE PROTEOLYTIC ACTIVITY

Several proteolytic activities are implicated in apoptosis and necrosis (see *UNIT 2.1*). The activation of caspases, a family of apoptotic proteases, plays a key role in apoptosis induced by diverse stimuli. Caspases, which have been detected in numerous tissues and cell types, are synthesized as a precursor form, or proenzyme, and an apoptotic signal converts the precursor into mature enzyme. Moreover, up to now there has been no evidence concerning the involvement of caspase activities in necrosis. Therefore the detection of caspase activity in cells can be used as a discriminating criterion to distinguish apoptosis from necrosis.

All members of the caspase family of proteases share a number of amino acid residues crucial for substrate binding and catalysis. Despite their uniform requirement for an aspartate residue at the P_1 position of the substrate site, caspases can be divided into three different groups according to their substrate preferences. The first group (caspases 1, 4, and 5) has the optimal substrate cleavage sequence WEXD; the second (caspases 2, 3, and 7) preferentially cleaves targets at the DEXD motif; and the third (caspases 6, 8, and 9) has the optimal substrate cleavage sequence (L/V)EXD (Thornberry et al., 1997). The predicted caspase specificities correspond to the cleavage sites in the different intracellular caspase targets. Analysis of caspase activation is also based on the substrate specificity of the enzymes. Described here are two methods recently developed and currently used for analysis of caspase activation.

Detection of Caspase Activity by Specific Substrate Cleavage

BASIC PROTOCOL 10

This assay was adopted from the protocol first described by Thornberry (1994). Detecting proteolytic cleavage of fluorescent substrates assesses caspase activity. To determine the specificity of the assayed samples for the substrate, appropriate aldehyde-conjugated inhibitors (see Table 2.2.3 in Reagents and Solutions, below) can be added at a final concentration of 50 nM to the complete buffer containing the substrate. The resulting inhibition is biphasic: initially V_0 is equivalent to the substrate cleavage rate, and then a plateau in the rate of substrate cleavage occurs, usually within 5 to 8 min of the assay. As with all enzyme-substrate and -inhibitor interactions, the extent of inhibition is dependent on the concentration of the other components.

Materials

Cell suspension
1× PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
1× substrate buffer (SB; see recipe)
Caspase substrate and inhibitor stock solutions (see recipe)
Liquid nitrogen

96-well tissue culture plates (e.g., LabSystems)
Fluoroscan II (LabSystems)

1. Place duplicate samples containing 2–3 × 10^6 cells in microcentrifuge tubes, and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Wash pellet with PBS, and centrifuge 5 min at 1000 × *g*, 4°C.
3. Remove and discard supernatant. Resuspend each pellet in 25 µl PBS (check pH, which should be neutral), and transfer into individual wells of a 96-well culture plate.

   The plate should be kept very cold (either by keeping it for some time at –20°C, or by having it "floating" on liquid nitrogen). If necessary, plates with cells can be stored for several days at –80°C.
4. Set up the computer control for the Fluoroscan II plate reader. Set temperature to 37°C.

   This takes about 3 to 4 min. Several computer programs are available for acquisition and data processing. The authors recommended Genesis II Windows-based microplate software (LabSystems and Life Sciences).
5. Immediately prior to use, prepare complete 1× SB by adding 1 µl of 200 mM stock solution of the substrate of interest (final concentration 50 µM) to 4 ml of 1× SB.
6. Dispense 50 µl of complete SB with substrate to each test well of cells at room temperature, and place plate immediately on the Fluoroscan II.

   The final concentration of substrate in the wells is 33.3 µM.
7. Read samples. The maximum absorption for AMC (7-amino-4-methyl coumarin) is 354 nm. Fluorometric detection for AMC cleaved from peptide is at excitation 380 nm and emission 460 nm.

BASIC PROTOCOL 11

Immunodetection of Active Caspases During Apoptosis

All caspases are expressed as proenzymes (30 to 55 kDa) that contain three domains: an NH_2-terminal domain, a large subunit (17 to 35 kDa), and a small subunit (10 to 12 kDa). Activation involves proteolytic processing between domains, followed by association of the large and small subunits to form a heterodimer. Thus, detection of large or small subunits by Western blotting can be used as a marker of caspase activation. All caspases can be described according to function as either activators or executioners of cell death. Their relative order appears to vary widely depending on the cellular background and apoptotic stimuli. Therefore, it is necessary to investigate the cleavage and activation of several caspases. Since the activation of the caspase 3–like proteases has been shown during most apoptotic process, it is reasonable to first investigate the activation of caspase 3 and then continue to look for the activation of caspases located up- and downstream (see *UNIT 2.1*). To compare the cleavage/activation of different caspases in the same samples. the membrane may be reprobed. Moreover, for densitometric analysis of results of protein degradation, the same membranes can be reprobed and stained with antibodies against marker proteins, such as glyceraldehyde-3-phosphate dehydrogenase or actin.

Materials

Cell suspension
PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
Sample buffer (see recipe)
Prestained SDS-PAGE markers, low range (e.g., Bio-Rad)
1× electrode buffer (see recipe)
4× high-salt Tris base buffer (HSB; see recipe)
High-salt Tris base buffer with Tween 20 (HSBT; see recipe)
Low-salt Tris buffer (LSB; see recipe)
Transfer buffer (see recipe)
Dry nonfat milk
BSA fraction V (e.g., Sigma)
Sodium azide
Stripping buffer (see recipe)
Primary antibodies:
  Anti–caspase 1 (Calbiochem)
  Anti–caspase 2 (Transduction Laboratories)
  Anti–caspase 3 (Pharmingen)
  Anti–caspase 6 (Research Diagnostics)
  Anti–caspase 7 (Transduction Laboratories)
  Anti–caspase 8 (Pharmingen)
  Anti–caspase 9 (Calbiochem)
  Anti–caspase 10 (Calbiochem)
Appropriate secondary antibodies for the primary antibodies listed above: peroxidase-conjugated goat anti–rabbit IgG, goat anti–mouse IgG, and mouse anti–goat IgG (Pierce)
Minigel (see Support Protocol 2)
Anti-glyceraldehyde-3-phosphate dehydrogenase (Trevigen)
Anti-actin (Sigma or Boehringer Mannheim)

ECL Western blotting detection system (Amersham Pharmacia Biotech) or equivalent
Boiling water bath
Mini-Protean II Electrophoresis Cell (Bio-Rad) or equivalent
Prot/Elec pipet tips for protein gel (Bio-Rad)
Power supply (Power-Pac 300, Bio-Rad, or equivalent)
0.45-µM nitrocellulose membranes (Sartorius AG)
Whatman 3MM filter paper
Mini Trans-Blot Transfer Cell (Bio-Rad) or equivalent
X-ray film (e.g., FujiFilm)

Additional reagents and equipment for one-dimensional SDS-PAGE, minigels (see Support Protocol 2), and immunoblotting (*UNIT 2.3*)

Prepare samples

1. Place 1×10^6 cells in a microcentrifuge tube and centrifuge 5 min at $2000 \times g$, 4°C. Resuspend pellet in 1 ml PBS, and centrifuge 2 min at $1000 \times g$, 4°C.

   Two methods may be used to extract proteins from cells for immunoblotting. Either the intact cells are resuspended directly in sample buffer, or an equal amount of proteins extracted from cells can be mixed with sample buffer. Direct resuspension of cells in sample buffer is described here.

2. Resuspend pellet in 100 µl sample buffer and incubate 4 min in boiling water bath. Let cool at room temperature.

   If samples become highly viscous as a consequence of the release of chromosomal DNA, shear the DNA either by sonication or by repeated passage through a 23-G hypodermic needle.

Set up and run gel electrophoresis

3. Release the gel holder from the casting stand (see Support Protocol 2). Assemble the inner cooling core with gels according to manufacturer's instructions, and lower them into the buffer chamber.
4. Add 300 to 350 ml of 1× electrode buffer to the bottom of the chamber so that both the bottom 1 cm of the gel and electrode are covered. Add ~120 ml of buffer to the upper buffer chamber, filling until the buffer reaches a level halfway between the short and long plates.

   Do not overfill the upper buffer chamber.
5. Remove the comb by pulling it straight up slowly and gently.
6. Load samples (20 to 30 µl) into wells under the electrode buffer with Prot/Elec Tips. Load one well with 5 µl of low-range prestained SDS-PAGE markers.
7. Attach the electrophoresis apparatus to an electric power supply. Run gel at constant 130 V in a 4° to 8°C cold room until the bromphenol blue reaches the bottom of the resolving gel (~1.5 hr).
8. After electrophoresis is complete, turn off the power supply and disconnect the electrical leads.

Immunoblot proteins

9. Remove cell lid and carefully pull inner cooling core out of lower chamber. Pour off upper buffer.
10. Remove glass plate sandwich from the inner cooling core. Push one of the spacers of the sandwich out to the side of the plates without removing it. Gently twist the spacer so the upper glass plate pulls away from the gel.
11. Mark gel orientation by cutting a right corner from bottom of gel, then immerse gel in transfer buffer.
12. Transfer the proteins from gel onto a nitrocellulose membrane by electrotransfer (see *UNIT 2.3*).

    CAUTION: *It is important to wear gloves when handling gel, filter paper, and nitrocellulose membranes.*

    The authors normally use a Mini Trans-Blot Module and Bio-Ice cooling unit, and transfer at a constant 100 V for 2 hr in a cold room.

    Control for transfer efficiency by checking transfer of prestained SDS-PAGE markers.
13. Transfer the nitrocellulose membrane into 1× HSB containing 5% dry nonfat milk, 1% BSA, and 0.05% sodium azide. Keep at least 1 hr (overnight is preferable) on a rocker in the 4° to 8°C cold room.
14. Wash membrane two times, 20 min each, in HSBT on a rocker at room temperature.
15. Put membrane into a plastic bag, and add desired primary antibody in appropriate dilution (usually 1:100 to 1:5000) in 1× HSB containing 1% BSA and 0.05% sodium azide. Incubate 1 to 2 hr on a rocker at room temperature.
16. Wash three to five times, 10 min each, with HSBT on a rocker at room temperature.
17. Add peroxidase-conjugated secondary antibody in appropriate dilution (usually 1:5,000 to 1:10,000) in 1× HSBT containing 1% BSA. Incubate for 1 hr on a rocker at room temperature.

18. Wash three times, 10 min each, with HSBT on a rocker at room temperature.
19. Wash two times, 30 min each, with LSB on a rocker at room temperature.

    No Tween 20 in this buffer!

20. Develop nitrocellulose membrane with ECL according to manufacturer's instructions.
21. Cover membrane with plastic wrap, and immediately expose to X-ray film for 30 sec to 5 min in X-ray cassette.
22. Scan the film using a densitometer, and plot graph of optical density versus concentration.

    Following ECL detection, it is possible to reprobe the nitrocellulose membrane with other antibodies against different caspases or against marker proteins such as glyceraldehyde-3-phosphate dehydrogenase or actin to either clarify the results or to obtain more information. To do this, proceed with the next steps.

    Figure 2.2.4 shows the results of a time-course study of caspase activation.

23. Submerge the membrane in stripping buffer, and incubate for 30 min at 50°C with agitation.
24. Wash the membrane with water, and repeat steps 14 to 22.

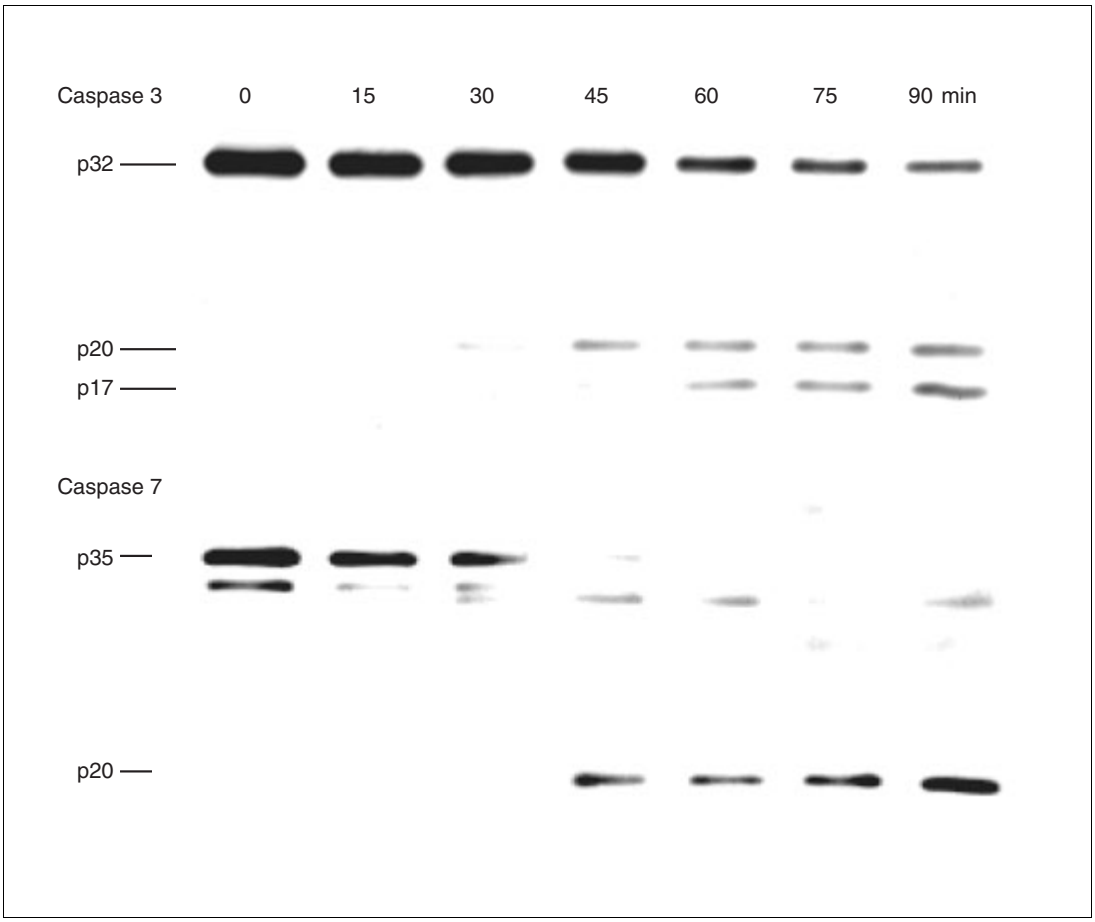

Figure 2.2.4 Time course of caspase activation in Jurkat cells treated with anti-CD95 antibodies.

SUPPORT PROTOCOL 2

Preparation of SDS-Polyacrylamide Minigels

Minigels are useful because they require shorter run times and they use smaller quantities of reagents (the latter especially helpful in immunoassays).

Materials

29% (w/v) acrylamide/1% (w/v) bisacrylamide stock (e.g., Bio-Rad)
10% (w/v) ammonium persulfate (APS; e.g., Bio-Rad): 100 mg in 1 ml water, prepared just before gel casting
1.5 M Tris·Cl, pH 8.8 (see recipe)
10% (w/v) sodium dodecyl sulfate (SDS; see recipe)
TEMED (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine; e.g., Bio-Rad)
Isobutanol, water saturated
1.0 M Tris·Cl, pH 6.8 (see recipe)

Mini-Protean II Electrophoresis Cell (Bio-Rad)
Casting stand

Additional reagents and equipment for one-dimensional SDS-PAGE (see *APPENDIX 3*)

1. Assemble the glass plates for Mini-Protean II system according to the manufacturer's instructions, and check for leakage.
2. Prepare separating gel (12% gel/0.375 M Tris·Cl, pH 8.8). To make one set (two gels) for Mini-Protean II with 1.5-mm thick spacers, combine the following:

   6.7 ml H_2O
   5 ml 1.5 M Tris·Cl, pH 8.8
   200 µl 10% SDS
   8 ml 29% acrylamide/1% bisacrylamide stock
   100 µl 10% APS
   10 µl TEMED.

   Because the molecular weights of caspases vary between 30 and 55 kDa, a 12% gel is recommended.

3. Pour separating gel into the gap between the glass plates. Leave sufficient space for stacking gel to be added later (the length of the comb teeth plus 4 to 5 mm). Using a pipet, carefully overlay the gel with water-saturated isobutanol.

   The advantage of using isobutanol is that the overlay solution can be applied rapidly with a pipet and bulb with very little mixing. If water is used, the overlay must be applied carefully with a needle and syringe, using a steady, even rate of delivery to prevent mixing.

4. Allow gel to polymerize 45 to 60 min. Rinse off the overlay solution completely with distilled water.

   This is especially important with isobutanol overlays. Do not allow alcohols to remain on the gels >1 hr, or the top of the gel will dehydrate. If necessary this gel can be stored 1 to 2 days at 4°C with distilled water on top.

5. Prepare the stacking gel (4% gel/0.125 M Tris·Cl, pH 6.8). For two gels (one set), combine the following:

   7.3 ml H_2O
   1.25 ml 1.0 M Tris·Cl, pH 6.8
   100 µl 10% SDS
   1.3 ml 29% acrylamide/1% bisacrylamide stock
   50 µl 10% APS
   10 µl TEMED.

6. Pour stacking gel solution directly on top of the polymerized separating gel. Immediately insert a clean Teflon comb into the stacking gel solution, being careful to avoid trapping air bubbles. Top up with more stacking gel. Allow gel to polymerize 20 to 30 min.

The gel cannot be stored at this stage and should be used within 1 to 2 hours.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified or other ultrapure water for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agarose buffer *(for molds; used in Basic Protocol 9)*

Prepare 500 ml in H_2O:
0.15 M NaCl
2 mM KH_2PO_4/KOH, pH 6.8
1 mM EGTA
5 mM $MgCl_2$
Filter sterilize through 0.2-µm filter
Store at 4°C

Caspase substrate and inhibitor stock solutions

Prepare 200 mM stock solutions of each substrate and inhibitor to be tested (see Table 2.2.3) in sterile ultrapure water. Dispense into 2-µl aliquots and store at −20°C.

Diphenylamine reagent

100 ml glacial acetic acid
1.5 g diphenylamine
1.5 ml concentrated sulfuric acid
0.5 ml 16 mg/ml acetaldehyde stock
Prepare just before use

Prepare acetaldehyde stock in ultrapure water; store in a dark flask up to 1 month at 4°C.

DTT, 1 M

Add 309 mg 1,4-dithiothreitol (DTT; Boehringer Mannheim) to 2 ml of 0.01 M sodium acetate, pH 5.2. Filter sterilize, dispense into 50-µl aliquots, and store at −20°C.

Electrode (Tris-glycine) buffer, 10×

Dissolve 90 g Tris base, 432 g glycine, and 30 g SDS in 3 liters water. Do not adjust pH with acid or base. Store up to 1 month at 4°C. If precipitation occurs, warm to 37°C before use.

For one electrophoretic run, mix 50 ml of 10× stock with 450 ml water just before electrophoresis. Concentrations in 1× buffer: 25 mM Tris, 192 mM glycine, and 0.1% SDS, pH 8.3.

Table 2.2.3 Caspase Substrates and Inhibitors

Substrate	Inhibitor	Supplier (for substrate and inhibitor)
Ac-DEVD-AMC	Ac-DEVD-CHO	Peptide Institute
Ac-VEID-AMC	Ac-VEID-CHO	Peptide Institute
Ac-IETD-AMC	Ac-IETD-CHO	Peptide Institute
Ac-WEHD-AMC	Ac-WEHD-CHO	Peptide Institute
Z-YVAD-AMC	Z-YVAD-CHO	Enzyme Systems Products
Ac-LEHD-AMC	Ac-LEHD-CHO	Enzyme Systems Products

Ethidium bromide, 10 mg/ml

Stir 10 mg/ml ethidium bromide in water on magnetic stirrer for several hours. Store up to 2 months in a dark bottle at 4°C.

HEPES buffer, pH 7.4

10 mM HEPES (*N*-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid), pH 7.4 (adjusted with NaOH)
150 mM NaCl
5 mM KCl
1 mM $MgCl_2$
1.8 mM $CaCl_2$
Store up to several months at 4°C

All components may be obtained from Sigma.

HSB (high-salt Tris buffer), 4×

Dissolve 48.4 g Tris base and 233.76 g NaCl in 1.5 liters water. Adjust pH to 7.5 with 10 M HCl, and add water to 2 liters. Store up to several weeks at 4°C.

Concentrations in 1× buffer: 50 mM Tris·Cl and 500 mM NaCl, pH 7.5.

HSBT (high-salt Tris buffer with Tween)

Mix 500 ml of 4× HSB (see recipe) and 1500 ml water. Add 1 ml Tween 20 and gently mix. Store up to several weeks at 4°C.

Concentrations in 1× buffer: 50 mM Tris·Cl, 500 mM NaCl, and 0.05% Tween 20, pH 7.5.

LSB (low-salt Tris buffer)

Dissolve 12.1 g Tris base and 18 g NaCl in 1500 ml water. Adjust pH to 7.5 with 10 M HCl, and add water to 2000 ml. Store up to several weeks at 4°C.

Concentrations: 50 mM Tris·Cl and 150 mM NaCl, pH 7.5.

NP-40, 0.1% (v/v)

Add 1 µl of Nonidet P-40 (Boehringer Mannheim) to 1 ml water, vortex, and keep at 4°C.

Paraformaldehyde, 4% (w/v)

Add 8 g paraformaldehyde powder (e.g., Sigma) to 100 ml water and heat to 60°C in a fume hood. If necessary, add NaOH dropwise (one or two drops each time) to help dissolve the powder. When the solids have completely dissolved, let the solution cool to room temperature. Then add 100 ml of 2× PBS (*APPENDIX 2A*). Store at 4°C.

Because this solution cannot be kept indefinitely, it is better to prepare small volumes every week.

Phenol, TE saturated

Allow phenol to warm to room temperature, and then melt it at 68°C. Add hydroxyquinoline to a final concentration of 0.1%. Add a volume of TE buffer, pH 8.0 (10 mMTris·Cl/1 mM EDTA), equal to the volume of phenol, and vortex extensively. Allow the two phases to separate, and aspirate the upper aqueous phase. Repeat this saturation with TE buffer two to three times until volume of TE remains unchanged and the pH of the phenol phase has reached 8.0 (as measured with pH paper). Remove the aqueous phase, and add 0.1 vol fresh TE. Store up to 1 month in the dark at 4°C.

Hydroxyquinoline, a yellow antioxidant, provides a convenient way to identify the organic phase during extraction.

Proteinase buffer *(for treatment of plugs)*

Prepare 500 ml of buffer consisting of:
10 mM NaCl
10 mM Tris·Cl, pH 9.5
25 mM EDTA

Add *N*-lauroylsarcosine (Sarkosyl) to 1% final concentration and dissolve using magnetic stirrer. Check pH, and if necessary adjust to 9.5 with NaOH. Filter through 0.2-µm filter and store at 4°C.

RNase A, 50 mg/ml

Dissolve RNase A (e.g., Sigma) at a concentration of 50 mg/ml in 10 mM Tris·Cl, pH 7.5/15 mM NaCl. Heat 15 min at 50°C. Allow to cool at room temperature. Divide into aliquots and store up to several months at −20°C.

RNase T1/A stock

Mix 50 µl of 500,000 U/ml RNase T1 and 50 mg of RNase A in 5 ml of 10 mM Tris·Cl, pH 7.5/15 mM NaCl. Heat for 15 min at 50°C. Allow to cool at room temperature. Divide into aliquots and store up to several months at −20°C.

Sample buffer

625 µl 1.0 M Tris·Cl, pH 6.8 (62.5 mM final; see recipe)
2 ml glycerol (20% final)
2 ml 10% SDS (see recipe; 2% final)
0.5 ml 0.5% (w/v) bromphenol blue in H_2O (0.025 %)
0.5 ml 2-mercaptoethanol (5% final)
H_2O to 10 ml
Store up to several weeks at 4°C

This buffer is derived from Laemmli (1970).

SDS, 10% (w/v)

Dissolve 10 g of sodium dodecyl sulfate (SDS) in 90 ml of water by mixing on magnetic stirrer for several hours or by heating to 65°C to assist dissolution. Adjust the volume to 100 ml with water. Store at room temperature for up to 1 month.

Staining buffer

54.2 µl water
25 µl 20× sodium cacodylate (SSC) stock solution
20 µl blotto (25% low-fat dried milk in PBS)
0.7 µl avidin-FITC (160×)
0.1 µl Triton X-100
Store up to several weeks at 4°C

Stripping buffer

100 mM 2-mercaptoethanol
2% SDS
62.5 mM Tris·Cl, pH 6.8 (see recipe)

Add 6.25 ml of 1 M Tris·Cl, pH 6.8; 0.77 ml β-mercaptoethanol; and 20 ml 10% SDS to 73 ml water and mix. This buffer should be prepared immediately before use.

Substrate buffer (SB)

Concentrated stock:
100 mM HEPES (e.g., Boehringer Mannheim)
10% (w/v) sucrose
0.1% (w/v) CHAPS (3-[{3-cholamidopropyl}dimethylammonio]-1-propanesulfonate) (e.g., Sigma)

Do not adjust pH. Divide into aliquots and store in 40-ml Falcon tubes or equivalent. Store up to 6 months at −20°C or 2 to 3 weeks at 4°C.

1× buffer: For each 96-well plate to be processed, add 25 µl of 1 M DTT (see recipe; 5 mM final) and 5 µl of 0.1% NP-40 (see recipe; 10^{-4}% final) to 5 ml concentrated SB stock, and adjust pH to 7.25. This buffer can be kept for several hours at room temperature.

TBE (Tris/borate/EDTA) buffer, 5×

445 mM Tris base
445 mM boric acid
10 mM trisodium EDTA
Store at room temperature

All components may be obtained from Sigma. Do not adjust pH, which should be about 8.0 at room temperature. When this solution is stored for a long time, a precipitate forms. To avoid problems, discard batches that develop a precipitate.

Transfer buffer

Dissolve 22.13 g CAPS (3-cyclohexylamino-1-propanesulfonic acid) in 800 ml water. Adjust pH to 11.0 with 10 M NaOH (*APPENDIX 2A*). Add water to bring volume to 1 liter (0.1 M CAPS, pH 11.0), and store at 4°C. One hour prior to transfer, prepare the working solution. For one transfer, mix 100 ml of 0.1 M CAPS, pH 11.0; 700 ml water; and 200 ml methanol. Keep at 4°C to allow the exothermic reaction to cool down.

Tris·Cl, 1.0 M, pH 6.8

Dissolve 36.3 g of Tris base in 150 ml of water; adjust pH to 6.8 with 10 M HCl. Add water to bring volume to 300 ml, and store at room temperature for up to 1 month.

Tris·Cl, 1.5 M, pH 8.8

Dissolve 54.5 g of Tris base in 150 ml of water; adjust pH to 8.8 with 10 M HCl. Add water to bring volume to 300 ml, and store at room temperature for up to 1 month.

COMMENTARY

Background Information

A number of techniques have been developed to detect cytotoxicity and cell death in various cell types. The methods developed in the last two decades have been aimed at distinguishing between cell toxicity leading to apoptosis and that leading to necrosis. The choice of a particular method for analysis of cellular toxicity depends on the cell system; the toxin or toxicant; the expected mode of cell death; the type of information being sought; and, finally, technical limitations. There is no one single method that is satisfactory for obtaining all the information required. This is largely a result of technical and practical limitations. Therefore, to make the right interpretation of data and to draw the correct conclusions regarding the mode of cell death, a combination of some of the methods mentioned above should be used. It is recommended that a combination of at least three criteria of cell death be evaluated: cell morphology (see Basic Protocol 4), DNA fragmentation (see Assays for Chromatin Cleavage), annexin V binding (see Basic Protocol 5), and/or caspase activation (see Basic Protocols 10 and 11).

Although morphological changes are obviously secondary to biochemical alterations,

many of the published reports on cellular toxicity are based mainly on histological, cytological, and electron microscopy studies (Kerr et al., 1972; Bowen, 1980). The interpretation of histological data is based on the changes in membrane permeability. However, as mentioned in the introduction to this unit, analysis of plasma membrane integrity fails to identify cells in the early stages of apoptosis, although it can be used to identify necrotic cells in a population of interest. Alternative morphological methods draw on a mixture of optical and electron microscopy techniques. Combination of these methods allows one to distinguish between apoptotic changes—cell shrinkage, high cytoplasm density, membrane blebbing, compaction of chromatin, and formation of apoptotic bodies—and those indicative of necrosis—chromatin clumping, gross swelling of organelles, early membrane breakdown, and cell disintegration. In addition, confocal microscopy allows the combination of morphological analysis with subcellular localization of biochemical changes within damaged cells.

Other changes that accompany cell death can be used as indicators of the mode of cell death. It has been shown that phagocytosis is a response to cell death and is particularly efficient in apoptosis. Apoptotic cells can be recognized by macrophages through a number of cell surface markers. The presence of PS on the outer plasma membrane is one such marker, and it can be detected efficiently by phagocytic cells, as blockage of PS renders phagocytosis less efficient. Therefore, PS exposure can be considered a biochemical feature of apoptosis with physiological importance (Koopman et al., 1994). Annexin V has recently been utilized as a probe to monitor changes in phospholipid distribution in the plasma membrane of cells undergoing apoptosis (see Basic Protocol 5). In combination with propidium iodine, annexin V staining can reliably discriminate apoptosis from necrosis. Flow cytometry is a useful technique to examine not only changes in the plasma membrane, but also changes in cell size and granularity (see Basic Protocol 4; Darzynkiewicz et al., 1994; Robinson et al., 1999). Apoptosis is accompanied by a dramatic loss of water and consequent cell shrinkage, which can be distinguished from necrosis by a difference in light-scatter pattern. This is a rapid technique to identify apoptotic versus necrotic cells and is very widely used nowadays.

Several biochemical methods based on the detection of changes in chromatin structure have been developed. These vary from methods for detecting single-strand DNA nicks or breaks, to those for demonstrating high-molecular-weight DNA fragments, to those for showing the subsequent internucleosomal cleavage. DNA nicks can be detected using TUNEL (see Basic Protocol 6; Gavrieli et al., 1992). However, this method apparently recognizes not only nicks formed during apoptosis, but also those formed during necrosis. Thus this method should always be used in combination with other more discriminating methods.

Some other methods used for the analysis of DNA or chromatin damage appear to be better suited to discriminate between the two types of cell death. The different DNA gel electrophoresis techniques that are described here (see Basic Protocols 7 and 9; see Alternate Protocols 2, 3, and 4) can be utilized for a qualitative analysis (Wyllie, 1980; Sorenson, 1990). Although the quantitative analysis (see Basic Protocol 8) can provide limited information concerning the general cleavage of chromatin (Burton, 1956), the combination of different methods of gel electrophoresis provides more specific information concerning the type of chromatin cleavage (high-molecular-weight DNA fragments, DNA ladder, or smear). It has been shown that DNA laddering is not apparent in all apoptotic systems (Oberhammer et al., 1993a). In many types of cells, chromatin cleavage is restricted to the formation of high-molecular-weight DNA fragments (Walker et al., 1991; Oberhammer et al., 1993b). In such cases, again, the combination of two independent methods assists in drawing the correct conclusions in the study of cell death or toxicity. However, when DNA laddering occurs, it is highly indicative of apoptosis.

Activation of the caspase family of proteases has been detected in numerous cell systems and appears to function as a pathway through which apoptotic mechanisms operate (for review see Zhivotovsky et al., 1997). Upon apoptotic triggering, a hierarchy of caspases is believed to become activated in a process where more proximal caspases cleave and activate downstream caspases, giving rise to a proteolytic cascade that serves to amplify the death signal. However, not all of these caspases normally function in cell death. A recent classification divided caspases into two groups, one involved in cytokine processing (caspase 1–like proteases) and the other playing a role in cell death (Alnemri et al., 1996; Cryns and Yuan, 1998). This latter group can be further subdivided according to function as activators or executioners of cell death. Up to now there

has been no evidence concerning the involvement of caspase activities in necrosis. Therefore the detection of caspase activity in cells can be used as a discriminating criterion to distinguish apoptosis from necrosis. Caspase activity is assessed by proteolytic cleavage of flurogenic substrates (see Basic Protocol 10) or by immunodetection of protein bands corresponding to active caspases (see Basic Protocol 11).

In summary, a combination of morphological and biochemical methods is recommended to discriminate between the mode of cell death, especially if the manifestations of cell death or the stimuli used have not been previously characterized in the cell type of interest.

Critical Parameters and Troubleshooting

Morphological assays

A characteristic feature of apoptosis is that membrane integrity of the dying cell is maintained long after the process has begun. However, a reduction in membrane integrity usually occurs during the late stages of apoptosis when the cells undergo a process commonly called "secondary necrosis" or "postapoptotic necrosis." Therefore, a disadvantage of the trypan blue exclusion assay (see Basic Protocol 1) is underestimation of the level of apoptosis in a cell population.

If the cytopsin preparations are understained after a full cycle of fixation and differential staining (see Basic Protocol 2), then the procedure can be repeated a second time until the desired staining is achieved. If overstaining is the problem, preparations can be destained by immersing them in 100% methanol for up to 5 sec, followed by rinsing with water. Because membrane blebbing is a feature common to both apoptosis and necrosis, one should take care not to use this as the sole criterion for determination of the mode of cell death.

If assessing the nuclear changes in apoptotic cells is problematic, then use other conventional methods of inducing apoptosis in cells as a positive control, stain cells treated both ways with Hoechst dye (see Basic Protocol 3), and observe nuclear changes under the UV microscope. If no apoptotic changes are evident in cells, try to increase the time of incubation with apoptosis-inducing agents.

If ethanol is added too quickly to the cells for flow cytometry (see Basic Protocol 4), they may clump together, which in turn may cause blockage of the flow cytometer. Fixation of the cells in ethanol may result in dehydration and shrinkage of cells, but incubation in propidium iodide solution made in PBS rehydrates the cells. Also, if all cells dehydrate to the same extent, this should not interfere with obtaining accurate results.

Binding of annexin V to PS is Ca^{2+} dependent, and therefore the correct Ca^{2+} concentration is required for optimal binding (see Basic Protocol 5). Care should be taken when analyzing necrotic cells or cells in the late stages of apoptosis, when the cells are undergoing secondary necrosis. At this stage the plasma membrane is damaged and annexin V can enter the cell and bind to the PS in the inner leaflet of the membrane. Thus, it is possible to get false-positive results. It is therefore important to run a dye exclusion assay to confirm the results. A suitable assay would be assessment of propidium iodide (PI) exclusion, since PI cannot enter cells with intact membranes and its presence can be assessed simultaneously with annexin V binding by flow cytometry. Therefore, if a cell is positive for annexin V and negative for PI, one can conclude that apoptosis is the mode of cell death. However, if double-positive results are obtained, necrosis is implicated (see Figure 2.2.2).

Chromatin cleavage assays

The TUNEL technique (see Basic Protocol 6) is used to detect DNA strand breaks. There are rare situations when apoptosis proceeds without DNA degradation. Conversely, extensive DNA degradation may accompany necrosis. Thus, one should always use another independent assay, along with the TUNEL method, to confirm whether cells have undergone apoptosis. Costaining cells with propidium iodide or Hoechst is a very useful method to discriminate between apoptosis and necrosis in samples that have stained positively with the TUNEL technique. TUNEL-positive cells that express condensed, fragmented nuclei after staining with PI or Hoechst are apoptotic, whereas those with diffuse staining of the nuclei with PI or Hoechst are necrotic.

If a high background is present in TUNEL-treated samples, make sure that there is no DNase contamination in the test tubes or buffers. It is also possible that the number of DNA strand breaks is so large that one cannot quantify the degree of cell labeling. To eliminate this probelm, use fewer cells or decrease the incubation time.

For exogenous enzymes, such as the TdT enzyme used in TUNEL, to enter the cell, the plasma membrane has to be permeable. In

many cases, the fixation procedure is sufficient to permeabilize cells; however, sometimes an additional short incubation on ice or short (1- to 2-min) treatment with proteinase is required. To avoid loss of low-molecular-weight DNA, the permeabilized cells have to be fixed with formaldehyde before permeabilization. This fixation cross-links DNA fragments to other cellular constituents and prevents their leakage during the permeabilization step.

The procedures for assessment of DNA fragmentation in whole cells (see Basic Protocol 7) may cause the samples to become viscous and difficult to load into gel sample wells. If this is the case, dilute samples with 1× DNA loading buffer. If no detectable DNA laddering is observed in a population of cells that are known to be apoptotic, increase the number of cells used for the assay. If it is difficult to observe distinctive bands because of high background, wash gel extensively with water. If an unusual band appears in the middle of the gel in all lanes, incubate gel longer with RNase (step 17).

For analysis of fragmentation in total genomic DNA (see Alternate Protocol 2), the reagents are optimized for the stated number of cells. If larger numbers of cells are used, RNA and protein digestion will not be complete, which may interfere with electrophoresis. In addition, the procedures cause the samples to be viscous. Therefore, for minimum sheering of DNA, it is better to use pipet tips that have the ends (3 to 4 mm) cut off with a razor blade to make wide-bore tips.

If no laddering is observed in DNA phenol extracted from a population of apoptotic cells (see Alternate Protocol 4), the DNA may have been lost in the organic phase during extraction. The aqueous phase should be removed carefully during extraction to prevent DNA loss. Another possible reason for failure to detect laddering may be degradation of DNA by exogenous nucleases. All solutions must be free of nuclease contamination. If, instead of a DNA ladder, a smear appears on the gel, this indicates random and general cleavage of chromatin, indicative of necrosis (see Figure 2.2.3A, lane 3).

For quantitative assays of DNA fragmentation (see Basic Protocol 8), if absorbance of DNA in supernatant samples is below the sensitivity of detection, increase the number of cells. If all absorbance is present in the supernatant and absent from the pellet, then the pellet was mistakenly transferred together with supernatant to the labeled conical glass tubes (step 4).

There could be several reasons for large fragments not to appear on the pulsed-field electrophoresis gel (see Basic Protocol 9). If the material is still in the wells, the pulse generator power supply may not have been working properly. If some of the material is in the wells, but no sharp bands are visible and the material moved in the wrong direction, the current may not have been applied in the correct direction. If there is no material in the wells, the chromatin may have been digested by exogenous exonucleases during the preparation. If very little material is in the well, a bigger slab may have to be cut from the sample plugs. If too much material is in the lane, a smaller slab may have to be cut from the sample plugs. If thin stripes appear in any lanes in the gel, it means that either a bubble was in the well or the slab was not placed flat. Sometimes there is a leakage of buffer from the top reservoir, which may also influence the results.

Caspase assays

Release of a fluorogenic group from the peptide substrates is dependent on caspase activity and is proportional to the percentage of apoptotic cells in a cell population. In lysates of 10^6 cells, proportions of apoptotic cells of 5% to 10% can be detected by this method (see Basic Protocol 10). However, the lower limit of detection of caspase activity in cellular lysates of apoptotic cells varies with the kinetics of the apoptotic process, the percentage of apoptotic cells in a population, and the efficiency of cellular response to the apoptosis-inducing agent. If caspase activity is too low, first verify that the cells of interest are apoptotic using the morphological criteria described in this unit. Second, if cells are apoptotic, confirm that a sufficient number of cells and the right concentration of substrate are being used. If caspase activity is too high, use fewer cells.

For immunoassays of caspase activation (see Basic Protocol 11), too many bands on the film may indicate too high a concentration of primary and/or secondary antibodies. If the background of nonspecific binding of immunological probes is unacceptably high, increase the length of time washing with HSBS and LSB. If only a band corresponding to native procaspase is on the film, verify that the cells are apoptotic using other methods described in this unit. If there is no band on the film, increase duration of incubation with primary antibodies, up to 18 hr at room temperature. If a white spot on the film makes it difficult to detect the protein band of interest, a bubble may have been introduced during blotting and the whole procedure must be repeated.

If a band on the film is too strong, decrease exposure time of X-ray film to ECL-stained membrane. If gel runs too fast or too slow and poor resolution of protein occurs, decrease or increase voltage, respectively, or check buffer recipe. If no prestained markers appear on the nitrocellulose filter, check transfer buffer recipe, or reposition the location of gel towards the cathode and anode.

Anticipated Results

Morphological assays

In the trypan blue exclusion assay (see Basic Protocol 1), several thousand cells are sufficient to quantify the number of trypan blue–positive cells and to count the percentage of cells with an intact plasma membrane. Necrotic cells with rapidly disrupted membrane take up trypan blue as well.

Differential staining (see Basic Protocol 2) is one of the fastest and easiest methods for identifying dead cells. Cells are viewed under a light microscope (40× magnification), and ~300 cells are counted from separate fields of view and scored as normal, apoptotic, or necrotic based on the following morphological characteristics: membrane blebbing, chromatin condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume, and formation of apoptotic bodies for apoptotic cells; nuclear swelling, chromatin flocculation, cell membrane blebbing and disruption, and finally cell lysis resulting in the appearance of "ghost cells" for necrotic cells (see Figure 2.2.1).

Because chromatin condensation is one of the early events of apoptosis, apoptotic cells stained with Hoechst 33342 have increased blue fluorescence compared with live cells similarly stained (see Basic Protocol 3). The intensitivity of the blue fluorescence changes with the incubation time, so that an optimal incubation time should be found for each cell system for discrimination of apoptotic cells (usually 5 to 10 min). For quantification of apoptosis, a minimum of 150 cells, from 10 to 15 fields, should be evaluated for the changes described above.

During flow cytometry analysis (see Basic Protocol 4), the cells with reduced FSC and SSC represent the apoptotic population, that is, apoptotic cells and apoptotic bodies. On the DNA content histograms, the subdiploid, pre-G_1 nonstained DNA represents the DNA from dead cells. An accumulation of subdiploid DNA content is indicative of cell death. However, if cell shrinkage is also detected, this indicates that apoptosis is the predominant mode of cell death.

The annexin V binding assay (see Basic Protocol 5) is very quick because no fixation or permeabilization of cells is required. Another advantage of this assay is the detection of apoptosis during the early stages of the death process. If a flow cytometer is not available to quantify annexin V–FITC binding during apoptosis, this assay can also be performed by directly visualizing the binding using a fluorescence microscope.

Chromatin cleavage assays

In both TUNEL protocols (see Basic Protocol 6 and Alternate Protocol 1), very little material is required for quantitative measurement of TUNEL-positive cells. Proportions of apoptotic cells as low as 10% to 15% can be detected by this method. Although the enzymatic labeling methods are time consuming (due to multiple incubation and washing steps), they are very sensitive. The method can also be applied to cryostat sections. In this case, the proteolytic pretreatment (see Alternate Protocol 1, step 4) can be shorter or even be omitted.

The whole-cell DNA fragmentation method (see Basic Protocol 7) requires only $4–5 \times 10^5$ cells. It can be used for cells growing in suspension as well as attached cells. Usually, the resolution of DNA fragmentation using this protocol is distinct and high. This method does not require DNA purification and is relatively simple and fast. Although Basic Protocol 7 and Alternate Protocol 2 are equally sensitive, the latter is less time consuming. In addition, the dry loading prevents the loss of material. Alternate Protocol 3 is particularly useful for detecting chromatin cleavage in different lymphoid cells.

Phenol extraction (see Alternate Protocol 4) is the most commonly used technique for investigating internucleosomal chromatin cleavage. Although it takes much more time than other techniques (almost $2\frac{1}{2}$ working days) and needs many more cells for preparation ($2–5 \times 10^6$ cells), it yields very clean, protein-free DNA fragments.

The quantitative assay of DNA fragmentation described (see Basic Protocol 8) is only one quantitative method for measurement of DNA fragmentation. This method is very simple, and very reproducible results can usually be obtained.

Pulsed-field gel electrophoresis can be used to detect the presence of high-molecular-

weight DNA fragments in apoptotic cells (see Basic Protocol 9). The method is very sensitive and requires 5×10^5 cells. Depending on which system is available, one can use either horizontal or vertical gel systems. If necessary, plugs can be kept for several months and run on another gel.

Caspase assays

Basic Protocol 10 is a highly sensitive, rapid, convenient, and quantitative method for in vitro determination of caspase activity. It is based on the ability of caspases to proteolytically cleave a substrate to form a free fluorescent group that can be measured fluorometrically. A number of caspase substrates conjugated to alternative fluorogenic groups are now commercially available. These include AFC (7-amino-4-trifluoromethyl coumarin), MNA (4-methoxy-2-naphthylamine), and pNA (*p*-nitroaniline). Fluorometric detection of AFC cleaved from its peptide substrate is at excitation 400 nm and emission 505 nm, and that of MNA is at excitation 340 nm and emission 425 nm. The initial rate of increase in the pNA concentration upon release from peptide can be monitored photometrically at 405 nm. Using different substrates, one can discriminate between activities of different caspases. With this method, kinetic study of enzyme activation can also be performed.

The immunological method for measuring caspase activation (see Basic Protocol 11) can be used to describe and visualize the process in apoptotic cells. The method is very sensitive, and 1×10^6 cells provide enough sample for several gels. As was mentioned above, procaspases are proteolytically cleaved to become active enzymes. With the antibodies listed in the protocol, large or small subunits (cleavable fragments) of active caspases can be detected. Appearance of these fragments can serve as an early marker of apoptosis. Crude cellular extracts can also be used to detect these fragments. This nonradioactive method does not require prelabeling of proteins.

Time Considerations

Morphology assays

The time required for preparing solutions for trypan blue exclusion is 20 to 30 min; the solutions can then be kept up to 1 to 2 months at 4°C. Trypan blue staining takes 5 min, and calculation takes 10 min.

It takes 30 min to prepare the solutions for differential staining (which can be stored 1 to 2 months at room temperature); this time is not required if the commercial kit is used. 1 hr is required to prepare and analyze samples, and 30 min to evaluate results.

It takes about 30 to 40 min to prepare solutions for Hoechst staining and 1 hr to run the test. No more than 30 min are required to evaluate results.

It takes 20 to 25 min to prepare solutions for flow cytometry, which can be stored up to 1 month. Sample preparation and analysis take 1 to 1.5 hr, and evaluation of results takes 30 min.

The whole annexin V binding test (staining and detection) takes 30 to 40 min, and evaluation of results takes another 30 to 40 min.

Chromatin cleavage assays

Approximately 3 to 4 hr are required to run TUNEL assays. The evaluation of results requires an additional 1 to 2 hr, depending on the investigator's experience.

About 1 to 2 hr are required to prepare the buffers for assessment of fragmentation in whole cells, which then can be stored for at least 1 month. Usually, gel and sample preparation, which can be done simultaneously, take 2 hr, and gel electrophoresis takes 15 to 16 hr (overnight is better). Incubation with RNase, staining, and destaining take another 6 to 7 hr. Thus, the whole experiment takes almost 1.5 days.

Analysis of fragmentation in total genomic DNA takes 1 working day.

Preparing solutions for quantitative analysis of DNA fragmentation takes 1.5 to 2 hr; however, the solutions can be stored for up to several weeks. The procedure takes 1.5 working days and 1 hr to evaluate results.

It takes about 1 week to perform the whole pulsed-field gel electrophoresis procedure. Vertical gels require a relatively shorter time (1 day less) compared with horizontal gels, with no difference in resolution.

Caspase assays

Approximately 2 hr are required to perform the whole substrate-cleavage procedure and an additional 2 hr to evaluate results.

The immunological analysis is time consuming. Only two tests (on two membranes) may be performed simultaneously. Usually, it takes several hours to prepare solutions, which can, however, be stored for months. Gel electrophoresis, blotting, and staining with antibodies take 1.5 to 2 working days, and evaluation of results takes 1 to 2 hr.

Detection of Covalent Binding

Earlier studies of protein covalent binding were based primarily on detection of covalently bound metabolites from radioactive xenobiotics that were administered in vivo or added to in vitro preparations. Generally, such studies involved repetitive extraction of protein suspensions to remove unbound drug or metabolites. The radioactivity that remained with the protein fraction after the extraction procedure was considered to be covalently bound. Such approaches are useful for quantifying bound metabolites in tissue homogenates or subcellular fractions and for localizing bound metabolites in tissue sections by autoradiography. However, the radiometric approach is generally not practical for studies aimed at the identification of xenobiotics bound to individual protein targets. Mechanistic research in toxicology today is not merely interested in quantification and localization of bound drug. Rather, there is increasing interest in identifying the specifically targeted proteins as a key step to clarifying the mechanistic contributions of the binding to the ensuing toxicity. To this end, immunochemical methods have been developed to detect and identify xenobiotics covalently bound to cellular proteins. Binding to individually targeted proteins as detected immunochemically has been shown to be better associated with toxicity than total covalent binding as assessed radiometrically (Beierschmitt et al., 1989).

This unit presents two protocols for the immunochemical detection of xenobiotic covalent binding to proteins. The first (see Basic Protocol 1) outlines the use of specific antibodies for detection of individual xenobiotic-protein adducts on immunoblots, and the second (see Basic Protocol 2) outlines the use of the antibodies in immunohistochemical analysis of fixed tissue sections. Support protocols are included to provide direction for the synthesis of an artificial antigen (see Support Protocol 1) and subsequent immunization (see Support Protocol 2) of a suitable host species (e.g., rabbit or goat), and for affinity purification and characterization of the antibodies in noncompetitive and competitive ELISA (see Support Protocols 3 to 7).

The details of antibody development will vary with the nature of the bound drug or metabolite, i.e., the hapten. As an example of this process, a method to elicit production of antibodies against the analgesic/antipyretic acetaminophen (*N*-acetyl-*p*-aminophenol, APAP) is described (Support Protocols 1 and 2).

The various methods described in this unit emphasize general considerations and salient features. For a more comprehensive review of the theory on individual topics, the reader is referred to additional sources (Taleporos and Ornstein, 1976; Towbin and Gordon, 1984; Tijssen, 1985; Harlow and Lane, 1988; Login and Dvorak, 1988; Ostrove, 1990; Osborn and Isenberg, 1994).

DETECTION OF COVALENT BINDING BY IMMUNOBLOTTING

BASIC PROTOCOL 1

The basic principle of immunoblotting is the use of an electrical field to transfer a complex mixture of proteins from a gel matrix to a membrane support (nitrocellulose, nylon, or PVDF) where proteins are thought to be retained by noncovalent hydrophobic interactions. Immunoblotting thus maximizes the resolving power of polyacrylamide gel electrophoresis (SDS, native, or isoelectric focusing; see *APPENDIX 3A*) to provide a discrete pattern of proteins bound to a membrane for further characterization and identification by immunodetection or protein sequencing. Two types of equipment are most widely used, and there are advantages and disadvantages to each. Wet transfer consumes ~4 liters of buffer and requires complete immersion of the gel-membrane sandwich. For semidry transfer, the sandwich is placed between absorbent paper that has been soaked in transfer

Contributed by Mary K. Bruno and Steven D. Cohen
Current Protocols in Toxicology (1999) 2.3.1-2.3.35

buffer. Wet transfer generally offers greater flexibility with respect to temperature control, voltage settings, and blotting times without buffer depletion; however, reagent consumption, cost, and experimental time are greater. The procedure described in this protocol has been employed for routine immunochemical detection of APAP-protein adducts in tissue homogenates or subcellular fractions (Bartolone et al., 1987, 1988)

The following protocol is for wet transfer of proteins from full-size (12 × 14.5–mm) 10% SDS-PAGE gels (0.75-mm thickness)—see *APPENDIX 3A* for electrophoresis protocols. It incorporates the specific instructions for use of equipment from Bio-Rad, but should be generally applicable. Modifications may be required if different equipment or a semidry blotting method are used. SDS-PAGE and steps 1 to 11 of the immunoblot protocol must be done on the same day. Incubation with primary antibody and subsequent detection of bound antibody may be done at a later time. Inclusion of prestained molecular weight protein standards during electrophoresis is recommended for orientation of the membrane during and after transfer. Gloves should be used throughout these procedures to protect the operator and to prevent contamination of gels with skin proteins.

CAUTION: If radioactivity will be used for detection, the user is required to have received institutional training in the handling of radioisotopes, and the experiment must be performed in an area designated for radioactivity use under the supervision of a licensed investigator. All steps must be carried out in accordance with the Nuclear Regulatory Commission (NRC) and institutional guidelines (also see *APPENDIX 1A*).

Materials

SDS-PAGE gel with resolved proteins
Transfer buffer (see recipe)
Methanol
Coomassie brilliant blue solution (see recipe)
Destaining solution (see recipe)
Blocking buffer (see recipe)
Primary antibody against protein-xenobiotic adduct (Support Protocol 2), affinity-purified if necessary (see Support Protocol 6)
Tris-buffered saline (TBS; see recipe) containing 0.05% (w/v) Tween 20 (store up to 1 week at room temperature)
Secondary antibody: ^{125}I-, alkaline phosphatase–, or horseradish peroxidase–conjugated IgG raised against the host animal used for production of the primary antibody
10 mg/ml nitroblue tetrazolium (prepare fresh)
25 mg/ml 5-bromo-4-chloro-3-indolyl-phosphate (BCIP) in *N*,*N*-dimethylformamide (prepare fresh)
Developing buffer (see recipe)
4-chloro-1-naphthol solution (see recipe)
30% hydrogen peroxide (store up to 1 month at 4°C)
Chemiluminescence-based detection system: e.g., ECL Kit (Amersham) or SuperSignal Kit (Pierce Chemical)

Trans-Blot apparatus (Bio-Rad) including:
  Fiber pads
  Transfer tank
  Cassette gel holder
Transfer membranes: nitrocellulose (0.2 to 0.45 μm pore size) or polyvinylidene difluoride (PVDF; 0.45 μm pore size)
23 × 33–cm and 21.5 × 21.5–cm glass baking dishes

continued

Whatman no. 1 filter paper
Platform shaker or rocker
Kodak X-Omat AR or equivalent 8 × 10–in. (20.32 × 25.4–cm) X-ray film
Lead autoradiography cassette with intensifying screen

Additional reagents and equipment for SDS-PAGE (*APPENDIX 3A*)

Transfer proteins

1. Perform SDS-PAGE (*APPENDIX 3A*), including the appropriate prestained molecular weight standards on the gel. Approximately 30 min prior to the completion of SDS-PAGE, presoak fiber pads (included with Trans-Blot apparatus) in transfer buffer in a 23 × 33–cm glass dish (e.g., a baking dish).

   Prestained molecular weight standards should always be included during gel electrophoresis to serve as a reference on the membrane. These are readily available from several commercial sources.

   The pH of the transfer buffer ranges from 8.1 to 8.3, depending on the quality of the reagents used. The inclusion of SDS in the transfer buffer facilitates complete transfer of proteins of <200 kDa molecular weight (Towbin and Gordon, 1984).

2. Cut membrane to be slightly larger than the gel—i.e., 13 × 15 cm—and cut off a small section from one corner to provide a consistent orientation marker.

3a. *For nitrocellulose membranes:* Prewet membrane in water by capillary action, then equilibrate in transfer buffer along with the fiber pads.

3b. *For PVDF membranes:* Prewet membrane in methanol for 2 to 3 sec, then rinse with distilled water for 1 to 2 min. Equilibrate in transfer buffer along with the fiber pads.

   Membranes of smaller pore size are more effective in retaining proteins of low molecular weight.

4. Cut two 14 × 16–cm pieces of Whatman no. 1 filter paper and soak in transfer buffer.

   Paper shreds easily when wet; do not soak along with the membranes.

5. Set up a separate glass baking dish containing 50 ml transfer buffer for equilibrating the gel. Following SDS-PAGE, remove gel and discard stacking gel, then cut off a small corner of the gel for orientation. Invert the gel plate, with the gel attached, into the dish containing 50 ml of transfer buffer and let the gel detach from the glass plate. Equilibrate the gel 10 to 15 min.

Assemble the transfer cassette

6. Assemble a sandwich in the cassette holder in the following sequence: a wetted fiber pad, wetted filter paper, the gel, the wetted membrane, and a second piece of wetted filter paper, aligning the cut corners of the gel and membrane during assembly.

   The polarity of transfer is from cathode (−) to anode (+). In the presence of SDS the proteins will be negatively charged and will migrate toward the positive pole (anode) and adsorb to the membrane.

7. Verify the color coding for anode (usually red) and cathode (usually black) on the equipment, and carefully orient the sandwich so that proteins will move from the gel to the membrane with the current flow.

   Transfer direction will be reversed, i.e., from anode to cathode, if the transfer buffer is of acidic rather than basic pH.

8. Roll a glass pipet over the filter paper face of the sandwich to remove any air bubbles and establish good contact between the gel and membrane.

   Good contact is important for efficient transfer.

9. Place the second fiber pad upon the filter paper to complete the sandwich, then secure the cassette assembly.

   The final sequence in the "sandwich" should be: black (cathode) face of cassette, fiber pad, filter paper, gel, membrane, filter paper, fiber pad, and red (anode) face of cassette.

10. In a 4°C cold room or refrigerated chamber, fill the transfer tank of the Trans-Blot apparatus with transfer buffer chilled to 4°C. Place the cassette assembly into the tank. Orient the cathode (black) side of the cassette toward the cathode (black). Add a magnetic stir bar.

    The membrane in the "sandwich" should be between the gel and the anode when the cassette is placed in the tank The buffer should reach to the outside bottom of the electrode holder.

11. Set up the power supply and magnetic stirrer. Before connecting the tank and power supply, remove any salts that may have built up on the electrode leads. Connect the top of the tank to the power supply, cathode to cathode, anode to anode. Electroblot 90 min at 65 V for gels containing 30 to 40 µg protein/lane.

    The temperature will rise during transfer; stirring will help to ensure uniform temperature and conductivity.

    The voltage and time of transfer can vary and may need to be determined empirically for the system being studied. Gels can be electroblotted at 30 V overnight, followed by 60 V for 1 hr. SDS should not be included in the transfer buffer if overnight blotting is used, since it will precipitate out of solution.

    The rate of protein transfer is dependent on the apparent molecular weight of the proteins. Longer transfer times are necessary for proteins of higher molecular weight (>150 kDa) or gels of higher percentage acrylamide and thickness. Decreased blotting times may be necessary for gels of lower protein load, and to prevent the loss of low-molecular-weight proteins by passage completely through the membrane. One can determine if this has occurred by adding a second membrane to the sandwich behind the first. Transfer time should be adjusted accordingly if proteins are detected on the second membrane.

Probe the membrane with antibodies

12. Disassemble the cassette. Stain blotted gel 20 min in Coomassie brilliant blue solution, then destain 1 to 2 hr in destaining solution (until most of the stain has been removed).

    If transfer was complete, only bands corresponding to higher molecular weight (>150 kDa) proteins should remain.

13. Block the membranes by incubating 1 hr at room temperature in the appropriate blocking buffer (see Reagents and Solutions for alternatives), then pour off the blocking buffer prior to adding the primary antibody.

    Nitrocellulose membranes may be allowed to dry prior to blocking and probing with antibody. PVDF membranes should be placed in blocking buffer for 15 to 60 min before drying. Alternatively, if PVDF membranes are allowed to dry without soaking in buffer, they must be prewetted again with methanol prior to blocking and probing with antibody. Drying the membranes is preferable to storing them in transfer buffer or blocking buffer overnight. Such storage in aqueous solutions will result in protein desorption, since binding to the membrane is not covalent.

Expose membrane to antibodies

14. Dilute the primary antibody (1:50 to 1:100 for affinity-purified anti-APAP antibody) in 50 ml of blocking buffer (or other volume sufficient to cover the membrane and prevent it from drying out, depending on the size of the membrane and container being used) and apply to the membrane. Incubate 3 hr at room temperature with shaking on a platform shaker.

Antibody dilutions and incubation times will vary depending on the antibody titer and the amount of antigen present. Antibodies of low avidity dissociate more rapidly from the antigen-antibody complex; therefore, lower dilutions and shorter incubation times are recommended. Antibodies of higher avidity can tolerate higher dilutions and longer incubation times (e.g., 18 to 24 hr at 4°C; Towbin and Gordon, 1984).

15. Pour off the antibody solution and wash the membrane three times, each time by immersing for 10 min in 50 to 100 ml TBS containing 0.05% Tween 20, with shaking on a platform shaker.

    The antibody solution may be reused if stored at 4°C with a preservative (e.g., 0.02% sodium azide or 0.01% merthiolate). Sodium azide inhibits horseradish peroxidase (HRP) and thus cannot be used if the secondary antibody to be used for immunodetection is conjugated with this enzyme.

16. Dilute the secondary antibody in blocking buffer and incubate the membrane for 90 min using the technique described in step 14.

    Dilution of the secondary antibody will vary depending on the type of conjugate (radiolabel or enzyme for colorimetric or chemiluminescent detection) and the commercial supplier. With anti-APAP, alkaline phosphatase and ^{125}I-conjugated secondary antibodies have been used at 1:2000 and 0.1 μCi/ml blocking solution, respectively. For chemiluminescent detection systems, e.g., ECL, follow protocols supplied by the manufacturer.

    If using a chemiluminescence system for detection, the length of the incubation with the secondary antibody may be shortened (e.g., 20 min).

17. Pour off the antibody solution and wash three times as described in step 15.

Detect bound antibody

18a. *For ^{125}I-labeled secondary antibody:* Allow membrane to dry. Enclose membrane in plastic wrap and expose to Kodak X-Omat AR film in a lead autoradiography cassette with an intensifying screen for 24 to 40 hr at −70°C. Bring the cassette to room temperature before removing and developing the film.

All manipulations involving film should be done in a darkroom. The detection limit of this method is 10 ng (Promega, 1993).

Radioactive and chemiluminescence-based detection systems have the advantage of ease of quantification. They also permit the membrane to be stripped of adsorbed antibodies and then probed again.

18b. *For alkaline phosphatase–conjugated secondary antibody:* Just before use, combine 0.5 ml of 10 mg/ml nitroblue tetrazolium and 0.5 ml of 25 mg/ml BCIP with 50 ml of developing buffer. Incubate the blotted membrane with this substrate-chromogen solution until color development of specific bands is observed. Stop the reaction by rinsing with water.

The 50 ml prepared here is sufficient volume for one full-size gel. The reaction product is an intense purple-black precipitate at the site of enzyme-conjugate binding. The background may be lavender, depending on the development time, but will revert to white upon complete drying overnight. The detection limit of this method is ~50 to 100 pg (Hoefer, 1994; Promega, 1993).

18c. *For horseradish peroxidase–conjugated secondary antibody:* Just before use, add 20 μl of 30% hydrogen peroxide to 48 ml 4-chloro-1-naphthol solution. Incubate the blotted membrane with this substrate-chromogen solution until color development of specific bands is observed. Stop the reaction by rinsing with water.

The reaction product is a brown-black precipitate at the site of enzyme-conjugate binding. The color intensity tends to fade with time and thus does not provide a good permanent record. The detection limit for this method is 1 ng (according to Promega technical applications guide).

18d. *For enzyme-linked secondary antibodies, using chemiluminescence:* Follow instructions supplied by the manufacturer of the chemiluminescence detection kit being used. For example, after washing the membrane (step 17), incubate 1 min with the mixed ECL detection reagents when using the Amersham ECL system. Drain off excess solution, then cover the membrane with plastic wrap, remove air bubbles, and place in autoradiography film cassette with the protein side facing toward the film. Expose film for optimal time required for visualization of bands, then develop film.

It is best to perform these steps in the darkroom, turning the lights off when exposing and developing film. Work as quickly as possible following the addition of the detection solution. For a given batch of antibody used under standardized conditions, the time of film exposure that gives the greatest signal-to-noise ratio will remain fairly constant. This must be determined empirically when assay conditions and reagents are changed. For anti-APAP, film-exposure times typically range between 2 and 10 min. Because of the stability and sensitivity of the reagents, the same membrane may be exposed sequentially to new film for varied lengths of time. This allows for optimization of signal detection of adducts on the film. The intensity of the signal is maximal between 1 and 5 min, with a half-life of decay of 1 hr. The limit of detection is as low as 1 pg of antigen.

Radioactive and chemiluminescence-based detection systems have the advantage of ease of quantification. They also permit the membrane to be stripped of adsorbed antibodies and then probed again.

BASIC PROTOCOL 2

DETECTION OF COVALENT BINDING BY IMMUNOHISTOCHEMISTRY

Immunohistochemistry has become increasingly important diagnostic and experimental techniques to determine the intracellular localization of a particular antigen. Methods of tissue preparation are versatile and often empirically determined based upon the tissue type and antigen-antibody interaction. Similarly, morphological examination of tissue sections can utilize light, fluorescence, or electron microscopy. The method described below localizes APAP-protein adducts in tissue sections prepared by microwave fixation and processed for immunohistochemistry (Emeigh Hart et al., 1995)

Kits other than the AS/AP kit used here, which incorporate enzyme-based detection (alkaline phosphatase or peroxidase) in combination with streptavidin/avidin and biotin interactions offer greater sensitivity and are highly recommended over the traditional enzyme-based detection systems. Such kits are available from BioGenex and Vector Laboratories.

Materials

Tissue sections (1 mm thickness) containing protein-xenobiotic adducts
0.9% NaCl (*APPENDIX 2A*)
50%, 95%, and 100% ethanol
Xylene
Tris-buffered saline (TBS; see recipe)
0.5% pepsin in 0.1 N HCl (prepare fresh), prewarmed to 37°C
Nonimmune serum from species in which secondary antibody was raised
Primary antibody: anti-APAP (see Support Protocol 2), affinity purified (see Support Protocol 6)
TBS (see recipe) containing 0.5% bovine serum albumin (BSA)
AS/AP Universal Rabbit Detection System (Bio-Can Scientific; or equivalent detection system employing alkaline phosphatase–conjugated anti-rabbit secondary antibody)

continued

Double-strength (2×) Gill's hematoxylin (see recipe or purchase from Polyscientific)
Ammonium hydroxide
Aqueous mounting medium (CrystalMount from BioMedia or equivalent)

Coverslips
Tissue-processing cassettes
Microwave oven with temperature probe
Programmable automated tissue processor (e.g., Model LX-120, Innovative Medical Systems)
Equipment for paraffin embedding and sectioning (e.g., dedicated histology laboratory)
Vacuum desiccator
Poly-L-lysine-coated glass microscope slides (see recipe)
60°C and 80°C drying ovens
Coplin jars
Glass staining pan with metal slide rack

Fix tissue

1. Trim tissue samples to 1 mm thickness and place into plastic tissue-processing cassettes.

   Tissue samples >1 to 2 mm in any dimension may be damaged by conductive heat during microwave fixation. Also, in such sections, chemical fixatives will penetrate too slowly for proper fixation.

2. Place up to five cassettes into a beaker containing 150 ml of 0.9% NaCl and insert into a microwave oven equipped with a temperature probe.

   Samples must be immersed in the buffer or buffered fixative to prevent dessication and loss of antigenicity during microwave irradiation. If samples are instead contained in individual vials, a beaker containing 300 to 400 ml water must also be placed in the microwave oven. Irradiating a small sample volume without the additional water load will lead to overheating of the samples. The water load will improve the reproducibility of microwave fixation conditions (Login and Dvorak, 1988).

3. Place the temperature probe into the beaker and microwave 5 min at 60°C.

   The time and temperature for microwave fixation may be varied as appropriate and should be optimized for tissue type, antibody, chamber design, and power output of the microwave oven.

   Samples immersed in a fixative rather than a saline solution will require much shorter microwave irradiation (e.g., seconds).

4. Transfer cassettes quickly to a beaker containing 10 vol of 50% (v/v) ethanol per vol tissue.

   Rapid replacement of the hot fixing buffer with the ethanol solution is necessary to prevent overfixation. Samples may be stored in 50% ethanol until further processing is initiated. Duration of storage without loss of antigenicity and architecture may vary and should be determined experimentally.

Process samples for histology

5. Dehydrate tissues using a programmable automated tissue processor, omitting the alcohol-formalin step. Embed tissues in paraffin and store in a vacuum dessicator until ready to section.

   These operations will normally be performed in a dedicated histology laboratory.

6. Cut 5-μm sections. Mount sections on poly-L-lysine coated glass microscope slides by warming in a drying oven set at 60°C for 30 min.

   Proper adhesion of sections to slides requires: (1) clean slides, (2) contact of the entire section with the glass surface, and (3) thorough drying. Coating with positively charged poly-L-lysine will prevent detachment of the negatively charged tissue sections. This is necessary if the sections will be subsequently treated with proteases. Tissue sections with folds and wrinkles will not have good contact with the slide surface and will adhere poorly.

7. Rehydrate and deparaffinize tissue sections by immersing sequentially, 5 min each, in Coplin jars containing the following solutions:

   Xylene
   Xylene1
   100% ethanol
   100% ethanol
   95% ethanol
   95% ethanol
   70% ethanol.

8. Transfer the slides to a staining rack and rinse with running tap water in a staining pan for 5 min.

   The position of the tissue section can be marked with a diamond pen or water-repellent marker. If peroxidase-antiperoxidase will be used for immunodetection, treat slides with 3% hydrogen peroxide for 15 min after the water rinse to quench endogenous peroxidase activity. Slides are then washed with tap water after the peroxide quench. Metal staining racks should not be used to support slides during hydrogen peroxide staining.

9. Immerse slides in TBS for 5 min.

Treat slides with pepsin

10. Incubate slides 15 min at 37°C in prewarmed 0.1 N HCl containing 0.5% pepsin.

    This treatment promotes the accessibility of epitopes for antibody recognition. Avoid metal racks and containers during the digestion step.

11. Rinse slides in running tap water for 5 min, then immerse slides in TBS for 5 min. Blot slides to remove most liquid, leaving the tissue section moist.

    This will prevent further protease digestion.

Block tissue

12. Place slides in incubation tray with the tissue section facing upward. Block the tissue by covering the section with nonimmune serum (diluted 1:50), collected from the same species used to produce the secondary antibody, then incubating 30 min at room temperature.

    Use sufficient volume to cover the tissue section. Pretreatment with nonimmune serum will reduce the nonspecific binding of the subsequently applied antibodies.

Incubate in primary antibody

13. Remove blocking serum from the slide by shaking and replace with affinity-purified anti-APAP antibody diluted 1:10 in TBS containing 0.5% BSA. Use sufficient volume to cover the tissue section. Allow antibody to bind for 18 to 21 hr at 4°C.

    A dilution series is recommended to establish the appropriate concentration of primary antibody. Most polyclonal antibodies can be diluted 1:20 to 1:100; affinity-purified antibodies may be used in the range of 5 to 20 μg/ml. Incubation of slides in a humidified atmosphere will prevent dehydration.

    Also include the appropriate controls (see Critical Parameters and Troubleshooting).

14. Wash slides three times with TBS in Coplin jars, each time for 5 min with shaking.

Separate jars must be used for slides incubated with different immunoreactants, to prevent cross-contamination. Tween 20 (0.05% w/v) may be included in the wash steps.

Incubate with enzyme-conjugated secondary antibody

15. Blot slides dry and lay flat in a staining tray. Place 2 to 4 drops of alkaline phosphatase–conjugated secondary antibody, provided with the AS/AP Universal Rabbit Detection System from Bio-Can Scientific, on the tissue section and incubate 30 min at room temperature. Wash slides as in step 14

If a kit is not used, the concentration of secondary antibody may be determined experimentally. Typical dilutions range between 1:50 and 1:150. Peroxidase-conjugated secondary antibody may be used instead of alkaline phosphatase.

Visualize staining

16. Blot slides and return to staining tray. Incubate with the chromogenic substrate supplied with the AS/AP kit for 20 min or until color development is visible.

17. Rinse slides thoroughly in running water for 5 min. Counterstain by immersing for 3 min in double-strength (2×) Gill's hematoxylin, then rinse thoroughly in running water for 5 min and blot dry.

It is advisable to purchase prepared staining solutions (e.g., from Polyscientific) as commercial preparations give more uniform results. Conditions for storage (usually room temperature) and expiration dates are provided on the label. Also note that some histology laboratories favor Mayer's hematoxylin over Gill's formulation, due to the blue staining of the nucleus and the contrast provided when used with other staining protocols.

18. Dip slides 10 times in dilute ammonium hydroxide (6 to 8 drops ammonium hydroxide in 300 ml water). Rinse thoroughly in running tap water.

Slides will turn blue.

19. Place 3 to 4 drops of aqueous mounting medium (e.g., CrystalMount) over each tissue section. Tip slides as required to coat each section uniformly with a thin film.

Avoid the use of organic solvents which may solubilize some chromogens.

20. Place slides on a metal tray and incubate in oven 15 min at 80°C. Add coverslips after cooling.

Slides may be examined under the microscope at this step. Compare slides from experimental groups to those from positive and negative controls that were run through the process simultaneously (see Commentary). For photography, permanently mount cover slips with Permount (Fisher).

PREPARATION OF APAP ANTIGEN

SUPPORT PROTOCOL 1

This method involves the use of a linker molecule (*p*-aminobenzoic acid, PABA) between the hapten (acetaminophen, also called *N*-acetyl-*p*-aminophenol or APAP is used as the example here) and the carrier protein, keyhole limpet hemocyanin (KLH). Since the 3 and 5 positions of the aromatic ring of APAP have been identified as sites for protein-adduct formation, the coupling chemistries were selected to retain the natural binding conformation. Construction of the antigen requires a three-step procedure (Fig. 2.3.1) which involves (1) diazotization of the amino group of PABA, (2) conjugation of the diazonium cation of PABA to APAP at the nucleophilic 3 or 5 positions of the APAP ring, and (3) coupling of the hapten-conjugate (APAP-PABA) to the carrier protein KLH by the mixed anhydride method, where an amide bond is introduced between the carboxyl

group of PABA and the free amino groups on KLH (Bartolone et al., 1988). Radiometric methods are used to monitor formation of the hapten conjugate and to determine epitope density.

CAUTION: If radioactivity will be used for detection, the user is required to have received institutional training in the handling of radioisotopes, and the experiment must be performed in an area designated for radioactivity use under the supervision of a licensed investigator. All steps must be carried out in accordance with the Nuclear Regulatory Commission (NRC) and institutional guidelines (also see *APPENDIX 1A*).

NOTE: All aqueous solutions should be made in water of high purity (i.e., double-distilled, or deionized using Milli-Q or equivalent filtration system).

Materials

p-aminobenzoic acid (PABA)
0.1 N HCl, 4°C
1% (v/v) sodium nitrite

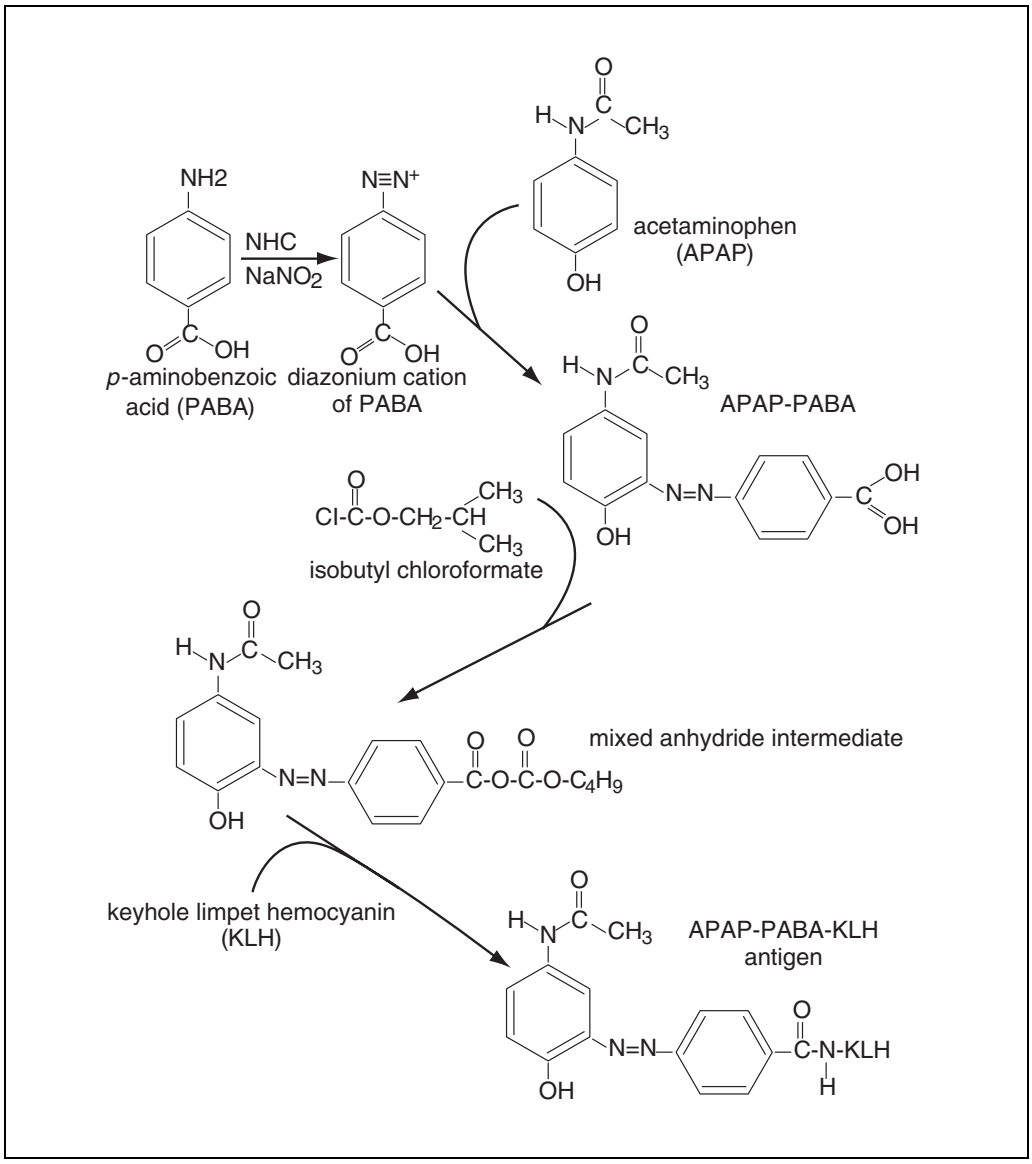

Figure 2.3.1 Synthetic scheme for formation of acetaminophen (APAP) antigen.

Source of starch (e.g., 1% starch solution, starch paper, or slice of potato) saturated with freshly prepared 50 mM potassium iodide
Acetaminophen (APAP; Sigma; minimum purity, 99%)
0.5 M carbonate/bicarbonate buffer, pH 9.0 (see recipe)
^{3}[H]acetaminophen ([^{3}H]APAP; 15.5 Ci/mmol, uniformly labeled; must be custom-synthesized)
1.0 N and 0.1 N NaOH
N,*N*-dimethylformamide
Keyhole limpet hemocyanin (KLH)
Isobutyl chloroformate (Aldrich)
Phosphate-buffered saline (PBS), pH 7.0 to 7.2 (see recipe)
6 N perchloric acid
50 mg/ml bovine serum albumin (BSA; store up to 24 hr at 4°C)
80% methanol containing 5 mM unlabeled APAP, ice-cold
Nitrogen source
Tissue solubilizer (e.g., Solvable from NEN Life Science or Amplify from Amersham; optional)

Acetone/dry ice or ethanol/dry ice bath
Lyophilizer
6000 to 8000 MWCO dialysis tubing (pretreated; see recipe) and dialysis clamps

Diazotize p-aminobenzoic acid (PABA)

1. Dissolve 4 mmol (548 mg) of PABA in 100 ml 0.1 N HCl at 4°C.

   This is best done with stirring in a large, e.g., 250-ml, beaker.

2. Add 1% (v/v) sodium nitrite solution dropwise with stirring until a yellow-green color appears. Test for completeness of the titration by placing the solution dropwise onto a source of starch, e.g., a slice of potato saturated with freshly made 50 mM KI solution, and observing for the appearance of a blue-black color which should form on the potato in ~1 min. Allow the solution to stir for an additional 15 min and retest. If starch test remains positive, proceed to step 3. If the starch test is negative, add more sodium nitrite solution, avoiding large excesses, and retest. Repeat as required.

   PABA is converted to the diazonium ion in the presence of nitrous acid. When diazotization approaches completion, the excess free nitrous acid can be detected by a positive starch test whereupon iodide is oxidized to iodine yielding a blue-black color in the presence of starch. Alternative sources of starch include 1% starch plus 50 mM potassium iodide or starch paper saturated with 50 mM potassium iodide. Free nitrous acid should remain detectable 15 min after the last addition of sodium nitrite, as determined by a positive starch reaction. Since the reaction between PABA and sodium nitrite is stoichiometric, this offers a test for completion of diazotization (Nisonoff, 1967). The reaction should consume ~27 ml of sodium nitrite solution.

Derivatize APAP to diazotized PABA

3. Dissolve 4 mmol (600 mg) of APAP in 20 ml 0.5 M carbonate/bicarbonate buffer, pH 9.0, with heating at 50° to 55°C. Add 5 µCi ^{3}[H]APAP to determine epitope density (see step 15).

   Prepare the solution just before use to avoid problems with overheating or crystallization upon cooling. APAP has limited solubility at this concentration (200 mM), and thus it is necessary to heat to 50° to 55°C. At pH 9.0, the solution of APAP will be pink.

4. Using a Pasteur pipet, slowly add the APAP solution to the diazotized PABA from step 2.

   As the solution approaches neutral pH, the yellow-green solution of PABA will turn red.

5. Quickly adjust the pH to 9.5 with 1.0 N NaOH.

   The color will deepen to a dark red. It is critical for successful derivatization that the pH not decrease below 9.0.

6. Stir the solution at 4°C, periodically checking the pH.
7. Shell freeze in an acetone/dry ice bath or ethanol/dry ice bath, then lyophilize to dryness.

   Lyophilization may take 24 to 36 hr.The product should be a fine powder. It is critical that no water be present for the subsequent steps.

Conjugate APAP-PABA to KLH

8. Set up an ice-water bath in a well-ventilated hood. Maintain temperature at 10°C.

   CAUTION: *The following reaction is exothermic. Combine reagents slowly. Take appropriate safety precautions and use chemical-resistant latex gloves.*

9. Dissolve the lyophilized APAP-PABA powder in 9.0 ml *N*,*N*-dimethylformamide and cool to 10°C.
10. Dissolve 50 mg KLH in 50 ml of 50 mM carbonate/bicarbonate buffer, pH 9.0.

    KLH dissolves slowly.

11. Add 260 µl isobutyl chloroformate to the solubilized APAP-PABA from step 9 and stir for 30 min at 10°C.

    IMPORTANT NOTE: *It is essential to avoid water. The reaction of isobutyl chloroformate with the carboxyl group of PABA-APAP to form the mixed anhydride is water-sensitive. It is also advisable to conduct the reaction in an environment with low atmospheric humidity. Anhydrides can be rapidly hydrolyzed. If water is present, competition between the acylation and hydrolysis will reduce product yield.*

12. Slowly add the KLH solution prepared in step 10 to the acid anhydride of PABA-APAP formed in step 11. Stir for 4 hr while maintaining the temperature at 10°C throughout the reaction.
13. Dialyze the antigen 2 days against PBS, pH 7.0 to 7.2, at 4°C, with at least 5 changes of buffer, using pretreated 6000 to 8000 MWCO dialysis tubing.

    The dialysate color will decrease in intensity with repeated changes of buffer.

14. Remove two 1.0-ml aliquots for determination of epitope density (see steps 15 to 21) and place in 1.5-ml microcentrifuge tubes. Divide the remaining antigen solution into 1-ml aliquots and store at −70°C.

    Antigen may be stored for several months at this temperature. Alternatively it may be stored up to 2 weeks at 4°C. The amount of protein adduct used for immunization can be determined by any protein assay presently used in the laboratory—e.g., Lowry or Bradford.

Determine epitope density

15. In each of the two 1.0-ml aliquots taken from the antigen solution (step 14), acid-precipitate the protein with 0.2 ml of 6 N perchloric acid and add 100 µl of 50 mg/ml BSA. Let stand on ice for 10 min, then microcentrifuge 5 min at 14,000 × *g*, 4°C.

    The BSA is added as a carrier protein to prevent loss of ^{3}[H]APAP-KLH.

16. Remove supernatants and discard. Resuspend pellets by vortexing in 1.0 ml ice-cold 80% methanol containing 5 mM unlabeled APAP.
17. Add 30 µl of 1.0 N NaOH to the methanol solution/resuspended pellet and confirm that the pH is alkaline with pH paper.

    This step is necessary since BSA is soluble in acidic methanol. The methanol washes remove residual APAP that is not covalently bound to KLH.

18. Let stand on ice 10 min, and microcentrifuge 5 min at 14,000 × *g*, 4°C. Repeat methanol wash (removal of supernatants followed by addition of methanol/APAP and microcentrifugation) twice more.
19. Evaporate the residual methanol solution remaining in the pellet under nitrogen.
20. Solubilize the pellet in 0.2 ml of 0.1 N NaOH or a commercially available tissue solubilizer.
21. Determine the amount of ^{3}[H]APAP associated with KLH by liquid scintillation spectrometry.

Due to the multisubunit structure and size heterogeneity of KLH, epitope density is best expressed as nmol APAP bound per μg KLH protein. The following is a sample calculation.

Starting material: 4 mmol APAP and 5 μCi [^{3}H]APAP.

Reaction volume: 9.0 ml (step 9) + 50 ml (step 10) containing 50 mg KLH

Sample volume: 1.0 ml

Specific activity of [^{3}H]APAP: 11.0 × 10^{6} dpm/4 mmol APAP = 2730 dpm/μmol

1 ml sample volume would contain 847 μg KLH with a measured amount (x) of [^{3}H]APAP. The number of μmol APAP bound per μg KLH is determined as follows:

x/2730 (specific activity of [^{3}H]APAP)/847 μg KLH.

IMMUNIZATION AND SERUM COLLECTION TO PREPARE ANTI-APAP POLYCLONAL ANTIBODIES

SUPPORT PROTOCOL 2

Historically, immunization of female New Zealand rabbits has been done with the synthetic antigen (see, e.g., Support Protocol 1) and Freund's adjuvant. Freund's adjuvant results in the formation of granulomas and ulcers at the sites of injection. Alternative adjuvants that are less injurious are now widely available and should be used in accordance with the protocols supplied by the manufacturers (Adjuvax from Alpha-Beta Technology; Hunter's Titermax from CytRx; and RAS from RIBI Immunochemical Research). Two or more rabbits should be immunized with the hapten conjugate prepared in Support Protocol 1, since not all animals will respond equally to the antigen. New Zealand rabbits that are outbred and commonly used for antibody production exhibit varied response to APAP-PABA-KLH. All personnel should receive prior instruction regarding the care and handling of laboratory animals.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Female New Zealand white rabbits (3.5 to 4.5 kg)
APAP-PABA-KLH conjugate (see Support Protocol 1)
Adjuvant (Adjuvax from Alpha-Beta Technology, Hunter's Titermax from CytRx, or RAS from RIBI Immunochemical Research)

20- and 22-G needles
15- and 30-ml Corex glass centrifuge tubes
Refrigerated centrifuge
0.5-ml glass syringes

Additional reagents and equipment for detection of anti-APAP antibodies by ELISA (see Support Protocol 4)

Collect preimmune serum

1. One to two weeks prior to immunization, collect 5 to 10 ml of blood from unimmunized rabbit by inserting a 20-G needle into the central vein of the ear and gently holding it in place while allowing blood to drain from the open end of the needle directly into a 15-ml Corex tube.

   This will serve as the source of preimmune serum, which will be used to determine the specificity of antibody production and to detect any innate immune cross-reactivity with proteins that lack the antigenic adduct.

   Blood collection is facilitated by wrapping the rabbit in a towel, exposing only the head and ears. Heat generated from a lamp is recommended for keeping the ear warm to ensure adequate blood circulation. Shave a localized area of the ear. Palpation, rather than the use of chemical irritants (i.e., xylene), should be used to dilate the blood vessel. Donovan and Brown (1995) describe the procedure for collection of blood from the auricular vein of the rabbit.

2. Allow blood to clot at room temperature.

   The clot will retract from the wall of the tube. This can be facilitated by rolling a glass rod or similar device around the inside of the tube.

3. Centrifuge 10 min at 10,000 × *g*, 4°C. Carefully remove the serum, retain a 1-ml aliquot for initial screening, and store the remainder in 1-ml aliquots at −70°C.

Immunize rabbits

4. In a 1.5-ml microcentrifuge tube, mix 1 part APAP-PABA-KLH (containing 400 µg of the conjugate) with 1 part adjuvant.

   Antigen concentrations can range from 50 to 1000 µg/ml for rabbits.

5. Vortex 5 to 10 min to emulsify, then inject the immunogen preparation into the rabbit at multiple sites using a 0.5-ml glass syringe and 22-G needle.

   Plastic syringes are not recommended as they may swell on contact with the adjuvant. Avoid trapping air in the syringe or needle.

   The volume for injection varies with the site. A typical immunization protocol may include intramuscular injections of 0.3 to 0.5 ml into each hind leg along with two subcutaneous injections (0.1 to 0.25 ml each) at sites along the lower back.

6. Give booster injections 3 to 4 weeks after the initial immunization. Use the same formulation procedure as in step 4, but add only 200 µg antigen.

Collect and test antiserum

7. At a point 10 to 14 days after the booster injection, collect 5 ml of blood and process into serum as in steps 1 to 3. Test serum for the presence of anti-APAP antibodies by ELISA (see Support Protocol 4).

   If ELISA testing of this initial blood sample indicates the presence of specific antibodies, 20 to 25 ml should be drawn during subsequent blood collections. If no antibodies are detected, the rabbit may be given a second booster and the serum retested. If antibodies are not detected at this time, immunization of that particular rabbit should be discontinued. Peak levels of antibody are usually achieved 10 to 14 days following the booster injection and persist for 2 to 4 weeks. Subsequent booster injections may be given as needed, but should not be more frequent than every 4 to 6 weeks.

   A recommended frequency for blood collection is at 4-month intervals, at which ~30 to 40 ml of blood is withdrawn.

PREPARATION OF NAPQI-PROTEIN ADDUCTS AS COATING ANTIGEN FOR ELISA

N-acetyl-*p*-benzoquinoneimine (NAPQI)-protein adducts are used to coat the wells of the plate for the ELISA that will be used to test for antibody specificity (see Support Protocol 4). Antibodies elicited in response to conjugated haptens may be directed against the hapten, the carrier protein, and the linker molecule. To determine whether the antibodies produced following hapten-conjugate immunization can specifically recognize APAP, it is important that ELISA be performed (see Support Protocol 4) using a coating antigen that contains neither the linker, PABA, nor the carrier protein, KLH. Both BSA and aldolase which have been reacted with the APAP electrophile, NAPQI, have been used successfully as coating antigens. The unmodified protein serves as a negative control in the ELISA.

This protocol describes the method of Dahlin and Nelson (1982) and Streeter et al. (1984). APAP is converted to NAPQI and allowed to bind to BSA.

Materials

Acetonitrile
Sodium sulfate, anhydrous
Acetaminophen (APAP; Sigma; minimum purity 99%)
[^{3}H]acetaminophen ([^{3}H]APAP; 15.5 Ci/mmol; must be custom-synthesized)
Silver (I) oxide
Bovine serum albumin (BSA) or aldolase
Phosphate-buffered saline (PBS), pH 7.4 (see recipe)
10 mg/ml BSA in PBS (see recipe for PBS)
1 N perchloric acid
80% methanol, ice-cold
50 mM carbonate/bicarbonate buffer, pH 9.6 (see recipe)

5- to 7-ml glass screw-cap vials
6000 to 8000 MWCO dialysis tubing (pretreated; see recipe) and dialysis clamps

Synthesize NAPQI

1. Add the following ingredients sequentially to 625 µl acetonitrile in a 5- to 7-ml glass vial while stirring with a micro stir-bar:

   5 mg (35 µmol) anhydrous sodium sulfate
   5 mg (33 µmol) APAP
   13.2 µCi [^{3}H]APAP
   10 mg (43 µmol) silver (I) oxide.

   Anhydrous sodium sulfate is used to dry organic solvents. Silver oxide is a catalyst in the reaction and is not soluble. Sufficient radioactivity is included to facilitate quantitation of the amount of NAPQI bound to protein using an aliquot of the protein reaction as described below.

2. Stir 15 to 30 min at room temperature.

   The acetonitrile solution will change from colorless to pale yellow.

3. Transfer the reaction to a 1.5-ml microcentrifuge tube. Microcentrifuge 1 min at 14,000 × *g*, room temperature, to bring down the silver oxide precipitate.

4. Transfer the supernatant to a clean tube.

React with BSA or aldolase

5. Solubilize 10 mg BSA or aldolase in 10 ml PBS, pH 7.4

   BSA is available as a crystalline powder; aldolase is supplied as a suspension in ammonium sulfate solution and must be dialyzed against PBS to remove the salt.

6. Divide the BSA or aldolase solution into 2-ml aliquots in 7-ml glass screw cap vials. Add the appropriate volume of NAPQI solution (from step 4) to give molar ratios of NAPQI/protein of 25:1, 50:1, and 100:1 in the reaction mixture, assuming 100% conversion of APAP to NAPQI. Prepare additional vials as controls containing the unmodified protein and the unmodified protein plus the maximum volume of acetonitrile used in generating the protein adducts.

   The reaction of NAPQI with purified proteins in vitro must be carefully monitored to avoid artifactually high binding ratios of NAPQI to protein. Cysteine residues are the primary sites on proteins that react with NAPQI. BSA (66 kDa) has one free -SH residue; therefore the optimal binding of NAPQI to BSA should approximate a 1:1 molar ratio. A ratio in excess may indicate nonspecific binding or polymerization of NAPQI. Aldolase, a tetrameric protein of 160 kDa, may offer greater flexibility as a coating antigen, with 12 and 24 -SH groups available under nondenaturing and denaturing conditions, respectively.

7. React for 30 min at room temperature with shaking.

   Longer reaction times may result in decomposition of NAPQI.

8. Dialyze overnight against 2.0 liters of PBS to remove unincorporated isotope ([^{3}H]APAP), using pretreated 6000 to 8000 MWCO dialysis tubing. Following dialysis, remove two 100-µl aliquots and proceed to step 9. Store remaining volume of adduct solution at 4°C.

   It is recommended that the protein adducts, especially aldolase adducts, not be stored for >1 week. Protein denaturation may contribute to decreased sensitivity and greater variability in ELISA.

Determine amount of [^{3}H]APAP bound to the protein

9. Precipitate each of the 100-µl aliquots of [^{3}H]APAP-protein adducts (from step 8) with 1.0 ml of 1 N perchloric acid, then add 50 µl of 50 mg/ml BSA to each aliquot as a cold carrier.

   The carrier is added to prevent losses of the small amount of radioactive protein.

10. Let stand on ice for 10 min, then centrifuge 5 min at 14,000 × *g*, 4°C.

11. Remove supernatants and discard. Resuspend pellets by vortexing in 1.0 ml ice-cold 80% methanol. Add 30 µl of 1.0 N NaOH to the resuspended pellet and confirm that the pH is alkaline with pH paper. Repeat the methanol washes twice more using the technique described in Support Protocol 1, step 18.

    The step for ensuring basic pH is necessary since BSA is soluble in acidic methanol.

12. Determine the amount of bound [^{3}H]APAP (see Support Protocol 1, steps 19 to 21).

13. Calculate the nanomoles of NAPQI bound to the protein by dividing the ^{3}H dpm obtained in step 12 by the specific activity of APAP used in step 1—i.e., 0.4 µCi/µmol.

14. Calculate nanomol of NAPQI bound per nanomol protein in the aliquot sampled.

    100 µl of 1 mg/ml BSA is equivalent to 1.5 nmol BSA.

Dilute NAPQI adducts for ELISA

15. Dilute the protein adducts and corresponding controls in 50 mM carbonate/bicarbonate buffer, pH 9.6, to give 2 μg/ml. Use 100 ng (50 μl) for coating quadruplicate wells of a microtiter plate (see Support Protocol 4).

    To coat each well of the plate, 100 ng of protein adduct in 50 μl of 50 mM carbonate/bicarbonate buffer, pH 9.6, is used. From step 5, the starting concentration of protein (BSA or aldolase) is 1 mg/ml. Therefore, to obtain the desired concentration for coating, dilute the 1 mg/ml protein-adduct solution 1:10 by adding 100 μl of the protein adduct to 900 μl buffer (the volume of NAPQI solution added to the reaction with protein is <100 μl and is ignored in this calculation). Further dilute the protein adduct solution (now 100 μg/ml) 1:50 by taking 20 μl and adding to 980 μl buffer. This will give the 2 μg/ml solution used for coating the wells of the microtiter plate. Volumes can be proportionally scaled up to accommodate the number of samples being tested.

    For BSA, coat with the adduct that best approximates the 1:1 molar ratio (see step 6). With aldolase adducts, test two or more molar ratios to identify one that most conveniently facilitates detection of antibody binding on ELISA (e.g., linear kinetics with optimum color development within a convenient time frame).

DETECTION OF ANTI-APAP ANTIBODY BY NONCOMPETITIVE ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA)

SUPPORT PROTOCOL 4

The basic principle of enzyme immunoassays takes advantage of the specificity and high affinity of the antibody for its corresponding antigen. Detection of the interaction is achieved by enzymatic coupling and amplification to yield a chromogenic product. The reactions are done on a solid support, which greatly facilitates the separation of bound and free molecules. Generally, 96-well polysytrene or polyvinyl chloride (PVC) microtiter plates are used. Permutations of the assay vary according to whether the antigen or antibody is immobilized within the wells (the solid support). The assays may also be designed to be competitive or noncompetitive in nature, to permit quantification and characterization of either antigen or antibody. The application described in this protocol uses a noncompetitive ELISA to screen for the production and determination of the titer of APAP antibodies.

Materials

Coating antigen: 2 mg/ml NAPQI-protein adduct solution (see Support Protocol 3) *and* unmodified control protein solution (see Support Protocol 3, step 6)
PBST (see recipe)
1% (w/v) BSA *or* 0.2% to 0.5% (w/v) gelatin in 50 mM carbonate/bicarbonate buffer, pH 9.6 (see recipe)
Immune and preimmune rabbit serum to be assayed for anti-APAP antibodies (see Support Protocol 2)
Phosphate-buffered saline (PBS; see recipe)
Horseradish peroxidase (HRP)–conjugated anti-rabbit IgG (or IgG made against other host animal used in primary antibody production)
2,2′-azino-di-(3-ethylbenzthiazoline) sulfonic acid (ABTS)
50 mM sodium citrate, pH 4.0 (see recipe)
30% hydrogen peroxide (store up to 1 month at 4°C)
37 mM sodium cyanide (optional)

96-well flat-bottom polystyrene or polyvinyl chloride (PVC) microtiter plates
Multichannel pipettor
Microtiter plate reader with variable-wavelength filters

Coat and block the wells

1. In alternating rows of a 96-well polystyrene or polyvinyl chloride (PVC) microtiter plate, place 100 ng NAPQI-protein adduct (coating antigen) in 50 µl (i.e., 50 µl of 2 µg/ml solution) using a multichannel pipettor. Place equivalent amount of the unmodified control protein in the remaining wells.

   Antibodies elicited in response to conjugated haptens may be directed against the hapten, the carrier protein, and the linker molecule. To determine whether the antibodies produced following hapten-conjugate immunization can specifically recognize APAP, it is important that the coating antigen contain neither the linker, PABA, nor the carrier protein, KLH. Both BSA and aldolase which have been reacted with the APAP electrophile, NAPQI (Support Protocol 3), have been used successfully as coating antigens. The unmodified protein serves as a negative control in the assay.

   Coating buffers used for solubilizing and diluting the antigen include 50 mM carbonate, pH 9.6, 10 mM Tris·Cl (pH 8.5)/100 mM NaCl, or 10 mM sodium phosphate, (pH 7.2)/100 mM NaCl. Carbonate buffer is commonly used (see Support Protocol 3, step 15). The presence of detergents should be avoided during coating, since they compete with the protein for binding to the solid phase and prevent the formation of the desired hydrophobic interactions (Tijssen, 1985).

2. Incubate the plate in a humidified atmosphere at 37°C for 1 hr or at 4°C overnight to coat wells.

   Important variables for adsorption of protein to the wells are time, temperature, and concentration. Incubation time may be decreased by increasing temperature or antigen concentration.

3. Empty the contents of the plate by inversion and tap dry over paper towels on the benchtop. Wash the wells five times with PBST.

   The use of polyoxyethylene sorbitan (Tween 20) in the PBST wash solution reduces nonspecific adsorption and minimizes formation of new hydrophobic interactions between the solid support and the primary and secondary antibodies without significant disruption of bonds already formed between the coating antigen and plastic surface (Engvall, 1980).

4. Block wells by adding 100 µl of 1% BSA or 0.2% to 0.5% (w/v) gelatin in carbonate/bicarbonate buffer to each well and incubating 1 hr at room temperature.

5. Empty plate and wash five times with PBST (step 3).

   Blocking prevents direct adsorption of antibody to the plastic if all sites have not been saturated, and thus decreases nonspecific binding. If comparison of ELISAs run with or without this blocking step reveal no differences, steps 4 and 5 may be omitted from the routine protocol.

Incubate with primary and secondary antibodies

6. Serially dilute the rabbit antiserum from 1:4 to 1:1024 in PBS. Add 20 µl of each dilution to the designated well and incubate 3 hr at 37°C.

7. Empty plate and wash five times with PBST (step 3).

8. Dilute horseradish peroxidase (HRP)–conjugated goat anti–rabbit IgG 1:1000 in PBST. Add 50 µl to each well and incubate 1 hr at 37°C.

   Alkaline phosphatase–conjugated secondary antibody may be used in place of HRP-conjugated antibody, although the latter is more frequently used.

   Dilution of the secondary antibody may vary with its commercial source. Recommended dilutions are often supplied with the technical data sheets that accompany the product. Otherwise, optimal dilutions need to be determined empirically.

Detect bound antibodies

9. Turn on the microtiter plate reader and allow to warm up for 10 to 15 min or in accordance with manufacturer's instructions.
10. Empty plate and wash five times with PBST (step 3).
11. Dissolve 6.6 mg ABTS in 10 ml 50 mM sodium citrate, pH 4.0. Add 40 µl of 30% hydrogen peroxide (H_2O_2).

    This solution should be made up just before use. H_2O_2 is both a substrate and inhibitor of HRP and therefore the concentration range in which it can be used is limited (Tijssen, 1985). ABTS is a both a chromogen (absorbance at 415 nm) and hydrogen donor in the reaction catalyzed by peroxidase where cleavage of H_2O_2 is coupled to oxidation of the hydrogen donor (Engvall, 1980). Other chromogens/hydrogen donors include 5-aminosalicylic acid, o-dianisidine, o-toluidine, o-phenylenediamine, and tetramethylbenzidine (TMB).

    CAUTION: *ABTS should be handled with care because of its potential mutagenic properties. Check the MSDS for more information.*

12. Add 60 µl of the substrate-chromogen solution to each well. Determine the change in absorbance at 415 nm over the period between 4 and 7 min following addition.

    CAUTION: *NaCN is poisonous and care is advised in handling.*

    Oxidation of ABTS during the reaction will result in the formation of a greenish-blue color.

    Alternatively, endpoint determinations can be obtained by stopping color development with 0.2 vol of 37 mM NaCN. Color development should be linear throughout the interval selected (prior to the endpoint), and this may need to be determined empirically. For example, the 4- to 7-min interval selected for the kinetic reaction was based on the linearity of the reaction. Addition of NaCN results in enzyme inactivation without affecting the color produced, and is therefore advantageous over HCl, H_2SO_4, or NaOH as a stopping reagent. Lowering the pH nonspecifically increases color development, and raising the pH nonspecifically decreases it (Engvall, 1980).

Analyze data

13. Plot the difference in absorbance values between NAPQI-modified and unmodified protein as a function of antibody dilution, beginning with the lowest antibody concentration (highest dilution).

    If rate rather than endpoint measurements are used, plot the rate of change in absorbance as a function of antibody dilution. A sigmoidal curve should be obtained. A leveling off at either end of the curve is due to the fact that either the antigen or antibody is rate-limiting. A direct relationship between the absorbance and the amount of antibody is indicated by a linear response within a range of antibody concentration. This denotes the working concentration range for the antibody. Some background absorbance will be observed with the unmodified protein and whole serum; however, the specificity of antibody recognition for APAP is indicated by a 2-fold or greater difference in absorbance between the NAPQI-conjugated versus unconjugated protein. Upon affinity purification of the antibody, the background will be significantly reduced and the difference between conjugated and nonconjugated coating antigen maximized.

CHARACTERIZATION OF APAP ANTIBODY BY COMPETITIVE ELISA

SUPPORT PROTOCOL 5

A competitive ELISA is also used in the presence of compounds structurally related to APAP to determine the epitopes recognized by the antibody. The compounds *p*-aminophenol and BSA-NAPQI, as well as APAP and its dimethylated analogs, 2,6-dimethylacetaminophen and 3,5-dimethylacetaminophen, are used as competitors for antibody reactivity against BSA-NAPQI coated onto microtiter wells. Similar structures or stereospecificites to the xenobiotic to which an antibody has been newly constructed would be the basis for selection of potential competitors.

Additional Materials *(also see Support Protocol 4)*

Competitors: e.g., *p*-aminophenol, BSA-NAPQI, APAP, 2,6-dimethylacetaminophen, or 3,5-dimethylacetaminophen

1. Coat wells of microtiter plate with protein-adduct or unmodified protein, then block and wash wells (see Support Protocol 4, steps 1 to 5).
2. Prepare serial dilutions of competitor to give 0.12 to 500 µg/ml in PBS.

   The concentration of competitor per well should span a broad range (i.e., 0 to 10^5). Either units of weight/well (i.e., 1 to 100,000 ng/well) or moles/well (i.e., 1 to 100,000 pmol/well) may be used. Units of moles would be more accurate when the molecular weights of the competitors differ significantly from the compound against which they are tested. It is important that the concentration of the competing compound be in excess relative to the amount of adduct present as the coating antigen.

3. Dilute the antibody in PBST (also see Support Protocol 4, step 6).

   The antibody concentration should be rate-limiting and the final dilution of the antibody (antibody plus competing compound) should fall within the linear portion of the antibody titration curve (as determined by noncompetitve ELISA as in Support Protocol 4).

4. Combine equal volumes of diluted competitor and diluted antibody. Add 20 µl of the mixture per well and incubate plate 3 hr at 37°C.
5. Empty plate and wash five times with PBST (see Support Protocol 4, step 3).
6. Add HRP–conjugated secondary antibody to wells and incubate, then incubate plate with substrate-chromogen solution (see Support Protocol 4, steps 8 to 12).
7. Calculate the percentage inhibition by determining HRP activity in the presence and absence of the competitors.

SUPPORT PROTOCOL 6

CONSTRUCTION OF APAP AFFINITY COLUMN

The principle of affinity chromatography is based on the specific and reversible interactions between two molecules, one of which has been immobilized to a chromatographic matrix. The interactions involved in such binding are noncovalent in chemical nature and are likely to include hydrogen bonding, electrostatic forces, and van der Waals forces. Affinity purification of polyclonal anti-APAP antibody decreases the nonspecific binding in immunoblotting and immunohistochemistry. Epoxy-activated Sepharose was selected for its ability to couple ligands containing hydroxyl, amino, or thiol groups to the free epoxide groups on the oxirane spacer arm, resulting in the formation of ether, alkylamine, or thioether linkages, respectively. With APAP as the ligand, the hydroxyl group is coupled to the matrix to form a stable ether linkage. The long spacer arm is also advantageous in promoting interaction between bound APAP and its specific antibodies. This protocol is an adaptation of that provided by Amersham Pharmacia Biotech, the supplier of the epoxy-activated Sepharose.

Materials

Epoxy-activated Sepharose 6B (Amersham Pharmacia Biotech)
0.1 M NaOH, pH ~11.8
Acetaminophen (APAP; Sigma; minimum purity, 99%)
0.1 M sodium borate, pH 8.0 (see recipe), containing 0.5 M NaCl
0.1 M sodium acetate, pH 4.0 (see recipe)
1 M ethanolamine, pH 9.0 (see recipe)
Phosphate-buffered saline (PBS), pH 7.4 (see recipe)

0.04% (w/v) sodium azide in PBS (see recipe for PBS)

Sintered-glass funnels (coarse or medium) and filter flasks
50-ml conical plastic centrifuge tubes with caps
Platform shaker (e.g., Nutator from Becton Dickinson Primary Care Diagnostics)
1.0 × 10.0–cm glass column (e.g., Econo-Column from Bio-Rad or Kontes-Flex column from Kontes Glass) and 2-way stopcock valve

Couple APAP to epoxy-activated Sepharose

1. Add 2.5 g epoxy-activated Sepharose 6B to 10 ml water and allow gel to swell for 15 to 30 min.

   1.0 gram of dry powder swells to ~3 ml of gel.

2. Transfer gel to a sintered-glass funnel and wash with 500 ml water by adding 50 to 100 ml at a time, allowing the funnel to drain without allowing the Sepharose to dry out, then applying more water.

   This will remove the manufacturer's additives. A coarse sintered-glass funnel is preferable; washes can be done by gravity flow rather than under a vacuum aspirator. If washes are done under vacuum, do not allow the Sepharose to dry out.

3. After the final wash, remove as much water as possible but be careful to keep the Sepharose moist. Wash with 25 ml of 0.1 M NaOH, then allow to drain well. Transfer to a 50-ml plastic-capped centrifuge tube or similar vessel.

4. Solubilize 62 mg (0.4 mmol) APAP in 15 ml of 0.1 M NaOH (pH ~11.8) and add to the Sepharose from step 3. Place tube containing suspension on a platform shaker and allow the coupling reaction to run overnight at room temperature.

   The ratio of binding buffer (containing ligand) to gel matrix is ~2 to 1. A magnetic stirrer should not be used since it can damage the Sepharose matrix. The amount of ligand is determined from the oxirane (epoxy) group concentration of the Sepharose, which will vary from batch to batch. For example, for an epoxy group concentration of 19 to 40 µmol per ml of drained gel and assuming a 1:1 coupling ratio, this would require between 140 to 300 µmol of APAP for ~7.5 ml of gel. The efficiency of coupling is experimentally determined from the difference in absorbance at 250 nm of the APAP solution (in 0.1 M NaOH) just prior to and directly after the coupling reaction when the Sepharose has settled.

   Coupling to Sepharose oxirane groups occurs in the pH range of 9 to 13. Optimal reaction with the hydroxyl group on APAP is conducted at pH 11 to 13. Carbonate or borate buffers are preferred; at the higher pH range, dilute solutions of NaOH may be used. Tris or other nucleophilic reagents should be avoided since these will couple to the oxirane groups. The temperature for coupling can be in the range of 20° to 40°C with a reaction time of 16 hr most frequently used (Pharmacia). However, the reaction time may vary with the stabilities of the epoxy-activated Sepharose and ligand to be immobilized under the conditions of the coupling reaction. For further information, see Critical Parameters and Troubleshooting.

5. Place coupled Sepharose in a sintered-glass funnel and remove excess ligand by successive washes with the following:

   100 ml 0.1 M NaOH
   200 ml distilled H_2O
   100 ml 0.1 M sodium borate, pH 8.0, containing 0.5 M NaCl
   100 ml 0.1 M sodium acetate, pH 4.0.

6. Transfer the washed coupled Sepharose to a 50-ml capped plastic tube. Block any unreacted oxirane groups by incubating gel for 4 hr at at room temperature with ~40 to 50 ml of 1 M ethanolamine, pH 9.0 with shaking on a platform shaker.

   At this pH, the oxirane groups interact with the amino groups of ethanolamine.

7. Wash gel with 200 ml distilled water and preequilibrate by washing twice with 100 ml PBS, pH 7.4.
8. Transfer gel to a filter flask and allow to settle (the gel should occupy ~70% of the total volume). Remove excess volume to obtain a slurry consistency and degas under vacuum just prior to packing the column.

Pack the column

9. Attach a stopcock valve to a 1.0 × 10.0–cm column and turn valve to the closed position.
10. To prevent entrapment of air in the bottom of the column, add 2 to 3 ml of PBS to the empty column and allow to partially drain. Close valve when ~1.0 ml remains.
11. Pour degassed gel slurry (step 8) along the wall of the column to minimize introduction of air bubbles.
12. Fill the remainder of the column with PBS and connect with buffer reservoir; allow the gel to settle.
13. Open stopcock and establish flow. Continue equilibration of column with 200 ml PBS under gravity flow.

    After equilibration, typical flow rates are ~ 0.2 ml/min.

14. Store column at 4°C with 0.04% (w/v) sodium azide in PBS as a preservative.

    The column has been found to be stable for ≥2 years under these conditions.

15. Before purification of APAP antisera, bring the column to room temperature and wash with 300 to 500 ml PBS overnight to remove azide.

SUPPORT PROTOCOL 7

AFFINITY PURIFICATION OF APAP ANTISERUM

Affinity purification of antiserum reduces the background in immunodetection protocols. In this protocol, ammonium sulfate–precipitated and dialyzed anti-APAP antiserum is passed over a column with antigen (APAP) coupled to the Epoxy-activated Sepharose solid support. Specific antibody is eluted with a solution of unbound antigen and dialyzed to remove the antigen.

This procedure has been performed with up to 8 ml of serum. Due to the cost of the Epoxy-activated Separose, and the time involved in the preparation of the column, it is recommended that the column size not be increased but rather that the column be reused as often as needed. With proper care, the column is stable for at least 1 year.

Materials

Antiserum to APAP (see Support Protocol 2)
Saturated ammonium sulfate (SAS; see recipe)
2.0 N NaOH
Phosphate-buffered saline (PBS; see recipe)
1% (w/v) barium chloride
APAP affinity column (see Support Protocol 6)
Acetaminophen (APAP; Sigma; minimum purity, 99%)
0.04% (w/v) sodium azide in PBS (see recipe for PBS)

15-ml Corex glass centrifuge tubes
Refrigerated centrifuge

8,000 to 10,000 MWCO dialysis tubing (pretreated; see recipe) and clamps
Fraction collector
Spectrophotometer

Precipitate antibody with ammonium sulfate

1. Thaw 4 ml serum from a single rabbit and precipitate the IgG fraction by adding 2.4 ml saturated $(NH_4)_2SO_4$ solution (SAS) dropwise while stirring at room temperature.

   The IgG is precipitated at 38% $(NH_4)_2SO_4$. Do not combine batches of serum from different rabbits.

2. Adjust the pH to 7.4 with 2.0 N NaOH if necessary. Stir at room temperature for 30 min.
3. Transfer the mixture to a 15-ml Corex glass centrifuge tube and let stand on ice for 30 min.
4. Centrifuge 10 min at 10,000 × *g*, 4°C.
5. Discard the supernatant. Resuspend the pellet in 4 ml PBS and precipitate with 1.8 ml SAS, to give a final concentration of 31% $(NH_4)_2SO_4$. Let stand on ice for 30 min and repeat step 4.

   This step removes serum albumin.

6. Discard the supernatant and resuspend the pellet in 2.0 ml PBS. Transfer the resuspended protein pellet to pretreated dialysis tubing with a Pasteur pipet.
7. Dialyze overnight at 4°C against 2.0 liters of PBS to remove $(NH_4)_2SO_4$.
8. Test dialysate for removal of sulfate ions by adding an equal volume of 1% barium chloride to a 1.0-ml aliquot of dialysate. If a precipitate is observed, then replace dialysis solution with fresh PBS and continue dialysis until the test for sulfate is negative.

   If sulfate is present, barium sulfate will precipitate out of solution, giving a cloudy, milky appearance.

Affinity purify antibody

9. Close the stopcock at the base of the affinity column and remove residual PBS from above the column bed.
10. Apply the dialyzed protein solution to the column bed and open the stopcock to allow the solution to enter the column. Close the stopcock and allow the antibodies to adsorb to the APAP ligand on the column for 15 to 30 min.
11. Fill the remaining portion of the column with PBS and connect to a buffer reservoir.
12. Open the stopcock and collect 1.0-ml fractions.
13. Measure absorbance at 280 nm to monitor the elution of serum proteins not retained by the column.

    Anti-APAP antibodies are retained by the column.

14. Dissolve 25 mg of APAP in 5 ml PBS.
15. When the absorbance of fractions collected in step 13 returns to baseline, disconnect the buffer reservoir. Remove PBS from above the column bed. Add the solution prepared in step 14 to elute anti-APAP antibodies.
16. Resume fraction collection and continue to monitor absorbance at 280 nm.

    Due to the high concentration of APAP in the eluate, the absorbance will again rise above baseline since APAP also absorbs at 280 nm.

17. Pool fractions, beginning with the first fraction that showed absorbance over the baseline value.

The total pooled fraction volume is usually 5 to 7 ml, or ~2.5 to 3.5 times the volume of dialyzed protein applied.

If fractions are collected until the absorbance again returns to baseline, this could result in dilution of the antibody.

Dialyze the antibody

18. Transfer pooled fractions into dialysis tubing and dialyze against 2.0 liters PBS at 4°C.

19. Change dialysate daily for 10 to 14 days until the presence of APAP in the dialysate is no longer detectable at 250 nm.

The process of dialysis is driven by differences in the concentration of solutes on either side of the membrane. A decrease in the solute concentration in the buffer solution is achieved by changing the dialysis buffer. Extensive dialysis is required at this step, not only to remove excess free APAP in the eluate, but also to remove APAP that was specifically bound to the antibody as it was displaced from the Sepharose column. Failure to dissociate this bound APAP will result in a blocked (inhibited) antibody that will not recognize adducts in subsequent immunoassays.

20. Store the affinity-purified antibody in 1.0-ml aliquots up to 3 months at −20°C.

Reequilibrate the column

21. Treat the affinity column following purification of the antibody as follows.

a. Wash the column overnight with 500 ml PBS.
b. Continue to wash the column with 0.04% sodium azide in PBS for 2 hr.
c. Store column with 0.04% azide at 4°C.

With proper care, the column is stable for at least 1 year.

REAGENTS AND SOLUTIONS

*Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Blocking buffer

Suitable blocking buffers include the following:
3% to 5% (w/v) nonfat milk in Tris-buffered saline (TBS; see recipe)
3% (w/v) bovine serum albumin (BSA) in TBS
3% to 5% fish gelatin (e.g., Sigma) in TBS

With anti-APAP, nonfat milk in TBS was found to be the least effective blocking agent.

Carbonate/bicarbonate buffer, 50 mM, pH 9.6 (for ELISA)

Stock solutions:
0.2 M sodium carbonate (21.2 g anhydrous Na_2CO_3/liter)
0.2 M sodium bicarbonate (16.8 g $NaHCO_3$/liter)

Combine 16 ml of 0.2 M sodium carbonate and 34 ml of 0.2 M sodium bicarbonate and dilute to 200 ml. Verify that pH is 9.6; adjust if necessary with 1 N NaOH or 1 N NaCl.

Carbonate/bicarbonate buffer, 0.5 M, pH 9.0 (for antigen construction)

0.55 g Na_2CO_3 (anhydrous)
8.00 g $NaHCO_3$
Adjust volume to 200 ml
Verify that pH is 9.0; adjust with concentrated NaOH or HCl if necessary

4-Chloro-1-naphthol solution

Dissolve 5 mg of 4-chloro-1-naphthol in 8 ml methanol. Add 40 ml Tris-buffered saline (TBS; see recipe). Prepare fresh. Immediately before use, add 20 µl of 30% H_2O_2.

Coomassie brilliant blue solution

Dissolve 0.5 g Coomassie brilliant blue in 125 ml methanol. Adjust volume to 250 ml with double-distilled water, then add 17.5 ml glacial acetic acid.

Destaining solution (25% methanol/7% acetic acid)

Mix 250 ml methanol and 70 ml glacial acetic acid, then adjust volume to 1 liter with double-distilled water.

Developing buffer

100 mM 2-amino-2-methyl-1,3-propanediol
1 mM magnesium sulfate
1 mM levamisole
Adjust pH to 9.6 using concentrated HCl
Store up to 4 months at room temperature

Ethanolamine, 1 M, pH 9.0

Prepare a 1 M solution by diluting 6.1 ml of liquid ethanolamine (density = 1.01 g/ml; mol. wt. = 61.08) to 100 ml. Adjust pH with HCl.

Gill's hematoxylin, 2×

Mix the following in the order indicated:
730 ml double-distilled water
250 ml ethylene glycol
4.0 g anhydrous hematoxylin
0.4 g potassium iodate
70.4 g aluminum sulfate
20 ml glacial acetic acid
Stir 1 hr at room temperature

Recipe from Sheehan and Hrapchak (1980). It is advisable to purchase prepared staining solutions (e.g., from Polyscientific) as commercial preparations give more uniform results. Conditions for storage (usually room temperature) and expiration dates are provided on the label. Also note that some histology laboratories favor Mayer's hematoxylin over Gill's formulation, due to the blue staining of the nucleus and the contrast provided when used with other staining protocols.

PBST

Stock solutions:
0.2 M monobasic sodium phosphate (13.9 g $NaH_2PO_4 \cdot H_2O$/500 ml)
0.2 M dibasic sodium phosphate (26.8 g $Na_2HPO_4 \cdot 7H_2O$/500 ml)

Combine 19 ml of 0.2 M monobasic sodium phosphate and 81 ml of 0.2 M dibasic sodium phosphate. Dilute to 400 ml to obtain 50 mM sodium phosphate, pH 7.4. Add NaCl to 0.8% (w/v) and Tween 20 (polyethoxyethylene sorbitan) to 0.05% (w/v). Store up to 1 week at room temperature.

Phosphate-buffered saline (PBS)

20× stock solution:
80 g NaCl
2.0 g KCl
11.5 g $Na_2HPO_4 \cdot 7H_2O$

continued

2.0 g KH_2PO_4
H_2O to 500 ml
Store up to 1 month at room temperature

Prepare 1× working solution by diluting 1 part 20× stock with 19 parts H_2O. pH should be 7.0 to 7.2; adjust to desired pH if necessary with 1 N NaOH or 1 N HCl.

Pretreated dialysis tubing

Using gloves to avoid contamination, cut dialysis tubing to slightly longer than that needed to accommodate the volume to be dialyzed, so as to allow for an increase in volume during dialysis and for closure of both ends with dialysis clamps.

As dry dialysis tubing may be contaminated with heavy metals and sulfur-containing compounds, pretreat by placing in a beaker containing 100 mM sodium bicarbonate ($NaHCO_3$)/10 mM EDTA, pH 7.0 (Pohl, 1990). Bring the solution to a boil. Allow to cool and rinse well with distilled H_2O.

Poly-L-lysine coated slides

Prepare poly-L-lysine stock solution by dissolving 1.0 g poly-L-lysine in 100 ml double-distilled water. Store in 100-µl aliquots at –20°C. Clean glass slides with ethanol before coating. Dilute stock poly-L-lysine 1:10 in distilled water (0.1% final). Place 5 µl of diluted poly-L-lysine onto each slide and streak the solution evenly over the entire surface using another glass slide. Dry the coated slides at room temperature before use.

Saturated ammonium sulfate (SAS)

Dissolve 7.67 g $(NH_4)_2SO_4$ in 10 ml distilled water in small increments with stirring under mild heat, allowing each increment of the salt to dissolve before adding more. Prepare fresh.

Sodium acetate, 0.1 M, pH 4.0

Stock solutions:
0.2 M acetic acid (dilute 5.77 ml glacial acetic acid to 500 ml)
0.2 M sodium acetate (13.6 g $NaC_2H_3O_2 \cdot 3H_2O$/500 ml)

Combine 41 ml of 0.2 M acetic acid with 9 ml sodium acetate and dilute to 100 ml. Verify that pH is 4.0; adjust if necessary with 1 N HCl or 1 N NaOH.

Sodium borate, 0.1 M, pH 8.0/0.5 M NaCl

Stock solutions:
0.2 M boric acid (6.2 g/500 ml)
0.05 M borax (sodium tetraborate decahydrate; 9.52 g/500 ml)

Combine 50 ml of 0.2 M boric acid with 4.9 ml 0.05 M borax and dilute to 100 ml. Add 2.9 g NaCl. Verify that pH is 8.0; adjust if necessary with 1 N HCl or 1 N NaOH.

Sodium citrate, 50 mM, pH 4.0

Stock solutions:
0.1 M citric acid (2.10 g/100 ml)
0.1 M sodium citrate (2.94 g $Na_3C_6H_5O_7 \cdot H_2O$ in 100 ml)

Combine 33 ml of 0.1 M citric acid and 17 ml of 0.1 M sodium citrate and dilute to 100 ml. Verify that pH is 4.0; adjust if necessary with 1 N HCl or 1 N NaOH.

Transfer buffer

25 mM Tris·Cl, pH 8.1 to 8.3 (*APPENDIX 2A*)
192 mM glycine
20% (v/v) methanol
0.05% (w/v) sodium dodecyl sulfate (SDS)
Store up to 2 weeks at room temperature

continued

The acceptable pH range for transfer buffer is 8.1 to 8.3 and the pH should not be adjusted once the buffer has been prepared.

Tris-buffered saline (TBS)

25 to 50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.9% (w/v) NaCl (*APPENDIX 2A*)
Store up to 2 weeks at room temperature

COMMENTARY

Background Information

The biotransformation of many chemically dissimilar xenobiotics can generate highly reactive intermediates that interact with and covalently bind to proteins. Covalent binding of reactive intermediates to proteins has been associated with both the development of target-organ toxicity and immune-mediated hypersensitivity reactions (Cohen and Khairallah, 1997; Pumford and Halmes, 1997). The relationship between covalent binding and the development of target-organ toxicity was first proposed in the early 1970s (Brodie et al., 1971). Initial studies that relied on radioisotopic methods for detection of the protein adducts were limiting with respect to cost, availability, and more importantly, the ability to identify the target proteins. The development of immunochemical methods as an alternative approach (Bartolone et al., 1987, 1988; Roberts et al., 1987) has gained widespread acceptance and greatly facilitated the task of identifying the protein adducts (Cohen et al., 1997), and this has been especially noteworthy for recent research on APAP toxicity (Cohen and Khairallah, 1997).

The support protocols described in this unit outline specific methods for construction of the hapten conjugate and characterization of polyclonal antibodies to acetaminophen. For other xenobiotics, selection of coupling chemistry for antigen construction and affinity chromatography will require modification of the existing protocols to accommodate the chemistry of the compound under investigation. Moreover, an understanding of the bioactivation, metabolism, and detoxification pathways is essential to predict the interaction between the putative reactive intermediate and proteins for design of the appropriate immunogen. This is a critical and complicating factor for compounds that are converted to multiple intermediates, not all of which bind to proteins. As examples, selected methods used to generate antibodies against other xenobiotics are briefly summarized.

Acetaminophen (APAP)

In addition to the method described in this unit, antibodies to APAP have also been obtained by two independent approaches (Roberts et al., 1987; Matthews et al., 1996). Bioactivation of APAP to the reactive electrophile, *N*-acetyl-*p*-benzoquinoneimine (NAPQI; Miner and Kissinger, 1979; Corcoran et al., 1980; Dahlin et al., 1984) results in covalent binding primarily to protein sulfhydryl residues (Streeter et al., 1984; Hoffman et al., 1985). To compare detection of APAP specifically bound to cysteine residues versus total binding, carboxyl groups were introduced into the APAP molecule to generate either *N*-acetylcystein-*S*-yl-APAP or 4-acetamidobenzoic acid, respectively. Carbodiimide was then used to couple the carboxyl group of modified APAP to amino groups on KLH. The resulting antisera specifically detected the 3-(cystein-*S*-yl) linkage or arylacetamide epitopes of APAP protein adducts, respectively. Anti-3-(cystein-*S*-yl)-APAP was affinity purified using sulfhydryl cellulose derivatized with NAPQI and eluted from the affinity matrix with excess APAP (Pumford et al., 1990). Comparison of immunoblots probed with these antisera to those generated by the method described in this unit yield a similar pattern of protein adducts (Matthews et al., 1996; Bartolone et al., 1987, 1988) despite differences in the antigenic determinants recognized by each of the antibodies.

Halothane

Sera from halothane hepatitis patients exhibited immune reactivity with liver microsomes from humans and animals that had been exposed to halothane. Binding of the trifluoroacetyl chloride metabolites of halothane to hepatic proteins was implicated in this process when it was demonstrated that the sera also reacted with trifluoroacetylated rabbit serum albumin (TFA-RSA). TFA-RSA was synthesized from *S*-ethyl trifluorothiolacetate and RSA and used to immunize rabbits. Immunoblot analysis of microsomes from rats and humans treated with halothane using the resulting antibody indicated that the protein fractions that had reacted with the patients' serum antibodies also reacted with the TFA-RSA antibodies (Pohl, 1993).

Carboxylate drugs (clofibric acid, diflunisal, valproic acid, and zomepirac)

Most drugs containing a carboxylic acid functional group are conjugated to glucuronic acid to form reactive acyl glucuronide metabolites. Antibodies were raised against each of the carboxylate drugs by coupling to KLH with *N*-hydroxysulfosuccinimide (sulfo-NHS) and 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluenesulfonate (Bailey and Dickinson, 1996). Inclusion of sulfo-NHS improves the efficiency of coupling and forms more stable intermediates in aqueous environments at acidic and neutral pH. Antisera were used in immunoblotting protocols without prior affinity purification.

Diclofenac

Binding of diclofenac to proteins is believed to occur via an acyl glucuronide intermediate. Antisera against diclofenac-protein adducts have been obtained by several laboratories, all of which used a two-step reaction involving the carbodiimide EDC (1-ethyl-3-[3-dimethyaminopropyl]carbodiimide hydrochloride) as a cross-linking agent to conjugate diclofenac to KLH (Pumford et al., 1993; Kretz-Rommel and Boelsterli, 1994; Gil et al., 1995; Wade et al., 1997). Diclofenac antisera were used in immunoblot applications without purification. Despite the use of the same coupling chemistry, differences were reported between laboratories with respect to the major protein adducts detected.

3-methylindole (3-MI)

Metabolism of 3-MI produces a reactive electrophilic intermediate, 3-methyleneindolenine, which alkylates cysteine residues on proteins (Ruangyuttikarn et al., 1992). Antigen was constructed by base-catalyzed dehydration of indole-3-carbinol to form 3-methyleneindolenine. Interaction with the carrier protein metallothionein proceeded by a Michael-type thiolate addition. The antiserum demonstrated high selectivity for the thioether adducts of 3-methyleneindolenine and was used in ELISA without further purification for comparison of organ and species reactivity (Kaster and Yost, 1997).

Sulfamethoxazole (SMX)

N-hydroxylation of SMX yields an hydroxylamine intermediate which can be acetylated or oxidized to nitroso and nitro metabolites. The nitroso metabolite is the putative species involved in covalent binding. Antigen was constructed by diazotization of SMX followed by conjugation to KLH at neutral pH. Antiserum was used in immunoblotting without further purification and detected protein adducts generated in vitro but not in vivo (Cribb et al., 1996).

Trichloroethylene (TRI)

Metabolism of TRI is expected to yield dichloroacetyl chloride as one of several reactive intermediates. Antibodies were raised against dichloroacetylated protein adducts by reacting dichloroacetic anhydride directly with the protein carrier KLH (Halmes et al., 1996). Antiserum was purified on an affinity column that had been constructed by activation of dichloroacetic acid with EDC, followed by coupling to a suspension of diaminodipropylamine immobilized agarose. Antibodies were eluted from the column at low pH (0.2 M glycine, pH 2.6) and immediately neutralized with 1 M Tris·Cl, pH 8.0.

Critical Parameters and Troubleshooting

Immunoblotting

Success with the technique is dependent on the optimization of three basic components: protein transfer, antibody binding, and detection method. The objective of optimal transfer is to obtain complete and quantitative migration of proteins out of the gel and onto the membrane. Factors that influence protein mobility and affect binding to the membrane include (1) buffer composition, (2) the presence or absence of methanol and SDS, (3) the properties of the gel itself (i.e., the percentage cross-linking and thickness), and (4) the membrane.

The buffer system should be one that has low conductivity but maintains buffering capacity. Tris-glycine buffer, pH 8.1 to 8.3, containing 10% to 20% methanol (Towbin et al., 1979) is perhaps the most commonly used for transfer of most proteins to nitrocellulose or PVDF membranes. However, since the net charge on a protein molecule determines its migration, proteins with pI equivalent to the pH of the buffer will not migrate. Transfer buffers of higher or lower pH may be required for such proteins. Different buffer systems have also been developed to increase the transfer efficiency of high-molecular-weight proteins (Bolt and Mahoney, 1997).

The inclusion of methanol and/or SDS in the transfer buffer can influence both protein transfer and binding steps. Methanol minimizes swelling of the gel during electroblotting and enhances the hydrophobic interactions be-

tween the proteins and membrane (Towbin and Gordon, 1984). Methanol is especially important for protein binding to nitrocellulose, which is less hydrophobic than PVDF. However, for proteins resolved by SDS-PAGE, methanol can strip some of the SDS from the protein, especially those of higher molecular weight (>100 kDa), resulting in protein precipitation within the gel. Addition of a low concentration of SDS (0.01% to 0.1%) to the transfer buffer can improve the efficiency of transfer, but this may vary with the properties of the membrane. PVDF will tolerate higher concentrations of SDS, whereas the detergent can reduce protein binding to nitrocellulose.

Successful transfer of proteins is also dependent on gel thickness and the percentage acrylamide and cross-linker used. Lower percentages result in more rapid and efficient transfer. For most SDS-PAGE applications, a 10% resolving gel containing 2.7% to 3.4% cross-linker with 0.5 to 0.75 mm thickness will be adequate.

Membranes can bind protein noncovalently (nitrocellulose, nylon, PVDF) or covalently (activated papers). Nitrocellulose and PVDF are the most frequently used. PVDF is more hydrophobic than nitrocellulose and offers several advantages including its ease of handling, tolerance to SDS, lower susceptibility to protein loss by desorption during the subsequent incubation steps for immunodetection, and lower background staining with ^{125}I. However, the protein-binding capacity of PVDF is less than that of nitrocellulose (100 μg/cm^2) and more stringent blocking conditions are required prior to probing with antibody.

The efficiency of transfer can be determined by staining the membrane for total protein prior to immunodetection. Ponceau S is both rapid and reversible but not very sensitive (2 μg detection limit; Harlow and Lane, 1988). India ink staining is sensitive (80 ng), permanent, and generally does not interfere with the antigen-antibody reaction (Glenney, 1986). India ink cannot be used with enzyme-based detection methods because it does not provide sufficient background contrast to the colored reaction products.

It is important to keep in mind that each antigen-antibody interaction is unique, and that much success associated with immunoassays is derived from the performance of preliminary experiments aimed at optimizing conditions. The problems that may be encountered in immunoblotting can be quite extensive, and a comprehensive discussion of them is not possible here. Some of these have been addressed as they arise at specific steps in the protocol. The detection sensitivity of immunoblotting is determined by the antibody specificity. Thus, two types of problems generally occur: (1) little or no binding of the antibody to the antigen, and (2) high background (nonspecific) staining. Poor antibody-antigen interactions may be due to low titer of antibody, and this may be evidenced by nonspecific staining of multiple protein bands. Prescreening of immune serum or affinity-purified antibody against an antibody standard by ELISA or immunoblot test strips, respectively, should permit selection of the best available batches of antibody or serum to eliminate this problem. In some cases, binding to specific target antigens will be diminished if the antibody is adsorbed by one or more components of the blocking solution. Comparison of different blocking solutions will identify the problem. Alternatively, the antibody may not recognize the antigen in its denatured form following SDS-PAGE. This can be verified with dot blots using native and denatured cell extracts and can sometimes be overcome by increasing the blocking time to permit renaturation of the proteins. Transfer conditions also may contribute to poor antigen-antibody reactions. Failure to maintain good contact between the membrane and gel during electroblotting, or precipitation of proteins in the gel as a result of high methanol concentrations, result in poor transfer and thus lowers the concentration of antigen present on the membrane. In addition, extended blotting times may result in protein loss as a result of migration completely through the membrane. Staining the gel and/or membrane with a protein stain following transfer will determine if these are contributing factors.

Two types of background staining problems are often encountered: (1) a general diffuse staining, or (2) nondiffuse, apparently specific staining of nonantigen proteins. Diffuse staining may result from insufficient blocking or nonspecific interaction of the primary or secondary antibodies with the blocking buffer. This is easily remedied by increasing blocking times or changing the blocking buffer. In some cases greater dilution of the primary or secondary antibodies may also alleviate the problem. Troubleshooting experiments in which the incubation with the primary antibody is omitted or in which different dilutions of the secondary antibody are tested in the presence of a fixed concentration of primary antibody will determine if the secondary antibody alone is contributing to the background-staining problem. Al-

ternatively, the primary antibody may be contributing to the nonspecific background. This is often observed with whole serum of low titer where the relative titers of specific and nonimmune IgG determine the signal-to-noise ratio. In such instances, affinity purification of the antibody may significantly reduce the nonspecific staining. Nondiffuse background appears as distinctly stained protein bands that do not contain the specific antigen of interest. This is most likely attributable to antibody cross-reactivity with the nonantigen. Thus, it is important to include proteins from untreated tissue or cells (negative control) along with tissues or cells known to contain covalently bound xenobiotic adducts (positive control). Any immunostaining of proteins in the negative control samples must be considered as background. Affinity purification of the antibody may also reduce this type of background binding.

Immunohistochemistry

A number of factors contribute to the success of immunohistochemical techniques, but common and most critical to all is the preservation of tissue ultrastructure without destruction of antigenic determinants. This, in turn, is dependent on the choice of methods for tissue preparation, fixation, embedding and dehydration.

During tissue preparation, tissues undergo rapid decomposition once removed from the animal. To minimize tissue/cell damage and decrease metabolic activity, thereby preserving normal ultrastructure, fixation of samples should occur as rapidly as possible, usually within 15 min following excision. The volume of the tissue sample is also critically important to ensure rapid fixation. Tissue blocks between 1 and 10 mm in at least one dimension are recommended to facilitate penetration of the fixative.

Optimal fixation should (1) minimize changes to cellular morphology, (2) result in minimal denaturation of the antigen, (3) retain the antigen in its normal pattern of cellular distribution and localization, and (4) minimize diffusion of endogenous soluble components but allow penetration of the antibody for reaction with antigen. Different tissues may fix at different rates depending on their physical characteristics. Fixation methods that work well for one tissue may not be directly transferable to another. Overfixation may cause the masking or destruction of antigens whereas underfixation may result in incomplete immobilization.

Tissues can be fixed by chemical or physical agents. Organic-solvent or precipitant fixatives, such as 100% methanol or acetone, typically require immersion of the specimen in the solvent for 15 min at −20°C and subsequent washing in buffer to return the pH to neutrality. Such fixatives, although relatively mild, are more susceptible to diffusion artifacts. Cross-linking fixatives (e.g., formaldehyde and glutaraldehyde) are excellent for preserving ultrastructure but frequently destroy antigenicity, although this may be dependent on the concentration and the antigen itself. Microwave fixation has become increasingly popular for its ability to retain both ultrastructure and antigenicity (Moran et al., 1988; Login and Dvorak, 1988, 1994). It has also been used to unmask antigens that previously had no or low immunoreactivity following conventional aldehyde fixation (Login and Dvorak, 1994). Microwave irradiation of tissues at 40° to 55°C for <50 sec is commonly used. The specimen may be immersed in either saline or a buffered aldehyde solution. However, the concentration of aldehyde is very critical for retention of morphology and antigenicity. Modified Karnovsky's fixative (0.05% v/v glutaraldehyde/2% v/v formaldehyde/0.1 M sodium cacodylate, pH 7.4/0.025% v/v calcium chloride) has been used successfully (Login and Dvorak, 1988).

Dehydration in graded solvents (i.e., ethanol) is a necessary step prior to embedding and sectioning the tissue, despite its potential for causing structural damage. Embedding medium (i.e., paraffin) facilitates the handling and sectioning of the tissue sample by providing a uniform support to stabilize it against deformation generated by the pressure of the cutting knife blade. Tissue sections of ≤5 μm in thickness are difficult to obtain with unembedded tissue. Some antibody-antigen reactions may not be compatible with fixation and embedding procedures, and in such cases frozen or cryostat sections would offer a suitable alternative.

High-resolution immmunohistochemical detection of covalent adducts generally requires optimization of both the tissue fixation and immunodetection methods. For a given antibody-antigen reaction, different fixation methods should be compared to identify a method that optimizes the preservation of both morphology and antigenicity. Also, inadequate rinsing of tissue sections or failure to restore the pH to neutral following fixation can both contribute to poor results. Reagent quality is also important. Formaldehyde-based fixatives

should be prepared from depolymerized paraformaldehyde, since commercial formaldehyde contains stabilizers and methanol that may interfere with tissue fixation (Osborn, 1994). The pH of fixation should be maintained at 7.4, since the process occurs more slowly at lower pH and may lead to artifacts.

As with other immunochemical procedures, immunohistochemistry is subject to difficulties related to nonspecific staining or high background staining. These can result from inappropriate dilutions of the primary or secondary antibodies, residual peroxidase or alkaline phosphatase activity in the tissue section, poor washing of the sections, and use of inappropriate substrate concentrations during the detection step. Quenching of residual peroxidase activity is described in step 8 of Basic Protocol 2. Problems may arise if the concentration of hydrogen peroxide used in this step falls outside of its optimal range (0.003% to 0.01% is recommended). This can be further complicated by the instability of hydrogen peroxide during storage, which may make determination of its actual concentration difficult. Residual alkaline phosphatase activity in tissue sections may be inhibited by 1 mM levamisole. This inhibitor is ineffective against the intestinal form of the enzyme, which is conjugated to the secondary antibody as the detection enzyme (Tijssen, 1985).

Proper interpretation of immunohistochemical data requires concomitant analysis of the appropriate controls. Tissue sections processed for immunohistochemistry should, where possible, include both a positive (antigen present) and negative (antigen absent) control on each slide. For antibodies raised against drug-protein adducts, this involves using tissues from drug- and vehicle-treated animals, respectively. Comparison of replicate slides should include (1) the standard incubation with primary and secondary antibodies, (2) preadsorption of primary antibody with purified drug-protein adduct or the drug itself followed by the standard incubation with the preadsorbed primary and secondary antibodies, (3) replacement of the primary antibody with preimmune serum followed by incubation with secondary antibody, and (4) incubation in the presence of secondary antibody alone. Replicates 2, 3, and 4 provide the negative controls necessary to evaluate specificity of the primary antibody and to detect any nonspecific binding.

Preparation of APAP antigen

Haptens are small compounds that are not immunogenic themselves, but which, when coupled to larger protein molecules, can elicit production of antibodies. Because of their small size, haptens can provide the epitopes for binding to recognition sites on the B cell surface, but fail to provide appropriate sites for binding to class II proteins and T cell receptors (Harlow and Lane, 1988). Conjugation of the hapten with a protein carrier provides these other important sites. All three interactions are necessary to elicit the immune response. A brief summary of factors to consider in the selection of methods for hapten conjugation is presented, but for more comprehensive information the reader is referred to other texts (Tijssen, 1985; Harlow and Lane, 1988).

Bovine serum albumin (BSA), keyhole limpet hemocyanin (KLH), and ovalbumin are the most commonly used carrier proteins (Harlow and Lane, 1988); however, the choice of coupling chemistry can vary with each hapten and the reactive sites on the protein to be modified. The latter include carboxyl, α- and ε-amino, imidazole, phenolic, and sulfhydryl groups. The reaction chemistries of protein-modifying reagents can be broadly classified into three groups (Tijssen, 1985). The first group, acylating reactions, which activate the carboxyl group on haptens for conjugation with amino groups on proteins, are the most commonly used. Haptens that lack the carboxyl moiety may require the introduction of such a group. Examples of acylating reagents include acetic or mixed anhydride and *N*-hydroxysuccinimide esters. The second group, alkylating reactions, can be used to modify sulfhydryl or amino groups; maleimides are suitable reagents for this reaction. Finally, electrophilic agents, such as diazonium salts, are useful for the modification of amino or hydroxyl groups. Direct conjugation of hydroxyl groups is generally not possible. Redox reactions are also not used for conjugation.

The use of a spacer or linker molecule between the hapten and carrier protein may be advantageous. Antibodies generated against a hapten coupled to a spacer molecule are generally directed toward the portion of the hapten farthest removed from the protein linkage, thereby improving specificity and recognition of the hapten (Tijssen, 1985). However, if a spacer molecule is used, appropriate controls are needed to determine that the linker molecule itself has not elicited antibody production. Linkers may also provide a means to select and

optimize the coupling chemistry if specific reactive groups on the hapten are either absent or to be maintained intact, or if steric hindrance must be avoided.

Optimization of the number of hapten groups per carrier-protein molecule is important for immunization. Optimal coupling ratios have been reported to range between 1 mole hapten per 50 amino acid residues (Harlow and Lane, 1988) and 10 to 20 moles hapten per mole protein (Tijssen, 1985). The reader is also cautioned against conjugating too many hapten molecules per carrier, as this may lead to immune tolerance.

Immunization

Since a number of factors may contribute to antibody variability, the following guidelines are recommended to assure consistency and reproducibility of the antibody in various immunoassays. It is important to immunize more than one animal, since not all animals will respond equally to the hapten conjugate. Serum collected from each animal should be screened by ELISA to determine titer. For anti-APAP, the serum should be able to be diluted up to 200-fold in the ELISA in order to give specificity and low background in immunoblot and immunohistochemistry. This may vary for other hapten conjugates. Once a suitable antibody has been produced, aliquots should be retained as "standards" for comparison in ELISA and immunoblots with subsequent batches of serum. It is necessary to record and label serum with bleed dates and rabbit ID. The greater the similarity between antibodies from different rabbits, the greater confidence one will have in the results.

ELISA

Immobilization of the antigen (or antibody) to the plastic surface occurs by passive adsorption. Binding is noncovalent and is generally attributed to hydrophobic interactions between nonpolar groups of the protein and the plastic support (Engvall, 1980). Important variables for protein adsorption are concentration, ratio of surface area to volume, binding capacity of the support, and time and temperature of the reaction. For most soluble proteins, 100 µl of a 1 to 10 µg/ml solution is recommended for coating the wells, with the optimal concentration determined by the binding capacity of the solid support. For example, PVC has a binding capacity of 100 ng/well (Harlow and Lane, 1988). At higher protein concentrations, leaching of antigen may occur or result in multiple protein-protein interactions (Tijssen, 1985).

Competitive ELISA assays are based on bimolecular interaction similar to that described for affinity chromatography (see below). The molecules may either be identical or different, but possess structural features similar to the epitope on the immobilized antigen. When present in solution with the antibody, a competition is established between the molecule and the bound antigen for binding to the antibody. Decreased antibody binding to the immobilized antigen results in decreased binding of the enzyme-conjugated secondary antibody and is reflected by a decrease in absorbance. The concentration of the test molecule is varied while those of the immobilized antigen and the antibody are constant. The sensitivity of the assay is dependent on the concentration of antibody as being rate-limiting but within the linear portion of the antibody dilution curve.

Affinity column

Important factors to consider for the purification of xenobiotic antibodies are choice of ligand, chromatographic support, and methods used to desorb the purified antibody from the matrix in an active form. Ligands should possess chemically modifiable groups for attachment to the support and once coupled should retain specific binding affinity for the antibody to be purified. Selection of the type of chromatographic matrix is dependent on the most suitable coupling chemistry between the ligand and support. Also important are the length and type of spacer arm on the support. The spacer arm should increase the availability of the ligand binding site to the antibody. For example, when ligands of low molecular weight are used to purify samples of higher molecular weight (as described for APAP and its corresponding antibody), a long spacer arm is preferred, to limit steric hindrance and promote accessibility. Matrices that are "activated" (e.g., epoxy-activated Sepharose) are ready for use in that they require no further modification prior to ligand coupling. Desorption of the antibody from the matrix in an active form is most easily accomplished by increasing the concentration of ligand in the elution buffer relative to that bound to the matrix. Displacement results from a concentration-dependent competition between the eluant and the immobilized ligand for the bound antibody. This method was used in the purification of the APAP antibody in Support Protocol 7. Alternatively, changes in ionic

strength or pH of the elution buffer may also release bound antibody.

The amount of chromatographic matrix to use is dependent on its binding capacity; however, in general, it is recommended that two to three times the gel binding capacity be used (Ostrove, 1990). Accordingly, the concentration of ligand should be in excess of the total binding capacity of the matrix. Following coupling, nonspecific interaction arising from unreacted sites can be significantly reduced by the addition of a blocking solution at a concentration in excess of the reactive sites on the support. Choice of the blocking agent is dependent on the chemistry of the matrix. For epoxy-activated Sepharose, 1 M ethanolamine is recommended.

As noted for anti-APAP antibody purification, the reaction time depends on the stabilities of the epoxy-activated Sepharose and ligand at the pH and temperature used for the coupling reaction. At the higher pH range, an increase in hydrolysis of the epoxide groups occurs. Higher temperatures decrease the time required for coupling. Thus both the coupling chemistry and efficiency need to be considered in defining optimal conditions.

Affinity purification

Since a number of factors may contribute to antibody variability, the following guidelines are recommended to assure consistency and reproducibility of the antibody in various immunoassays. Using an ELISA, pretest new batches of serum against standard serum prior to affinity purification. Affinity purify those batches that show the best activity in the ELISA relative to this standard. This will avoid wasting time purifying batches of serum that have little activity. Screen affinity-purified antibody using immunoblot test strips containing 20 to 30 µg of protein known to contain the adduct of interest. Control protein lacking the adduct should be used for comparison. For anti-APAP antibody, the authors use liver cytosol obtained from APAP-treated and control animals or cells. Probe the immunoblot with two or more dilutions of the antibody and detect with secondary antibody (see Basic Protocol 1). Compare results to those obtained with a previous batch of affinity-purified antibody.

The goal here is to identify a batch and dilution that gives minimal reactivity with the control protein, but which exhibits significant reactivity with the test (adducted) protein. If, as is the case with APAP, several proteins of different molecular weights are targeted, it is important that the selected antibody batch consistently detect all targets.

Anticipated Results

Appropriate design and construction of the antigen should yield antibodies of good titer, demonstrating low background and selectivity in immunoassays (ELISA and immunoblot) and immunohistochemical staining. The same antigen preparation may result in antisera of different titers as a function of the individual host animal response. Thus it is advised that at least two rabbits be immunized simultaneously for evaluation of the antigen preparation. Representative results for competitive ELISA, immunoblots, and immunohistochemistry may be found in Bartolone et al. (1988, 1989), and Emeigh Hart et al. (1995), respectively.

Time Considerations

Construction of antigen (Support Protocol 1): Three consecutive days are needed, with time allocations for the following steps: diazotization of PABA and derivatization with APAP, 2 to 4 hr; lyophilization, 24 to 36 hr; conjugation to KLH, 5 to 6 hr; dialysis of the antigen, 24 to 36 hr.

Immunization and serum collection (Support Protocol 2): Blood collection and processing of serum can be completed within 90 min; immunization requires ~30 min.

Preparation of NAPQI-protein adducts (Support Protocol 3): About 1 hr is necessary for the synthesis of NAPQI and reaction with proteins. Dialysis requires 12 to 16 hr. Approximately 2 to 3 hr is needed to determine the amount of [^{3}H]APAP associated with the protein adduct depending on the rapidity of solubilization.

ELISA (Support Protocols 4 and 5): Dilution of protein adducts and coating of microtiter plates can be completed within 1 hr; incubation after coating can either be done for either 1 hr at 37°C or overnight at 4°C depending on convenience. The remaining steps will require ~6 hr.

Affinity column preparation (Support Protocol 6): The entire procedure is completed within 24 hr with the following time allocations: matrix preparation, ~90 min; coupling, 12 to 16 hr (overnight); washing, 90 min; blocking, 4 hr; washing and equilibration, 1 hr; and packing the column, 1 hr.

Affinity purification of serum (Support Protocol 7): Two consecutive days are needed. Ammonium sulfate precipitation of serum requires ~2 hr followed by dialysis overnight.

Affinity purification can be completed within 3 to 4 hr, also followed by overnight dialysis.

Immunoblotting (Basic Protocol 1): Two days are required. SDS-PAGE and transfer are completed on the first day, requiring 6 to 8 hr for full-size gels. After the membrane is dried, subsequent incubations with antibodies and washes can be done in ~6 hr. Times for detection will vary according to the method selected; 15 to 30 min is needed for enzyme-linked detection; for ^{125}I, film exposures can range from 24 to 40 hr.

Immunohistochemistry (Basic Protocol 2): Three days are needed, two of which should be consecutive. Tissue preparation and fixation and dehydration and embedding can be completed on day 1. Subsequent steps of sectioning, rehydration and deparaffinization, protease digestion, reequilibration, and blocking each require ~1 hr. Incubation with primary antibody is for 18 to 21 hr (overnight). On day 3, washes and incubation with secondary antibody require ~1 hr and detection and mounting can be done in 90 min.

Measurement of Lipid Peroxidation

There is currently considerable interest in what is termed "oxidative stress," or the oxidation of biological macromolecules, with an emphasis on its involvement in various diseases and toxicities and on methods to limit either its occurrence or effects. This unit describes traditional methods to measure the extent or rate of lipid peroxidation—assays for conjugated dienes (see Basic Protocol 1), lipid hydroperoxides (see Basic Protocol 2), the polyunsaturated lipid breakdown product malondialdehyde (see Basic Protocol 3), and hemolysis (see Basic Protocol 4)—along with some discussion of alternative methods that have been published (see Background Information).

ASSAY FOR CONJUGATED DIENES

BASIC PROTOCOL 1

Evidence for lipid peroxidation, or the rate of initiation of the process, can be determined by assays for the formation of conjugated dienes, which arise from the rearrangement of double bonds on the polyunsaturated fatty acid (PUFA) side chain (Rao and Recknagel, 1968; Buege and Aust, 1978; Pryor and Castle, 1984; Recknagel and Glende, 1984). These conjugated dienes exhibit an absorbance maximum at 233 nm. However, partially peroxidized lipids, biological materials, and extracted contaminants tend to have overlapping absorbance at 233 nm, which may limit the applicability and sensitivity of this assay when using biological samples. To account for absorbance due to partially peroxidized lipids, difference spectra obtained from 230 to 235 nm between the partially peroxidized lipids and an equivalent amount of nonperoxidized lipids can be used. Because of the overlapping absorbance of many biochemicals, this assay is best suited for use as a measure of lipid peroxidation in in vitro lipid peroxidation systems containing purified lipid; however, the conjugated diene assay may be used to analyze biological samples provided that the lipid fraction is first partially purified by Folch extraction (see Support Protocol 1; Folch et al., 1957; Bligh and Dyer, 1959).

Materials

Aqueous lipid suspension (see recipe)
Argon-purged 2:1 (v/v) chloroform/methanol (see recipe)
Argon
Cyclohexane
45°C water bath

1. To aqueous lipid suspension add 5 vol of argon-purged 2:1 (v/v) chloroform/methanol. Mix thoroughly, and centrifuge 10 min at $1000 \times g$, 4°C, to separate the aqueous and organic layers.
2. Remove the upper aqueous layer by suction or pipetting and recover the chloroform layer, which contains the lipid. Evaporate the chloroform to dryness with a constant flow of argon and maintain at 45°C in a water bath.
3. Resuspend the lipid residue in 1.5 ml cyclohexane and determine the absorbance at 233 nm versus a cyclohexane blank.
4. Calculate the approximate concentration of conjugated dienes using the extinction coefficient of 2.52×10^4 M^{-1} cm^{-1}.

It is advisable to obtain absorption spectra to assess the possibility of interference due to end absorbance of nonperoxidized lipid and other contaminants.

ASSAY FOR LIPID HYDROPEROXIDES

Lipid hydroperoxides formed during the peroxidation of polyunsaturated fatty acids can be measured using the iodometric assay. The assay is based on the ability of lipid hydroperoxides to oxidize I^-, ultimately generating the triiodide anion, which absorbs at 353 nm. This process is represented by the following reactions.

$$2H^+ + ROOH + 2I^- \rightarrow ROH + H_2O + I_2$$
$$I_2 + I^- \rightleftharpoons I_3^-$$

Under the conditions described, lipid hydroperoxides are selectively assayed and endoperoxides—which ultimately give rise to malondialdehyde—are excluded (Buege and Aust, 1978). Although using isopropyl alcohol as the reaction solvent can reduce the unwanted oxidation of iodide, the acetic acid/chloroform mixture described below is preferable since it promotes the reaction of iodide with hydroperoxides (Mair and Hall, 1971). Oxidation can be prevented by maintaining anaerobic conditions and purging the solutions with argon (Mair and Hall, 1971; Buege and Aust, 1978). In addition, cadmium is added as a complexing agent for unreacted iodide to prevent the iodide from becoming oxidized during quantification (Buege and Aust, 1978; Pryor and Castle, 1984). The amount of hydroperoxide present at a given time will depend upon the rate of initiation as well as the rate of decomposition by heme proteins, iron, and other transition metals. This procedure is useful for the analysis of lipid peroxidation both in vitro and in vivo; however, its use in vivo may be limited since lipid hydroperoxides are readily metabolized. In addition, the data may be altered during the assay, since lipid hydroperoxides are prone to reduction by transition metal contaminants in vitro.

Materials

Aqueous lipid suspension (see recipe)
1 mM EDTA
3:2 (v/v) acetic acid/chloroform (see recipe)
1.2 g/ml potassium iodide in argon-purged H_2O (prepare immediately before use and keep on ice protected from light)
0.5% (w/v) cadmium acetate in argon-purged H_2O (prepare fresh)
2:1 (v/v) chloroform/methanol (see recipe)
Argon
Cumene hydroperoxide or *t*-butyl hydroperoxide
45°C water bath

Additional reagents and equipment for extraction and recovery of lipids (see Basic Protocol 1)

NOTE: It is essential to minimize the exposure of solutions containing iodide to oxygen.

1. Add 1 mM EDTA (or other water-soluble iron chelator; e.g., DETAPA or PDTA) to aqueous lipid suspension. Also prepare a blank without lipid, and process in parallel in the steps that follow.
2. Extract and recover the lipids as described for the conjugated diene assay (see Basic Protocol 1, steps 1 to 2).
3. While maintaining the dried sample under a stream of argon, add 1 ml of 3:2 acetic acid/chloroform to tube to resuspend the lipid residue, immediately followed by 0.05 ml of 1.2 g/ml potassium iodide. Quickly cap the vial and mix thoroughly.
4. Incubate 5 min in the dark at room temperature.

5. Add 3.0 ml of 0.5% cadmium acetate. Mix thoroughly and centrifuge 10 min at 1000 × *g*, room temperature.
6. Determine the absorbance of the upper aqueous phase at 353 nm versus that of the extracted blank (containing all components except lipid).
7. Determine absorbance for a series of dilutions of cumene hydroperoxide or *t*-butyl hydroperoxide (approximately five increments between 0 and 150 nmol hydroperoxide/sample) and use the values to construct a standard curve of absorbance versus concentration. Estimate the concentration of lipid hydroperoxide in the sample based on the standard curve.

   The extinction coefficient for cumene hydroperoxide as a standard is 1.73×10^4 M^{-1} cm^{-1} (Buege and Aust, 1978).

MEASUREMENT OF MALONDIALDEHYDE

BASIC PROTOCOL 3

Malondialdehyde (MDA) is a product of lipid peroxidation that appears to be produced in relatively constant proportion from the breakdown of polyunsaturated fatty acids. Quantification of MDA is therefore a good indicator of lipid peroxidation, particularly in vitro (Aust, 1994). Quantification of MDA is done by reaction with thiobarbituric acid (TBA) and measurement of the pink chromophore produced. This method may be used for the analysis of MDA in vivo; however, it is limited by the interference of endogenous biochemicals that react with TBA and give rise to products that exhibit absorption spectra similar to that of the TBA-MDA adduct.

Materials

Aqueous lipid suspension (see recipe)
4× TBA/TCA/HCl reagent (see recipe)
2% (w/v) butylated hydroxytoluene (BHT) in ethanol (store protected from light up to 1 month at room temperature)
1,1,3,3-Tetramethoxypropane (optional)
Boiling water bath
Spectrophotometer or spectrofluorometer

1. Prepare 1× working solution of TBA/TCA/HCl reagent by diluting the stock solution 4-fold in water. While stirring the solution with a magnetic stir bar, add BHT to a final concentration of 0.03%.

   This solution must be prepared daily and continually stirred.

2. Combine the aqueous lipid suspension and blank (without lipid) with the TBA/TCA/HCl reagent at a reagent/sample ratio of 2:1 (v/v). Mix thoroughly, and place the samples in a boiling water bath for 15 min.
3. Allow the samples to cool to room temperature and then centrifuge 10 min at 1000 × *g*, room temperature.
4. Determine the absorbance of the solution at 535 nm against the blank that contains all reagents except lipid.

   It is also advisable to obtain an absorption spectrum to ensure that the compound detected is TBA-MDA adduct; only the TBA-MDA adduct absorbs maximally at 535 nm.

5. Calculate the concentration of MDA using the extinction coefficient of 1.56×10^5 M^{-1} cm^{-1} (Wills, 1969), or by preparing a standard curve between 0 and 50 nmol MDA/sample using 1,1,3,3-tetramethoxypropane as the standard.

   The TBA-MDA adduct may also be quantified using fluorescence emission at 553 nm upon excitation at 532 nm.

BASIC PROTOCOL 4

RED BLOOD CELL LYSIS

Peroxidation of erythrocyte membrane lipids dramatically increases their susceptibility to hemolysis. As such, the lysis of red blood cells (hemolysis), or their sensitivity to hemolysis, can be used as an estimate of lipid peroxidation or as an index of oxidative stress (Pfeifer and McCay, 1971). This method is written for use with in vitro lipid peroxidation systems; however, it may be adopted for use in vivo by comparing the sensitivity of erythrocytes obtained from treated and control animals to lysis induced by decreasing ionic strength (Hogan, 1990).

Materials

Erythrocytes (see recipe)
0.9% NaCl, pH 6.8 to 7.5 (*APPENDIX 2A*; sterile filter and store up to 1 week at 4°C)

1. Incubate the components of the lipid oxidation system being investigated at 37°C with 10% (v/v) packed erythrocytes prepared in 0.9% NaCl, pH 6.8 to 7.5, or another suitable buffer (e.g., 0.1 M Tris·Cl, pH 6.8 to 7.5). Prepare a standard with the other samples by resuspending an identical amount of erythrocytes in water (this represents 100% lysis).
2. After a specific incubation time, terminate the reactions by centrifuging the samples 10 min at 10,000 × *g*, 4°C, to pellet the remaining erythrocytes and erythrocyte ghosts.
3. Measure the absorbance of the supernatant at 545 nm (hemoglobin absorbance peak) versus a water blank and the standard. Express the values as percent hemolysis, determined by the ratio of the absorbance of the sample to that of the standard.

SUPPORT PROTOCOL 1

ANAEROBIC EXTRACTION OF LIPID

The initial purification of lipid involves the selective extraction of hydrophobic lipid from other water-soluble macromolecules (Folch et al., 1957). The inclusion of specific mineral salts in the subsequent wash steps serves to increase the ionic nature of the aqueous phase, which increases the yield of lipid. In order to minimize the oxidation of lipid during the extraction, all steps should be performed at 4°C under argon, unless otherwise stated.

Materials

Tissue to be extracted (e.g. Pel-Freez Biologicals, or live animal)
Argon gas
2:1 (v/v) chloroform/methanol (see recipe)
Aqueous Folch salt (see recipe)

Erlenmeyer and vacuum flasks
Separatory funnel
Rotary evaporator
Water bath

1. Homogenize ~1 to 3 g tissue in a minimal volume (e.g., 4 vol) of argon-purged water at 4°C, then extract with 300 ml of 2:1 chloroform/methanol by stirring 5 to 10 min in an Erlenmeyer flask on ice under a constant stream of argon.

   Approximately 50 ml homogenization solution (e.g., water) should be a sufficient volume, however, volumes up to 500 ml can be extracted with 300 ml solvent. In general, the homogenization solution should be at least four times the tissue weight.

2. Remove insoluble material by filtration using a Buchner funnel (lined with glass wool or cheese cloth) and vacuum flask. Transfer the chloroform/methanol/water solution to a separatory funnel and purge with argon 10 to 15 min.
3. Add 0.2 vol argon-purged aqueous Folch salt, mix, and allow phases to separate.
4. Aspirate off the top, aqueous phase and any precipitate at the interface. Purge the air space of the funnel with argon.
5. Add 0.4 vol argon-purged modified Folch salt, mix, and allow phases to separate.
6. Repeat steps 4 and 5, except do not remove the upper aqueous phase obtained from the second wash.
7. Collect the lower organic phase into a 1000-ml round-bottom flask.
8. Evaporate the chloroform/methanol to dryness using a vacuum evaporator equipped with a water bath maintained at 50°C.
9. Resuspend the lipid residue in 5 to 10 ml of 2:1 chloroform/methanol, and purge with argon.
10. Store the lipid under argon as 1- to 3-ml aliquots at −20°C in foil-wrapped, screw-capped culture tubes. The lipid can be stored for several months under these conditions.
11. Determine the phosphorus content of lipid samples (see Support Protocol 2).

COLORIMETRIC QUANTITATION OF PHOSPHORUS

SUPPORT PROTOCOL 2

The basis of this assay is the reduction of phosphomolybidic acid by 1-amino-2-naphthol-4-sulfonic acid in the presence of sulfite to yield a blue color (Bartlett, 1958). Total phosphate is quantitated by hydrolysis of organic phosphate esters in the presence of 10 N H_2SO_4 and high temperature. Although a variety of methods can be used to quantitate lipid, the phosphorus assay is a convenient method to estimate the concentration of phospholipid.

Materials

2:1 (v/v) chloroform/methanol (see recipe)
Stock lipid (see Support Protocol 1)
1 mM phosphoric acid or 1 mM monobasic sodium phosphate
10 N H_2SO_4
30% (v/v) H_2O_2
0.22% (w/v) ammonium molybdate
Fiske-Subbarow reagent (see recipe)

18 × 150–mm test tubes
Glass marbles
Boiling-water bath
Oven heated to 150°C
Spectrophotometer

1. In 18 × 150 mm test tubes place 50 to 500 µl aliquots of a 1:100 dilution of stock lipid in 2:1 chloroform/methanol. Bring volume up to 0.5 ml with distilled water.
2. Prepare a standard curve with 1 mM phosphoric acid or 1 mM monobasic sodium phosphate. Pipet 0, 50, 100, 150, 200, 250, and 300 µl stock phosphate into separate labeled test tubes and bring the volume up to 0.5 ml with distilled water.

A typical curve should range from 0 to 300 nmol phosphorus.

3. Add 0.5 ml 10 N H_2SO_4 to each tube, cover with a glass marble, and heat 3 hr at 150°C.
4. Remove the tubes from the oven and allow to cool. Add 20 µl of 30% H_2O_2 to each tube and cover.
5. Heat tubes an additional 1.5 hr at 150°C.
6. Add 4.6 ml of 0.22% ammonium molybdate. Mix thoroughly.
7. Add 0.2 ml of Fiske-Subbarow reagent, mix, and heat in a 100°C water bath for 7 to 10 min. Cool to room temperature.
8. Determine the absorbance of samples at 660 nm using a spectrophotometer.
9. Quantitate the amount of phosphorus in the lipid samples from a standard curve of absorbance versus phosphorus concentration.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acetic acid/chloroform, 3:2

Working at <4°C, combine 3 vol glacial acetic acid with 2 vol chloroform. Purge with argon for 15 min. Seal in a glass container and allow the solution to reach room temperature prior to use. Store up to 1 month at 4°C.

Mixing must be done at <4°C to prevent unequal evaporation of the components.

Aqueous Folch salt

0.04 g $CaCl_2$
0.034 g $MgCl_2$
0.58 g NaCl
100 ml H_2O
Store up to several months at 4°C

Be sure to account for water weight when weighing mineral salts.

Aqueous lipid suspension

Prechill sonicator probe in an ice-water bath. Place ~10 µmol of lipid phosphorus (stored as a stock solution in 2:1 chloroform/methanol; see Support Protocol 1) into a thin-walled plastic tube and evaporate the solvent under a constant stream of argon. Add 1 ml of argon-purged assay solution (e.g., 50 mM NaCl) and cap the tube with a rubber stopper under a stream of argon. Keeping the lipid sample in an ice-water bath, sonicate it ~5 min using a sonication current of ~10 amps. Determine the concentration of lipid phosphorus present as a suspension (see Support Protocol 2).

Sonication is be performed anaerobically to minimize lipid oxidation.

Chloroform/methanol, 2:1

Combine 2 vol chloroform with 1 vol methanol. Purge with argon for 15 min at 0°C prior to use. Store indefinitely at 4°C.

Erythrocytes

Collect whole blood in sterile containers containing 10% (w/v) heparin as an anticoagulant. Centrifuge 10 min at 10,000 × *g*, 4°C, to isolate red blood cells. Remove the supernatant and the whitish buffy coat with a pipet. Wash the red cells three times as follows: resuspend in 0.9% (w/v) NaCl, pH 6.8 to 7.5 (*APPENDIX 2A*), and then centrifuge 10 min at 10,000 × *g*, 4°C. Store under argon at 4°C (can be stored for several days before becoming too fragile to use).

Fiske-Subbarow reagent

Combine 0.5 g 1-amino-2-naphthol-4-sulfonic acid, 30 g sodium bisulfite, and 1 g sodium sulfite as a dry mixture. Add 0.158 g of this mixture per milliliter of H_2O to make a saturated solution. Stir and filter. Prepare this solution immediately before use. Protect from light.

Modified Folch salt

Combine chloroform, methanol, and aqueous Folch salt in a 3:48:47 ratio. Store in a glass screw-cap container up to several months at 4°C.

TBA/TCA/HCl reagent, 4×

150 g trichloroacetic acid (15% final)
500 ml H_2O
20.8 ml concentrated HCl (0.2 N final)
3.7 g thiobarbituric acid (0.37% final)
H_2O to 1 liter
Heat to 70°C
Store up to several months at room temperature
Discard reagent if a precipitate forms

Heating helps dissolve the TBA.

COMMENTARY

Background Information

Oxidation of biomolecules by mechanisms other than "normal" oxidative metabolism can potentially be detrimental. Oxidation of DNA, for example, may be involved in carcinogenesis and other diseases. Oxidation of protein has also been proposed to be involved in disease, as well as in the aging process. DNA and protein oxidation are relatively new subjects of research into oxidative stress in comparison to lipid oxidation and its role in diseases and toxicities, for which extensive and long-established literature exists.

Because lipid oxidation (generally referred to as lipid peroxidation since lipid peroxides are intermediates in the process) has been linked to a variety of toxicities and pathological conditions, accurate methods for quantifying this process both in vitro and in vivo are needed. Unfortunately, the transient nature of the intermediates and products of lipid peroxidation, as well as the potential for interference by other endogenous compounds, makes the accurate quantification of lipid peroxidation in vivo extremely difficult. As a result, the study of lipid peroxidation, in many instances, is performed using in vitro model systems. In vitro lipid peroxidation systems overcome many of the difficulties associated with the study of lipid peroxidation in vivo; however, results obtained with such systems may not necessarily reflect the susceptibility and/or capacity of a tissue to undergo lipid peroxidation in vivo. The key difference is due primarily to the removal of factors that can either promote or prevent the initiation or termination of lipid oxidation in vivo (i.e., the type of lipid, antioxidant systems, transition metals). As such, the development of assays suitable for the analysis of lipid peroxidation both in vitro and in vivo is presently a priority. This unit describes the basic procedures and improvements for several assays that are frequently used to assay for lipid peroxidation and the advantages and disadvantages of each assay under different conditions.

Lipid peroxidation was most likely first recognized because of the unique susceptibility of PUFA to oxidation. This may be due to the vulnerability of lipid side chains to hydrogen abstraction from their methylene carbon(s) (LH). These methylene hydrogens have relatively low bond energy, resulting in a predisposition to abstraction. In addition, the resulting lipid radical (L·) undergoes structural rearrangement to the conjugated diene, whose relative stability helps to drive the initial oxidation reactions. The lipid radical also readily reacts with molecular oxygen to generate a lipid peroxyl radical (LOO·). Lipid peroxyl radicals can be reduced to generate lipid hydroperoxides (LOOH) by abstraction of an additional hydrogen from another PUFA side chain to continue the peroxidation process. This is termed propagation. In addition, lipid, lipid alkoxyl, and lipid peroxyl radicals may also be reduced by lipophilic antioxidants such

as vitamin E (α-tocopherol), which limits, and therefore terminates, propagation of lipid peroxidation. However, lipid hydroperoxides are also very reactive, particularly with reduced transition metals and hemoproteins. For example, lipid hydroperoxides will react with hemoglobin to produce lipid alkoxyl radicals (LO·), which can also propagate lipid peroxidation.

Systems used to study lipid peroxidation in vitro generally consist of transition metals, such as iron, and either a reductant or an oxidant of the metal, depending upon the metal's oxidation state. Ascorbic acid has been used extensively as a reductant of ADP-chelated ferric iron in a reaction that results in the initiation of lipid peroxidation (Miller and Aust, 1988). The maximum rate of lipid peroxidation was observed when a 1:1 molar ratio of ferric iron/ascorbic acid was used. Likewise, when H_2O_2 was used as an oxidant of ADP-chelated ferrous iron, the maximum rate of lipid peroxidation was observed when the concentration of H_2O_2 was enough to generate a 1:1 ratio of Fe(II):Fe(III) (Minotti and Aust, 1986). The rate of lipid peroxidation did not correlate with the rate of hydroxyl radical generation, indicating that the ·OH radical was probably not responsible for the initiation of lipid peroxidation. The authors proposed that the formation of a Fe(III)-O_2-Fe(II) complex was essential for the initiation of lipid peroxidation, and the rate was ultimately dependent upon the relative concentrations of ferric and ferrous iron (Minotti and Aust, 1986; Miller and Aust, 1988). However, the formation of this complex is debated, because the requirement for dioxygen in the complex cannot be proven since oxygen is required for lipid peroxidation.

Because free iron is capable of catalyzing a variety of deleterious reactions in the presence of oxygen, the probability that high concentrations of free iron exist in vivo is small. Although the existence of a low-molecular-weight chelated pool of iron has been proposed, attempts to isolate this form of iron have thus far been futile. In vivo, iron is primarily found complexed with proteins; ferritin is responsible for the storage of iron in vivo, and represents the single most concentrated pool of iron in cells. To more closely model the source of iron within cells, redox-cycling xenobiotics capable of mobilizing iron from ferritin, such as the bipyridyl herbicides paraquat and diquat (Saito et al., 1985; Thomas and Aust, 1986a) and the anthracycline antibiotics daunomycin and adriamycin (Thomas and Aust, 1986b; Li, 1991), were used to mobilize iron from ferritin and to initiate lipid peroxidation. The toxicity of these chemicals has been attributed to reduction by NADPH-cytochrome P-450 reductase and subsequent redox cycling with dioxygen (Bus et al., 1974; Bachur et al., 1979). In addition it has been shown that iron chelators such as Desferal mitigate the toxic effects of these substances, indicating a role for iron in the toxicity (Herman and Ferrans, 1983; Kohen and Chevion, 1985). It has been shown in vivo that diquat causes a decrease in the amount of iron associated with ferritin isolated from the livers of treated animals (Reif et al., 1988). In addition, exposure to paraquat and adriamycin causes an increase in lipid peroxidation in vivo (Bus et al., 1974; Goodman and Hochstein, 1977). Redox cycling of adriamycin and paraquat in vitro efficiently reduced and mobilized ferrous iron from ferritin and ultimately provided the iron complex needed to initiate lipid peroxidation (Saito et al., 1985; Thomas and Aust, 1986a,b; Li, 1991). The rate of ferritin-dependent lipid peroxidation was affected by the rate of iron release, the type and concentration of iron chelator(s) present, and the concentration of ferrous iron oxidants; increasing the rate and extent of ferrous iron oxidation, by treatment with chelators or H_2O_2, decreased the rate of lipid peroxidation by affecting the formation and maintenance of the needed 1:1 Fe(II)/Fe(III) ratio. These studies suggest that a plausible mechanism of toxicity for redox-cycling xenobiotics is mobilization of iron from ferritin and the subsequent initiation of lipid peroxidation.

Assays for lipid peroxidation (i.e., using conjugated dienes, hydroperoxides, and MDA as substrates) have been reported in the literature for many years. Although these assays have limitations, they are still valid for measuring lipid peroxidation in many situations (Slater, 1984). In addition, several useful improvements have been developed to enhance the specificity and applicability of these assays.

The oldest, simplest, and least time-consuming lipid oxidation assay methodology is the TBA test for MDA (Bird and Draper, 1984). MDA results from the decomposition of lipid endoperoxides during lipid peroxidation and/or during the assay, both catalyzed at least in part by transition metals. The TBA test can also be used to estimate the concentration of lipid hydroperoxides. This is achieved by comparing the amount of TBA-MDA adduct

formed in the presence and absence of an antioxidant (0.03% BHT); BHT inhibits the formation of MDA during the assay due to hydroperoxide-dependent lipid peroxidation, initiated by transition metal-dependent decomposition of lipid hydroperoxides (Wills, 1964; Aust, 1994). The assay of MDA using the TBA test is not specific for MDA but rather detects a variety of lipid breakdown products (Halliwell and Gutteridge, 1984). As a result, the data are frequently expressed in terms of thiobarbituric acid–reactive substances (TBARS). Fortunately, the TBA-MDA adduct exhibits a rather unique absorbance maximum at 535 nm, as well as a fluorescence emission at 553 nm upon excitation at 532 nm (Halliwell and Gutteridge, 1984). For this reason, the TBA test is exceptionally useful for in vitro studies of lipid peroxidation, where purified lipid is tested. As such, the TBA test is not particularly well suited for the analysis of MDA in vivo since the oxidation products of several endogenous compounds (e.g., sucrose, ascorbate, and deoxyribose) tend to react with TBA to give rise to adducts that exhibit an absorbance spectrum similar to, and may in fact be, MDA. In addition, MDA is readily metabolized by microsomal aldehyde dehydrogenases, and thus has a very short half-life in vivo (Halliwell and Gutteridge, 1984). For these reasons, the TBA test for MDA is not always appropriate for analysis of MDA in vivo. However, if specific measurement of MDA is desired, several sensitive methods for detecting the TBA adduct of MDA have been developed using high-performance liquid chromatography (HPLC; Esterbauer et al., 1984; Young and Trimble, 1991; Li and Chow, 1994; Londero and Lo Greco, 1996). In general, analysis of MDA using HPLC requires the extraction of the TBA-MDA adduct with isobutyl alcohol, followed by separation using HPLC, and then detection of the TBA-MDA adduct using UV-absorption or fluorescence-emission spectroscopy. In addition, very sensitive methods utilizing gas chromatography–mass spectrometry (GC-MS) have been developed to assay for MDA (Yeo et al., 1994). HPLC and GC-MS methods are very sensitive and more selective; however, they are considerably more time consuming because of sample processing.

Another popular method used to assay for the oxidation of PUFA is monitoring the formation of lipid hydroperoxides. Direct measurement of lipid hydroperoxides has several advantages over the TBA test in that it measures only lipid hydroperoxides, can give information relative to the rate of initiation of lipid peroxidation, is independent of the type of fatty acids constituting the lipid membrane, and is specific for the oxidation of lipid. A simple method for estimating hydroperoxide formation is by monitoring the decrease in dissolved oxygen concentration during lipid peroxidation using an oxygraph equipped with a Clark-type electrode (Halliwell and Gutteridge, 1984). Alternatively, the susceptibility of hydroperoxides to redox reactions may be exploited to quantify the amount of lipid hydroperoxide present. A common method of this type used to assay for lipid hydroperoxides is the iodometric assay (Mair and Hall, 1971; Buege and Aust, 1978; Pryor and Castle, 1984; Recknagel and Glende, 1984). The crux of the iodometric assay is the formation of the triiodide anion upon oxidation of iodide by lipid hydroperoxides. The specificity of this assay for lipid hydroperoxides is achieved by first performing a Folch extraction for lipids (see Support Protocol 1; Folch et al., 1957) with chloroform/methanol (2:1); extracting the lipid removes potential endogenous oxidants of iodide, including H_2O_2 (Wills, 1969; Buege and Aust, 1978). When performing the iodometric assay, it is absolutely essential to minimize the exposure of solutions containing iodide to oxygen; exposure to oxygen will promote the oxidation of iodide and give rise to high background concentrations of I^{3-} (Pryor and Castle, 1984). In addition, to minimize decomposition of the hydroperoxides during this assay, it is advisable to include a water-soluble iron chelator (e.g., EDTA or desferrioxamine) to minimize the coextraction of iron (Buege and Aust, 1978). In the absence of an effective iron chelator, the iron will associate and extract with the lipid, ultimately interfering with the analysis.

A second method for analyzing lipid hydroperoxides utilizes hemoglobin to catalyze the oxidation of methylene blue derivatives (Yagi et al., 1996). In this assay, lipid hydroperoxides oxidize hemoglobin, which in turn catalyzes the oxidation of methylene blue. The oxidized product of methylene blue can be quantified spectrophotometrically at its absorbance maximum. In addition, HPLC and GC-MS methods for the analysis of specific lipid hydroperoxides or their reaction products have been developed (Van Kuijk et al., 1985a,b; Yamamoto et al., 1986; Tokumaru et al., 1995).

The assay of lipid hydroperoxides is a sensitive index of lipid peroxidation both in vitro and in vivo. However, the in vivo assay may

be limited by the short half-life of lipid hydroperoxides, which results from metabolism by a variety of enzymes including glutathione peroxidase and prostaglandin synthase. In fact, several methods have been developed to quantify lipid hydroperoxides using glutathione peroxidase or another peroxidase (Heath and Tappel, 1976; Marshall et al., 1984). Enzyme-based assays for lipid hydroperoxides are quite sensitive and in some cases selective for the type of hydroperoxide; however, they are quite arduous.

Another method to directly measure the rate of initiation of lipid peroxidation is to assay for the formation of conjugated dienes resulting from rearrangement of lipid radicals. Detection of conjugated dienes can serve as a sensitive method for assaying lipid peroxidation both in vitro and in vivo. Folch extracts of biological samples and of pure lipid used within in vitro lipid peroxidation systems can be analyzed for changes in absorbance at 233 nm. This method is quite simple and can be used for a variety of sample types (Buege and Aust, 1978). It has, for example, been used by Rao and Recknagel (1968) to show changes in the concentrations of conjugated diene in rat liver following the exposure of test animals to carbon tetrachloride (a potent hepatotoxin that manifests its toxicity, in part, as lipid peroxidation).

Lysis of red blood cells is also a good index for lipid peroxidation and oxidative stress (Pfeifer and McCay, 1971). Although erythrocyte lysis may not be directly proportional to the peroxidation of membrane lipids, measurement of erythrocyte lysis can provide an estimate of oxidative damage that involves lipid peroxidation. In addition, the fragility of the erythrocyte membrane can be assessed by a simple modification of the hemolysis assay in order to obtain information on the extent of oxidative damage to the membrane; lipid peroxidation leads to an increase in membrane fragility and decreased fluidity, thus increasing the sensitivity of erythrocytes to osmotic lysis (Pfeifer and McCay, 1971; Hogan, 1990). The hemolysis assay is by far the simplest method to assay oxidative damage to membranes and may be used in concert with the other methods discussed within this unit to characterize the peroxidation of lipid membranes under a specific set of conditions. In addition, the hemolysis assay can be adopted for use with animals; comparing the hemolysis of erythrocytes isolated from both treated and control animals can serve as an index of oxidative damage to lipid membranes in vivo (Hogan, 1990).

When planning experiments that utilize lipid peroxidation as a measure of oxidative stress, it is essential to use a method of analysis that will generate the information the experiments are designed to provide. It is also advisable to fully understand the mechanisms of the reaction used to oxidize the lipid so that the data obtained from the experiments in vivo can be appropriately interpreted. For simple in vitro experiments designed to elucidate the effects of a specific chemical on lipids, all of the assays discussed in this unit are suitable, differing only in the ease of the procedure and the point in the peroxidation process being monitored. Unfortunately, there is no perfect assay for studying lipid peroxidation in vivo; however, several modifications of the assays discussed have permitted their use as an index of lipid oxidation in vivo. For example, the TBA test has been used on biological samples to accurately quantitate MDA by altering the experimental conditions such that interfering substances are not detected and/or do not react with TBA. Using this procedure, samples are first exposed to potassium iodide to reduce any lipid hydroperoxides present, and then reacted with TBA at 60°C. The TBA-MDA adduct is extracted into isobutyl alcohol, separated by HPLC, and detected using fluorescence-emission spectroscopy. This modified TBA test allows more specific and accurate determination of MDA in biological samples (Li and Chow, 1994). Although the procedures discussed in this unit are directed towards the study of lipid peroxidation in vitro, analysis of extracted biological samples by identical procedures permit their use in the study of lipid peroxidation in vivo.

Critical Parameters

The most crucial aspect of any lipid peroxidation study is careful selection of an appropriate assay that can fulfill the objectives of the experiment. A second important issue is the need to fully understand the assay. For example, lipid hydroperoxides are extremely labile, and thus susceptible to decomposition both in vivo and in vitro; assaying for lipid hydroperoxide is not advisable when metals such as iron are used to initiate lipid peroxidation. When transition metals are used to initiate lipid peroxidation, extreme care must be taken to remove and/or minimize the presence of transition metal contaminants in reagents used in the analysis procedure (Buege and Aust, 1978). It

is also important to remove contaminating transition metals to prevent the misinterpretation of results. A common method for removing transition-metal contaminants from solutions is chromatography over Chelex 100 resin (Bio-Rad). When buffers that chelate metals (e.g., acetate, Tris, phosphate) are used, it may be necessary to extract the metals using iron chelators such as phenanthroline dissolved in amyl alcohol. This extraction is necessary because the buffers have a higher binding affinity for certain metals than does Chelex; therefore, buffers and salts undergo ligand-exchange reactions with the metals complexed with the resin, ultimately removing the metals from the resin.

It is absolutely necessary to be cognizant of the probability that transition metal contaminants are present in the preparations of almost all chemicals and reagents, and that substantial amounts of metal contaminants may be introduced by common laboratory instruments and supplies such as syringes and glassware (Buettner, 1990; Buettner and Jurkiewicz, 1996). It is a popular misconception that chemicals such as ascorbic acid, cysteine, and hydroquinones autoxidize or undergo direct one- or two-electron transfer reactions with dioxygen to generate O_2^- and H_2O_2, respectively. The direct reaction of dioxygen with singlet molecules such as ascorbate is, in some instances, thermodynamically favorable. However, due to the spin restriction associated with the reaction of singlet molecules with triplet molecules (such as dioxygen) as a result of the ground electronic character of dioxygen, this reaction is kinetically inhibited ($<10^{-5}\ M^{-1}\ s^{-1}$) and requires a transition metal catalyst, such as iron (Miller et al., 1990). Ferric iron is reduced to ferrous iron by a variety of chemicals, and ferrous iron can catalyze the sequential one-electron reduction of dioxygen in the Haber-Weiss reactions. Thus, transition metals play a multifaceted role in the oxidation of chemicals; transition metals can serve as a primary oxidant, or as a means of altering the ground-electronic character of dioxygen such that oxygen radicals are generated and the reaction between singlet molecules and oxygen can occur. The resulting redox cycle between the metal, oxygen, and chemical continues until all the available reductant is oxidized. A good test for iron contamination in solutions is described by Buettner (1990). This method is based on the oxidation of ascorbic acid by metal-contaminated reagents. Ascorbate oxidation can be monitored spectrophotometrically as a decrease in absorbance at 265 nm or by electron-spin resonance (ESR) spectroscopy to measure the formation of the ascorbyl radical. It is always advisable to assess the possibility of iron contamination in reagents used to study lipid peroxidation, because it will undoubtedly affect the quality and interpretation of the data (Buege and Aust, 1978; Aust, 1994).

An additional precaution to prevent unwanted lipid oxidation is to limit exposure to light and maintain anaerobic conditions as much as possible in handling the lipid. To eliminate oxygen, argon should be continually blown over the top of solutions containing lipid. Argon is generally preferred over nitrogen since it is slightly heavier than air and tends to remain layered over the top of the solution during transfer steps. This procedure is extremely important during the extraction of lipids and subsequent evaporation of solvents where iron contaminants may be present.

Anticipated Results

The results obtained from in vitro lipid peroxidation experiments will vary, depending primarily upon the experimental conditions used to oxidize the lipid, the method used to measure peroxidation, and the type of fatty acid used. However, the results obtained for a given set of experiments can be extremely precise provided consistent technique is used to execute the particular procedure. When enough research is done prior to performing the assays and the proper controls are included, excellent results can be obtained with little difficulty. In general, the extent of lipid peroxidation observed during in vitro lipid peroxidation studies will be significantly greater, with less variation in the data, than is seen when studying lipid peroxidation in vivo. Inherent differences in metabolism of the products being assayed, individual differences in susceptibility to oxidative damage, and differences in the concentrations of endogenous compounds that can potentially interfere with the assay all contribute to the higher percentage error of in vivo studies. Nonetheless, data obtained from experiments in vivo are generally sufficiently meaningful to allow basic conclusions to be drawn regarding the oxidative processes that occur under a given set of conditions.

Time Considerations

The time required to complete a lipid peroxidation experiment will vary with the assay and the experimental conditions. In general,

however, the following amounts of time should be allotted for the respective assay: assay for conjugated dienes: 1 to 1.5 hr; assay for lipid hydroperoxides: 1 to 2 hr; measurement of malondialdehyde (MDA): 0.5 to 1 hr; red cell lysis: 0.5 to 1 hr.

Measurements of Intracellular Free Calcium Concentration in Biological Systems

Calcium is a very closely regulated ion in both serum and interstitial fluid and within the cytosol of every type of cell. Ion-specific electrodes and dyes whose absorbance spectra change upon binding calcium have allowed accurate measurement of serum and interstitial free calcium concentration ($[Ca^{2+}]$) for years; however, it is only recently, with the advent of calcium-specific fluorescent probes, that rapid, accurate measurement of intracellular free Ca^{2+} concentration has been possible. The sensitivity of the fluorescence technique permits measurement with amounts of probe small enough to avoid most problems with probe toxicity, while K_d's for calcium binding (down to hundreds of nanomolar) permit accurate measurement of intracellular $[Ca^{2+}]$. Techniques that permit these probes to be loaded into the cell in a membrane-permeable form with conversion to a membrane-impermeable, Ca^{2+}-sensitive form by the action of intracellular enzymes permit convenient loading and use of these new probes.

Intracellular $[Ca^{2+}]$ measurements are performed today using several approaches, most of which make use of fluorescent probes: (1) measurements on suspensions of cells using fluorescence spectroscopy (see Basic Protocol 1); (2) measurements on plated cells using single-cell photometry or ratio detection by means of fluorescence digital imaging microscopy (FDIM; see Basic Protocol 2) or confocal microscopy with digital imaging capability; (3) measurements using flow cytometry techniques; and (4) measurements using the bioluminescent peptide aequorin. Measurements on suspensions of cells using fluorescence spectroscopy and measurements on plated cells using FDIM are the most commonly used approaches to measurements of intracellular $[Ca^{2+}]$, in part because confocal microscopy and flow cytometry require special and expensive equipment. For this reason, and because many of the techniques used to obtain measurements of $[Ca^{2+}]$ with a confocal microscope or single-cell photometry are similar to those used with FDIM, these techniques will not be discussed separately. The focus here will be on these more commonly used approaches.

This unit contains protocols for spectroscopic measurement using ratiometric (see Basic Protocol 1) or nonratiometric probes (see Alternate Protocol) as well as FDIM using ratiometric (see Basic Protocol 2) and nonratiometric probes. In addition there are protocols for determination of K_d in suspension (see Support Protocol 1) and plated cells (see Support Protocol 2).

CAUTION: Material safety data sheets (MSDSs) can be obtained from the vendor or via the Internet at *http://siri.org/msds/index.html* for hazardous chemicals. Chemicals dissolved in DMSO, which aids in the absorption of solutes directly through the skin, are especially hazardous.

STRATEGIC PLANNING

The first choice is that of the fluorescent probe to be used. Some Ca^{2+} probes change their excitation or emission spectra upon binding Ca^{2+}, while others change their extinction coefficient or quantum yield (number of photons emitted to number of photons absorbed). Those that change their spectra are referred to as "ratiometric probes." Ratiometric probes have significant advantages over nonratiometric probes in measurement of intracellular $[Ca^{2+}]$ and should be used unless there are technical reasons (to be discussed below) for using a nonratiometric probe. A good discussion of the properties of the various probes is contained in Kao (1994).

Current Protocols in Toxicology (1999) 2.5.1-2.5.52

Table 2.5.1 Properties of Various Ratiometric Ca^{2+} Fluorescent Indicators[a]

Indicator	Low-Ca^{2+} Properties			High-Ca^{2+} Properties			Approx. K_d (nm)[b]
	Ex. (nm)	$\varepsilon \times 10^{-3}$ ($cm^{-1}M^{-1}$)	Em. (nm)	Ex. (nm)	$\varepsilon \times 10^{-3}$ ($cm^{-1}M^{-1}$)	Em. (nm)	
Bis-fura	366	49	511	338	59	504	525
Fura-2[c]	363	28	512	335	34	505	224
Fura-PE3[c]	364	28	508	335	34	490	204
Fura red[d]	472	29	657	436	41	637	224
Indo-1[e]	346	33	475	330	33	401	250

[a]This information was obtained from Molecular Probes and Texas Fluorescence Laboratories (TEFLABS). Abbreviations: Ex., peak excitation; ε, extinction coefficient; Em., peak emission in aqueous media.

[b]Approx. K_d is given in the presence of 1 mM Mg^{2+}, since experiments depend upon the K_d inside cells, which contain Mg^{2+} close to this value.

[c]The quantum yield of the low-Ca form is ~0.25; that of the high-Ca form is ~0.46.

[d]The fluorescence quantum yield of Fura red is low, ~0.013 in Ca^{2+}-free solution.

[e]The quantum yield of the low-Ca form is ~0.38; that of the high-Ca form is about ~0.56.

Table 2.5.2 Properties of Various Non-ratiometric Ca^{2+} Fluorescent Indicators[a]

Indicator	Low-Ca^{2+} Properties			High Ca^{2+} Properties			Approx. K_d (nM)[b]
	Ex. (nm)	$\varepsilon \times 10^{-3}$ ($cm^{-1}M^{-1}$)	Em. (nm)	Ex. (nm)	$\varepsilon \times 10^{-3}$ ($cm^{-1}M^{-1}$)	Em. (nm)	
Calcium green 1[c]	506	81	531	506	82	531	190
Calcium green 2	506	95	536	503	147	536	550
Calcium orange	549	80	575	549	80	576	185
Calcium crimson	590	96	615	589	92	615	185
Fluo-3[d]	503	90	526	506	100	526	390
Oregon green 488 BAPTA-1[c]	494	76	523	494	78	523	170
Oregon green 488 BAPTA-2	494	105	523	494	140	523	580
Rhod-2	549	79	581	552	82	581	570

[a]This information was obtained from Molecular Probes and Texas Fluorescence Laboratories (TEFLABS). Abbreviations: Ex., peak excitation; ε, extinction coefficient; Em., emission in aqueous media.

[b]Approx. K_d is given in the absence of Mg^{2+}, Since the K_d inside of cells is what is really measured, and cells contain ~0.5 mM Mg^{2+}, the K_d inside of cells is likely to be much higher than this value.

[c]The fluorescence quantum yield is high, ~0.75 in high Ca^{2+} solution.

[d]The fluorescence quantum yield is ~0.18 in high Ca^{2+} solution.

The most commonly used ratiometric probes are Fura-2 and Indo-1. The primary disadvantages of these two probes are that they are excited in the ultraviolet and can suffer considerable interference from the autofluorescence of cells. Fura-2 is very resistant to photobleaching. Indo-1 has a greater tendency to partition into mitochondria (see Table 2.5.1 for a list of the properties of the useful ratiometric probes). Fura PE-3 is similar to Fura-2, except it is much more leakage-resistant and should be used if leakage of probe over the time course of an experiment is a problem. The probe bis-Fura is similar to Fura-2, except it has a much higher K_d and must be microinjected into cells before use; however, it has a high extinction coefficient and quantum yield and hence is very bright. Fura red has the advantage of being excited in the visible range but the disadvantage of having a low quantum yield. The most commonly used nonratiometric probes are Fluo-3 and Rhod-2. Fluo-3 is generally used in situations where rapid changes in calcium must be followed, since it binds calcium rapidly; however, significant binding to proteins affects its K_d. Rhod-2 is generally used when it is desired to follow calcium in mitochondria, since the majority of Rhod-2 is converted inside mitochondria because of its positive

charge in the AM form (Trollinger et al., 1997; see Table 2.5.2 for a list of the properties of the useful nonratiometric probes). Calcium green 1 and 2 and Oregon green 488 BAPTA 1 and 2 have quantum yields of 0.75 as compared to 0.18 for Fluo-3, which means that they can be less phototoxic to cells than Fluo-3 because less is needed. Calcium orange and calcium crimson, because of their excitation wavelengths, should have less interference from autofluorescence. However, calcium crimson tends to compartmentalize in some cell types.

The choice of probe depends on the available equipment, whether anything that interferes with any specific probe must be present in the experiment, in what location the $[Ca^{2+}]$ is to be measured, and the sensitivity. Ratiometric probes can give higher accuracy of $[Ca^{2+}]$ determination and are largely insensitive to variations in probe concentration. In some toxicological experiments, heavy metal ions may be present that can quench the fluorescence of some probes or that can bind to the probe and distort the spectra. These effects vary with the probe selected. Sometimes multiple probes are to be used in an experiment and the wavelengths to be used with the selected probe must not interfere with those of another probe to be used. Very often, the vendors of the fluorescent probes can give sound advice as to the best probe to choose to measure intracellular $[Ca^{2+}]$ in a given experiment.

If more than one type of instrument is available (spectrofluorometer, digital imaging microscope, single-cell ratio detection, or confocal microscope), the second choice involves what instrument to use. When one is interested in the statistical behavior of a large number of cells and how the average Ca^{2+} levels change, and when the Ca^{2+} transient behavior of the individual cells is not important, then a spectrofluorometer is the instrument of choice. A spectrofluorometer usually has simpler optics, a wide range of wavelength response, and excellent sensitivity. Disadvantages are that it requires suspended cells (which often behave differently from plated cells and from cells in vivo). In addition, it requires a larger number of cells for each sample than the plated-cell techniques, and probe leakage can cause severe errors in the measurement of internal free Ca^{2+}. When one is interested in the differential responses of a group of individual cells, the digital imaging microscope is the instrument of choice, since the individual responses of a large group of cells can be compared in the same field of view. In addition, if the cells are difficult to keep in suspension, it is still possible to get an idea of the statistical behavior of these cells by using this technique, which employs plated cells. Far fewer cells are needed for digital imaging microscopy than for fluorescence spectroscopy. Fluorescence digital imaging microscopy (FDIM) is good for following the behavior of free Ca^{2+} in the cytosol (including following Ca^{2+} transients), but unless the cell is very flat, this technique is not ideal for observing free Ca^{2+} in compartments such as mitochondria. Another common disadvantage of FDIM is a limited range of permitted intensity values (commonly 256). If one needs to follow free Ca^{2+} in compartments such as mitochondria or the nucleus, it is better to use a confocal microscope. The confocal microscope can have the same problems with limited range of intensity values as digital imaging microscopy. Its primary advantages are better resolution and its ability to produce a three-dimensional image of the cell. However, it requires higher light exposure, which increases the possibility of photodamage to the cells, and it requires the use a laser for excitation, which limits the probes that can be used. The last technique is single-cell ratio detection. This technique uses a microscope in conjunction with a photomultiplier rather than the SITS or CCD camera of digital imaging. It can be used to observe a group of plated cells in the same way that fluorescence spectroscopy observes a group of cells in suspension and it can be very sensitive. It has the advantages of the digital imaging microscope in that leakage of probe from the cell does not generally cause interference by the external probe, and it uses far fewer cells per experiment than the cuvette system uses. It can also be used to observe single cells, but is inefficient in this mode if sample additions to the plate cause

irreversible changes to all of the cells on the plate, in which case it is possible to observe only one cell per plate.

BASIC PROTOCOL 1

MEASUREMENT OF INTRACELLULAR [Ca^{2+}] USING FLUORESCENCE SPECTROSCOPY

Where sources of fluorescence (fluorophores) behave independently—i.e., do not transfer energy to or from one another—the total emission at a given wavelength, $\lambda_{m,}$ due to excitation at another wave length, λ_x, can be looked upon as the sum of the contributions from each type of fluorescent molecule present, including the specific probe or probes of interest. Under these conditions, a specific excitation and emission spectrum can be associated with each fluorescent species. Examples of fluorescent species are the Ca^{2+} probe of interest with a Ca^{2+} ion bound, the Ca^{2+} probe of interest without a Ca^{2+} ion bound, or the common endogenous fluorophore NADH. In general, if there is no energy transfer, one could attempt to analyze an experimental spectrum into its component parts where each part is due to a separate fluorescent species. This approach of separating the experimental spectrum into its component parts by curve (spectrum) fitting is the basis of the fluorescence spectroscopic analysis technique for determining [Ca^{2+}] (Gunter et al., 1988, 1990).

The same assumptions lead to the equations usually used in determining [Ca^{2+}] when fluorescent probes are used. In the following equation:

$$\left[Ca^{2+}\right] = K_d\left[\left(F - F_{min}\right)/\left(F_{max} - F\right)\right]$$

Equation 2.5.1

where F is the fluorescence emission of the sample containing the Ca^{2+} probe, at any wavelength, F_{min} is the fluorescence of the sample with no Ca^{2+} bound, and F_{max} is the fluorescence of the sample saturated with Ca^{2+}(Grynkiewicz et al., 1985). K_d is the apparent dissociation constant of the probe for Ca^{2+} within the cell. Any background contributions that do not change as [Ca^{2+}] is changed are automatically subtracted out using this equation. This equation can be used whether the Ca^{2+} probe of interest is ratiometric or not.

Another equation (Grynkiewicz et al., 1985) that can be used with ratiometric probes is:

$$\left[Ca^{2+}\right] = K_d\left[\left(R - R_{min}\right)/\left(R_{max} - R\right)\right]\left(S_f / S_b\right)$$

Equation 2.5.2

For probes that are ratiometric in excitation, S_f and S_b are the fluorescence emissions at any wavelength (λ_m) for a unit amount of the unbound probe and bound probe, respectively, where excitation is at wavelength λ_2. K_d is again the apparent dissociation constant, and R is the ratio of emission of the experimental sample at λ_m where excitation is at λ_1 to that where excitation is at λ_2. R_{max} and R_{min} are the ratios where [Ca^{2+}] is saturating and negligible, respectively. For probes that are ratiometric in emission, R should be interpreted as the ratio of emission at λ_1 to that at λ_2 where excitation is at any wavelength λ_x. R_{max} and R_{min} are the same where [Ca^{2+}] is saturating and negligible, respectively. S_f and S_b are the fluorescence emission at λ_2 for excitation at any wavelength λ_x for the unbound and bound probe, respectively. While it is not obvious from the equations, any background contributions that do not change with [Ca^{2+}] are correctly handled through this equation, without explicit subtraction, if the R, R_{max}, and R_{min}, as well as S_f and S_b, are all measured with identical background contributions present.

The operant words here are identical background contributions. If the background contributions due to autofluorescence at λ_1 and λ_2 (F_{a1} and F_{a2}) and incomplete conversion products (F_{i1} and F_{i2}) are large with respect to the minimum corrected fluorescence (sample fluorescence minus supernatant fluorescence) and there is >5% loss of internal probe over the course of the experiment, it is possible to get a 5% error in measured free [Ca^{2+}] even when the supernatant fluorescence (F_{s1} and F_{s2}) is subtracted. In addition, autofluorescence can change significantly during certain experimental protocols (Jiang and Julian, 1997); these changes must be ascertained as well as their strength relative to the internal calcium-sensitive probe. Thus, if one does not in general plan to subtract background contributions from the fluorescence measurements, one should still measure F_{a1}, F_{a2}, F_{i1}, F_{i2}, and probe leakage rate to ensure the accuracy of the results. F_{a1}, F_{a2}, and probe leakage rate are easy to measure; F_{i1} and F_{i2} are very difficult to measure, but it is possible to get an estimate of F_{i1} and F_{i2} and work to decrease their size by altering the incubation procedure. Note that the membrane-permeable form of the probe, often called the AM or acetoxymethyl ester form, should not be a problem because proper washing of the cells should reduce this form of the probe to very small values.

The following equations are pertinent:

in media of any [Ca^{2+}]

$$F_t = F_a + F_i + c_d\left[f_{hi}F_{hi} + (1 - f_{hi})F_{lo}\right] + F_s$$

Equation 2.5.3

in high [Ca^{2+}] media

$$(F_t)_{hi} = F_a + F_i + c_d F_{hi} + (F_s)_{hi}$$

Equation 2.5.4

in low Ca^{2+} media

$$(F_t)_{lo} = F_a + F_i + c_d F_{lo} + (F_s)_{lo}$$

Equation 2.5.5

where F_t is total, uncorrected fluorescence, F_s is the fluorescence of the supernatant, F_a is the autofluorescence of the cells, and F_i is the calcium-insensitive, incomplete conversion products of the probe, c_d is the μM concentration of Ca^{2+}-sensitive probe inside the cells, F_{hi} and F_{lo} are the fluorescence of 1 μM concentrations the Ca^{2+}-sensitive probe inside the cells in high- and low-Ca^{2+} forms, respectively and f_{hi} is the fraction of the Ca-sensitive probe in the high-Ca^{2+} form under any conditions. Autofluorescence is given by:

$$F_a = F_{ta} - F_{sa}$$

Equation 2.5.6

where F_{ta} is the fluorescence of cells without the probe at the same concentration as is used in the rest of the experiment in standard medium (see Reagents and Solutions), and F_{sa} is the fluorescence of the supernatant obtained when these cells are centrifuged 3 min at $200 \times g$.

It would be nice if F_i could be measured as easily as F_a, but measurement of F_i is difficult. It is best to estimate F_i and vary the incubation procedure to minimize its contribution. Accurate measurement of the parameters on the right side of Equations 2.5.1 and 2.5.2 is the essence of the most common way of determining intracellular [Ca^{2+}] by these fluorescence techniques. In general, this means at the very least subtracting F_s, and if F_a is a substantial fraction of the total fluorescence, it should be subtracted as well.

The steps of the measurements consist of: (1) choosing the fluorescent probe to use and checking its fluorescent characteristics in the system; (2) incubating the cells with a fluorescent probe; (3) setting up the instrument for initial measurements; (4) making measurements using a ratiometric probe; (5) assessing leakage problems; and (6) measuring of K_d.

IMPORTANT NOTE: Fluorescence is a very sensitive optical technique, but the price paid for high sensitivity is that the quantum yield, the absorbance or excitation, and even in some cases the spectra vary with many changes in conditions. Therefore, the key to accuracy in fluorescence measurements of free ion concentration is to make sure that the experimental spectra and all of the control experiments necessary for quantification are measured under conditions that are as similar as possible.

Materials

5 μM fluorescent probe free acid (FA) in low-Ca medium (see recipe)
5 μM FA in high-Ca medium (see recipe)
2 to 5 mM AM form of fluorescent Ca^{2+} probe (see recipe)
Standard medium (see recipe), ice cold
2×10^6 to 1×10^7 cell/ml suspension of sample cells in standard medium
1× calibration medium (see recipe)
2 × high-Ca medium (see recipe)
Detergent: e.g., *N*-octyl β-D-glucopyranoside
2× low-Ca medium (see recipe)
10 μM FA solution (see recipe)
Factor that will induce changes in [Ca^{2+}]
0.1 mM thapsigargin (see recipe)
2 mM oligomycin (see recipe)
1 mM carbonyl cyanide *m*-chlorophenyl hydrazone (CCCP) in ethanol (store indefinitely at −20°C; use caution as compound is hazardous)
1 mM ionophore (see recipe)
Experimental factors

Fluorescence spectrometer that can excite and detect in necessary wavelength ranges and has ability to constantly stir samples
Low-speed centrifuge for washing cells
Absorption cuvettes
Fluorescence cuvettes
37°C shaker bath
4°C agitator or shaker bath
Cuvette stir bars, preferably star head or X-shaped

Choose and characterize fluorescent probe

1. Choose the probe (see Strategic Planning).

   When working with a new [Ca^{2+}] probe, it is worthwhile to take spectra over the range of sensitivity of the probe. These measurements require the Ca^{2+}-sensitive form of the probe.

2. Make up mixtures of 5 μM probe free acid (FA) in high-Ca solution/5 μM FA in low-Ca solution at the following ratios: 0:100, 50:50, 60:40, 65:35, 70:30, and 100:0.

   These will result in [Ca^{2+}] of approximately the following: <1 nM, 67 nM, 198 nM, 678 nM, 5 μM and 50 μM, respectively.

3. Turn on the fluorescence spectrometer.

   When using an excitation ratiometric probe such as Fura-2, or a nonratiometric probe, start with the excitation slits set to between 1 and 2 nm in width and emission slits set to between 2 and 20 nm. When using Indo-1, set the excitation slits between 2 and 20 nm and the emission slits to between 1 and 2 nm in width. The actual slit widths to be used will depend upon the sensitivity of the system.

   CAUTION: *Make sure the bandwidth for excitation does not overlap the bandwidth for emission. If they overlap, the light scattering peak may be intense and might damage the detector. For a slit that is only used to attenuate the incident light, start with it partially closed in order to protect the photomultiplier tube.*

4. Add 3 ml of either the 0:100 or 100:0 solution from step 2 to a cuvette, choosing the solution which is expected to have the most intense emission. Turn on stirring.

   Always use stirring while obtaining cell fluorescence in a cuvette.

5. With emission set to the value suggested in Table 2.5.1 or Table 2.5.2, scan excitation, then set excitation at the peak excitation value and scan emission. Set the emission at the peak emission value, and then, while monitoring fluorescence, slowly open the protective slit while decreasing the emission slits (excitation slits for Indo-1) until the protective slit is wide open and the emission slits (excitation slits for Indo-1) are open just enough to obtain a maximum signal.

   For example, for Fura-2, use the 100% high-Ca solution for this step.

6a. *For all probes except ratiometric emission probes such as Indo-1:* With emission set at its peak value and all slits remaining fixed, scan excitation. Replace the above solution in turn with each of the high-Ca/low-Ca mixtures (prepared as in step 2) and scan them.

6b. *For ratiometric emission probes such as Indo-1:* With excitation set at its peak value and all slits remaining fixed, scan emission. Replace the above solution in turn with each of the high-Ca/low-Ca mixtures (prepared in step 2) and scan them.

7. Plot all these spectra on the same graph to give the characteristic spectra to be expected from the chosen Ca^{2+}-sensitive probe in the system and an idea of the slit widths that may be needed for use in the experiments.

   These spectra will give an approximate indication of R_{max} and R_{min} and also the approximate location of the probe's isosbestic point, λ_i, for the system. The wavelengths to be used for a ratiometric probe are usually chosen to make the sensitivity range as large as possible, which means making the ratio of R_{max}/R_{min} as large as possible. For Fura-2 and its analogs, these wavelengths are 340 nm and 380 nm with emission at 505 to 510 nm. For Indo-1 these wavelengths are 405 nm and 480 nm with excitation at approximately 350 nm. These wavelength pairs should only be used if the minimum fluorescence is never very close to background; if it is, the wavelength for which the signal is too close to background will have to be modified to increase its intensity, even if this means a loss in sensitivity. This is usually only a problem for FDIM (see Basic Protocol 2) where only a limited range of values for F are available.

   For a nonratiometric dye, these spectra will indicate the best excitation and emission wavelengths to use as well as the maximum sensitivity of the dye, F_{min}/F_{max}. Here, F_{min} equals the minimum fluorescence in the presence of low (or high) calcium and F_{max} equals the maximum fluorescence in the presence of high (or low) calcium.

If the spectrometer has dual-excitation monochromators with rapid switching between them, it is not necessary to balance the light intensity from the two monochromators. In fact it is often advantageous to purposely vary the light intensity between the two monochromators in order to increase sensitivity—i.e., provide more light at the wavelength for which F is lowest. This changes the measured values of R_{max} and R_{min} from day to day; however, the maximum range is independent of manipulations of this type and is characteristic of the probe and its condition. In order to obtain values of R_{max} and R_{min} that are independent of this variation, measured values of R, R_{max} and R_{min} should be corrected for this difference in light intensity (see Basic Protocol 1, step 11). This correction should also be applied when using dual-emission monochromators. When using a dual-excitation spectrometer, be sure to check for cross-talk between the two monochromators and eliminate it before starting to take data. A probe's maximum sensitivity varies slightly from lot to lot of commercially available probe and generally decreases with time as the probe changes chemically. In addition, these ratios are also a function of the solvent and hence will likely be different in the cytosol from what is measured here.

Incubate cells with probe

8. Dilute an aliquot of the AM form of the probe to a concentration of 2 to 20 μM in standard medium and mix well by vortexing or shaking. Immediately mix with an equal volume of sample cells in suspension to a final concentration of 1 to 10 μM probe with cells at $1–5 \times 10^6$ (do not incubate all of the cells with the permeant form of the probe because some probe-free cells are needed for autofluorescence corrections; see steps 13 and 18). Allow this mixture to incubate at 37°C in a shaker bath for between 30 min and 1 hr.

   IMPORTANT NOTE: *The final concentration of probe should be no more that 5 μM if at all possible because higher concentrations tend to result in incomplete enzymatic hydrolysis of the AM esters, accumulation of lipophilic AM esters in membrane lipids, and accumulation of formaldehyde from AM ester hydrolysis. Incubation should be done at 37°C unless it is desirable to have the probe present in intracellular organelles such as mitochondria, in which case, incubation should be carried out at 4°C for ~2 hr.*

   Approximately 10^8 cells will be needed to complete an experiment with 20 samples.

   While injection or other special techniques are sometimes used to load a cell with probe, the most common loading technique is to incubate the cells with a membrane-permeable, Ca^{2+}-insensitive form of the probe. The acetoxymethyl ester forms of Fura-2 and Indo-1 are used for this purpose. They are converted by the esterases in the cell interior to the pentacarboxylic acid (free acid; FA) form which is Ca^{2+}-sensitive and relatively membrane-impermeable. The operant word here is "relatively," since many cell types contain organic ion transporters (di Virgilio et al., 1990; Kao, 1994) and/or the P-glycoprotein multidrug transporter (Homolya et al., 1993), which extrude FA and AM esters of these probes from the cell, respectively. If such leakage is a problem for the cell type, use one of the leakage-resistant probes such as Fura PE-3 or add transport inhibitors such as probenecid or sulfinpyrazone.

9. Wash cells two to three times in ice-cold standard medium, each time by centrifuging 3 min at ~$200 \times g$, 4°C, removing the supernatant, and gently resuspending cells in standard medium to the original concentration. Resuspend the final pellet at 2×10^6 to 1×10^7 cells/ml using standard medium. Store the incubated cells at 4°C with constant agitation to prevent anoxia. Dilute 3 x 10^6 cells with standard medium to a final volume of 3 ml and centrifuge 3 min at ~200 x g at 4° C. Carefully remove the supernatant for measuring $(F_s)_1$ and $(F_s)_2$ at $t = 0$.

   Keeping the cells at 4°C also decreases the leakage of probe into the external medium and hence decreases problems associated with external probe. As long as $[Ca^{2+}]$ in the external medium is the same as that of the standard medium, a plot of (F_s) at λ_1 or λ_2 versus time gives a measure of leakage rate at 4°C.

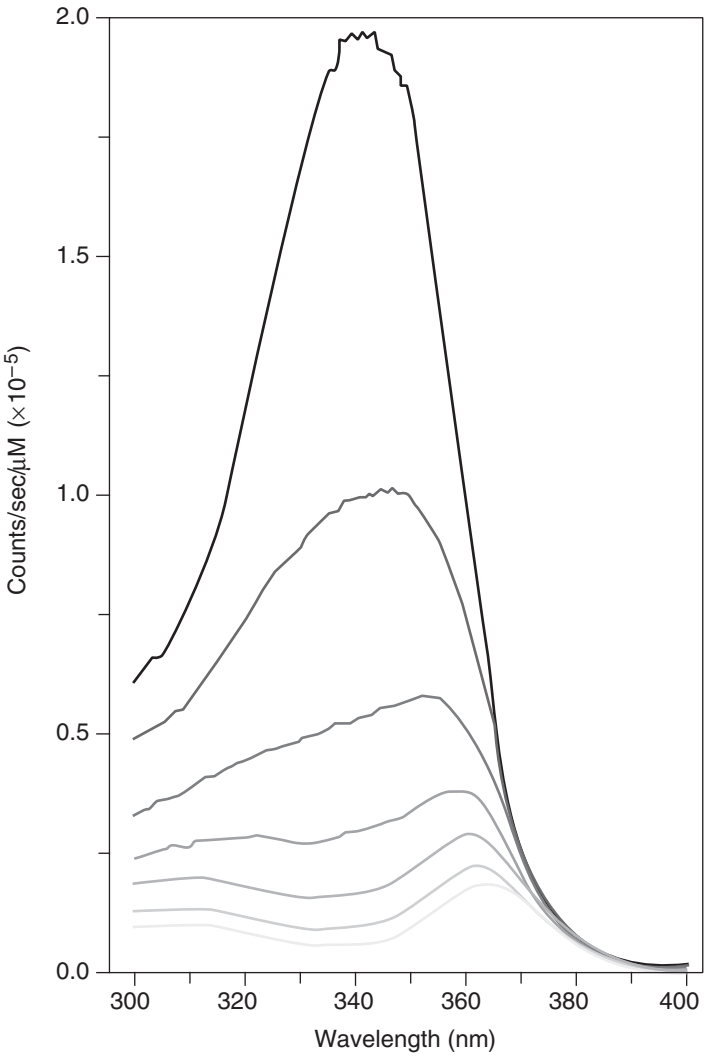

Figure 2.5.1 Inner filter effect on the Ca-bound spectra of Fura-2 FA. The curves are normalized to counts/sec/μM. As the curves decrease in height, Fura-2 FA concentrations are 3, 17.73, 45.93, 32.04, 59.43, and 72.56 μM, respectively.

Set up the instrument for initial measurements

10. Place an aliquot of incubated cells in an absorption cuvette at a concentration of 10^6 cells/ml (most instruments require a volume of 2 to 3 ml). Check the attenuation (light scattering plus absorbance) of the incident beam by the cell suspension at the excitation wavelength(s).

    IMPORTANT NOTE: *For this and all further spectrophotometric measurements, turn on stirring and temperature control for the cuvette and allow time for the sample to reach the temperature of the experiments (37°C or room temperature). From this point on it will be assumed that cells will be run at a concentration of 10^6 cells/ml in a volume of 3 ml. If this not the case, modify these instructions accordingly.*

    As a rule of thumb, the attenuation should be <0.05 absorbance units. If the turbidity (light scattering) or absorbance is too high, the intensity of the excitation beam is significantly decreased before reaching the region of the fluorescence cuvette within which fluorescence is measured (inner-filter effect; Fig. 2.5.1). Since this attenuation is a function of wavelength, it can artificially distort the spectra (or the ratios) and must be avoided. It is usually

possible to study fluorescent probes in a suspension of 10^6 cells per ml. Sensitivity can be increased by increasing the concentration of cells, but the cell concentration must not be increased to the point where inner filter effect due to the absorbance and scattering by the cells becomes a problem at any relevant wavelength.

Perform measurements

The following steps apply to all ratiometric probes except those ratiometric in emission such as Indo-1. For the latter types of probes, follow the instructions in parentheses regarding either excitation or emission.

Estimate calcium-insensitive fluorescence (F_i)

11. Wash 6.5×10^6 incubated cells three times in ice-cold 1× calibration medium, each time by centrifuging 3 min at ~200 × *g*, 4°C, removing the supernatant, and resuspending at 2×10^6 cells/ml in 3.25 ml of 1× calibration medium. Place 1.5 ml of 2× high-Ca medium in a cuvette, then add 1.5 ml of the washed cells and sufficient detergent (~0.1% to 1% w/v final concentration) such as *N*-octyl b-d-glucopyranoside to dissolve the cells. Check the intensity of fluorescence by gradually opening the protective slit as in step 5 while alternating between the two excitation (emission) wavelengths λ_1 and λ_2. If necessary, adjust the emission (excitation) slits until the total fluorescence in the presence of detergent at λ_1 $(F_{td})_{hi1}$ is ~80% of the maximum permissible fluorescence intensity. Measure total fluorescence in the presence of detergent and high calcium, $(F_{td})_{hi}$, at the wavelengths λ_1 and λ_2. Do a scan, $(S_{td})_{hi}$, of excitation (emission) including λ_1, λ_2, and the likely isosbestic point. When using dual-excitation (emission) monochromators, set both monochromators to the same wavelength (λ_1), and measure the ratio of the light between the two monochromators R_L, where $R_L = F_{mono1}/F_{mono2}$. Mono1 is the monochromator that measures λ_1 and mono2 is the monochromator that measures λ_2. Measured ratios can then be corrected for this artifact by dividing all ratios by R_L.

    R_L is generally constant during the course of a single experiment, but tends to vary between experimental sessions. Hence, it should be measured at least twice in every experimental session. Any sample containing the probe will be adequate for this measurement.

    How to choose the wavelengths, λ_1 and λ_2, was discussed in the annotation under step 7. For Fura-2 and its analogs, λ_1 is generally 340 nm and λ_2 is generally 380 nm with emission at 505 to 510 nm. For Indo-1, λ_1 is generally 405 nm and λ_2 is generally 480 nm with excitation at 350 nm.

    The estimation of F_i will be described first, since this procedure can also be used to determine the proper slits to be used for the experiment. In addition, measurement of F_i can immediately indicate whether or not the incubation procedure is adequate for the application. The goal is to identify a procedure that results in negligible F_i. This goal can usually be attained. For more details on estimating F_i, see Commentary.

    IMPORTANT NOTE: *N-octyl β-d-glucopyranoside is suggested as the best detergent because it causes few changes in the extinction coefficient or quantum yield of either the high- or low-Ca^{2+} forms of most Ca^{2+} probes. To use another detergent, check its effects on the spectra and intensity of the high or low Ca^{2+} FA forms of the probe and on the AM form of the probe.*

12. Place 1.5 ml of 2 × low-Ca medium in a cuvette, add 1.5 ml of cells washed as in step 11, and add the same amount of detergent as in step 11. Measure total fluorescence in the presence of detergent and low calcium, $(F_{td})_{lo}$, at the wavelengths λ_1 and λ_2. Do a scan, $(S_{td})_{lo}$ as in step 11.

13. Wash cells that were not exposed to the probe in 1× calibration medium as in step 11 and resuspend them in 1× calibration medium at 1×10^6 cells/ml. Place 3 ml of these cells in a cuvette and add the same amount of detergent used in steps 11 and 12.

Measure total autofluorescence in the presence of detergent, F_{ad}, at the wavelengths λ_1 and λ_2. Do a scan, S_{ad} as in step 11.

14. Place 1.5 ml of 2× high-Ca medium in a cuvette, add 1.5 ml of 2 to 10 μM FA in 1× calibration medium, and add the same amount of detergent used in step 11. Measure total fluorescence at the wavelengths λ_1 and λ_2—which is equal to $(d_c - F_{hid})$ where d_c is the concentration of Fura-2 FA in μM and F_{hid} is the fluorescence of 1 μM of the Ca-sensitive form of the probe in high-calcium medium in the presence of detergent. Do a scan, S_{hid}, as in step 11.

15. Dilute 10 μM FA solution with 1× calibration medium to create a probe concentration in the range of 2 to 10 μM. Place 1.5 ml of 2× low-Ca medium in a cuvette, add 1.5 ml of the 2 to 10 μM FA in 1× calibration medium, and add same amount of detergent used in step 11. Measure total fluorescence at the wavelengths λ_1 and λ_2—equal to $(d_c - F_{lod})$, where F_{lod} is the fluorescence of 1 μM of the Ca-sensitive form of the probe in low-Ca medium in the presence of detergent. Do a scan, S_{lod}, as in step 11.

    The actual concentration of the diluted FA added to the cuvette should be such that it is unnecessary to change the excitation or emission slits.

16. Calculate c_d using the values of $(F_{td})_{hi}$, $(F_{td})_{lo}$, F_{hid}, and F_{lod} measured at λ_1 above in steps 11, 12, 14, and and 15, respectively.

    Starting with Equation 2.5.4 and Equation 2.5.5, it is easy to see that $c_d = [(F_{td})_{hi} - (F_{td})_{lo}]/[F_{hid} - F_{lod}]$, regardless of the wavelength used to make the measurements.

17. With values for c_d, $(F_{td})_{hi}$, F_{hid}, and F_{ad} (see step 13), calculate $F_{id} = (F_{td})_{hi} - c_d F_{hid} - F_{ad}$ for each wavelength. Using the appropriate software program or a spreadsheet such as Excel, calculate $S_{id} = 0.5[(S_{td})_{hi} - (c_d/d_c)S_{hid} + (S_{td})_{lo} - (c_d/d_c)S_{lod}] - S_{ad}$. Assume that F_{id} (in the presence of detergent) approximately equals F_i (inside the cell in the absence of detergent) at each wavelength.

    IMPORTANT NOTE: *If F_i is negligible, steps 11 through this step can be skipped in future work using the same incubation protocol with the same cell type.*

Measure autofluorescence (F_a)

18. Dilute 3×10^6 cells that were not incubated with the probe to a final volume of 3 ml in standard medium and place in the cuvette. Measure total autofluorescence, F_{ta}, at the two wavelengths λ_1 and λ_2, under the same conditions that will be applied to the experimental samples. Remove this sample and centrifuge it at $200 \times g$ for 3 min. Carefully remove the supernatant and place it in the cuvette. Measure total fluorescence of the supernatant, F_{sa}, at the two wavelengths λ_1 and λ_2. Calculate $(F_a)_1 = (F_{ta})_1 - (F_{sa})_1$ and $(F_a)_2 = (F_{ta})_2 - (F_{sa})_2$.

    IMPORTANT NOTE: *If F_a is negligible, this step can be skipped in future work using the same incubation and sample protocols with the same cell type.*

Determine R_{max}, R_{min}, S_f, and S_b

19. Wash incubated cells in standard medium and resuspend at 1×10^6 cells/ml in a cuvette. Set the spectrometer to scan excitation (emission for probes that are ratiometric in emission) around the likely isosbestic point λ_i. Add some factor that will induce changes in $[Ca^{2+}]$ and immediately initiate multiple scans around λ_i until the pulse is more or less complete. Plot all of these scans on the same graph and determine λ_i.

    Factors which induce changes in $[Ca^{2+}]$ are dependent upon the cell type. Many cells when exposed to high potassium in the external medium will depolarize which results in a high calcium pulse. Most cell types respond to specific hormones. For example, chondrocytes respond to parathyroid hormone; liver cells respond to vasopressin, catecholamines, and

angiotensin; brain cells respond to almost all of the neurotransmitters. In addition, many cell types respond to thapsigargin, and muscle cells respond to caffeine.

20. Wash 6.5×10^6 incubated cells (from step 9) with 1× calibration medium and resuspend at 2×10^6 cells/ml. Place 1.5 ml of 2× high-Ca medium in a cuvette and add 1.5 ml of the cells which have just been washed.

21. When the proper temperature is reached, add 30 µl of 0.1 mM thapsigargin, 15 µl of 2 mM oligomycin, 15 µl of 1 mM CCCP, and 30 µl of 1 mM ionophore. Immediately start recording the time-based changes in fluorescence at λ_1 and λ_2 [$(F_t)_{hi1}$ and $(F_t)_{hi2}$, respectively]. As soon as these values reach an apparent steady state, record their average values and then scan excitation $(S_t)_{hi}$ (emission for probes that are ratiometric in emission). Remove the sample and immediately centrifuge it at $200 \times g$ for 3 min and save the supernatant (SN_{high}), which is taken to evaluate leakage and to correct $(F_t)_{hi1}$ and $(F_t)_{hi2}$ for spectral changes due to leakage.

    Final concentrations are 1 µM thapsigargin 10 µM oligomycin, 5 µM CCCP, and 10 µM ionophore. The CCCP is used to break down all of the cell's pH gradients. Vanadate (in the calibration medium) is used to inhibit the plasma membrane Ca^{2+} ATPase. The ionic composition of the calibration medium is used to prevent the Na^+-Ca^{2+} plasma membrane exchanger from generating a Ca^{2+} gradient. Together the ionomycin, vanadate, and ionic composition are used to equilibrate internal free Ca^{2+} with external free Ca^{2+}. Ouabain (in calibration medium) is used to inhibit the Na-K ATPase, and thapsigargin is used to empty the internal endoplasmic or sarcoplasmic reticulum stores. Oligomycin is used to prevent the mitochondria from utilizing all of the cellular ATP in an attempt to regenerate its membrane potential. The idea is to obtain the fluorescent intensities from inside the cell before cell death causes substantial loss of probe to the external medium. If too much time is allowed to elapse, probe will begin to leak out of the cell, and if the spectrum of the probe in the external medium is different from that inside the cell, these values will begin to change as soon as substantial leakage occurs.

    One of the biggest problems in calibration is accurately determining (S_f/S_b), because any variation in probe leakage will cause an error in this ratio. The amount of probe leakage can be determined by the intensity of fluorescence at the isosbestic point. However, because of association with intracellular proteins, the isosbestic point of the intracellular probe may be shifted from that in medium. To determine the intracellular isosbestic point λ_i, subject an aliquot of the cells to an agent that will induce significant changes in $[Ca^{2+}]$ (e.g., an agonist or transient depolarization with Ca^{2+} uptake through channels) and identify the wavelength at which there is no change of fluorescence intensity.

    Making sufficient ionophore available to the cells can be a real problem. Williams and coworkers (Williams and Fay, 1990) suggest that Br-A23187 may sometimes work better than ionomycin because its action is independent of pH. If there is difficulty in obtaining a substantial change in R in going from R_{min} to R_{max}, see Troubleshooting.

    When using an instrument that has two (dual excitation/emission) monochromators, $(F)_1$ or $(F)_2$ measured in the ratio mode will not necessarily be identical to the values of fluorescence taken at λ_1 and λ_2 from the excitation (emission) scan. This is because most of these machines scan either the first or second monochromator but not both. The values of $(F)_1$ or $(F)_2$ measured in the ratio mode will be used to calculate R_{max}, R_{min}, S_f and S_b. The scans will be used to correct S_f/S_b for loss of probe during calibration.

22. Repeat steps 20 and 21 using 1.5 ml of 2× low-Ca medium instead of 2× high-Ca medium.

    The resulting measurements are time scans of $(F_t)_{lo1}$ and $(F_t)_{lo2}$ at λ_1 and λ_2, respectively, and the excitation (emission for probes that are ratiometric in emission) scan $(S_t)_{lo}$. The resulting supernatant is SN_{low}.

23. For each of the supernatants (SN_{high} and SN_{low}), measure average fluorescence at λ_1 and λ_2 [$(F_s)_{hi1}$, $(F_s)_{lo1}$ and $(F_s)_{hi2}$, $(F_s)_{lo2}$, respectively] and then scan excitation (emission) of the supernatants [$(S_s)_{hi}$ and $(S_s)_{lo}$].

24. If the value of F_a found in step 18 is not negligible with respect to the internal probe fluorescence values ($F_t - F_s$) at λ_1 and λ_2 for both high and low calcium concentrations, then repeat steps 20 to 23 using 6.5×10^6 cells that were not treated with the probe—the resulting average fluorescence values will be $(F_{ta})_{hi1}$, $(F_{ta})_{hi2}$, $(F_{ta})_{lo1}$, $(F_{ta})_{lo2}$, $(F_{sa})_{hi1}$, $(F_{sa})_{hi2}$, $(F_{sa})_{lo1}$, and $(F_{sa})_{lo2}$. Use Equation 2.5.6 ($F_a = F_{ta} - F_{sa}$) to calculate $(F_a)_{hi1}$, $(F_a)_{hi2}$, $(F_a)_{lo1}$, and $(F_a)_{lo2}$. Use the appropriate software program or a spreadsheet such as Excel to calculate $(S_a)_{hi} = (S_{ta})_{hi} - (S_{sa})_{hi}$ and $(S_a)_{lo} = (S_{ta})_{lo} - (S_{sa})_{lo}$.

25. Calculate the calcium-sensitive cellular probe fluorescence, $(F) = (F_t) - (F_s) - (F_a) - (F_{id})$, for each wavelength and calcium concentration—i.e., calculate $(F)_{hi1}$, $(F)_{hi2}$, $(F)_{lo1}$, and $(F)_{lo2}$ where the values of $(F_{id})_1$ and $(F_{id})_2$ were obtained in step 17. Use the appropriate software program or a spreadsheet such as Excel to calculate the spectrum $(S)_{hi}$ and $(S)_{lo}$, where $S = S_t - S_s - S_a - S_{id}$. Compare $(S)_{hi}$ with the high-calcium spectrum found in step 7 for the high-calcium form of the probe in solution.

These two spectra should be very similar if S_{id} is small. If they are not, it is likely that either the sample did not reach a sufficiently high value of $[Ca^{2+}]_{inside}$ or that there are problems with inner filter effect. If $[Ca^{2+}]_{inside}$ approximately equals $[Ca^{2+}]_{outside}$, then $(S)_{hi}$ will look like a combination of the high- and low-calcium spectra found in step 7. If this is not the case, there probably are problems with the inner-filter effect, which is the result of having too much total dye in the viewing volume (see Troubleshooting for discussion of the impact of the inner-filter effect on spectra). Likewise, $(S)_{lo}$ should be very similar to the low-calcium spectrum found in step 7.

If $[Ca^{2+}]$ inside the cells does not approximately equal $[Ca^{2+}]_{outside}$ during these measurements, the resulting values of R_{min} and R_{max} will be incorrect and result in erroneous values of $[Ca^{2+}]$. See Support Protocol 1 for information on how to determine how bad the measured values of R_{min} and R_{max} may be and how to determine more accurate values while measuring K_d.

The assumption that F_{id} is equal to F_i will likely overestimate the value of F_i since it assumes that none of the Ca-insensitive probe was lost from the cells during the calibration procedure. Unless little or no dye was lost during calibration, this will not be true, and so it is very important that F_{id} be much less than F at λ_1 and λ_2 for both high and low calcium concentrations.

26. Calculate $R_{min} = (F)_{lo1}/(F)_{lo2}$ and $R_{max} = (F)_{hi1}/(F)_{hi2}$. Plot $(S)_{hi}$ and $(S)_{lo}$ on the same graph and calculate the constant K such that the spectrum $K - (S)_{lo}$ crosses $(S)_{hi}$ at the isosbestic point λ_i.

λ_i was found in step 19. From the result of the above calculation $(S_f/S_b) = K$—$(F)_{lo2}/(F)_{hi2}$.

If the values obtained for R_{min}, R_{max} and (S_f/S_b) from multiple measurements on the same cell type are approximately constant for the same bandpasses for λ_1 and λ_2 ,then it is probably unnecessary to measure R_{min}, R_{max} and (S_f/S_b) for every experiment as long as the bandpasses for λ_1 and λ_2 remain constant. Instead use the average values of these constants found from multiple experiments.

For dual-excitation (emission) monochromators, $R_{min} = (F)_{lo1}/(F)_{lo2}/R_L$ and $R_{max} = (F)_{hi1}/(F)_{hi2}/R_L$. R_L was found in step 11.

Measure the ratio of samples of interest

27. Start by measuring $(F_s)_1$ and $(F_s)_2$ for the $t = 0$ supernatant that was obtained in step 9. Next, add 3×10^6 incubated cells to the cuvette. Add standard medium and any other needed components for a final volume of 3 ml.

    If much time has elapsed since the cells were incubated, wash them in standard medium before adding them to the cuvette. This becomes necessary only if $(F_s)_1$ or $(F_s)_2$ represents 40% to 50% of $(F_t)_1$ or $(F_t)_2$ after correction for autofluorescence and calcium insensitive dye. Once the cells have been washed a new $t = 0$ time has been created.

    Other needed components are the experimental factors listed in Materials. In some cases, there are no such factors. For example, if the experiment involves following $[Ca^{2+}]$ as a function of time after irradiation or magnitude of irradiation, then each sample is simply suspended in standard medium and measured until a steady state value of R is obtained. On the other hand, perhaps the experiment involves determining the average $[Ca^{2+}]$ versus time for a group of cells after the addition of hormone. In this case, the experimental factor is the hormone. If the time involved in following the cells' response is large, then it will be necessary to start with a large aliquot of cells at 1 x 10^6/ml in standard medium plus the experimental factor in order to determine F_s as a function of time at 37°C or room temperature in order to correct for dye loss during the measurement.

28. Measure $(F_t)_1$ and $(F_t)_2$ and then centrifuge the sample 3 min at $200 \times g$. Record the time when the sample was centrifuged. Carefully remove the supernatant and use it to measure $(F_s)_1$ and $(F_s)_2$. Calculate $(F)_1 = (F_t)_1 - (F_s)_1 - (F_a)_1 - (F_{id})_1$, and $(F)_2 = (F_t)_2 - (F_s)_2 - (F_a)_2 - (F_{id})_2$, where $(F_{id})_1$ and $(F_{id})_2$ were measured in step 17 and $(F_a)_1$ and $(F_a)_2$ were measured in step 18, and then calculate $R = [(F)_1/(F)_2]$. $[Ca^{2+}]$ can then be calculated manually or via the appropriate software program from Equation 2.5.2, where R_{min}, R_{max}, and (S_f/S_b) were calculated in step 26. Either use an estimated K_d such as 225 nM for Fura-2, or measure it as described below for a particular cell type.

    If it was found in calculating R_{max} and R_{min} above that $(F_t)_{hi} - (F_s)_{hi}$ is much greater than $(F_a)_{hi} + (F_{id})$ and $(F_t)_{lo} - (F_s)_{lo}$ is much greater than $(F_a)_{lo} + (F_{id})$ at λ_1 and λ_2, then little error will be generated by eliminating the F_a and F_{id} terms from the sample ratio calculations. That is, instead of calculating $R = [(F_t)_1 - (F_s)_1 - (F_a)_1 - (F_{id})_1]/[(F_t)_2 - (F_s)_2 - (F_a)_2 - (F_{id})_2]$ for the samples, use $R = [(F_t)_1 - (F_s)_1]/[(F_t)_2 - (F_s)_2]$.

    For dual-excitation (emission) monochromators, $R = (F)_1/(F)_2/R_L$ and R_L was found in step 11.

ALTERNATE PROTOCOL

MEASUREMENT OF F_{MIN} AND F_{MAX} WITH NONRATIOMETRIC PROBES

Nonratiometric probes are used in a similar manner to ratiometric probes (see Basic Protocol 1) except that only fluorescent intensities and not ratios are used. That is, $[Ca^{2+}] = K_d [(F - F_{min})/(F_{max} - F)]$ where $F = F_t - F_s - F_a - F_{id}$, $F_{min} = (F)_{lo} = (F_t)_{lo} - (F_s)_{lo} - (F_a)_{lo} - F_{id}$, and $F_{max} = (F_t)_{lo} - (F_s)_{lo} - (F_a)_{lo} - F_{id}$. Clearly, the F_{id} values cancel in calculating $[Ca^{2+}]$ and so it is not necessary to attempt to measure F_{id}. Furthermore, if one can show that F_a approximately equals $(F_a)_{lo}$ and $(F_a)_{hi}$, then autofluorescence can be neglected as well even if the autofluorescence term is not small with respect to probe fluorescence. The main problem with nonratiometric dyes is leakage of dye from the cells with time. If this leakage is approximately zero over the total time course of the experiment, leakage is not a problem. On the other hand, if leakage is measurable over the course of the experiment, then F_{max}, F_{min} and each value of F must be corrected to the zero leakage case in order to obtain the correct value of $[Ca^{2+}]$. This is exactly what is done in steps 11 and 13 where k_{hi}, k_{lo} and k are calculated.

The steps used to measure calcium using nonratiometric probes are essentially the same as those for ratiometric probes except it is generally unnecessary to record wavelength

scans and all of the measurements are made at a single excitation and emission wavelength (see Basic Protocol 1, steps 1 to 7).

Measure autofluorescence (F_a)

1. Measure total autofluorescence, F_{ta}, and the autofluorescence of the supernatant, F_{sa}, as described in Basic Protocol 1, step 18. Calculate $F_a = F_{ta} - F_{sa}$.

   IMPORTANT NOTE: *If F_a is negligible, this step can be skipped in future work using the same incubation protocol and cell type.*

Determine F_{max} and F_{min}

The procedure used to measure F_{max} and F_{min} is basically the same as that used to measure R_{max} and R_{min} for ratiometric dyes. The main source of error that can occur during these measurements is the loss of probe from the cells during the course of the measurements. This fractional loss of probe can only be determined by using standards made with detergent and determining the fraction of probe that escaped into the supernatant during the course of the experiment. Each time the incubated cells are washed as a group, new standards must be made. The group of incubated should be washed as a group whenever F_2 equals 40% to 50% of F. Even so, calcium concentrations determined with nonratiometric dyes are not as accurate as those determined using ratiometric dyes.

2. Wash 1.25×10^7 incubated cells with 1× calibration medium and resuspend at 2×10^6 cells/ml. Measure the total high- and low-calcium fluorescence $(F_t)_{hi}$ and $(F_t)_{lo}$, after an apparent steady state is reached, as described in Basic Protocol 1, steps 20 to 22. Scan excitation of the high-calcium sample and save the spectrum, $(S_t)_{hi}$. Save the supernatants (SN_{high} and SN_{low}).

   SN_{high} and SN_{low} are taken to evaluate probe leakage and to correct $(F_t)_{hi}$ and $(F_t)_{lo}$ for intensity changes due to leakage.

3. Repeat Basic Protocol 1, steps 20 and 21, except along with everything else added, add enough detergent (e.g., *N*-octyl β-d-glucopyranoside) to just dissolve the cells. After a steady state is reached, measure $(F_{td})_{hi}$.

4. Repeat Basic Protocol 1, step 22, except along with everything else added, add the same concentration of detergent that was used in step 31. After a steady state is reached, measure $(F_{td})_{lo}$.

5. Measure the fluorescence of 2.75 ml of SN_{high} obtaining a good average value and save it as $(F_s)_{hi}$. Scan excitation of the high-calcium supernatant and save the spectrum, $(S_s)_{hi}$. Add the same concentration of detergent that was used in step 3. Measure fluorescence again, obtain a good average value, and save it as $(F_{sd})_{hi}$.

6. Measure the fluorescence of 2.75 ml of SN_{low} obtaining a good average value and save it as $(F_s)_{lo}$. Add the same concentration of detergent that was used in step 3. Measure fluorescence again, obtain a good average value, and save it as $(F_{sd})_{lo}$.

7. Wash the remaining incubated cells with standard medium. Add 3×10^6 cells to the cuvette then add standard medium until the final volume is 3 ml. Add the same amount of detergent that was used in step 3. After a steady state is reached, measure F_{td}.

8. If the value of F_a found in step 1 is not negligible with respect to the internal probe fluorescence values $(F_t - F_s)$ for both high and low calcium concentrations, repeat steps 2, 5, and 6. (except do not add detergent to the supernatant) using 6.5×10^6 cells that were not treated with the probe. Scan excitation (emission for probes that are ratiometric in emission) of the high-calcium sample, both total and supernatant.

The resulting spectra are $(S_{ta})_{hi}$ and $(S_{sa})_{hi}$, respectively. The resulting average fluorescence values will be $(F_{ta})_{hi}$, $(F_{ta})_{lo}$, $(F_{sa})_{hi}$, and $(F_{sa})_{lo}$. Use Equation. 2.5.6 ($F_a = F_{ta} - F_{sa}$) to calculate $(F_a)_{hi}$ and $(F_a)_{lo}$. Use the appropriate software program or a spreadsheet such as Excel to calculate $(S_a)_{hi} = (S_{ta})_{hi} - (S_{sa})_{hi}$. If F_a is approximately equal to $(F_a)_{hi}$ and $(F_a)_{lo}$, autofluorescence can be neglected in the calculations below.

9. Calculate the calcium-sensitive cellular probe fluorescence, $(F) = (F_t) - (F_s) - (F_a)$, for each calcium concentration—i.e., calculate $(F)_{hi}$ and $(F)_{lo}$ where F_t was measured in step 2, F_s was measured in steps 5 and 6, and F_a was calculated in step 9. Use the appropriate software program or a spreadsheet such as Excel to calculate the spectrum $(S)_{hi} = (S_t)_{hi} - (S_s)_{hi} - (S_a)_{hi}$, where $(S_t)_{hi}$ was measured in step 2, $(S_s)_{hi}$ was measured in step 5, and $(S_a)_{hi}$ was calculated in step 6. Compare $(S)_{hi}$ with the high-calcium spectrum found in Basic Protocol 1, step 7, for the high-calcium form of the probe in solution.

   These two spectra should be very similar. If they are very different, there are probably problems with inner-filter effect, which must be corrected (see Troubleshooting for discussion of the impact of the inner-filter effect on spectra).

10. Calculate the leakage correction factor $k_{hi} = [(F_{td})_{hi} - (F_{sd})_{hi}]/(F_{td})_{hi}$ where $(F_{td})_{hi}$ was measured in step 3 and $(F_{sd})_{hi}$ was measured in step 5. Likewise, calculate the leakage correction factor $k_{lo} = [(F_{td})_{lo} - (F_{sd})_{lo}]/(F_{td})_{lo}$ where $(F_{td})_{lo}$ was measured in step 4 and $(F_{sd})_{lo}$ was measured in step 6.

11. Calculate $F_{max} = (F)_{hi}/k_{hi}$ and $F_{min} = (F)_{lo}/k_{lo}$, where $(F)_{hi}$ and $(F)_{lo}$ were calculated in step 9.

    IMPORTANT NOTE: *$F_{max} = (F)_{hi}/k_{hi}$ and $F_{min} = (F)_{lo}/k_{lo}$ are the definition of F_{max} and F_{min}. For some nonratiometric probes, F_{min} is larger than F_{max}.*

    If $[Ca^{2+}]$ inside the cells does not approximately equal $[Ca^{2+}]_{outside}$ during these measurements, the resulting values of F_{min} and F_{max} will be incorrect and result in erroneous values of $[Ca^{2+}]$. See Support Protocol 1 for information on how to determine how bad the measured values of F_{min} and F_{max} may be and how to determine more accurate values while measuring K_d.

Measure fluorescence of samples of interest

12. Add 3×10^6 incubated cells to the cuvette. Add standard medium and any other needed components for a final volume of 3 ml.

13. Measure F_t and then centrifuge the sample 3 min at $200 \times g$. Carefully remove the supernatant and measure F_s. Add the same concentration of detergent that was used in step 3. Measure fluorescence again, obtain a good average value, and save it as F_{sd}. Calculate the correction factor $k = (F_{td} - F_{sd})/F_{td}$, where F_{td} was measured in step 7. Calculate $F = (F_t - F_a - F_s)/k$, where F_a was calculated in step 8. Then calculate $[Ca^{2+}] = K_d \cdot [(F - F_{min})/(F_{max} - F)]$, where F_{min} and F_{max} were calculated above in step 11, and either use an estimated K_d such as 390 nm for Fluo-3, or measure it below for the particular cell type under examination.

    IMPORTANT NOTE: *If the additions made to a particular sample result in changes in the free calcium in the external medium, it is necessary to make another measurement of F_{td} (step 7) for cells in this particular medium and calculate the value of k for this particular medium. Likewise, it is necessary to incubate more cells, make another measurement of F_{td} and recalculate k. In this case, this new value of F_{td} must be used to correct the previously calculated values of F_{max} and F_{min} for the new total dye concentration.*

    See Troubleshooting for assessment of leakage problems.

DETERMINATION OF K_d FOR CELLS IN SUSPENSION

The apparent K_d for Ca^{2+} binding to the probe in the cytosol of the cell is not the same as that in medium made up to mimic the cytosol. The reason is that inside the cell, the probe is subject to binding to cell components, as well as to the effects of heavy-metal ions and viscosity differences that cannot be easily mimicked by an artificial medium. Furthermore, part of the intracellular probe may be in compartments of the cell other than the cytosol. The method below assumes that the probe is located within the cytosol and discusses control experiments that can determine if probe fluorescence from mitochondria or other intracellular compartments contributes significantly to the resultant cellular fluorescence signal.

Determination of the intracellular K_d of the probe can be a difficult measurement. Many researchers begin work by assuming a K_d near that for the probe in ionic medium similar to that found in the cell cytosol and only after results have made it clear that accurate measurement of $[Ca^{2+}]$ is important, do they proceed to determine K_d in the cytosol.

For these measurements it is necessary to use combinations of EGTA and Ca^{2+} whose concentrations have been verified by analytical methods. The simplest way to do this is to purchase a calibration kit commercially, e.g., from Molecular Probes. Use a kit that allows dilutation of the Ca^{2+} concentrates into buffered solutions of any composition, so Mg, for example, can be included. These kits contain information on how to use them, but because they have been created to measure K_d in solution, not inside cells, it is necessary to use the procedure discussed below. Standards of this type are essential for measuring K_d in cells in suspension.

For purposes of discussion, the concentrated calibration kit will be assumed to contain solutions that are concentrated by a factor of 10, e.g., like the Molecular Probes Kit, which contains 100 mM K_2EGTA and 100 mM CaEGTA.

This protocol describes methods for measuring K_d for ratiometric and nonratiometric probes for cells in suspension and using either a calibration kit or prepared solutions.

IMPORTANT NOTE: Use extreme care in making dilutions because the accuracy of the calibration depends upon the accuracy of the dilutions made.

Additional Materials (also see Basic Protocol 1)

EGTA solution (see recipe for Ca^{2+} calibration standards)
CaEGTA solution (see recipe for Ca^{2+} calibration standards)
Ca solution (see recipe for Ca^{2+} calibration standards)
1 M $CaCl_2$
Cells incubated with probe (see Basic Protocol 1, step 9)

Determine K_d of a ratiometric probe for cells in suspension at 20°C

1. Make up solutions 1 through 13 using EGTA solution and CaEGTA solution in the proportions shown in Table 2.5.3.

   Table 2.5.3 shows $[Ca^{2+}]$ at 20°C for each of these solutions as well as for the EGTA solution, the CaEGTA solution, and the Ca solution.

   If the calibration is to be performed at 37°C, use Table 2.5.4 to make up solutions 1 through 13. Table 2.5.4 shows $[Ca^{2+}]$ at 37°C for each of these solutions as well as for the EGTA solution, the CaEGTA solution, and the Ca solution.

2. Wash 5.3×10^7 incubated cells with calibration medium and resuspend them in 1× calibration medium at 2.0×10^6 cells/ml.

3. Place 1.50 ml of the 20 mM EGTA solution in a cuvette. Add 1.50 ml of the washed cells. When the proper temperature is reached add 30 µl of 0.1 mM thapsigargin, 15 µl of 2 mM oligomycin, 15 µl of 1 mM CCCP, and 30 µl of 1 mM ionophore to yield final concentrations of 1 µM thapsigargin 10 µM oligomycin, 5 µM CCCP and 10 µM ionophore, respectively. Immediately start recording the time-based changes in fluorescence at λ_1 and λ_2 [$(F_t)_{EGTA\lambda1}$ and $(F_t)_{EGTA\lambda2}$, respectively]. As soon as they reach an apparent steady state, record their average values. Remove the sample and immediately centrifuge it at $200 \times g$ for 3 min and save the supernatant (SN_{EGTA}).

4. Repeat step 3 for each of the EGTA/CaEGTA solutions prepared in step 1 as well as the CaEGTA solution and the Ca solution, resulting in $(F_t)_{1\lambda1}$, $(F_t)_{2\lambda1}$, ..., $(F_t)_{9\lambda1}$, $(F_t)_{CaEGTA\lambda1}$, $(F_t)_{1\lambda2}$, $(F_t)_{2\lambda2}$, ..., $(F_t)_{9\lambda2}$, $(F_t)_{CaEGTA\lambda2}$, $(F_l)_{Ca\lambda2}$, and supernatants SN_1, SN_2, ..., SN_{13}, SN_{CaEGTA}, and SN_{Ca}.

5. For each of the sixteen supernatants, carefully pipet 2.75 ml of the supernatant into the cuvette, and get a good average value of fluorescence at λ_1 and λ_2 resulting in $(F_s)_{EGTA\lambda1}$, $(F_s)_{1\lambda1}$, ..., $(F_s)_{CaEGTA\lambda1}$, $(F_s)_{Ca\lambda1,}$ $(F_s)_{EGTA\lambda2}$, $(F_s)_{1\lambda2}$, ..., $(F_s)_{CaEGTA\lambda2}$ and $(F_s)_{Ca\lambda2}$. Calculate $(F_t - F_s)$ at $_{\lambda1}$ and $_{\lambda2}$ for all of the sixteen samples. Before removing each supernatant, carefully add the same concentration of detergent used in step 11 of Basic Protocol 1 and 40 µl of 1 M $CaCl_2$. Obtain a good average value of fluorescence at λ_1 while stirring. The resulting signals are $(F_{sd})_{EGTA\lambda1}$, $(F_{sd})_{1\lambda1}$, ..., $(F_{sd})_{CaEGTA\lambda1}$, and $(F_{sd})_{Ca\lambda1}$, respectively.

   F_{sd} will be used to determine the fraction of probe lost to the supernatant during the calibration.

6. If the value of F_a found in step 18 of Basic Protocol 1 is not negligible with respect to the internal probe fluorescence values $(F_t - F_s)$ at λ_1 and λ_2 for all of the sixteen samples, then correct F for autofluorescence.

   If this is the case, $(F_a)_{hi1}$, $(F_a)_{hi2}$, $(F_a)_{lo1}$, and $(F_a)_{lo2}$ will have been measured in step 24 of Basic Protocol 1. If $(F_a)_{hi1}$ approximately equals $(F_a)_{lo1}$ and $(F_a)_{hi2}$ approximately equals $(F_a)_{lo2}$, then it can be assumed that $(F_a)_{\lambda1}$ and $(F_a)_{\lambda2}$ are the same for all of the samples. If this is not the case, it will be necessary to calculate $(F_a)_{\lambda1}$ and $(F_a)_{\lambda2}$ for all sixteen samples using the procedure detailed in step 24 of Basic Protocol 1.

7. Calculate $(F)_{x\lambda1} = (F_t)_{x\lambda1} - (F_s)_{x\lambda1} - (F_a)_{x\lambda1} - (F_{id})_{\lambda1}$ and $(F)_{x\lambda2} = (F_t)_{x\lambda2} - (F_s)_{x\lambda2} - (F_a)_{x\lambda2} - (F_{id})_{\lambda2}$ for each of the sixteen different samples, x, where F_{id} is the calcium-insensitive fluorescence found in step 17 of Basic Protocol 1.

8. Place 1.50 ml of the Ca solution in a small beaker. Add 1.50 ml of the washed cells. Add 30 µl of 0.1 mM thapsigargin, 15 µl of 2 mM oligomycin, 15 µl of 1 mM CCCP and 30 µl of 1 mM ionophore while stirring. Carefully pipet 2.75 ml of this mixture into a cuvette. Carefully add the same amount of detergent used in step 5 and 40 µl of 1 M $CaCl_2$ while stirring. Once equilibrium is reached obtain a good average value of fluorescence at λ_1. The resulting signal is $(F_{td})_{Ca\lambda1}$. Calculate the leakage correction factor $k_x = [(F_{td})_{Ca\lambda1} - (F_{sd})_{x\lambda1}]/(F_{td})_{Ca\lambda}$ 1 where $(F_{sd})_{xl1}$ was measured in step 5 for each of the sixteen standards. The results are k_{EGTA}, k_1, ..., k_{CaEGTA}, and k_{Ca}.

   The leakage correction factor corrects F to the value it would have if all of the dye were inside the cells. F_{td} will be used to determine the total probe in each sample. This correction makes it possible to accurately plot F as a function of $[Ca^{2+}]$ and to correctly calculate (S_f/S_b).

9. Once all of the proper fluorescence values have been determined, calculate the corrected fluorescence for each sample x, $F_1 = F_{x\lambda1}/k_x$, $F_{min1} = (F)_{EGTA\lambda1}/k_{EGTA} \equiv (F)_{EGTA1}$ and $F_{max1} = (F)_{Ca\lambda1}/k_{Ca} \equiv F_{Ca1}$). Using equation 2.5.1, plot log $[(F_1 - F_{min1})/(F_{max1} - F_1)]$ versus log ($[Ca^{2+}]$). Fit the linear portion of the data with the linear

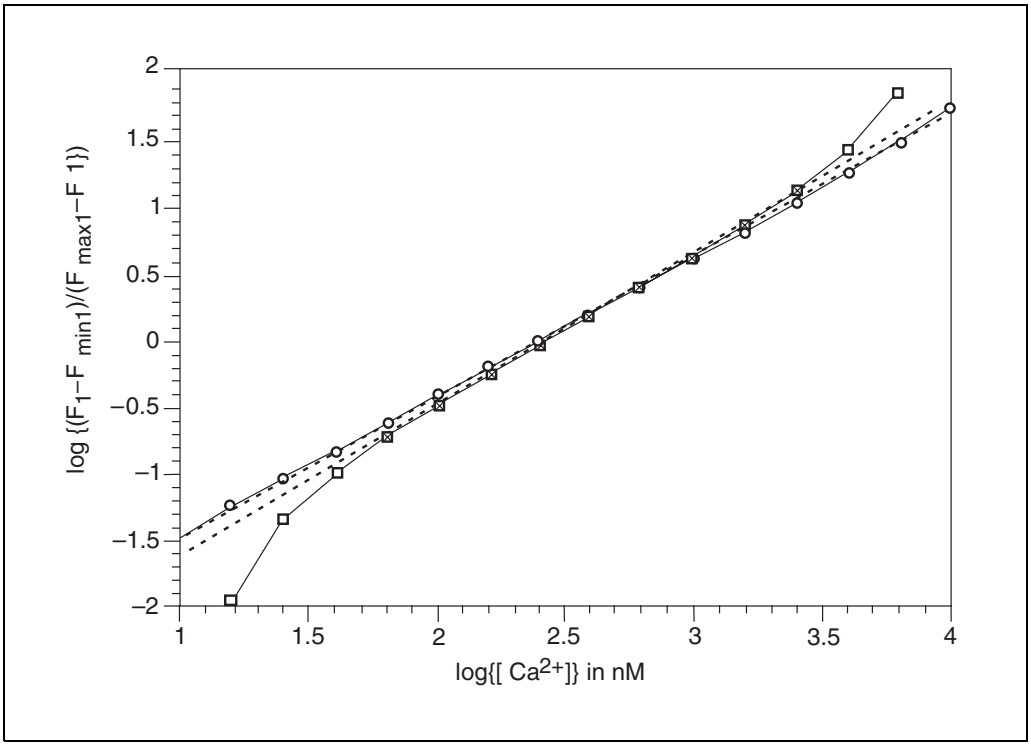

Figure 2.5.2 Sample K_d calibration curves for two different simulated calibrations. In both cases, $[Ca^{2+}]_{inside}$ does not equal $[Ca^{2+}]_{outside}$ when measuring F_{lo} and F_{hi}. In the first case (open circles), $[Ca^{2+}]_{inside}$ reached a minimum of 1 nM and a maximum of 40 μM. All of these data points can be fitted reasonably well with a straight line shown by a dotted line with the equation of the line $y = -2.5014 + 1.0408x$ with $R^2 = 0.99962$. The fact that the slope does not equal one indicates that the true value of F_{lo} and $F_{hi}$was not reached; even so, the calculated value of $K_d = 10^{2.5014/1.0408} = 253$ nM compares reasonably well to the true K_d of 258 nM. In the second case (open square), $[Ca^{2+}]_{inside}$ reached a minimum of 13 nM and a maximum of 10 μM. This data is definitely not linear and clearly indicates that the measured values of R_{min}, R_{max} and (S_f/S_b) obtained step 26 of Basic Protocol 1 will be incorrect. The X points indicate the linear portion of the data which yields a calculated value of $K_d = 10^{2.7265/1.1198} = 272$ nM, which is surprisingly close to the true value of K_d. The equation of this line is $y = -2.7265 + 1.1198x$ with $R^2 = 0.99962$.

least squares best fit line (see Fig. 2.5.2). The value of $[Ca^{2+}]$ for which $y = 0$ is a measure of the apparent K_d of the probe. If the values of F_{EGTA} and F_{Ca} are very close to their true values, the slope of the line will be one. If the values of F_{EGTA} and F_{Ca} are not close to their true values, all the data will clearly not fit a straight line, and the slope will not be one. Even when the data are poor, a reasonable approximation of the true K_d can still be found. However, in this case the use of the values of R_{max}, R_{min} and (S_f/S_b) found in step 26 of Basic Protocol 1 will lead to incorrect values of $[Ca^{2+}]$ inside the cells. Instead of using the measured values of R_{max}, R_{min} and (S_f/S_b), calculate them as follows. Using only the intermediate data points, plot fluorescence in counts/sec for both wavelengths λ_1 and λ_2 versus $[Ca^{2+}]$ and fit both sets of data with an equation of the form $F = (F_{lox} + F_{hix}/K_d[Ca^{2+}])/(1 + [Ca^{2+}]/K_d)$ where F_{lox}, F_{hix}, and K_d are unknown (see Fig. 2.5.3). If the data are very accurate, accurate values of $R_{min} = (F)_{lo1}/(F)_{lo2}$, $R_{max} = (F)_{hi1}/(F)_{hi2}$,, $(S_f/S_b) = (F)_{lo2}/(F)_{hi2}$ and K_d can be obtained from data for which $[Ca^{2+}]_{outside}$ ranges between 15 nM and 6 μM.

For dual-excitation (emission) monochromators, $R_{min} = (F)_{lo1}/(F)_{lo2}/R_L$ and $R_{max} = (F)_{hi1}/(F)_{hi2}/R_L$.where R_L was found in step 11 of Basic Protocol 1.

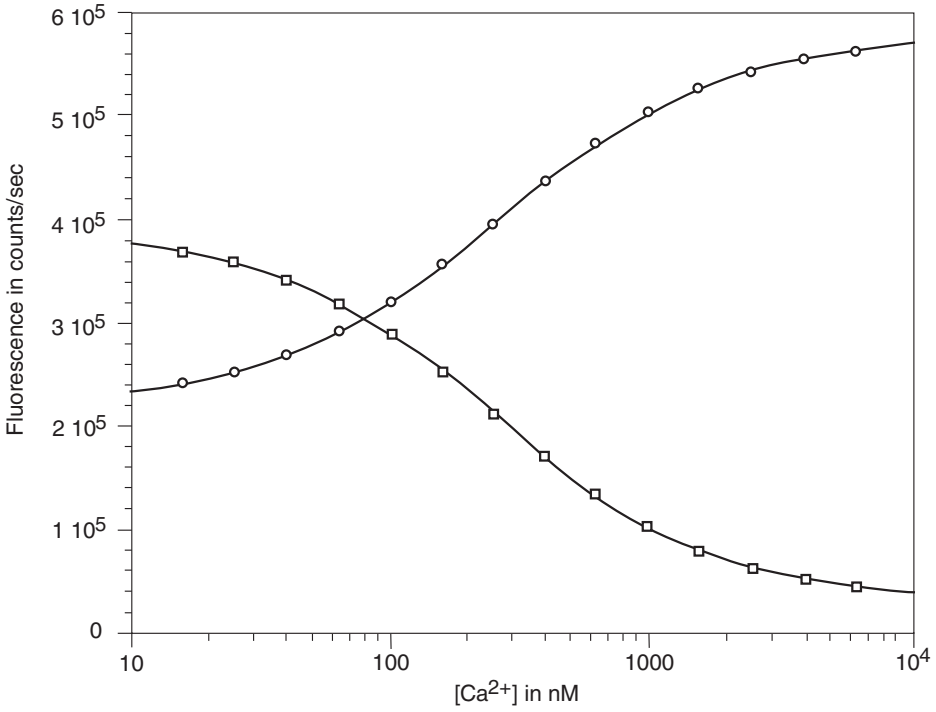

Figure 2.5.3 Alternate dye calibration technique. The open circle represents data measured for Fura-2 at a wavelength of 340 nm; the open square represents data measured for Fura-2 at a wavelength of 380 nm. Each set of data was restricted to $[Ca^{2+}]_{outside}$ ranging from approximately 15 nM to 6 μM. Each set of data was fitted by an equation of the form $F = (F_{lox} + F_{hix} \times [Ca^{2+}]/K_d)/(1 + [Ca^{2+}]/K_d)$ where F_{lox}, F_{hix} and K_d are unknown. The best fit lines are shown by the solid lines. (Most plotting programs such as KaleidaGraph permit the user to generate their own curves for fitting data.) The two calculated values of K_d can be averaged and if the data are very accurate, it is possible to calculate $R_{min} = (F)_{lo1}/(F)_{lo2}$, $R_{max} = (F)_{hi1}/(F)_{hi2}$ and $(S_f/S_b) = (F)_{lo2}/(F)_{hi2}$ very accurately.

Determine K_d of a nonratiometric probe for cells in suspension at 20°C

10. Follow steps 1 though 6 of this protocol, except record F_t values at a single wavelength only.
11. Calculate $(F)_x = (F_t)_x - (F_s)_x - (F_a)_x$ for each of the sixteen different samples x.
12. Follow steps 8 and 9 of this protocol for a single wavelength only and calculate F_{max} and F_{min}.

MEASUREMENTS OF $[Ca^{2+}]$ IN PLATED CELLS USING FLUORESCENCE DIGITAL IMAGING MICROSCOPY (FDIM)

BASIC PROTOCOL 2

For use in this protocol, cells can usually be plated on coverslips, or other systems designed for observation using microscopes, by incubating them overnight covered with complete medium. After attachment, these cells can be incubated in 1 to 5 μM concentrations of the membrane-permeable form of the probe of interest very much as described in Basic Protocol 1, and washed by simply exchanging the medium bathing the cells.

A number of commercial systems exist for viewing plated cells with an epifluorescence microscope (with excitation and emission pathways below the microscope stage). The

following will assume use of a common system in which cells are attached to a 25-mm glass coverslip mounted in a Leiden chamber; however, many current systems could be similarly described.

Note that it is not usually necessary to constantly flush the chamber with probe-free medium because the internal volume of the plated cells is very small compared to the volume of external medium and hence probe leakage cannot usually be detected.

Read the discussion at the beginning of Basic Protocol 1. According to Equation 2.5.3, $F_t = F_a + F_i + c_d [f_{hi}F_{hi} + (1 - f_{hi})F_{lo}] + F_s$. When using a cuvette-based system, F_s can be a very substantial fraction of F_t and can seldom, if ever, be ignored. On the other hand, in FDIM, F_s is basically a measurement of background and is usually used to correct for inhomogeneities of the camera/intensifier image. This background correction makes for the creation of a better mask for the images. For an intensity scale of 0 to 255, F_s should never be >3. If F_s is >3, then either probe leakage is a major problem, the standard medium contains a fluorescent component, or the compound used to help the cells adhere is fluorescent. Which of the three possibilities is causing the problem can easily be determined by checking the fluorescence of the standard medium alone and in combination with plates covered with the cell adhesive. If probe leakage is the problem, feed standard medium slowly into the chamber on one side and withdraw it by suction at the other. In this case, any probe that leaks from the cells is removed from the chamber in a short time.

F_i is not easily determined in this system. If a spectrofluorometer is available and the cells can be kept in suspension, use the procedure discussed under Basic Protocol 1 to determine the best incubation procedure to minimize F_i such that F_i is much less than $F_t - F_s$ at the detection wavelengths for any concentration of calcium. If no spectrofluorometer is available, it is still sometimes possible to determine if F_i is much less than F_t if one has a relative idea of the spectral shape of F_i. Choose a wavelength λ_i such that either $(F_i)_{\lambda i}$ is much greater than $(F_{hi})_{\lambda i}$ or $(F_i)_{\lambda i}$ is much greater than $(F_{lo})_{\lambda i}$ (see Equation. 2.5.4 and Equation 2.5.5). Next, subject the cells to either high or low calcium as is done during the calibration discussed below and measure $(F_t) - (F_s) - (F_a)$ at λ_i and see if it is much greater than expected for the Ca-sensitive form of the probe. For example, the spectrum of the Ca-insensitive form of Fura-2 (Gunter et al., 1988) is fairly similar to that of the low-calcium form and is much higher than that of the high-calcium form at 380 nm. Once everything possible is done to minimize F_i, for purposes of calculation, assume $F_i = 0$.

Because FDIM equipment permits such a limited range of intensity values, it is always important to maximize the range of intensities that the samples and standards undergo. Thus, always measure F_t first in order to determine what light intensity, excitation slits, and camera/intensifier gain should be used. Because the calibration samples represent the extremes in intensity that the samples can undergo, they should always be measured first. If, on the basis of previous samples, the value of light intensity and camera/intensifier gain are known, measure F_s first and automatically subtract F_s from F_t if the software being used has this capacity.

Because of the characteristics of the epifluorescence microscope (both excitation and emission light passing through the coverslip) and the optical frequency response of the microscope optics, there may be some distortion of the spectra and ratios of probes using near-UV wavelengths. This may alter the characteristics of the probe from those observed with a good fluorescence spectrometer, decrease the sensitivity of a probe, and change the wavelengths at which optimum sensitivity can be obtained; however; the same probes can still be used for measurement of $[Ca^{2+}]$ with modifications of the wavelengths used.

In addition, the intensity of illumination of microscope systems is usually nonuniform across the field of view. Thus, some cells receive more incident light than others.

It is important to note that when using a ratiometric probe one should always save the raw data. A ratio to observe can be calculated while data is taken, if preferred, but the raw data must be saved, not the ratio. The only exception to this rule is to automatically subtract the background from raw data if the machine has the capacity.

CAUTION: When neither viewing the cells's fluorescence nor recording an image, stop the excitation light from reaching the cells to minimize photobleaching.

Materials

Adherent cells and incubation medium
25-mm glass coverslip mounted in a Leiden chamber (Medical Systems Corp.)
1× low calcium medium (see recipe)
1× high calcium medium (see recipe)
Standard medium with cyanide (see recipe)
Fluorescence microscope with FDIM system (Photon Technology International, Inc.)
Additional reagents and equipment for fluorescence measurement of intracellular [Ca^{2+}] (see Basic Protocol 1)

Choose fluorescent probe to be used and check its fluorescent characteristics

1. Chose the fluorescent probe to be used (see Basic Protocol 1).

   To be able to calculate [Ca^{2+}], use a ratiometric probe. Except in special circumstances, it is only possible to obtain approximate values of [Ca^{2+}] with a nonratiometric probe, and the process of obtaining such information is very labor-intensive.

2. Without cells on the coverslip, turn on the equipment. Start with the excitation slits set to between 2 and 5 nm in width. Insert the proper dichroic for the probe being used. Check and adjust black level.

   For Indo-1, the equipment must have dual-emission capacity. The actual slit widths to be used depend upon the sensitivity of the system.

3. Also without cells on the coverslip, set up the equipment as follows.

   a. Add 1 ml of either the 5 μM FA in low-Ca solution or 5 μM FA in high-Ca solution. Choose the solution that is expected to have the most intense emission. For example, for Fura-2, use the high-Ca solution.

   b. Set the microscope for binocular viewing and using the white light, focus on the coverslip and then raise the focus above the coverslip using ~1.5 turns of the fine-focusing knob so as to focus well into the solution. Turn off the white light, set excitation at the peak excitation for the probe and attempt to observe the fluorescence.

   c. If there is no fluorescence, increase the intensity of the incident light but do not increase excitation band-pass much beyond 12 to 15 nm if using a ratiometric probe like Fura-2.

   d. Once fluorescence is observed (or has reached maximum band-pass for the excitation), close the shutter for the excitation light, switch the microscope to camera, turn on fast focus or its equivalent which permits observation of the coverslip in real time, and slowly open the shutter for the excitation light, making sure not to saturate the camera. If necessary, decrease the intensity of the incident light by decreasing band-pass or slits.

e. If the camera shows no image of the illuminated field of fluorescent medium, gradually increase the voltage applied to the intensifier or camera gain until a satisfactory image is observed.

Initially the maximum intensity in the image should be ~80% of the maximum possible value.

Even if there are only filters in the excitation setup, it is still necessary to determine the proper slits to use. Generally, signal can be increased by either increasing the excitation slits or by increasing the voltage applied to the intensifier or camera gain. When using an excitation ratiometric probe like Fura-2, the wider the excitation band-pass, the smaller the range of overall sensitivity to [Ca^{2+}] becomes, but increasing the voltage applied to the intensifier or camera gain increases noise, so it becomes a tradeoff between sensitivity and noise. Nonratiometric probes are less demanding, and it is usually possible to increase band-pass to increase sensitivity.

4. If the excitation setup contains a monochromator, scan excitation in order to locate the maximum excitation for the probe. When using an excitation ratiometric probe such as Fura-2, make up probe-free acid solutions in high-Ca/low-Ca solutions (see Basic Protocol 1, step 2). Obtain the excitation spectra for each one of these mixtures and plot them on the same graph. Do not change high voltage or gain while measuring these spectra.

   This usually involves creating a single large region of interest (ROI) in the field of view, choosing to record its median value, and then scanning the spectra. These are the characteristic spectra to be expected from the chosen Ca^{2+}-sensitive probe in the system. The point at which all of the spectra cross is the isosbestic point λ_t.

   IMPORTANT NOTE: *When not using the camera, turn off the high voltage or decrease gain. Furthermore, if it is necessary to observe the cells in step 6, change the microscope from camera to binocular when finished with the camera. This precaution is taken to protect the camera from being accidentally exposed to excess light intensity. In addition, when neither viewing the cells's fluorescence nor recording an image, stop the excitation light from reaching the cells to minimize photobleaching.*

5. When using dual-excitation monochromators, set both monochromators to the same wavelength (λ_1), and using one of the calcium mixtures and the ROIs from step 4, measure the median fluorescent intensity of the light between the two monochromators (F_{mono1} for the monochromator that measures λ_1 and F_{mono2} for the monochromator that measures λ_2) Measured ratios can then be corrected for this artifact by dividing all ratios by R_L, where $R_L = F_{mono1}/F_{mono2}$.

   R_L is generally constant during the course of a single experiment, but tends to vary between experimental sessions. Hence, it should be measured at least twice in every experimental session. Any sample containing the probe will be adequate for this measurement.

6. Calculate R_{max}, R_{min} and R_{max}/R_{min}.

   If R_{max}/R_{min} is much more than 20, it is necessary to adjust either λ_1 or λ_2 to increase the average intensity of the dimmest image at λ_1 or λ_2. If it is much less than that expected for the probe in question, it may be necessary to decrease the band-pass of the excitation slits. (See comments under step 7 of Basic Protocol 1 for more details.) When using an emission type of ratiometric probe, it is normally impossible to scan emission, but it is possible to calculate the median value of a large ROI for both wavelengths in high- and low-calcium media in order to calculate R_{max} and R_{min}.

Incubate cells with the probe

7. Unless the cells are already plated out, resuspend at 1×10^6 cells/ml and place 50 µl of cells in the center of a coverslip. Cover and incubate at 37°C for 2 hr to give the cells a chance to adhere, then flood with incubation medium.

If the cell type has difficulty adhering to glass, coverslips may be pretreated with an extracellular matrix material such as type I collagen or laminin.

Cells should be close to touching but without overlapping. Because the number of cells in a field of view is limited and the quality of cells can vary from plate to plate, take at least two views per plate (provided no additions to the plate cause irreversible changes in the cells) and run triplicate plates per sample. Complete calibrations can be performed on the same plate, but it often requires two or more plates. Likewise, a K_d calibration requires a minimum of two to three plates and can require as many as 20 to 40, depending on how well the cells hold up under calibration conditions. The time it takes to run these samples limits how many experimental samples can be analyzed.

8. When the cells are ready for incubation with the AM form of the probe (also see Basic Protocol 1, step 8), remove the incubation medium and replace with 0.5 ml standard medium. Add 2 to 10 μM of the AM form of the probe to 0.5 ml standard medium and mix well by vortexing or shaking and immediately add to the cells to be incubated, making sure the solution is well mixed. Allow this mixture to incubate at 37°C for 30 min to 1 hr. After incubation, rinse the cells with standard medium two to three times (see Basic Protocol 1, step 9).

   Once rinsed, these cells should be stored at room temperature or 4°C until they are used to decrease probe leakage. In the following steps, these cells will be called "incubated cells."

Make measurements using ratiometric probes

Steps 9 to 20: Perform measurements needed for calculating R_{max} and R_{min} (also see Basic Protocol 1, steps 19 to 26, for discussion on measuring R_{max}, R_{min}, S_f, and S_b).

9. Place incubated cells in the holder, rinse twice with low-Ca medium, remove all of the rinse, and then add 1.0 ml of low-Ca medium.

   IMPORTANT NOTE: *If cells cover the entire coverslip, wipe a small area free of cells for the background measurement.*

   CAUTION: *The most important step is making sure the two components are well mixed. If mixing is not complete, many or perhaps all of the cells in the field of view will not respond to changes in external [Ca^{2+}].*

10. Place the coverslip on the microscope stage, make sure the microscope is set to binocular view, and use the white light to focus on the cells. Find a likely group of cells, then turn off the white light and turn on the excitation light to examine the cells.

    The cells should be dimly visible. If not, increase the intensity of incident light if possible (see discussion about excitation band-pass in step 3 of this protocol).

    IMPORTANT NOTE: *Once the excitation band-pass to be used in an experiment is determined, do not modify it unless a new set of R_{max}, R_{min}, S_f, and S_b is determined for each change in band-pass. This is because R_{max}, R_{min}, S_f, and S_b are sensitive to band-pass. However, it is possible to modify lamp intensity, slit widths that do not change band-pass, and intensifier high voltage or camera gain without having to remeasure R_{max}, R_{min}, S_f, or S_b.*

11. Set the microscope to camera, turn on fast focus (or its equivalent), and slowly increase high voltage to the intensifier or increase camera gain until a bright image is observed at either λ_1 or λ_2. Next, vary fine focus to provide the brightest, sharpest image. Make a note of the final high voltage or gain setting.

    The brightest cell should have a maximum intensity of ~90% to 95% of the maximum permissible intensity. In the future, the expression "turn on HV/G" will mean turn on the high voltage and/or gain to the values determined in the step indicated afterwards in

parentheses. For example, "turn on HV/G (step 4). In addition, "turn off HV/G" always means" turn off the high voltage and set gain = 0."

IMPORTANT NOTE: *If it is not possible to obtain a sufficiently bright image even with high voltage or gain set to the maximum, many systems permit summing several images to increase the overall intensity of the image. This feature should only be used as a last resort because it also greatly increases noise. In addition, most intensified camera systems offer the option of averaging several images. Average as many images as are practical because averaging images reduces noise by the square root of the number of images averaged.*

12. Turn off HV/G, change the microscope to binocular, turn on the white light, and locate an area of the coverslip that has no cells in the field of view. Turn off the white light, switch the microscope to camera, turn on HV/G (step 12), and take a set of background images at λ_1 and λ_2. The resulting images are $(I_s)_{lo1}$ and $(I_s)_{lo2}$.

This region is the background for this plate and is basically a supernatant image. The primary purpose of this set of background images is to ensure that the background is not too high. If it is, determine the cause and correct the problem before continuing the measurements.

IMPORTANT NOTE: *If at any time during the course of the experiment a change is made in lamp intensity, slits not associated with band-pass, intensifier high voltage, or camera gain, take a new background for that coverslip. In general, it is best to take a background for each coverslip unless all of the backgrounds appear to be the same, in which case it is necessary only to take new backgrounds whenever a change is made in lamp intensity, slits, intensifier high voltage or camera gain.*

13. Turn off HV/G, change the microscope to binocular, turn on the white light, and locate an area of the coverslip that has discrete cells and bring them into focus. Turn off the white light, switch the microscope to camera, turn on HV/G (step 11), and turn on fast focus. Vary fine focus to provide the brightest, sharpest image, then take a set of images at λ_1 and λ_2 with backgrounds found in step 11 automatically subtracted.

If the software program cannot automatically subtract the background, the backgrounds must be subtracted manually before the images are used in any further analysis.

IMPORTANT NOTE: *If at all possible, set up an aspirator that can remove all of the liquid from the chamber without accidentally moving the coverslip. This makes it possible to make repeated measurements on exactly the same cells in exactly the same position while changing the medium between measurements. An aspirator should be set up whenever multiple changes are to be made to the same cells on a coverslip.*

14. Turn off HV/G and switch to analysis mode. If the software permits one to take the maximum of two images, take the maximum of these two images (see Fig. 2.5.4A, B, and C) and create a mask from this image, setting threshold high enough to eliminate any of the background outside of the cell but not so high as to eliminate portions of the cell (see Fig. 2.5.4D). Use the minimum of the two images to create ROIs that include only those cells whose minimum intensity image is significantly above background and whose maximum intensity image does not go off the intensity scale (see Fig. 2.5.4E).

If the software being used cannot take the maximum of two images, choose the brightest of the two images to create the mask.

The ROIs [$(ROI)_{lo}$] should be just inside of the masked cell.

15. Aspirate all of the medium from the coverslip. Add 10 µl of 0.1 mM thapsigargin, 7.5 µl of 2 mM oligomycin, 7.5 µl of 1 mM CCCP and 10 µl of 1 mM ionophore to 1.0 ml of low-Ca medium in a small tube to yield final concentrations of 1 µM thapsigargin 10 µM oligomycin, 5 µM CCCP and 10 µM ionophore, respectively.

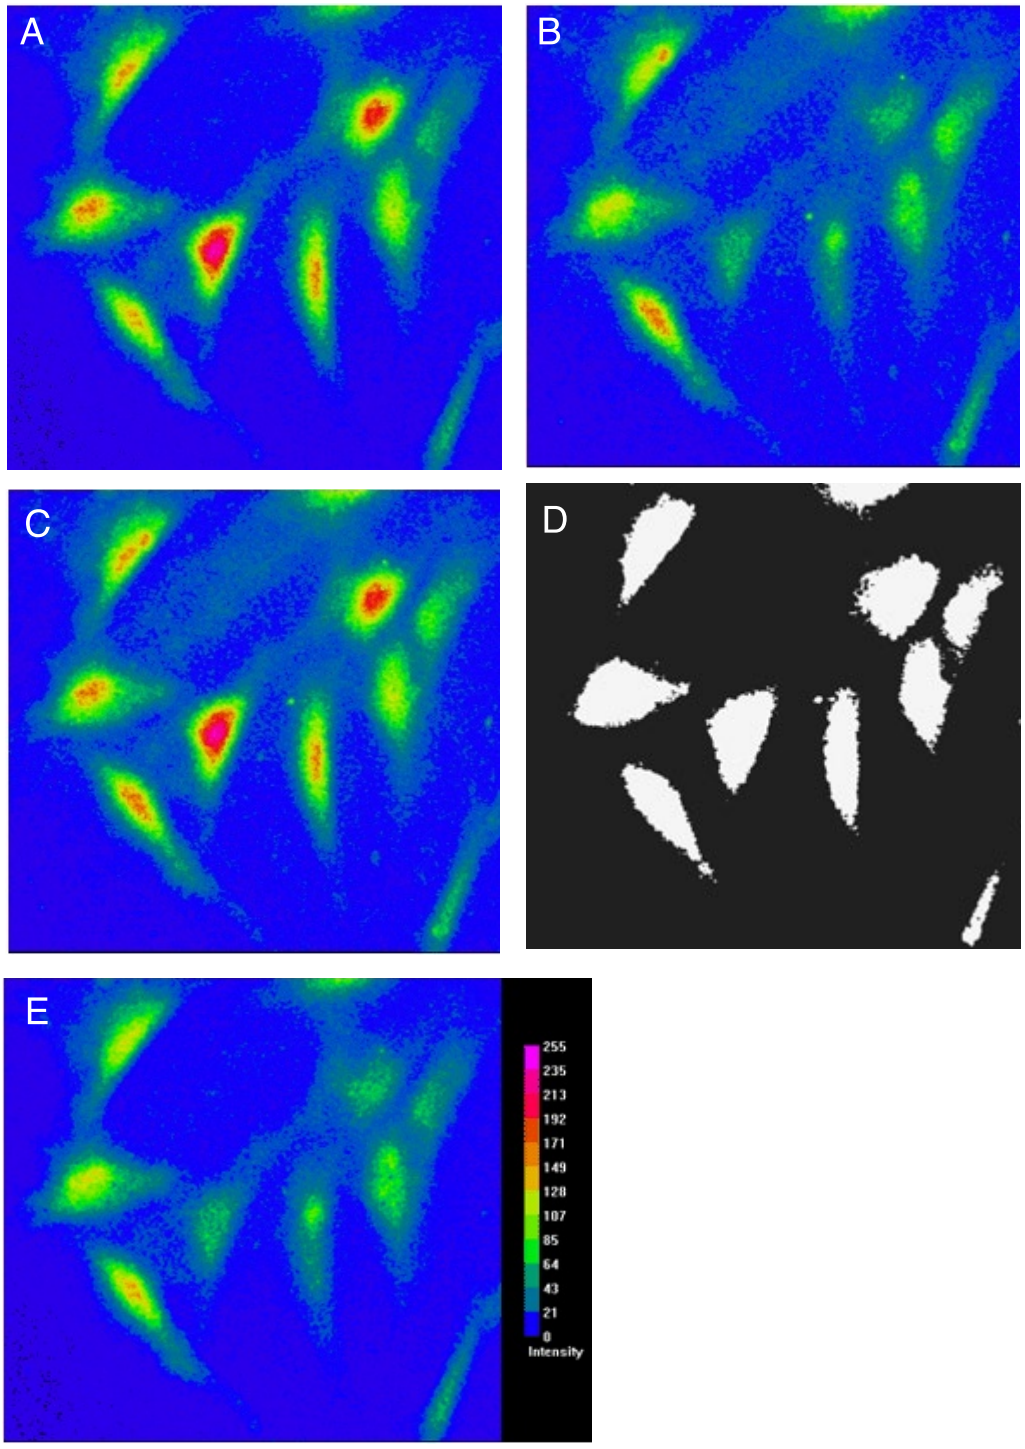

Figure 2.5.4 (**A**) Fura-2 FA 340-nm image of osteoblasts. (**B**) Fura-2 FA 380-nm image of osteoblasts. (**C**) Image created by taking the maximum of images in panel A and panel B. (**D**) Mask created by using the maximum of images in panel A and panel B and setting the threshold to an intensity of 45. (**E**) Image created by taking the minimum of images in panel A and panel B. The color scale for **A** through **D** is the same as that depicted in **E**. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures*

Immediately shake or vortex this mixture and then add it to the coverslip. Note the time at which this addition was made.

16. Switch back to data-acquisition mode and change the setup to record the median value of intensity inside each ROI. Turn on HV/G (step 11), take a set of images about once a minute, and plot the ROIs versus time. When the median values of most of the ROIs at both λ_1 and λ_2 reach a steady state, set the software to average the maximum number of images and save a pair of images [these are the low-calcium images $(I_t)_{lo1} - (I_s)_{lo1}$ and $(I_t)_{lo2} - (I_s)_{lo2}$]. Calculate the time it took to reach a steady state from the time the medium containing the ionophores and inhibitors was added to the coverslip (this is the minimum time required to reach low calcium inside the cell type).

    The images taken while following median values do not need to be solved.

    If too many pixels inside of the ROIs are off-scale, it may be necessary to change HV/G before saving a pair of images. In this case, turn off automatic background subtraction before taking the uncorrected low-calcium images, $(I_t)_{lo1}$ and $(I_t)_{lo2}$. If HV/G is changed, new background images, $(I_s)_{lo1}$ and $(I_s)_{lo2}$, will need to be taken and subtracted manually from the uncorrected images (see step 19).

17. If the probe is ratiometric in excitation and the equipment includes optional scanning of excitation, switch the software from time-based mode to wavelength mode, turn off automatic background subtraction, and using the ROIs, scan the entire wavelength range including λ_1 and λ_2 plus a little extra on either side. Save the resulting median values of intensity for each of the ROIs as a function of wavelength as the uncorrected low calcium spectra $(S_t)_{lo}$ inside the cells.

18. If HV/G was changed in step 16 repeat step 12 with HV/G (step 6) and the software set to average the maximum number of images to obtain the proper background images $(I_s)_{lo1}$ and $(I_s)_{lo2}$. If the probe is ratiometric in excitation, repeat step 16 on this background area using the same ROIs $[(ROI)_{lo}]$ in order to obtain the low-calcium background spectra $(S_s)_{lo}$. Turn off HV/G and switch the microscope back to binocular mode.

19. If it appears that too much probe was lost from the cells during the low-calcium calibration, place a new set of incubated cells in the holder; otherwise, use the current coverslip. Repeat steps 11 through 17 of this protocol using high-Ca medium. If the images are background corrected, the resulting images are the high-calcium images $(I_t)_{hi1} - (I_s)_{hi1}$ and $(I_t)_{hi2} - (I_s)_{hi2}$ and the ROIs $(ROI)_{hi}$. Calculate the time it took to reach a steady state from the time the medium containing the ionophores and inhibitors was added to the coverslip. This is the minimum time required to reach high calcium inside the cell type being used.

20. If the probe is ratiometric in excitation, repeat step 16. Save the resulting median values of intensity as a function of wavelength as the uncorrected high-calcium spectra $(S_t)_{hi}$ inside the cells. Repeat step 18 to obtain $(I_s)_{hi1}$ and $(I_s)_{hi2}$ [and $(S_s)_{hi}$ if the probe is ratiometric in excitation].

    IMPORTANT NOTE: *If the cells have not greatly changed relative intensities at the two different wavelengths, it is highly likely that $[Ca^{2+}]$ inside the cells is not equilibrating with external $[Ca^{2+}]$. In this case, see Troubleshooting.*

Perform measurements needed for calculating S_f and S_b for probes that are ratiometric in excitation or for systems that cannot scan excitation

Steps 21 to 22: Equipment that includes the option of scanning excitation makes it possible to measure S_f and S_b quite accurately for probes that are ratiometric in excitation. If the equipment does not include this option, then measure S_f and S_b as discussed below for

probes that are ratiometric in emission (also see Basic Protocol 1, steps 19 to 26, for discussion on measuring R_{max}, R_{min}, S_f, and S_b).

21. Place a new set of incubated cells in the holder, rinse twice with standard medium, and then add 1 ml of standard medium. Repeat steps 10 and 11 with HV/G set to the level used in step 19. Create ROIs as discussed in step 14. Switch back to data-acquisition mode and change the setup to record the median value of intensity inside of each ROI.

22. Switch the software from time-based mode to wavelength mode, turn on HV/G (step 19), and using the ROIs, scan a wavelength range centered about the isosbestic point λ_i that was found in step 4. Using a flashlight as a dim source of light in order to protect the camera (since the high voltage is on and light is reaching the camera), aspirate all of the medium, and then add 1 ml of medium containing some factor that will induce changes in $[Ca^{2+}]$ and immediately initiate multiple scans around λ_i until the pulse is more or less complete. Plot all of these scans on the same graph and determine λ_i for probe inside the cells.

    Factors which induce changes in $[Ca^{2+}]$ are dependent upon the cell type. Many cells when exposed to high potassium in the external medium will depolarize which results in a high calcium pulse. Most cell types respond to specific hormones. For example, chondrocytes respond to parathyroid hormone; liver cells respond to vasopressin, catecholamines, and angiotensin; brain cells respond to almost all of the neurotransmitters. In addition, many cell types respond to thapsigargin, and muscle cells respond to caffeine.

    Many researchers have found that both λ_i and K_d of probes inside cells can be quite different from that found in a cell-free medium (Baker et al., 1994; Brandes et al., 1993; Lipp et al., 1996).

Make measurements needed for calculating S_f and S_b for probes that are ratiometric in emission or for systems that cannot scan excitation

The major problem in accurately measuring S_f and S_b is the loss of probe from inside the cells during the course of the measurements. By repeating the low- and high-calcium calibrations on the same group of cells with λ_1 set to λ_i, the isosbestic point, it is possible to estimate dye loss between the two measurements. Since it is not possible to measure the true value of λ_i in the system, assume it is equal to the value given in the literature or that found using a spectrometer.

23. Replace the band-pass filter for λ_1 with one that will transmit λ_i. Since the same set of cells must be used for both low and high calcium measurements, set up a system that can automatically remove all of the medium from the holder. Repeat steps 9, 10, 12, and 17 except set HV/G equal to the value found that results in the brightest images at λ_2. Set the software to average the maximum number of images, wait the minimum time required to reach low calcium inside the cell type under examination, and take a set of images, which will be the uncorrected low-calcium images, $(I_t)_{loi}$ and $(I_t)_{loi2}$.

    This same set of cells must be used for the high-calcium measurements, so it is necessary to be very careful not to move the microscope stage.

24. Repeat step 15 using high-Ca medium, except use the automatic system to remove the low-Ca medium and rinses and make all additions very carefully so as to not change the field of view. Turn on HV/G and repeat step 11. Set the software to average the maximum number of images, wait the minimum time required to reach high calcium inside the cell type, and take a set of images, which will be the uncorrected high-calcium images, $(I_t)_{hii}$ and $(I_t)_{hii2}$.

25. Take a set of background images, $(I_s)_i$ and $(I_s)_{i2}$, by following the procedure of step 12 after setting HV/G (step 23) and setting the software to average the maximum number of images. If HV/G used in step 24 is different from that used in step 23, Take another set of background images, $(I_s)_{hii}$ and $(I_s)_{hii2}$, by following the procedure of step 12 after setting HV/G (step 24) and setting the software to average the maximum number of images.

If HV/G for high and low calcium measurements are the same, $(I_s)_{hii} = (I_s)_{loi}$ and $(I_s)_{hii2} = (I_s)_{loi2}$.

Measure autofluorescence (F_a)

Except for Fura red, for which autofluorescence is not a problem, the usual major source of autofluorescence for the ratiometric [Ca^{2+}] probes is NADH, whose fluorescence varies with the metabolic state of the cells. Maximum autofluorescence occurs in the presence of cyanide (5 mM); minimum autofluorescence occurs in the presence of protonophores such as CCCP (Jiang and Julian, 1997). For Fura-2 and its analogs, maximum autofluorescence will occur at λ_i or 380 nm. For Indo-1, maximum autofluorescence will occur at 480 nm. If one is unable to detect autofluorescence in the presence of 5 mM cyanide under the experimental setup, it is negligible and can be neglected. If autofluorescence cannot be neglected, make autofluorescence measurements for each value of HV/G used, as well as the corresponding background measurements. For autofluorescence and background images always set the software to average the maximum number of images.

26. Place cells that have not been incubated with the probe in the holder, rinse twice with standard medium, and then add 1 ml of standard medium. Repeat steps 9 and 10, except set HV/G to the largest value used (step 16 or 19) and observe λ_i and λ_2 for probes such as Fura-2 and 480 nm for Indo-1 If no cells can be detected in either image, replace the standard medium with standard medium containing 5 mM cyanide and repeat the measurements after 10 to 15 min. If cells still cannot be detected in either image, autofluorescence can be ignored. If autofluorescence is detected, continue with the following steps.

27. Place cells that have not been incubated with the probe in the holder. Repeat steps 9 and 10, except locate an area that contains no cells. Set the microscope to camera, turn on HV/G (step 16) and take two background images, $(I_{sa})_{lo1}$ and $(I_{sa})_{lo2}$. If steps 23 through 25 were performed, change HV/G (step 23) and take two background images, $(I_{sa})_{loil}$ and $(I_{sa})_{loi2}$. Turn off HV/G, change the microscope to binocular, turn on the white light, locate a large group of cells, and bring them into focus. Set the white light so dim you can barely seen the cells. Set the microscope to camera, turn HV/G to 0. Turn on fast focus and slowly increase HV/G and/or the intensity of light until you obtain a decent white image. Save this image as I_w and turn off white light. Change HV/G (step 17). If it is possible to automatically subtract a background image, set the backgrounds to $(I_{sa})_{lo1}$ and $(I_{sa})_{lo2}$. After the minimum time required to reach low calcium (determined in step 18), take two images of autofluorescence, $(I_a)_{lo1}$ and $(I_{sa})_{lo2}$. If steps 23 through 25 were performed, change HV/G (step 23). If it is possible to automatically subtract a background image, then set backgrounds to $(I_{sa})_{loi1}$ and $(I_{sa})_{loi2}$ and take two more images, $(I_a)_{loi1}$ and $(I_a)_{loi2}$.

Since the autofluorescence images may be very dim, the white light image can be used to help locate the cells and to create the ROIs.

28. If the software cannot subtract background automatically, manually subtract the background images from the autofluorescence images. Make a mask and create ROIs for the autofluorescence images as discussed in step 14. (If necessary, use I_w to create the ICOIs but not the mask.) Use these ROI's to measure the median values of fluorescence inside of the masked images. Calculate the average of these median

values at λ_1, λ_i, and λ_2, which will be $(F_a)_{lo1}$, $(F_a)_{lo2}$, $(F_a)_{lo1lo}$, $(F_a)_{loi1}$, and $(F_a)_{loi2}$ (see Basic Protocol 1, step 24). If the average median value $(F_a)_{lo2}$ is noticeably greater than background, measure the corresponding uncorrected low calcium autofluorescence spectra $(S_{ta})_{lo}$ at HV/G (step 17) as described in step 18 of this protocol, and then the low-calcium background spectra $(S_{sa})_{lo}$ as described in step 19. For each ROI, calculate $(S_a)_{lo} = (S_{ta})_{lo} - (S_{sa})_{lo}$ and then calculate the average spectra $[(S_a)_{lo}]_{ave}$ for HV/G (step 17). Turn off HV/G and switch the microscope back to binocular mode.

29. Repeat steps 27 and 28 with high-Ca medium instead of low-Ca medium.

This will result in $(F_a)_{hi1}$ and $(F_a)_{hi2}$ and where pertinent, $(F_a)_{hi1}$, $(F_a)_{hi2}$, and $[(S_a)_{hi}]_{ave}$.

Calculate the excitation spectra of probe inside cells for probes that are ratiometric in excitation

30. Switch to analysis and use the appropriate software program or a spreadsheet such as Excel to calculate the spectra. For each of the ROIs in $(ROI)_{lo}$ (step 17) calculate $(S)_{loj} = (S_t)_{loj} - (S_s)_{loj} - [(S_a)_{lo}]_{ave}$, where $(S_t)_{loj}$ and $(S_s)_{loj}$ were measured in steps 17 and 18 for the *j*th cell and $[(S_a)_{lo}]_{ave}$ was measured in step 28 (or is negligible). Compare these spectra with the low-calcium spectrum found in step 4 and eliminate any cells whose spectrum appears to be a combination of low- and high-calcium spectra. Using the remaining cells, calculate the average low-calcium spectrum inside the cells, $[(S)_{lo}]_{ave}$ = (sum of all of the remaining spectra $(S)_{loj}$)/(the number of cells included in the average).

If none of the spectra have approximately the correct shape, either the cells did not reach low calcium inside the cell or there are problems with inner-filter effect which must be corrected. (see Troubleshooting for discussion of the impact of the inner-filter effect on spectra).

31. In the same way, using the ROIs in $(ROI)_{hi}$ (step 19), calculate $(S)_{hij} = (S_t)_{hij} - (S_s)_{hij} - [(S_a)_{hi}]_{ave}$, where $(S_t)_{hij}$ and $(S_s)_{hij}$ were measured in step 20 for the *j*th cell and $[(S_a)_{hi}]_{ave}$ was measured in step 29 (or is negligible). Compare these spectra with the high-calcium spectrum found in step 4 and calculate the average high-calcium spectrum inside the cells, $[(S)_{hi}]_{ave}$ = (sum of all of the remaining spectra $(S)_{hij}$)/(the number of cells included in the average).

If none of the spectra have the correct shape, either the cells did not reach high calcium inside the cell or there are problems with inner-filter effect which must be corrected.

Determine R_{max}, R_{min}, S_f, and S_b

Steps 32 to 38: When taking a ratio image, most programs require setting the ratio range. If too large a range is set, the measured ratios will only cover a small part of the overall range. Since most digital imaging systems only have a limited set of intensity or ratio values, this causes a decrease in the precision to which one can measure individual ratios. Alternatively, if too small a range is set, some of the ratios may be out of range (i.e., have a ratio either larger or smaller than the set range). Some programs indicate the pixels in a ratio image that are outside the range, but others "wrap" the image around, which means that the pixels that are out of range appear to be in range, but have incorrect ratio values (see Fig. 2.5.5A). Therefore, in analyzing data, it is essential to be sure that the image never wraps around inside of cells to be used in the analysis (it does not matter if data is "wrapped" inside of cells that are not used). Below is a detailed procedure on how to avoid this problem.

32. Switch to analysis mode. Calculate $(I_{t\text{-}s})_{lo1} = (I_t)_{lo1} - (I_s)_{lo1}$ and $(I_{t\text{-}s})_{lo2} = (I_t)_{lo2} - (I_s)_{lo2}$, where $(I_t)_{lo1}$ and $(I_t)_{lo2}$ were measured in step 16 and $(I_s)_{lo1}$ and $(I_s)_{lo2}$ were measured in step 12 (or 19 if backgrounds were not automatically substracted). If the software

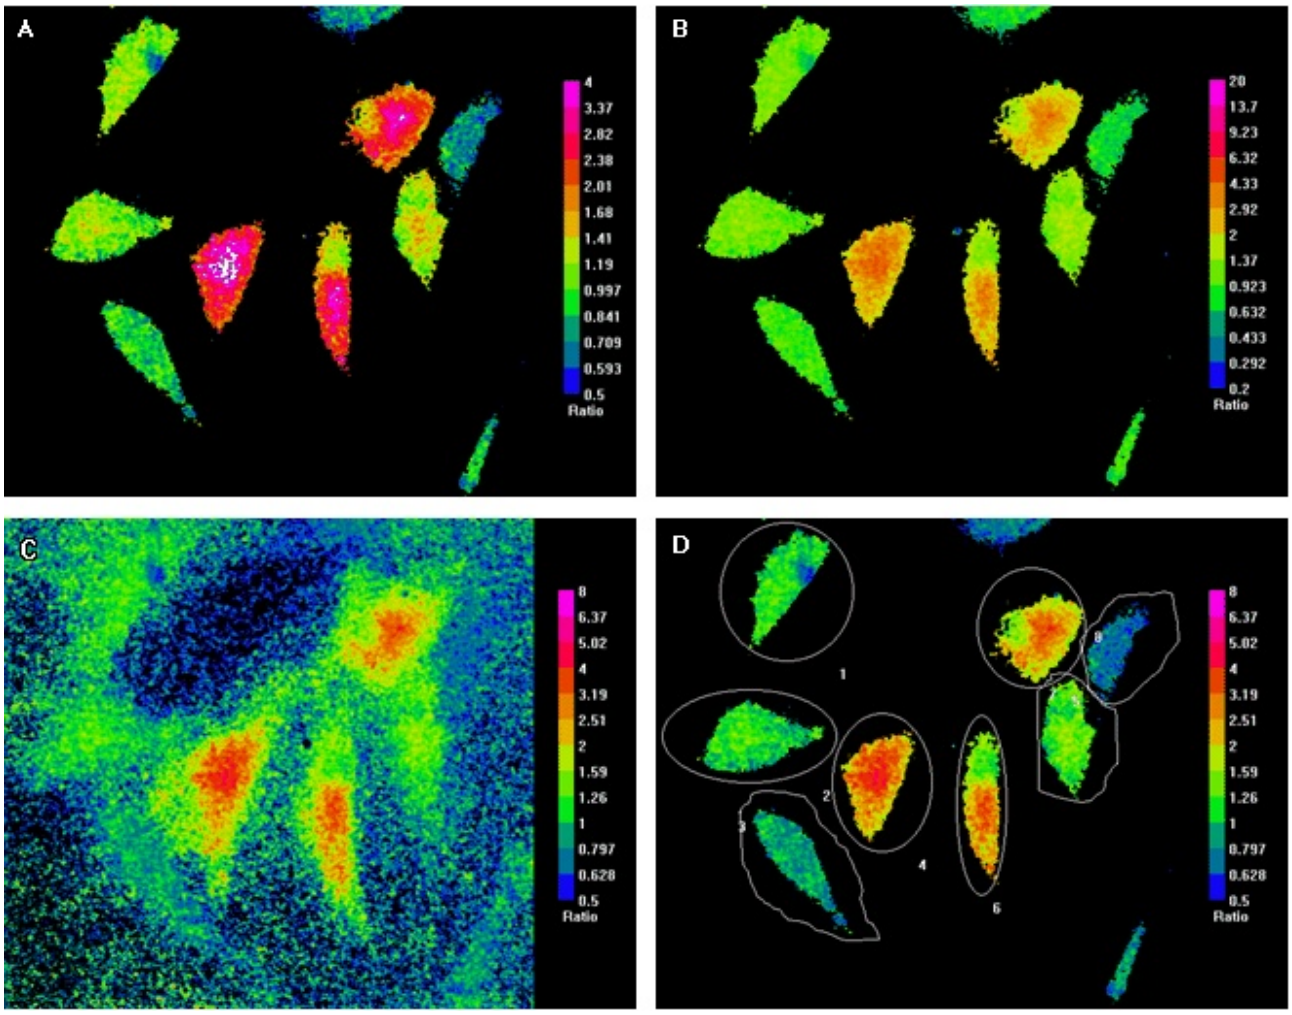

Figure 2.5.5 (**A**) Image created by taking the ratio of images in Figure 2.5.2, panels A and B, where the ratio range is too small, resulting in "wrapping" of the image. (**B**) Image created by taking the ratio of images in Figure 2.5.2, panels A and B, where the ratio range is large enough to guarantee that the image will not "wrap." (**C**) Image created by taking the ratio of images in Figure 2.5.2 panels A and B, where the ratio range is large enough to guarantee that the image will not "wrap" but small enough to easily display the differences between neighboring cells and to improve the accuracy of calculated median values. (**D**) The image in panel C of this figure with the mask applied and regions of interest drawn. These ROIs are either ellipses or free hand (software used is ImageMaster by Photon Technology International). *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures*

permits taking the maximum of two images, take the maximum of $(I_{t\text{-}s})_{lo1}$ and $(I_{t\text{-}s})_{lo2}$. If the software cannot take the maximum of two images, choose the brightest of the two images. Use the linear profile tool to observe the linear profiles through the brightest cells and ascertain that the profile is generally bell-shaped and not too flattened across the top.

Flattening occurs when the maximum intensity for the system is reached in the raw image. A small amount of flattening in the center of the cell may be acceptable, but if large amounts of flattening occur, the data from that cell should be eliminated from the analysis.

33. Load the regions of interest $(ROI)_{lo}$ that were created in step 14 and eliminate any cells that have too much flattening (it is also possible to add any additional cells that might be bright enough to use). Use this maximum to create a mask (low-cal-mask), setting the threshold high enough to eliminate any of the background outside of the cell but not so high as to eliminate portions of the cell. If $(F_a)_{lo1}$ and $(F_a)_{lo2}$ found in step 28 are not negligible, subtract a constant equal to $(F_a)_{lo1}$ from $(I_{t\text{-}s})_{lo1}$ and subtract a constant equal to $(F_a)_{lo2}$ from $(I_{t\text{-}s})_{lo2}$—the results are $(I)_{lo1}$ and $(I)_{lo2}$, respectively.

Next, take the minimum of these two images. If the software cannot take the minimum of two images, choose the dimmest of the two images. Use the linear profile to determine that only those cells whose minimum intensity profile is significantly above zero are included. Apply the low-cal-mask; the ROI's boundaries should be just outside of the masked cells, if they are not, adjust the size of the ROIs.

This ROI will be called low-cal.roi.

CAUTION: *Suggesting that the boundaries of the ROI should be just outside of the masked cell assumes that the software does not include the masked area in any calculation of median value. If this is not the case, then be very careful in drawing the boundaries of the ROI to include as much of the cell as possible without including any area outside of the cell.*

34. Set the ratio range to be large with respect to the expected range—i.e., both higher and lower than expected (see Fig. 2.5.5B). Take the ratio $(I)_{lo1}/(I)_{lo2}$, apply low-cal-mask to the image as well as low-cal.roi and observe the result. Locate the cell or cells that are included in low-cal.roi and have the highest ratio. Use a histogram or linear profile of the cells to determine the actual maximum value of the ratio inside these cells. Set the maximum value of the ratio range, R_{hi}, slightly larger than this value. Now locate the cells or cells that are included in low-cal.roi and have the lowest ratio. Use a histogram or linear profile of these cells to determine the actual minimum value of the ratio inside these cells. Set the minimum value of the ratio range, R_{lo}, slightly smaller than this value. Change the ratio range to go from R_{lo} to R_{hi}, recalculate the ratio $(I)_{lo1}/(I)_{lo2} = I_{min}$ and apply low-cal-mask. Use low-cal.roi to measure the median value for each cell included in the ROIs (see Fig. 2.5.5C and D). Average these median values and calculate the standard deviation of the result. If any of these median values are located more than two standard deviations from the average, eliminate them from the calculation (some cells will not reach low calcium).

The final result is R_{min}. When using dual-excitation monochromators, the true value of $(R_{min})_{true} = R_{min}/R_L$ where R_L was measured in step 5.

35. Repeat steps 32 to 34 for the high-calcium images measured in step 19, the background images measured in step 20, and the median values of autofluorescence measured in step 30.

The result will be the value of R_{max} and its corresponding image I_{max}, where the ratio range for I_{max} will be quite different from that for I_{min}. When using dual-excitation monochromators, the true value of $(R_{max})_{true} = R_{max}/R_L$ where R_L was measured in step 5.

36. If the probe used is ratiometric in excitation and excitation spectra were obtained in steps 30 and 31, the ratio (S_f/S_b) is calculated as follows. Plot $[(S)_{lo}]_{ave}$ and $[(S)_{hi}]_{ave}$ on the same graph. Calculate the constant c such that $c\cdot[(S)_{lo}]_{ave}$ crosses $[(S)_{hi}]_{ave}$ at the isosbestic wavelength λ_i that was determined in step 22 and then determine the values of $[(S)_{lo}]_{ave}$ and $[(S)_{hi}]_{ave}$ at λ_2 ($[(F)_{lo2}]_{ave}$ and $[(F)_{hi2}]_{ave}$, respectively).

The ratio $(S_f/S_b) = c\cdot[(F)_{lo2}]_{ave}/[(F)_{hi2}]_{ave}$.

37. If the probe used is ratiometric in emission or it was not possible to obtain excitation spectra in steps 30 and 31, calculate the ratio (S_f/S_b) as follows. Repeat steps 23 to 24 for the low, $(I_t)_{loi}$ and $(I_t)_{loi2}$, and high, $(I_t)_{hii}$ and $(I_t)_{hii2}$, calcium images measured in steps 22 and 23, respectively.

The background images, $(I_s)_{lo1}$, $(I_s)_{lo2}$, $(I_s)_{hii}$, and $(I_s)_{hii2}$, were measured in step 25 and the median values of autofluorescence, $(F_a)_{loi}$ and $(F_a)_{loi2}$, can be obtained from step 28. The results are $(I)_{loi}$ and $(I)_{loi2}$ in low-Ca medium and $(I)_{hii}$ and $(I)_{hii2}$ in high-Ca medium, respectively.

38. Calculate $(I)_{hii}/(I)_{hii2}$ and $(I)_{loi}/(I)_{loi2}$ directly and measure the median values of these ratios, $(R)_{hij}$ and $(R)_{loj}$, respectively for the jth cell using the ROIs and mask created

in step 37. Calculate $(R)_{hij} \times (R)_{loj}$ for each cell *j* and then calculate the average value $[(R)_{hij}/(R)_{loj}]_{ave}$, for all the cells in the ROIs as well as its standard deviation. If any of these values, $(R)_{hij}/(R)_{loj}$, are located more than two standard deviations from the average, eliminate them from the calculation.

The ratio $(S_f/S_b) = [(R)_{hij}/(R)_{loj}]_{ave}$.

Measure the ratio of samples of interest

Steps 39 to 41: If it was found in step 26 that autofluorescence could not be detected under the experimental conditions, then the F_a term can be eliminated from the sample calculations. If this is not true, then autofluorescence images must be taken for every different value of HV/G and it is necessary to check to make sure that autofluorescence does not vary significantly as a result of the experimental protocol.

39. Place cells that have been incubated with the permeant form of the probe (see step 8) in the holder, rinse twice with standard medium, and then add 1 ml of standard medium. Adjust focus and HV/G as was discussed in step 12 to get a sharp, bright image. Then take a set of background images as discussed in step 13 and set the software to automatically subtract these background images or else subtract them manually later.

40. If desired, take several sets of images (at λ_1 and λ_2) of different fields of view. To study the effects of any agent on the cells, use one of the following options. Either add a concentrated solution of the agent directly to the chamber and attempt to mix it with the solution already in the chamber, remove the standard medium from the chamber and replace it with a solution of the agent under study, or use a flow cell and flow the mixture to study through the chamber. Take a series of image pairs, particularly to follow the effects of the agent on the cells with time. When the study is complete, take another set of background images to make sure that the agent added did not change the background substantially.

    IMPORTANT NOTE: *It is very difficult to add a concentrated solution to the chamber and get reproducible results for the following reasons. First, some cells may see a more concentrated solution of the agent than others, and if the response is concentration-dependent, this effect will produce errors. Second, it is difficult to get complete mixing of the agent in the chamber, especially without disturbing the field of view.*

41. Analyze these images in the same way the low-calcium images were analyzed in steps 32 to 34. If autofluorescence (F_a) is not negligible, then correct each sample image by subtracting the proper autofluorescence constant—i.e., $(F_a)_1$ or $(F_a)_2$ before calculating the ratios of the images. Calculate the ratio R_j for each chosen cell in each set of images as was discussed in steps 32 to 34 (it is not necessary to use the same ratio range for every set of images but remember the ratio range that was used to calculate each ratio image). Next, calculate $[Ca^{2+}]_j = K_d \times [(R_j - R_{min})/(R_{max} - R_j)](S_f/S_b)$ where $[Ca^{2+}]_j$ is the free calcium concentration in the *j*th cell, R_{min} was calculated in step 33, R_{max} was calculated in step 35, and (S_f/S_b) was calculated either in step 36 or 37. Either use an estimated K_d such as 225 nM for Fura-2, or measure it as described below for a particular cell type.

    When using dual-excitation monochromators, the true value of $(R_j)_{true} = R_f/R_L$ *where* R_L *was measured in step 5.*

Measurement of [Ca^{2+}] in plated cells using FDIM and nonratiometric probes

Nonratiometric probes are used in a similar way to ratiometric probes, except that only fluorescent intensities and not ratios are used—i.e., $[Ca^{2+}] = K_d \times [(F - F_{min})/(F_{max} - F)]$ where $F = F_t - F_s - F_a - F_{id}$, $F_{min} = (F)_{lo} = (F_t)_{lo} - (F_s)_{lo} - (F_a)_{lo} - F_{id}$, and $F_{max} = (F)_{hi} = (F_t)_{hi} - (F_s)_{hi} - (F_a)_{hi} - F_{id}$. Clearly, the F_{id} values cancel in calculating $[Ca^{2+}]$. In addition,

the background measurements also cancel out because all of the measurements must be carried out under identical conditions. F_a is almost certainly negligible for the currently available nonratiometric probes, because the major source of autofluorescence is NADH, which has peak excitation at 356 nm with emission at 510 nm (Jiang and Julian, 1997). Furthermore, it is easy to see that if F_a approximately equals $(F_a)_{lo}$ and $(F_a)_{hi}$, then autofluorescence can be neglected even if the autofluorescence term is not small with respect to probe fluorescence. Nonratiometric probes are fine for following changes in free calcium in a single set of cells with time, but difficult to use for accurately measuring $[Ca^{2+}]$ for different sets of cells. Leakage is a major problem with these probes when using plated cells in attempting to ascertain free calcium. To measure even approximate free calcium inside of cells using a nonratiometric probe, one must calibrate each cell in each sample at the end of the experimental procedure and hope that little leakage or bleaching of the probe occurred during the experiment, which is unlikely to be true. This process is very labor intensive and definitely not recommended. In addition, the resulting images must be corrected for nonuniformity of illumination to compare the fluorescence intensity from one cell to that of another. Such corrections are also not simple and will not be discussed here. For these reasons, the authors will not discuss how to calibrate nonratiometric probes in this system. With the exceptions noted below, the steps used to measure calcium using nonratiometric probes are essentially the same as that for ratiometric probes but it is generally unnecessary to record wavelength scans, and all of the measurements are made at a single excitation and emission wavelength (see Basic Protocol 1, steps 1 to 7).

Initial set up of the instrument

It is necessary to get an idea of the range of intensities that the probe might undergo. If the probe being used has its maximum intensity in high-calcium medium, start with high-Ca medium. If the probe being used has its maximum intensity in low-calcium medium, start with low-Ca medium. Once the cells come close to maximum intensity, adjust light intensity, band-pass, or HV/G until the brightest cell is ~90% to 95% of the maximum permissible intensity.

42. Incubate the cells in probe using the procedure described in steps 7 and 8. Follow the procedure described in steps 9, 10, and 11, using either low-Ca medium or high-Ca medium. Observe the intensity of the brightest cell. When it reaches an apparent maximum, adjust HV/G so this intensity is 90% to 95% of the maximum permissible intensity. From this point on, no adjustments should to be made to light intensity, excitation band-pass, or HV/G—to avoid having the fluorescence exceed the maximum permissible intensity.

    IMPORTANT NOTE: *As the free calcium inside of the cell equilibrates with the external free calcium, the probe's fluorescence inside the cell will increase until it reaches either $(F)_{hi}$ or $(F)_{lo}$. If one must use high-Ca medium for this step, at some point the cells will begin to die, the probe will leak out, and the dying cell's fluorescence will decrease. Attempt to adjust the high voltage or gain before this occurs. This is not usually a problem in low-Ca medium.*

Check for inner-filter effect and assess leakage

Steps 43 to 45: The inner-filter effect, which distorts the probe's spectra, will distort measurements of $[Ca^{2+}]$ (Moore et al., 1990). Therefore, it is important to check that the inner-filter effect is not a problem for the system and incubation procedure. In order to easily check for inner-filter effect, the equipment must be able to scan the excitation spectra (see Troubleshooting). Leakage is not usually a serious problem with ratiometric probes when using a microscope system, since it seldom contributes much to the supernatant background image (which is subtracted anyway), and the ratio is independent

of probe concentration. However, leakage is a very serious problem with nonratiometric probes because a change in fluorescence due to a change in [Ca^{2+}] cannot easily be distinguished from a change in fluorescence due to a change in probe concentration. Therefore, it is important to get a measure of the normal probe leakage rate from the cell type.

43. Place incubated cells in the holder, rinse twice with standard medium. Follow the procedure detailed in step 12 except set HV/G (step 42), and save a background image, I_s. Follow the procedure detailed in step 13 except set HV/G (step 42) and save an image $I_{t\text{-}s}$ or I_t. Turn off HV/G. If it is not possible to automatically subtract I_s, switch to analysis and calculate $I_{t\text{-}s} = I_t - I_s$.

44. Switch to analysis, create a mask and a set of ROIs, as described in step 14 using the image $I_{t\text{-}s}$. Switch back to acquisition, if the equipment includes optional scanning of excitation, switch the software from time-based mode to wavelength mode, turn off automatic background subtraction and using ROIs and mask, scan the excitation spectra. Save the resulting median values of intensity for each of the ROIs as the uncorrected dye spectra S_t inside the cells. Compare S_t with the spectra found in step 4.

    If many of the spectra do not have the correct shape, there are problems with inner-filter effect, which must be corrected by reducing probe concentration during incubation or reducing incubation time. If none of the spectra have the correct shape, either there are problems with inner-filter effect or with autofluorescence. (see Troubleshooting).

45. Use time-based acquisition and the ROIs and mask from step 44 and acquire median values from ROIs every minute for 20 to 30 min. Save the median values for the ROIs as a function of time. Since only cells that maintain a constant value of [Ca^{2+}] can be used to determine dye loss, eliminate cells from the ROIs whose median fluorescence (F) versus time data cannot be fit reasonably well with a straight line.

    Any change in the median value of the jth cell represents the loss of probe from the cell. Normally resting cells will not spontaneously change [Ca^{2+}]. If the machine doesn't have an automatic shutter in the excitation beam, acquire median values manually, taking care to block the excitation beam except when taking data to avoid photobleaching the dye.

Measure autofluorescence (F_a)

Do not bother to measure autofluorescence unless it appears that it is causing an apparent inner-filter effect or is large enough to cause fluctuations in F during an experimental procedure.

46. Repeat step 26 except set HV/G (step 42) and take only one image for each experimental medium.

    If autofluorescence is significant in the medium containing 5 mM cyanide, then follow steps 27 and 29 to obtain $(F_a)_{lo}$ and $(F_a)_{hi}$ repeat this measurement for any procedure that might result in significant changes in autofluorescence, in order to determine that changes detected in F are not the result of changes in F_a.

Measure the fluorescence of samples of interest

47. Place incubated cells in the holder, rinse twice with standard medium, and then add 1 ml of standard medium. Adjust focus to get a sharp, bright image. Take a background image as discussed in step 12 and set the software to automatically subtract these background images.

48. To determine the average rate of dye leakage from the cells, analyze the median values for the ROIs as a function of time found in step 45.

a. Transfer the data from the plot of F versus time found in step 45 to a spreadsheet such as Excel.

b. Average all of the data at a given time point to obtain $F_{ave}(t)$ and plot $F_{ave}(t)$ versus time.

c. Find the least squares best fit line to the plot of $F_{ave}(t)$ versus time.

The resulting slope, s_{loss}, can be used to back calculate the approximate original dye concentration in any cell. That is, if the median value of fluorescent intensity in the kth cell at time t is $(F_t)_k$, then its approximate value at t = 0 is $(F_0)_k = (F_t)_k - s_{loss}\, t$. (Note: $- s_{loss}$ is positive since s_{loss} is always negative.) This equation can be used to correct the median value of fluorescent intensity for any cell to the value it would have had if no dye loss had occurred assuming that all cells lose dye at the same rate.

49. To properly analyze the results from a time-based experiment, use step 48 to correct all of the median values of fluorescent intensity in the *k*th cell to the value they would have had if no dye loss had occurred. Plot these corrected values versus time for each cell.

Obtain approximate values of [Ca^{2+}]

If some estimate of [Ca^{2+}] is desired, the same group of cells that is used in the experiment must be used for a complete calibration. Set up a system to aspirate all of the medium from the coverslip because exactly the same group of cells must be used for the entire procedure. This must be done before the first experimental images are taken.

50. Follow the procedure described in steps 10, 12 and 13 except use the experimental medium, set HV/G (step 42) and take images at a single wavelength only. Run the experimental procedure on the group of cells (the resulting images are I_1, I_2, ..., I_{t_i}) recording the time at which each image was taken. At the end of the procedure, follow steps 16 and 17 to obtain a low-calcium image, I_{lo1}. Without changing or moving the coverslip, follow step 19 to obtain a high-calcium image, I_{hi}. Repeat steps 16 and 17 to obtain another low-calcium image, I_{lo2}. Note the time at which each of these images were saved.

The rate of dye leakage often changes during the calibration steps due to the stress caused by the additions (especially high [Ca^{2+}]) during this time. Approximate the dye loss during the calibration procedure by making a two-point plot of the fluorescence intensities of the median fluorescence intensities of the ROIs of the low Ca images and following step 48 to obtain an approximate slope of dye loss during calibration, $s_{c\text{-}loss}$.

51. Use the brightest image found in step 50 to create a mask and a set of ROIs. Use the system software to create a plot of median fluorescent intensity $(F_t)_k$ versus time for all of the data acquired in step 50 for all of the cells in the ROIs. Correct all of the data back to zero dye loss as follows. $(F_{t\ corr})_k = (F_t)_k - s_{loss}\, t$, except $(F_t)_k$ at high calcium, for which $(F_{t\ corr})_k = (F_t)_k - s_{loss}\, t_{loCa} - s_{c\text{-}loss}\,(t - t_{loCa}) = (F_{hi})_k$ where t_{loCa} is the time at which the first low-calcium image was saved. $(F_t)_k$ for the first low-calcium measurement = $(F_{lo})_k$. (Note: $- s_{loss}$ and $- s_{c\text{-}loss}$ are positive since s_{loss} and $s_{c\text{-}loss}$ are always negative.)

For any cell k in the ROIs, $[Ca^{2+}]_k \approx K_d[(F_{t\ corr})_k - (F_{lo})_k]/[(F_{hi})_k - (F_{t\ corr})_k]$.

DETERMINATION OF K_d FOR PLATED CELLS USING RATIOMETRIC PROBES

SUPPORT PROTOCOL 2

This protocol describes the method for determining the K_d for plated cells using ratiometric probes. Read the discussion in Support Protocol 1. If at all possible, measure K_d in a cell suspension rather than using plated cells because it will be more accurate.

Additional Materials (also see Basic Protocols 1 and 2)

EGTA solution (see recipe for Ca^{2+} calibration standards)
CaEGTA solution (see recipe for Ca^{2+} calibration standards)
Ca solution (see recipe for Ca^{2+} calibration standards)
1 M $CaCl_2$
Cells incubated with probe (see Basic Protocol 1, step 9)

Determine K_d of a ratiometric probe for plated cells at 20°C

1. Prepare the FDIM apparatus (see Basic Protocol 2).
2. Make up solutions 1 through 13 using EGTA solution and CaEGTA solution in the proportions shown in Table 2.5.3.

   Table 2.5.3 shows [Ca^{2+}] at 20°C for each of these solutions as well as for the EGTA solution, the CaEGTA solution, and the Ca solution.

   If the calibration is to be performed at 37°C, use Table 2.5.4 to make up solutions 1 through 13. Table 2.5.4 shows [Ca^{2+}] at 37°C for each of these solutions as well as for the EGTA solution, the CaEGTA solution, and the Ca solution.
3. Place incubated cells in the holder, rinse twice with the EGTA solution (created in step 2) and add 0.5 ml of the EGTA solution. Place another 0.5 ml of the EGTA solution in a small tube, add 10 µl of 0.1 mM thapsigargin, 7.5 µl of 2 mM oligomycin, 7.5 µl of 1 mM CCCP, and 10 µl of 1 mM ionophore to yield final concentrations of 1 µM thapsigargin, 10 µM oligomycin, 5 µM CCCP, and 10 µM ionophore, respectively. Immediately shake or vortex this mixture and then add it to the coverslip, making sure the two components are well mixed. Note the time at which this addition was made.

   IMPORTANT NOTE: *If cells cover the entire coverslip, wipe a small area free of cells for the background measurement.*
4. Place the coverslip on the microscope stage, obtain a set of background images, and set the program to automatically subtract background. Find a likely group of cells, use fast focus to provide the brightest, sharpest image, and take a set of images. Create ROIs (Basic Protocol 2, step 14) and then collect median values from the ROIs, waiting for an apparent steady state to be reached. (which should take approximately the same time it took to reach low calcium in step 15 of Basic Protocol 2). When an apparent steady state is reached, take a set of images, $(I)_{EGTA\lambda1}$ $[(I_t)_{EGTA\lambda1}]$ and $(I)_{EGTA\lambda2}$ $[(I_t)_{EGTA\lambda2}]$, respectively.

   If background was not automatically subtracted, subtract it now to obtain $(I)_{EGTA\lambda1}$ and $(I)_{EGTA\lambda2}$.
5. Repeat steps 3 and 4 for each of the solutions created in step 2, as well as for the CaEGTA solution and the Ca solution resulting in $(I_t)_{1\lambda1}$, $(I_t)_{2\lambda1}$, ..., $(I_t)_{13\lambda1}$, $(I_t)_{CaEGTA\lambda1}$, $(I_t)_{Ca\lambda1}$, $(I_t)_{1\lambda2}$, $(I_t)_{2\lambda2}$, ..., $(I_t)_{13\lambda2}$, $(I_t)_{CaEGTA\lambda2}$ and $(I_t)_{Ca\lambda2}$.

   IMPORTANT NOTE: *Be extremely careful in rinsing the chamber and in adding and removing solutions, because the same set of cells must be used for the entire procedure, and it is therefore necessary to be very careful not to move the microscope stage. Set up a system that can automatically remove all of the medium from the holder.*

   As the free calcium concentration increases, probe may begin to leak out of the cells. This is not too much of a problem for the ratiometric probes until the images become too dim to analyze properly.

   Replace the coverslip with a new one whenever necessary. For each new coverslip, take a new set of backgrounds.

6. If the values of F_a found in steps 26, 27, 28, and, and 29 of Basic Protocol 2 are not negligible with respect to the internal probe fluorescence values at λ_1 and/or λ_2 for all of the eleven samples, then correct F for autofluorescence. Measure $(I_a)_{lo1}$, $(I_a)_{lo2}$, $(I_a)_{hi1}$, and $(I_a)_{hi2}$, and calculate the average median values at λ_1, and λ_2 [these median values of intensity are $(F_a)_{lo1}$, $(F_a)_{lo2}$, $(F_a)_{hi1}$, and $(F_a)_{hi2}$].

   If $(F_a)_{hi1}$ approximately equals $(F_a)_{lo1}$ and $(F_a)_{hi2}$ approximately equals $(F_a)_{lo2}$, then it can be assumed that $(F_a)\lambda_1$ and $(F_a)\lambda_2$ are the same for all of the samples. If this is not the case, it will be necessary to calculate $(F_a)\lambda_1$ and $(F_a)\lambda_2$ for all eleven samples using the procedure detailed in steps 26 to 28 of Basic Protocol 2.

7. Create the proper masks and ROIs (see Basic Protocol 2, step 14) and eliminate any cells that are either too bright (cells whose linear profiles exhibit flattening) or too dim (cells whose linear profiles are not significantly above background) from the ROI (see Basic Protocol 2, step 32). Also, adjust the ROI to ensure that all of the ROI's boundaries are outside the masked cells.

   Each ROI should only include cells that fit the above criteria for all sixteen calibration solutions. Remember that the threshold used to create masks (if more than one mask is needed) must be identical for all masks. If the autofluorescence (see Basic Protocol 2, steps 26 to 29) is negligible, it can be ignored. Otherwise, correct each image for autofluorescence by subtracting a constant equal to $(F_a)_{j\lambda 1}$ from $(I_t)_{2\lambda 1}$ and subtracting a constant equal to $(F_a)_{j\lambda 2}$ from $(I_t)_{j\lambda 2}$ where $(F_a)_j$ is the autofluorescence found in step 6 of this protocol for the jth solution.

8. Calculate the ratio image, RI_j, for the *j*th solution using the corrected images. Set the ratio range as described in Basic Protocol 2, step 34 to the optimal value for each solution. Apply masks to these ratios and use the ROI on the masked images to collect median fluorescence ratios $(R)_{kj}$ for each cell *k* and each solution *j*, and place the results in a spreadsheet. Calculate the average value and standard deviation of $(R)_{kj}$ for the EGTA and Ca solutions. Eliminate any values that are more than two standard deviations from the averages and recalculate the average value and standard deviation.

   $(R)_{kj}\}_{ave}$ for the EGTA solution equals $R_{min;}$ $\{(R)_{kj}\}_{ave}$ for the CaEGTA solution equals R_{max}. The ratio (S_f/S_b) is calculated as in steps 33 or 36 of Basic Protocol 2.

9. Calculate the average value and standard deviation of $(R)_{kj}$ for all of the other solutions. Eliminate any values that are more than two standard deviations from the averages and recalculate the average value and standard deviation. $\{(R)_{kj}\}_{ave}$ for the jth solution equals R_j equals R as a function of $[Ca^{2+}]$. Using Equation 2.5.2, plot $\log\{[(R - R_{min})/(R_{max} - R)](S_f/S_b)\}$ versus $\log\{[Ca^{2+}]\}$. Fit the linear portion of the data with the linear least squares best fit line. The resulting graph should look just like Figure 2.5.2. The value of $[Ca^{2+}]$ for which $y = 0$ is a measure of the apparent K_d of the probe. If the values of R_{min} and R_{max} are very close to their true values, the slope of the line will be one. If the values of R_{min} and R_{max} are not close to their true values, all the data will clearly not fit a straight line and the slope will not be one. Even when the data are poor, a reasonable approximation of the true K_d can still be found. However, in this case the use of the values of R_{max}, R_{min} and (S_f/S_b) found in steps 34, 35, and 36 or 38 of Basic Protocol 2 will lead to incorrect values of $[Ca^{2+}]$ inside the cells.

10. When it is clear that values of R_{max}, R_{min} and (S_f/S_b) found in steps 34, 35 and 36 or 38 of Basic Protocol 2 are incorrect, plot R versus $[Ca^{2+}]$ using only the intermediate data points and fit the data with an equation of the form $R = \{(R_{min} + R_{max}/C\}[Ca^{2+}]/(1 + [Ca^{2+}]/C)$ where R_{min}, R_{max}, and C are unknown and $C = K_d (S_f/S_b)$ (see Fig. 2.5.3). If the data are very accurate, accurate values of R_{min}, R_{max}, and $C = K_d (S_f/S_b)$ can be obtained from data for which $[Ca^{2+}]_{outside}$ ranges between 15 nM and 6 μM for Fura-2.

For dual-excitation (emission) monochromators, $(R_{min})_{true} = R_{min}/R_L$ and $(R_{max})_{true} = R_{max}/R_L$ where R_L was found in step 5 of Basic Protocol 2.

11. Repeat steps 3 through 9 for the intermediate calcium concentrations only for the wavelength pair λ_i and λ_2, where λ_i is the isosbestic point that was determined in Basic Protocol 2, step 22. Plot the resulting R versus $[Ca^{2+}]$ and fit the data with an equation of the form $R = \{(R_a + R_b/K_d)[Ca^{2+}]\}/(1 + [Ca^{2+}]/K_d)$ where R_a, R_b and K_d are unknown. Then $(S_f/S_b) = C/K_d$.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. To eliminate calcium contamination as much as possible, glassware should be rinsed several times in Milli-Q-purified water, dried, and stored in such a way as to eliminate dust from inside the glassware. For common stock solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AM form of fluorescent Ca^{2+} probe, 2 to 5 mM

Dissolve the Ca^{2+}-insensitive, membrane-permeable form of fluorescent Ca^{2+} probe in anhydrous, reagent grade DMSO (see recipe) to a final concentration of 2 to 5 mM. Immediately split this solution into small airtight containers such as microcentrifuge tubes at 20 to 50 µl per tube. Freeze immediately and store at –20°C in the dark in a dessicator until immediately before use, because DMSO readily takes up moisture which leads to decomposition of the dye. Thaw each aliquot only once.

CAUTION: *DMSO is slightly hazardous.*

Ca^{2+} calibration standards

1. For 40 mM EGTA, carefully add 40 ml of calibrated 100 mM EGTA (see recipe) to 55 ml of 1.67× calibration medium (see recipe), adjust pH to 7.20 at the calibration temperature (either 20°C or 37°C) with 2 M KOH. Bring to a final volume of 100 ml with 1.67× calibration medium, pH 7.20 at the calibration temperature.
2. For 40 mM $CaCl_2$, carefully dilute 40 ml of calibrated 100 mM $CaCl_2$ (see recipe) to 100 ml with 1.67× calibration medium (see recipe), pH 7.20 at the calibration temperature.
3. For EGTA solution, carefully mix 1 part of 40 mM EGTA (see recipe) with 1 part 1× calibration medium (see recipe), pH 7.20 at the calibration temperature.
4. For CaEGTA solution, carefully mix 1 part of 40 mM EGTA (see recipe) with 1 part 40 mM $CaCl_2$ (see recipe), pH 7.20 at the calibration temperature.
5. For Ca solution, carefully mix 1 part of 40 mM $CaCl_2$ (see recipe) with 4 parts of 1× calibration medium (see recipe), pH 7.20 at the calibration temperature.
6. Use table 2.5.3 to create solutions 1 through 13 for calibrations at 20°C or use table 2.5.4 to create solutions 1 through 13 for calibrations at 37°C.

Calibrated $CaCl_2$, 100 mM

Purchase calibrated 100 mM $CaCl_2$ from Orion, Corning, or Molecular Probes as part of their concentrated calcium calibration kit. Carefully remove aliquots and keep tightly sealed in between removals. Store for 1 to 2 years at room temperature.

Calibrated EGTA, 100 mM

Purchase calibrated 100 mM EGTA from Molecular Probes as part of their concentrated calcium calibration kit, or make calibrated 100 mM EGTA using the technique of Moisescu and Pusch (1975) described below using ultrapure EGTA from Calbiochem or Sigma.

continued

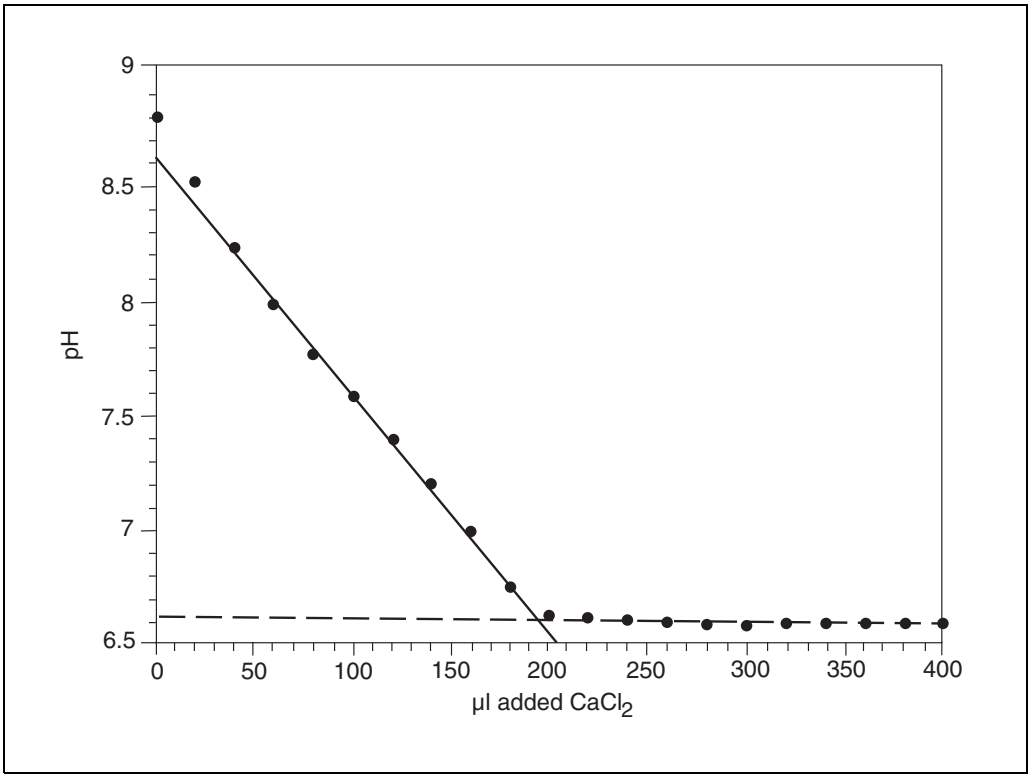

Figure 2.5.6 pH titration of EGTA. The two linear portions of the data are fitted with a linear least squares best fit straight line with the equations of the lines being $y = 8.6329 - 0.010446x$ with $R^2 = 0.99834$ and $y = 6.6286 - 0.00016818x$ with $R^2 = 0.63379$. The x value of the intercept of these two lines equals the total µmoles of EGTA in the sample.

1. Make nominal 200 mM EGTA by adding 7.608 gm of free acid ultrapure EGTA to 50 ml water alternately with 20 ml of 1 M KOH. While observing pH, add additional 1 M KOH until pH = 7.20 at room temperature. Bring to a final volume of 100 ml with water.

   The best ultrapure EGTA contains only 99+% EGTA. In addition, it can accumulate water, so this nominal 200 mM EGTA solution will be <200 mM.

2. Make 100 mM HEPES or TES by adding 2.383 gm ultrapure acid HEPES or 2.292 gm ultrapure acid TES to 80 ml water, and adjusting pH to 9.0 at room temperature with 1 M KOH. Bring to a final volume of 100 ml with water.

   Use ultrapure acid HEPES or TES from Calbiochem or Sigma. Treat glassware to eliminate calcium.

3. Make nominal 2 mM EGTA in buffer by carefully adding 1 ml of nominal 200 mM EGTA and 4 ml of 100 mM HEPES or TES to 90 ml water. Adjust pH to between 8.8 and 9.0 with 1 M KOH. Bring to a final volume of 100 ml with water.

   Starting with this solution and from this point on, the success of this technique for making 100 mM EGTA requires that all pipetting be highly accurate.

4. Titrate the EGTA by carefully pipetting 10 ml of the nominal 2 mM EGTA in buffer. Measure the pH while stirring. (Insulate the stir plate from the sample to prevent a change in temperature in the sample during this process.) Add 10 to 20 µl aliquots of 100 mM calibrated $CaCl_2$ (see recipe) and measure the pH after each addition while stirring. Plot pH versus added µl of 100 mM $CaCl_2$.

continued

The resulting graph will have a distinct V shape like that shown in Figure 2.5.6. Draw linear best fit lines through the linear portions of the data and calculate the x value of the intersection of the two lines. The µmoles of added calcium at the intercept = the µmoles of EGTA in the solution. For example, for Figure 2.5.6, the intercept occurs at 195.0 µl of added calcium which equals 19.5 µmoles calcium (= 0.195 × 100) = 19.5 µmoles EGTA in 10.195 ml. The true concentration of EGTA in this solution before dilution was 1.95 mM (= 19.5/10.0).

Thus, for this example, the true concentration of the nominal 200 mM EGTA is 195 mM for a purity of 97.5%.

5. For 100 mM calibrated EGTA, carefully dilute the nominal 200 mM EGTA whose true concentration has just been measured to 100 mM EGTA with water.

Calibration medium, 1× and 1.67×

1× medium:
130 mM KCl
15 mM NaCl
20 mM MOPS
20 mM glucose
1 mM $MgCl_2$
1 mM vanadate pentoxide (V_5O_5)
1 mM ouabain
Adjust to pH 7.2 at calibration temperature using 1 M HCl and 1 M KOH
Store up to 4 to 6 months at −20°C

1.67× medium: Prepare medium containing 1.67× all of the above components, so that when used to dilute the standards (6:4), it becomes ~1×.

Dimethylsulfoxide (DMSO), anydrous

Purchase anhydrous, reagent-grade DMSO from Aldrich or Fluka. The DMSO should be relatively fresh (<1 year old). It must be anhydrous, which means that it must be stored well sealed under argon or nitrogen and desiccated. Each time the bottle is opened, it must be flushed with argon or nitrogen before resealing

CAUTION: *DMSO is slightly hazardous.*

FA (probe free acid) in high-Ca medium, 5 µM

Add $CaCl_2$ to 1× calibration medium (see recipe) to a final concentration of 0.1 mM. Very carefully dilute this solution 1:1 with 10 µM FA solution (see recipe). Store up to 4 to 6 months in the dark at −20°C.

IMPORTANT NOTE: *It is vital that the 5 µM FA in low-Ca solution and the 5 µM FA in high-Ca solution have exactly the same amount of the FA form of fluorescent Ca^{2+} probe.*

FA (probe free acid) in low-Ca medium, 5 µM

Add EGTA to calibration medium (see recipe) to a final concentration of 0.2 mM. Very carefully dilute this solution 1:1 with 10 µM FA solution (see recipe). Store up to 4 to 6 months in the dark at −20°C.

IMPORTANT NOTE: *It is vital that the 5 µM FA in low-Ca solution and the 5 µM FA in high-Ca solution have exactly the same amount of the FA form of fluorescent Ca^{2+} probe.*

FA (probe free acid) solution, 10 µM

Stock solution: Prepare a 1 mM stock solution of the Ca-sensitive (FA) form of the fluorescent probe in water. Store up to 4 to 6 months at −20°C in the dark.

10 µM solution: Add the FA form of the fluorescent probe to a final concentration of 10 µM in 1× calibration medium (see recipe) using the 1 mM stock solution.

High-Ca medium, 2×

130 mM KCl
15 mM NaCl
20 mM MOPS
20 mM glucose
1 mM $MgCl_2$
8 mM $CaCl_2$ (or higher)
1 mM vanadate pentoxide (V_5O_5)
1 mM ouabain
Adjust pH to 7.2 at calibration temperature using 1 M HCl and 1 M KOH
Store up to 4 to 6 months at −20°C
For 1× high-Ca medium, dilute 1:1 with calibration medium (see recipe)

If one wishes to measure R_{max} within 0.5% of its true value, the amount of free calcium must be ~200 K_d of the probe in situ, or greater.

Ionophore, 1 mM

Dissolve ionomycin or dibromo A-23187 (Calbiochem) in anhydrous, reagent-grade DMSO (see recipe) to a concentration of 1 mM. Store up to one year at 4°C in the dark.

Keeping this solution anhydrous is not essential since small amounts of water cause no problems.

CAUTION: *These ionophores are hazardous.*

Low-Ca medium, 2×

130 mM KCl
15 mM NaCl
20 mM MOPS
20 mM glucose
1 mM $MgCl_2$
10 to 20 mM EGTA
1 mM vanadate pentoxide (V_5O_5)
1 mM ouabain
Adjust pH to 7.2 at calibration temperature using 1 M HCl and 1 M KOH
Store up to 4 to 6 months at −20°C
For 1× low-Ca medium, dilute 1:1 with calibration medium (see recipe)

The amount of EGTA necessary depends upon the pH of the standard medium; the more acid it is, the more EGTA is needed. The resulting free Ca^{2+} should be <1 nM when diluted 1:1 with calibration medium.

Any of the available calcium chelator programs such as MaxChelator (cpatton@leland.stanford.edu) can be used to determine how much EGTA is needed.

Oligomycin, 2 mM

Dissolve oligomycin in anhydrous, reagent-grade DMSO (see recipe) to a concentration of 2 mM. Store up to one year at −20°C in the dark.

Keeping this solution anhydrous is not essential since small amounts of water cause no problems.

CAUTION: *Oligomycin is hazardous.*

Standard medium

This is any medium that can support and nourish the cells for the time required for the experiments (min to hr), which is either nonfluorescent or minimally fluorescent. This medium should contain a buffer other than bicarbonate, since most spectrome-

continued

ters and microscopes are not set up to maintain a CO_2 atmosphere. To keep extracellular hydrolysis of AM esters to a minimum, this medium should be free of primary and secondary amines, serum (which may contain endogenous esterase activity), and phenol red.

Standard medium with cyanide

Add 5 mM potassium or sodium cyanide to standard medium (see recipe). Make this solution in the hood and handle with extreme care. Cyanide will tend to make solutions more basic.

CAUTION: *Cyanide in acid medium can generate cyanide gas which can be deadly; therefore adjust the pH of this solution with the acid form of a zwitter ion such as HEPES (1 or 2 M).*

Neutral cyanide solutions are not stable. They should be used within a day and stored in the refrigerator until use.

Thapsigargin, 0.1 mM

Dissolve thapsigargin (Calbiochem, Sigma) in anhydrous, reagent-grade DMSO (see recipe) to a final concentration of 0.1 mM. Immediately split into small airtight containers such as microcentrifuge tubes at 50 to 100 µl per tube. Freeze immediately and store at −20°C in the dark in a dessicator until immediately before use, because DMSO readily takes up moisture which leads to decomposition of thapsigargin. Thaw each aliquot only once.

CAUTION: *Thapsigargin is hazardous.*

COMMENTARY

Background Information

Ca^{2+} is a very important ion in biological systems. It is the most closely regulated ion in serum, with a free ion concentration of ~2 mM (which varies somewhat from species to species). Its concentration in the cytosol of cells is much lower (usually <100 nM) and also closely regulated. It is used as a signaling molecule or second messenger in many types of cells and during these periods of excitation can reach concentrations of >1 µM during Ca^{2+} transients or pulses.

For years, total Ca^{2+} in cells has been measured using atomic absorption spectroscopy, and free Ca^{2+} concentration ($[Ca^{2+}]$) in serum and interstitial fluid has been measured using Ca^{2+} electrodes. $[Ca^{2+}]$ inside cells has sometimes been measured in specialized laboratories using microelectrode techniques or using the bioluminescent Ca^{2+}-binding peptide aequorin, which until recently had to be injected into the cell using a micropipette. More recently the technique of choice for intracellular $[Ca^{2+}]$ measurement has been the use of Ca^{2+}-binding fluorescent indicators or probes, which can be diffused into the cell in a membrane-permeant form (usually the acetoxymethyl ester form; AM) where it is converted by intracellular esterase activity into a membrane-impermeant, Ca^{2+}-sensitive form (usually a carboxylic acid form).

The first such indicator of this type was Quin-2, which was introduced by Roger Tsien (Tsien et al., 1982). Quin-2 was followed by better probes, some of which were ratiometric such as Fura-2 and Indo-1, some of which were much brighter than Quin-2, e.g., Calcium red and Calcium green, some of which were fast binders, e.g., Fluo-3, and some of which associated with special subcellular compartments, e.g., Rhod-2. Today, many Ca^{2+} probes are available for use with either fluorescence spectroscopy, fluorescence single-cell photometry, or fluorescence digital imaging analysis.

Atomic absorption spectroscopy can only measure total Ca^{2+} in cells, and hence cannot be used to measure free Ca^{2+} concentration. Calcium-sensitive electrodes are not very sensitive below ~1 µM free calcium but can give reasonable estimates of $[Ca^{2+}]$ down to about 0.3 to 0.5 µM. Aequorin can reach lower levels of $[Ca^{2+}]$ but is difficult to calibrate accurately. On the other hand, Ca^{2+}-binding fluorescent probes can give accurate values of $[Ca^{2+}]$ down to 10 nM or less. The biggest problems with Ca^{2+}-binding fluorescent probes are the diffi-

culties in accurately measuring K_d, R_{max} (F_{max}), and R_{min} (F_{min}) inside cells (i.e., in situ), as well as the leakage of probe from cells.

Historically, K_d, R_{max} (F_{max}), R_{min} (F_{min}), and (S_f/S_b) were generally measured in vitro, and the assumption was made that these values were the same in vitro and in situ. (Many software programs used with spectrofluorometers and FDIM only describe in vitro calibrations.) That is, it was assumed that: (1) the only form of the probe inside cells is fully de-esterified, either free or bound to calcium; (2) the probe inside the cells is the only source of fluorescence; (3) the spectral properties of the probe are the same inside and outside the cell; and (4) the probe's K_d is the same inside and outside the cell (Moore et al., 1990). These assumptions are rarely true. The probe is often incompletely de-esterified (Gunter et al., 1988; Oakes et al., 1988; Moore et al., 1990; Roe et al., 1990) and leaks from inside the cells (Moore et al., 1990; Roe et al., 1990; di Virgilio et al., 1990; Kao, 1994). The probe can distribute into intracellular compartments where $[Ca^{2+}]$, K_d, R_{max} (F_{max}), R_{min} (F_{min}), and (S_f/S_b) can all be different from the cytosolic values (Gores et al., 1989; Moore et al., 1990; Roe et al. 1990; Kao, 1994) as well as from the in vitro values (Moore et al., 1990; Roe et al., 1990; Williams and Fay, 1990; Harkins et al., 1993; Baker et al., 1994; Bassani et al., 1995; Lipp et al., 1996). Exposure to intense light can damage the cell as well as bleach the probe, where the bleached probe can be fluorescent but insensitive to $[Ca^{2+}]$ in the nM or µM range (Moore et al., 1990; Roe et al., 1990). Poenie et al. (1986) found that the in situ spectra of Fura-2 were different from its in vitro spectra. They found that they could make the in situ and in vitro spectra match by increasing the viscosity of the in vitro medium, or by decreasing the in vitro R_{max} and R_{min} values by 15% and using them in Equation 2.5.2 for $[Ca^{2+}]$. This "viscosity" correction is often found as a parameter in fluorescence software to correct in vitro measurements of R_{max} and R_{min}, which can then be used to yield the proper value of $[Ca^{2+}]$ in cells. The problem with this assumption is that it has since been shown that binding of probe to cytosolic proteins is almost certainly the main source of the differences between in situ and in vitro calibrations, and (S_f/S_b) measured in situ and in vitro are not necessarily the same (Brandes et al., 1993; Harkins et al., 1993; Baker et al., 1994; Bassani et al., 1995). Baker et al. (1994) and Brandes et al. (1993) showed that K_d and (S_f/S_b) increase as protein increases, and the isosbestic point (λ_{iso}) decreases as protein increases. Baker et al. (1994) found that all of these parameters can be fit with a simple binding relationship described by $F = F_o + \Delta F_{sat} \times P/(P + P_{50})$ for a fixed concentration of probe, where F is the parameter to be fitted (K_d, (S_f/S_b), or λ_{iso}), F_o is the value of the parameter in the absence of any protein, ΔF_{sat} is the maximum change in F extrapolated to saturating protein, P is the protein concentration in the calibration media, and P_{50} is the protein concentration that causes a 50% change in F. All of the parameters are a function of the type of protein used, pH, and the relative concentrations of protein and probe. For example, they found that at pH 7.3, the K_d at saturating protein for Indo-1 was 808 ± 26 nM for frog muscle proteins and 638 ± 72 nM for rat heart proteins. Although nonratiometric probes do not have corresponding values of (S_f/S_b) and λ_{iso}, protein does cause K_d to increase and ($F_{max} - F_{min}$) to decrease (Harkins et al., 1993). Thus, to perform an in vitro calibration, ideally protein from the cell type should be included. Even then, it is necessary to vary protein concentration as above and then find the value of λ_{iso} that matches the value of λ_{iso} found in situ in order to decide upon the appropriate values of K_d and (S_f/S_b) to be used. If $[Ca^{2+}]_{in}$ cannot be forced to equal $[Ca^{2+}]_{out}$, then it is not possible to calibrate the probe in situ. Many procedures have been used to ensure that $[Ca^{2+}]_{in}$ equals $[Ca^{2+}]_{out}$ during in situ calibration. Bassani et al. (1995) exposed myocytes to caffeine in order to empty sarcoplasmic reticulum stores and then incubated the cells in low-calcium medium to remove the excess intracellular calcium. They then added the equivalent of 1 nm CCCP and 10 mM 2-deoxyglucose to achieve metabolic inhibition and to limit hypercontracture. Their calibration medium, containing 130 mM KCl, 10 mM NaCl, and the ionophore Br-A23187, was added to determine R_{max} and R_{min}. After equilibrium was apparently reached, selected cells were aggressively "poked" with a 2- to-3 µm-diameter electrode to cause external calcium to leak into the cells. If a true equilibrium had been reached, no change in fluorescence was observed. Williams and Fay (1990) mention that the main impediment to getting $[Ca^{2+}]_{in}$ to equal $[Ca^{2+}]_{out}$ during in situ calibration is the ATP-dependent Ca pump and $[Na^+]_{out}$-$[Ca^{2+}]_{in}$ exchange in the plasma membrane. The ATP-dependent Ca pump can often be inhibited by vanadate or calmodulin inhibitors such as trifluoperazine. $[Na^+]_{out}$–$[Ca^{2+}]_{in}$ exchange can be inhibited by including the Na^+-ionophore

monensin or by using medium containing 130 mM KCl and 10 to 15 mM NaCl. If the Na^+K^+-ATPase is highly active, include either a K^+-ionophore such as nigericin or a pump inhibitor such as ouabain or oligomycin, which is a potent inhibitor of many Na^+K^+-ATPases. It is seldom possible to calibrate nonratiometric probes in situ since the probe concentration must be known in order to calibrate it, and probe concentration can vary from cell to cell.

Critical Parameters

Always protect the camera or photomultiplier tube from excess light. That is, when not certain how intense the fluorescence to be detected is, use a variable aperture that can be opened slowly in the excitation beam path so that the camera/photomultiplier tube can be exposed gradually to the fluorescent light. Putting a shutter in the excitation beam path will also protect the sample from photobleaching. Photobleaching can change the spectroscopic parameters of the probe, resulting in erroneous values of $[Ca^{2+}]$ (Moore et al., 1990; Roe et al., 1990).

When preparing cells for fluorescence measurements, beware of anoxia, both during and after incubation. In addition, leakage of probe from the cells increases the difficulty of making measurements in the cuvette system for any fluorescent probe, and makes the calculation of $[Ca^{2+}]$ using FDIM for nonratiometric probes almost impossible. Leakage can be reduced by storing the cells after incubation at 4°C until use and running the experiments at room temperature if at all possible. Some cell types actively extrude either the AM form of the probe using the multidrug resistance protein (Homolya et al., 1993) or the free acid form using the organic anion transport system (Moore et al., 1990; di Virgilio et al., 1990; Kao, 1994). The first problem results in insufficient loading of the Ca-sensitive form of the probe and can often be alleviated with a monoclonal anti-MDR1 antibody, verapamil, vincristine, sodium orthovanadate or oligomycin. The second problem can result in very rapid loss of the Ca-sensitive form of the probe once it is in the cell. Probenecid and sulfinpyrazone are inhibitors of the organic anion transport system and may reduce such leakage.

Perfecting the incubation procedure to minimize autofluorescence, remaining fluorescent AM form of the probe, and the production of calcium-insensitive fluorescent forms of the probe is critical. Although large autofluorescence values can be handled, it is much simpler if autofluorescence can be ignored. If probe concentration during incubation is too high, or the incubation is too long, it is sometimes very difficult to remove all of the remaining AM form of the probe at the end of the incubation period (Homolya et al., 1993). This remaining AM form of the probe causes the same sort of problems that the other calcium-insensitive fluorescent forms of the probe do. Albumin can often be used in a rinse medium to remove extracellular AM and other calcium-insensitive fluorescent forms of the probe (Oakes et al., 1988). The calcium-insensitive fluorescence F_i can only be estimated when using fluorescence spectroscopy, and even an estimate is hard to obtain when using FDIM (Gunter et al., 1988; Moore et al., 1990; Roe et al., 1990). For fluorescence spectroscopy, the estimated value of F_i is probably correct within a factor of two, but a factor of two can be a problem unless F_i is small with respect to fluorescence from the calcium-sensitive probe at the wavelength(s) used to detect the probe. Therefore, it is well worthwhile it to spend time perfecting the incubation procedure to minimize or eliminate these problems (Gunter et al., 1988; Oakes et al., 1988; Moore et al., 1990; Roe et al., 1990; Kao, 1994).

Surprisingly, too much probe inside the system can also cause problems. If the concentration of internal dye is too large (~100 μM for Fura-2), the probe will substantially change the buffering capacity of the cell and affect the $[Ca^{2+}]$ that is being measured. If the concentration of internal dye multiplied by the thickness of the cells is greater than ~12,000 μM μm, there will almost certainly be problems with the inner-filter effect which distorts the probe's spectra (Fig. 2.5.1) and will invalidate the measurements of $[Ca^{2+}]$ (Moore et al., 1990). In addition, when interested in cytosolic $[Ca^{2+}]$, make sure that little or no probe is converted in cellular organelles. The best way to determine if probe is inside cellular organelles is to look for it with a fluorescence microscope (Gores et al., 1989; Moore et al., 1990; Roe et al., 1990; Kao, 1994; Lemasters, 1996; Trollinger et al., 1997). Fluorescence spectroscopy can be used to estimate this problem by using increasing amounts of digitonin to sequentially permeabilize cell membranes to release internal probe, but it cannot determine precisely which cellular compartment contains probe (see Troubleshooting for details).

It is important to obtain the spectra of the Ca-sensitive probe in both the bound and free forms using the same equipment that will be

used for cell experiments, because the spectral shapes are dependent upon the optics of the equipment. Once the spectra are obtained, decide which wavelengths to use if the probe is ratiometric. Usually choose the wavelength pair that provides the greatest range of sensitivity (i.e., where R_{max}/R_{min} is as large as possible; Moore et al., 1990). However, with some equipment, this range results in R_{max} or R_{min}, which is so large that either the fluorescence at one wavelength is too close to the upper limit of sensitivity or the fluorescence at the other wavelength is too close to background, in which case, one or the other of the two wavelengths should be changed.

Any time the incident light intensity or the detector sensitivity is varied, remeasure background, supernatant fluorescence, autofluorescence, and Ca-insensitive fluorescence, unless it has been demonstrated that they are negligible with respect to the Ca-sensitive signal. With a ratiometric probe, the incident light intensity or the detector sensitivity can be varied without changing R_{max}, R_{min}, or (S_f/S_b), provided the band-pass of the incident light is not changed. For a nonratiometric probe, any time there is any change in light intensity or in detector sensitivity, remeasure F_{max} and F_{min}.

When using fluorescence spectroscopy, it is absolutely essential that the supernatant signal be subtracted from the total fluorescence signal, since any Ca-sensitive probe in the supernatant will report a different $[Ca^{2+}]$ from that reported by the probe inside the cell. In addition, when interested in changes in cytosolic $[Ca^{2+}]$, make sure that no Ca-sensitive probe is sequestered in any cellular subcompartment because $[Ca^{2+}]$ in any particular subcompartment is unlikely to follow changes in cytosolic $[Ca^{2+}]$ exactly. See Troubleshooting for details on how to determine if any Ca-sensitive probe is located in organelles.

Whenever attempting to measure R_{max} (F_{max}), R_{min} (F_{min}), and (S_f/S_b) in situ, it is absolutely essential that internal $[Ca^{2+}]$ equals external $[Ca^{2+}]$. This is not necessarily easy to accomplish, and because calibration in vitro is so much simpler, many people use in vitro calibration. The main problem with in vitro calibration is that it assumes that the spectral shapes and intensities of the Ca-bound and Ca-free forms of the probe are identical in vitro and in situ. This is true only if the in vitro calibration solution has exactly the same properties as the cytosol of the cell, and this means that one must create a calibration solution that has the same properties as the cytosol of the cell and has the same concentration of probe (Baker et al., 1994). In order to reach a steady state where internal $[Ca^{2+}]$ equals external $[Ca^{2+}]$, several things must occur. First, the internal stores of calcium must be emptied and kept from refilling. Second, the electrochemical gradient for $[Ca^{2+}]$ must be set to zero. Third, the plasma membrane's Na^+/Ca^{2+} exchanger must be neutralized. Fourth, the plasma membrane ATP-dependent calcium pump must be rendered ineffective. Finally, the Na^+K^+-ATPase must be inhibited.

Caffeine can be used to empty some sarcoplasmic reticulum stores, but not all Ca-ATPases are sensitive to caffeine. However, if the cells are incubated in low-calcium medium containing 1 μM thapsigargin, the sarcoplasmic and endoplasmic reticulum calcium stores will empty within about 5 min and stay empty as long as the thapsigargin is present. The addition of a protonophore such as 5 μM CCCP will break down the mitochondrial membrane potential. This results in emptying the mitochondrial calcium stores. It has an additional benefit in that protonophores such as CCCP reduce NADH autofluorescence (Jiang and Julian, 1997), which is a major source of F_a. The addition of oligomycin is used to prevent the mitochondria from utilizing all of the cellular ATP in an attempt to regenerate its membrane potential. In addition, it is an inhibitor of many ATPases. The Na^+/Ca^{2+} exchanger can be neutralized by adding a Na^+ ionophore such as monensin and either a K^+ ionophore such as valinomycin or an inhibitor of the plasma membrane Na^+K^+-ATPase such as ouabain. Equilibration of K^+ depolarizes the plasma membrane. A simpler way to neutralize the Na^+/Ca^{2+} exchanger is to dissipate the Na^+ and K^+ gradients across the plasma membrane by using a calibration medium that contains intracellular concentrations of Na (10 to 15 mM) and K (130 to 140 mM). Because the plasma membrane Na^+K^+-ATPase will attempt to reestablish the normal Na^+ and K^+ gradients across the plasma membrane, 1 mM ouabain or a similar inhibitor must be added to inhibit it. The plasma membrane ATP–dependent calcium pump can often be inhibited by vanadate or calmodulin inhibitors such as trifluoperazine. The last necessary component is the calcium ionophore, which in conjunction with CCCP dissipates the Ca^{2+} electrochemical potential. Either ionomycin or dibromo A-23187 can be used. Making sufficient ionophore available to the cells can be a real problem. Sometimes Br-A23187 works better than ionomycin because its action is independent of pH. Ionomycin should not be used at pH values less than ~7.2 (Williams and Fay,

1990). When measuring R_{max} (F_{max}) use sufficient free calcium; the amount of calcium needed depends upon the K_d of the probe in situ. To obtain R_{max} within about 0.5% of its true value, the amount of calcium needed is ~200 times the K_d of the probe in situ. When engaged in in situ calibration with a fluorescence microscope, avoid moving the microscope stage, since the same cells must be used for the entire calibration in order to measure (S_f/S_b). Likewise do not include cells whose intensity profiles are flattened due to too intense fluorescence, or cells whose intensities are too close to background.

If it is not necessary to know the absolute value of $[Ca^{2+}]$, then it is not necessary to measure K_d in situ even if it is different from the in vitro value. If it is necessary to measure K_d in situ, be very careful to control pH, temperature, and ionic strength of the calibration solution, since EGTA is sensitive to all of these parameters. Also be very careful in dilutions to make sure of how much free calcium is employed, to calculate R_{max} (F_{max}).

If K_d in situ is measured later and found to be very different from K_d in vitro, it is very easy to correct all of the data since $[Ca^{2+}]$ is proportional to K_d. If K_d in situ equals x times K_d in vitro, then $[Ca^{2+}]_{corr} = x[Ca^{2+}]_{measured}$, where $[Ca^{2+}]_{measured}$ was calculated assuming the in vitro value of K_d.

Troubleshooting

If the cells will not attach to glass coverslips, adherence can be improved by treating the coverslips with an extracellular matrix material such as type I collagen or laminin. Rinse coverslips in ethanol, dry them, and place them in plastic petri dishes. Add 1 or 2 drops of type I collagen (1 mg/mL in 0.1% acetic acid) or laminin (0.1 mg/mL in Tris-buffered saline) and spread the drops over the coverslips. After air drying overnight, rinse the coverslips with standard medium and then add cells in the usual manner (Lemasters, 1996).

If there is difficulty in loading sufficient probe into the cells, many manufacturers recommend the use of the nonionic, low-toxicity detergent Pluronic F-127. This detergent can usually be obtained free of charge upon request of the manufacturer of the probes. Prepare a 20% (w/v) solution of this surfactant in DMSO. Gentle warming (~40°C) may assist in dissolving the detergent. This solution may be prepared in bulk and stored at room temperature. When ready to incubate the cells, add 0.5 µl of 20% Pluronic F-127 per µl of the AM form of the fluorescent probe in a small glass tube and vortex or sonicate to obtain complete mixing (Kao, 1994). Immediately before use, dilute to ~2 to 20 µM of the AM form of the fluorescent probe with standard medium and vortex. This mixture should then be added to the cell suspension or plated cells and mixed by stirring, vortexing, or pipetting. Most researchers have found that Pluronic F-127 has little effect in improving the solubility of most probes, and hence in increasing total conversion of probe. Be aware that solutions of AM esters in DMSO are unstable to hydrolysis. The presence of Pluronic F-127 may further decrease the stability of the AM ester solution, so make no more of the Pluronic F-127:AM mixture than can be used immediately.

A more likely reason for such difficulty is that the cell type either has very low esterase activity, in which case the cells should be incubated for a longer time in the cell-permeant form of the probe, or it has a very active multidrug resistance protein (Homolya et al., 1993), which can be inhibited with a monoclonal anti-MDR1 antibody, verapamil, vincristine, sodium orthovanadate, or oligomycin.

In general, it is not a good idea to incubate the cells with more than 5 µM probe in the cell-permeant form, since high concentrations of the probe can result in the uptake and conversion of the probe inside cellular organelles. High probe concentrations in the AM form also make it very difficult to remove the residual permeant probe from the cells after incubation. If it is suspected that there are problems with residual permeant probe, include 2% (w/v) albumin in the medium used to wash the cells after incubation (Oakes et al., 1988). In addition, too high a concentration of the free acid form of the probe can substantially change the Ca-buffering capacity of the cells, which will change the $[Ca^{2+}]$ that the cells will display in response to stimuli. An internal probe concentration that is <100 µM will generally not cause substantial Ca buffering (Moore et al., 1990). If the spectrum obtained for the Ca-sensitive form of the probe in situ (after subtraction of autofluorescence and the calcium-insensitive portion of the probe) does not look like some combination of the Ca-free and Ca-bound forms of the probe but looks "strange," there is likely too high a concentration of probe, which causes the inner-filter effect. Figure 2.5.1 shows the impact of the inner-filter effect on the excitation, high-calcium spectra of Fura-2 FA. Notice that as the concentration of Fura-2

increases the peak begins to flatten relative to the rest of the spectrum and eventually becomes a relative minimum. If a problem with the inner-filter effect is suspected, decrease probe concentration and/or incubation time. If a cuvette is being used, decrease the concentration of cells/ml instead. If using a tissue slice, try to decrease the thickness of the slice.

Incomplete hydrolysis of the probe is only a problem for those probes whose cell-permeant forms and partial hydrolysis forms are fluorescent. The AM forms of calcium orange, calcium crimson, Fura-2, Indo-1, and Rhod-2 are all fluorescent. The AM forms of calcium green 1 and 2, Fluo-3 and Oregon green 488 BAPTA 1 and 2 are not fluorescent. The incomplete hydrolysis of an AM fluorescent probe generally results in Ca^{2+}-insensitive fluorescence similar to that of the low Ca^{2+} form of the Ca^{2+}-sensitive probe. The presence of this incomplete hydrolysis product presents a problem only when using ratiometric probes such as Fura red, Fura-2, and Indo-1. If incomplete hydrolysis of the AM form of the probe is suspected, it can usually be detected by lysing the cells using *N*-octyl β-D-glucopyranoside (*N*-octyl glucoside), CHAPS, or CHAPSO in a high-Ca^{2+} buffer and either measuring the ratio of $(F)_{\lambda 1}/(F)_{\lambda 2}$ or scanning excitation (emission). The resulting ratio (or spectrum) should be very similar to that obtained from placing the FA form of the probe in the same high-Ca^{2+} buffer containing the same amount of detergent. Note that *N*-octyl β-D-glucopyranoside is suggested as the best detergent because it causes few changes in the extinction coefficient or quantum yield of either the high- or low-Ca^{2+} forms of most ratiometric Ca^{2+} probes, and it is not fluorescent. If another detergent is used, its effects on the high- or low-Ca^{2+} FA forms of the probe and on the AM form of the probe must be checked for intensity and spectral changes. If the accumulation of the incomplete hydrolysis products of the AM esters cannot be prevented, then it is necessary to use the spectral component curve-fitting technique of Gunter et al. (1990) to use a ratiometric probe to accurately determine intracellular free Ca^{2+}.

In general, when using a new cell line or a new probe, test to see if there is substantial conversion of probe inside cellular organelles. The most definitive way to determine the location of probe inside of a cell is to use a fluorescence microscope. If there is punctate distribution of the probe or nuclear localization, there are problems (Gores et al., 1989; Moore et al., 1990; Roe et al., 1990; Kao, 1994). One common source of such punctate fluorescence is the accumulation of probe in pinocytic or endocytic vesicles. This problem can generally be solved by prechilling the cells at 4°C for 5 to 15 min before loading at room temperature or 37°C (Roe et al., 1990). Sometimes probe distribution appears to be cytosolic (diffuse, nonlocalized) in origin but may in fact be located in organelles whose $[Ca^{2+}]$ is similar to that of the cytosol. This possibility can be verified by adding increasing concentrations of digitonin to the cells. Use 10 to 20 μM digitonin to solubilize the plasma membrane and release the cytosolic probe. The proper amount of digitonin can be determined using the titration technique of Fiskum (1985). 100 μM digitonin will release probe from lysosomes and endosomes. 0.1% Triton X-100 will release probe from mitochondria (Gores et al., 1989; Roe et al., 1990; Kao, 1994). To quantitate the results for a ratiometric probe, collect median values of fluorescence from inside the cells at the isosbestic wavelength. See the discussion about probe leakage below, for information on how to locate the isosbestic wavelength. The fraction of probe in the cytosol equals 1 − (median fluorescence after permeabilization of the plasma membrane)/(the median value of fluorescence before permeabilization). For a nonratiometric probe, any wavelength will do. In the absence of a fluorescence microscope, it is still possible to obtain similar information as follows. For a suspension of washed cells that have been incubated in the proper way with the membrane-permeable form of the probe, measure total fluorescence, supernatant fluorescence, and autofluorescence, and determine the amount of probe inside the cells. To an identical aliquot of cells, add 10 to 20 μM digitonin to permeabilize the plasma membrane but not the mitochondrial inner membrane or endoplasmic reticulum membranes. Measure total fluorescence and supernatant fluorescence and determine the amount of probe still inside the cells. From this determine the fraction of probe which is cytosolic.

Leakage of a fluorescent probe from the cells being studied is a common and serious problem in measurement of intracellular $[Ca^{2+}]$. This should be investigated during the initial work with a new probe or with a new cell line. Perhaps the simplest way to determine the amount of probe that has leaked from a suspension of cells in a given time is to spin the cells down at the end of this period and compare the

spectrum of the supernatant with that of fresh suspending medium. The spectrum of the probe that has leaked generally stands out clearly. This problem is particularly troublesome with [Ca^{+}] measurements because the [Ca^{2+}] of even "Ca^{2+}-free" medium that does not contain a Ca^{2+} buffer is in the micromolar range. While typical intracellular [Ca^{2+}] is usually 100 nM or less, any probe that leaks out of the cell will report a much higher concentration. Unless a correction is made, leakage of 10% of the probe into the medium can easily cause a 100% erroneously high result in the intracellular [Ca^{2+}] measurement. One of the advantages of using ratiometric probes is that results do not vary with the amount of probe left in the sample cells, so the usual correction for leakage of probe is simply to subtract away the signal from the external probe F_s before setting up the ratio. If F_s varies linearly with time, then in the future it will not be necessary to measure F_s for each sample. Instead, measure F_s at the beginning and end of the experiment as well as at a few intermediate points, and then calculate F_s for each sample, depending upon when it was measured and subtract the calculated value of F_s from F_t instead of having to measure it.

It is important to note that this technique of calculating F_s will only work if any additives included with the samples do not change the free calcium in the external medium.

Leakage is a much more serious problem for nonratiometric probes because F, F_{max}, and F_{min} are all proportional to c, the concentration of calcium-sensitive probe inside the cells, and hence if c changes so do they. The easiest way to handle this problem is to back-calculate F, F_{max}, and F_{min} to time $t = 0$, which is essentially what is done in steps 10 and 11 of Alternate Protocol. Once it has been determined that the loss of calcium-sensitive probe from the particular cell type is linear with time, it is only necessary to take occasional measurements of F_{sd} in order to generate a plot of k versus time. This plot can be used to calculate k for any sample as long as the time the sample was measured is known and the concentration of free calcium in the external medium is constant.

If there is substantial probe leakage, add one of the inhibitors of the organic anion transporter such as probenecid or sulfinpyrazone to the cells (di Virgilio et al., 1990). Probe leakage and its severity are easy to determine in the cuvette system, since the increase of fluorescence in the supernatant can be used to measure leakage. Probe leakage in FDIM for a nonratiometric probe is determined by measuring changes in the fluorescence from resting cells, which are unlikely to undergo spontaneous changes in [Ca^{2+}]. If there is access to a spectrofluorometer and plenty of cells, the best technique to determine probe leakage is to follow the increased fluorescence of the supernatant with time. Probe leakage is not a problem for ratiometric probes except during calibration. Prolonged high calcium is toxic to most cells and can induce the permeability transition in mitochondria which can in turn cause apoptosis. The process of apoptosis not only changes the intracellular environment drastically but can also lead to more rapid loss of probe from the cell. This type of probe loss can be most severe when measuring R_{max}. If probe loss appears to be excessive while measuring R_{max}, try adding 400 nM cyclosporin A to inhibit the permeability transition. If it is suspected that substantial probe leakage is happening during the calibration, determine the isosbestic wavelength of the probe inside the cell, because such leakage will result in an incorrect value of (S_f/S_b). This procedure is discussed in detail in both protocols.

The calibration of these probes in situ can be incorrect as a result of two things—dye leakage or not obtaining $[Ca^{2+}]_{in}$ equal to $[Ca^{2+}]_{out}$. Determining that $[Ca^{2+}]_{in}$ equals $[Ca^{2+}]_{out}$ is not simple. In general, R_{max} and R_{min} measured in situ will not be greatly different from their values measured in vitro, especially if some protein is added to the in vitro solution. (S_f/S_b) in situ can be very different from its in vitro value. If the in situ measured values of R_{max} and R_{min} are very different from their in vitro values, the sample likely did not attain $[Ca^{2+}]_{in} = [Ca^{2+}]_{out}$. In this case, try to vary the concentration of the various ionophores and inhibitors mentioned in Critical Parameters; also see the following references: Roe et al. (1990); Williams and Fay (1990); Bassani et al. (1995); Lipp et al. (1996). If there is access to an electrode setup for a fluorescence microscope, try "poking" cells with a 2- to 3-µm diameter electrode while they are in the calibration solutions and see if the fluorescent ratio for the poked cell changes as a result (Bassani et al., 1995). If the ratio does not change, $[Ca^{2+}]_{in} = [Ca^{2+}]_{out}$.

The biggest problems in calculating K_d in situ are also dye leakage during the calibration and, of course, getting $[Ca^{2+}]_{in} = [Ca^{2+}]_{out}$. As was mentioned before, correcting for dye leakage in the cuvette system is relatively easy. For

a ratiometric probe using FDIM, either calculate the spectra for each concentration of calcium and correct each spectrum so all of the spectra have the same isosbestic point, or use the isosbestic point as one of the two wavelengths and use the change of fluorescence at the isosbestic point to calculate dye loss and hence correct fluorescence at λ_2 for dye loss. The second procedure requires less time than the first but is not as accurate.

Anticipated Results

Using the techniques described in this unit should permit determination of intracellular [Ca^{2+}] with good accuracy. The sources of the largest error in determination of intracellular [Ca^{2+}] are usually error in K_d, error in R_{min}, error in (S_f/S_b), and especially error in R_{max}. Provided that the incubation procedure is chosen to give a strong cytosolic probe signal and negligible partial conversion products, and provided that leakage is negligible, absolute error is inherently limited by how far from the K_d of the probe the measured [Ca^{2+}] is, and the value of R_{max}/R_{min} of the probe. For a probe having a high R_{max}/R_{min} such as Fura-2 and a measured value of [Ca^{2+}] near the K_d, the accuracy should be within ± 5 nM under optimal conditions.

Time Considerations

Cell incubation should take no more than 1 hr. Setting up the instrument should take 30 min to 1 hr. Measuring calcium-insensitive fluorescence should take 30 min to 1 hr, and measuring autofluorescence should take 5 min to 1 hr depending upon whether it is negligible or not. Once an optimal incubation has been found, measuring calcium-insensitive fluorescence or autofluorescence will either be unnecessary or take no more than 30 min for both. A day should probably be set aside the first time for measuring R_{max} (F_{max}), R_{min} (F_{min}), S_f, and S_b in order to find out which procedure works best. Subsequently, such calibration should take no longer than 1 to 2 hr depending upon how long it takes the cell type to equilibrate $[Ca^{2+}]_{in}$ with $[Ca^{2+}]_{out}$. Measuring a sample of interest can go quite rapidly and the number of samples will determine how long it will take. Depending upon how many samples are measured, analysis can take 2 to 4 days.

In Vitro Methods for Detecting Cytotoxicity

The protocols provided in this unit are methods for determining cytotoxicity, a term which includes the effects toxicants can have on cell growth, metabolic functioning, or viability. These tests have value because they can provide a general indication of the sensitivity of cells to toxicants, making them appropriate for screening purposes. Although not specific indicators of the mechanisms associated with toxicant-induced effects, positive results with cytotoxicity tests indicate that physiologic or morphologic changes have occurred in exposed cells. These tests, therefore, may suggest other endpoints to be investigated to provide more specific mechanistic information about the interactions of toxicants and cells.

Cytotoxicity is generally used as an inclusive term for changes that can become irreversible and that can ultimately affect cell viability. This is true even for cytotoxicity tests that determine effects on cell growth or metabolic functioning because, with increased exposure to the toxicant, changes in growth and metabolism, too, can become irreversible and cell viability can be decreased.

This unit includes protocols for cytotoxicity determinations but does not provide protocols for culturing cells (see *APPENDIX 3B*) or protocols for exposure of cells to toxicants. These procedures vary widely both with cell type and with toxicant. Because cytotoxicity testing in vitro can be done efficiently and economically, one or more of the methods described in the sections that follow may be used to screen chemicals for the possibility they might be toxic before tests are done in animals. This screening could be followed by in vitro and/or in vivo determination of endpoint alterations more specific to the toxicant in question and/or to the organ(s) affected. The in vitro cytotoxicity tests themselves alone cannot be used independently to provide indication of hazard to man or animals.

Seventeen protocols that can be used to indicate cytotoxicity in vitro are included in this unit. They fall into three groups. First are tests primarily used to indicate the toxicant has altered cell viability. These tests are valuable for initial general screening. They can also be used in combination with endpoint assays more specific to the toxicant or target tissue to provide indication if the more specific change occurs in cells at concentrations below concentrations needed to decrease viability. This group includes: trypan blue dye uptake (see Basic Protocol 1); lactate dehydrogenase (LDH) leakage (see Basic Protocol 2 and Alternate Protocols 1 to 4); neutral red dye retention (see Basic Protocol 3 and Alternate Protocol 5); and propidium iodide (see Basic Protocol 4) or fluorescent marker (see Alternate Protocol 6) attachment to double-stranded nucleic acids.

Second, there are tests to indicate the toxicant has effects on cell growth and cell proliferation. These tests are generally more sensitive to lower concentrations of toxicants than tests affecting cell viability. These tests can also be used at concentrations of toxicant that do not necessarily cause irreversible cell damage. Therefore, they could be used to determine if recovery occurs when the cells are no longer exposed to the toxicant. This group includes: cell counts (see Basic Protocol 5); [^{3}H]thymidine uptake (see Basic Protocol 6); and cell cycle analysis with propidium iodide (see Basic Protocol 7).

Finally there are tests to indicate the toxicant has affected cellular metabolic processes. These tests may be useful to indicate if the toxicant is likely to target the cell membrane, an intracellular organelle, or a biochemical process. They can be used along with viability tests to determine concentration and time sensitivities. This group includes MTT dye conversion by mitochondria (see Basic Protocol 8); alamar blue reduction by respiring cells (see Basic Protocol 9); and fluorescent dye loss (see Basic Protocol 10) and

Current Protocols in Toxicology (2000) 2.6.1-2.6.27

[^{3}H]2-deoxy-D-glucose loss (see Alternate Protocol 7) from cells with compromised membranes.

The procedures for cytotoxicity included in this unit are a sampling of those available; they do not provide an all-inclusive list. The protocols do, however, include tests that differ by indicators of irreversible cell damage and by technical complexity and efficiency.

NOTE: All solutions and equipment coming into contact with cultured cells must be sterile, and aseptic techniques should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

BASIC PROTOCOL 1

TRYPAN BLUE UPTAKE TO ASSESS VIABILITY

Trypan blue uptake is commonly determined as cells are counted. This vital dye only enters dead cells (the cell membrane must be damaged before the dye can enter). Live cells exclude the dye; therefore, this procedure is used to estimate the percentage of viable cells in an incubate (also see *APPENDIX 3B*).

Materials

Cells treated with toxicant, vehicle, or 10% (v/v) Triton X-100 in suspension
Phosphate-buffered saline (PBS; see recipe), pH 7.2 to 7.4
0.1% (w/v) trypan blue (see recipe)

Hemocytometer
Phase-contrast inverted microscope
Hand counter

1. Prepare cells treated with toxicant, vehicle, or 10% (v/v) Triton X-100 in suspension.

   Cells that have attached to culture dishes need to be disassociated. This can be done by removing the medium, adding a solution of trypsin/EDTA (see recipe) for 1 to 5 min, centrifuging, and removing the trypsin solution (see APPENDIX 3B).

   Cells that are treated with 10% Triton-X100 are permeabilized and serve as a positive control.

2. Wash cells one to three times with PBS, preparing a final resuspension in an exact volume of PBS (e.g., 1.0 ml, 10.0 ml).

   The final resuspension provides the cell concentration counted on the hemocytometer.

3. Place a clean, dry hemocytometer slide on a microscope stage; apply a cover slip over the chamber so it rests equally across both overflow slots. Set the microscope to use the 10× objective and focus until the grid lines on the hemocytometer are clear.

   The hemocytometer grid has nine large squares, each with an area of 1 mm^2. The large squares are subdivided into smaller squares. (For example, each of the four corner squares contains sixteen smaller squares; see Fig. A.3B.1.) The depth of the curved chamber underneath the grid is 0.1 mm, so the volume of cell suspension under each of the nine large squares is 0.1 mm^3 or 10^{-4} ml.

4. Mix equal volumes of cell suspension and 0.1% trypan blue solution (e.g., 25 µl of each). Let the mixture stand for no longer than 3 min.

   This can be done in the well of the 96-well plate, or on any smooth hydrophobic surface (e.g., Parafilm, glass slide). Mixing can be done with a micropipet. The cell suspension/dye mixture should not stand for more than 3 min to prevent dye uptake by viable cells. Trypan blue may be used in concentrations between 0.08% and the 0.4% solution commercially available (Sigma). The cell suspension-to-dye ratio may differ from 1:1 (e.g., 1:2, 1:3, 1:4), but must be appropriately accounted for in the calculation step given below.

5. Slowly fill the hemocytometer chamber with the cell suspension/dye mixture by placing the tip of a micropipettor into the notch under the coverslip. Dispense slowly, allowing capillary action to draw the cell suspension into the chamber. Do not overfill or underfill the hemocytometer chamber.
6. Using the 10× objective of the microscope and a hand counter, count the stained (dead) and unstained (live) cells in one or more of the large squares.

   The total area counted needs to have an area of ≥1 mm^2; the total number of cells counted needs to be >100.
7. To calculate the cell concentration in the cell suspension (cells/ml), the total number of cells counted is divided by the total number of large squares counted and this number is multiplied by 2×10^4 (to account for the 0.1 mm^3, or the 10^{-4} ml volume of cells in a large square on the hemocytometer and the 2-fold dilution made when the trypan blue was added).
8. To calculate the percentage of viable cells, divide the number of viable (unstained) cells by the total number of cells counted (unstained + stained) and multiply by 100.

LACTATE DEHYDROGENASE (LDH) LEAKAGE TO ASSESS VIABILITY

BASIC PROTOCOL 2

This procedure is used as an indicator of increased membrane permeability and subsequent cell death. The increase in permeability associated with cell death causes release of the cytoplasmic enzyme, lactate dehydrogenase (LDH), which is present in mammalian cells. LDH is membrane impermeable and remains within live cells. Kits are available for LDH detection that decrease the technical complexity of this assay (Sigma).

Materials

Cells
Test compounds: toxicant, vehicle, and Triton X-100
LDH Reagent Kit (DG 1340K, Sigma) containing:
  NADH, 0.194 mmol/liter in phosphate buffer
  Phosphate buffer, 54 mmol/liter, pH 7.5
  Pyruvate, 6.48 mmol/liter in phosphate buffer

96-well microtiter plates, for cell culture
Microtiter plate spectrophotometer with wavelength at 340 nm

1. Set up a 96-well microtiter plate with 1 to 2×10^4 cells/100 µl/well or 100 µl medium/well (controls). Incubate for 18 to 48 hr to allow cells to attach and reach 60% to 80% confluency. Replace medium for adherent cells; for suspension cells, proceed directly to step 2.

   Use plates coated for cell culture. Use plates with flat-bottomed wells for attached cells and round-bottomed wells for cells in suspension.

   The plate should include wells with medium only to correct for background (e.g., serum and phenol red in medium), untreated and vehicle-treated cells (negative controls) to correct for spontaneous release of LDH, and cells treated with 10% Triton X-100 to kill all the cells (positive control) and allow estimation of the total possible LDH release.
2. Treat cells in remaining wells with test compound, using several concentrations and several time periods for incubates. Include a vehicle control.
3. To microtiter wells on a second microtiter plate, add 250 µl of NADH solution (0.194 nmol/liter NADH; 54 mmol/liter phosphate buffer, pH 7.5). For suspension cells, add 10 µl of toxicant-treated cells (>10^4 cells/ml) or control cells to these wells. For

attached cells, add 10 µl of the supernatant of toxicant-treated or control cells to the wells. Mix.

4. Initiate the reaction by adding and mixing 25 µl of a solution of 6.48 mmol/liter pyruvate.
5. Record the decrease in absorbance at 340 nm at 3 to 5 min intervals over a period of time (up to 1 hr).

   The change in absorbance needs to be determined over sufficient time to obtain a meaningful value (change of >0.1 absorbance units over the time observed).

6. After subtracting the LDH release in the negative control from the experimental incubation and the positive control, compare the rate of decrease (change in absorbance/min) to that of the positive control (10% Triton-X-100-treated cells). Express the results as change in absorbance units/min (ΔA_{340}/min).

ALTERNATE PROTOCOL 1

IN SITU LDH ASSAY TO ASSESS VIABILITY

This assay is done by initially putting 10 µl of a 7 mM (0.8 mg/ml) solution of pyruvate in PBS in the microtiter well with 1 to 2×10^4cells (attached or suspension) in 100 µl medium and initiating the reaction with 20 µl of a freshly prepared 4.5 mM (3 mg/ml) NADH solution in PBS. Also, endpoint rather than kinetic assays can be used. To do this, terminate the reaction by adding 20 µl of the LDH inhibitor oxymate [138 mM (16.6 mg/ml) oxamic acid, sodium salt, in PBS] to microtiter wells containing a 130 µl incubate of pyruvate, cells, and NADH solution. Read the absorbance at 340 nm.

ALTERNATE PROTOCOL 2

PHENYLHYDRAZINE COLORIMETRIC LDH ASSAY TO ASSESS VIABILITY

Colorimetric assays can also be used for LDH determinations. One of these procedures measures the phenylhydrazone produced when pyruvic acid not converted to lactic acid is quantified as it undergoes reaction with 2,4-dinitrophenylhydrazine. The endpoint is measured at any wavelength between 400 and 550 nm after 60 min of incubation at 37°C. This protocol can be performed using Diagnostic Kit 500 (Sigma). The choice of wavelength depends on the optional wavelength, which is determined prior to the beginning of the experiment.

ALTERNATE PROTOCOL 3

INT COLORIMETRIC LDH ASSAY TO ASSESS VIABILITY

Another colorimetric LDH assay uses the tetrazolium dye 2-*p*-iodophenyl-3-nitrophenyl tetrazolium chloride (INT), with absorbance measured at 490 nm. This can be done as an endpoint, rather than as a kinetic assay.

Materials

1 to 2×10^5 cells/ml treated with toxicant, vehicle, or 10% (v/v) Triton X-100
36 mg/ml lactate in 10 mM Tris·Cl, pH 8.5 (*APPENDIX 2B*)
INT dye (see recipe)
NAD^+ solution (see recipe)
Phosphate-buffered saline (PBS; see recipe), pH 7.2 to 7.4
16 mg/ml oxymate (oxamic acid, sodium salt) in PBS
Microtiter plate reader at 490 nm

1. Set up microtiter plate and treat cells (see Basic Protocol 2, steps 1 and 2).
2. Aliquot 100 µl of cells to each well of a microtite plate.
3. Add 20 µl freshly prepared 26 mg/ml lactate in 10 mM Tris·Cl, pH 8.5.

4. Add 20 µl 2 mg/ml INT dye.
5. Add 20 µl NAD^+ solution to each well. Incubate 20 min at room temperature.
6. After the incubation, stop the reaction by adding 20 µl of 16.6 mg/ml oxymate at specific time points <1 hr.
7. Read the absorbance at 490 nm (A_{490}).
8. Calculate the percentage of cells lysed by subtracting the change in absorbance in negative control cells from the change in absorbance in experimental cells, dividing by the total absorbance in positive control cells, and multiplying by 100.

KINETIC INT COLORIMETRIC LDH ASSAY TO ASSESS VIABILITY

ALTERNATE PROTOCOL 4

The colorimetric assay described in Alternate Protocol 3 can also be done as a kinetic assay. For this procedure, mix 100 µl of cells (10^5/ml) with 100 µl of LDH substrate (see recipe), adding the substrate mixture to each well at 3-sec intervals. Read absorbance at 490 nm at 3 to 5 min intervals.

NEUTRAL RED DYE RETENTION TO ASSESS VIABILITY

BASIC PROTOCOL 3

Neutral red is a vital dye. It is taken up and retained in viable cells that adhere to the plastic of microtiter plates. This colorimetric assay can be done in 96-well microtiter plates, meaning the assay can be conducted simultaneously on a number of incubates containing cells and various concentrations of toxicant (Babich and Borenfreund, 1992; Veronesi and Ehrich, 1993).

Materials

10^5 cells/ml cell suspension
Test compound: toxicant, vehicle, or positive control (1% w/v SDS or 1% w/v saponin)
Phosphate buffered saline (PBS; see recipe)
1% (w/v) SDS
Neutral red solution (see recipe)
Dye extractor solution (see recipe)

Flat-bottomed, 96-well microtiter plates, cell culture coated
Blotter paper (e.g., absorbent paper towels or filter paper)
Plate mixer
Microtiter plate reader, 550 nm

1. Place 2×10^4 cells (0.2 ml of 10^5 cells/ml) in wells of a flat-bottom 96-well microtiter plate. Incubate for a sufficient time to assure attachment and 60% to 80% confluency (e.g., 18 hr to 3 days).

   These plates may need specific coating (e.g., collagen or laminin) for certain cell types that do not adhere well.

2. Replace medium to include up to 1% (v/v) of toxicant, vehicle, or positive control solution/well (20 µl per total volume of 200 µl in wells). Expose cells to 1% (w/v) sodium dodecyl sulfate solution (SDS) or 1% (w/v) saponin solution as a positive control.

   The positive control is included to ensure that the assay is working and to determine the range of absorbance for the experiment.

3. Incubate cells for time previously designated in the experimental protocol (e.g., 4, 8, 12, 24, 36, 72 hr).

   Note that the neutral red assay can be done in the same microtiter plate as the incubation with toxicant provided the cells are not too confluent and the presence of the test compound(s) does not significantly decrease cell numbers. If the cells are too confluent to be a monolayer or if the cells lose adherence, replate to a uniform density before proceeding to step 5.

4. After incubation with test compounds, remove the medium from the wells by pipetting. Gently wash the cells adhering to the plate twice with 100 µl PBS. Air dry the plates to increase adherence of cells to the plate.

5. Then add 40 µl freshly prepared neutral red solution to each well and incubate the plate for 90 min at 37°C.

6. Remove the neutral red solution and gently but rapidly wash the wells 2 times with 100 µl 37°C PBS. Remove the PBS and blot dry on absorbent paper.

7. Extract the dye from the remaining cells by adding 100 µl dye extractor solution per well. Mix plate on plate mixer at room temperature for 20 min.

8. Read absorbance on the microtiter plate reader at 550 nm. Compare neutral red retention in cells exposed to toxicant and those exposed to the vehicle (which is used to provide the comparative number for 100% viable cells).

   A standard curve of neutral red may be prepared to provide results in microgram per milliliter. Plates can be reread the next day, if needed, as the neutral red in the cells is stable overnight.

ALTERNATE PROTOCOL 5

NEUTRAL RED ENDPOINT ASSAY TO ASSESS VIABILITY

This assay can be done with endpoints either in the visible range (550 nm) or as a fluorescent assay (488 nm excitation, 645 emission). First the cells are treated with toxicant, vehicle, or positive control.

For cells in suspension in test tubes rather than microtiter wells, incubate 5×10^6/ml cells with 0.036% (w/v) neutral red (prepared in commercially available Hank's balanced salt solution) at 37°C for 30 min in a humidified 37°C, 5% CO_2 incubator. Then centrifuge cells 10 min at $400 \times g$, 4°C, and wash the cell pellet twice with medium centrifuging 10 min at $400 \times g$ between washings. After washing resuspend and dilute cells in medium to 5×10^6 cells/ml. Mix 100 µl cells with 100 µl of 0.1 M acetic acid containing 1% (w/v) SDS, dilute to 1.25 ml with normal saline and read the absorbance at 540 nm or fluorescence at 645 nm with 488 nm excitation.

Alternatively, for cells in suspension, incubate 100 µl cells (1 to 2×10^5 cells/ml) with 0.1% (w/v) neutral red for 3 hr at 37°C in microtiter plates, then wash with PBS by adding 200 µl PBS to each well, mixing by pipetting, and centrifuging the plate for 10 min at 1000 rpm in a centrifuge with a plate carrier. Carefully remove the PBS. Repeat the PBS wash two to three times. Next add 1% glacial acetic acid/50% methanol to extract the dye and fix the cells. Read absorbance at 540 to 550 nm or fluorescence at 645 nm with 488 nm excitation.

PROPIDIUM IODIDE ATTACHMENT TO DOUBLE-STRANDED NUCLEIC ACIDS TO ASSESS VIABILITY

BASIC PROTOCOL 4

The fluorescent dye propidium iodide (excitation 530 nm, emission 645 nm) is excluded from living cells, but enters and combines with double-stranded nucleic acids (i.e., DNA) of dead cells. The assay for cell viability using propidium iodide attachment to double-stranded nucleic acids can be done simultaneously with determination of membrane integrity using a variety of membrane-permeant fluorescent probes (e.g., CFDA-AM, which has an excitation 485 nm and emission 530 nm) because the fluorescent spectra do not overlap (Nieminen et al., 1992).

Materials

0.5×10^5 cells/ml
Test compounds: toxicant, vehicle, and positive control
Phosphate buffered saline (PBS; see recipe)
376 µM digitonin solution
30 µM propidium iodide dye (Molecular Probes)

Flat bottomed, 96-well microtiter plates, for cell culture
Fluorescence microtiter plate reader

1. Plate cells (0.5×10^4/well) and allow to attach overnight before exposing to toxicant. Incubate with toxicant at predetermined concentrations and times. Include wells for positive and negative controls on each microtiter plate.
2. Wash plate free of medium. Add 10 µl of 376 µM digitonin solution to positive control wells. Add 100 µl propidium iodide (30 µM) to all wells.
3. Incubate plate for 30 min at 37°C.
4. Read in a microtiter plate fluorescence spectrophotometer set with excitation at 530 nm and emission at 645 nm.

   Alternatively, excite at 488 nm.

5. Compare wells exposed to test compounds and wells exposed only to vehicle (negative control) to wells exposed to digitonin (100% cell death; the positive control).

   The positive control will provide wells with the highest fluorescence.

6. Calculate per cent of viable cells as fluorescence in test wells less negative control divided by fluorescence in digitonin-treated wells less negative control, with the quotient multiplied by 100.

USING FLUORESCENT MARKERS TO ASSESS VIABILITY

ALTERNATE PROTOCOL 6

Several kits that use binding of fluorescent markers to nucleic acids as an indicator of loss of cell viability are available from Molecular Probes (Haugland, 1996). For example, the Live/Dead Assay includes calcein-AM, a membrane-permeable dye, which is cleaved by intact cells to calcein (fluoresces green) and ethidium homodimer, a membrane-impermeable dye that labels nucleic acids of membrane-compromised (nonviable) cells to produce a red fluorescence. With excitation of 488 nm, emission at 530 nm will indicate live cells and emission at 585 nm will indicate dead cells.

BASIC PROTOCOL 5

ASSAYS TO ASSESS CELL GROWTH

Cell counting is done along with determination of viability using trypan blue and is described under Basic Protocol 1. Another indicator of cytotoxicity is the loss of ability of certain cell types to extend processes (extensions >2× the length of the cell body) when exposed to agents that promote process development (e.g., retinoic acid; Abdulla and Campbell, 1993). A change in expression of specific proteins can also be an indication of cytotoxicity and forms the basis for kits manufactured by Xenometrics.

Estimation of cells counts can also be made using protein determinations, such as the Kenacid Blue dye binding method recommended by the European Fund for Replacement of Animals in Medical Experiments (FRAME; O'Hare and Atterwill, 1995).

Materials

Cells (1 to 2×10^5 cells/well) or 150 µl of 1×10^6 cells/ml, treated with toxicant, vehicle, or control in microtiter plates
Phosphate-buffered saline (PBS; see recipe), 37°C
Fixative: 1% (v/v) glacial acetic acid/50% (v/v) ethanol/49% (v/v) water
Kenacid blue dye (see recipe)
Washing solution: 10% (v/v) ethanol/5% (v/v) glacial acetic acid/85% (v/v) water
Microtiter plate reader, 577 nm

1. After cells have been exposed to toxicant, vehicle, or control solution, remove medium and rinse cells one to three times with warm PBS.
2. Add 150 µl fixative solution to each well and fix 20 min.
3. Remove fixative solution and add 150 µl freshly prepared Kenacid working solution. Shake the plate 2 to 3 hr.
4. Wash wells twice with 150 µl wash solution.
5. After last wash, fill the wells with wash solution and shake for 20 min until the dye has completely gone into solution.
6. Read absorbance at 577 nm using a well with no cells as a reference well.

   The absorbance of the reference well which contains no cells should be zero when the spectrophotometer is set at 404 nm. Absorbance of wells with cells could be read at 600 nm rather than at 577 nm.

BASIC PROTOCOL 6

[^{3}H]THYMIDINE UPTAKE TO ASSESS CELL GROWTH

This procedure can be used as an indication of cytotoxicity because toxicants can decrease the rate of cell division. The assay can also be used as an indicator of cell proliferation, as [^{3}H]thymidine incorporates into the nucleic acids of proliferating cells. This is a relatively complex, yet sensitive procedure that requires used of radiolabeled chemicals.

Materials

1 to 15×10^5 cells/ml
Serum-free chemically-defined medium (e.g., RPMI 1640 or DMEM), 37°C and ice-cold
Test compounds(s): toxicant and vehicle
20× [^{3}H]thymidine solution (see recipe)
10% (w/v) trichloroacetic acid (TCA) solution, ice-cold
0.3 N sodium hydroxide
Scintillation fluid

continued

24-well plates, coated for cell culture
Liquid scintillation counter
Radioactive waste disposal system

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety offices (also see *APPENDIX 1A*).

CAUTION: Trichloroacetic acid is very caustic. Handle it with care.

NOTE: All incubations should be performed at 37°C using an incubator or water bath.

1. Place 1 ml cells in 24-well tissue culture plates and incubate 6 to 24 hr to allow cells to attach.

   Cells with density of 1 to 15 × 10^5/ml may be used.

2. Wash medium from wells and replace with 1 ml serum-free, chemically defined medium 24 to 48 hr before treating cells with test compounds.

   Alternatively, cells (e.g., lymphocytes) can be collected from toxicant-treated animals.

3. For in vitro exposure to toxicants, add toxicant or vehicle, 50 µl/well, to cells for the times specified in the testing protocol.

4. Add 50 µl/well sterile 20× [^{3}H]thymidine solution for the last 2 hr of incubation with the test substance. Continue to incubate at 37°C.

   For certain cell types (e.g., lymphocytes), incubation with [^{3}H]thymidine may be as long as 72 hr. When incubation is done for very short periods of time (e.g., 15 min), the concentration of [^{3}H]thymidine incubated with cells should be increased (e.g., 2.5 µCi/ml).

   Other components of nucleic acids may also be used, such as BrdU (bromo-deoxyuridine) in a relatively similar procedure. [^{3}H]leucine and [^{3}H]glycine incorporation, which are used as indicators of the rate of protein synthesis, would also be expected to provide similar results.

5. Stop the reaction by placing plates on ice. Wash cells 3 times with 1 ml of ice-cold serum-free medium, then carefully remove all medium by vacuum aspiration.

   Remember that the medium and washes are radioactive and dispose of appropriately.

6. Add 1 ml ice-cold 10% trichloroacetic acid (TCA) to each well. Leave plates on ice for 10 min to allow precipitation of DNA and protein. Remove trichloroacetic acid by aspiration.

   This aspirate may be discarded or counted for determination of unincorporated [^{3}H]thymidine.

   Rather than using the caustic TCA solution, cells may be harvested by centrifugation or harvested by using a cell harvester with fiberglass filters (the filters are subsequently placed in vials with scintillation fluid and counted).

   If cells are collected by centrifugation, wash once with warm conditioned medium (medium in which cells have been grown), and recentrifuge at low speed (e.g., centrifuge a 1- to 2-ml sample 3 min at 430 × g at 37°C in pre-warmed 12-ml glass conical centrifuge tubes). Following centrifugation, remove the supernatant, and air dry the pellet before resuspending for scintillation counting. Alternatively, the pellet may be resuspended in 0.5 ml hypertonic solution (e.g., 1.8% saline), placed on a slide for histological examination, fixed by sequential exposure for 10 min each to 5% to 7% trichloroacetic acid (at 5°C), 70% ethanol at room temperature, and 95% ethanol at room temperature, and air-dried. For example, the Kodak Emulsion slidemailer system could be used. After the cells are fixed and air-dried, the slides are covered with emulsion, exposed, developed according to the manufacturer's instructions and analyzed using a microscope.

7. Add an additional 1 ml of 10% TCA to the plates and leave on ice for an additional 5 min. Wash a third time with 10% TCA and leave on ice an additional 5 min to complete the precipitation. Remove the TCA.
8. Solubilize the precipitated protein with 0.5 ml of 0.3 N sodium hydroxide by incubating for 30 to 60 min at room temperature. Transfer 250 µl to a miniscintillation vial with 5 ml scintillation fluid and count.

Concentration and length of incubation with sodium hydroxide may be increased (e.g., to 1 N and to 24 hr) to increase digestion of the cells.

Although [^{3}H]thymidine uptake is usually the endpoint, [^{3}H]thymidine release could also be measured. With this system, incubate cells with [^{3}H]thymidine (concentration and time of incubation predetermined by protocol), wash three times, then resuspend at 4×10^4 cells/well in 24-well tissue culture plates in 1.0 ml medium. Following overnight incubation at 37°C in 5% CO_2, aspirate the medium, mix aliquots with scintillation fluid, and count. Cytotoxicity (in per cent) is calculated by comparing the radioactivity counted in the sample and control wells.

BASIC PROTOCOL 7

CELL CYCLE ANALYSIS WITH PROPIDIUM IODIDE TO ASSESS CELL GROWTH

This procedure can be used as an indicator of cytotoxicity for toxicants that affect DNA synthesis and, therefore, cause cell arrest mostly in the G1/G0 phase of the cell cycle. Some of these cells may undergo apoptosis later, whereas others may have decreased rates of cell growth and proliferation.

Propidium iodide (PI), a DNA-binding fluorochrome, is the most commonly used DNA dye for cell cycle analysis. Because it can be excited at 488 nm, it can be used on most common flow cytometers. Its stoichiometric binding to double-stranded nucleic acids allows fluorescent intensity (>620 nm) to be used as an indicator of cellular DNA content. Using propidium iodide is now a common procedure for DNA analysis (Krishan, 1975).

Materials

Toxicant-treated and control cells in suspension
Standard azide buffer (see recipe)
Vindelov's PI (see recipe)

12 × 75–mm clear polystyrene tubes
30-µm mesh (optional)
Flow cytometer

1. Harvest cells, centrifuge 5 min at 1000 × *g*, decant supernatant, and vortex pellet.
2. Resuspend cells in 1 ml standard azide buffer, count the cells, and recentrifuge 5 min at 1000 × *g*.
3. Resuspend cells in standard azide buffer so that cell concentration is 10^6/ml.
4. Transfer 1 ml of this suspension to another tube and add 0.5 ml of Vindelov's PI.
5. Let cells sit at 4°C for 5 min to 1 hr, then filter through 30-µm mesh if necessary to remove noncellular particulate material.

Filtering is optional.

6. Analyze cells by flow cytometry using 488 nm excitation, gating out doublets and clumps using pulse processing, and measuring fluorescent emission at >620 nm.

For cell proliferation determinations, the CyQUANT Cell Proliferation Assay Kit is available from Molecular Probes. Fluorescence increases when the dye binds to nucleic acids. To perform this procedure, plate cells at 10^3 to 10^4 cells per well in 200 µl medium in 96-well plates. Incubate the cells 6 to 18 hr to allow the cells to attach, replace the medium, and treat the cells with toxicant. Then remove culture medium from cells, freeze and then thaw the cells, add the reagent and cell lysis buffer provided in the kit, then measure fluorescence with 485 ± 10 nm for excitation, and 530 ± 12.5 nm emission. The manufacturer states that this method is sensitive enough to detect fluorescence in cells at a concentration as low as 50 cells/ml.

MTT DYE CONVERSION TO ASSESS METABOLIC CAPABILITY

BASIC PROTOCOL 8

This assay requires cells that are actively able to metabolize 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) to an insoluble formazan precipitate. The assay is used as an indicator of mitochondrial function in live cells; however, loss of activity cannot be used to distinguish compromised cells from dead cells. As an indicator of cytotoxicity, MTT results have been reported to be comparable in sensitivity to those obtained using [^{3}H]thymidine incorporation (Mosman, 1983). The assay can be used with cultured cells or with tissues, as the colored product is solubilized and extracted from the test system. Because the dye needs to be extracted from the cells, this procedure cannot be used to provide cell counts.

Materials

5×10^4 cells/ml cell suspension
Test compound: toxicant or vehicle
Culture medium
5 mg/ml MTT in PBS (store 2 to 3 weeks at 4°C or longer at −20°C)
Dimethyl sulfoxide (DMSO), photometric grade
Sorensen's buffer (see recipe)

96-well microtiter plates, for cell culture
Aspiration system for removal of medium from cells
Micropipettor (20 to 200 µl) with sterile micropipettor tips
Microtiter plate reader

1. Plate cells at 1×10^4 cells/well by adding 200 µl of a 5×10^4 cells/ml suspension to each well of a 96-well tissue culture plate. Include control wells with medium and no cells. Incubate overnight at 37°C 5% CO_2.

   Test compounds (toxicant and vehicle) may be added before or after this incubation.

   Use plates with flat-bottomed wells for adherent cells and round-bottomed wells for suspension cells.

2. Carefully aspirate off the medium, avoiding removal of cells. If not previously incubated with toxicant, replace medium with fresh medium (200 µl) containing up to 0.1 ml of test substance. Include wells with medium without cells or test compound, medium without cells but with test compound, cells without test compound (but with test compound vehicle) as controls. Incubate at 37°C, 5% CO_2, for predetermined times (e.g., several hours, overnight, and/or for several days).

3. After incubation with test compound, carefully aspirate off medium and replace with medium and 20 to 50 µl MTT solution for a total volume of 200 µl. Incubate for 4 to 6 hr at 37°C, 5% CO_2.

4. Carefully remove the MTT-containing medium. Add 200 µl DMSO with 25 µl Sorensen's buffer per well. Mix the plate until the formazan crystals are dissolved.

Rather than DMSO, 200 µl of 0.04 N HCl in isopropanol may be used to solubilize the formazan product made from the MTT dye.

A 10% (w/v) solution of SDS in 0.01 M HCl rather than DMSO can be used to lyse the cells during an overnight incubation at 37°C.

5. Read plate on microtiter plate reader at 550 to 570 nm.

   If medium contains phenol red, readings may need to be compared to those taken at 660 nm, which is a wavelength where quenching by the medium is minimized.

6. Compare absorbance in wells containing the test substance with wells containing untreated control cells.

   Provided appropriate concentrations are used, a concentration-response curve can be constructed.

BASIC PROTOCOL 9

ALAMAR BLUE REDUCTION TO ASSESS METABOLIC CAPABILITY

This bioassay uses a water-soluble indicator of cytotoxicity, eliminating the need for the washing and fixation steps needed in other assays using vital dyes (e.g., neutral red, MTT). As dye extraction is not done, the time needed for data collection is decreased. Data may be collected as either fluorescence (excitation at 530 to 560 nm; emission at 590 nm) or absorbance at 570 or 600 nm. Either cells adhering to the plastic of microtiter plates or cells in suspension culture can be used for this assay. Since the dye is nontoxic to the cells, the same cultures can be monitored over a series of time points. This assay can be used for cell proliferation determinations as well as for cytotoxicity assays. The dye and reagents for this assay are available in a kit from Biosource International, whose technical literature states that it provides results that compare favorably with the MTT assay.

Materials

Cells in microtiter plates
Test compound: toxicant or vehicle
Alamar blue assay kit (Biosource International)
Microtiter plate reader

Additional reagents and equipment for counting cells and assessing viability using trypan blue dye (Basic Protocol 1)

1. Do preliminary experiments to establish optimal cell density and incubation time for the cells used for testing.
2. Harvest cells in log-phase growth; count and estimate viability with trypan blue (see Basic Protocol 1).
3. Plate cells using the number that provides a predetermined optimal density (e.g., 200 µl of 1×10^4 cells/ml for some cancer cell lines) and at cell numbers that provide optical densities above and below optimal. Allow cells to grow at 37°C, 5% CO_2, for sufficient time that they reach log phase (e.g., 2 to 3 days).
4. Aspirate growth medium from the wells and add 200 µl of new medium containing up to 10% volume of test compound to the wells.

   These cells should be incubated for selected periods of time with several concentrations of test compound and the plate should include some wells in which the medium contains only vehicle.

5. Aseptically add an amount of alamar blue equal to 10% of the culture volume (e.g., 20 µl in a well that will contain 200 µl total or 22 µl to a well containing 200 µl medium).

6. Return cultures to the incubator for selected incubation times (e.g., from several hours to several days).

   For all data points data can be collected immediately after the incubation or plates can be stored overnight at 4°C and read the next day. Cell proliferation can be measured once or several times over a 3- to 5-day time period. The assay should be stopped (by refrigeration at 4°C) when cells reach 80% to 90% confluence.

7. Measure fluorescence (excitation 530 to 560 nm; emission 590 nm) or absorbance (at 570 and 600 nm) in a microtiter plate reader at desired time points.

   If using absorbance, subtract the background at 600 nm from the absorbance measured at 570 nm.

   Appropriate time points should be determined by preliminary experiments analyzing the growth of the cells.

8. Calculate cytotoxicity as absorbance (or fluorescence) in treated cells over absorbance (or fluorescence) in control cells. Generate a graph that plots log concentration of test compound on the *x* axis and percent decrease in absorbance (or fluorescence) from control on the *y* axis. Compare dye reduction over time in wells containing test compound and control wells.

MEASURING FLUORESCENT DYE LOSS TO ASSESS METABOLIC CAPABILITY

BASIC PROTOCOL 10

The acetoxymethyl ester derivative of 5-carboxyfluorescein diacetate (CFDA-AM) is one of several membrane-permeant dyes available from Molecular Probes that can be used to indicate membrane integrity (Haugland, 1996). For CFDA-AM and other such dyes, membrane integrity is indicated because the product formed upon esterase-induced cleavage will not leave cells if the cell membrane is intact. The ability to leak CFDA is considered an early indicator of cell damage. This assay for cytotoxicity can be performed at the same time as the propidium iodide assay for cell viability (see Basic Protocol 4), as the spectra for fluorescence do not overlap (Nieminen et al., 1992).

Materials

Cells
Test compound: toxicant or vehicle
50 µg/ml CFDA-AM in PBS (prepared fresh)
Phosphate-buffered saline (PBS; see recipe)
Fluorescence microtiter plate reader

1. Add 0.5×10^4 cells to each well of a 96-well plate. Allow to attach overnight. Incubate with test compounds according to the experimental protocol.
2. Remove medium, wash cells with PBS, and add 100 µl of a 50 µg/ml solution of CFDA-AM.

   Other membrane-permeable dyes may be used, such as the calcein-AM that is included in the Live/Dead Viability/Cytoxicity Assay of Molecular Probes.

3. Incubate cells for 30 min in a 37°C incubator.
4. Read fluorescence using excitation at 485 nm and emission at 530 nm.

   The microtiter plate fluorescence reader should be set to a sensitivity that provides 1000 to 2000 fluorescence units per 1 to 2×10^4 cells/well.

5. Compare fluorescence in wells treated with toxicant with that of wells containing cells but no test compound or vehicle.

ALTERNATE PROTOCOL 7

USING [^{3}H]2-DEOXY-D-GLUCOSE TO ASSESS METABOLIC CAPABILITY

Another means of determining cell membrane integrity is by exposing cells to [^{3}H]2-deoxy-D-glucose, which is membrane permeable. This substrate will be converted to membrane impermeant [^{3}H]2-deoxy-D-glucose-6-phosphate within living cells, and will remain within the cells if the membrane is intact (O'Hare and Atterwill, 1995).

Materials

10^6 cells grown in 60-mm culture dishes
Test compound: toxicant or vehicle
Phosphate-buffered saline (PBS; see recipe)
0.55 µCi/ml [^{3}H]2-deoxy-D-glucose in PBS
1 mg/ml glucose in PBS
1 M NaOH
1 M HCl
Scintillation fluid

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety offices (also see *APPENDIX 1A*).

1. Grow 10^6 cells in 60-mm culture dishes to the appropriate state of confluency.

   The appropriate state of confluency corresponds to a number estimated for each type of cell, which is determined before starting the experiment.

2. Remove the growth medium, and wash the cells twice with 5 ml PBS each wash.
3. Add 5 ml of 0.55 µCi/ml [^{3}H]2-deoxy-D-glucose in PBS. Incubate for 2 hr to load cells.
4. Remove incubation solution and wash 3 times with 5 ml PBS per wash.
5. Add 2 ml PBS containing 1 mg/ml glucose and the appropriate concentration of test compound. Incubate for predetermined times (e.g., 6, 12, and 24 hr).
6. At up to three time points during the incubation, take 50-µl samples and add the samples to 3 ml scintillation fluid.
7. At the end of the incubation, remove the medium from the cells. Add 1 ml 1 M NaOH and incubate for 30 min to dissolve the cells.
8. Add the cell lysate to 3 ml scintillation fluid.
9. Rinse the dish with 1 ml 1 M HCl and add the rinse to 3 ml scintillation fluid.
10. Count the samples, lysate, and rinse. Calculate concentration depletion of radioactivity over the time of incubation.

    The values obtained will provide a means to differentiate what remains within and what is released by the cells.

    This procedure may also be done using a patented polycarbonate perfusion block (O'Hare and Atterwill, 1995).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Dye extractor solution

Citrate buffer: Mix 21.01 g/liter citric acid with 200 ml 1 M NaOH. Bring volume to 1 liter with water and check that pH is 4.2. To 60 ml of this solution add 40 ml of 0.1 M HCl. Store 2 to 3 months at 4°C.

Working solution: Mix citrate buffer 1:1 (v/v) with absolute alcohol.

INT dye

Stock solution: Dissolve tetrazolium dye INT (2-*p*-iodophenyl-3-nitrophenyl tetrazolium chloride) at a final concentration of 40 mM (20 mg/ml) in DMSO to provide a stock solution that can be stored in a tightly closed bottle for 2 to 3 months at room temperature.

Working solution: Dilute the stock 1:10 (v/v) with PBS (see recipe) to prepare a 4 mM (2 mg/ml) working solution just before doing the assay.

Kenacid blue dye

0.2 g Coomassie brilliant blue R-120
125 ml ethanol
315 ml H_2O
Store for 1 to 2 months at 4°C

Kenacid Blue working solution: Add 3 ml glacial acetic acid to 22 ml Kenacid blue dye solution immediately before use.

LDH substrate

5.2×10^{-2} M L(+) lactate
6.6×10^{-4} M INT (2-*p*-iodophenyl-3-nitrophenyl tetrazolium chloride)
2.8×10^{-4} M phenazine methosulfate
1.3×10^{-3} M NAD^+
0.2 M Tris·Cl, pH 8.2 (*APPENDIX 2A*)
Prepare just before assay

NAD^+ solution

4.5 mM NAD^+ (3 mg/ml)
13.5 U/ml diaphorase
0.03% (w/v) bovine serum albumin
1.2% sucrose in PBS, pH 8.2
Prepare just before assay

Neutral red stock solution

Prepare 0.1% (w/v) neutral red in distilled water, autoclave, and acidify with 2 drops of glacial acetic acid per 100 ml. Store up to 3 months in a dark container at 4°C.

Working solution: Dilute stock solution 1:10 (v/v) with PBS (see recipe) or 1:10 with 1.8% NaCl immediately before use.

Phosphate buffered saline (PBS)

For 1 liter:
8 g NaCl (0.138 M final)
0.2 g KCl (3 mM final)
1.15 g disodium monophosphate (Na_2HPO_4; 8 mM final)
0.2 g potassium dihydrophosphate (KH_2PO_4; 2 mM final
H_2O to 1 liter

continued

Adjust pH to 7.2
Filter sterilize through a 0.4-μm filter
Store up to 3 months at 4°C

Sorenson's buffer

0.1 M glycine
0.1 M NaCl
Adjust pH to 10.5 with NaOH
Store up to 2 months at 4°C, but check pH before use

Standard azide buffer

10 gram FA Bacto buffer (Difco 2314-15-0)
10 ml of 10% (w/v) sodium azide solution
10 ml heat-inactivated fetal bovine serum (FBS)
980 ml distilled water
Adjust pH to 7.2 ± 0.05
Store in foil-wrapped bottle up to 1 month at 4°C

[^{3}H]thymidine solution, 20×

20 μl of 1 mCi/ml [^{3}H]thymidine
980 μl sterile, serum-free medium
Prepare fresh on the day of assay

For the assay 50 μl of the stock is diluted to 1000 μl with serum-free medium to give 1 μCi/ml in well.

Trypan blue, 0.1% (w/v)

Dilute 1 ml commercially available 0.4% (w/v) trypan blue solution (Sigma) with 3 ml PBS (see recipe) or balanced salt solution (Sigma). Store tightly closed up to 6 months at room temperature.

Trypan blue in concentrations of 0.08% to 0.4% (w/v) can be used to determine percentage of viable and dead cells seen on the hemocytometer. With 0.1% trypan blue the cells are not as darkly stained and are easier to visualize.

Trypsin/EDTA

To prepare 100 ml of trypsin 0.05% (w/v) with 0.02% (w/v) EDTA, add 2 ml of 10× (2.5%) trypsin (Sigma) and 0.133 ml of 15% (0.5 M) EDTA, pH 8.0, to 97.87 ml of PBS (see recipe). Keep refrigerated, but warm to 37°C before use.

A ready-made solution is available from Sigma and Life Technologies (Gibco). The trypsin solution can be kept up to 4 weeks at 4°C. If it is not used frequently, it can be stored > 1 yr frozen at −5° to −20°C.

Vindelov's propidium iodine stain (PI)

1.21 g Tris base (0.01 M final)
584 mg NaCl (10 mM final)
10 mg ribonuclease (700 U final)
50.1 mg PI (7.5×10^{-5} M final)
1.0 ml Igepal CA-630 (Sigma; 0.1% final)
1 liter H_2O
Mix until dissolved
Adjust pH to 8.0
Filter through a 0.45-μm filter
Store in foil-wrapped bottle up to 1 month at 4°C

CAUTION: *Propidium iodide is toxic and potentially carcinogenic; handle with care and label solution appropriately.*

COMMENTARY

Background Information

All of the protocols provided in this unit can be used to detect damage to cells following in vitro application of toxicants to cells. In addition, several of the procedures can also be used as in vitro determinants of cytotoxicity for cells derived from animals tested with toxicants. The endpoints are nonspecific. In other words, they can occur in many types of cells damaged under a wide variety of situations, including exposure to chemicals, anoxia, and physical agents. Cytotoxicity tests, therefore, cannot be expected to be used to define specific mechanisms of injury induced by specific toxicants. Some tests, however, can suggest a subcellular structure (e.g., the nucleus, mitochondria, membranes) affected by particular toxicants, and more specific tests could then be performed to better describe the toxicant effects (Barile, 1994; Forsby et al., 1995). Although the protocols provided in this unit have been grouped according to one of three primary endpoints (viability, cell growth, metabolic capability), all can be used to indicate dose-related toxicant-induced changes that can eventually result in cell death. For investigators hoping to use such tests to indicate toxicant-induced effects without having toxicant-induced cell death, a prudent first choice among the protocols for cytotoxicity would be among those without viability as a primary endpoint, with inclusion of concentration and time-response effects in the investigation. As an example, the investigator interested in functional disruption rather than cell death could examine concentration-related changes in metabolic capability as a more reasonable endpoint than viability (e.g., for neurotoxicants and reversible hepatotoxicants).

Concentration response is an important part of cytotoxicity determinations and should be included to provide indication of the range over which toxicant-induced cytotoxicity or response occurs. This is especially important if comparisons are to be made between irreversible effects indicative of cytotoxicity and any other, more specific, functional, biochemical, or morphological changes that occur after exposure to the toxicant. If concentrations for cytotoxicity and other alterations are similar, the toxicant-induced general cytotoxicity may contribute to the changes in all endpoints determined. If a functional change occurs at lower concentrations than cytotoxicity, the change may be reversible, and the toxicant may be having effects on more specific endpoints at concentrations lower than those that cause general cell damage. Time-response studies are also useful in cytotoxicity determinations because they, too, indicate relative sensitivities between irreversible cell damage and functional changes.

The investigator should recognize that higher concentrations or longer times of exposure may be needed for expression of some endpoints than others (e.g., loss of cell viability versus alteration of cell growth), that some toxicants may require metabolic activation before they are cytotoxic, and that it is difficult to compromise metabolic function without causing subsequent loss of viability. In fact, any of the protocols provided could be used as indicators of irreversible cell damage. Some of the protocols, however, especially those that indicate cell growth, can be used at concentrations of toxicants that are low enough for recovery to occur if the toxicant is removed.

Cytotoxicity assays can be used with cells of various tissue origin; however, the sensitivity to toxicant-induced cytotoxicity may vary with the cell type used for testing. Such differences could provide the basis for studies that determine tissue-specific sensitivities to toxicants. For example, if cells that originate in the nervous system are more sensitive than cells of other tissue origin (e.g., hepatic, kidney), it may be possible to suggest that the toxicant in question could target the nervous system. However, certain cell types used for cytotoxicity determinations (e.g., those of neoplastic origin, regardless of tissue origin) may be very hardy, and concentrations required for cytotoxic effects may or may not be physiologically relevant.

The investigator may choose an assay method based on endpoint (e.g., viability, metabolic effects), sensitivity, ease of manipulation for multiple incubates, time needed, and availability of equipment. Indications are that all procedures presented in detail in this unit, if used with sufficiently high concentrations of toxicants, may be reasonably expected to detect comparable cytotoxicity (irreversible cell damage), without indication of toxicant-specific mechanistic effects on cell function. Therefore, choice of protocol would be determined by the other factors listed above, rather than by effectiveness at detecting cytotoxicity alone. For example, if large numbers of tests are to be done, the colorimetric assays with the vital dyes neutral red, MTT, and alamar blue may be the

test systems of choice because these procedures can all be done in 96-well microtiter plates. If the investigator wishes to observe toxicant effects on the same cells over a period of time, the alamar blue procedure may be chosen. This is because, among the vital dyes, only alamar blue forms a water-soluble product; with neutral red and MTT the assay needs to be terminated to extract the colored product formed by cellular metabolic processes. Some assays can be used at lower and higher toxicant concentrations, respectively, to determine cell proliferation as well as cytotoxicity (e.g., alamar blue, MTT, propidium iodide, [^{3}H]thymidine incorporation), with the latter radiometric assay, although more complex, more sensitive than simple addition of alamar blue for this particular endpoint. The fastest and simplest method for cytotoxicity, trypan blue uptake, is too laborious for precision if large numbers of samples are to be examined for cytotoxicity. Some cytotoxicity assays are available in kit form, decreasing their technical complexity (e.g., LDH; fluorescent assays that measure attachment of markers to nucleic acids in dead cells or indicate membrane permeability; alamar blue; stress gene assays). The availability of kits as well as the detailed technical information included with such kits may make them the protocols of choice in certain situations.

For investigators initiating studies on the cytotoxic effects of toxicants, testing is best done in the cells of tissue origin relevant to the investigation. In other words, cytotoxicity testing for neurotoxicants should be done in cells of nervous system origin; cytotoxicity testing for hepatotoxicants is best done in cells of hepatic origin. Comparisons, however, should be made between sensitivities in cells of various origin if the toxicant is to be identified by its effects on a specific organ or system (e.g., a neurotoxicant or a hepatotoxicant). Dose- and time-response investigations should be included. Dose- and time-related endpoint determinations specific for the tissue in question or for the toxicant target, if known, are useful to determine if changes occur at concentrations lower than those that cause general cytotoxicity. Examples of specific endpoints are the toxicant-induced inhibition of enzymes responsible for neurotransmitter degradation in neuronal cells, toxicant-induced changes in the quantity of a protein marker for astrocytes, loss of intercellular adhesion in cells with barrier function, and alteration of extracellular markers in lymphocytes. In the absence of an endpoint that indicates a specific cellular function, comparisons of dose- and time-related changes in cell growth and proliferation assays for cytotoxicity may be made with dose- and time-related changes in viability.

Assays for cell viability

The trypan blue procedure (Basic Protocol 1) is commonly used because it not only provides indication of how many cells are alive, but also how many live cells are being used for any subsequent experiment. This quantitative test is very simple and results can be rapidly obtained. The technique requires no specific training or specialized equipment.

Measurement of LDH activity (Basic Protocol 2 and Alternate Protocols 1 to 4) is another indicator of cell viability. The enzyme activity is measured external to the cells, as it leaks from dead cells. LDH activity can be measured in the ultraviolet range (340 nm), based on the loss of NADH due to its oxidation to NAD^+ as pyruvate is converted to lactate. If a colorimetric assay is preferred, a colored phenylhydrazone produced when 2,4-dinitrophenylhydrazine is incubated with the remaining pyruvate can be measured.

LDH release can also be measured as NAD^+ is reduced when lactate is converted to pyruvate. The resultant production of NADH then reduces FAD coupled to diaphorase with subsequent transfer of $FADH_2$ electrons to the tetrazolium dye INT (2-*p*-iodophenyl-3-nitrophenyl tetrazolium chloride).

Neutral red (Basic Protocol 3 and Alternate Protocol 5) is a third assay for cell viability. Neutral red is a weakly cationic dye that is bound to anionic sites on intracytoplasmic vacuoles and granules. It accumulates in lysosomes and other intracellular vacuoles of living cells. Ability to retain this dye is lost when cell die. Neutral red needs to be extracted from the cells; to do so requires that cells be lysed. This procedure, therefore, cannot be used like trypan blue exclusion to quantitate the number of live cells taking up the dye.

Propidium iodide retention (Basic Protocol 4) is another method for determining loss of cell viability. This fluorescent dye passes through compromised cellular membranes and then intercalates between base pairs in double-stranded nucleic acids. This agent has different signals when free or bound in cells, with emission at >600 nm detecting the bound species that is formed once it passes through the compromised membranes of dead cells. Experiments by Nieminen et al. (1992) indicated that results of assays using propidium iodide for

determining cell viability correlated with the results obtained by measuring lactate dehydrogenase (LDH) release.

Assays for cell growth

The number of cells in a growing culture (Basic Protocol 5) can be decreased by exposure to toxicants. This may or may not be due to loss of viability of a certain portion of the cells. Cell numbers can be indicated directly, by counting the cells, or indirectly, by measuring protein levels, and comparing results to cultures that have not been treated with the toxicant.

Proliferating cells incorporate [^{3}H]thymidine (Basic Protocol 6) into nucleic acids, competing with unlabeled thymidine. If the toxicant inhibits cell proliferation, with or without affecting cell viability, the incorporated radioactivity will be decreased.

Like cell counting or [^{3}H]thymidine incorporation, cell cycle analysis (Basic Protocol 7) is another means for determining the effects of toxicants on cell growth and differentiation. Alterations may or may not be due to effects on cell viability. Cell cycle analysis using propidium iodide is based on the fact that DNA content is not the same during different phases of the cell cycle. It is normally diploid in G1. When cells start to synthesize new DNA in the S phase, DNA content will be greater than diploid. After DNA synthesis is completed and the cell enters the G2 phase, it has a tetraploid DNA content. During mitotic division (M phase), the DNA content comes back to normal (diploid). If the DNA is stained with a DNA-specific dye, such as propidium iodide, and the DNA content per cell is estimated by flow cytometry, the G1/S/G2 ratio can be evaluated and compared between untreated and toxicant-treated cells.

Assays for metabolic capability

Still other protocols have been included because they are reputed to indicate cytotoxicity because they measure change in the metabolic functioning of the cell. Cell functions can be compromised by toxicants, and this compromise could result in loss of viability. The MTT colorimetric assay (Basic Protocol 8) determines the ability of viable cells to convert the soluble tetrasodium salt MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] to an insoluble formazan precipitate. The salts initially formed can be reduced within the cell to blue-colored formazan crystals that can be visualized on a spectrophotometer. The assay is best performed on cells that have active mitochondria. It, therefore, can be used as an indication of cellular proliferation, and it is far easier to perform than [^{3}H]thymidine incorporation.

Estimation of cytotoxicity using the alamar blue technique (Basic Protocol 9) involves incorporation of an oxidation-reduction (redox) indicator that both fluoresces and changes color in response to the reduction that occurs in medium as the cells grow. Reduction occurs in the presence of $FMNH_2$, $FADH_2$, NADH, NADHPH, and cytochromes. The reduction of the dye requires that it be taken up by the cells and participate in cellular respiratory processes. The water-soluble dye is nontoxic, and growing cells, which provide a reducing environment, cause the indicator to change from a non-fluorescent to a fluorescent product.

Compromised membranes affect metabolic functioning of cells and may be used to indicate cytotoxic effects of toxicants. Membrane damage may lead to cell death. Fluorescent dye loss (Basic Protocol 10) indicates that membrane leakage is occurring. These assays make use of the fact that cells in culture contain nonspecific esterases. The basic protocol provided is based on the principle that CFDA-AM, which is able to cross cell membranes, will be hydrolyzed by intracellular esterases to CFDA, which does not cross the membrane. The CFDA will remain within the cells and fluoresce, unless membrane integrity is impaired and it leaks out. Similarly, loss of [^{3}H]2-deoxy-D-glucose from cells (Alternate Protocol 7) is also an indication of loss of membrane integrity.

Critical Parameters and Troubleshooting

These protocols alone may not provide all the information needed to obtain optimal results when in vitro methods for cytotoxicity are used. Additional details are, therefore, provided for each of the protocols in the paragraphs that follow.

When using typan dye exclusion (Basic Protocol 1) to estimate viable cell concentrations, it is important that the cell suspension be homogenous or erroneous results will be obtained as the relatively small volume counted is multiplied by the total volume of cells available. Even in the small volume of cells used for this procedure, a relatively large number of cells must be counted (>100), and some means for recording differential counts is needed, such as using a double-scale hand counter for live and dead cells or a hand counter for live cells and

pencil marks for dead cells. A decision needs to be made before starting as to how to count cells that fall on lines (i.e., count cells touching the lines at the top and left of any square but omit cells touching the lines on the bottom and right sides of the square).

Cell suspensions on which trypan blue exclusion is to be measured should be placed on the hemocytometer so they are not too concentrated or counting will be difficult. If it appears that >10% of the cells are clustered, the suspension should be redispersed by vigorous pipetting and the suspension recounted.

For trypan blue exclusion determinations, it is important not to let the cell suspension stand with the dye too long, as viable cells may then begin to take up the trypan blue. Also, trypan blue has a greater affinity for serum protein than for cellular protein; therefore, counting cells suspended in PBS is preferred to counting cells in serum-containing media.

The trypan blue uptake and cell counting procedure can be tedious if a large number of cell suspensions need to be counted. Furthermore, the hemocytometer needs to be clean and dry before counting is done. A hemocytometer that is not dry will dilute the sample and underestimate cell counts. Washing with 70% ethanol can decrease the time needed for cleaning and drying; remaining ethanol could, however, lead to underestimation of viability.

When LDH leakage (Basic Protocol 2) is used to indicate loss of cell viability, a number of cautions need to be observed in order to obtain good, reproducible results. For kinetic and endpoint assays, the negative control should produce <5% of the change in absorbance of the positive control. In addition, the positive control needs to provide a sufficiently high change in absorbance that meaningful results can be obtained. Furthermore, the reaction should be conducted under constant temperature conditions to decrease interassay variability. Since results are based on differences between control and experimental incubates, cell concentrations need to be similar. Preliminary experiments with untreated cells are useful for optimization of conditions for a particular cell type that is to be used for subsequent experiments.

Among the problems which could be encountered with the LDH assay is the possibility of a high background reading, which may be noted when LDH is present in serum-containing medium. If this occurs, decreasing the serum content of the cell culture medium to 5% (provided it does not affect cell viability) may be a reasonable alternative. Another alternative would be to grow the cells in a different type of serum and/or different medium.

Care must be taken with cell cultures, because high spontaneous release of LDH can occur in the case of suboptimal cell culture conditions (e.g., when cell density is too high or when cell damage occurs during transfer of cells or addition of medium).

Low overall absorbance values may occur during LDH determinations, especially during colorimetric assays, if substrates are degraded by light.

Neutral red uptake (Basic Protocol 3 and Alternate Protocol 5) is a technically simple method for determination of cell viability but use of this assay still requires caution. For example, neutral red solution can form crystals, especially when prepared in phosphate buffers; such crystals are unlikely to form if the solution is prepared in distilled water whether the solution is stored at 4°C or at room temperature.

If the neutral red assay is done in wells in which cells were incubated with toxicant, care must be taken when removing the medium from cells in the microtiter wells before addition of the neutral red solution. If adhering cells die, they may become less attached than control cells. Color would then be less intensive and more related to cell number than to cytotoxicity, which would be underestimated.

Plates used for the neutral red assay may be processed twelve wells at a time to ensure uniformity of adhesion.

If the cell number in incubates with toxicant is too high or if the toxicant decreases cell numbers, the cells should be replated before the neutral red assay is run.

Propidium iodide binding (Basic Protocol 4) to the DNA of dead cells is another indicator of cytotoxicity. For proper use of this protocol, optimal conditions for a particular fluorescence scanner should be determined by preliminary experiments in which both propidium iodide concentration and cell number per well are varied. Concentrations of propidium iodide >50 μM in microtiter wells are unlikely to further increase fluorescence.

The propidium iodide assay is more reproducible with cells that strongly adhere to plastic than with cells that stay in suspension.

Propidium iodide is a light-sensitive, hygroscopic powder, red to dark red in appearance. If properly stored (dry at 0° to 4°C), it will remain stable for ≥4 years. Propidium iodide dissolves readily in water at 1 mg/ml; a higher concentration (10 mg/ml) requires heating and

may contain some insolubles. Either water or PBS can be used for solubilizing propidium iodide. Solutions are stable for up to 2 years if stored at 0° to 4°C in the dark with 0.1% (w/v) sodium azide as preservative. Propidium iodide is toxic and possibly carcinogenic, so protective clothing should be worn when handling this chemical.

When cell counts (Basic Protocol 5) are used to indicate cytotoxicity, cultures that are to be used as control and cultures that are to be exposed to the toxicant need to be identical before the experiment begins. When cell number or quantity of cell protein is used as an endpoint, the culture needs to be one that continuously divides and multiplies over time. Inhibition of growth should follow a concentration response.

Because changes in cell counts or cell protein may take several days, the toxicant needs to be water soluble, relatively stable, and nonvolatile in order to remain in contact with the cells. Toxicants that need metabolic activation may not cause a response.

Cell proliferation using [^{3}H]thymidine (Basic Protocol 6) requires use of radiolabeled compounds and use of such compounds requires special precautions.

Careful pipetting of the [^{3}H]thymidine solution is needed so wells do not become contaminated. Variability increases if pipetting is not precise and if contamination occurs. Large volumes of diluted [^{3}H]thymidine should not be prepared; prepare what is needed for the experiment only.

Medium removed from the plates after the incubation with [^{3}H]thymidine is radioactive. A closed collection system that is properly labeled reduces risk.

[^{3}H]thymidine assays that use trichloroacetic acid (TCA) need to be done with extreme care because TCA is very caustic.

For cell cycle analysis (Basic Protocol 6), cell membranes need to be permeable to allow the propidium iodide to enter. This can be done by treating the cells with azide buffer or by using ethanol. The propidium iodide needs to enter and stain the DNA in all cells. Other information about propidium iodide is in the paragraphs describing Basic Protocol 4.

The propidium iodide used for cell cycle analysis binds to double-stranded nucleic acids through intercalation between base pairs, with no preference for purine or pyrimidine base pairs. It does not bind to single-stranded nucleic acids. Propidium iodide also stains double-stranded RNA and, thus, can give a wrong estimation of DNA content and placement of cells in the cell cycle. Therefore, ribonuclease treatment is critical for the staining. (The RNAase is a part of Vindelov's solution; however, further incubation of cells with 1 mg/ml ribonuclease for 5 min at room temperature may be useful in some situations. Use DNAase-free ribonuclease, or DNA damage will occur and that will interfere with the assay.)

The use of standard azide buffer is recommended for assays of phenotypic markers where there is a possibility of capping surface receptors when doing cell cycle studies. Azide prevents capping and allows an assay to be performed at room temperature (or higher, if necessary). Azide is also a microbial inhibitor.

Obtaining quality histograms from the flow cytometer during cell cycle analysis may be difficult. Each cell type may need a slightly different treatment, but saturating concentrations of propidium iodide always need to be used to be sure that all cells are stained.

The MTT assay (Basic Protocol 8), although relatively simple from a technical aspect, may differ for different cells, as each has different metabolic capability. Therefore, preliminary experiments are needed to establish the optimal cell number for each well, the duration of the experiment, the time of MTT incubation necessary in order to provide a final absorbance that can easily be measured, and conditions to provide control values sufficiently high that loss of mitochondrial function in toxicant-treated cells can be measured. (Number of cells seeded per well, for example, should be sufficient to maximize the number of cell doublings that occur over a toxicant treatment period of 2 to 5 days.) Once established, these parameters need to be kept constant over the experiments in which data are to be collected and compared.

The metabolic state of the cells will affect the outcome of MTT assays; the cells should be kept as uniform as possible. Variability among wells on a single plate can occur.

If volumes of medium differ among the wells (e.g., by >10%) during the MTT assay, absorbances will also differ. Evaporation needs to be controlled to avoid this potential cause of variability. Old medium can decrease the efficiency of the assay, causing underestimation of the metabolic capability of control cells. Absorbance can also be affected by the concentration of D-glucose in the culture medium. It can be expected to be unaffected by pH or phenol red concentrations <10 mg/ml.

Some test substances may increase mitochondrial activity; this could be a cytotoxic

effect, but would not be indicated by the lower absorbances usually expected when MTT is used to indicate cytotoxicity.

MTT does not deteriorate if kept in a light-proof container at 4°C for several weeks.

The formazan product formed from MTT needs to be completely solubilized before reading absorbance.

As with the MTT assay, optimal conditions for the alamar blue assay (Basic Protocol 9) may vary with cell line, cell density, and incubation time. Preliminary experiments are necessary to establish a cell density at a particular incubation time that provides a linear response of alamar blue reduction correlating with the cell density. Preliminary experiments should also be done to determine the incubation time that provides maximal conversion of dye added to control cells from the oxidized (blue) form to the fully reduced (red) form of the dye. Although concentration-response curves may be obtained as early as 1 hr after alamar blue is added, longer incubations are preferred to increase absorbance or fluorescent signals.

High cell numbers or extended incubation times (>24 hr) can cause loss of linearity in production of the reduced (red form) of the alamar blue dye; absorbance may not only loose its linearity, but may actually decline under these conditions. Microbes that may contaminate cultures will also reduce alamar blue.

Bovine serum concentrations up to 10% (w/v) do not interfere with the alamar blue assay, nor does the presence of phenol red in the growth medium. Phenol red, however, may increase background absorbance by as much as 0.3 optical density units. Alamar blue itself is not cytotoxic at concentrations as high as 25% with exposures for up to 20 hr.

Fluorescent dye loss (Basic Protocol 10) can also be used as an indicator of cytotoxicity. As the membrane-permeable fluorescent dye is an ester, it needs to be kept dry to avoid spontaneous hydrolysis.

[^{3}H]-2-deoxy-D-glucose retention (Alternate Protocol 7) has been used as a means for determining cell integrity. However, because the compound is radioactive, special precautions are required; thus many laboratories now prefer to use the fluorescent dyes.

Anticipated Results

In vitro methods for cytotoxicity use a variety of endpoints. For example, assessment of viability using trypan blue exclusion (Basic Protocol 1) is done by direct observation. Cell are counted by viewing them through a microscope. Live cells exclude trypan blue; dead cells do not. Control cells should be >85% viable (>85 of 100 cells counted not taking up the dye). Provided cell suspensions are homogenous and the procedure is carried out appropriately, repetitive counting of the same suspension should provide counts that do not vary by more than 20%.

LDH leakage (Basic Protocol 2 and Alternate Protocols 1 to 4) is detected spectrophotometrically. Untreated cells should retain LDH and have minimal loss over the time the assay is run; the greatest loss should be with the positive control, the Triton-X-100-treated cells. An example of results from a study that used LDH leakage is provided in Figure 2.6.1 (Song et al., 1997). In this study, LDH leakage was used as an indicator of the cytotoxic effects of MPTP (1-methyl-4-phenyl-1,2,4,6-tetrahydropyridine), an agent that induces a Parkinsonian-like syndrome in primates, and its metabolite MPP^+. With cultured cells, reproducibility among positive controls and reproducibility within negative controls should be within 20%.

The neutral red assay (Basic Protocol 3 and Alternate Protocol 5) is another spectrophotometric assay for viability. When this protocol is used, absorbance is higher when there are more live cells in a well, so values in control wells of dividing cells depend on time of incubation. The product extracted from the cells is a reddish color. As an approximate estimate, absorbances of 0.2 to 0.4 could be expected in wells containing 10^5 cells/ml. This would be ~3 µg/ml neutral red. The limit of sensitivity is estimated to be ~1000 cells/well; changes in dye retention with 2000 cells in a well have been reproducibly detected (± 20%).

With binding of propidium iodide to DNA (Basic Protocol 4), fluorescence is used as an indicator of cytotoxicity. In this protocol for cytotoxicity, untreated cells should show little fluorescence, as the dye is excluded from normal cells. The positive control cells, treated with digitonin, should show the maximal fluorescence. Propidium iodide absorbs blue-green light and fluoresces red. Reproducibility should be within ± 20%.

Cytotoxicity can also be indicated by fewer cell numbers (Basic Protocol 5) or less protein in cultures exposed to the toxicant. The decrease seen on exposure to the toxicant should follow a concentration response, with at least three points on a concentration-response curve that are significantly different from the cell number or protein in the control incubate.

Another means for detecting cytotoxicity by reduction in cell growth or proliferations is by the uptake of [^{3}H]thymidine (Basic Protocol 6). Radioactivity is dependent on the number of cells in an incubate (Fig. 2.6.2; Ahmed et al., 1994). If cytotoxicity occurs, [^{3}H]thymidine uptake should be less in treated cells than in control cells. This assay is quite sensitive, and, by increasing the time of liquid scintillation counting, discrimination among incubates can be made even if [^{3}H]thymidine incorporation is low.

Flow cytometry is used when cell cycle analysis (Basic Protocol 7) provides indication of cytotoxicity. Histograms obtained by flow cytometry allow estimation of the percentage of cells in different phases of the cell cycle. If the toxicant interferes with DNA synthesis, the

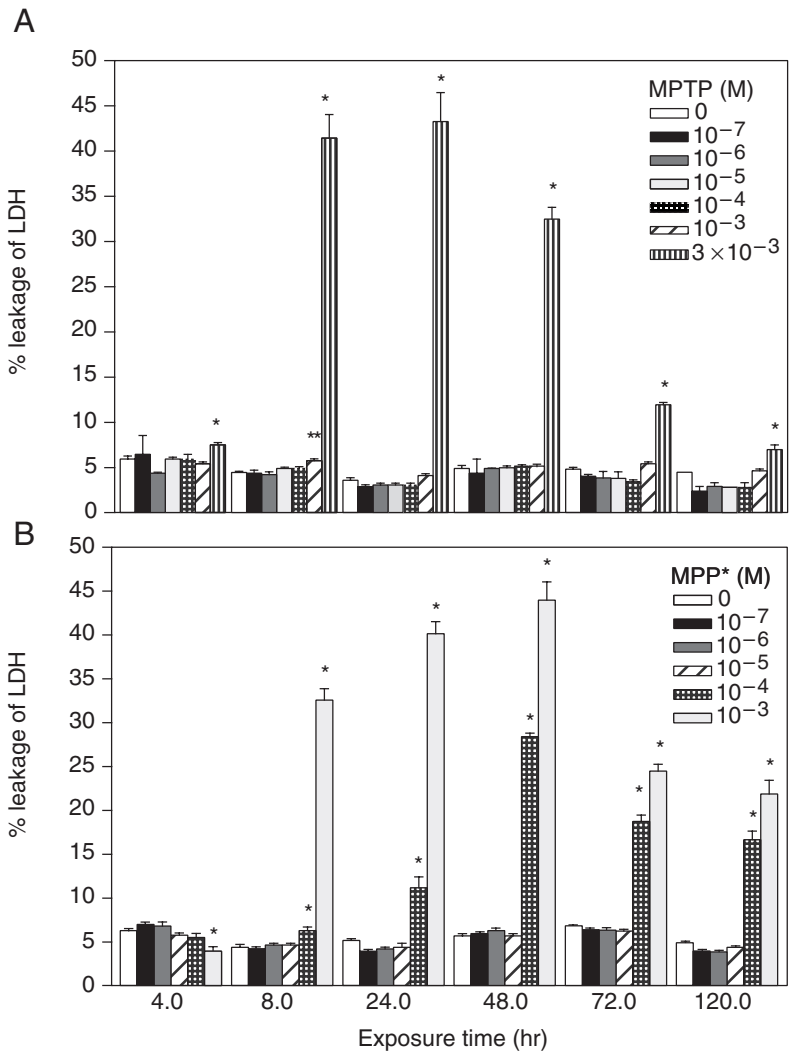

Figure 2.6.1 Effects of (**A**) MPTP and (**B**) MPP on the LDH leakage in SH-SY5Y human neuroblastoma cells. After treatment (10^{-7} to 3×10^{-3} M) for 4, 8, 24, 48, 72, 120 hr. Percent LDH leakage was determined by comparing to cells treated with Triton X-100 (100%). At the assay conditions, the LDH activity that leaked from Triton X-100-treated cells was 198.69 ± 12.81 mOK/min; the leakage of LDH from untreated cells was 4.36 ± 0.51% of the Triton X-100 treated cells. Results were averages of at least 3 individual experiments (mean ± SE). The results for MPP-treated cells are significantly different from the control ($p < 0.05$). Reprinted, with permission, from Song et al. (1997). Intox Press. (See discussion of reference for an explanation of the decrease in release of LDH after 48 hr.) Abbreviations: MPP, 1-methyl-4-phenyl-pyridine; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

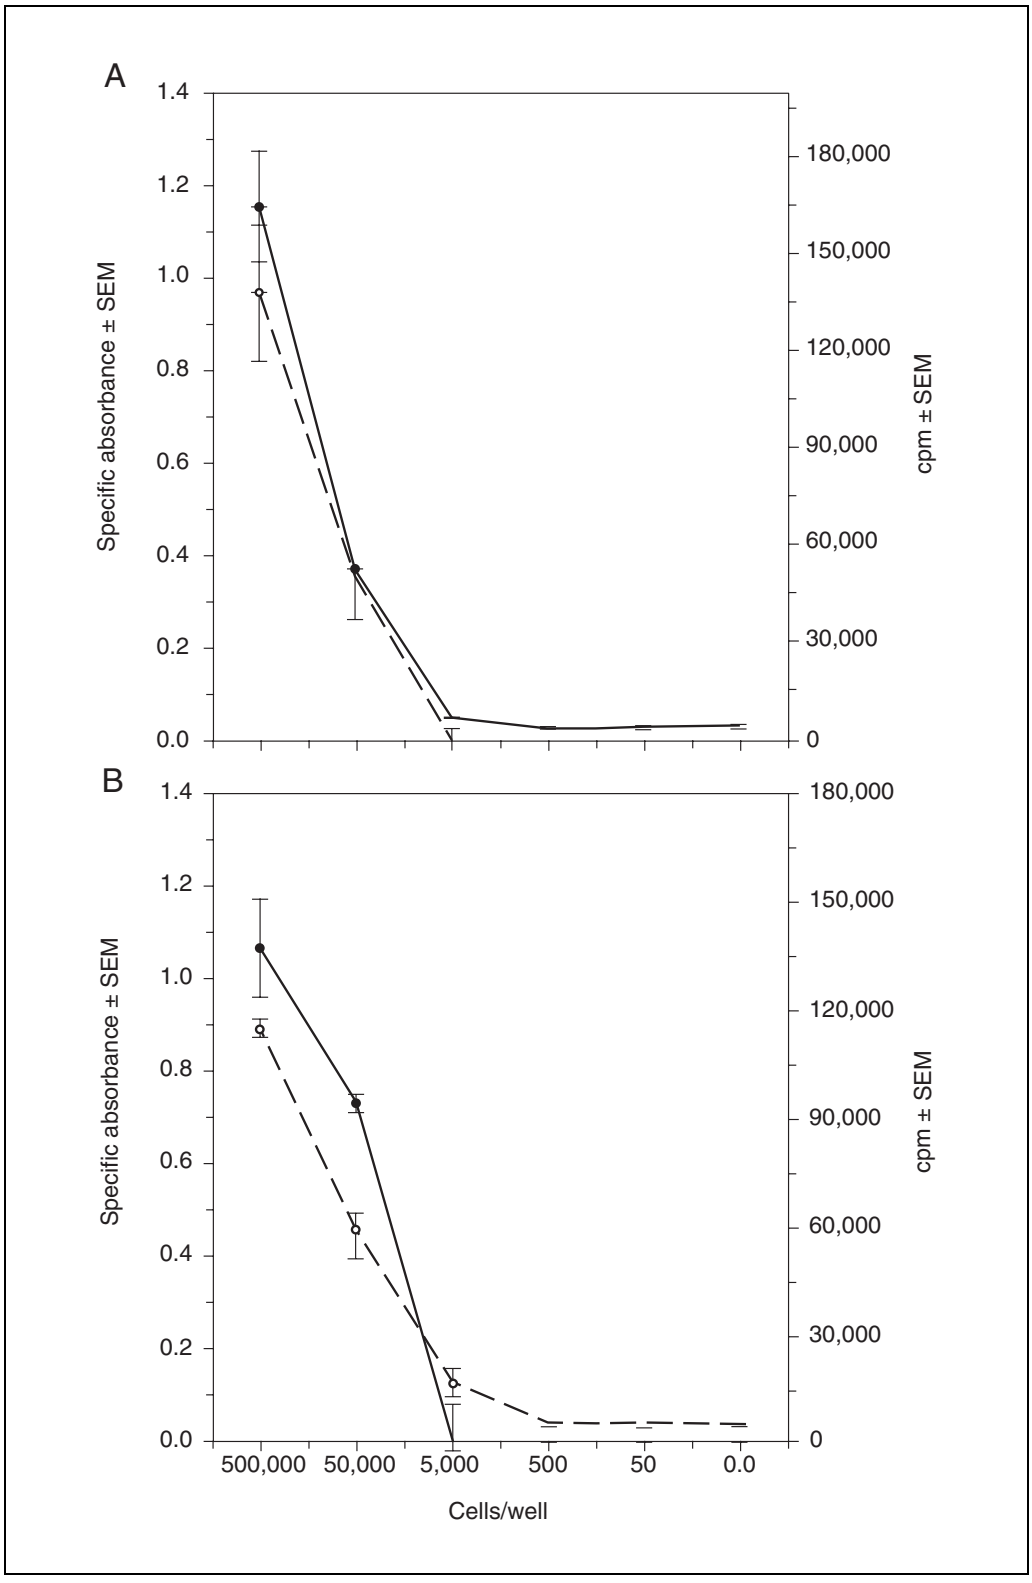

Figure 2.6.2 The spontaneous proliferation of YCD3-1 cells at indicated cell numbers per well was determined by Alamar blue (solid line) and [^{3}H]thymidine (interrupted line) assays. Alamar Blue and [^{3}H]thymidine were added 3 hr after the culture set up and proliferation determined at 24 (**A**) and 48 hr (**B**) post culture. The specific absorbance was determined by subtracting A_{600} from A_{570}. [^{3}H]thymidine incorporation data are presented as mean cpm. Reprinted, with permission, from Ahmed et al. (1994). Elsevier Science B.V.

[a]Data from Rowles et al., 1995.

[b]Abbreviations: MPP, 1-methyl-4-phenylpyridine; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

[c]Results presented as percentage of control activity, mean (SEM) of 3 to 5 replicate assays (with wells done in triplicate in each assay).

[d]Differences from control ($p < 0.05$). Values in untreated cells for retention of CFDA (indicator of membrane integrity) measured as fluorescence units = 1221 ± 115 for 1 to 2×10^{-4} cells/well (sensitivity 2 on Cytofluor fluorescence plate reader). Viability (measured with propidium iodide, verified with trypan blue) over all assays = 97% ± 1. Viability determined by binding of propidium iodide to nuclei of nonviable cells based on comparison with positive control (digitonin). Reprinted, with permission, from Rowles et al., 1995; Mary Ann Liebert, Inc., Publishers.

majority of the cells will be in the G1 phase, and a very low percentage will be in the S and G2 phases.

Metabolic capability of cells may be compromised when they are exposed to toxic substances. One method for detecting the effects of toxicants on the metabolism of cells uses MTT, which cells with intact mitochondria convert to a formazan dye which can be detected spectrophotometrically. The MTT assay (Basic Protocol 8) is rapid, versatile, quantitative, and highly reproducible, with a low intratest variation (± 15% standard deviation). Results are expressed as a percentage of control absorbance, and cell numbers per well are not quantified. Although an indicator of a cytotoxic effect on mitochondrial function, the test cannot distinguish between cells with reduced effects and those that are dead.

The alamar blue reaction (Basic Protocol 9) is a spectrophotometric or fluorescent assay that depends on the number of cells in the incubate (Fig. 2.6.2; Ahmed et al., 1994). Cytotoxicity causes cells to decrease metabolic functioning and stop growing. This will lessen the reduced environment usually present when cells are growing, and decrease the amount of fluorescent product produced. Results are comparable with other assays using vital dyes (e.g., MTT), and reproducibility should be ± 20%.

Decreased membrane integrity is indicated by fluorescent dye loss (Basic Protocol 10) in the wells of the microtiter plate that contain test compound and cells. Membrane changes can occur at time points earlier or at concentrations lower than needed for loss of cell viability, as can seen in a study with MPTP and MPP^+ (Table 2.6.1; Rowles et al., 1995). For a fluorescent dye assay, reproducibility should be ± 20%. An assay which indicates viability (e.g., propidium iodide binding, Basic Protocol 4) may be done at the same time as assays which indicate membrane compromise (Table 2.6.1; Rowles et al., 1995).

Time Considerations

The trypan blue assay (Basic Protocol 1) is probably the easiest of all protocols included

in this chapter. A cell count and viability calculation can be done in <5 min per sample.

More time is needed when LDH leakage (Basic Protocol 2 and Alternate Protocols 1 to 4) is used to indicate loss of cell viability. For this procedure, a microtiter plate which contains 96 wells would provide triplicate wells for over 20 samples and the positive and negative controls. Pipetting would take ~10 min; the plate may be stabilized by delaying the first reading of a kinetic assay for up to 7 min after initiation of the reaction. The reaction may run as long as an hour. With a microtiter plate reader, all wells can be read simultaneously; some microtiter plate readers can be programmed to do the appropriate calculations. Total time per plate would be expected to be ~2 hr.

Cell in microtiter plates previously incubated with toxicants could be processed for neutral red retention (Basic Protocol 3 and Alternate Protocol 5) in ~2.5 hr. The longest times are those needed for incubating with the dye (90 min) and the time needed for dye extraction (20 min). Over 20 samples, and positive and negative controls, could be run in triplicate on a single plate. The process can be interrupted at the air-drying step, with plates stored for several days before addition of the neutral red solution.

Propidium iodide binding to DNA of dead cells (Basic Protocol 4) can also be used to indicate toxicant effects on cell viability. For each plate processed after incubation of cells and toxicant, ~1 hr is needed.

When counting cells (Basic Protocol 5) to compare cell growth between control and toxicant-treated cells, the time at which the counting is done is dependent on the growth rate of untreated cells. Doubling time may vary from several hours to several days. The procedure itself takes little time (see Basic Protocol 1), but the time needed to determine if cytotoxic effects are occurring may take days.

After incubation for predesignated times with toxicant, [^{3}H]thymidine incorporation (Basic Protocol 6) may take from 0.25 to 24 hr. Preparation of cells for scintillation counting may take 1 to 3 hr, and scintillation counting will take additional hours.

Flow cytometric analysis for cell cycle determinations (Basic Protocol 7) may be relatively rapid (<1 hr), but time is needed for preparation and interpretation of the graphs provided. The staining procedure needed before the flow cytometry can be expected to take ~30 min. Longer incubations of cells with propidium iodide can improve results but will increase the time needed to do this assay. Incubations of cell suspensions with propidium iodide stain (at 4°C) may be overnight or even longer. To determine cytotoxicity, incubations with the toxicant may require hours to days before the staining and flow cytometry are done.

After incubation with toxicant, 4 to 6 hr are required for MTT incorporation (Basic Protocol 8). An additional hour may be required for MTT removal, dye extraction, crystal solubilization, and reading on the microtiter plate.

After incubation with toxicant, the time of the alamar blue assay (Basic Protocol 9) depends on the optimal time for incubation of dye with cells (determined by preliminary experiments). This can range from 1 to 24 hr.

Using loss of fluorescent dye (Basic Protocol 10) to determine toxicant-induced compromise of membrane integrity is a relatively straight-forward, simple procedure. After incubation of cells and toxicant ~1 hr should be sufficient to do this assay.

In Situ Hybridization Histochemistry

This unit describes in situ hybridization for analyzing specific cellular mRNA in frozen and cryostat-sectioned tissue. The localization and levels of different mRNA in the tissue of interest can be detected by using radioactive (see Basic Protocol) or nonradioactive (see Alternate Protocol) oligonucleotide probes. Support Protocols 1 and 2 describe how to prepare radioactive and nonradioactive probes. Support Protocol 3 describes the procedure for cryostat sectioning of frozen specimens.

IN SITU HYBRIDIZATION WITH RADIOACTIVE PROBES

BASIC PROTOCOL

Cryostat-sectioned, paraformaldehyde-fixed, dehydrated tissue specimens (see Support Protocol 3) are hybridized to [^{35}S]dATP-labeled oligonucleotide probes overnight, then washed, dehydrated, and exposed to X-ray film or dipped into photographic emulsion for visualization of radioactive signal. The Alternate Protocol describes hybridization with nonradioactive probes.

Materials

Hybridization buffer (see recipe)
10 mg/ml salmon testes DNA
1000 Ci/mmol [^{35}S]dATP-radiolabeled probe (see Support Protocol 1)
5 M DTT (see recipe)
Glass slide with fixed and dehydrated specimen of interest (see Support Protocol 3)
1× SSC (see recipe), 55°C
70%, 80%, 95%,and 100% ethanol
D19 X-ray film developer (Kodak)
X-ray film fixer (Kodak or equivalent)
K5 photoemulsion (Ilford)
AGFA G333 fix
Cresyl violet stock solution: 5 g cresyl violet in 1 liter H_2O
10% (v/v) acetic acid
Xylene
Mounting medium (DPX, Permount, or Petrex)

1.5-ml microcentrifuge tubes, sterile
Humidified chamber: box with tight lid and wet filter paper placed to prevent contact with slides
42°C incubator
40°C and 55°C water bath
Staining dish and slide racks
Autoradiographic ^{14}C microscale (Amersham)
Hyperfilm β-max X-ray film (Amersham)
Slide box
Black electrician's tape

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety offices (also see *APPENDIX 1A*).

Current Protocols in Toxicology (2000) 2.7.1-2.7.13

Prepare hybridization mix

1. Add the following to a sterile 1.5-ml microcentrifuge tube:

   900 µl hybridization buffer
   50 µl 10 mg/ml salmon testes DNA (final concentration 500 µg/ml)
   [^{35}S]dATP-radiolabeled probe to (1×10^7cpm/ml final) 40 µl 5 M DTT

   Adjust volume to 1 ml with hybridization buffer.

   The amount of hybridization mix should be scaled to accommodate the number of slides to be hybridized. The 1 ml of hybridization mix prepared here is for four slides.

Apply hybridization mix to sections

2. Place the glass slide with the fixed and dehydrated specimen of interest in the humidified chamber with sections upward.
3. Apply ~250 µl of hybridization mix per slide evenly distributing it over the sections. Be sure not to touch the sections with the pipet tip.
4. Cut Parafilm into pieces of size appropriate to cover the area of the slide containing the fixed specimen.
5. Place the piece of Parafilm on the slide and spread hybridization mix evenly over the sections without causing bubbles. Start on one side and gently smooth bubbles out the other.
6. Put the lid on the humidified chamber, seal it with tape, and place into the 42°C incubator for 16 to 18 hr (i.e., overnight).

Wash the sections

7. Take slides out of the humidified chamber and remove Parafilm.
8. Rinse quickly in 1× SSC, 55°C, to remove hybridization mix.
9. Place slides in the slide rack of a staining dish filled with 1× SSC, 55°C, and place the dish in a 55°C water bath.
10. Change the 1× SSC, 55°C, three times, once every 15 min.
11. For the last wash, add 1× SSC, 55°C, remove the staining dish from the 55°C water bath, and allow the solution to cool to room temperature, (~1.5 hr).
12. Wash slides twice, each time for 2 min, in water at room temperature.

Dehydrate and dry sections

13. Dip slides successively in 70%, 80%, 95%,and 100% ethanol, for 2 min in each solution.
14. Air dry the slides at room temperature.

Visualize the signal

To visualize probe by film autoradiography

15a. Place slides and autoradiographic ^{14}C microscale in an X-ray film cassette and secure their positions with tape, being careful not to cover the specimens with tape.

16a. Place X-ray film over the slides in the darkroom (the rounded corner of the film should be placed in left up corner of the cassette), close the lid of the box tightly, and expose for 1 to 21 days at 4°C.

The exposure time depends on the abundance and expression level of the gene of interest.

17a. Prepare developer by dissolving 160 g of D19 developer in 1 liter water.

Development and fixation of the film should be performed in the dark or under safelight illumination, and the temperature of the solutions should be 20° ± 5°C.

18a. Place the film in a bath filled with developer for 4 min.

19a. Rinse film in water for 10 sec and place in X-ray film fixer for no longer than 10 min.

20a. Wash film in clean running water at 20° ± 5°C for ≥5 min and air dry.

To visualize probe by emulsion autoradiography

NOTE: Dipping and developing of slides should be performed in the dark or under safe light illumination.

15b. Put a vial containing 20 ml water in the 40°C water bath. Monitor the temperature with a thermometer. When the temperature of the water in the vial reaches 40°C add 20 ml K5 photoemulsion (40 ml final volume). Mix gently every 30 min for 2 hr, avoiding bubbles.

16b. One at a time, dip slides in the vial of emulsion. Take slides out quickly and gently. Holding vertically, check that the whole surface of the slide is equally covered by the emulsion. Place the slides vertically in the slide holder and air dry them in the dark for at least 4 hr (preferably overnight).

A tube holder can be used if a slide holder is not available.

17b. Put the slides into a slide box, seal the box with black tape, and place in a refrigerator for the necessary exposure time.

The time of exposure differs from probe to probe (from 1 to 8 weeks). For old slides (3 to 4 months), exposure time should be doubled.

18b. When exposure has been completed, prepare developer by dissolving 80 g of D19 developer in 1 liter water. Place slides in the slide rack of a staining dish filled with developer for 3 min.

19b. Rinse slides for 10 sec in water and fix 10 min in AGFA G333, diluted 1:5 with water.

20b. Rinse slides with water for 10 sec, then wash them in clean running water 15 to 20 min at 20° ± 5°C and air dry.

Counterstain slides with cresyl violet and cover slip

21. Add 1.5 ml of 10% (v/v) acetic acid to 250 ml cresyl violet stock solution and filter to get rid of crystals.

22. Place developed slides in slide rack and dip them as follows:

Three times in xylene for 5 min each
Three times in 100% ethanol for 2 min each
Two times in 95% ethanol for 2 min each
Once in 70% ethanol for 2 min
Once in H_2O for 5 min
Once in cresyl violet solution prepared in step 21, for 30 sec to a few minutes
Once H_2O for 2 min
Once in 70% ethanol for 2 min

Two times in 95% ethanol for 2 min each
Three times in 100% ethanol for 2 min each
Three times in xylene for 2 min each.

CAUTION: *Xylene is a toxic solvent and all steps of counter staining and coverslipping should be carried out in a fume hood or ventilated table.*

Optimal staining time in cresyl violet varies from tissue to tissue.

23. Take slides from the xylene one by one and cover slip them directly with mounting medium.

IMPORTANT NOTE: *Avoid introducing air bubbles.*

24. Remove extra mounting medium with filter paper, place the slides flat, and let dry ≥2 days in fume hood.

ALTERNATE PROTOCOL

IN SITU HYBRIDIZATION WITH NONRADIOACTIVE PROBES

In situ hybridization can be performed not only with probes labeled with radioactivity, but also by using nonradioactive probes that allow rapid detection of hybrids without using potentially hazardous radioisotopes. Cryostat-sectioned, paraformaldehyde-fixed, dehydrated tissue specimens (Support Protocol 3) are hybridized overnight to digoxigenin (DIG)-labeled oligonucleotide probes (Support Protocol 2), and washed; hybrids are detected using antibodies and color reactions.

Materials

DIG-labeled probe (Support Protocol 2)
Hybridization buffer (see recipe)
Glass slides with fixed and dehydrated specimen
1× SSC (see recipe), 48°C
Binding buffer (see recipe), prepare fresh
Anti-DIG-alkaline phosphatase–labeled antibody (Roche Molecular Biochemicals)
Normal sheep serum
Triton X-100
Wash buffer (see recipe), prepare fresh
Color solution (see recipe)
Stop buffer (see recipe), prepare fresh
Mounting medium, aqueous (Aquamount, BDH)

Humidified chamber: box with tight lid and wet filter paper placed to prevent contact with slides
Slide racks and staining dishes
48° and 55°C water baths

Prepare hybridization mix

1. Add 2 µl DIG-labeled probe to 1 ml hybridization buffer.Vortex and keep on ice until use.

The amount of hybridization mix (in this case probe plus hybridzation buffer) should be scaled to accommodate the number of slides which are to be hybridized (prepare 1 ml hybridization mix for 4 slides).

Apply hybridization mix to the sections

2. Place the glass slide with the fixed and dehydrated specimen of interest in the humidified chamber with sections upward.

3. Apply ~250 µl hybridization mix per slide evenly distributing it over the sections. Be sure not to touch the sections with the pipet tip.
4. Cut Parafilm into pieces of size appropriate to cover the area of the slide containing the fixed specimen.
5. Place the piece of Parafilm on the slide and equally spread hybridization mix over the sections without causing bubbles.
6. Put the lid on the humidified chamber, seal it with tape, and place in a 37°C incubator for 16 to 18 hr (i.e., overnight).

Wash slides

7. Take slides out of the humidified chamber and remove Parafilm.
8. Rinse slides quickly in 100 ml of 1× SSC, 48°C, one by one, to remove hybridization mix.
9. Place slides in the slide rack of a staining dish filled with preheated 1× SSC, 48°C, and place the dish in the 48°C water bath.
10. Change 1× SSC, 48°C, three times, once every 30 min.
11. For the last wash, add 1× SSC, 48°C. Remove the staining dish from the 48°C water bath and allow the solution to cool to room temperature (~1.5 hr).
12. Wash slides twice, each time for 5 min, in binding buffer at room temperature.
13. Prepare binding buffer containing 1:500 anti-DIG-alkaline phosphatase-labeled antibody, 1% (v/v) normal sheep serum, and 0.3% (v/v) Triton X-100. Add 300 to 400 µl of this solution to each slide.
14. Incubate slides 3 hr in a humidified chamber.
15. When incubation is completed, rinse slides briefly in binding buffer.
16. Wash slides three times, each time for 10 min, in binding buffer at room temperature.
17. Rinse briefly in wash buffer.
18. Wash for 5 min in wash buffer.

Stain slides

19. Apply 150 µl color solution and incubate in the dark for 12 to 24 hr at room temperature.
20. Stop the reaction by washing slides twice, each time for 5 min, in stop buffer.
21. Wash slides twice, each time for 5 min, in water at room temperature.
22. Air dry slides overnight.
23. Coverslip sections with aqueous mounting medium (Aquamount).

    Do not use xylene-based mounting solutions. This will form crystals of color precipitate.

24. Analyze by light microscopy.

SUPPORT PROTOCOL 1

3′ LABELING OLIGONUCLEOTIDE PROBES WITH [^{35}S]dATP

Oligonucleotide probes can be end labeled with either radioactive or nonradioactive labels. In this protocol, ^{35}S labeling of oligonucleotides is described, although labeling with other isotopes (^{3}H, ^{32}P, or ^{125}I), or (nonradioactively) with biotin, can also be performed. Nonradioactive labeling (with digoxigenin) is described in Support Protocol 2. Oligonucleotides can be labeled at the 5′ end using T4 polynucleotide kinase or at the 3′ end using terminal deoxynucletidyl transferase (TdT). 3′ end labeling of oligonucleotide probes with [^{35}S]dATP is described here.

Materials

10 U/µl terminal deoxyribonucleotidyl transferase (TdT; Amersham Pharmacia Biotech)
TdT reaction buffer (supplied with TdT enzyme; also see recipe)
DEPC-treated H_2O (see recipe)
10 mCi/ml [^{35}S]dATP (1000 Ci/mmol)
Oligonucleotide to be labeled, ~50-mer
Absolute methanol (HPLC grade)
0.1 M Tris·Cl, pH 8.0 (see recipe)
20% ethanol, ice-cold
Scintillation fluid
5 M DTT (see recipe)

1.5-ml microcentrifuge tubes, sterile
NENSORB column (DuPont NEN Research Products)
10-ml syringe
Scintillation vial

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety offices (also see *APPENDIX 1A*).

Label oligonucleotide probe

1. Place a sterile microcentrifuge tube on ice and add the following:

   2.5 µl TdT reaction buffer
   10.5 µl DEPC-treated H_2O
   7.5 µl 10 mCi/ml [^{35}S]dATP
   2 µl oligonucleotide (80 ng)
   2.5 µl TdT (25 U; keep in freezer and use a cooling block).

   Total volume should be 25 µl. If volume is less due to higher concentration of some solutions, adjust to 25 µl by adding DEPC-treated H_2O.

   Always add TdT last and never vortex.

2. Incubate tube in a 37°C water bath for 2 to 2.5 hr.

Purify labeled oligonucleotide

3. Pack the resin of a NENSORB column (one per reaction) by tapping until the column matrix is at the bottom.
4. Remove the cap and attach the column to a ring stand. Place a disposable tube under the column.

5. Add 3 ml of absolute methanol to the column directly and pass through the column with a 10-ml syringe attached to the column adapter.
6. Add 3 ml 0.1 M Tris·Cl, pH 8.0, and pass through the column with the syringe
7. Add 500 µl 0.1 M Tris·Cl, pH 8.0, to the labeled probe, mix by pipetting, and apply to the column.
8. Gently press syringe (to obtain a drop speed of 1 to 2 drops/sec) until solution has passed through the column.
9. Wash the column by forcing 1.5 ml of 0.1 M Tris·Cl, pH 8.0, through the syringe.
10. Elute the labeled oligonucleotide probe with 500 µl of 20% ice-cold ethanol, with a drop speed of 1 to 2 drops/sec.
11. Collect the first 12 to 13 drops in a sterile microcentrifuge tube.

Determine activity of probe

12. Vortex and add 2 µl from microcentrifuge tube to a small piece of filter paper and place in a scintillation vial. Add 10 ml scintillation fluid and measure radioactivity by liquid scintillation counting.

    A good probe should have at least 500,000 cpm/µl (1-2 × 10^6 cpm/ng).

13. Add 2 µl of 5 M DTT per 100 µl probe (final concentration of 10 mM) to the labeled, purified probe from step 11.
14. Store labeled, purified probe at −20°C.

3′ LABELING OF OLIGONUCLEOTIDE PROBES WITH DIGOXIGENIN

SUPPORT PROTOCOL 2

Oligonucleotide probes can be end-labeled with digoxigenin (or biotin) as an alternative to radioactive labeling techniques (Support Protocol 1). Nonradioactive in situ hybridization is much faster and safer and does not require special facilities to handle radioactive isotopes.

Materials

5× DIG labeling buffer (see recipe)
DEPC-treated H_2O (see recipe)
25 mM $CoCl_2$
1 mM DIG-dUTP (Roche Molecular Biochemicals)
Oligonucleotide
10 U/µl terminal deoxyribonucleotidyl transferase (TdT)
1.5-ml microcentrifuge tubes, sterile

1. Place a sterile microcentrifuge tube on the ice and add the following:

    5 µl 5×DIG labeling buffer
    7 µl DEPC-treated H_2O
    4 µl 25 mM $CoCl_2$
    1 µl 1 mM DIG-dUTP
    5 µl oligonucleotide (200 ng)
    3 µl TdT (30 U; keep in freezer and use a cooling block).

    Total volume should be 25 µl. If volume is 25 µl, due to a higher concentration of some solutions, bring volume to 25 µl by adding DEPC-treated water.

    Always add TdT last and never vortex.

2. Incubate tube in a 37°C water bath for 2 hr.

Use without further purification. Store at −20°C.

SUPPORT PROTOCOL 3

PREPARATION OF TISSUE

The main aim of tissue preparation is to preserve tissue morphology during in situ hybridization and at the same time create good conditions for the penetration of the probes.

Slides should be coated in order to prevent sections from falling off during different steps of hybridization and washing. Slides can be coated with either poly-L-lysine or chrome alum.

Materials

4% paraformaldehyde (see recipe)
Phosphate buffered saline (PBS; see recipe)
70%, 80%, and 90% ethanol
Poly-L-lysine or chrome alum coated slides (see recipes)

Additional materials and reagents for cryosectioning (Watkins, 1989).

Section tissue

1. Section fresh-frozen specimen on a cryostat (10- to 14-µm in thickness) and thaw mount sections on either poly-L-lysine or chrome alum–coated glass slides.
2. Dry slides at room temperature for 10 min and place at −20°C until ready for use for in situ hybridization.
3. When starting in situ hybridization take slides out of the freezer, and place them at room temperature for 10 to 15 min.

Fix and dehydrate tissue sections

4. Fix the sections 15 min in 4% paraformaldehyde.
5. Wash the sections as follows:

   Twice in PBS, each time for 10 min
   Twice in H_2O, each time for 5 min
   Twice in PBS, each time for 3 min.

6. Dehydrate sections by dipping slides in 70%, 80%,and 95% ethanol for 2 min each. Air dry the slides.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see **APPENDIX 2A;** for suppliers, see **SUPPLIERS APPENDIX.***

Binding buffer

Dissolve the following in 400 ml H_2O:
4.38 g NaCl
25 ml 2 M Tris (see recipe)
Adjust pH to 7.5 with 2 M HCl
Adjust volume to 500 ml with H_2O

Prepare fresh just prior use and do not autoclave.

To prepare 2 M HCl, add 16.6 ml concentrated HCl to 100 ml DEPC-treated water (see recipe).

5-Bromo-4-chloro-3-indolyl-phosphate (BCIP) solution

Dissolve 75 mg BCIP 4-toluidine salt in 1ml 100% dimethylformamide
Store up to 6 months at –20°C

Chrome alum–coated slides

Incubate slides in 100% ethanol for 5 min. Let slides dry. Heat 500 ml DEPC-treated water (see recipe) to 60°C and dissolve 2.5 g gelatin and 0.25 g chrome alum (chromium potassium sulfate). Filter solution and cool to room temperature. Dip slides once for 3 min (avoid bubbles). Air-dry slides overnight at room temperature. Store slides up to 6 months at – 20°C before using.

Color solution

Add 45 µl 75 mg/ml NBT (see recipe) and 35 µl 50 mg/ml BCIP (see recipe) to 10 ml wash buffer (see recipe). Prepare fresh.

DEPC-treated water

Add 250 µl DEPC (diethylpyrocarbonate) to 1 liter distilled water. Leave at room temperature overnight, then autoclave and store up to 6 months at 4°C.

Denhardt solution, 50×

Dissolve 1 g polyvinylpyrrolidone, 1 g BSA, and 1 g Ficoll in 77 ml DEPC-treated water (see recipe). Adjust volume to 100 ml with DEPC-treated water and filter sterilize. Divide solution into aliquots and store up to several months at –20°C.

Final concentrations are 1% (w/v) polyvinylpyrrolidone, 1% (w/v) BSA, and 1% (w/v) Ficoll.

DIG labeling buffer, 5×

1 M potassium cacodylate
0.1 M Tris·Cl, pH 6.6 (see recipe)
1.3 mg/ml bovine serum albumin
Store up to 6 months at –20°C.

Dithiothreitol (DTT), 5 M

Dissolve 7.7 g DTT in 10 ml DEPC-treated water (see recipe). Filter through a disposable 0.45-µm syringe filter Divide into aliquots and store up to 6 months at –20°C

The solution is filter sterilized because autoclaving will destroy DTT.

Hybridization buffer

Add the following to a glass dish and place on a magnetic stirrer:
50 ml deionized formamide (Sigma)
20 ml 20× SSC (see recipe)
2 ml 50× Denhardt solution (see recipe)
5 ml 20% sarkosyl (see recipe)
10 ml 0.2 M phosphate buffer, pH 7.0 (see recipe)
5 ml 11 mg/ml salmon testes DNA
10 g dextran sulfate
Adjust volume to 100 ml with 0.2 M phosphate buffer, pH 7.0 (see recipe)
Divide into aliquots and store up to 6 months at –80°C

The dextran sulfate must be added while stirring. Ensure that it has completely dissolved before adjusting the volume with phosphate buffer.

Nitroblue tetrazolium (NBT), 75 mg/ml

Dissolve 75 mg 2, 2′-di-*p*-nitrophenyl-5, 5′-diphenyl-3, 3′-(3, 3′-dimethoxy-4, 4′-diphenylene) ditetrazolium chloride (nitroblue tetrazolium, or NBT) in 1 ml 70% dimethylformamide. Store up to 6 months at −20°C.

Use dimethylformamide in glass tubes or microcentrifuge vials only (other plastics will dissolve).

Paraformaldehyde, 4% (w/v)

Dissolve 40 g paraformaldehyde in 800 ml water, adding 3 to 4 ml 5 M NaOH (10 g NaOH in 100 ml water), and heat to 60°C to dissolve. When the paraformaldehyde has been dissolved add 100 ml 10 × PBS (see recipe). Adjust the pH to 7.0 with concentrated HCl. Filter and adjust volume. Prepare fresh.

PBS, 10×

Add the following to 800 ml DEPC-treated water (see recipe):
80 g NaCl
14.4 g Na_2HPO_4
2 g KCl
2.4 g KH_2PO_4
Adjust the pH to 7.4 with concentrated HCl
Adjust volume to 1 liter with DEPC-treated H_2O
Store up to 6 months at room temperature

Phosphate buffer, 0.2 M

Dissolve 27.6 g $NaH_2PO_4 \cdot H_2O$ in 1 liter DEPC -treated water (see recipe). Dissolve 28.4 g Na_2HPO_4 in 1 liter DEPC-treated water. Mix the two solutions in a 1:3 ratio. Store up to 6 months at room temperature.

Poly-L-lysine coated slides

Incubate slides in 100% ethanol for 5 min, then allow to dry. Dissolve 25 mg poly-L-lysine in 500 ml DEPC-treated water (see recipe). Incubate slides in poly-L-lysine for 10 min. Air dry slides overnight at room temperature. Store the slides up to 6 months at −20°C before using.

Sarkosyl, 20% (w/v)

Dissolve 2 g *N*-laurylsarcosine in 10 ml DEPC-treated water (see recipe). Store 1 to 2 months at room temperature.

SSC, 20×, pH 7.0

Dissolve 175.3 g NaCl and 88.2 g sodium citrate dihydrate ($C_6H_5Na_3O_7 \cdot 2H_2O$) in 800 ml DEPC-treated water (see recipe). Adjust pH with 5 M NaOH (10 g NaOH in 100 ml DEPC-treated water), or concentrated HCl. Adjust the volume to 1 liter with DEPC-treated water. Autoclave and store up to 6 months at room temperature.

Stop buffer

Dissolve 4.38 gNaCl, 2.5 ml 2 M Tris (see recipe) and 0.186 g EDTAin 400 ml DEPC-treated water (see recipe). Adjust pH to 7.5 with 2 M HCl (16.6 ml concentrated HCl in 100 ml DEPC-treated H_2O). Adjust volume to 500 ml with DEPC-treated water.

Prepare fresh just prior use and do not autoclave.

TdT reaction buffer

500 mM sodium cacodylate, pH 7.2
10 mM $CoCl_2$
1 mM 2-mercaptoethanol
Store at −20°C

Tris·Cl, 0.1 M, pH 8.0

Dissolve 1.2 g Tris base in 80 ml DEPC-treated water (see recipe). Adjust pH to 8.0 with concentrated HCl. Adjust volume to 1 liter with DEPC-treated H_2O.

Tris, 2 M

Dissolve 24 g Tris base to 80 ml DEPC-treated water (see recipe). Adjust volume to 1 liter with DEPC-treated H_2O. Store up to 6 months at room temperature.

Wash buffer

Dissolve the following in 400 ml H_2O:
2.92 g NaCl
25 ml 2 M Tris (see recipe)
Add pH to 9.5 with 2 M HCl.
Add 5.07 g $MgCl_2 \cdot 6H_2O$ and dissolve
Adjust pH to 9.5 with 2 M HCl
Adjust volume to 500 ml with DEPC-treated H_2O

Make fresh just prior use and do not autoclave. To prepare 2 M HCl, add 16.6 ml concentrated HCl to 100 ml DEPC-treated water (see recipe).

COMMENTARY

Background Information

In situ hybridization is a powerful tool which combines anatomical and molecular biology techniques for detection and localization of specific nucleic acid sequences (usually messenger RNA) within individual cells or tissue preparations. This method is based on the formation of double-strand hybrid molecules between labeled probes and nucleotide sequences of interest by means of the hydrogen binding of complementary base pairs. High sensitivity and the possibility for precise anatomical localization of labeled mRNA make this technique valuable not only for identification of the few cells expressing a specific gene of interest, but also for quantification of changes in the synthesis of mRNA to assess the functional condition of the corresponding gene. In situ hybridization was originally developed in parallel by Pardue and Gall (1969) and John et al. (1969). Since then this technique has developed dramatically, and today it is an inevitable part of biological research. Many protocols have been developed for different types of in situ hybridization and have been published as articles or book chapters (Young, 1990; Wilkinson, 1992; Emson, 1993; Wilcox, 1993). Basically, all protocols can be divided in two main categories depending on what type of probes they describe: long DNA or RNA (e.g., complementary RNA) or short DNA (oligonucleotide) probes. The sensitivity of long probes is much higher, but if the gene of interest is highly expressed, oligonucleotide probes have several advantages: they are easy to synthesize on a DNA synthesizer, and much simpler to handle (e.g., labeling, purification, hybridization).

Probes can be labeled in two different ways: with radioactive isotope or nonradioactive marker. In general, probes labeled with radioactivity are more sensitive and give the possibility of assessing the degree of expression of a particular gene, while nonradioactive in situ hybridization is much faster, safer, and does not require special facilities to handle radioactive isotopes.

Critical Parameters and Troubleshooting

The in situ hybridization method can be subdivided in four main steps: specimen preparation (Support Protocol 3), probe labeling (Support Protocol 1 or 2), hybridization of probe to the tissue, and finally washing and detection of the probe (see Basic Protocol or Alternate Protocol). Each of these steps might be modified depending on the abundance of the target gene, type of probe, and nature of the specimen.

During all steps of in situ hybridization, it is essential to employ RNase-free conditions. Use gloves, baked glassware, sterile disposable plastic tubes, and deionized, sterile, diethylpyrocarbonate (DEPC)-treated water in all steps. Post-hybridization washes and further handling of slides do not require these precautions.

Tissue fixation for the detection of mRNAs by in situ hybridization is one of the most important steps. The main aim of tissue fixation is to preserve tissue morphology, and at the

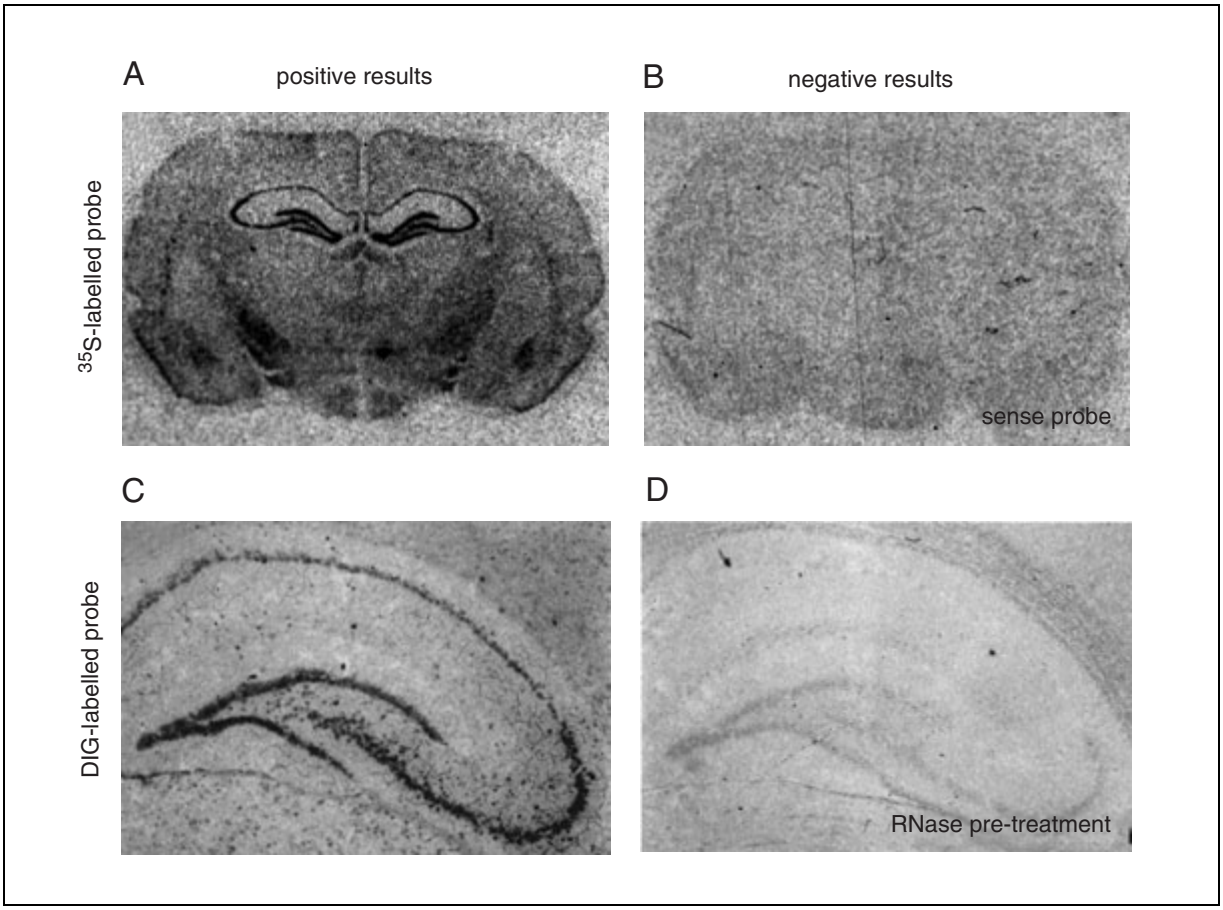

Figure 2.7.1 Expression of brain-derived neurotrophic factor mRNA in coronal sections of rat brain detected by [^{35}S]dATP and digoxigenin-labeled probes. Panels (**A**) and (**B**) represent images from X-ray film autoradiography showing a whole section hybridized to the ^{35}S-labeled antisense (A) and sense (B) probes. Panels (**C**) and (**D**) are bright-field photomicrographs of the hippocampal formation from the brain section hybridized to the digoxigenin-labeled probe without pretreatment (C) or after pretreatment with RNase (D). Note the absence of positive specific signal on (B) and (D).

same time to create conditions favorable for penetration of the probe to its target. The tissue could be fixed by transcardial perfusion with cross-linking fixative (e.g., 4% paraformaldehyde; Cassela et al., 1997), or the specimen can be frozen immediately after sacrificing the animal, and fixed after cutting sections and mounting them on the slides. Use of fresh-frozen tissue is preferable; transcardial fixation should be used only if in situ hybridization is performed in combination with immunocytochemistry. Cross-linking fixatives reduce permeability of the probes, and sometimes it becomes necessary to treat tissue (deproteinate) in order to increase signal. It is important to optimize the fixation procedure for each specific type of tissue and probe.

Use of [^{35}S]dATP or DIG-dUTP together with TdT for labeling of oligonucleotide probes gives high specific activity by adding a polymer of labeled bases (tail) to the 3′-end of oligonucleotide probe. The choice of probe label should depend on the abundance of the mRNA in the tissue. Since ^{35}S-labeled probes are more sensitive, that label is recommended for use when the expression level of the gene of interest is low or when the levels of gene expression need to be quantified. On the other hand, when the gene of interest is highly expressed or the laboratory does not have special facilities for handling radioactive isotopes, nonradioactive probes should be used.

It is very important to control for the specificity of in situ hybridization, especially when the probe is used for the first time. Use two sets of slides and hybridize them under the same conditions but use a standard, antisense probe for one set of slides and a sense probe (with opposite orientation as compared to antisense probe) for another set. This will show how specific the degree and pattern of expression of gene of interest is and will also allow assessment of the nonspecific background.

Another control is to pretreat sections with RNase (this will destroy cellular RNA) and then perform in situ hybridization. This control will reveal the nonspecific binding of the probe to tissue components (e.g., proteins, lipids) other than mRNA. Often, adding an excess (i.e., 100×) of unlabeled (cold) probe to the hybridization mix is used as a control. If the probe is detecting specific signal, this treatment will lead to the disappearance of tissue labeling. Finally, it is also advised that two or more probes be used, designed against different fragments of the gene of interest. A similar pattern of tissue labeling with different probes indicates a high level of specificity of hybridization (see Fig. 2.7.1).

Anticipated Results

Properly performed in situ hybridization will identify the location and degree of expression of the gene of interest in the tissue or defined population of cells as shown in Figure 2.7.1. Low background, reproducibility of results, and small variations in expression pattern and levels between the specimens will indicate high specificity of these results.

Time Considerations

The time required for performing an in situ hybridization experiment might vary depending on which types of probes (i.e., radioactive or nonradioactive) are used, as well as the expression levels of the gene of interest. Normally, in situ hybridization with nonradioactive probes requires 3 to 4 days. The duration of in situ hybridization with radioactive probes depends mainly on how long slides are exposed to X-ray film and/or auto radiographic emulsion. This step might last from a few days up to several weeks.

Confocal Microscopy

Confocal microscopy makes it possible to view a very thin optical plane in a specimen by excluding light from all planes above or below the focal plane. This is achieved by letting light from the focal plane pass through a small aperture, a so-called pinhole, while light from other planes in the specimen is excluded by the pinhole. By this so-called optical sectioning, sharp images of structures deep within thick sections may be obtained.

Confocal microscopy is suitable for reflecting and fluorescing specimens. It is best suited for fluorescence, since a reflecting marker largely obscures structures beneath it. The optical sectioning capacity is best realized when applied to a thick fluorescent specimen. In conventional wide-field fluorescence microscopy it would not be possible to resolve fine structures deep within such a specimen; fluorescence signals would be collected from all planes throughout the depth of the specimen, and resolution and contrast of structures in the focal plane would be lost. The optical sectioning capacity of the confocal microscope excludes fluorescence signals from planes above and below the focal plane.

Several different types of confocal microscopes have been developed for different imaging purposes with different technical solutions to the scanning procedure like stage scanning, beam scanning, tandem scanning, pinhole scanning, or slit scanning confocal microscopes (Pawley, 1995a). In this context, only the confocal laser scanning microscope will be considered, and at the end of this chapter a brief outlook on recent technical developments and their future applications will be given.

In confocal laser scanning microscopy (CLSM), the specimen is illuminated by a laser beam that scans a part of the specimen, and the fluorescence (or reflected) light is detected through the pinhole. Light passing through the pinhole is converted to a digital electronic signal, and the digital signal is passed on to a computer for storage and transformation into an image on the computer monitor. By scanning consecutive optical planes at increasing depth in the specimen, series (i.e., "stacks") of images can be collected that may be used for three-dimensional reconstruction with the computer. Moreover, by projecting all images of the consecutive optical planes onto one image plane, it is possible to view all parts of the specimen "in focus" simultaneously.

In biomedicine, CLSM is preferentially used for analysis of fluorescent specimens. By use of multiline lasers, or combinations of different types of lasers, it is possible to analyze the distribution of different fluorescent markers in the tissue. Presently, immunofluorescence is by far the predominant technique, but rapid progress is being made in the field of fluorescence in situ hybridization (FISH). The capacity to scan regions deep in the tissue obviates the necessity to use thin histological sections for high-resolution microscopy and allows the use of thick sections, or even tissue blocks, with better structural integrity than conventional histological sections. As a consequence, CLSM is the method of choice for analysis of spatial distribution of different markers, e.g., colocalization of markers in cells or cell organelles and topography of cell-cell contacts. It is beyond the scope of this unit to discuss all ways that CLSM may be used in histopathology. Instead, the information presented here is intended to give a basic insight into the theoretical and practical possibilities and limitations of the technique and to provide practical guidelines for the novice in confocal microscopy.

IMAGE CAPTURING

The focused-laser beam scans an area in the specimen, in a manner analogous to the raster scanning of a cathode ray tube (Fig. 2.8.1A). Reflected/fluorescent light from each point in this area is captured by a photon-catching device, and the intensity in each point is integrated over time illuminated by the laser (or the number of photons is counted). The signal is digitalized and transmitted to a computer. The signals from each point in the scanned area are represented as a frame, for example, 512×512 pixels.

Each pixel in the frame represents an area. The pixel size is determined by the sweep area, which depends on the magnification of the objective. In addition, an electronic zoom gives optional sweep areas for each objective. Thus, scanning a smaller area at a given frame size gives pixels representing smaller areas.

The image of the frame represents one confocal section. By scanning consecutive confocal sections at increasing depth in the specimen, it is possible to combine the different frames to

Current Protocols in Toxicology (2000) 2.8.1-2.8.21

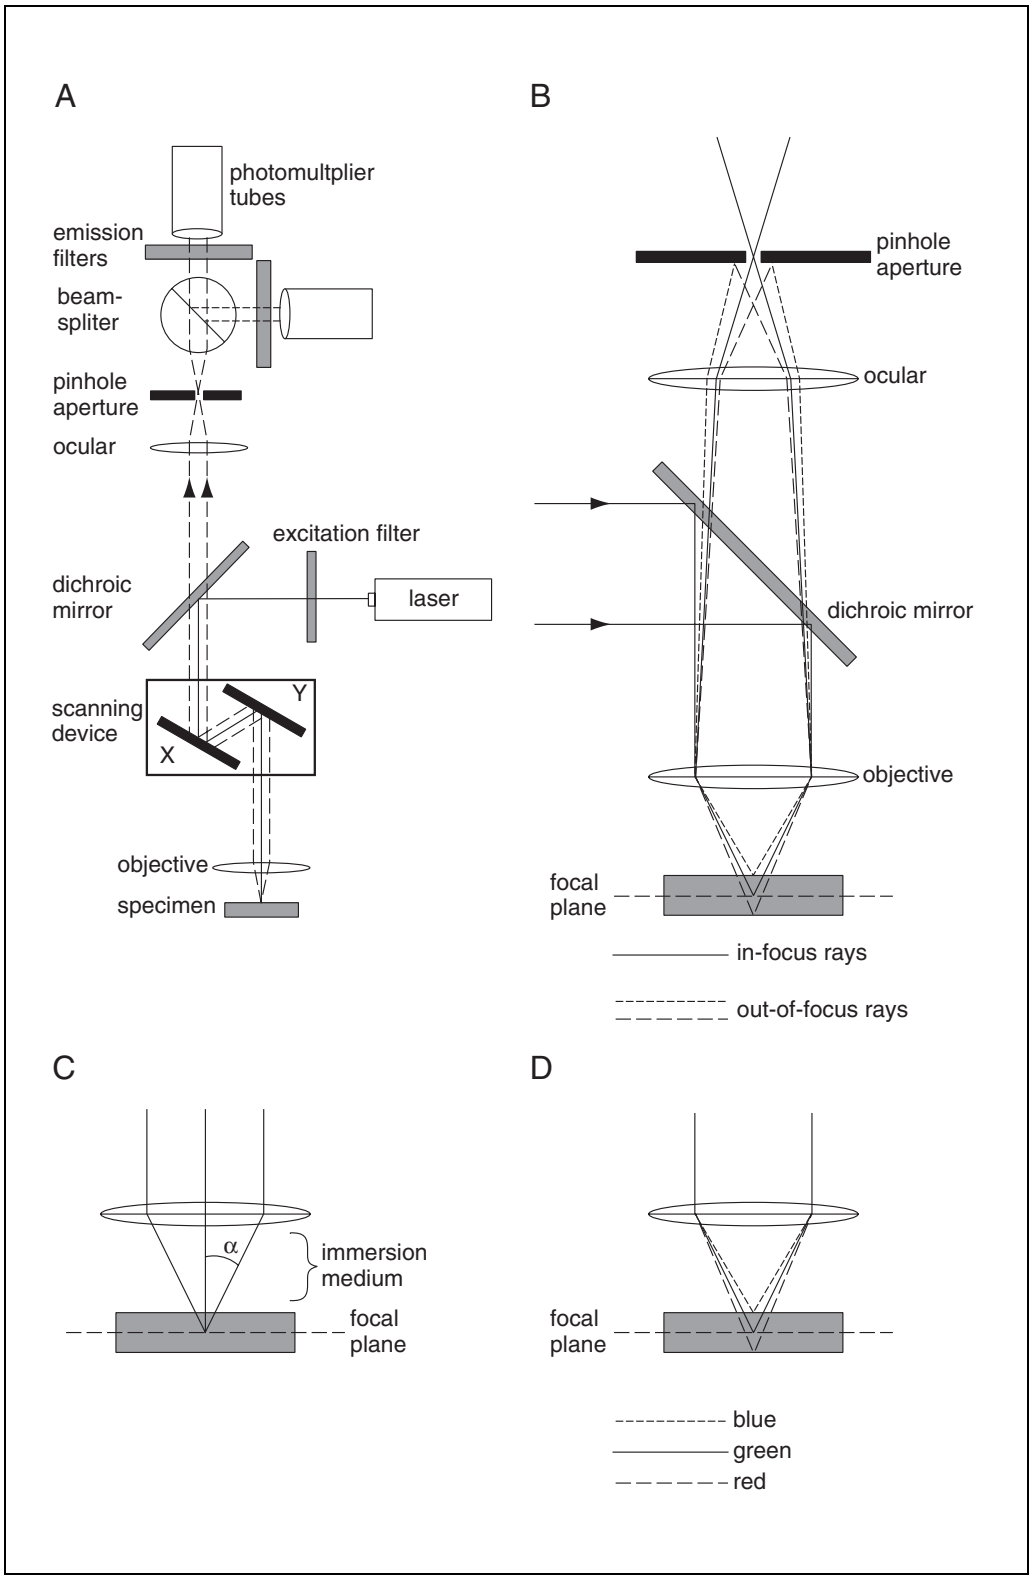

Figure 2.8.1 Legend at right.

make a three-dimensional reconstruction of the specimen. A number of consecutive confocal sections is usually called a "stack." When using stacks for three-dimensional reconstructions we deal with volume units, voxels, which represent the pixel area times the distance between the consecutive focal planes.

PRACTICAL AND THEORETICAL LIMITATIONS

To make full use of the power of confocal microscopy, it is important to appreciate its inherent limitations. The physical constraints will be briefly considered, as well as how each component of the CLSM setup contributes to the quality of the final image. For thorough analyses of these topics, the reader is referred to the Handbook of Biological Confocal Microscopy (Pawley, 1995a).

Resolution

Optical resolution depends on the numerical aperture of the objective lens, on the refractive indices of the immersion medium, coverslip, mounting medium, and specimen, as well as on the type of light used, and the wavelengths of the excitation and emission light, thus the choice of fluorescent marker. In confocal laser scanning microscopy, the small and sharply defined laser light spot for excitation, the size of the pinhole detector aperture, and the electronic system for sampling and digitalizing the fluorescent light signal, all contribute to the effective resolution.

Lateral resolution

The image of an infinitely small luminous object point is itself not infinitely small, but is in fact a circular Airy diffraction image with a central bright disk and progressively weaker concentric dark and bright rings (Fig. 2.8.1). The radius r_{Airy} of the first dark ring depends on the wavelength of the light, λ, and the numerical aperture of the objective, NA.

$$r_{\text{Airy}} = \frac{\lambda}{\text{NA}}$$

Two equally bright points of light, separated by a small distance, d, may be resolved if $d \geq r_{\text{Airy}}$. This is known as the Rayleigh criterion. Thus, the lateral resolution (x,y resolution) of point objects is defined by the least distance, x, between two objects when they still may be discerned as two objects.

$$x = K\frac{\lambda}{\text{NA}}$$

The factor K is determined by the quality of the light. The K value is higher (i.e., 1.0) for axial coherent light (i.e., laser light), and lower (i.e., <1.0) for noncoherent light (i.e., nonlaser light). Low coherence is required for bright-field and reflection microscopy, whereas high coherence is required for phase and interference microscopy. The degree of coherence is less important in fluorescence microscopy, but in fluorescence confocal laser scanning microscopy low coherence is preferred because of the lower K value, as out-of-focus defects in the

Figure 2.8.1 *(at left)* (**A**) Schematic drawing of confocal laser scanning microscope and light path. Laser light passes an excitation filter, by which the appropriate excitation wavelength is selected. The light beam is reflected by a dichroic mirror to the scanning device, into the objective, and is focused onto the specimen. The specimen is scanned line by line in a raster system. Fluorescence from the specimen travels back through the objective, via the scanning device, through the dichroic mirror to the pinhole aperture. An emission filter selects the appropriate emission wavelength range, and an ocular focuses light from the focal plane in the specimen on the small pinhole aperture. Light passing through the pinhole is captured by a photomultiplier tube. Simultaneous two-wavelength scanning requires that the dichroic mirror reflects both excitation wavelengths and lets both emission wavelengths through. Also, the two emission wavelengths passing through the pinhole are separated by a beamsplitter, and captured by two photomultipliers. (**B**) The confocal principle. The parallel light of the laser beam is focused in the specimen. Light from the focal plane is focused on the pinhole aperture, whereas light from planes above or below focus either in front of, or behind, the pinhole, thus contributing only low photon flux through the pinhole. (**C**) The numerical aperture (NA) of an objective is given by the formula NA = $\eta\sin\alpha$, where η is the refractive index of the immersion medium between the objective and the specimen, and α is half the opening angle of the objective. (**D**) Chromatic aberration. Light of different wavelengths have different focal lengths with a given lens. Unless this is corrected for (e.g., by using high-quality planapochromat lenses), scanning at different wavelengths will give incorrect optical sectioning. (Adapted from Shotton, 1995.)

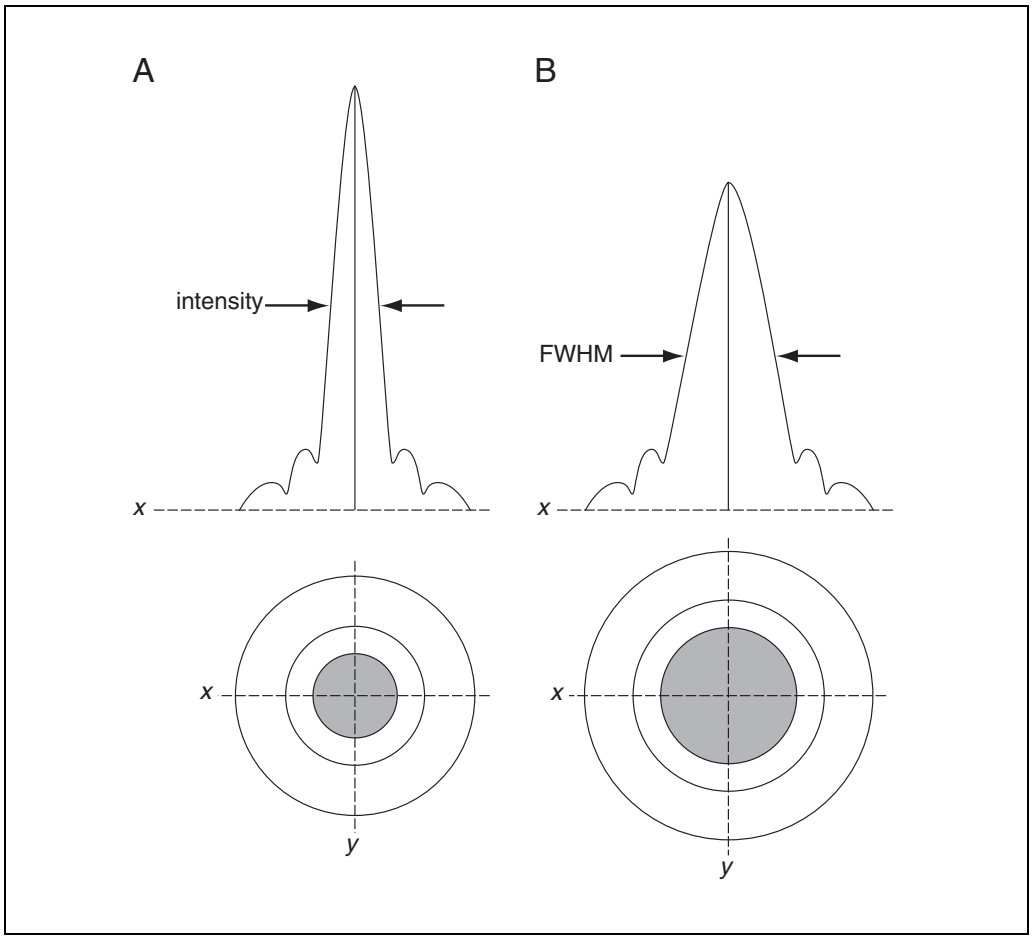

Figure 2.8.2 Intensity distribution and diffraction pattern of (**A**) laser light and (**B**) normal light. Due to a high degree of parallelism, the diameter of the diffraction-limited laser light spot is smaller than that obtained with normal light. This results in better lateral resolution with the CLSM. The full width half maximum (FWHM), i.e., the full width of the irradiance distribution at 50% irradiance, is often referred to as the optical section thickness. (Adapted from Tekola et al., 1994.)

light path may induce severe interference problems. Therefore, the coherent laser light is "scrambled" and rendered noncoherent.

In conventional optical (e.g., fluorescence) microscopy, K is set to 0.61 when the objects are two points.

$$x = 0.61\frac{\lambda}{\mathrm{NA}}$$

The intensity (irradiance) distribution in the focal point is defined by its point-spread function (PSF). In conventional fluorescence microscopy, resolution is largely determined by the PSF of the emitted (fluorescence) light. In CLSM, the laser light is focused to a confined high-intensity (diffraction-limited) light spot that illuminates a very small volume of tissue, from which light is emitted and captured by a photon-catching device. Thus, resolution depends on the PSFs of both focused laser light and emitted light.

Since laser light has a higher degree of parallelism, the diameter of the diffraction-limited laser light spot is smaller than that obtainable with nonlaser light (Fig. 2.8.2). "Scrambling" does not reduce parallelism. The restriction of illumination and detection to a very small volume gives an improvement in both lateral and axial resolution. Theoretically, in confocal microscopy the lateral resolution is 32% higher.

$$x = 0.46\frac{\lambda}{\mathrm{NA}}$$

This means that the ultimate resolution limit with the confocal microscope, using objectives with high numerical aperture (NA = 1.4), is 0.33λ.

However, this calculation is based on the assumption that an infinitely small pinhole diameter is used. In fluorescence microscopy,

light levels are often low, and the pinhole aperture has to be increased in order to obtain a strong enough signal. Thus, the theoretical improvement of lateral resolution cannot be realized, and the effective lateral resolution will approach that obtainable by conventional fluorescence microscopy. Nevertheless, illumination with a diffraction-limited light spot does contribute to a higher resolution than can be achieved with wide-field illumination. Also, due to diffraction phenomena, discussed below, lateral resolution is better with confocal microscopy, especially when viewing a focal plane deep in the tissue.

It follows that at a given (optimized) pinhole aperture size, one should always choose an objective with as high NA as possible and use short-wavelength light to achieve optimal resolution. Unfortunately, there are limitations to this strategy, as will be evident further on.

Axial (depth) resolution and optical sectioning

The axial resolution of the CLSM is determined by its optical sectioning property. The strength of the optical sectioning is the rate at which the detected intensity falls off with axial distance. It is a function of both the detector size and the object feature. Consider the situation when the object is in focus: reflected light is focused onto the pinhole and a large signal is detected. When the object is out of focus, a defocused spot is formed at the pinhole and a small signal is detected. Thus, the smaller the pinhole size, the stronger the optical sectioning (Fig. 2.8.1B).

The axial resolution can be defined as the minimum distance that the diffraction images of two points can approach each other along the z axis, yet still be seen as two. The image of a point source produced by a diffraction-limited optical system is periodic around the point of focus in the focal plane (i.e., x/y plane), and it is periodic above and below the focal plane along the z axis. The distance from the center of the three-dimensional diffraction pattern to the first axial minimum is given by:

$$z_{\min} = \frac{2\lambda\eta}{\left(\mathrm{NA}_{\mathrm{obj}}\right)^2}$$

where $z_{\min}$ is the distance in the z plane between the central maximum and the first intensity minimum, and η is the refractive index of the specimen. However, in a conventional fluorescence microscope there is no depth discrimination, and the recorded light intensity is independent of whether the object is in focus or not (i.e., one cannot see the axial minima). In confocal microscopy, due to the optical sectioning capacity, there is a dramatic drop in light intensity as the object becomes defocused (i.e., one can "see" the axial minima). The full-width-half-maximum (FWHM: the full width of the irradiance distribution at one half the maximum irradiance value; Fig. 2.8.2) of the light intensity along the z axis for reflected light confocal microscopy is given by:

$$\mathrm{FWHM} = \frac{5.6\lambda}{8\pi\eta\sin^2\left(\frac{\alpha}{2}\right)^2}$$

where α is obtained from $\mathrm{NA} = \eta\sin\alpha$ (Fig. 2.8.1C). In fluorescence confocal microscopy, the FWHM is increased by ~50%. Although this equation is not strictly correct at high numerical apertures (Wallén et al., 1992; Cogswell and Larkin, 1995), it can be seen that the axial resolution depends on the square of the NA (and thus also lateral magnification), the wavelength, and the refractive index of the specimen. Also, the size of the pinhole aperture is important, as is the optimal setting of the photon-capture device (i.e., to reduce noise).

The size of the detector pinhole aperture obviously affects the optical sectioning property. However, the strength of the sectioning is insensitive to an increase in pinhole diameter up to a certain limit, which can be estimated to the normalized pinhole radius $\upsilon_p \approx 2.5$ optical units. From the relationship between the normalized radius and real radius of the pinhole, we can calculate the actual diameter (d) of the largest pinhole with which optimal sectioning is retained.

$$\frac{M}{\mathrm{NA}} \geq \left(\frac{\pi}{2.5}\right)\frac{d}{\lambda} \quad \Leftrightarrow \quad d \leq \left(\frac{2.5}{\pi}\right)\frac{\lambda M}{\mathrm{NA}}$$

where M is the magnification of the lens system between the object and the detector. Actually, an increase in pinhole diameter will affect lateral resolution before axial resolution. To obtain true confocal lateral resolution improvement, a value of $\upsilon_p \leq 0.5$ optical units is required (Wilson, 1993).

In fluorescence confocal microscopy, axial resolution is also dependent on the β value, which in turn depends on the ratio $\lambda_{em}/\lambda_{ex} = \beta$. With increasing β value, i.e., increasing Stokes shift, the strength of the optical sectioning deteriorates. This is related to the wavelength-dependent change in the focal length of the ob-

jective lens (Fig. 2.8.1D). Without correction for this longitudinal chromatic aberration, the foci, for example, for blue and green light, will be at different depths in the specimen. As a consequence, green fluorescence emission from the focal plane defined by blue excitation light will be out of focus at the pinhole aperture (Shotton, 1995). Although objectives that are well corrected for a number of wavelengths or wavelength intervals are available, one should take great care to select the appropriate type of objective (Keller, 1995). UV-excited fluorescence, especially, requires replacement of several optical components, not only the objective (Carlsson, 1993). Also, one should attempt to operate as close to $\beta = 1$ as possible, while still being able to avoid cross-talk of fluorescent and reflected light (Wilson, 1995).

The refractive index (η) in the specimen is usually different and variable, with values between $\eta = 1.5$ for glass and immersion oil, and $\eta = 1.3$ for water. When looking into a typical biological sample, mounted in water (e.g., buffer, medium) using a high-NA oil immersion objective, the difference in refractive index creates a serious deterioration of axial resolution. When the thickness of the water layer increases from 0 to 300 μm, the optical section thickness increases by a factor of eight in fluorescence confocal microscopy (Carlsson, 1991). To obtain optimal optical sectioning it is vital that the specimen is as close to the coverslip as possible, with no intervening mounting medium (Shotton, 1995).

It is obvious that axial resolution is worse than lateral resolution. Different attempts to measure their ratio empirically, as well as theoretical calculations, have shown that axial resolution is at best 2.5 to 3 times worse than lateral resolution.

Sampling frequency

Adequate choice of sampling frequency is important not only for optimal resolution but also to ensure that no aliasing occurs. Aliasing is the introduction of false low-frequency elements by sampling at too low a frequency.

Before plunging into how optimal sampling frequency is determined, it is useful to consider some aspects of sampling theory that are important for a general understanding of how an image with optimal resolution can be generated (for more detail see Sheppard and Gu, 1992; Webb and Dorey, 1995).

First, one may consider not the size of the objects themselves, but the inverse of their size—how many objects can be seen per millimeter. By doing this, one enters the spatial frequency domain, in which the image is considered as consisting of the sum of a number of different spatial frequencies. The highest spatial frequency that can be imaged by a lens is defined by its cut-off frequency (f_c) of its optical transfer function (OTF).

$$f_c = 2\frac{\mathrm{NA}}{\lambda}$$

Resolution may be defined as the highest spatial frequency at which the image contrast is above a given value. All optical systems reduce the contrast of the low spatial frequencies (large details) less than they do higher spatial frequencies (small details), shown by the contrast transfer function (CTF) of the optical system. The CTF affects the final image, since the contrast in the image is proportional to the contrast in the object, as degraded by the CTF of the imaging system. Due to the CTF, the contrast of small features just inside the resolution limit is much lower than that of larger features.

Closely linked to the resolution of contrast is the intensity resolution of the detector. This is the capacity to resolve differences in photon flux and to transfer this into a resolvable difference in output signal. Intensity resolution can be described by the just detectable difference (jdd), which depends on Poisson statistics.

A measurement of a voltage proportional to n photons is only just detectably larger than one representing $n-\sqrt{n}$ photons, and just detectably smaller than one representing $n + \sqrt{n}$ photons. Then, jdd equals $\sqrt{n}$. It can be immediately seen from this relation that the relative magnitude of one jdd step varies with the signal intensity—i.e., the relative size of the jdd step is determined by the number of photons captured by the detector. Thus, at low photon fluxes, jdd represents a small value, but it represents a high value at high photon fluxes. This should be considered together with the relatively lower contrast of high spatial frequencies due to the CTF of the optical system.

One is usually interested in visibility, i.e., the ability of an observer to recognize two closely spaced features as being separate. Visibility depends also on the signal-to-noise ratio ($R_{S/N}$). As smaller objects have lower contrast, they require more photons to be counted in order to reduce the intrinsic noise of the background. According to the Rose criterion, to be visible, a feature that is a single pixel in size must have an intensity that differs from that of

the background by at least five times the noise level of the background.

So, what sampling frequency should be used in order not to violate the aforementioned rules concerning spatial frequencies, contrast, and visibility? According to the Nyquist criterion, the sampling frequency should be more than two times higher than the highest frequency in the data. The highest frequency in the data is determined by the size of the smallest elements in the specimen and the resolution of the optical system. The maximum frequency that can be represented using the sampling rate Δ, i.e., the Nyquist critical frequency (f_c), is as follows:

$$f_c = \frac{1}{2}\Delta$$

For nonperiodic data, the sampling rate $\Delta \geq 2.3\ f_c$. This means that, in order to preserve information that could be recorded using a given CTF, the pixels must be smaller than $1/(2.3 f_c)$. It also follows that, for a given optical system, only one pixel size (and therefore one zoom factor) matches the Nyquist criterion. For example, consider a case where the microscope resolution is 0.24 µm (e.g., at λ = 568 nm; NA = 1.4). The display is 512 × 512 pixels. The field width should be (512/2.3) × (0.24 µm) = 53.4 µm, and thus the side of each pixel 0.10 µm. For critical sampling it may be noted that the sampling distance increases with the factor √2 along the diagonal of the pixel.

It may be useful to consider the resel (R), the smallest optically resolvable entity of an object, as defined (arbitrarily) by the Rayleigh limit—the necessary separation of two self-luminous point sources such that their diffraction patterns show a detectable drop in intensity between them. "Detectable" here denotes (arbitrarily) ~20%, which means that the separation equals r_{Airy}. Thus, for conventional microscopists:

$$R = \frac{0.61\lambda}{NA}$$

In the CLSM, the confocal resel in the x/y plane is $R_{x/y} = 0.46\lambda/NA$, and in the z plane $R_z = 1.4\lambda 104\ /(NA)^2$. According to the Nyquist theorem, we need 2.3 samples for each point in a resolved pair, i.e., 2.3 pixels per resel. Therefore, we need at least a two-to-one match along a line. In a plane, we need 2 × 2 pixels per resel. When adding axial resolution we actually need 2 × 2 × 2 pixels per resel, or 8 pixels. However, we should really use 2.3 × 2.3 × 2.3 or ~12 pixels per resel in a three-dimensional volume to satisfy the Nyquist criterion. Hence, a minimum of 12 pixels is needed to resolve two separate points in space.

From the reasoning above, a few rules of thumb can be extracted:

1. For optimal lateral resolution, sample at 2.3 times the highest frequency, the side of each pixel should be 1/2.3 of the lateral resolution with the given wavelength and numerical aperture.
2. For optimal axial resolution, step size between sections can be three times the pixel width. If the specimen permits, and sampling is critical, sampling frequency can be higher to facilitate post-acquisition image processing.
3. When not working at optimal resolution of a given objective, step size axial = lateral resolution.

Signal-to-noise ratio ($R_{S/N}$) and signal-to-background ($R_{S/B}$) ratio

The term "noise" implies unwanted or nonspecific signal in the image. This signal can be derived from the specimen, the optical system, and the detector. Strictly speaking, in the CLSM, noise is any variation in the detected and digitized signal that is not associated with the specimen. The unwanted signal derived from the specimen is commonly termed background and comprises (in fluorescence CLSM) autofluorescence and specific fluorescence from other than the focal plane. In an ideal confocal microscope (i.e., with a pinhole aperture whose diameter is equal to half the width of the Airy disk), all background is rejected, and all "noise" is true noise, i.e., is derived from the optical system and/or the detector. However, in practice, a larger pinhole aperture must be used; thus, all background is not rejected. Still, with a reasonable pinhole aperture most of the background is rejected, and this is the great strength of the CLSM.

The terminology is somewhat confounded by the use of the term "background noise", which usually denotes stray light, i.e., light emanating from within the optical system. A typical example of stray light is noise emanating from autofluorescence in the cements and coatings of the optical elements of microscope systems, particularly the objective lens. Consistent with the terminology defined above, stray light, in this example, is considered noise.

The distinction between noise and background is important. Hence, signal-to-background ratio ($R_{S/B}$) is different than signal-to-noise ($R_{S/N}$). Nevertheless, both contribute to

the degradation of the image in similar ways, and both are similarly affected by some of the adjustments in the CLSM. For further discussions of $R_{S/B}$, $R_{S/N}$, and different types of noise, see Pawley (1994) and Sandison et al. (1994).

$R_{S/N}$ in the optical system

The basic limitation of the optical system is dictated by the presence of shot noise in the detected signal. Shot noise is generated by stray light and by detector noise (which will be considered below). Stray light is constant in strength throughout the image. Although it can be subtracted from the signal electronically to improve contrast, it does affect the signal-to-noise ratio ($R_{S/N}$). With a high $R_{S/N}$ (only stray light considered) the size of the pinhole has little effect on $R_{S/N}$ and may be varied within a fairly wide range. When the signal decreases in strength, the size of the pinhole becomes more critical, and for optimal performance at low $R_{S/N}$, pinhole size may only be varied within narrow limits; $R_{S/N}$ increases with both smaller and larger pinhole sizes. In practice, however, in "normal" biological specimens the $R_{S/N}$ in the optical system can be improved by decreasing the pinhole aperture size.

To minimize the impact of shot noise (regardless of its origin) on the quality of the image, it is desirable to sample at a high resolution frame (i.e., $\leq 500 \times 500$ pixels) and follow the Nyquist criterion for optimal resolution of true frequencies/objects in the sample. Moreover, sampling at a slower scan speed means that, when counting/integrating photons over a longer time per pixel, a stronger signal is achieved at each pixel and shot noise is better averaged over the image.

$R_{S/N}$ in the detector

Shot noise in the detector results from the statistical variation in the number of detected photons, which obeys a Poisson distribution. The Poisson distribution has the property that its mean is equal to its variance, and, as the noise is given by the square root of the variance, the shot noise on a signal of n_p is $\sqrt{n_p}$. Thus, the $R_{S/N}$ for this signal is:

$$n_p/\sqrt{n_p} = \sqrt{n_p}$$

The $R_{S/N}$ of the detector also depends on the quantum efficiency (Q_E) of the detector, and the sensor noise (n_n).

$$R_{S/N} = \frac{Q_E n_p}{\sqrt{\left(Q_E n_p + n_n{}^2\right)}}$$

The quantum efficiency of the detector is a measure of the proportion of photons arriving at the detector that contribute to its output signal. For any detector, the quantum efficiency is strongly dependent on the wavelength of the incoming light (Art, 1995). There are several types of sensor noise (1) subtractive noise, (2) additive noise, (3) multiplicative noise, and (4) digitization noise (Pawley, 1994).

Subtractive noise (N_1) is a measure of the photons impinging on the detector that do not contribute to the signal and thus depends on the quantum efficiency of the detector. Additive noise (N_2) includes random and periodic signals that are added to the real intensity signal. Such signals may arise either within the detector itself or be the result of stray light striking an insufficiently shielded detector. The chief source of N_2 in the photomultiplier tube (PMT) is the dark current, which is mostly caused by thermally excited photoelectrons and thus is strongly temperature-dependent; therefore, avoid heating the PMT.

Multiplicative noise (N_3) arises when some photons contribute more than others to the final recorded signal. This is because the charge amplification process in the PMT [whereby the photoelectrons (PEs) generated by captured photons generate secondary electrons (SEs) that are amplified in a number of steps] is also governed by Poisson statistics. For example, if the average number of SEs generated by a PE in the first step is 9, then one would expect that 67% of the interactions will produce between 6 and 12 SEs, whereas 33% will generate either more or fewer SEs. This process is then repeated at each amplification step. Multiplicative noise can be largely eliminated by operating the detector in the photon-counting mode. Photon-counting can be achieved with the PMT operated in pulse-counting mode. Instead of measuring the average level of output current during the time for each pixel, the individual output pulses that result from the emission of individual PEs are counted. The photon pulses are passed through a discriminator; each time the PMT output exceeds a preset threshold, one pulse is counted (Pawley, 1994, 1995b).

Digitization noise (N_4) arises because the process of digitizing the electronic signal from the detector is never perfect. The single PE-output pulses from a PMT not only vary in size, they also arrive at random time intervals. Be-

cause the analog-to-digital converter (ADC) samples the signal current in a periodic manner, it is possible for a mismatch to occur, and N_4 to be introduced.

The $R_{S/N}$ in the PMT (currently the most common detector type in commercial CLSMs) can be improved by using a sensitive low-noise PMT and by operating close to the optimal voltage of the PMT. If there is too much noise, try to reduce the PMT voltage.

The importance of choosing the correct type of photon detector cannot be overestimated. There is a wide choice of photon detectors, e.g., PMTs, cooled CCD (charge-coupled device) arrays, avalanche photodiodes, and vacuum avalanche photodiodes, which vary widely in their response properties. The quantum efficiency, responsivity, spectral response, response time, linearity, and sensor noise of the detector should be optimized for its application. In most commercial confocal laser scanning microscopes, PMTs are used as detectors, while most custom modifications include optimization of the detector(s). For a thorough description of different detector types and their usefulness in confocal microscopy, see Art (1995).

$R_{S/B}$ in the specimen

Low $R_{S/B}$ in the specimen is encountered when there is high background fluorescence, weak specific signal, or a combination of the two. There are several ways to improve $R_{S/B}$ in the image of such a specimen, but it should be remembered that the $R_{S/B}$ of this particular specimen will not be improved.

First, the pinhole size is obviously of great importance, as it rejects out-of-focus light that contributes to unwanted signal (background) in the image of the focal plane. With a small pinhole size, a confocal system behaves as a true confocal microscope, whereas with a large pinhole, the imaging capacity is identical to that of a conventional microscope. Because the signal strength in biological specimens usually precludes use of an optimal (very small) pinhole size, it is important to know what happens when one opens the pinhole aperture to get a stronger signal. Actually, increasing the size of the pinhole beyond the first minimum of the Airy disk does not increase signal strength from the focal plane appreciably. Still, increasing the size of the pinhole further does give a stronger signal, but this is because the confocal sectioning capacity is violated, and light is collected from a larger volume (i.e., a thicker optical section). This can be desirable in this case, as the optical sectioning capacity still removes a large amount of signal from the planes outside the optical section.

To improve $R_{S/B}$ further, it may be useful to first set the dark level of the detector to exclude collection of low-intensity pixels. Then, from each optical section plane, accumulate scans (add or average) at low laser intensity and optimal PMT voltage. It is also desirable in this case to scan at a high resolution frame.

In some instances, it may be desirable to operate at longer (i.e., red to far-red) wavelengths, although this compromises resolution somewhat. This may occur when one cannot circumvent the use of thick and/or highly refractive specimens, or when background fluorescence is intolerable. In such cases it may help to choose a marker molecule with longer λ_{ex} and λ_{em}, as there is generally lower background fluorescence at longer wavelengths. Moreover, long-wavelength light penetrates deeper into tissue and exhibits a lower degree of light scattering due to refraction than light of shorter wavelengths.

Optimization of $R_{S/N}$ and $R_{S/B}$

In practice, it is necessary to empirically find a good balance between pinhole size, scan speed, laser effect, and PMT voltage, for each type of specimen and labeling. After aquiring the image, the $R_{S/N}$ in the image can be further improved by image processing/filtering.

PRACTICAL GUIDELINES

Immunofluorescence

In principle, any specimen good enough for conventional immunofluorescence microscopy can be used for fluorescence CLSM. Thus, specimens can be processed and prepared in basically the same way. However, to truly benefit from the optical sectioning capacity with the highest possible resolution of the confocal microscope, attention must be given to specific steps in the protocol. The most significant difference between an immunofluorescence protocol for CLSM and one for conventional microscopy is that for CLSM it is possible to adapt the staining protocol for optimal signal; increasing background fluorescence at the same time is of little consequence, as the optical sectioning capacity eliminates most out-of-focus light.

Fixation, embedding, and sectioning

Fixation, embedding, and sectioning are performed as for conventional immunofluorescence. The choice of fixative is obviously de-

termined by its preservation of antigenicity as well as structural integrity. However, since CLSM is particularly suited for spatial analysis of fluorescent markers, it is advisable to use an aldehyde-based fixative, since alcohol-based or acetone fixation may induce shrinking and/or swelling. Commonly, the routine fixative 4% formaldehyde (freshly prepared from paraformaldehyde) in buffer is adequate, but superior tissue integrity may be achieved by the inclusion of glutaraldehyde and/or picric acid (usually 0.1% to 0.25% for both compounds).

If thick tissue sections or tissue blocks are to be processed for immunocytochemistry, it is necessary to permeabilize the tissue. Some straightforward but rather harsh methods are to subject the tissue to repeated freeze-thaw cycles, or else dehydrate it through an ascending alcohol series, rinse in xylene and then absolute alcohol, and finally rehydrate it through a descending alcohol series. As an alternative, chemical permeabilization with a detergent may be considered, e.g., Triton X-100 or saponin. Triton X-100 is an irreversible permeabilization reagent, and may be used prior to immunocytochemical processing by incubating the tissue 2 to 24 hr in 0.1% to 1.0% (v/v) Triton X-100 in incubation buffer (optimal duration and concentration have to be determined for each tissue/antibody combination). Triton X-100 may also be included in the primary antibody incubation medium (usually 0.1% to 0.25%), but it should be carefully rinsed out before incubation with fluorophore-conjugated antibodies. Saponins are less harsh to the tissue, and since saponin permeabilization is reversible, it has to be included in all incubation and rinse media. An efficient but time-consuming permeabilization method that is excellent for preservation of fine structure is to impregnate the fixed and rinsed tissue block with dimethylsulfoxide (DMSO) added dropwise to buffer, e.g., phosphate-buffered saline, to a final concentration of 25%. The tissue is then frozen in the DMSO/buffer mixture with liquid nitrogen, and permeabilized by keeping frozen at −80° for ~1 week (Brandon, 1987). We have noted that long-term storage of tissue in DMSO/buffer is possible for most antigens, but one should try it out before applying the method to critical material.

Immunofluorescence protocol

Immunofluorescence protocols basically follow a standard method (e.g., Donaldson, 1998). Even after permeabilization, tissue penetration of antibodies may be critical. Therefore it is advisable to use fluorophore-conjugated $F(ab')_2$ or Fab fragments, rather than intact IgGs.

Mounting and applying the coverslip

Critical confocal microscopy is usually performed with high-NA oil-immersion objectives. Therefore, the refractive index of the mounting medium should be as close as possible to that of the immersion medium and ideally also to that of the coverslip. For histological specimens, it is usually not necessary to use buffer or culture medium as mounting medium, and one may attempt to approach the η_{glass} of 1.5. Still, it is desirable to use a mounting medium that does not distort the tissue (e.g., by dehydration or osmotic forces). Ideally, it should also stabilize the tissue against the forces generated in the mounting medium by the placement of the coverslip and pressure changes when focusing an oil-immersion objective. The least distortion of tissue, and reasonable stabilization, is obtained with a 1:1 mixture of glycerol and PBS (Baccalao et al., 1995).

The cyanine fluorochromes (i.e., Cy2, Cy3, and Cy5) are compatible with organic solvents, and thus with mounting in nonaqueous medium, whereas the other fluorochromes require mounting in aqueous medium. It is also important to consider the necessity of including antifading compounds in the mounting medium. Antifade compounds retard photobleaching, usually by antioxidative actions. There are several commercially available mounting media, which contain antifading compounds that are more or less optimized for specific fluorochromes. An alternative is to make one's own mounting medium, including stabilizing and antifade agents. Unfortunately, most antifading agents reduce fluorescence intensity; therefore, one should initially try a mounting medium composed of a glycerol/PBS mixture without additives. If fluorescence is bright enough, and scanning can be performed without lengthy searches for suitable structures under wide-field illumination, this may prove adequate, as it has done so for the author for over 4 years. If fading is a problem, one may then first try an anti-fading agent that primarily increases fluorescence half-life, without affecting intensity too much, like DABCO (1,4-diazo-bicyclo-2,2,2)octane, 25 mg/ml in glycerol/PBS; or Citifluor (Agar, Essex, UK; ready-to-use mounting medium). If these are still not adequate, one may use an agent proven to dramatically increase fluorescence half-life, e.g., Vec-

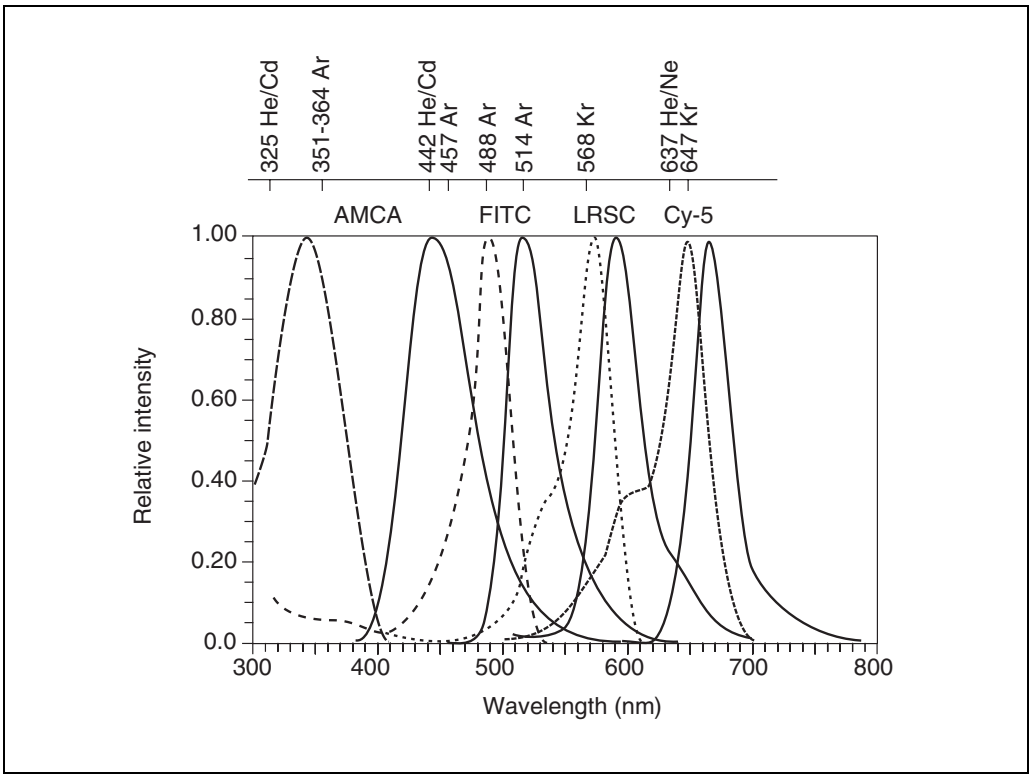

Figure 2.8.3 The excitation (dashed lines) and emission (solid lines) spectra of three fluorophores, FITC, LRSC, and Cy-5, that are excellently suited to the emission lines of the mixed gas Ar/Kr ion laser (arrows). Also, the spectra of a UV-excited fluorophore, AMCA, is included. Above, the emission lines of some commonly used laser types are shown. (Adapted from Wessendorf and Brelje, 1993 and Tsien and Waggoner, 1995.)

tashield (Vector; ready-to-use mounting medium). Other agents are in wide use, like *p*-phenylenediamine and *n*-propyl gallate, and one may refer to the more thorough discussions of different anti-fading agents by Baccalao et al. (1995) and Florijn et al. (1995).

Most microscope objective lenses are corrected for the spherical aberration generated by coverslips of a thickness of 0.17 mm. For optimal resolution, it is important to use this type of coverslip, especially for thick specimens mounted in aqueous medium. When forced to work with tissue in an aqueous medium, synthetic "Cytop" coverslips ($\eta = 1.34$) and water immersion objectives may be useful (Keller, 1995). The coverslips should be sealed around the edges, e.g., with nailpolish, to prevent dislocation and leakage of the mounting medium.

Choice of Fluorophores

Fluorescence occurs when a fluorescent molecule (i.e., fluorophore or fluorochrome) absorbs a photon of light of a particular wavelength, i.e., the excitation wavelength (λ_{ex}). The energy of this photon causes the fluorophore to enter a transient excited state; the subsequent decay from the excited state to the ground state has a characteristic delay and is accompanied by the emission of photons of a characteristic wavelength (energy; λ_{em}). The spectrum of emitted light has a longer wavelength (lower energy) range than the excitation light: $\lambda_{em} > \lambda_{ex}$. The difference $\lambda_{em} - \lambda_{ex}$ is called the Stokes shift. The Stokes shift makes it possible to separate the excitation and emission light. When choosing fluorophores for the CLSM, one has to consider the excitation wavelength, Stokes shift, quantum yield, and molar extinction coefficient of the fluorophores (Wells and Johnson, 1994).

The excitation wavelength should obviously correspond with the wavelengths available from the laser (Fig. 2.8.3). Currently, the most common lasers in CLSM are the mixed-gas argon/krypton (Ar/Kr) laser (λ: 488, 568, 647 nm), the argon ion laser (λ: 488, 514 nm; note that lines between 454 and 528 nm are also available), the argon ion UV laser (λ: usually between 334 and 364 nm; by frequency doubling down to 229 nm), and the helium/neon laser (λ: 534, 594, 612, 632 nm, infrared). As laser technology develops, more types of lasers with other useful characteristics will be available. Different types of laser light sources have

recently been discussed by Gratton and vande Ven (1995).

The Stokes shift should be sufficiently large to allow easy separation of excitation and emission light, but not so large that it may induce errors due to chromatic aberration and differential resolution properties. A small Stokes shift reduces differences in diffraction by light between the λ_{em} and λ_{ex}, but may increase noise by reflected light.

The quantum yield (Q_f) denotes the ratio of photons absorbed to photons emitted as fluorescence and is a measure of the integrated photon emission over the entire spectral band. It is generally not a function of wavelength, and the excitation spectrum of a fluorophore will thus approximate its absorbance spectrum.

The molar extinction coefficient (ε) is a measure of absorption. The product of ε and Q_f is proportional to fluorescence intensity at subsaturating excitation rates and is a practical measure of fluorescence intensity of a given compound.

Photobleaching of the fluorophore may be a serious problem in CLSM, especially when an area in the specimen is scanned repeatedly during the acquisition of a large stack of confocal sections, or in quantitative fluorescence measurements. It is a poorly understood phenomenon, but it often depends on the presence of molecular oxygen. Thus, removal of O_2 from the mounting medium and/or inclusion of protective agents like singlet oxygen quenchers may alleviate the problem (Tsien and Waggoner, 1995).

CLSM with one fluorophore—single labeling

When the CLSM should be used to study specimens labeled with one fluorophore, the choice of fluorophore is rather straightforward. Obviously, one should try to find a fluorophore with strong fluorescence (i.e., high $Q_f \times \varepsilon$ value), slow photobleaching, a reasonable Stokes shift, and optimal excitation maximum with respect to laser excitation wavelength and tissue autofluorescence (Table 2.8.1).

CLSM with multiple fluorophores—multiple labeling

Fluorophore selection should be such that each has the characteristics defined above for single labeling. Ensure that the excitation curves of the fluorophores are sufficiently well separated to be individually excited by their respective excitation wavelengths. For a CLSM with a mixed Ar/Kr ion laser, this means fluorophores with excitation maxima at or near 488, 568, and 647 nm. Then, ensure that that the emission curves are also sufficiently well separated to be distinguished by the use of proper filters. When these criteria have been fulfilled, the risk of channel crosstalk due to the choice of improper fluorophore combination is greatly reduced. Channel crosstalk occurs when one laser wavelength excites both fluorophores, or is reflected in the other channel, or when the detector and barrier filters do not distinguish the two emission wavelengths (i.e., signal "leakage").

In the author's experience, the optimal combinations of fluorophores currently used in the CLSM in immunofluorescence and fluorescence in situ hybridization (Table 2.8.1) are, when used with the Ar/Kr laser, fluorescein isothiocyanate (FITC) and lissamine rhodamine sulfonyl chloride (LRSC) for double labeling and FITC, LRSC, and Cy-5 for triple labeling (see Fig. 2.8.4A to C). However, the recently introduced Akexa Fluor 488 and 568 will probably prove powerful alternatives to FITC and LRSC, respectively. In all cases, regardless whether one or many fluorophores are to be visualized, consider the following.

First, mount specimens without antioxidants, as each compound affects the various fluorophores in different ways (Florijn et al., 1995). If photobleaching is a problem, choose an appropriate antifading compound (e.g., propyl gallate, *p*-phenylenediamine, DABCO), if possible. This should reduce photobleaching in many (but not all) cases. Because of the differential influence mentioned above, mixing may be a good idea, or commercially available anti-fade-mixtures may be purchased.

It may be advantageous to further explore the use of carbocyanine fluorophores, e.g., Cy2, Cy3, and Cy5. These are compatible with η = 1.5 mounting media, which give superior resolution and reduce the amount of available oxygen. However, dehydration may compromise structural integrity.

It is generally considered preferable to use a fluorophore with a longer excitation maximum than the laser emission line, rather than the other way around if a perfect match cannot be attained. Excitation spectra tend to quickly fall off at wavelengths longer than that of maximum excitability, whereas they tend to have a long "tail" toward shorter wavelengths (see Fig. 2.8.3; Wessendorf and Brelje, 1993).

Finally, use higher antibody concentrations than for conventional fluorescence microscopy. Background may largely be removed by confocal sectioning, and all light is needed.

Table 2.8.1 Fluorophores for CLSM[a]

Compound	λ_{ex} (nm)	λ_{em} (nm)	Laser line (nm) and type	Suitable combinations in multiple labelling
Alexa Fluor 350[b]	350	442	351, Ar UV[c]	All other listed
Alexa Fluor 488	491	515	488, Ar or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 568, Cy-5
Alexa Fluor 568	573	596	568, Kr or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 488, Cy-5
Cy-2, indodimethinecyanine	492	510	488, Ar or Ar/Kr	Cy-3, Cy-5
Cy-3, indotrimethinecyanine	554	566	568, Kr or Ar/Kr	Cy-2, Cy-5
Cy-5, indopentamethinecyanine	650	670	647, Kr or Ar/Kr; 637, He/Ne	All other listed
FITC, fluorescein isothiocyanate	492	520	488, Ar or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 568, LRSC, Texas Red, Cy-5
LRSC, lissamine rhodamine sulfonyl chloride	570	590	568, Kr or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 488, FITC, Oregon Green, Cy-5
Oregon Green 488	490	520	488, Ar or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 568, LRSC, Texas Red, Cy-5
TRITC, tetramethyl rhodamine isothiocyanate	550	570	568, Kr or Ar/Kr	Alexa Fluor 350[b], Cy-5
Texas Red	590	610-620	568, Kr or Ar/Kr	Alexa Fluor 350[b], Alexa Fluor 488, FITC, Oregon Green, Cy-2

[a]Approximate peak wavelengths for excitation and emission for a number of fluorophores often used to conjugated with antibodies in confocal laser scanning immunofluorescence. Note that the values are approximate, as they depend on type of conjugate, conjugation efficiency, pH, and type of spectrofluorometer used for determination.

[b]Alexa Fluor 350 is given as one example only of UV-excited fluorophores, since UV lasers are not commonly used in CLSM setups for analysis of multiple labeling. Fluorophores with similar properties include AMCA (aminomethylcoumarin acetate), Cascade Blue, and DAMC (diethylaminoisothiocyanatophenylmethylcoumarin).

[c]UV excitation requires special optics, that may not be optimal for longer wavelengths.

Choice of Objectives

For confocal fluorescence microscopy of histological sections, any objective that is well corrected for spherical and chromatic aberration at the relevant wavelengths will suffice, in principle. Usually, oil-immersion objectives are used because of their higher numerical aperture, but there are now several brands of high-quality objectives equipped with correction collars for different immersion media, different concentrations of solute (for water-immersion objectives), or different coverslip thickness. It is important to note, that, for UV microscopy, it is necessary to use fluorite, or glass with fluorite characteristics, for optimal performance (for in-depth discussion of different types of objective lenses, see Keller, 1995). The choice of objective is ultimately dictated by the wavelengths used, the preferred immersion medium, and the necessary working distance of the objective.

Scanning

Optimization of $R_{S/N}$ in multiple fluorescence: Single scan or sequential scan?

The factors affecting $R_{S/N}$ have been considered in an earlier section. There are, however, practical aspects concerning the actual sampling of data, i.e., the scanning procedure. It is often claimed that, when analyzing double-labeled specimens, one should strive to scan with two wavelengths and detect two fluorophores simultaneously (single scan). The single scan method, when two excitation wavelengths are used simultaneously, works well if fluorescence intensity and $R_{S/N}$ are similar for both fluorophores. This method gives the most reliable optical sectioning. The drawback of this method is that with one laser effect and two PMTs, more noise in one channel, or channel cross-talk, is likely to occur.

There is no general rule regarding the preference for single or sequential scanning. However, in the author's experience it is seldom possible to achieve optimal $R_{S/N}$ for both fluorophores with the single-scan strategy. Instead, sequential scanning with one wavelength at a time allows finer tuning of laser energy and photon detector for each fluorophore. Thus noise and channel cross-talk are reduced, and $R_{S/N}$ is appreciably better for both fluorophores. The sequential scan method is, however, much more sensitive to movement, especially stepper

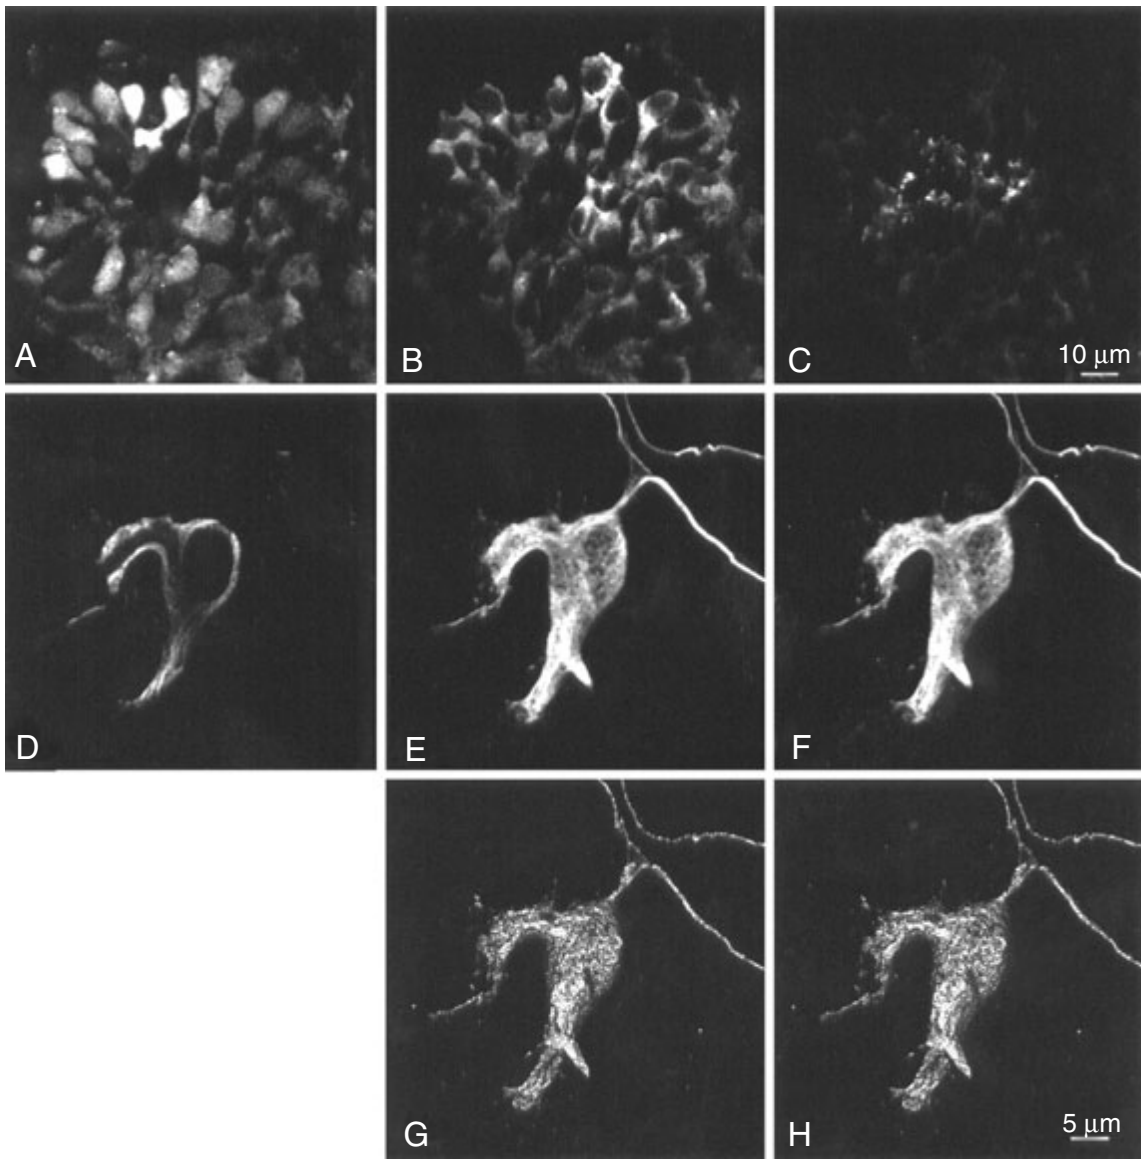

Figure 2.8.4 (**A-C**) Autofocus projections of a three-dimensional Gaussian filtered stack comprising 50 confocal sections, showing photoreceptor cells immunoreactive for serotonin (**A**, LRSC fluorescence), the phototransduction protein arrestin (**B**, FITC fluorescence), and the photopigment apoprotein opsin (**C**, Cy5 fluorescence), in the pineal organ of the salmon. The scanning was performed with a MultiProbe 2001 CLSM, using the excitation wavelengths 488 nm (B), 568 nm (A) and 647 nm of the Ar/Kr laser. (**D**) Confocal section, after three-dimensional Gaussian filtering, of a neuron that exhibits immunoreactivity for acetylated α-tubulin (mouse monoclonal clone 6-11B-1), in the salmon pineal organ. (**E-H**) Stereo pairs of (E, F) an autofocus projection, and (G, H) a surface rendering projection of 100 confocal sections of the same neuron as in (D). Scale bars represent 10 µm in A-C, and 5 µm in D-H.

drift (although modern focus-steppers are actually very reliable).

In either case, it is important to scan with a carefully adjusted laser photon flux. The photon flux should be primarily regulated by the use of NG (neutral gray) filters; usually the laser has an optimum effect range, below which irregularities in the photon flux may occur and disturb the sampling. The photon flux should be adjusted so that, at the given pinhole size and detector setting, an increase in laser power does not further increase the signal or $R_{S/N}$. This adjustment greatly reduces the risk of excitation of other fluorophores at the head or tail of their excitation curves. In some cases, it may be useful to perform repetitive scans for frame averaging or addition. It should, however, be emphasized that channel cross-talk is actually seldom a problem when using the fluorophore combinations mentioned above.

Channel cross-talk: What to do?

If channel cross-talk does occur in spite of the precautions outlined above, one must of course try to eliminate it. One way is to try to adjust laser illumination, pinhole size, and detector gain so that cross-talk is abolished (i.e., in practice, to perform the scanning at suboptimal settings). But, in the author's opinion, it is not a good idea to scan at suboptimal settings; this means losing a great part of the relevant information in the specimen. If the experiment cannot be performed again, and the data have to be collected/saved, one should try to measure the degree of cross-talk already present during the scanning procedure. This is easily done. If one has, for example, a specimen labeled with FITC and LRSC, then first select an area with only FITC label and scan it with the optimal settings for LRSC used in the "real" experiment. Then, conversely, select an area with only LRSC label and scan it with the optimal FITC settings. In this way, datasets are acquired in which one can assess the cross-talk signal levels in the two channels. This level is subtracted from each of the digital images after scanning. With luck, enough relevant information is left, but usually, it is not.

Another case of channel cross-talk, which is not related to the instrumentation and sampling, is when the fluorescent marker substances do not specifically label what they are supposed to. This possibility should also be considered, although it is outside the scope of this text to deal with labeling specificity controls. It is always necessary to determine the specificity of the labeling by the use of appropriate control specimens (Donaldson, 1998).

Image Processing and Presentation

The acquisition of images of optical sections in confocal laser scanning microscopy depends on electronic processing—digitization—of the photon flux from each point in the specimen, and the digitized signal is converted to an image by computer software. Since computer processing is an integral part of confocal laser scanning microscopy, it is necessary to briefly consider some basic principles of image processing. For a brilliant and thorough treatise on image processing, the reader is referred to *The Image Processing Handbook* (3rd ed.; Russ, 1998). Also, a recent compilation and evaluation of available image processing software is available (White, 1995).

First, it is necessary to define the goal of the experiment. Is it to visualize objects or to obtain numerical measurements of objects? Is it to achieve high-resolution images of specific elements labeled with one or more markers? Is it to perform a three-dimensional reconstruction of one or more specific elements? Is it to analyze structural relationships between objects, i.e., cell-to-cell contacts or other contacts, or "colocalization" of substances, or presence of objects within specific boundaries (e.g., *E. coli* bacteria inside epithelial cells)?

Before further analysis, data usually have to be filtered. The choice of filtering procedure depends on the goal(s) outlined above. Filters are used to reduce noice, smooth the signal, and enhance features (especially edges). By filtering, pixel intensity is adjusted by comparison with neighboring pixels' intensities within a block of pixels (a kernel). A kernel may be a two-dimensional or a three-dimensional kernel and may be of different sizes and configurations (i.e., square/cubic, rectangular, hexagonal, octogonal, "round"). Application of a two-dimensional kernel means that pixels are compared only in the plane—i.e., one confocal section—whereas with a three-dimensional kernel, pixels are compared within the confocal section and between adjacent sections. Pixel comparison is done by averaging, ranking, or a combination of averaging and ranking (so-called hybrid filters). Adequate noise suppression requires that the pixels in the image must be much smaller than the smallest important detail (remember the Nyquist criterion). Smoothing implies replacement of individual pixels that deviate strongly. Edge-definition filters are based

on comparisons of rates of change in pixel intensity.

Kernel averaging smooths the image but reduces contrast, blurs edges, and displaces boundaries. The most commonly used filters for kernel averaging are Mean filters and Gaussian filters. With a Mean filter, the central pixel of the kernel acquires the mean value of the kernel. With a Gaussian filter, the pixels are weighted according to a Gaussian distribution and the mean of the weighted pixel values is assigned to the central pixel. By changing the standard deviation of the Gaussian distribution, one can alter the weighting of pixels in the kernel. Thus, contrast reduction and blurring is much reduced compared to the Mean filter, and the Gaussian filter is the most versatile and popular averaging filter.

As previously mentioned, it is possible to use kernels of different sizes. A large kernel smooths the signal more, and is not always detrimental to preservation of fine detail, although the edges are more blurred. Also, repeated use of a small kernel is equivalent to one use of a larger kernel. Considering the blurring and displacement of edges, kernel averaging is not optimal as a preamble to quantitative analysis.

With neighborhood ranking filters, the image is less smoothed but edges are not displaced. There are several types of neighborhood ranking filters, especially for edge detection. For an overview of edge detection filters, refer to Russ (1998). The common Median filter, by which the central pixel acquires the median value of the kernel, is excellent for removal of "shot noise," i.e., isolated spikes of extreme values, as it suppresses spikes smaller than kernel width. Moreover, because the Median filter does not average or weigh pixels, and neither reduces brightness differences nor shifts boundaries, it gives minimal degradation of edges and permits repeated application without increased blurring. A Mode filter, or a Truncated Median filter, is a useful filter for assymetric distributions of pixel intensities. With the Mode filter, the central pixel acquires the value of the mode (i.e., the highest point of the distribution curve), and pixel intensities farthest from the mode are removed.

Confocal images are usually obtained as stacks of images representing consecutive confocal sections. They may be presented as single selected confocal sections, or as a mosaic layout of the sections in the series. Often, one wishes to present an overview of the scanned area by projecting all (or selected) sections onto one plane, as if one were viewing all section planes simultaneously in focus. With a so-called extended-focus projection, the intensity values of all pixels in each x,y coordinate are added along the z-axis. With a so-called autofocus projection, the maximum intensity value along each z-line is extracted from the data. The autofocus projection method produces the sharpest images, especially when performed on unfiltered images; a Median or Gaussian filter may then be applied to the resulting projected image to remove shot noise and/or smooth the image. Extended-focus projections are usually best performed on stacks that have already been filtered.

With most computer software designed for confocal microscopy, it is possible to create "sections" through the sampled volume in virtually any direction. It is also possible to view projections of the sampled volume, or parts thereof, from any direction, and thus create a series of images that simulate rotation of the volume. Moreover, it is possible to create surface simulations of the labeled elements, as well as stereo pairs. It is beyond the scope of this unit to deal with this issue in detail; Figures 2.8.4, 2.8.5, and 2.8.6 give a sample of presentation options.

The Choice: Wide-Field Microscopy or Confocal Microscopy

In some instances it is not desirable to use confocal microscopy. There are drawbacks to using confocal microscopy in comparison to wide-field (WF) microscopy, regardless of whether the image is captured on film (photomicrography) or with a cooled CCD (charge-coupled device) array camera. The most dramatic drawbacks are that the time required to achieve an image in confocal microscopy is much longer and that the sampling area per image is much smaller when sampling with reasonable confocality and optimal sampling frequency. Thus, WF microscopy is preferable when spatial information is of less value and it is possible to work with thin tissue sections (<3 μm), when large numbers of images are to be collected for analysis, and/or when large areas have to be sampled.

It is also possible to use WF microscopy for three-dimensional analysis. This requires mathematical reduction of image degradation by light from planes other than the focal plane. This process—deconvolution—may yield images comparable with those obtained by CLSM, but it may be extremely time-consuming unless appropriate computer instrumenta-

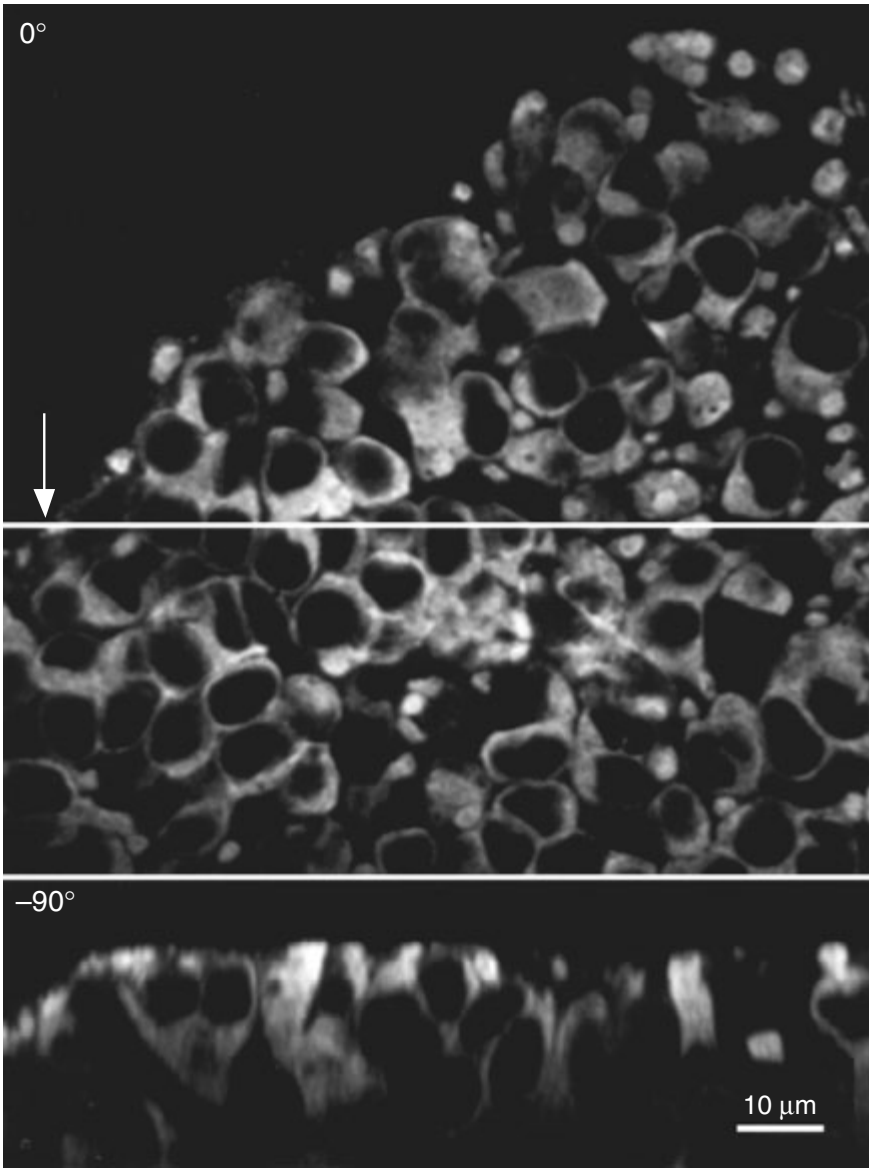

Figure 2.8.5 Confocal section (0°) of a whole-mounted salmon pineal organ, showing photosensory cells exhibiting immunoreactivity for the phototransduction protein arrestin (mouse monoclonal clone 5C6-47; courtesy of Dr. L. Donoso). The section was chosen out of a stack of 80 confocal sections. The line indicated by the arrow shows the plane of section through the stack shown below (–90°); the thickness of this digital section corresponds to a 0.5-μm-thick physical section. Note that the resolution and fluorescence intensity decreases dramatically with depth. The scanning was performed with a MultiProbe 2001 CLSM, using the excitation wavelength 488 nm (FITC fluorescence).

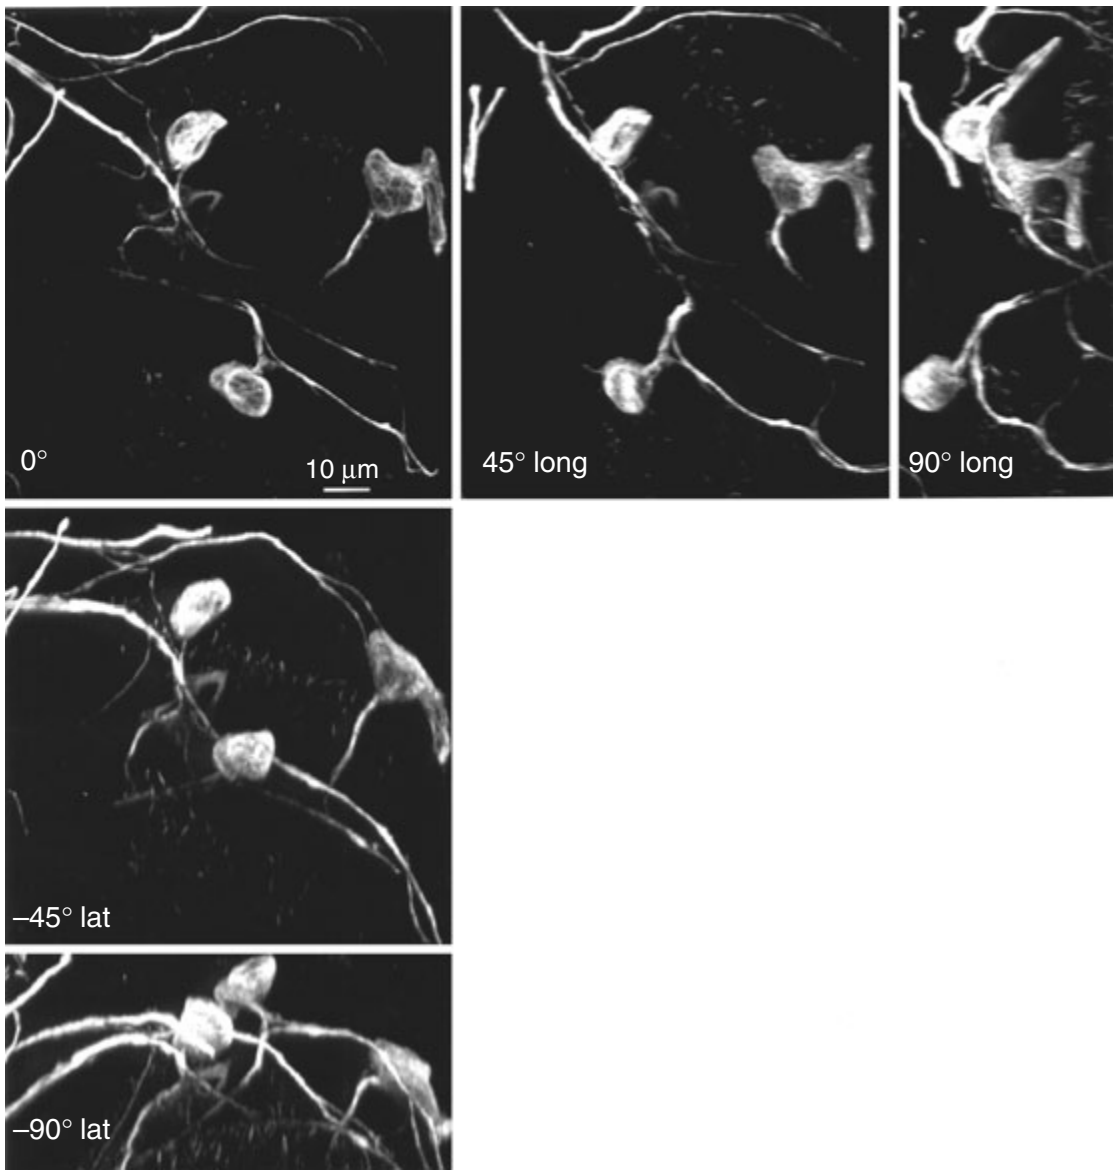

Figure 2.8.6 Autofocus projections of 125 confocal sections of a region in the salmon pineal organ that contains three neurons that exhibit immunoreactivity for acetylated α tubulin (mouse monoclonal clone 6-11B-1). Tilting the volume around the *x* axis (–45° or –90° lat.), and around the *y* axis (–45° or –90° long.) allows inspection of the volume from different angles. Presentation of such views as stereo pairs (not shown here) are of great help in determining spatial relationships between cells. When viewing the volume from a 90° angle, it is apparent that thin structures, like axons, appear broader than at 0°. This is because axial resolution is worse than lateral resolution. The scanning was performed with a MultiProbe 2001 CLSM, using the excitation wavelength 488 nm (FITC fluorescence).

tion is used (Shaw and Rawlins, 1991; Shaw, 1995).

Future Directions

There are some fairly recent developments that are of special interest in the field of confocal microscopy. One relies on the use of two-photon excitation with a tunable pulsed high-energy titanium (Ti)/sapphire laser. In two-photon excitation, two photons of longer wavelengths (λ_1 and λ_2) are simultaneously absorbed, and their combined energies excite a fluorophore that would otherwise require a single photon with a shorter wavelength $(1/\lambda_1 + 1/\lambda_2)^{-1}$. This simultaneous absorption can only take place in the plane of focus. Thus, this technique gives excellent optical sectioning even without a detector pinhole, and out-of-focus bleaching is dramatically less than in CLSM. Moreover, it is possible to use UV-excited fluorophores without special UV-laser and UV-optics (Denk et al., 1995).

Another development relies on intensity modulation of two laser beams of different wavelengths. The laser beams, which illuminate the specimen simultaneously and excite one fluorophore each, are intensity-modulated at different frequencies. The fluorescent light is divided into two wavelength regions, which are detected by two PMTs whose output signals are connected to lock-in amplifiers. Being frequency-selective, the lock-in amplifiers can distinguish the contributions to the total fluorescence signal from the two laser beams. This technique strongly reduces cross-talk between the channels (Carlsson et al., 1994).

While the intensity modulation technique relies on distinguishing the emission spectra, there is another technique that relies on the distinguishing of fluorophores by their fluorescence lifetimes. The latter technique may be used to distinguish fluorophores with overlapping emission spectra, under certain given circumstances, and may be used in parallel with "normal" confocal imaging on the same instrument (Brismar and Ulfhake, 1997).

During the quest for further improvement of the axial resolution, confocal microscopes in the 4Pi and Theta configurations have been developed. Such microscopes can also be operated in the two-photon mode (Lindek et al., 1995). Due to their complex configurations, it is not likely that they will be widely used in the analysis of histological specimens.

Typical Results

Fluorescent structures should stand out crisply against a virtually black background in a single optical section. In relatively thin (physical) sections, and with bright fluorescence, it may be possible to achieve *x*/*y* images that are of superior resolution to that possible with conventional fluorescence microscopy. This is very useful for fine-grained analysis of intracellular compartmentalization and possible colocalization of various antigens. However, the great improvement over conventional fluorescence microscopy is achieved when the fluorescence is sufficiently bright and resistant to photobleaching to allow the acquisition of large numbers of confocal sections for subsequent reconstruction of three-dimensional images. The tissue volume that may be investigated, i.e., the area and maximal depth from which images may be obtained, is determined by the characteristics of the objective lens (magnification, NA, and working distance) as well as by the match in refractive indices of the immersion and mounting media, the wavelength of light, and the scattering and refraction of light by the specimen. In optimal specimens, this would mean that it is possible to image structures at depths near the limit of the working distance; in practice, however, image quality (especially depth resolution) deteriorates with depth, the rate of deterioration being dependent on the factors above.

Measurement of Expression of the HSP70 Protein Family

The HSP70 (heat shock protein 70) superfamily is comprised of different genes encoding proteins of molecular mass between 68 and 78 kDa, including the rodent HSP72 (inducible HSP70), HSP73 (constitutive HSP70), and the glucose-regulated proteins, GRP75 and GRP78. These proteins have the common ability to bind and hydrolyze ATP. The functions of the HSP70 family are diverse but generally involve interaction with and stabilization of unfolded and/or nascent proteins, mediating their proper folding, preventing aggregation, and facilitating transport to and across membranes (molecular chaperoning). Members of the HSP70 family are inducible by a variety of stimuli including heat shock, ischemia, toxic metals, amino acid analog, and some chemotherapeutic and anesthetic agents (see Table 2.9.1). Induction of mRNA is often observed 4 to 8 hr after the insult and can persist up to 24 hr. In contrast, induction of proteins peaks 24 to 48 hr (or later) after the stimulus. Because HSP73 mRNA and protein is constitutively present in most tissues, its induction by different stimuli is generally very small compared to that of HSP72 or the other HSP70 members.

This unit describes selected methods for the detection and quantification of the HSP70 family of proteins and mRNAs in cell culture and whole tissue—northern blot hybridization (see Basic Protocol 1), in situ hybridization with film (see Basic Protocol 2) or emulsion autoradiography (see Alternate Protocol 1), metabolic labeling and SDS-PAGE (see Basic Protocol 3), immunoblotting (see Basic Protocol 4 and Alternate Protocol 2), and immunohistochemistry (see Basic Protocol 5 and Alternate Protocols 3 and 4). This unit also contains a protocol for combining TUNEL with immunohistochemistry to detect cells that are dying and expressing stress proteins (see Alternate Protocol 5). Support protocols are included for counterstaining (see Support Protocol 1), coverslipping slides (see Support Protocol 2), Coomassie blue staining of proteins in gels (see Support Protocol 3), reversible staining of proteins on membranes (see Support Protocol 4), and preparing gelatin-coated slides (see Support Protocol 5).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

QUANTITATIVE DETECTION OF HSP70 FAMILY mRNA BY NORTHERN BLOT

BASIC PROTOCOL 1

Gene expression results in the production of RNA transcripts within cells. Northern blot analysis is a useful method to quantify the amount of mRNA present in tissue extracts. It is also the method of choice to determine if the oligonucleotide probe used for in situ hybridization experiments (see Basic Protocol 2) is detecting the right size transcript(s) under similar salt, formamide, and temperature conditions. Table 2.9.2 reports the sequence of common antisense oligonucleotide probes used for the detection of the HSP70 gene family in rodents. The oligonucleotide used to detect the inducible hsp70 mRNA produces two bands (hsp70 homologs) on northern blots of brain tissue samples after ischemia, heat shock, acidosis, and amphetamine treatment (Miller et al., 1991; Kinouchi et al., 1993; Narasimhan et al., 1996). In contrast, hsc70, grp75, and grp78 oligonucleotides each recognize a single transcript (Miller et al., 1991; Massa et al., 1995, 1996). The conditions described in the present protocol are adapted for the use of 30- to 45-bp long oligonucleotides.

Contributed by Marcelle Bergeron and Frank R. Sharp
Current Protocols in Toxicology (2001) 2.9.1-2.9.40

When working with RNA during northern blotting (Basic Protocol 1) or in situ hybridization (Basic Protocol 2), care should be taken to avoid contamination by RNases. It is therefore important to wear clean, powder-free disposable gloves at all time when handling all reagents and solutions. The use of RNase-free solutions (made up with DEPC-treated water, unless otherwise stated) is recommended for the preparation of all solutions before and during the hybridization steps. Because DEPC-treated water from commercial sources (e.g., from Ambion) is quite expensive. The use of low-cost, DEPC-treated water made in the lab is recommended. It is also recommended to use sterile

Table 2.9.1 Experimental Treatments That Induce the HSP70 Family in Brain Tissue

Inducer	Treatment	Species	HSP72[a]	HSP73[a]	GRP75[a]	GRP78[a]
Heat shock						
In vitro	0.5-3.0 hr incubation at 43.5°C	Primary mouse astrocytes	+	–	ND	ND
Ischemia						
Global	≥2-3 min of transient bilateral carotid artery occlusion	Gerbil	+	+	+	+
Focal	≥30 min of transient unilateral intraluminal occlusion of the middle cerebral artery	Rat	+	+	+	+
Focal	2-3 hr combined unilateral permanent carotid occlusion and concurrent 8% O_2 exposure	Rat (newborn)	+	ND	ND	ND
In vitro	3-4 hr of oxygen and glucose deprivation	Primary mouse astrocytes	+	–	ND	ND
Other inducers						
Acidosis	40 min of incubation in media at pH 5.2	Primary rat astrocytes	+	ND	ND	ND
Subarachnoid hemorrhage	Injection of 0.15 ml of lysed blood into the cisterna magna	Rat	+	ND	ND	ND
Kainic acid	10 mg/kg i.p.	Rat	+	+	ND	+
Ketamine	40-160 mg/kg i.p.	Rat	+	ND	ND	ND
MK-801	0.1-10 mg/kg i.p.	Rat	+	ND	ND	ND
Phenylcycline	5 mg/kg i.p.	Rat	+	ND	ND	ND

[a]+, induction; –, unchanged. Abbreviations: GRP, glucose-regulated protein; HSP, heat shock protein; i.p., intraperitoneal injection; ND, not determined.

Table 2.9.2 Sequence of Antisense Oligonucleotide Probes Commonly Used for Detection of HSP70 Family mRNAs in Rat Tissues

Gene	Oligonucleotide sequence	Reference	Expected band size
hsp70	5′-CGATCTCCTTCATCTTGGTCAGCACCATGG-3′	Narasimhan et al. (1996)	2.5-2.7 and 2.9 kb
hsc70	5′-ATGCCTGTGAGCTCAAACTTCCCAAGCAGG-3′	Miller et al. (1991)	2.55 kb
grp75	5′-GGTCAAATCAACCCCTGTCTCCCTCTTGAACTC-3′	Massa et al. (1995)	3.3 kb
grp78	5′-CTTCAGATCAGAAGTCTTCCAACACTTTCTG-3′	Massa et al. (1995)	2.7 kb

glassware, microcentrifuge tubes, and pipet tips. The use of RNase-free solutions is not required in post-hybridization procedures because of the resistance of RNA:RNA hybrids to RNase degradation. At this stage, the use of deionized water is adequate.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Materials

Animals subjected to a stressful stimulus (Table 2.9.1)
Anesthesia cocktail (see recipe)
TRIzol reagent (Life Technologies; TRIzol Reagent, Sigma; or RNA STAT-60, Tel Test)
5:1 (v/v) acid phenol/chloroform solution, pH 4.7 (Ambion)
Horizontal formaldehyde/1% (w/v) agarose gel (*APPENDIX 3E*)
Nylon membrane, positively charged (e.g., Hybond, Amersham; Nytran SuPerCharge, Schleicher and Schuell; BrightStar-Plus, Ambion)
0.02% (w/v) methylene blue staining solution (see recipe)
2× and 20× SSC (see recipe)
^{32}P-labeled antisense oligonucleotide probe (Table 2.9.2) and sense control probe, (single-stranded, unlabeled oligonucleotides are obtained from Oligos Etc., or other commercial source)
Prehybridization solution (for recipe, see *APPENDIX 3E*, Basic Protocol, step 25)
50% (w/v) dextran sulfate (see recipe)
2× and 1× SSPE (see recipe)
20% (w/v) SDS

UV cross-linker (Stratagene)
Sealable bag or glass hybridization bottle
Hybridization oven or 42°C shaker water bath

Additional reagents and equipment for RNA extraction, agarose gel electrophoresis (*APPENDIX 3A*), oligonucleotide labeling (*APPENDIX 3E*), and northern blot hybridization (*APPENDIX 3E*)

NOTE: To protect from RNase contamination and fingerprint smudges, always wear clean, powder-free gloves when working RNA. Do not reuse gloves.

Prepare cell lysate

1. Subject test animal to stressful stimulus. At the appropriate time after stressful stimulus (see Table 2.9.1), anesthetize animal by intraperitoneal injection of anesthesia cocktail, excise tissue, and either freeze it promptly on powdered dry ice and store at −70°C until use or start the RNA extraction procedures immediately (see *APPENDIX 3E*).

   The speed at which the excision and processing of the tissue are performed is crucial to reduce RNA degradation.

2. Extract total RNA using TRIzol reagent and 5:1 acid phenol/chloroform (*APPENDIX 3E*).

   Isolation of mRNA using commercially available kits (such as Fastrack 2 from Invitrogen or Oligotex mRNA extraction kit from Qiagen) is highly recommended for tissue samples suspected to have a low abundance of the mRNA of interest.

Separate and immobilize RNAs on membrane

3. Size-fractionate an equal amount of total RNA or mRNA per sample (cell lysate) by electrophoresis on a horizontal formaldehyde/1% agarose gel (*APPENDIX 3E*). Use 4 to 10 μg mRNA or 20 to 40 μg total RNA per lane.

4. After separation, transfer the RNA onto a positively charged nylon membrane (*APPENDIX 3E*) using upward (Fig. A.3E.1A) or downward (Fig. A.3E.1B) capillary flow transfer.

   Make sure that the agarose gel is no more than 5 to 6 mm thick, otherwise it will reduce the transfer efficiency.

5. Cross-link RNA to the membrane in a UV cross-linker according to the manufacturer's instructions.

6. Stain the membrane with 0.02% methylene blue staining solution until the lanes become visible (~15 min). Mark the RNA marker bands on the side of the membrane with a pencil or a fluorescent pen or dye.

7. Destain with 2× SSC. Cut one corner of the membrane away to establish the orientation of the lanes.

Hybridize and detect RNA

8. Prepare and purify a [^{32}P]3′-end-labeled antisense (see Table 2.9.2) or sense oligonucleotide probe with terminal deoxynucleotidyl transferase (*APPENDIX 3E*).

   For the labeling reaction, avoid DEPC-treated water because DEPC residues may inhibit enzyme activity and decrease labeling efficiency. Use sterile water free of nuclease.

9. Transfer the membrane to a sealable bag or a glass hybridization bottle. Prehybridize the membrane in 8 ml/10 cm^2 prehybridization solution (for recipe, see *APPENDIX 3E*, Basic Protocol, step 25) for ≥2 hr, 42°C, in either a hybridization oven (for glass bottle) or submerged in a shaker water bath (for sealable bag).

10. Add 2 ml of 50% dextran sulfate to the prehybridization solution and mix well (total volume 10 ml/10 cm^2).

11. Add 10^6 to 10^7 cpm labeled probe per milliliter prehybridization solution and hybridize overnight at 42°C.

12. The next day, wash the membrane with prewarmed solutions as follows:

    2× SSPE containing 0.1% SDS for 15 min at 42°C
    2× SSPE containing 0.1% SDS for 15 min at 42°C
    1× SSPE containing 0.1% SDS for 15 min at 42°C.

13. Check the specific activity of the membrane after each wash by holding a Geiger counter 2 to 3 cm above the membrane surface. At the first sign of significantly decreased signal intensity, stop the washing procedures.

    The signal should be very intense after the first wash. With increasing wash stringency, the signal should decrease.

    If necessary, increase the temperature by 5°C after each subsequent wash as described below. If the membrane is still too radioactive after washing at 60°C, decrease the SSPE concentration to 0.5×, 0.2×, and then 0.1× SSPE. The SDS concentration remains the same (0.1%) throughout wash procedures. Increasing the temperature and decreasing the SSPE concentration provide more stringent conditions that facilitate the elimination of mismatched probe, thus decreasing non-specific background. The washes would then be:

1× SSPE containing 0.1% SDS for 15 min at 45°C
1× SSPE containing 0.1% SDS for 15 min at 50°C
1× SSPE containing 0.1% SDS for 15 min at 55°C
1× SSPE containing 0.1% SDS for 15 min at 60°C.

14. Drain the excess solution, seal the wet membrane in plastic wrap, and expose to an autoradiographic film at −70°C (*APPENDIX 3E*) for 1 to 7 days, depending on the abundance of the mRNA of interest and the specific activity of the probe.

15. Develop the film and visualize the bands.

    The probes listed in Table 2.9.2 should detect bands of the indicated sizes.

    Wet membranes can be stripped from bound radioactive oligonucleotides and reprobed with another labeled oligonucleotide (APPENDIX 3E) for direct comparison of different mRNAs on the same blot.

16. *Optional:* To account for differences in loading and mRNA concentration/integrity, strip the membrane (*APPENDIX 3E*) and reprobe with another oligonucleotide probe targeting a housekeeping gene (i.e., gene for which constitutive expression does not change with a given treatment).

    Ideally, the bands from any transcript of interest should always be normalized against a housekeeping gene like cyclophilin (5′-GAGTTGTCCACAGTCGGAGATGGTGATCTT CTTGCTGGTCTTGCC-3′; expected transcript is ~1 kb). Other housekeeping genes such as actin, GAPDH, and 18S ribosomal RNA have been used successfully.

DETECTION OF HSP70 FAMILY mRNA ON TISSUE SECTIONS BY IN SITU HYBRIDIZATION

BASIC PROTOCOL 2

Once the specificity of an oligonucleotide probe has been established by northern blot analysis (see Basic Protocol 1), in situ hybridization is used to localize specific RNA transcripts in tissue sections or cell cultures. In situ detection of mRNAs is based on concepts and procedures similar to those described for northern blotting except that it is performed directly on tissue sections. The present method is optimized for use with fresh frozen (unfixed) tissue sections. After hybridization, sections are washed, dried, and exposed directly to an autoradiographic film.

Alternatively, to obtain a better resolution at the single cell level, each radiolabeled slide can be dipped directly in photographic emulsion. Developed silver grains can be observed directly on the tissue sections (see Alternate Protocol 1).

When working with RNA during both northern blotting (Basic Protocol 1) or in situ hybridization (Basic Protocol 2), care should be taken to avoid contamination by RNases. It is therefore important to wear clean, powder-free disposable gloves at all time when handling all reagents and solutions. The use of RNase-free solutions (made up with DEPC-treated water, unless otherwise stated) is recommended for the preparation of all solutions before and during the hybridization steps. Because DEPC-treated water from commercial sources (e.g., from Ambion) is quite expensive, the use of low-cost, DEPC-treated water made in the lab is recommended. It is also recommended to use sterile glassware, microcentrifuge tubes, and pipet tips. The use of RNase-free solutions is not required in post-hybridization procedures because of the resistance of RNA:RNA hybrids to RNase degradation. At this stage, the use of deionized water is adequate.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Materials

Animals subjected to a stressful stimulus (Table 2.9.1)
Anesthesia cocktail (see recipe)
5 M DTT (see recipe)
[^{35}S]- or [^{33}P]-labeled antisense oligonucleotide probe (Table 2.9.2) and sense control probe (single-stranded, unlabeled oligonucleotides are obtained from Oligo Etc. or other commercial source)
In situ hybridization cocktail (see recipe)
10 mg/ml heat-denatured salmon sperm DNA stock
1× SSC (see recipe), sterile, 55°C
H_2O, deionized, sterile
75%, 95%, and 100% ethanol

Dissecting instruments
Isopentane on powdered dry ice bath
Cryostat
Precoated slides with painted corners (e.g., ProbeOn or Superfrost Plus, Fisher Scientific)
Moist chamber with cover
Parafilm
Slide rack
Staining dish in a 55°C water bath
Hair dryer
Autoradiographic cassette
X-ray film (Kodak SB5 for manual processing or BioMax MR one sided emulsion for automated processor)

Additional reagents and equipment for oligonucleotide labeling (*APPENDIX 3E*)

NOTE: To protect from RNase contamination and fingerprint smudges, always wear clean, powder-free gloves when working RNA. Do not reuse gloves.

Prepare tissue

1. Subject test animals to stressful stimulus (see Table 2.9.1).
2. At the appropriate time after treatment, euthanize animals under deep anesthesia produced by an intraperitoneal injection of anesthesia cocktail. Quickly excise the tissue and freeze promptly in a bath of isopentane on powdered dry ice.

   Total sterility is not necessary at this point as long as all these steps are performed quickly.

3. Cut 14- to 20-µm sections with a cryostat and collect the slices on coated slides (e.g., ProbeOn or Superfrost Plus). Store tissue sections in a slide box at −70°C until analysis. Do not thaw and freeze again.

   The use of precoated slides is highly recommended for this step. These slides have a special coating that electrostatically adheres tissues sections to the glass without the need of special protein coating. It also reduces the slide manipulation that could introduce contaminants and RNases. Always wear gloves while manipulating the slides.

Hybridize with probe

4. Prepare and purify a [^{35}S] or [^{33}P]-3′-end-labeled antisense (see Table 2.9.2) or sense oligonucleotide probe with terminal deoxynucleotidyl transferase (*APPENDIX 3E*).
5. Just before hybridization, take the slides with specimen from the freezer and air dry for ~1 hr at room temperature.

   Always use gloves when handling the slides.

6. Determine the total amount of hybridization solution needed (~200 to 300 µl of hybridization solution for each pair of slides). Make the hybridization solution by mixing in the following order:

   12 µl 5 M DTT
   10^6 to 10^7 cpm labeled oligonucleotide probe
   In situ hybridization cocktail up to 1000 µl
   25 µl 10 mg/ml heat-denatured salmon sperm DNA stock.

   Antisense and sense oligonucleotide probes are both used with this method. Whereas the antisense probe hybridizes to the mRNA of interest, the sense probe is used to determine the level of nonspecific hybridization which should always be very minimal.

7. Pipet 200 to 300 µl radioactive hybridization solution on the surface of one slide and carefully apply another slide (face down) on top of it. Do this slowly to avoid trapping air bubbles on the slices.

   While facing each other, the tissue specimen on each slide can be incubated simultaneously in the viscous hybridization solution trapped between the two overlaying slides (Superfrost or equivalent slides have painted corners which are slightly elevated from the slide's surface, thus allowing this type of overlaying). This approach minimizes the amount of radioactive cocktail used and handled.

8. Place the slide sandwiches flat in a moist chamber containing one layer of wet paper towels at the bottom. Place a cover on the chamber and seal with Parafilm. Incubate 12 to 18 hr in an incubator-oven at 37°C.

Wash slides

9. The next day, separate the slides gently and rinse two times in 1× SSC, each time for 1 to 2 min, at room temperature.

10. Place the wet slides in a slide rack with the tissue sections all facing in the same direction.

11. Use a staining dish placed at the bottom of a 55°C water bath and immerse slides four times for 15 min in prewarmed, 55°C, 1× SSC solution (change the solution in between each 15-min wash) and a final 1× SSC wash for 1 hr at room temperature (i.e., outside the water bath).

    At this stage, the use of DEPC-water in the wash solutions is not necessary. The use of clean dishes and deionized water to make up the wash solutions is sufficient to preserve the quality of hybridization and the signal intensity.

12. Rinse 2 min in sterile water at room temperature. Dehydrate 2 min each in 75%, 95%, and 100% ethanol. Air dry the slides thoroughly using a hair dryer for ~1 hr at the lowest temperature setting.

Autoradiograph the slides

13. Once dry, tape the slides (face up) on a piece of cardboard and place at the bottom of an autoradiographic cassette.

14. In a dark room under safelight conditions, apply the emulsion side of an X-ray film directly on the radioactive slides and close the cassette tightly. Expose at room temperature for an appropriate amount of time, which depends on the abundance of the transcript in the specimen and the specific activity of the probe.

    For a medium-to-high abundance of mRNA transcript, the ^{35}S-probe signal is clearly detectable after 1 to 2 weeks exposure. ^{33}P-probes usually give stronger signal, so exposure time can be decreased.

ALTERNATE PROTOCOL 1

EMULSION AUTORADIOGRAPHY

Emulsion autoradiography coupled with counterstaining (see Support Protocol 1) allows detection of individual cells that are expressing the mRNA of interest. Individual slides are coated with an emulsion, incubated, developed, and counterstained.

Materials

NTB-2 autoradiographic emulsion (Kodak)
Slides with radioactively hybridized sections (see Basic Protocol 2, step 12)
D19 or Dektol developer and fixer (Kodak), freshly made
Milli-Q-purified water

43°C water bath
Black light-tight slide boxes
Dessicant packs (Drierite)
Dipping container
Forceps with blunt ends (optional)
Slide rack
Slide dryer (optional)
Black electrical tape
Staining dishes
Light microscope

NOTE: Use very clean glassware and reagent-grade solutions. Wear powder-free gloves for all procedures.

CAUTION: All procedures involving autoradiographic emulsion should be performed in complete darkness or under safelight conditions. The autoradiography emulsion must be refrigerated at 4°C until use. Because it is in a solid form at 4° to 10°C, the emulsion must be liquified by heating to ~45°C before use. Do not freeze or store the emulsion at room temperature to avoid high background fog and loss of detection ability.

Prepare the emulsion

1. In a darkroom under safelight conditions, place the 4-oz. (118-ml) bottle of NTB-2 autoradiographic emulsion in a water bath between 43° and 45°C. Gently swirl the emulsion bottle to speed up the liquefaction process.

   Too much agitation can result in the formation of bubbles that can interfere with the autoradiography. Liquefaction usually takes 45 to 55 min.

2. Pour the autiradiographic emulsion into a clean dipping container placed at 43°C.

3. Hold each radioactive slide at the frosted end with two fingers or with blunt-end forceps and slowly dip in the warm NTB-2 autoradiographic emulsion. Withdraw each slide slowly, drain the excess emulsion on the edge of the emulsion container, and place slide vertically against the wall or a box to air dry ≥1 hr, in complete darkness.

   Optionally, when the slides are dry to the touch (~15 min), a slide dryer may be used to accelerate the drying process.

4. Place the dried slides in a clean, black light-tight slide box containing a dessicant pack. Close the box and seal with black electrical tape, cover the entire box with foil, and store at 4°C.

   The slides should be stored in a refrigerator that contains no isotopes or organic chemicals that could react with the emulsion.

5. Expose slides two and a half to three times longer than the time generally required for direct X-ray film autoradiographic exposures.

   Several exposure times may be tested to determine optimal conditions. Because it requires long exposure periods, the dipping method is more appropriate for slides hybridized with ^{35}S-labeled probes, which have a radioactive half-life of 87 days compared with 25 days for ^{33}P-labeled probes.

Develop slides

6. Take the slide box out of the 4°C refrigerator and allow to warm up at room temperature before proceeding.
7. In the darkroom, prepare the following in separate staining dishes at room temperature:

   Freshly made D-19 developer
   Milli-Q-purified water
   Freshly made D-19 fixer
   Cold tap water.

8. In the dark, transfer the slides in a slide rack and develop as follows:

   4 min in D-19 developer
   1 min in Milli-Q-purified water (stop solution)
   5 min in D-19 fixer.

   Agitate gently during each step.

9. Rinse in gently running cold tap water for 30 min.

   It is now safe to turn on the lights.

10. Rinse briefly in Milli-Q-purified water. While still wet, scrape off the emulsion on the back of each slide with a razor blade.
11. Air dry the slides in a dust-free environment, counterstain if needed (see Support Protocol 1), and apply coverslips (see Support Protocol 2). Examine with a light microscope.

    The presence of mRNA can be visualized under a light microscope. mRNA appears as dark black spots of developed silver grains directly on the tissue specimen. Counterstaining is recommended to help identify the cellular localization of the signal.

COUNTERSTAINING WITH CRESYL VIOLET (NISSL)

SUPPORT PROTOCOL 1

Counterstaining of slides is used to permit visualization of the cellular structure of tissues.

Materials

Dry tissue specimen on slides from immunohistochemistry or in situ hybridization
Chloroform (optional)
Ether (optional)
70%, 95%, and 100% ethanol
Milli-Q-purified water
Cresyl violet staining solution (see recipe)
Glacial acetic acid

Slide racks
Glass staining dishes

NOTE: Perform all steps at room temperature, in a well-ventilated fume hood. Wear gloves at all times.

Prepare slides

1. Fill slide racks with the slides. Orient them so that the sections all face the same direction.
2. *Optional:* Immerse the slides in a glass staining dish filled with chloroform and incubate for 3 to 5 min to delipidize the tissue. Drain excess chloroform and incubate slides in ether for 3 to 5 min.

   Delipidization may be necessary in tissues with high lipid content such as the adult rat brain. For other tissues and cell cultures, it may be omitted. Try to stain a few slides first without the chloroform/ether steps to determine whether delipidization is required.

Stain sections

3. Prepare in separate glass staining dishes 70%, 95%, and 100% ethanol, Milli-Q-purified water, and Cresyl violet solution.
4. Incubate slides in 100% ethanol for 3 min. Drain excess solution and rinse slides in 95% ethanol for 3 min.
5. Drain excess solution and rinse slides in 70% ethanol for 3 min.
6. Drain excess solution and rehydrate slides in Milli-Q-purified water for 3 min.
7. Drain excess water, immerse in Cresyl violet solution and stain 5 to 10 min.
8. Drain excess staining solution and wash in water for 2 min.

Dehydrate/destain slides

9. Drain excess water and immerse in 70% ethanol. To promote the destaining process, add a few drops of glacial acetic acid in the staining dish and mix gently. Incubate 1 to 2 min.
10. Drain the excess solution and incubate in 95% ethanol 1 to 2 min.
11. Drain the excess solution and incubate in 100% ethanol 1 to 2 min.

    Each dehydration step also destains the tissue specimen. Depending on the nature and the thickness of the tissue stained, the incubation times for each ethanol/destain bath may need to be readjusted. The thinner the section, the easier it is for the Cresyl violet to penetrate the cells and the easier it is to wash the dye away in subsequent destaining steps. Very thick (>100 μm) sections may need the delipidization steps and longer destaining incubation times. Sections that show too weak staining by step 11 can be restained as follows: perform steps 10, 9, and 8, followed by steps 7 to 11.

12. Proceed with the dehydration steps and coverslip as described in Support Protocol 2.

SUPPORT PROTOCOL 2

COVERSLIPPING SPECIMENS ON SLIDES

Coverslipping specimens mounted on slides following immunohistochemistry or histological staining is a crucial step that helps preserve the stained tissue specimen and significantly increases the optical quality during light-microscope observations. It involves a brief surface rehydration of the specimens to wash off the excess salts and impurities that could interfere with the true staining signal. This is followed by successive dehydration in 75%, 95%, and 100% ethanol and clearing solutions such as xylene or Hemo-D. The specimen is then covered with a small amount of suitable water-repellant mounting medium, and a thin-glass coverslip is applied on its surface. All procedures should be performed at room temperature in a well-ventilated fume hood. Wear gloves at all times. The method described here is recommended for tissue specimen subjected to emulsion dipping after in situ hybridization (see Alternate Protocol 1), Cresyl violet

staining (see Support Protocol 1), and all chromogenic immunoreactions (see Basic Protocol 5). It is not recommended for specimen labeled with fluorescent tags (see Alternate Protocol 4).

Materials

Tissue specimens mounted and dried on slides
70%, 95%, and 100% ethanol
Clearing solution such as xylene or Hemo-D (Fisher)
Mounting medium (e.g., DePeX , BDH; Permount, Fisher; or equivalent)

Slide racks
Glass staining dishes
Forceps with blunt end
Glass coverslips, large enough to cover the tissue specimen

CAUTION: Xylene is a toxic solvent and all steps of counterstaining and coverslipping should be carried out in a fume hood or ventilated table.

Prepare slides

1. Fill slide racks with the slides to be coverslipped. Orient all slides to face in the same direction.
2. Immerse the slides in a glass staining dish filled with water and wash for 3 min.
3. Drain excess water and rinse slides in 70% ethanol for 3 min.

   Do not dry the tissue slices at anytime during the successive drainage and solution changes.
4. Drain excess solution and rinse slides in 95% ethanol for 3 min.
5. Drain excess solution and rinse slides in 100% ethanol for 3 min.
6. Drain excess solution and incubate slides in a dehydrating/clearing solution such as Hemo-D for 3 min.

   Alternatively, rinse the slides in 3:2 (v/v) xylene/ethanol for 3 min followed by two successive washes in 100% xylene for 3 min. Then follow steps 8 to 10.
7. Repeat step 6 using fresh Hemo-D.

Apply coverslip

8. With blunt-end forceps, pick one slide at a time from the clearing solution, drain briefly, and set flat on a paper towel. Immediately cover one edge of the slide with a small amount of water-repellant mounting medium and slowly apply (at a 45° angle) a thin-glass coverslip on top, being careful not to introduce any air bubbles.
9. Set slide flat on a leveled tray and air dry 1 to 2 days in a fume hood.

   Excess dried mounting medium at the edge of the slide can be scraped off gently with a clean razor blade. Wipe slides gently with 70% ethanol.
10. Store coverslipped slides in slide boxes in a cool and dry environment.

LABELING STRESS PROTEINS WITH [^{35}S]METHIONINE

BASIC PROTOCOL 3

Selective increase in the synthesis of stress proteins such as HSP70 family proteins, concomitant with a transient reduction in overall protein synthesis, is a typical response observed both in vivo and in vitro in cells exposed to a variety of insults including heat shock, ischemia, toxic metals, amino acid analogs, and some chemotherapeutic or anes-

thetic agents. This protocol introduces a rapid method to evaluate overall decreased protein synthesis and selective increases in the expression of stress proteins (Table 2.9.3), including the HSP70 family (Table 2.9.1), in cell culture at different time points after a stressful stimulus. This method depends on the incorporation of [^{35}S]methionine into cellular proteins. The ^{35}S-labeled cell lysate is then analyzed by polyacrylamide gel electrophoresis. Following staining with Coomassie blue (to verify equal loading) and drying on a filter paper, the gel is exposed to an X-ray film for subsequent band visualization (*APPENDIX 3D*). Decreased overall protein synthesis (or decreased [^{35}S]methionine incorporation into proteins) is reflected on the film emulsion as a decrease in the number and intensity of radioactive bands in each sample track. Concurrent induction of stress proteins is visualized as select bands of high intensity. In particular, the HSP70 family proteins show specific bands of molecular weights ranging from 68 to 78 kDa. Depending on the type of stressful stimulus used to treat the cells initially, some but not all stress proteins may be present and/or have increased intensity (see Table 2.9.3 for inducers). For example, hyperthermia specifically and strongly induces a band of ~72 kDa but not other bands in

Table 2.9.3 Characteristics of Some Mammalian Stress Proteins[a,b]

Stress function protein[b,c]	Major inducers	Location	Suggested function
HSP27	Heat shock, estrogen, glutamate, heavy metals, cysteamine, oxidative stress	Cytosol, nucleus	Microfilament stability
HSP32	Heat shock, hypoxia, ischemia, oxidative stress (gluthatione depletion), heme, heavy metals, UV irradiation	ER	Heme degradation
HSP34	Glucocorticosteroids	ER	Heme degradation
HSP47	Heat shock, ischemia	ER	Serine protease inhibitor, binds to collagen
HSP60	Heat shock	Mitochondria	Chaperone involved in the folding and translocation of new proteins
HSP72	Heat shock, ischemia, some anesthetic drugs, glutamate agonists, seizures, UV irradiation, acidosis	Cytosol, nucleus	Inducible HSP70, chaperone involved in folding of newly synthesized or denatured proteins, dissociates aggregates
HSP73	Ischemia, seizures	Cytosol, nucleus	Constitutive HSP70 homolog, molecular chaperone, clathrin-uncoating ATPase associated with microtubules and other cytoskeletal elements
HSP90	Heat shock, ischemia, estradiol	Cytosol, nucleus	Molecular chaperone, regulation of steroid receptors, modulation of protein synthesis
GRP75	Hypoglycemia, ischemia, calcium depletion	Mitochondria	HSP70 homolog, chaperone for newly synthesized proteins
GRP78	Hypoxia, hypoglycemia, ischemia, calcium depletion, okadaic acid	Golgi/ER	HSP70 family member, immunoglobulin heavy chain binding protein, chaperone for nascent glycoproteins
GRP94	Hypoxia, hypoglycemia, calcium depletion	Golgi/ER	Calcium binding glycoprotein
Ubiquitin	Heat shock, ischemia, pentobarbital	Cytosol, nucleus	Targets proteins for degradation

[a]For reviews, see Welch (1990, 1992), Parsell and Lindquist (1994), and Massa et al. (1996).

[b]Abbreviations: ER, endoplasmic reticulum; GRP, glucose-related protein; HSP, heat shock protein.

[c]Numbers represent the molecular weight of the protein in kilodatton.

the same molecular weight range, consistent with HSP72 being an inducible heat shock protein (Tables 2.9.1 and 2.9.3).

Although this method is simple, rapid, and relatively inexpensive, it is fairly nonspecific when it comes to discriminating between proteins of very similar molecular weight, even if optimal electrophoresis conditions are used. Therefore, the changes in expression of HSP70 family proteins should be validated by immunoblot analysis on the same cell lysate using specific antibodies against individual proteins (see Basic Protocol 4).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Materials

Tissue culture cells in 35- to 100-mm plates
Methionine-free medium for cell culture
stressful stimulus (see Tables 2.9.1 and 2.9.3)
1000 Ci/mmol [^{35}S]methionine (Amersham Pharmacia Biotech or NEN)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
1× SDS sample buffer (see recipe)
Protein quantitation kit (Pierce or Bio-Rad)
Bovine serum albumin (BSA) protein standards
Molecular weight markers
2-mercaptoethanol
1% (w/v) bromphenol blue (see recipe)
Water-based scintillant solution

1.5-ml microcentrifuge tubes
Cell scraper
100°C water bath
Filter-membrane spin column (optional; Amicon or Sigma)

Additional reagents and equipment for SDS-PAGE (*APPENDIX 3A*), Coomassie blue staining of gels (see Support Protocol 3), and gel drying and autoradiography (*APPENDIX 3D*)

Label cells

1. Incubate cells for 12 hr in a methionine-free medium to ensure that most of the endogenous methionine has been used up by the cells.
2. Expose cells to the stress/injury stimulus (see Tables 2.9.1 and 2.9.3).
3. At appropriate time points after the insult, add 40 µCi/ml of 1000 Ci/mmol [^{35}S]methionine directly to the medium. Incubate 2 hr at 37°C to ensure incorporation of the labeled methionine into cellular proteins.

   CAUTION: *At this point, standard radiosafety precautions should be taken for the manipulation and disposal of all radioactive solutions and plasticware.*

   Use a minimum volume of medium in the dish to minimize the volume of radioactive waste solution. Typically for this step, remove some of the incubating medium and leave a volume that is just enough to cover the cells, i.e., ~2 ml for 35-mm dish and ~4 ml for 100-mm dish. Then add the radioalabel directly to the dish. This concentration of radioactivity is fairly standard but can be adjusted depending on the level of incorporation and the desired final signal.

4. At the end of the 2-hr labeling period, pipet a small volume of the labeling medium into a microcentrifuge tube and set aside for later use. Remove the overlaying medium by aspirating through a radioactivity-approved vacuum line and rinse the cells quickly with ~2 vol ice-cold PBS to remove the unincorporated label.

Prepare lysate

5. After removing the PBS, lyse the cells directly in the dish by adding 300 to 500 µl of 1× SDS sample buffer per 100-mm dish. Use a cell scraper to detach the cells from the bottom of the dish.

6. Transfer the cell lysate into a clean microcentrifuge tube and heat 3 to 5 min in 100°C water bath. Pipet up and down several times with a 1-ml pipet tip to ensure homogeneity.

   This should help solubilize the proteins to homogeneity and inhibit all proteases. If the lysate is too viscous to be pipetted through a standard 1000-µl pipet tip, add a small volume of 1× SDS sample buffer (no more than 50 µl at a time) and mix with a pipet.

7. Microcentrifuge samples 5 min at 14,000 × *g*, room temperature. If there is cellular debris at the bottom of the tube, transfer the clear supernatant into a clean microcentrifuge tube.

   The samples (lysates) can also be clarified by centrifuging through commercially available filter-membrane spin columns adapted for use with microcentrifuge tubes.

8. Freeze samples at −70°C until further analysis.

   Since the half life of ^{35}S is ~87 days, samples can be analyzed within the next 1 to 2 weeks after collection without any significant loss of signal and sensitivity.

Prepare gel samples

9. After thawing on ice, heat samples for 1 min in a 100°C water bath.

10. Mix samples by inversion and cool to room temperature before pipetting.

    Failure to cool to ambient temperature may result in inaccurate pipetting of sample volumes.

11. Take a small aliquot of the lysate and measure the protein content in triplicate samples using a standard, commercially available protein analysis kit and BSA standards. Store the remainder of the lysate on ice.

    The use of the bicinchoninic acid protein method (Pierce) at a microscale level (4 µl of protein lysate per well) in a 96-multiwell format has proven to be very reliable and reproducible.

    If the samples already contain a dye or any substances that are incompatible with the protein assay, pipet an aliquot of an appropriate volume of protein lysates to be analyzed in a microcentrifuge tube, add 500 µl of cold 10% trichloroacetic acetic and incubate on ice for 30 min. Microcentrifuge the precipitated protein samples 10 min at 14,000 × g, 4°C. Slowly aspirate the supernatant through a <20-G needle. Then resolubilize the small protein precipitated pellet directly in an appropriate volume of protein assay reaction solution and analyze immediately. BSA standards should be treated in the same fashion.

12. Prepare samples. In separate microcentrifuge tubes, pipet an equal amount of protein for each sample. Prepare the molecular weight markers according to the manufacturer's recommendation. Bring all tubes to an equal volume by adding an appropriate amount of 1× SDS sample buffer to each tube. For each 10 µl of final protein sample, add 1 µl of 2-mercaptoethanol (final 5% v/v) and 1 µl of 1% bromphenol blue (final 0.1%). Mix well. Just before loading, heat samples for 1 min in a 100°C water bath.

Add the 2-mercaptoethanol and bromphenol blue to samples after protein determination because they interfere with the assay.

Electrophorese samples

13. Separate an equal amount of protein (20 µg) per lane by SDS-PAGE using an 8% or 10% gel (*APPENDIX 3A*), best to visualize proteins of 68 to 78 kDa.
14. After electrophoresis, stain gels with Coomassie blue to verify equal protein loading (see Support Protocol 3).
15. After drying on a filter paper, expose the gel to X-ray films overnight or longer depending on the intensity of the signal (*APPENDIX 3D*).
16. Using a scintillation counter, quantify the amount of radioactivity incorporated in total protein by adding an aliquot of the final protein lysate to a scintillation vial containing 5 to 10 ml of a water-based scintillant solution. Analyze aliquots of the original labeling medium (set aside in step 4) to verify that the initial amount of radioactivity added to each dish was equal.

COOMASSIE BLUE STAINING OF PROTEINS IN A POLYACRYLAMIDE GEL

SUPPORT PROTOCOL 3

Coomassie blue staining is based on nonspecific binding of the dye to proteins. The sensitivity of this method is 0.3 to 1.0 µg protein per track. Perform the following steps under a fume hood or in a well-ventilated room and wear gloves at all time.

Materials

SDS-PAGE gel from separation of stress proteins including the HSP70 proteins (see Basic Protocol 3, step 13)
Gel fixing solution (see recipe)
Coomassie blue staining solution (see recipe)
Gel destaining solution (see recipe)

Clean glass or plastic dishes slightly larger than the gel with lid or plastic wrap
Platform shaker
Foam sponge (optional)

1. Place the polyacrylamide gel in a clean glass or plastic dish, cover the container with a lid or plastic wrap, and incubate in gel fixing solution for 5 to 10 min at room temperature.
2. Remove the fixing solution and rinse briefly in water.
3. Remove the water, immerse the gel in Coomassie staining solution, and shake gently 4 hr to overnight at room temperature.
4. Remove staining solution and save.

   This solution can be reused many times before replacing (≤30 times).

5. Add the gel destaining solution. Shake gently for 1 hr and replace with fresh destaining solution. Continue destaining until blue bands appear against a clear background. Discard destaining solution when done.

   To accelerate the destaining process, lay a foam sponge directly on top of the gel in the destaining solution. The sponge will absorb and bind the dye by capillary action and increase transfer of the dye from the gel to the destaining solution to the sponge. Discard sponge when done.

BASIC PROTOCOL 4

QUANTITATIVE DETECTION OF HSP70 FAMILY PROTEINS BY IMMUNOBLOTTING

Immunoblotting is used to evaluate the specificity of an antibody and quantitate the amount of specific protein in tissue or cell lysates. Proteins in the lysate are separated by denaturing gel electrophoresis (*APPENDIX 3A*) and then electrotransferred onto a membrane (*UNIT 2.3*). After preincubation in a blocking solution, the membrane is probed with primary and secondary antibodies, and the protein is visualized either by chromogenic substrates or chemiluminescence (see Alternate Protocol 2).

Materials

Cell culture or animals subjected to a stressful stimulus
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1× SDS sample buffer (see recipe)
Protein quantification kit (Pierce or Bio-Rad)
Bovine serum albumin (BSA) standards
Molecular weight markers
2-mercaptoethanol
1% (w/v) bromphenol blue (see recipe)
0.2-µm mesh nitrocellulose or polyvinylidine difluoride (PVDF) membrane (Biorad, Scleicher and Schuell, NOVEX)
Immunoblot blocking solution (see recipe)
Immunoblot wash solution (see recipe)
Primary antibodies against the HSP70 protein family (see Table 2.9.4)
Secondary antibody, biotinylated or conjugated to horseradish peroxidase (Amersham Pharmacia Biotech or Vector)
0.1 M phosphate buffer, pH 7.4 (see recipe)
Standard Elite Vectastain ABC kit (Vector)
10-mg tablets of 3,3′-diaminobenzidine tetrachloride (DAB; Sigma)
30% hydrogen peroxide ≤1 to 2 months old

100°C water bath
Rotating platform shaker

Additional reagents and equipment for SDS-PAGE (*APPENDIX 3A*), transfer of proteins to membrane (*UNIT 2.3*), and Ponceau S staining (see Support Protocol 4)

Prepare sample

1a. *For cultured cells*: Rinse cells with 2 vol ice-cold PBS. Remove solution and prepare protein samples from stressed monolayer cell culture by adding 300 to 500 µl of 1× SDS sample buffer per 100-mm dish and proceed as described in Basic Protocol 3, steps 6 to 11.

1b. *For stressed animals*: Dissect fresh tissue from anesthetized stressed animals on ice, cut into small pieces and place in a microcentrifuge tube. For each 0.1 g of tissue, add ~300 to 500 µl of 1× SDS sample buffer. Heat the sample 2 to 5 min in a 100°C water bath. Dissociate the tissue by triturating through a 1000-µl pipet tip several times. Heat the sample an additional 5 min at 100°C. Triturate the sample through a 200-µl pipet tip. Clarify the lysate by microcentrifuging 5 min at 14,000 × *g*, room temperature as described in Basic Protocol 3, step 7.

The use of a micropestle adapted for microcentrifuge tubes is especially recommended for tougher tissues.

Samples can also be clarified by centrifuging through commercially available filter-membrane spin columns adapted for use with microcentrifuge tubes.

Table 2.9.4 Primary Antibodies Commonly Used to Study the HSP70 Protein Family[a]

Gene	Antibody	Molecular weight (kDa)	Suitability	Supplier
HSP72	Mouse monoclonal	72	IB, IHC	Amersham Pharmacia Biotech, StressGen
HSP73	Rat monoclonal	73	IB, IHC	StressGen
GRP75	Mouse monoclonal	75	IB, IHC	StressGen
GRP78	Rabbit polyclonal	78	IB, IHC	StressGen

[a]Abbreviations: GRP, glucose-regulated protein; HSP, heat shock protein; IB, immunoblot; IHC, immunohistochemistry. Numbers represent the molecular weight of the protein in kDa.

2. Measure the protein concentration using a protein quantitation kit and BSA standards.
3. Prepare samples. In separate microcentrifuge tubes, pipet out an equal amount of protein for each sample. Prepare the molecular weight markers according to the manufacturer's recommendation.
4. Bring all tubes to an equal volume by adding an appropriate amount of 1× SDS sample buffer to each tube. For each 10 µl of final protein sample, add 1 µl of 2-mercaptoethanol (final 5%) and 1 µl of 1% bromphenol blue (final 0.1%). Mix well. Just before loading, heat samples for 1 min in a 100°C water bath.

   Add the 2-mercaptoethanol and 1% bromphenol blue to samples after protein determination because they interfere with the assay.

Electrophorese and transfer samples

5. Separate an equal amount of protein per sample on a denaturing 8% to 10% polyacrylamide gel (*APPENDIX 3A*), to separate proteins in the 68- to 78-kDa range.

   In general and depending on the tissue and stressful stimulus, 20 to 50 µg of protein sample is sufficient to visualize the HSP70 family of proteins. In normal unstressed tissues, HSP72 is not expressed constitutively but HSP73, GRP75, and GRP78 are expressed constitutively. Following a stressful stimulus, most of these HSPs will be expressed at higher levels and will be easily detected.

6. After electrophoresis, transfer the proteins onto a 0.2-µm mesh nitrocellulose or PVDF membrane by tank transfer (*UNIT 2.3*), for 2 hr at 100 V or overnight at 15 V, 4°C.

   Alternatively, semi-dry transfer can be used. Transfer by this method should not be run for longer than 2 hr. Hydrophobic PVDF membranes have been used with success for immunoblot analysis of HSP70 proteins. However, because of its higher affinity for most proteins, nitrocellulose is the membrane of choice for the detection of HSP70 proteins. Nitrocellulose is easily wetted in water, is compatible with a variety of detection assays, and is associated with lower background.

7. To verify equal protein loading and transfer efficiency, reversibly stain the proteins on the membrane with the red water-soluble dye Ponceau S (see Support Protocol 4).

Immunodetect proteins

8. Incubate the membrane for ≥2 hr at room temperature or overnight at 4°C in freshly made immunoblot blocking solution on a rotating platform shaker.

For overnight incubation, add 1 ml of 2% (w/v) sodium azide solution (can be stored indefinitely at room temperature) to prevent bacterial growth. This amount of azide is easily removed by subsequent washes and does not interfere with subsequent reactions.

CAUTION: *Sodium azide is a neurotoxin. Use precautions when weighing powder and handling solutions.*

For monoclonal antibodies, the detergent in the incubating solutions can be omitted. The use of a monoclonal antibody on the tissues from the same species (e.g., rat monoclonal on rat tissues) may be associated with higher background depending on the tissue type. In that case, add 1% to 2% (v/v) of that species normal serum in the blocking solution to help block nonspecific sites.

9. Discard blocking solution and rinse briefly with the immunoblot wash solution.
10. Incubate the membrane for 2 hr at room temperature with the appropriate primary antibody diluted 1:1000 to 1:4000 in the wash solution on a rotating platform shaker.

    The concentration of primary antibody should be adjusted depending on the tissue, the species studied, and the level of protein expression. The appropriate concentration should be determined for each set of primary and secondary antibodies.

    Although a wide variety of antibodies against HSP72 are now commercially available, the use of the monoclonal anti-HSP72 antibody (e.g., Clone 92 from Amersham Pharmacia Biotech) is highly recommended due to its proven specificity and low background in different tissues. Antibodies against GRP75 and GRP78 proteins have not been extensively characterized and are not as widely available. The monoclonal antibodies from StressGen have been used successfully in different systems.

11. Remove the primary antibody solution and perform three 15-min washes in immunoblot wash solution.
12. Incubate the membrane for 1 to 2 hr at room temperature with the appropriate secondary antibody diluted in the immunoblot wash solution on a rotating platform shaker.

    The secondary antibody should be specific for the species in which the primary antibody was produced and should be conjugated with a suitable reporter group. The secondary antibody can be biotinylated, then incubated in an avidin-horseradish peroxidase (HRP) solution (Vectastain ABC, Vector), and visualized with a standard chromogenic method Alternatively, secondary antibodies directly conjugated to an enzyme such as horseradish peroxidase can be used for visualization by highly sensitive chemiluminescent methods (see Alternate Protocol 2).

13. Perform two 15-min washes at room temperature in immunoblot wash solution on a rotating platform shaker. Perform one wash of 15 min at room temperature in 0.1 M phosphate buffer, pH 7.4.

Visualize bound antibody

14. After incubation of the membrane with a biotinylated secondary antibody, prepare an avidin-horseradish peroxidase solution as described by the manufacturer (Standard Elite Vectastain ABC kit, Vector). In brief, mix 2 drops of reagent A with 2 drops of reagent B in 10 ml of 0.1 M phosphate buffer, pH 7.4, and let the solution react 30 min at room temperature.
15. Drain the excess wash solution and incubate the membrane in the avidin/horseradish peroxidase solution 30 min at room temperature on a rotating platform shaker.
16. Remove the solution and perform three 10-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature on a rotating platform shaker.

17. Make up the chromogen solution by dissolving a 10-mg tablet of DAB in 10 ml of 0.1 M phosphate buffer, pH 7.4. Filter through a filter paper and then add 1.67 µl of 30% hydrogen peroxide. Mix and use immediately.

    CAUTION: *DAB is a potent carcinogen and is highly toxic in both its solid and aqueous forms. Wear gloves at all time and discard all solutions and contaminated materials in accordance with the health and safety guidelines of the institution.*

18. Incubate the membrane in the DAB solution and shake gently and continuously until the bands of interest become visible (~2 to 10 min).

    DAB chromogenic visualization gives medium-dark brown bands on a light brown background. Do not prolong the incubation for too long because that could result in an unreasonably high background.

19. Stop the reaction by removing the DAB solution and washing two times for 5 min with 0.1 M phosphate buffer, pH 7.4. Air dry the membrane and store in plastic wrap at room temperature.

    Document results by taking a picture of the membrane soon after this final step because DAB signal on membranes tends to fade with time.

VISUALIZATION WITH CHEMILUMINESCENT SUBSTRATES

ALTERNATE PROTOCOL 2

Detection of low-abundance proteins in immunoblots can be achieved using chemiluminescent substrate methods, which have shown to be at least ten times more sensitive than other standard detection methods. The ECL chemiluminescent detection method (Amersham Pharmacia Biotech), described below, is quick and convenient (only one simple step), and shows high reproducibility and sensitivity. This method involves the horseradish peroxidase/hydrogen peroxide–catalyzed oxidation of luminol, which emits a blue light that can be captured on X-ray film.

Materials

Chemiluminescence horseradish peroxidase (HRP) substrate kit (e.g., ECL, Amersham Pharmacia Biotech or equivalent)
Immunoblot probed with secondary antibody directly conjugated to horseradish peroxidase (see Basic Protocol 4, step 13)
0.1 M phosphate buffer, pH 7.4 (see recipe)

50-ml conical plastic centrifuge tubes
Rotating platform shaker
X-ray film (e.g., X-Omat AR-5, Kodak)
Automatic X-ray film processor

1. In a 50-ml concial plastic centrifuge tube, mix 1 vol ECL reagent A and 1 vol ECL reagent B.

    The total volume can be adjusted depending on the size of the membrane to be analyzed. In general, 10 ml/10 cm^2 should be sufficient.

2. After the membrane has been incubated with the secondary antibody solution and washed, drain the excess wash solution. Using blunt-end forceps, transfer the membrane to a small clean container.

    The plastic lid of a small pipet tip box can be used as the clean container for minigels.

3. Add the ECL mixture and incubate the membrane at room temperature for exactly 1 min. Shake gently and continuously, making sure the membrane is always covered with the ECL solution.

4. At the end of the incubation, drain the excess ECL solution and wrap the membrane in plastic wrap. Do not dry the membrane.
5. In a dark room, expose the chemiluminescent membrane to an X-ray film for an appropriate length of time. Develop the film immediately in an automatic X-ray film processor.

   Because the ECL chemiluminescent reaction is transient and loses most of its intensity after 1 hr, expose the membrane to an X-ray film as soon as possible after incubation with the ECL reagent mixture. Several exposures are usually needed to determine the best signal-to-noise ratio. For this reason, the use of an automatic X-ray film processor for quick film development is highly recommended. In general, the time of exposure can vary from a few seconds (medium-high protein abundance) to several minutes (for low-abundance proteins).

SUPPORT PROTOCOL 4

REVERSIBLE STAINING OF TRANSFERRED PROTEIN ON MEMBRANES WITH PONCEAU S SOLUTION

To verify equal protein loading and transfer efficiency, proteins on membranes can be stained reversibly with the red water-soluble dye Ponceau S.

Materials

Membrane with transferred proteins (see Basic Protocol 4, step 6)
Ponceau S staining solution (see recipe)

1. Place the membrane in Ponceau S staining solution for 1 to 2 min at room temperature.
2. Pour out the staining solution and save.

   This solution can be reused several times.

3. Destain with deionized water for 1 to 2 min or until bands become visible against a light pink-white background.

   If using non-prestained molecular weight markers, mark the location of each standard band with a pencil or with a small cut in the membrane with a clean razor blade.

4. Completely destain the membrane for 5 to 10 min in distilled water at room temperature.

   Wet membranes can be processed directly for immunoblotting or stored at 4°C in a sealed bag for up to 1 week before analysis. Do not dry the membrane at any time.

BASIC PROTOCOL 5

DETECTION OF HSP70 FAMILY PROTEINS IN TISSUE SECTIONS BY IMMUNOHISTOCHEMISTRY

Immunohistochemistry is used to determine the cellular and regional distribution of specific proteins. This method is easily performed using tissue sections or adherent cell cultures. The method described here to detect the HSP70 protein family in tissue sections uses biotinylated secondary antibodies followed by chromogenic visualization with DAB. If the signal is weak, it can be enhanced using nickel-DAB intensification (see Alternate Protocol 3) or immunofluorescence (see Alternate Protocol 4). Fluorescence staining with two different primary antibodies—one specific for the stress protein and one specific for the cell type—and secondary antibodies conjugated with different fluorochromes (see Alternate Protocol 4) allows identification of specific cell types that are producing stress proteins. Stress-producing stimuli can be associated with cell death. TUNEL (*UNIT 2.2*) can be combined with immunofluoresence to determine the relationship between dying and stress-protein-producing cells (see Alternate Protocol 5).

Materials

Animals or cells subjected to a stressful stimulus (see Tables 2.9.1 and 2.9.3)
Anesthesia cocktail (see recipe)
0.9% (w/v) sodium chloride (saline) solution, ice cold
4% (w/v) paraformaldehyde working solution (PFA; see recipe), ice cold
30% (w/v) sucrose (see recipe)
0.1 M and 0.05 M phosphate buffer, pH 7.4 (PB; see recipe)
Immunohistochemistry peroxidase inhibiting solution (optional, see recipe)
Immunohistochemistry blocking solution (see recipe)
Primary antibodies against the HSP70 protein family (see Table 2.9.4)
Immunohistochemistry antibody dilution buffer (see recipe)
Secondary antibody conjugated to biotin
Avidin/peroxidase complex kit (e.g., ABC Standard Elite Vectastain kit, Vector)
10-mg tablets of 3,3′-diaminobenzidine tetrachloride (DAB, Sigma)
30% (v/v) hydrogen peroxide solution, stabilized, ≤1 to 2 months old (Sigma)

Vibratome or freezing microtome
Paintbrush with small, fine end
6- or 12-well tissue culture plates
Rotating platform shaker
Gelatin-coated histology slides (see Support Protocol 5)

Additional reagents and equipment for preparing gelatin-coated slides (see Support Protocol 5) and coverslipping slides (see Support Protocol 2)

Prepare tissue

1. Subject test animals to stressful stimulus (see Tables 2.9.1 and 2.9.3). At the appropriate time points after stressful stimulus, anesthetize the animal with an intraperitoneal injection of anesthesia cocktail.

2. Perfuse the whole animal through the left ventricle with cold 0.9% sodium chloride solution followed by cold 4% PFA.

3. Carefully remove the tissue of interest, post-fix in 4% PFA for no more than 1 to 4 hr, then transfer to 30% sucrose solution overnight at 4°C.

   When using the monoclonal anti-HSP72 antibody or anti-GRP-75 or anti-GRP 78 (see Table 2.9.4), it is extremely important that fixation with the aldehydes be kept to a minimum. Tissue post-fixation of >4 hr decreases or eliminates all HSP70 immunostaining when the antibody is used at a dilution of 1:2000.

   Post-fixation time will depend on the type of antigen studied and the type of tissue analyzed. The post-fixation time should always be kept to a minimum.

4. Cut 50- to 100-μm–thick sections on a vibratome or freezing microtome and distribute the slices with a small, fine-end paintbrush in a 12-well culture plate containing 2 ml of 0.1 M phosphate buffer, pH 7.4 (free-floating sections).

   Thin sections are essential for good quality immunohistochemistry as they are associated with less background than thicker sections.

   For HSP72 staining using the Amersham antibody (Clone 92, Amersham Pharmacia Biotech), the tissue should be sectioned immediately after intracardiac aldehyde perfusion or after a few hours of aldehyde post-fixation.

   A number of slices can be processed together in each of the 12 wells. If there are a large number of slices for each animal and a lot of antibody is available, 6-well tissue culture dishes can be used with 5 ml of phosphate buffer per well.

5. Wash the sections two times with 0.1 M phosphate buffer, pH 7.4, or store them in 0.1 M phosphate buffer, pH 7.4, overnight at 4°C to allow the excess PFA to diffuse out of the slices.

6. Remove the buffer solution from each well by carefully holding the slices on one side of the well with a small paintbrush or pipet tip and aspirating the solution with a vacuum line on the opposite side of the well.

Cut sections should be washed in several changes of phosphate buffer. Immunohistochemistry should be started as soon as possible after cutting.

Normally, it is important to reduce the amount of background in tissues containing a high level of endogenous peroxidases by incubating the sections in immunohistochemistry peroxidase inhibiting solution. However, in some cases, particularly for the HSP 70 family of proteins, this procedure can result in the loss of antigenicity.

Expose tissue sections to antibody

7. Incubate the sections for 2 hr at room temperature in immunohistochemistry blocking solution.

Serum or bovine serum albumin is needed to block nonspecific binding sites. Triton X-100 is a membrane detergent that improves the penetration of antibodies through tissues.

For monclonal anti-HSP 72, anti-GRP-75, and anti-GRP-78 (Table 2.9.4), the blocking solution can be simplified by omitting the nonfat dry milk solids and the whole rat serum.

8. Remove the blocking solution and wash once briefly with 0.1 M phosphate buffer, pH 7.4.

9. Remove the buffer solution and incubate the tissue sections for 12 to 24 hr at 4°C with an appropriate primary antibody (see Table 2.9.4) diluted in immunohistochemistry antibody dilution buffer.

As a negative control, incubate alternate sections from each tissue sample without the primary antibody or with preabsorbed immune serum. For each tissue, serial dilutions (1:1000, 1:2500, 1:5000, 1:10000, etc.) of primary antibody should be performed on a few slices to establish the appropriate concentration for optimal signal-to-noise ratio.

10. Remove the primary antibody solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature, on a rotating platform shaker.

11. Remove phosphate buffer wash and incubate all sections (including the negative controls) for 1.5 hr, at room temperature, with an appropriate biotinylated secondary antibody diluted 1:200 in immunohistochemistry antibody dilution buffer.

When used on rat tissues, biotinylated anti-rabbit (Vector) and anti-mouse (Amersham Pharmacia Biotech) secondary antibodies usually do not produce much of a background if diluted 1:200. When using rat tissue with an anti-rat secondary antibody, the dilution should be at least 1:300 to reduce the associated background.

12. Remove the secondary antibody solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature, on a rotating platform shaking.

Visualize bound antibody

13. Meanwhile, prepare an avidin-horseradish peroxidase solution (Standard Elite Vectastain ABC kit) by adding 2 drops of reagent A and 2 drops of reagent B to 10 ml of 0.1 M phosphate buffer, pH 7.4. Mix well and let the solution react at room temperature for ≥30 min.

14. Incubate sections in the avidin-horseradish peroxidase solution for 1.5 to 2 hr at room temperature.

15. Remove the solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature, on a rotating platform shaker.

16. Visualize the bound antibody with the DAB method. Make the DAB solution by adding a 10-mg tablet of 3,3′-diaminobenzidine tetrachloride to 50 ml of 0.1 M phosphate buffer, pH 7.4. Mix well and filter through a filter paper. Use within 30 min.

    CAUTION: *DAB is a potent carcinogen and is highly toxic in both its solid and aqueous forms. Wear gloves at all times and discard all solutions and contaminated materials in accordance with the health and safety guidelines of the institution.*

17. Incubate the tissue sections in the DAB solution for no more than 5 min (for 12-well plates, use 2 ml/well; for 6-well plates use 5 ml/well).

18. Meanwhile, prepare the hydrogen peroxide solution by adding 0.1 ml of 30% hydrogen peroxide to 10 ml of 0.1 M phosphate buffer, pH 7.4.

    Make sure the 30% hydrogen peroxide stock solution is no more than 1 to 2 months old.

19. Add 1 drop of diluted hydrogen peroxide solution for each 1 ml of DAB solution. Do this slowly, one drop at a time, on a rotating platform shaker. Incubate the tissue sections at room temperature until they turn to a light-to-medium brown color.

20. Stop the reaction by removing the DAB solution and washing twice with 0.1 M phosphate buffer, pH 7.4.

21. Mount the sections on gelatin-coated slides (see Support Protocol 5), air dry, and coverslip (see Support Protocol 2).

NICKEL-DAB INTENSIFICATION OF IMMUNOHISTOCHEMICAL SIGNALS

ALTERNATE PROTOCOL 3

Nickel intensification can be used in conjunction with the DAB method to enhance the signal of a low-abundance protein. Nickel intensification can also be followed by a second staining procedure using another primary antibody and the standard DAB method. In that case, one antigen is immunolabeled with a dark blue/black precipitate (nickel-DAB), and the second antigen is immunolabeled with a brown precipitate (standard DAB).

Additional Materials *(also see Basic Protocol 5)*

0.175 M sodium acetate, pH 6.7 (see recipe)
Nickel sulfate

1. Immunolabel tissue sections (see Basic Protocol 5, steps 1 to 14).

2. After incubation with the avidin-horseradish peroxidase solution (Vectastain ABC kit), wash the tissue slices once with 0.1 M phosphate buffer, pH 7.4, for 15 min and once with 0.175 M sodium acetate, pH 6.7, for 15 min at room temperature.

3. Prepare the substrate solution by dissolving 1.25 g of nickel sulfate and one 10-mg tablet of DAB in 50 ml of 0.175 M sodium acetate, pH 6.7. Mix well and filter the solution through filter paper. Use within 30 min.

   Because nickel ions precipitate with phosphates, the use of 0.175 M sodium acetate solution, pH 6.7, instead of phosphate buffer for regular DAB method is absolutely necessary.

4. Incubate the tissue sections in the nickel-DAB solution for no more than 5 min (for 12-well plates, use 2 ml/well; for 6-well plates, use 5 ml/well) at room temperature.

5. Meanwhile prepare the hydrogen peroxide solution by adding 0.1 ml of 30% hydrogen peroxide stock solution to 10 ml of 0.175 M sodium acetate, pH 6.7.

   Make sure the 30% hydrogen peroxide stock solution is <1 to 2 months old.

6. Add 1 drop of diluted hydrogen peroxide solution for each 1 ml of nickel-DAB solution. Do this slowly, one drop at a time, on a rotating platform shaker. Incubate the tissue sections at room temperature until they turn to a medium-purple color.

   Nickel ions coprecipitate with DAB, thus intensifying the staining. Whereas the standard DAB method results in a brown reaction product, the nickel-DAB intensification method yields a dark blue/black product. Because the nickel-DAB method can lead to unacceptably high background staining, avoid incubation times >5 to 7 min.

7. Stop the reaction by washing the tissue sections briefly in 0.175 M sodium acetate, pH 6.7, and for 15 min in 0.1 M phosphate buffer, pH 7.4.

   Prolonged incubation in 0.175 M sodium acetate, pH 6.7, should be avoided since it may result in nickel dissolution from the DAB reaction product.

8. Mount the sections on gelatin-coated slides (see Support Protocol 5), air dry, and coverslip (see Support Protocol 2).

ALTERNATE PROTOCOL 4

DOUBLE IMMUNOFLUORESCENCE STAINING FOR CELL-TYPE IDENTIFICATION

In a complex tissue, analysis of the morphology and location of a particular cell are usually not accurate enough to determine a specific cell type. Double-fluorescence immunolabeling using an antibody against cell-specific markers along with another antibody against a stress protein can be a useful method to determine in which particular cell type a stress protein is expressed. It is important to use primary antibodies of different types (made in different species) that can be recognized by two secondary antibodies also made in different host species. The two secondary antibodies have to be linked to different fluorochromes. The most common fluorescent probes used are rhodamine (emits a red signal) and fluorescein (emits a yellow/green signal). Whereas one of the secondary antibodies can be biotinylated and detected with an avidin-coupled fluorescence marker, the other secondary antibody can be directly coupled with a different fluorochrome. If the primary antibodies are made in the same species (for example, two mouse monoclonal antibodies), the stainings need to be done sequentially. The first staining should be done with the standard DAB method (see Basic Protocol 5) and the second one with fluorescence.

Additional Materials *(also see Basic Protocol 5)*

Two primary antibodies made in different species
Secondary antibodies: one conjugated to biotin, one conjugated to a fluorochrome
Avidin-conjugated fluorochrome
Fluorescence mounting medium: 3:1 (v/v) glycerol/0.1 M phosphate buffer, pH 7.4, containing 0.1% (w/v) paraphenylenediamine or Fluoromount-G (Southern Biotech) or Vectashield (Vector) or Slowfade-Light Antifade (Molecular Probes)
Light-proof box

1. Follow Basic Protocol 5, steps 1 to 9, except in step 9, substitute the primary antibody with a mixture of two primary antibodies of different types.

2. Remove the primary antibody solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature on a rotating platform shaker.

3. Remove buffer solution and incubate all sections for 2 hr at room temperature with a mixture of two appropriately conjugated secondary antibodies (one can be biotinylated and the other one can be directly conjugated to a fluorochrome) diluted in immunohistochemistry antibody dilution buffer.

   CAUTION: *All incubations involving the fluorescent probes should be performed in the dark (wrap the containers in foil) and work should be done in a dark or dim-light room.*

4. Remove the secondary antibody solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature on a rotating platform shaker.

5. Incubate, in the dark, tissue sections with an avidin-conjugated fluorochrome for 2 hr at room temperature.

   The fluorochrome linked to avidin should be different from the fluorochrome conjugated directly to the other secondary antibody used in step 3.

6. Remove the solution and perform three 15-min washes in 0.1 M phosphate buffer, pH 7.4, at room temperature, on a rotating platform shaker.

7. Mount the tissue sections on gelatin-coated slides (see Support Protocol 5) and coverslip immediately with fluorescence mounting medium.

   Do not dry the sections before coverslipping. The fluorescence mounting medium will help preserve the humidity and structure of the section and slow down fluorescence fading and photobleaching. Slides should be photographed shortly after the experiment. They can be stored horizontally in a light-proof box at 4°C or at −20°C for longer storage periods. Commercially available mounting media designed for working with fluorescent probes also provide very good results (e.g., Fluoromount-G, Southern Biotech or Vectashield, Vector or Slowfade-Light, Molecular Probes).

TUNEL STAINING OF DNA FRAGMENTATION IN COMBINATION WITH IMMUNOHISTOCHEMISTRY

ALTERNATE PROTOCOL 5

This method uses terminal deoxynucleotidyl transferase (TdT) to label the 3′-OH ends of fragmented genomic DNA in cultured cells and tissue slices (also see *UNIT 2.2*). In this assay, DNA fragments are visualized using avidin/peroxidase with nickel-DAB enhancement. Although TUNEL has been claimed to be relatively specific for apoptotic DNA fragmentation, recent studies suggest that the TUNEL method labels DNA fragmentation in both apoptotic and necrotic cells. Thus, TUNEL labeling is a marker of dying cells regardless of the mechanism. The distinction between apoptotic and necrotic cell death needs to be confirmed not only by typical morphology (chromatin condensation, cell shrinkage or swelling, cell membrane blebbing; see *UNITS 2.1 & 2.2*) and agarose gel electrophoresis analysis of genomic DNA laddering, but most importantly, by electron microscopy observation. To identify the areas of stress protein induction in relation to the areas of dying cells, the TUNEL method is used in combination with immunohistochemistry (see Basic Protocol 5 or Alternate Protocol 4).

Additional Materials *(also see Basic Protocol 5)*

0.3% (v/v) Triton X-100 in 0.1 M phosphate buffer, pH 7.4 (see recipe for buffer)
20 µg/ml proteinase K in 0.1 M phosphate buffer, pH 7.4 (see recipe for buffer; optional)
1× and 5× TdT buffer (Gibco BRL or Roche Molecular Biochemicals)
400 µM biotinylated 14-dATP (Life Technologies)
15 U/µl TdT (terminal deoxynucleotidyl transferase; Gibco BRL or Roche Molecular Biochemicals)
2× SSC (optional; see recipe)
2% (w/v) bovine serum albumin (BSA; see recipe; optional)

0.175 M sodium acetate, pH 6.7 (see recipe)
Nickel sulfate
75%, 95%, and 100% ethanol

Powdered dry ice
Cryostat
Gelatin-coated histology slides (see Support Protocol 5) or precoated slides (e.g., SuperfrostPlus or Probe-On, Fisher)
PAP pen or equivalent hydrophobic pen (ImmEdge Pen, Vector or PAP Pen, ScyTek)
Humidified chamber with lid
Coplin staining jars
Light microscope

Prepare tissue

1. Subject test animals to stress stimulus. At the appropriate time after the stimulus, euthanize animals under deep anesthesia induced by intraperitoneal injection of the anesthesia cocktail. Quickly remove the tissue of interest, freeze on powdered dry ice, and store at −70°C until analysis.

   These steps have to be performed quickly, since keeping the tissue at 20° to 37°C accelerates necrotic DNA fragmentation. To save time and prevent DNA degradation when many animals have to be dissected all at once, put the tissue in sterile saline at 4°C until all animals have been dissected, and then freeze.

2. Cut 14- to 20-µm thick sections on a cryostat and collect the slices on cold gelatin-coated or commercially precoated histology slides. Store at −70°C until analysis.

3. Prior to use, take slides from the freezer and dry at room temperature for ~10 to 20 min. Warm the slides at 40° to 55°C on a heating table to ensure better adhesion of the tissue sections to the slides. Make a circle around the sections with a hydrophophic (PAP) pen.

   This is to prevent run off of the solution to be applied in the following steps. It also saves probe, reagents, and solutions by restricting a smaller volume for incubation right over the tissue slice.

   For cell cultures grown on poly-D-lysine coated coverslips, wash the coverslip twice with cold 0.1 M phosphate buffer, pH 7.4 (see recipe), to remove the medium. Glue the dried coverslips on the surface of a microsope slide and circle with a (PAP) pen.

4. Fix the tissue sections by immersing the slides in 4% paraformaldehyde for 10 to 30 min at 4°C.

   A long fixation time may lead to low staining intensity, whereas too short a fixation time may result in a high background stain. If no proteinase K is used, fix for 10 min. If proteinase K is used, fix for 30 min. It is absolutely essential to fix the tissue onto the slide, because the steps hereafter, especially the TdT labeling step and proteinase K treatment, tend to dissolve the coating material of the slides.

5. Wash the slides in 0.3% Triton X-100 in 0.1 M phosphate buffer, pH 7.4, for 30 min at room temperature.

6. Wash two times in 0.1 M phosphate buffer, pH 7.4, for 15 min at room temperature.

7. *Optional:* Incubate the tissue sections in 20 µg/ml proteinase K for exactly 15 min at room temperature. Wash twice in 0.1 M phosphate buffer, pH 7.4, each time for 15 min at room temperature.

Do not overincubate with proteinase K if subsequent immunohistochemistry is to be performed on the same tissue section. This step is to remove all the proteins associated with genomic DNA to increase the labeling intensity. However, it significantly increases the chances of washing away the sections or cells. Furthermore, combining immunocytochemistry with TUNEL becomes very difficult if all proteins are digested by the proteinase K. Because the TUNEL staining intensity without proteinase K is usually acceptable, it is recommended that the first experiments be conducted without proteinase K treatment. If there is no TUNEL staining, proteinase K treatment may be used.

Perform TUNEL assay

8. Drain excess wash solution from the slide and preincubate in 150 to 200 µl of 5× TdT buffer/section in a humid chamber for 15 min at room temperature.

   The hydrophobic PAP pen trace should prevent this small volume of liquid from running over other areas of the slide. To avoid buffer evaporation, place slides in a humid chamber containing one layer of wet paper towels at the bottom.

9. After preincubation, drain the solution on a paper towel. To 450 µl of 1× TdT buffer, add 50 µl of 400 µM biotinylated 14-dATP (final concentration 40 µM) and 150 U TdT enzyme. Mix gently (do not vortex) and add 150 µl to 200 µl onto each tissue section. Incubate for 1 hr in a humid chamber placed in a 37°C incubator.

   Do not overincubate as it will result in nonspecific signal.

10. Wash the slides two times by immersing in 2× SSC for 15 min at room temperature in Coplin staining jars.

    SSC is used to terminate the TdT reaction.

11. Wash two times in 2% BSA for 15 min at room temperature.

    In general, washing with 0.1 M phosphate buffer, pH 7.4, is equally effective. The washes with BSA can be omitted if the background level without it is low.

12. Wash two times in 0.1 M phosphate buffer, pH 7.4, for 15 min at room temperature.

Visualize fragmented DNA

13. Meanwhile, prepare an avidin–horseradish peroxidase solution according to manufacturer's instructions (Standard Elite Vectastain ABC kit). Mix 5 µl each of reagent A and B in 500 µl of 0.1 M phosphate buffer, pH 7.4, and react at room temperature for ≥30 min.

14. Drain the excess wash solution and overlay the tissue specimens with a small volume (150 to 250 µl/slide) of avidin–horseradish peroxidase solution. Incubate for 30 min at room temperature in a humid chamber.

15. Wash two times, each time for 15 min at room temperature, by immersing slides in 0.175 M sodium acetate solution, pH 6.7, in a Coplin staining jar.

16. Prepare the substrate solution by dissolving 0.4 g of nickel sulfate and one 10-mg tablet of DAB in 40 ml of 0.175 M sodium acetate solution, pH 6.7. Mix well and filter the solution through filter paper. Just before use, add 100 µl of 30% hydrogen peroxide solution. Mix well and use immediately.

    CAUTION: *DAB is a potent carcinogen and is highly toxic both in solid and aqueous form. Wear gloves at all times and discard all contaminated solutions and materials in accordance with the health and safety guidelines of the institution.*

    Because nickel ions precipitate with phosphates, the use of 0.175 M sodium acetate solution, pH 6.7, instead of phosphate buffer as for the regular DAB method, is absolutely necessary.

17. Drain the excess wash solution from the slides and pipet a small volume of nickel-DAB solution directly on top of the tissue specimen. Monitor the staining reaction under a light microscope.

    Nickel ions coprecipitate with DAB, thus intensifying the staining. The nickel-DAB intensification method yields a dark blue/black product.

18. When the staining intensity is suitable, pour out the nickel-DAB solution and dip the slides briefly in 0.1 M phosphate buffer, pH 7.4, or 0.175 M sodium acetate solution, pH 6.7.

    Do not overincubate as it will increase background. This is especially important if immunohistochemistry is to be performed subsequently on the same section.

19. Wash the slides two times by immersing in water for 5 min at room temperature.

20. Proceed with immunohistochemistry immediately (see Basic Protocol 5 or Alternate Protocol 4).

    If desired, immunohistochemistry may be omitted.

21. Dehydrate successively in 75%, 95%, and 100% ethanol and coverslip (see Support Protocol 2).

SUPPORT PROTOCOL 5

PREPARING GELATIN-COATED SLIDES

Gelatin-coated slides improve the attachment of tissue sections to the slide surface.

Materials

Milli-Q-purified water
1% (v/v) hydrochloric acid solution
70% and 95% ethanol
Gelatin (type Bloom 275)
Chromium potassium sulfate

Slide racks
25 × 75–mm microslides with a frosted end, precleaned (Fisher)
Glass staining dishes
Whatman 3MM filter paper
Storage slide boxes

NOTE: To avoid fingerprint smudges, always wear clean, powder-free gloves when manipulating the slides. Wear safety goggles and gloves to avoid acid burn.

Wash slides

1. Fill slide racks with 25 × 75–mm microslides. Orient the slides so that they all face in the same direction. Immerse in hot soapy water for 1 hr.
2. Rinse in running tap water for 1 hr.
3. Rinse thoroughly in Milli-Q-purified water for 30 min.
4. Remove from water and drain.
5. Immerse in 1% hydrochloric acid solution for 3 min at room temperature.
6. Rinse in Milli-Q-purified water for 3 min.
7. Rinse in 70% ethanol solution for 3 min.
8. Rinse in 95% ethanol solution for 3 min.
9. Allow slides to dry before subbing.

Sub slides

10. Heat 600 ml water to 80°C. While stirring, add 3.0 g of gelatin until completely dissolved. Add 3.0 g of chromium potassium sulfate. Cool to room temperature and use immediately.
11. Filter the solution through a Whatman 3MM filter paper into a graduated cylinder.

    The final solution contains 0.5% gelatin and 0.05% chrome alum.

12. Dip the clean slides into the subbing solution for 2 min. Do this carefully to avoid air bubbles.
13. Remove slide rack from gelatin solution and drain excess solution by setting the rack tilted on its side, with the frosted sides of the slides facing downward. Air dry thoroughly or overnight before use.
14. Store the gelatin-coated slides in slide boxes at room temperature in a dry environment.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anesthesia cocktail

200 U/kg heparin
80 mg/kg ketamine
8 mg/kg xylazine
Prepare fresh before each use.

Bovine serum albumin (BSA) solution, 2% (w/v)

2 g BSA, fraction V
100 ml 0.1 M phosphate buffer, pH 7.4 (see recipe)
Prepare fresh before use

Bromphenol blue, 1% (w/v)

0.5 g bromphenol blue
Sterile H_2O to 50 ml
Mix well and store indefinitely at room temperature

Coomassie blue staining solution

500 ml H_2O
400 ml methanol
100 ml acetic acid, glacial
1 g Coomassie blue G-250

Mix methanol and then acetic acid in water. Add the Coomassie blue and stir until dissolved. Filter through Whatman no. 1 paper. Store indefinitely at room temperature.

Cresyl violet staining solution

0.3 g Cresyl Echt Violet in 50 ml H_2O
3.48 ml acetic acid in 300 ml H_2O
5.44 g sodium acetate in 200 ml H_2O

Combine all solutions above and filter through Whatman 3MM filter paper. Store indefinitely at room temperature.

Denhardt's solution, 100×

5 g Ficoll 400
5 g polyvinylpyrrolidone
5 g bovine serum albumin, fraction V
Add sterile H_2O to 250 ml
Divide into aliquots and store frozen up to 12 months at −20°C

DEPC-treated water

0.2 ml diethyl pyrocarbonate (DEPC)
1000 ml H_2O
Shake vigorously and incubate overnight at 37°C
Autoclave the solution to inactivate traces of DEPC
Store indefinitely at room temperature

CAUTION: *DEPC is a potent carcinogen. Work in a fume hood and wear gloves at all times.*

Dextran sulfate, 50% (w/v)

Add just enough sterile water to 25 g dextran sulfate to dissolve the bulk of the solid material (the solution is extremely viscous). When the solution has set, add sterile water to 50 ml. Store at room temperature.

Dithiothreitol (DTT), 5 M

7.7 g DTT
10 ml 0.01 M sodium acetate, pH 5.2
Filter through 0.22- to 0.45-µm filter
Divide into aliquots and store frozen up to 12 months at −20°C

Gel destaining solution

70 ml acetic acid
50 ml methanol
H_2O to 1000 ml
Mix well and store indefinitely at room temperature

Gel fixing solution

400 ml methanol
70 ml acetic acid
H_2O to 1000 ml
Mix well and store indefinitely at room temperature

Immunoblot blocking solution

5 g nonfat dry milk
1 g bovine serum albumin, fraction V
0.1 ml Tween 20 (optional)
0.1 M phosphate buffer, pH 7.4 (see recipe), to 100 ml
Make fresh before each use
For overnight incubation, add 1 ml of 2% sodium azide to prevent bacterial growth.

Immunoblot wash solution

5 g bovine serum albumin, fraction V (1% w/v)
0.5 ml Tween 20 (0.1% v/v; optional)
500 ml 0.1 M phosphate buffer, pH 7.4 (see recipe)
Store up to 1 week at 4°C

Immunohistochemistry antibody dilution buffer

1 ml bovine serum albumin (BSA), fraction V
0.1 ml Triton X-100
2 ml serum from the host species used to make the secondary antibody
0.1 M phosphate buffer, pH 7.4 (see recipe), to 100 ml
Mix well, aliquot and store at −20°C

Immunohistochemistry blocking solution

5 g nonfat dry milk
1 g bovine serum albumin, fraction V
0.1 ml Triton X-100
0.5 ml rat whole serum
2 ml serum from host species used to make the secondary antibody
0.1 M phosphate buffer, pH 7.4 (see recipe), to 100 ml
Make fresh before each use

Immunohistochemistry peroxidase inhibiting solution

0.65 g sodium azide
0.2 ml 30% hydrogen peroxide solution, <1 to 2 months old
Add 0.1 M phosphate buffer, pH 7.4 (see recipe), to 100 ml
Make fresh before each use

In situ hybridization cocktail

50 ml formamide, deionized
20 ml 20× SSC (see recipe)
2 ml 100× Denhardt's solution (see recipe)
10 ml 0.2 M phosphate buffer, pH 7.0 (see recipe)
10 g dextran sulfate
5 ml 20% (w/v) *N*-lauroylsarcosine (Sarcosyl)
Mix at 37°C overnight or until the dextran crystals are dissolved
Add sterile H_2O to 100 ml
Filter through a 0.45 to 0.8-µm filter
Divide into aliquots and store up to 6 to 12 months at −20°C

Do not store for >6 to 12 months. The solution should be discarded if it is cloudy when thawed.

Methylene blue RNA staining solution, 0.02% (w/v)

2.5 g sodium acetate, anhydrous
80 ml sterile H_2O
Adjust pH to 5.5 with acetic acid
Add 0.02 g methylene blue
Add H_2O to 100 ml
Store up to 6 months at room temperature

Paraformaldehyde solution, 4% (w/v)

8% paraformaldehyde stock: Add 40 g paraformaldehyde (PFA) to 480 ml water. In a fume hood, heat to 80°C while stirring. When at 80°C, turn off the heat and add a few drops of 1 N NaOH, until the solution becomes clear. Cool to room temperature and filter through a Whatman 3MM filter paper into a 500-ml graduated cylinder. Add water to 500 ml. Store the 8% PFA stock solution up to 1 to 2 months in air-tight bottle at 4°C.

4% working solution: To use in perfusion, combine one volume of 8% PFA with an equal volume of 0.2 M phosphate buffer, pH 7.4 (stock), for a final concentration of 4% PFA in 0.1 M phosphate buffer, pH 7.4.

Phosphate buffer (pH 7.4), 0.2 M

5.24 g $NaH_2PO_4 \cdot H_2O$
23 g $Na_2H_2PO_4$
800 ml H_2O
Adjust pH to 7.4
Add H_2O to 1000 ml

Add chemicals gradually to water while stirring (the solution may need to be heated to dissolve the chemicals). Store indefinitely at room temperature.

For 0.1 M and 0.05 M phosphate buffer, dilute 0.2 M appropriately in water.

Ponceau S staining solution

2 g Ponceau S
1 ml acetic acid
H_2O to 100 ml
Mix well and store indefinitely at room temperature

SDS sample buffer, 1×

0.7 g Tris base
10 ml glycerol
2 g SDS
H_2O to 80 ml
Adjust pH to 6.8 with concentrated HCl
Add H_2O to 100 ml
Store up to 1 to 2 months at room temperature

Sodium acetate solution, pH 6.7, 0.175 M

14.4 g sodium acetate, anhydrous
900 ml H_2O
Adjust pH to 6.7 with acetic acid
Add H_2O to 1000 ml
Store up to 1 month at 4°C

SSC, 20×

175.3 g NaCl
88.2 g sodium citrate (trisodium dihydrate)
800 ml H_2O
Adjust pH to 7.0
H_2O to 1000 ml
Autoclave
Store indefinitely at room temperature

SSPE, 20×

210 g NaCl
53.6 g $Na_2HPO_4 \cdot 7\ H_2O$
7.4 g EDTA
800 ml H_2O
Adjust pH to 7.0.
H_2O to 1000 ml.
Autoclave.
Store indefinitely at room temperature

Sucrose, 30% (w/v)

Dissolve 30 g sucrose in 70 ml warm water. Add water to 100 ml. Autoclave and store up to 1 month at 4°C.

COMMENTARY

Background Information

The induction of stress proteins is a ubiquitous cellular response of most tissues and organisms to a broad variety of metabolic and environmental insults. In the last fifteen years, major classes of stress proteins have been characterized with respect to inducers, organisms, and tissues (Table 2.9.3). Many of these proteins have been associated with resistance to cellular injury, since they preserve and recover the tertiary structure and the function of various cellular protein complexes (Bergeron et al., 1996; Massa et al., 1996; Sharp et al., 1999). The HSP70 protein family has been extensively characterized. It comprises different genes, encoding proteins of molecular mass between 68 and 78 kDa. HSP72 and HSP73 act as chaperones in the nucleus and cytoplasm by preventing the formation of abnormal protein conformation. In normal cells, HSP73 is constitutively expressed whereas HSP72 is only expressed at exceedingly low levels. Following various stimuli, HSP72 expression is markedly induced compared to HSP73. In contrast, GRP75 and GRP78 are chaperone proteins within the mitochondria and the endoplasmic reticulum, respectively. The GRPs are constitutively expressed in normal cells, but both are inducible by several stimuli (Tables 2.9.1 and 2.9.3). In addition to being molecular markers of cellular stress in tissues, recent studies using heat shock or viral overexpression suggest that the induction of some HSP70s may protect against specific types of injury or pathological processes (Sharp et al., 1999).

Critical Parameters and Troubleshooting

Northern blot hybridization

The most critical element for northern blotting is the quality of the RNA extracted. It is important to excise, freeze, and/or homogenize the tissue quickly before substantial degradation occurs. It is also essential to minimize RNase contamination with the use of RNase-free chemicals, solutions, and materials, and by wearing clean powder-free gloves at all times during the experiment. Make sure to allow enough time for isopropanol precipitation and do not dry out the final RNA pellet as it will result in low RNA recovery. Because mRNA represents only a small fraction (2% to 5%) of total RNA, use mRNA extracts (instead of total RNA) when the transcript of interest is low in abundance. The use of mRNA will result in a cleaner and enhanced signal.

In general, a suitable oligonucleotide sequence for northern analysis and in situ hybridization should be ~30 to 45 bp long with a 50% to 65% GC content (Stahl et al., 1993). The oligonucleotide sequence should fall within the protein coding sequence (open reading frame). Because coding sequences show the most homology between different species, it is possible to use the same oligonucleotide for tissues obtained from different species. The specificity of the selected sequence should be verified by comparing it to known sequences in GenBank. Northern blot analysis using the antisense oligonucleotide sequences described in Table 2.9.2 shows bands of expected size in rodent tissues (Miller et al., 1991; Massa et al., 1995; Narasimhan et al., 1996).

In situ hybridization

Although in situ hybridization performed with oligonucleotides can be insensitive for rare mRNAs, it is a very useful method for mapping the mRNA expression of the HSP70 family members, because their expression can be induced several fold by various stimuli (Tables 2.9.1. and 2.9.3). The use of ^{35}S-labeled probes (instead of ^{33}P or ^{32}P) is highly recommended since it is associated with higher efficiency of grain production and less signal scattering, thus providing greater resolution. Because ^{35}S has a longer half life (87 days) than the other isotopes (14 and 25 days for ^{32}P and ^{33}P, respectively), multiple film exposures can be performed and the use of autoradiographic emulsion (which requires long exposure) becomes possible.

The experimental conditions presented here are optimized for work with short oligonucleotides (i.e., 30- to 45-mer) with a 50% to 65% guanosine-cytosine (GC) base content. This is important because a higher percentage of GC content will result in higher melting temperatures that may compromise specimen preservation. In addition, higher GC content may result in higher intramolecular probe interactions that could affect the efficiency of hybridization with the target mRNA in the tissue and lead to nonspecific pairing. Nonspecific hybridization of the probe to cellular DNA appears unlikely because the conditions described are suboptimal for DNA denaturation

in tissue specimens (Pardue, 1985). To control for the possibility that the probe might bind significantly to DNA rather than RNA in a given tissue, some slides can be treated with RNase prior to hybridization. The signal obtained from such experiments indicates the level and location of DNA hybridization in the tissue. However, the most important control experiment is to perform the in situ hybridization with the sense oligonucleotide probe of the gene of interest. The signal should be very low to undetectable. The quality of tissue sections will greatly influence the distribution and the level of transcript detected. It is important to excise the tissue quickly and freeze it in a bath of isopentane maintained at −35°C to −40°C on dry ice (~1 min). This method helps preserve the shape of the tissue and prevents quick fractures and other freezing artifacts (i.e., ice crystals in tissue) that could significantly affect sectioning and the in situ signal. While cutting sections, always keep slides at approximately −20°C on the cryostat shelf. To add a section to a slide, warm up a small area with a gloved finger, collect the slice and put the slide back on the cryostat shelf. Avoid touching the frozen sections and tissue with fingers or warm instruments. Transfer the slides to −70°C until they are assayed. It is absolutely crucial to avoid freeze-thaw-freeze cycles, which will result in rapid degradation of transcript.

Protein labeling

The protocol described in this unit has been used successfully with confluent cultures of astrocytes, NIH3T3 cells, and other mammalian cell lines. It is important to incubate the cells in a methionine-free medium ≥12 hr before metabolic labeling to ensure that most of the endogenous methionine is used up. This will favor ^{35}S-methionine incorporation and thus increase the specific activity of the proteins in the cell lysate. Because cells only incorporate a certain amount of methionine per hour (depending on their metabolic rate), using too much radioactivity will be ineffective for increasing the amount of ^{35}S-methionine incorporated. It is also more difficult to wash out the excess radioactivity, which can contribute to higher background in the cell lysates. In most normal cell systems, a 2-hr labeling period is necessary, and this time period is generally sufficient to detect a significant amount of ^{35}S-methionine incorporation into proteins. The labeling period should be optimized for a given insult and cell system. In general, longer incubations with the radioactivity will result in higher incorporation but higher background (i.e., saturated signal on autoradiograms) whereas shorter incubations may not allow enough time for incorporation and reliable detection. A 2-hr labeling period at different time points after a stressful stimulus provides a means to follow the development of a stress response (i.e., decreased overall protein synthesis with concomitant increases in specific stress proteins). This method only provides information on the overall amount of ^{35}S-methionine incorporation, which is an indirect measure of protein synthesis. In addition, this approach is nonspecific and only identifies proteins based on their apparent molecular weight. To confirm the identity of a specific protein, it is recommended that an immunoblot analysis be performed on the radioactive cell lysate.

Immunoblotting

The mouse monoclonal antibody (C-92 Clone), originally described by Welch and Suhan (1986) and now sold by Amersham Pharmacia Biotech and StressGen, produces one major band and one minor band on immunoblots in rat brain (Narasimhan et al., 1996) and only one major band in mouse brain (Bergeron et al., 1996). This antibody demonstrates a clean signal on immunoblots without the use of a detergent such as Tween 20 in the incubating solutions. Similarly, the mouse monoclonal GRP75 antibody and rabbit polyclonal GRP78 antibody both recognize a single band on immunoblots.

Because members of the HSP70 family are fairly resistant to high temperatures, protein lysates can be prepared simply and quickly by homogenizing the tissue directly in 1× SDS sample buffer followed by incubating 2 to 5 min at 100°C. For more common problems associated with SDS-PAGE and immunoblotting techniques, refer to Table 2.9.5.

Immunohistochemistry

Immunohistochemistry performed with the mouse monoclonal HSP72 antibody (Clone 92, Amersham Pharmacia Biotech or StressGen) on astrocytes transfected with the rat hsp70 gene cloned from rat brain (Longo et al., 1993) yields specific staining (Narasimhan et al., 1996). This suggests that the C-92 recognizes the protein translated from the rat hsp70 gene and confirms the identity of the gene product studied in most of the published HSP70 immunohistochemistry studies to date.

Because the HSP72 antibody (C-92 clone) is very sensitive to overfixation, the tissue should be sectioned immediately after intracardiac aldehyde perfusion or after a few hours of aldehyde postfixation. Immunohistochemistry should be started as soon as possible after cutting sections. Tissue injury can activate endogenous peroxidase activity in cells and sometimes results in false-positive signals. To control for this problem, it is essential that alternate sections be processed for immunohistochemistry without the primary antibody and/or secondary (anti-IgG) antibody. Staining present after deletion of the primary antibody suggests that the secondary antibody recognizes nonspecific sites. If this occurs, dilute the antibody further or use another source of secondary antibody. Staining that is still present after deletion of the secondary antibody (or both antibodies) may be due to activation of endogenous peroxidase activity. The common practice of quenching endogenous peroxidase activity with hydrogen peroxide cannot be used with the Amersham Pharmacia Biotech antibody because peroxide treatment attenuates staining. Similar precautions have been used successfully with the anti-GRP75 and anti-GRP78 antibodies from StressGen. For more common problems associated with immunohistochemistry techniques, refer to Table 2.9.6.

Anticipated Results

Northern blot analysis

The antisense oligonucleotide probes shown in Table 2.9.2 are derived from rat cDNAs. Therefore, northern blot analysis should reveal bands of the expected size in rodent tissues. Whereas HSP73, GRP75, and GRP78 demonstrate constitutive levels of mRNA in most normal tissues, HSP72 mRNA levels are usually not detectable. An up-regulation of all mRNAs should appear as denser bands of the same predicted sizes. Depending on the abundance of each transcript in a given tissue, 10 to 20 µg of total RNA or 2 to 10 µg of mRNA should be sufficient to detect a signal within 2 to 7 days.

In situ hybridization

RNA hybridization on tissue sections using labeled oligonucleotides should appear as an increase in regional grain density on X-ray film autoradiography with low nonspecific background signal. Although hybridization signals from ^{35}S-probes can take from a few days to weeks of film exposure for detection (depending on the abundance of the transcript), it usually shows better resolution (i.e., less signal scattering and background noise) than the higher energy ^{33}P-probes. Emulsion autoradiography should provide a better cellular resolution, especially when a light counterstaining is applied on the slide. The signal should appear as black grains over a stained cell.

Detection of [^{35}S]-labeled proteins

Lysates from labeled, unstressed cells should show a wide range of labeled proteins with bands of medium-to-high intensity. Because most stressful stimuli result in decreased overall protein synthesis, the lane on the gel corresponding to a "stressed lysate" should appear fairly clean, with very few bands of low-to-medium intensity compared to control lysates. Concomittant with decreased protein synthesis (i.e., decreased overall ^{35}S-methionine incorporation), a selective increase of stress proteins will appear in "stressed lysates" as sharp bands of different molecular weights corresponding to several of the genes shown in Table 2.9.3. Typically, 10 to 20 µg of radioactive protein lysate is sufficient to produce a medium-to-strong signal on autoradiograms after overnight exposure.

Immunoblotting

Immunoblotting should result in the detection of a single band of the appropriate size as shown in Table 2.9.4. HSP72 protein is generally not detectable in normal tissues unlike HSP73, GRP75, and GRP78, which are constitutively expressed. With the appropriate stressful stimulus, increased band density may be observed. Use caution to prevent protein degradation, which may produce multiple nonspecific bands on the blot. In certain tissues or different rodent families, the C92 antibody against HSP72 has been shown to detect one major band at 72 kDa for HSP72 and a minor band right above it corresponding to HSP73. Depending on the abundance of each protein in a given tissue, 10 to 40 µg of protein lysate will be sufficient to detect a significant signal.

Immunohistochemistry

Because GRP75 and GRP78 proteins are associated with the mitochondria and the endoplasmic reticulum, respectively, good DAB immunolabeling at the light microscopy level should result in medium-brown staining in the cytoplasmic region of cells with minimal back-

Table 2.9.5 Troubleshooting Guide for SDS-PAGE Separation and Immunoblotting

Problem	Possible cause	Solution
Dye front on the gel and bands on blot curve up at the edges (smile)	Gel is hotter in the middle than at the edges	Run gel in a cooler room or run gel at lower power. If using a tank electrophoresis system, completely submerge the gel sandwich in cool running buffer.
Distorted protein bands	Insufficient polymerization of stacking gel	Make sure the stacking gel is well polymerized before removing the comb and loading samples
	Air bubbles trapped under the comb teeth resulting in uneven polymerization of sample well	Make sure no air bubble gets trapped under the comb and rinse the sample well carefully before loading to remove traces unpolymerized acrylamide
Protein bands are fuzzy and diffuse or poorly resolved	Too much sample volume is loaded	Sample should be loaded as a tight layer in the bottom of the well. Use as small a volume as possible. Alternatively, use a thicker gel and sample well.
	Sample has diffused out in the stacking gel around the well	Start electrophoresis immediately after loading
	Sample degradation	Keep SDS protein extract on ice at all times prior to heat-denaturation. For long-term storage, keep samples at −70°C.
	Inappropriate acrylamide concentration in separating gel	Use appropriate acrylamide concentration in separating gel according to the molecular weight of the protein of interest.
Poor transfer of proteins on membrane (assessed by Ponceau staining)	Gel is too thick or gel porosity is too low	Use appropriate acrylamide concentration in separating gel according to the molecular size of the protein of interest. For the HSP70 protein family, use 8%-10% acrylamide. Load less protein on a thinner gel.
	Incorrect transfer time	Small proteins need shorter transfer time whereas larger polypeptides may require overnight transfer at low voltage, at 4°C.

continued

Table 2.9.5 Troubleshooting Guide for SDS-PAGE Separation and Immunoblotting, continued

Problem	Possible cause	Solution
	Incomplete contact of gel with the membrane	Make sure there are no air bubbles between the gel and the membrane by rolling a pipet over the wet gel-membrane sandwich
	Incorrect transfer buffer composition	High concentration of methanol in transfer buffer can interfere with the transfer of large proteins. Decrease the methanol until conditions are appropriate.
High background	Nonspecific antibody binding	Affinity purify polyclonal antibodies. If background is still high, replace primary and secondary antibody since they could be denatured.
	Antibody concentration too high	Dilute primary and/or secondary antibodies.
	Incomplete blocking	Increase blocking time and/or increase the concentration of blocking agents such as milk and serum proteins. Add 0.05%-0.1% Tween 20 in the blocking and incubation buffers.
Low or no reactivity	Tween 20 concentration too high	>0.05%-0.1% Tween 20 may elute the proteins from the membrane or may prevent the interaction of some antibodies with the specific proteins. Do not use Tween 20 or other ionic detergents in buffers unless the background is unreasonably high.
	Incorrect primary antibody	Use primary antibody that recognizes the denatured antigen.
	Incorrect incubation conditions	Increase the primary antibody concentration or increase time of incubation with the primary antibody.

ground throughout the normal tissue. Similar results should be observed with immunofluorescence. Following a stressful stimulus, an increased GRP75 and/or GRP78 expression would appear as increased cellular staining intensity and increased number of immunopositive cells, without increasing the tissue background. Because HSP72 is not constitutively expressed in most tissues, there should be no (or minimal) immunostaining found in unstressed animals, which is in contrast to constitutively expressed HSP73. In addition, because both HSP72 and HSP73 chaperone nascent or misfolded proteins in the cytoplasm and nucleus, one can expect to find increased immunostaining in these compartments following a specific stressful stimulus.

Table 2.9.6 Troubleshooting Guide for Immunohistochemical Staining

Problem	Possible cause	Solution
Chromogenic visualization		
Labeling seems specific but background is high	Nonspecific binding of primary or secondary antibody	Increase blocking time and/or increase the concentration of blocking agents such as milk (to 5%), BSA (1%-2%) or serum (to 10%-20%). Use a serum from same species as that used to make the secondary antibody.
	High activity of endogenous peroxidases (for staining with DAB reaction)	Incubate sections in peroxidase blocking solution
	Duration of DAB reaction is too long	Reduce the incubation time or dilute DAB/hydrogen peroxide solution
No labeling is seen even if a clear signal was observed on immunoblots of the same tissue	The antibody does not recognize the native form of the antigen. This occurs when the antibody is raised against denatured rather than native antigen. Because polyclonal antibodies recognize multiple epitopes of the same protein, the problem is more common with monoclonal antibodies.	Use a different antibody if possible
	Overfixation caused conformational changes of the antigen	Reduce the fixation time and cut tissue as soon as possible. Incubate sections in several washes of phosphate buffer.
	No chromogenic reaction because of the use of old hydrogen peroxide stock solution	Use fresh hydrogen peroxide stock solution (30%) of no more than 1-2 months old. Store the solution at 4°C.
Staining intensity of the tissue section is uneven	The thickness of the tissue section is uneven. This can occur when cutting extremely soft tissue (which tends to deform slightly under the movement of the blade) on a vibratome. The intensity of background staining is proportional to the relative thickness of a cut area.	For softer tissue, the use of a freezing microtome is highly recommended. Cryostat sections are useful but can be labor intensive. Alternatively, the tissue can be embedded in agarose prior to cutting on the vibratome.

continued

Table 2.9.6 Troubleshooting Guide for Immunohistochemical Staining, continued

Problem	Possible cause	Solution
	Some parts of the tissue section were not totally immersed in the incubating solutions during the procedure. This results in uneven exposure to the blocking agents, primary and secondary antibodies, or DAB reagent.	Make sure that the tissue sections are totally immersed in incubating solutions at any time.
	Some sections got stuck together during the incubations, causing uneven exposure of some tissue areas to the blocking solution, antibody, or DAB reagent	Make sure that the tissue sections are not tangled together at any time during incubations and washes. Use a small brush to seperate them.
Fluorescent visualization		
Fluorescent staining is faded	Photobleaching occured because the slides were exposed to light and/or were not kept at 4°C prior to observation	Keep slides in the dark and at 4°C at all times
Presence of fluorescence in unlabeled tissue sections	Autofluorescence often caused by aldehyde fixatives	Wash sections thoroughly in phosphate buffer, or try another fixative
Presence of fluorescence in sections incubated without the primary antibody	The concentration of the fluorescent secondary antibody is too high	Dilute the secondary antibody
	Nonspecific binding of the secondary antibody	Increase blocking time and/or increase concentration of blocking agents such as milk or serum proteins. Change the secondary antibody.
Fluorescent labeling is weak and grainy with loss of defined cellular morphology	Sections on slide have dried during the procedure or before coverslipping	Do not allow slides to dry at any time during freezing, immunocytochemistry, or before coverslipping.

Time Considerations

Northern blot analysis

Total RNA or mRNA can be isolated in 1 day. The RNA is then separated on an agarose gel and capillary transferred onto a membrane overnight. The next day, the oligonucleotide probe is radiolabeled and purified while the membrane is undergoing prehybridization. Hybridization is performed overnight. The following day, the blot is washed and then exposed to an autoradiographic film for 1 to 7 days depending on the abundance of the transcript and the specific activity of the probe.

In situ hybridization

Once frozen sections are obtained on slides (day 1), the oligonucleotide can be labeled and purified the next day. Hybridization is performed overnight. The following day, the slides are washed, dried, and exposed to an autoradiographic film for 1 to 7 days, depending on the abundance of the transcript and the specific activity of the probe.

Detection of [^{35}S]labeled proteins

The radiolabeled cell lysate is prepared and the protein concentration is determined in 1 day. Protein samples are separated and the gel stained in 1 day. The next day the gel is destained, dried, and exposed to an autoradiographic film overnight (day 3). The next morning (day 4), the film is developed and a hard copy of the result can be analyzed by densitometry on an image analyzer.

Immunoblotting

After the cell lysate has been prepared, samples can be separated by SDS-PAGE and electrotransferred to a membrane in 1 day. However, the use of larger and thicker gels can increase the time required for electrophoresis and transfer to an additional day. After overnight incubation in blocking solution, exposure of the membrane to the primary and secondary antibodies and immunoreactivity detection can be performed in 1 day.

Immunohistochemistry

Perfusion-fixation, tissue cutting, and incubation in blocking solution can be performed in 1 day. After overnight incubation with the primary antibody, sections are exposed to the secondary antibody and visualization of bound antibodies is performed on the same day. Mounting on gelatin-coated slides, drying, and coverslipping of tissue sections takes 2 days.

Analysis of Mitochondrial Dysfunction During Cell Death

For many years mitochondria were considered only as a main energy supplier in the cell. In the middle of the 1990s it became clear that mitochondria actively participate in apoptosis, a form of cell death characterized by specific biochemical and morphological changes.

The following protocols represent basic tools widely used in estimating functional activity of mitochondria. The protocols are organized into three groups. The first group describes direct assessment of mitochondria in apoptotic cells—collection of proteins released from isolated mitochondria (see Basic Protocol 1), and from mitochondria within the cell (see Basic Protocol 2), immunoblot analysis of released proteins (see Basic Protocol 3), assessment of the mitochondrial membrane potential in apoptotic cells stained with TMRE (see Basic Protocol 4), and microscopy of apoptotic cells stained with MitoTracker Red (see Basic Protocol 5). The second group of protocols describes measurement of the mitochondrial permeability transition (MPT)—measurement of Ca^{2+} fluxes with an electrode (see Basic Protocol 6) or spectrophotometrically (see Alternate Protocol 1), measurement of the mitochondrial membrane potential with a TPP^{+} electrode (see Basic Protocol 7) or spectrophotometrically (see Alternate Protocol 2), estimation of mitochondrial swelling (see Basic Protocol 8), and measuring Ca^{2+} accumulation in permeabilized cells (see Basic Protocol 9). Support Protocols are included for the preparation of mitochondria from a number of sources—liver (see Support Protocol 1), brain (see Support Protocol 2), and cultured cells (see Support Protocol 3)—and for assessing the quality of the prepared mitochondria (see Support Protocol 4).

EVALUATION OF THE RELEASE OF PROTEINS FROM INTERMEMBRANE SPACE OF MITOCHONDRIA

The release of certain proteins from mitochondria in apoptotic cells is believed to be one of the key events in apoptosis. Therefore, estimation of the release of these proteins is important for understanding the role of mitochondria in apoptosis.

Collecting Samples of Proteins From Isolated Mitochondria

BASIC PROTOCOL 1

This method is based on the estimation of the amount of cytochrome *c* or any other protein released from the intermembrane space of mitochondria that remains in the incubation buffer after the mitochondria are removed by centrifugation. This protocol describes collecting samples of proteins released from isolated mitochondria incubated under different experimental conditions. Such experiments are very helpful in order to estimate a possible effect of certain pro-apoptotic compounds on mitochondria.

Materials

Isolated mitochondria (Support Protocols 1 to 3)
Buffer

1. Incubate mitochondria at a concentration of 1 mg protein/ml (time, conditions of incubation, and buffer to be used depend on the aim of the experiment).

   This buffer can be used for mitochondria isolated from different sources. The composition of the buffer is determined mainly by the aims of the experiment (see also Background Information, MPT-dependent release of cytochrome c). For example, estimation of the release of cytochrome c is more suitable to perform in KCl-based ionic buffer, since the

Contributed by Vladimir Gogvadze, Sten Orrenius, and Boris Zhivotovsky
Current Protocols in Toxicology (2004) 2.10.1-2.10.27

binding of cytochrome c to the inner mitochondrial membrane is significantly weaker as compared to mannitol-sucrose buffer. If the aim of the experiment is to assess MPT-independent release of cytochrome c, a calcium chelator EGTA, or cyclosporin A should be included.

2. Take a 200-µl aliquot and transfer to a microcentrifuge tube.
3. Microcentrifuge 5 min at 10,000 × *g*, 4°C.
4. Gently remove the supernatant without disturbing the pellet.
5. Resuspend the pellet in the original volume of the same buffer used for the incubation in step 1.
6. Freeze samples of supernatant (step 4) and pellet (step 5) and keep them at −20°C.

The samples are now ready for detection, e.g., of cytochrome c via immunoblotting (see Basic Protocol 3).

BASIC PROTOCOL 2

Evaluation of Cytochrome *c* Release from the Mitochondria of Apoptotic Cells

In order to analyze the release of certain proteins from mitochondria of apoptotic cells, the cellular plasma membrane should be disrupted and cytosolic fraction should be separated from membrane material. This can be achieved by preincubation of cells in a hypotonic solution that induces cell lysis.

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa)
Apoptotic stimuli (e.g., etoposide, staurosporine)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
S100 buffer (see recipe), ice-cold
Refrigerated low-speed centrifuge and ultracentrifuge

Additional reagents and equipment for immunoblot analysis (see Basic Protocol 3 and Gallagher et al., 1998)

1. Incubate cells with apoptotic stimuli (type, concentration, and incubation time determined by cell type).
2. Wash cells twice, each time with 5 ml of ice-cold PBS.
3. Resuspend cells at 75×10^6 cells/ml in ice-cold S100 buffer.
4. Incubate on ice for 10 to 20 min.
5. Centrifuge cells 15 min at 10,000 × *g*, 4°C.
6. Transfer supernatant to ultracentrifuge tube and ultracentrifuge 1 hr at 100,000 × *g*, 4°C.
7. Use supernatant for immunoblot analysis (see Basic Protocol 3 and Gallagher et al., 1998) with an antibody specific for cytochrome *c*.

Immunoblot Analysis of Proteins Released from the Mitochondria During Apoptosis

After separation as in Basic Protocol 1 or 2, the supernatant contains proteins released from mitochondria, while the pellet represents proteins associated with the organelles. The detection of these proteins is performed using electrophoresis with subsequent blotting and probing with specific antibodies.

Materials

Sample collected from apoptotic mitochondria (see Basic Protocol 1 or 2)
4× Laemmli's loading buffer (see recipe)
15% (w/v) SDS-PAGE gel (*APPENDIX 3F)*
5% (w/v) nonfat milk in PBS (see *APPENDIX 2A* for PBS)
Antibody specific for apoptotic protein of interest (e.g., Becton Dickinson Biosciences)
PBS (*APPENDIX 2A*) containing 2.5% (w/v) nonfat dry milk
Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 1% (w/v) bovine serum albumin and 0.01% (w/v) azide (NaN_3)
PBS (*APPENDIX 2A*) containing 15% (v/v) Tween 20
Horseradish peroxidase–conjugated secondary antibody (e.g., Pierce)
ECL Western Blotting Detection Reagents kit (Amersham Biosciences)
Additional reagents and equipment for SDS-PAGE (*APPENDIX 3F)* and electroblotting (Gallagher et al., 1998)

Perform electrophoresis

1. Mix 40 µl of sample with 12.5 µl of 4× Laemmli's loading buffer. Boil 5 min.
2. Separate the proteins on a 15% SDS-PAGE gel at 130 V (*APPENDIX 3F).*

Perform immunoblotting and detect apoptotic proteins

3. Transfer proteins to nitrocellulose membranes by electroblotting (Gallagher et al., 1998) for 2 hr at 100 V.
4. Block membranes for 1 hr with 5% nonfat milk in PBS at room temperature.
5. Probe overnight in a cold room with an antibody (diluted 1:2500 in PBS containing bovine serum albumin and 0.01% NaN_3) specific for the apoptotic protein of interest.
6. Rinse membranes for 10 min in 30 to 40 ml of PBS.
7. Rinse membranes for 15 min in 30 to 40 ml of PBS with 0.15% Tween 20.
8. Rinse membranes for 10 min in 30 to 40 ml of PBS.
9. Incubate with a horseradish peroxidase–conjugated secondary antibody (diluted 1:10,000 in PBS containing 2.5% nonfat dry milk).

Visualize bound antibodies

10. Following incubation with the secondary antibody, rinse the membranes for 10 min in 30 to 40 ml of PBS.
11. Rinse membranes for 15 min in 30 to 40 ml of PBS with 0.15% Tween 20.
12. Rinse membranes for 10 min in 30 to 40 ml of PBS.
13. Detect bound antibodies using enhanced chemiluminescence (ECL kit) according to the manufacturer's instructions.

BASIC PROTOCOL 4

Assessment of the Mitochondrial Membrane Potential in Apoptotic Cells

The mitochondrial membrane potential ($\Delta\psi$), which drives oxidative phosphorylation (Mitchell and Moyle, 1967) and which also drives mitochondrial calcium uptake, is generated by an electron-transporting chain. When electron transport ceases, for example during ischemia, the inner-membrane potential is developed at the expense of ATP hydrolysis by the mitochondrial ATP synthase. An early manifestation of apoptosis is often a decrease in the $\Delta\psi$, which is usually demonstrated using flow cytometry. The relationship between mitochondrial depolarization and apoptosis remains controversial. Some investigators consider a decrease in $\Delta\psi$ an early irreversible signal for apoptosis (Zamzami et al., 1996), while others describe it as a late event (Bossy-Wetzel et al., 1998).

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa)
RPMI-1640 medium (Life Technologies) supplemented with 5% (v/v) heat-inactivated fetal bovine serum, 2 mM L-glutamine, penicillin (100 U/ml), and streptomycin (100 μg/ml)
25 mM TMRE stock solution: dissolve 12.8 mg tetramethylrhodamine methyl ester (TMRE; Molecular Probes) in 1 ml ethanol; store per manufacturer's instructions
HEPES buffer (see recipe)
Flow cytometer (e.g., FACS; Becton Dickinson)

1. Prepare an aliquot of 10^6 cells in RPMI-1640 medium.
2. Dilute TMRE stock solution 1:1000 with HEPES buffer (for a concentration of 25 μM).
3. Add an aliquot of the diluted (25 μM) TMRE to cells for a final concentration of 25 nM.
4. Incubate cells with TMRE 20 min at 37°C.
5. Further dilute the 25 μM TMRE 1:1000 with HEPES buffer for a final concentration of 25 nM. Centrifuge cells 5 min at 200 × *g*, room temperature, and resuspend in fresh HEPES buffer containing 25 nM TMRE.
6. Analyze membrane potential by flow cytometry according to the manufacturer's instructions for the instrument used (see Fig. 2.10.1).

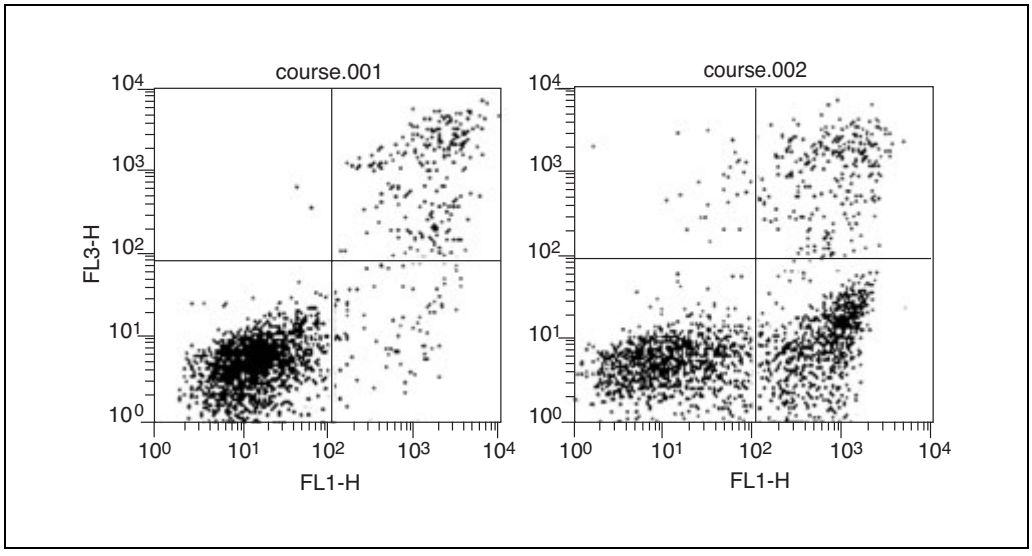

Figure 2.10.1 A typical image of FACS analysis of mitochondrial membrane potential in the cells undergoing apoptosis. Apoptosis was induced in Jurkat cells by 1 μM staurosporine and samples were analyzed 3 hr after initiation of apoptosis.

Microscopy of Apoptotic Cells Stained with MitoTracker

Fluorescent probes for mitochondria such as rhodamine 123 or tetramethylrosamine are readily sequestered by mitochondria. However, in experiments that require fixation of the organelles, these stains are easily washed out. In contrast, mitochondria-selective probes—e.g., MitoTracker Red (Molecular Probes)—are concentrated by active, energized mitochondria and retained during fixation. Once mitochondria are labeled, the cells can be fixed for further processing, for example, if cells are going to be subsequently labeled with antibody.

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa) and appropriate culture medium
MitoTracker Red (Molecular Probes); store according the manufacturer's instructions
Dimethylsulfoxide (DMSO)
4% (w/v) paraformaldehyde in serum-free culture medium
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS (*APPENDIX 2A*) containing 0.2% (v/v) Triton X-100
PBS (*APPENDIX 2A*) containing 1% (v/v) fetal bovine serum (FBS)
Mounting medium: 50% (w/v) glycerol/PBS
Fluorescent or scanning confocal microscope (e.g., Bio-Rad), with 581-nm excitation filter and 644-nm emission filter

Additional reagents and equipment for cell culture (*APPENDIX 3B*)

1. Grow cells on coverslips inside a petri dish filled with the appropriate culture medium to the optimal density.

   The optimal cell density depends on the cell type.

2. Open fresh vial of MitoTracker Red and add DMSO to create a 1 mM stock. Protect from light.

3. Dilute 1 mM MitoTracker Red to final working concentration in the culture medium used to grow the cells.

   Recommended Mito Tracker Red concentration is 100 to 500 nM. Diluted MitoTracker Red can be stored up to several months at –20°C

4. When cells have reached the desired confluence, remove the medium from the dish and add the prewarmed (37°) growth medium containing MitoTracker probe. Incubate for 30 min.

5. Replace the loading solution with fresh prewarmed medium.

Fix and permeabilize cells

6. Remove the growth medium covering the cells and replace it with fresh prewarmed medium containing 4% paraformaldehyde. Incubate 15 min at 37°C.

7. Rinse cells three times, each time for 5 min with room temperature PBS.

8. Incubate fixed cells in PBS containing 0.2% Triton X-100 at room temperature for 5 min.

9. Rinse cells three times, each time for 5 min with PBS containing 1% FBS.

10. Mount coverslips on glass slides in 50% glycerol/PBS and examine under fluorescent or scanning confocal microscope with excitation at 581 nm and emission at 644 nm.

ASSESSMENT OF THE MITOCHONDRIAL PERMEABILITY TRANSITION IN ISOLATED MITOCHONDRIA

The mitochondrial permeability transition (MPT) is one of the mechanisms that can lead to the release of cytochrome *c* from mitochondria during apoptosis. MPT is a consequence of Ca^{2+} overload. Accumulation of Ca^{2+} in mitochondria is driven by the mitochondrial membrane potential supported either by mitochondrial respiration or by ATP hydrolysis. Mitochondria release Ca^{2+} when the membrane potential is dropped either by inhibitors of mitochondrial respiratory chain (if the potential is supported by oxidation of a substrate) or by inhibitors of ATPase (if the source of potential is hydrolysis of ATP).

Retention of Ca^{2+} by mitochondria stimulates processes that result in mitochondrial deterioration. Mitochondria swell and become leaky, whereupon the membrane potential drops and Ca^{2+} is released. Although Ca^{2+} is obligatory for MPT induction, the sensitivity of mitochondria to permeability transition can be enhanced by different factors. Among these factors are elevated levels of phosphate, oxidative stress, and the depletion of adenine nucleotides. When phosphate or organic peroxide is added to Ca^{2+}-loaded mitochondria, these organelles swell, membrane potential decays, and accumulated Ca^{2+} is released. All of these manifestations can be prevented by cyclosporin A (CsA), an inhibitor of pore opening. Therefore, MPT in isolated mitochondria can be assessed by monitoring either swelling, membrane potential, or the level of Ca^{2+} in the incubation buffer.

Accumulation of Ca^{2+} by mitochondria, as well as Ca^{2+} retention and release induced by different stimuli, can be monitored using a Ca^{2+}-sensitive electrode or spectrophotometrically with the Ca^{2+}-sensitive dye arsenazo III.

BASIC PROTOCOL 6

Monitoring of Ca^{2+} Fluxes Across the Inner Mitochondrial Membrane with a Ca^{2+}-Sensitive Electrode

One relatively easy method applicable to mitochondria and permeabilized cells employs a Ca^{2+}-sensitive electrode to follow the Ca^{2+}. Accumulation of Ca^{2+} by mitochondria can be followed by a decrease in the concentration of Ca^{2+} in the incubation buffer.

Materials

Incubation buffer for calcium-sensitive electrode (see recipe)
Isolated mitochondria (Support Protocol 1, 2, or 3)
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month
0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:
Glass (or plastic) sample chamber large enough for incubation volume, which can be warmed by being connected to a water bath and can be constantly stirred
Ca^{2+}-sensitive electrode (e.g., Orion)
pH meter as source of current
Chart recorder with variable input and chart speed
Any commercially available reference electrode for pH measurements

1. Add 2 ml of incubation buffer for calcium-sensitive electrode to the sample chamber of the measurement apparatus and set to conditions of constant stirring. Add a volume of mitochondrial suspension (which will depend on the concentration of the mitochondrial preparation) containing 2 mg of protein to the sample chamber.
2. After 30 sec, add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.

   When mitochondria are energized with the complex II substrate succinate, rotenone prevents formation of oxaloacetate, an inhibitor of succinate dehydrogenase that supresses mitochondrial respiration.
3. Turn on the chart recorder.
4. After 1 min (or when stabilization has been achieved as observed by recorder trace) add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   The addition of Ca^{2+} to mitochondria leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+}.
5. After 1 min, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM.

   Inorganic phosphate is a trigger for permeability transition in mitochondria loaded with calcium.
6. Follow the retention of Ca^{2+} by its release as seen from the recorder trace (see Fig. 2.10.2).

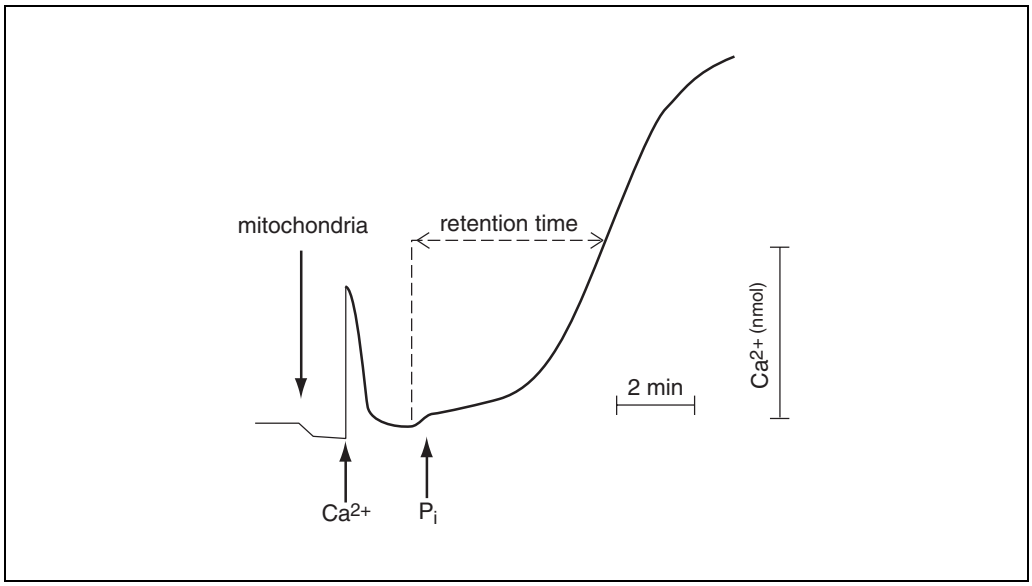

Figure 2.10.2 MPT monitored with a Ca^{2+}-sensitive electrode. Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 1-min stabilization period, mitochondria were loaded with Ca^{2+}, and, when accumulation was complete, MPT was induced by 5 mM KH_2PO_4.

ALTERNATE PROTOCOL 1

Monitoring of Ca^{2+} Fluxes Across the Inner Mitochondrial Membrane with a Spectrophotometer

Spectrophotometric estimation of Ca^{2+} fluxes across the mitochondrial membrane should be performed using a dual-wavelength spectrophotometer, in order to avoid interference from the turbidity of mitochondrial suspension.

Additional Materials *(also see Basic Protocol 6)*

25 mM arsenazo III: dissolve 19.4 mg arsenazo III (Sigma) in 1 ml H_2O; store frozen at –20°C up to 1 month

Dual-wavelength recording spectrophotometer set at 675 versus 685 nm, with appropriate cuvettes

1. Place 2 ml of incubation buffer for calcium-sensitive electrode in a spectrophotometric cuvette and set to conditions of constant stirring. Add 2 µl of 25 mM arsenazo III, for a final concentration of 25 µM.
2. Add an aliquot of mitochondrial suspension containing 2 mg of protein, for a final concentration of 1 mg/ml.

   The volume of the mitochondrial aliquot will depend on the concentration of the mitochondrial preparation.

3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
4. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per mg of mitochondrial protein.

   The addition of Ca^{2+} to mitochondria leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+}.

5. After 1 min, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM.

   The retention of Ca^{2+} is followed by its release upon induction of MPT as can be seen from the recorder trace.

DETERMINATION OF MITOCHONDRIAL MEMBRANE POTENTIAL

Estimation of the mitochondrial membrane potential ($\Delta\psi$) can be performed using an electrode sensitive to the lipophilic cation tetraphenylphosphonium (TPP^+) or spectrophotometrically with a $\Delta\psi$-specific dye, safranin.

BASIC PROTOCOL 7

Measurements of Mitochondrial Membrane Potential with a TPP^+-Sensitive Electrode

Energized mitochondria rapidly accumulate TPP^+ from the incubation buffer and release this cation as $\Delta\psi$ decays. Accumulation of TPP^+ by mitochondria can be followed by a decrease in the concentration of TPP^+ in the incubation buffer.

Materials

Incubation buffer for TPP^+-sensitive electrode (see recipe)

TPP^+ stock solution: dissolve 3.75 mg tetraphenylphosphonium chloride (Aldrich) in 10 ml H_2O; store up to 1 month at room temperature

Isolated mitochondria (Support Protocol 1, 2, or 3)

2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month

10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month

0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:

Glass (or plastic) sample chamber that can accommodate 2 ml of incubation buffer, which can be warmed by being connected to a water bath and can be constantly stirred

TPP^+ electrode (purchase from Microelectrodes, Inc. or prepare in the laboratory, Kamo et al., 1979)

pH meter as source of current

Chart recorder with variable input and chart speed

Any commercially available reference electrode

1. Place 2 ml of incubation buffer for TPP^+-sensitive electrode in the sample chamber of the measurement apparatus and set conditions to constant stirring. Add 4 µl of TPP^+ stock, for a final concentration of 2 µM TPP^+, and turn on the chart recorder.

   The recorder trace shows the basal level of TPP^+ in incubation buffer.

2. Add mitochondrial suspension to a final concentration of 1 mg/ml to the incubation buffer under conditions of constant stirring.

   The volume of the mitochondrial aliquot will depend on the concentration of mitochondrial preparation.

   Mitochondria accumulate TPP^+ according to the membrane potential so that the level of TPP^+ in the incubation buffer decreases.

3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.

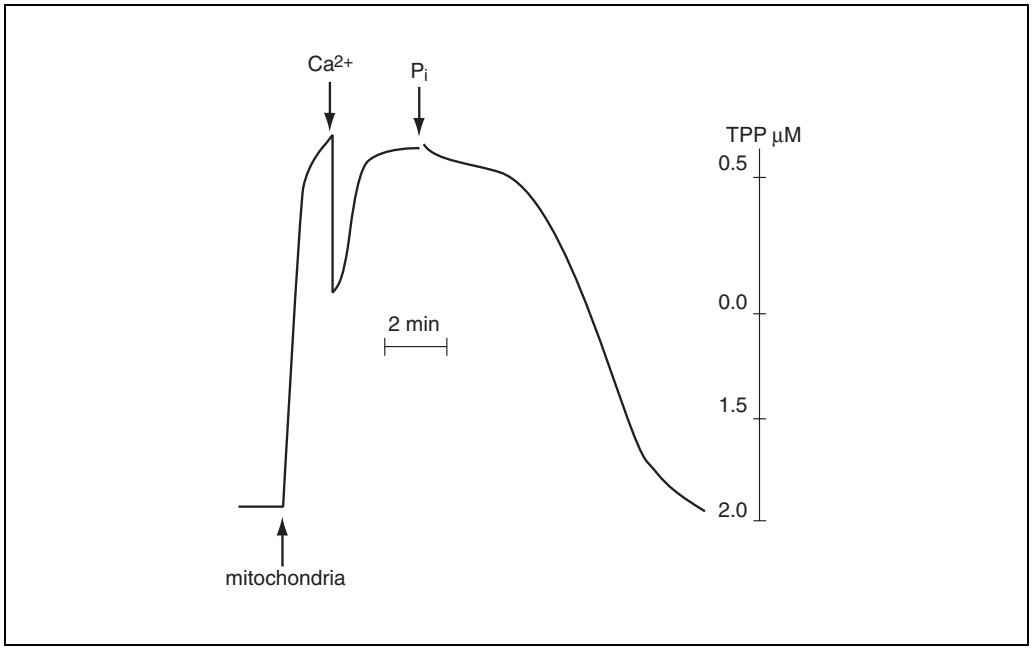

Figure 2.10.3 MPT monitored with a $\Delta\psi$-sensitive electrode. Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 1-min stabilization period mitochondria were loaded with Ca^{2+}, and, when accumulation was complete and potential was restored, MPT was induced by 5 mM KH_2PO_4. The concentration of TPP^+ was 2 µM.

4. After 1 min, add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   Upon addition of Ca^{2+}, the mitochondrial membrane potential decreases, with subsequent restoration when Ca^{2+} is accumulated.

5. After restoration of the membrane potential, add 20 µl of 0.5 M KH_2PO_4 for a final concentration of 5 mM and monitor the release of TPP^+ from mitochondria, which is indicative of the drop of the membrane potential upon induction of MPT (see Fig. 2.10.3).

   If Ca^{2+} loading is not sufficient to induce permeability transition, mitochondria will maintain membrane potential. In this case Ca^{2+} loading should be increased.

ALTERNATE PROTOCOL 2

Measurement of Mitochondrial Membrane Potential Using a Spectrophotometer

Spectrophotometric measurement of the membrane potential can be performed using safranin, a cationic dye, because of its accumulation in mitochondria and a shift in absorption spectrum that occurs when membrane potential is high. In these experiments, a dual-wavelength spectrophotometer should be used in order to avoid a contribution by the turbidity of the mitochondrial suspension to light absorption.

Additional Materials *(also see Basic Protocol 7)*

Incubation buffer for calcium-sensitive electrode (see recipe)
10 mM safranin: dissolve 3.5 mg safranin in 1 ml H_2O; store frozen at –20°C up to 1 month
Dual-wavelength recording spectrophotometer set at 511 versus 533 nm, with appropriate cuvettes

1. Place 2 ml of incubation buffer for calcium-sensitive electrode in a spectrophotometric cuvette and set to conditions of constant stirring. Add 2 µl of 10 mM safranin, for a final concentration of 10 µM.
2. Add an aliquot of mitochondrial suspension containing 2 mg of protein, for a final concentration of 1 mg/ml.

   The volume of the mitochondrial aliquot will depend on the concentration of the mitochondrial preparation.

3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
4. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   Upon addition of Ca^{2+}, the mitochondrial membrane potential decreases, with subsequent restoration when Ca^{2+} is accumulated.

5. After restoration of the membrane potential, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM, and monitor the decrease in the membrane potential upon induction of MPT.

Estimation of Mitochondrial Swelling

One of the most reliable manifestations of mitochondrial permeability transition is swelling of the organelles. Nephelometric or turbidometric techniques have generally been used to monitor mitochondrial swelling. Mitochondrial swelling can be monitored continuously as changes in OD_{540}.

Materials

Incubation buffer for swelling (see recipe)
Isolated mitochondria (Support Protocol 1, 2, or 3)
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Spectrophotometer with 540-nm filter, or multiwavelength spectrophotometer
Chart recorder with variable input and chart speed

1. Place 2 ml of incubation buffer for swelling in a spectrophotometric cuvette and set to conditions of constant stirring. Add a volume of mitochondrial suspension (which will depend on the concentration of mitochondrial preparation) for a final concentration of 0.5 mg/ml.
2. After 30 sec, add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
3. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.
4. After 1 min, add 20 µl of 0.5 M KH_2PO_4.
5. Monitor gradual decrease in OD_{540} nm due to mitochondrial swelling (see Fig. 2.10.4).

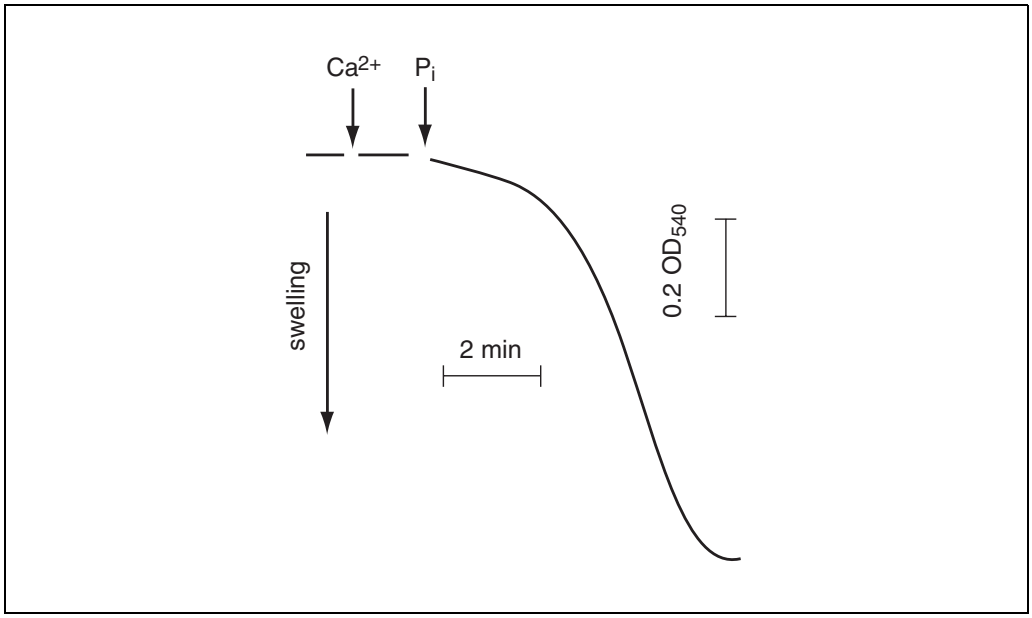

Figure 2.10.4 MPT assessed by mitochondrial swelling. Mitochondria (0.5 mg/ml) were incubated in 2 ml of KCl-based buffer. Mitochondria were loaded with Ca^{2+} and 5 mM phosphate was added. Swelling was monitored by a decrease of optical density at 540 nm.

BASIC PROTOCOL 9

Estimation of Mitochondrial Ca^{2+} Accumulation in Digitonin-Permeabilized Cells

Permeabilization of the plasma membrane allows measurement of mitochondrial activity in situ, without isolation of these organelles and the accompanying potential risk of mitochondrial damage. For the permeabilization, a steroid glycoside, digitonin, is widely used. The affinity of digitonin for cholesterol allows a selective disruption of the plasma membrane, making mitochondria accessible to specific substrates and Ca^{2+}. The concentration of digitonin must be chosen carefully and usually should not exceed 0.005% (w/v), since higher concentrations might affect the outer mitochondrial membrane barrier functions.

Permeabilization of the plasma membrane allows estimation of the main functional parameters of mitochondria, such as respiration, membrane potential, and accumulation and release of Ca^{2+}. A description of the monitoring of Ca^{2+} fluxes is given below.

Induction of MPT in apoptotic cells is thought to be one of the reasons for the decrease in $\Delta\psi$. Pore opening during apoptosis (even in a subpopulation of mitochondria) will impair the ability of the total mitochondrial population to accumulate Ca^{2+}; therefore estimation of a threshold level of Ca^{2+} loading (the Ca^{2+} capacity of mitochondria) in cells might be a criterion for changes on the mitochondrial level.

Materials

Cells of interest (Jurkat cells, U 937, HeLa)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Incubation buffer for digitonin-permeabilized cells (see recipe)
1% (w/v) digitonin: dissolve 10 mg digitonin in 1 ml H_2O; shake vigorously before adding to cells; store up to 2 to 3 months at room temperature
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:
Glass (or plastic) sample chamber large enough for incubation volume, which can be warmed up by being connected to a water bath and can be constantly stirred
Ca^{2+}-sensitive electrode (e.g., Orion)
pH meter as source of current
Chart recorder with variable input and chart speed
Any commercially available reference electrode for pH measurements

1. Centrifuge $3–5 \times 10^6$ cells 5 min at $200 \times g$, room temperature. Remove supernatant, resuspend cells in PBS, and centrifuge again under the same conditions.
2. Resuspend cells in 50 µl of incubation buffer for digitonin-permeabilized cells, then add the resuspended cells to 450 µl of the same buffer in sample chamber with Ca^{2+} electrode at constant stirring. Turn on the chart recorder.
3. Following a 2-min stabilization period, add 1% digitonin to a final concentration of 0.005% and 2.5 mM rotenone to a final concentration of 5 µM.
4. Load mitochondria with pulses of Ca^{2+} (20 to 25 nmol each, added from 10 mM stock) to induce MPT, which can be observed by the release of accumulated Ca^{2+} as measured by the Ca^{2+}-sensitive electrode (see Fig. 2.10.5).

The calcium capacity is calculated as a sum of the amount of Ca^{2+} in each addition.

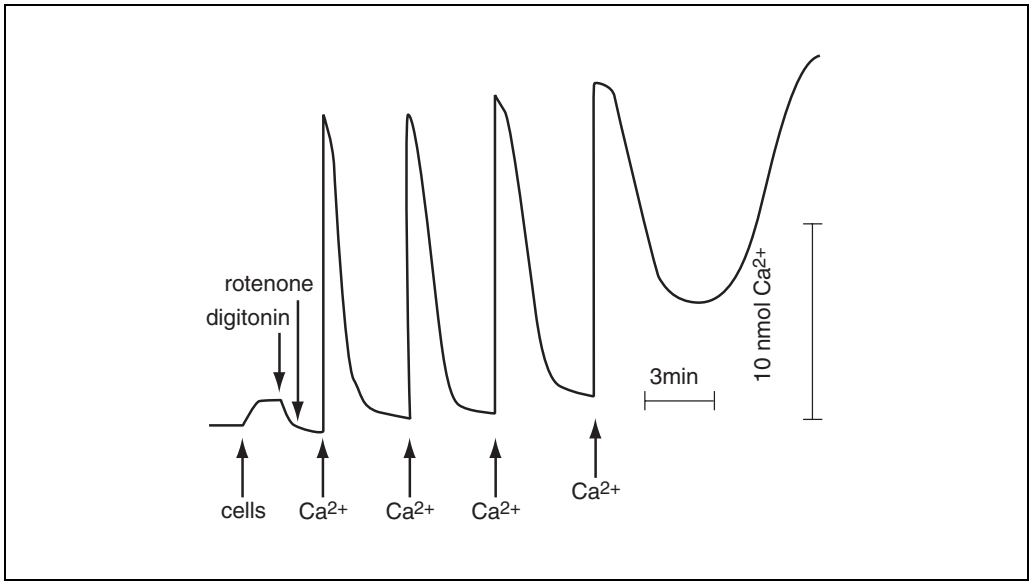

Figure 2.10.5 Estimation of mitochondrial Ca^{2+}accumulation in digitonin-permeabilized cells. Jurkat cells (2.5×10^6) were washed in PBS, resuspended in 500 µl of KCl-based buffer, and added to the incubation chamber. Following a 2-min stabilization period, cells were permeabilized with 0.005% digitonin, and 5 µM rotenone was added in order to maintain pyridine nucleotides in a reduced form. MPT was induced by sequential additions of $Ca^{2+}$and changes in the level of this cation were monitored using a Ca^{2+}-selective electrode.

ISOLATION OF MITOCHONDRIA

Experiments with isolated mitochondria are a helpful supplement to experiments on a cellular level. The former type of experiments provide better understanding of the mechanisms responsible for the mitochondrial changes in apoptotic cells. All the methods of isolation of mitochondria are based on the disruption of tissue and subsequent differential centrifugation of homogenate.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Mitochondria should be kept on ice at all times.

Isolation of Rat Liver Mitochondria

SUPPORT PROTOCOL 1

Isolation of liver mitochondria represents a relatively "easy" procedure giving a high yield. The liver from a 150 to 200-g rat weighs 5 to 6 g. Liver can be easily disrupted and homogenized. The most important thing is keeping the temperature not higher than 4° to 6°C.

Materials

150- to 200-g rat
Buffer A for liver (see recipe)
Buffer B: Buffer A (for liver) without EDTA

Dissecting equipment
Motor-driven glass Dounce homogenizer and tight Teflon pestle
Refrigerated centrifuge and 50-ml centrifuge tubes

Additional reagents and equipment for protein assay (*APPENDIX 3G*) and determination of the respiratory control ratio for mitochondria (Support Protocol 4)

NOTE: All operations should be done on ice, using ice-cold buffers and instruments.

Harvest the liver

1. Let the rat starve overnight.

   This step is necessary to decrease the content of fat and glycogen in the liver.

2. Sacrifice rat in accordance with institutional guidelines and the aims of the experiment.

   Donovan and Brown (1995) provide a variety of protocols for rodent euthanasia.

3. Remove liver and immerse immediately in ice-cold buffer A for liver.

4. Cut liver into pieces with scissors and wash several times by replacing the ice-cold buffer A with fresh ice-cold buffer, in order to remove as much blood as possible.

Homogenize the liver

5. Homogenize the liver in 60 ml of buffer A with 5 to 6 up-and-down strokes of the tight Teflon pestle.

   Homogenization occurs as the piston of the homogenizer rotates (driven by an electrical motor) and the pestle is slowly moved up and down five to six times, so that there are no pieces of liver big enough to be seen by eye.

6. Transfer homogenate into two cold centrifuge tubes and balance them.

7. Centrifuge the homogenate 8 min at 600 × *g*, 4°C, to remove nuclei and unbroken cells.

Isolate mitochondria

8. Discard the pellet and centrifuge supernatant 15 min at 5500 × *g*, 4°C, to form a mitochondrial pellet.

9. Remove floating fat droplets with a paper towel or piece of tissue paper.

10. Detach the pellet from the bottom of the tube with the piston of the homegenizer, add 0.2 to 0.3 ml of buffer A for liver, resuspend the pellet using the pestle, and pass mitochondria gently 3 to 4 times through the tip of a 1-ml pipet tip using automatic pipettor.

11. Dilute the mitochondrial suspension with 30 ml of buffer B, then centrifuge again as in step 9.

12. Resuspend the final mitochondrial pellet to a volume of ~1 ml in buffer B by gentle passing through a 1-ml pipet tip, then transfer into a 10-ml tube and keep on ice.

Assess the preparation

13. Determine the protein concentration using Lowry's method (or any other method available; see *APPENDIX 3G*) with bovine serum albumin as a standard.

    The protein concentration of a final suspension usually is about 90 to 100 mg/ml.

14. As a control of the mitochondrial preparation, estimate the respiratory control ratio (see Support Protocol 4). Use within 4 hr.

    Measurements can be started directly after mitochondrial isolation.

Isolation of Brain Mitochondria

Another source of mitochondria frequently used in the investigation of mitochondrial functioning (e.g., during apoptosis) is the brain. The method for isolation of brain mitochondria is similar to that for liver mitochondria (see Support Protocol 1); however, in order to get a purer preparation, a purification of homogenate with a Ficoll gradient is involved.

Materials

150- to 200-g rat
SET buffer (see recipe), ice-cold
3% and 6% (w/v) Ficoll solutions (see recipe)
MSH buffer (see recipe)

Motor-driven glass Dounce homogenizer and tight Teflon pestle
Refrigerated centrifuge and 50-ml centrifuge tubes

Additional reagents and equipment for protein assay (*APPENDIX 3G*) and determination of the respiratory control ratio for mitochondria (Support Protocol 4)

Dissect brain

1. Sacrifice rat in accordance with institutional guidelines and the aims of the experiment.
2. Open the skull with scissors, gently remove the brain, place it in ice-cold SET buffer, and chop it into pieces with scissors.
3. Wash pieces of brain several times in ice-cold SET buffer in order to remove as much blood as possible.

Homogenize brain

4. Homogenize manually chopped brain in 30 ml of SET buffer at 4°C using a Dounce homogenizer with six up-and-down strokes of the tight pestle.
5. Dilute homogenate to a final volume of 80 ml with SET buffer.
6. Place the homogenate in two cold centrifuge tubes, balance them, and centrifuge 3 min at 2000 × *g*, 4°C.
7. Decant supernatant and centrifuge again for 3 min at 2000 × *g*, 4°C.

Isolate mitochondria

8. Collect the supernatant and centrifuge 15 min at 12,000 × *g*, 4°C, to obtain a crude mitochondrial fraction.
9. Resuspend the pellet in 6 ml of ice-cold 3% Ficoll solution and layer onto 25 ml of ice-cold 6% Ficoll solution.
10. Centrifuge 10 min at 11,500 × *g*, 4°C.
11. Resuspend the final pellet in MSH buffer to a final volume of ~1 ml and keep on ice.

Assess preparation

12. Determine the protein concentration (*APPENDIX 3G).*
13. As a control of the mitochondrial preparation estimate the respiratory control ratio (see Support Protocol 4). Use within 4 hr.

Measurements can be started directly after mitochondrial isolation.

SUPPORT PROTOCOL 3

Isolation of Mitochondria from Cultured Cells

Isolation of mitochondria from cultured cells is more problematic than isolation from tissue, since it is difficult to disrupt the cell membrane without affecting the mitochondrial membrane. In order to make the plasma membrane more vulnerable, different tactics are used. The plasma membrane can be sensitized to disruption by using a buffer that contains digitonin, a steroid glycoside with a high affinity for cholesterol that selectively disrupts the cholesterol-rich plasma membrane. Another approach is based on passing cells through a needle. Both methods are followed by a differential centrifugation commonly used for preparation of mitochondria.

Materials

Tissue culture cells (e.g., Jurkat cells, U 937, HeLa; *APPENDIX 3B*)
Complete RPMI medium (*APPENDIX 3B*) or appropriate medium for cells
Buffer A for cultured cells (see recipe), ice-cold
Buffer B: Buffer A (for cultured cells) without EGTA
1% (w/v) digitonin: dissolve 10 mg digitonin in 1 ml H_2O; shake vigorously before adding to cells; store up to 2 to 3 months at room temperature
Refrigerated centrifuge and tubes

1. Take an aliquot containing 5×10^7 cells growing in culture in complete RPMI medium and centrifuge 5 min at $200 \times g$, 4°C. Remove supernatant.
2. Resuspend cells in buffer A for cultured cells. Centrifuge 4 min at $200 \times g$, 4°C.
3. Add 1% digitonin to buffer A for a final concentration of 0.01%. Resuspend cells in 5 ml of the buffer A containing 0.01% digitonin and incubate 10 min on ice.
4. Add 5 ml of ice-cold buffer A and mix well. Sediment lysed cells by centrifuging 7 min at $500 \times g$, 4°C.
5. Discard the pellet and centrifuge supernatant 15 min at $5500 \times g$, 4°C, to form a mitochondrial pellet.
6. Detach the pellet from the bottom of the centrifuge tube with a pipet tip and resuspend the pellet in 0.1 ml of buffer B using an automatic pipettor.
7. Dilute the mitochondrial suspension with 2 ml of buffer B and centrifuge again for 15 min at $5500 \times g$, 4°C.
8. Resuspend the final mitochondrial pellet in buffer B by gently passing through a pipet tip, then transfer into an microcentrifuge tube and keep on ice.

Measurements can be started directly after mitochondrial isolation.

Unfortunately, the yield from this protocol is sufficient material for an experiment but not enough to assess protein concentration and respiratory control ratio as well.

SUPPORT PROTOCOL 4

Estimation of the Quality of Isolated Mitochondria: Measuring the Respiratory Control Ratio (RCR)

One of the keystones of the chemiosmotic theory of energy transduction is impermeability of the inner mitochondrial membrane to protons. Oxidation of substrates results in extrusion of protons from the mitochondrial matrix to generate the mitochondrial membrane potential. High membrane potential suppresses further extrusion of protons and therefore inhibits respiration. Under resting conditions, the rate of respiration of mitochondria is quite low and determined by a passive leakage of protons into the matrix space.

Phosphorylation of ADP requires translocation of protons into the matrix through mitochondrial ATP synthase. This results in a decrease in membrane potential that stimulates respiration. Comparison of the rates of respiration in the resting state and during phos-

phorylation of ADP is a useful measure of the efficiency of mitochondrial functioning. The most reliable and widely used criterion of the quality of a mitochondrial preparation is the respiratory control ratio (RCR). RCR is defined as the rate of respiration in the presence of ADP (phosphorylating respiration, state 3) divided by the rate obtained following the expenditure of ADP, state 4.

Materials

Mitochondria (Support Protocol 1, 2, or 3)
Incubation buffer for testing mitochondrial quality (see recipe)
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
0.5 M sodium succinate: dissolve 135 mg of sodium succinate in 1 ml of H_2O, store frozen at –20°C up to 1 month
50 mM ADP: dissolve 23 mg of ADP in 1 ml H_2O and adjust pH to 7.5 with KOH; store frozen at –20°C up to 1 month
1 mM CCCP: dissolve 0.2 mg CCCP in 1 ml ethanol and mix thoroughly; store frozen at –20°C up to 1 month
Biological oxygen monitor equipped with a Clark-type oxygen electrode (Yellow Spring Instrument Co.) or similar equipment (operate per manufacturer's instructions)
Chart recorder with variable input and chart speed
10- and 50-µl Hamilton syringes (e.g., Sigma)

1. Place 2 ml of incubation buffer for testing mitochondrial quality into the sample chamber of the oxygen monitor and set conditions to constant stirring. Add an aliquot of mitochondrial suspension (the volume of which will depend on the concentration of the mitochondrial preparation) for a final concentration of 2 mg/ml mitochondrial protein.
2. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
3. Stop stirring and insert the electrode into the sample chamber. Expel all air through the slot in the plunger (slight twisting of the electrode helps to gather the bubbles at the slot) and set the chart speed.

   The desirable chart speed should be 10 to 15 mm/min.
4. After 1 min stabilization observed by recorder trace add 20 µl of 0.5 M sodium succinate, for a final concentration of 5 mM, through the slot on electrode's body with a Hamilton syringe.

   Mitochondria will now start to consume oxygen. The slope of the curve shows the rate of respiration.
5. After stabilization of respiration (~2 min) add 10 µl of 50 mM ADP.

   The rate of respiration will increase (state 3) with subsequent restoration of the initial rate of respiration (state 4) when all added ADP is phosphorylated.
6. Add 2 µl of 1 mM CCCP, for a final concentration of 1 µM.

   CCCP lowers the mitochondrial potential that stimulates oxygen consumption.
7. Calculate the rate of respiration from the recorder trace as the amount of oxygen consumed in 1 min (see Fig. 2.10.6).

   Assume that at room temperature and normal atmospheric pressure the concentration of oxygen in the incubation buffer is 250 µM.
8. Calculate the RCR by dividing the state 3 respiration rate by the state 4 respiration rate.

   Mitochondria with a respiratory control ratio above 4 are acceptable for use in the experiments.

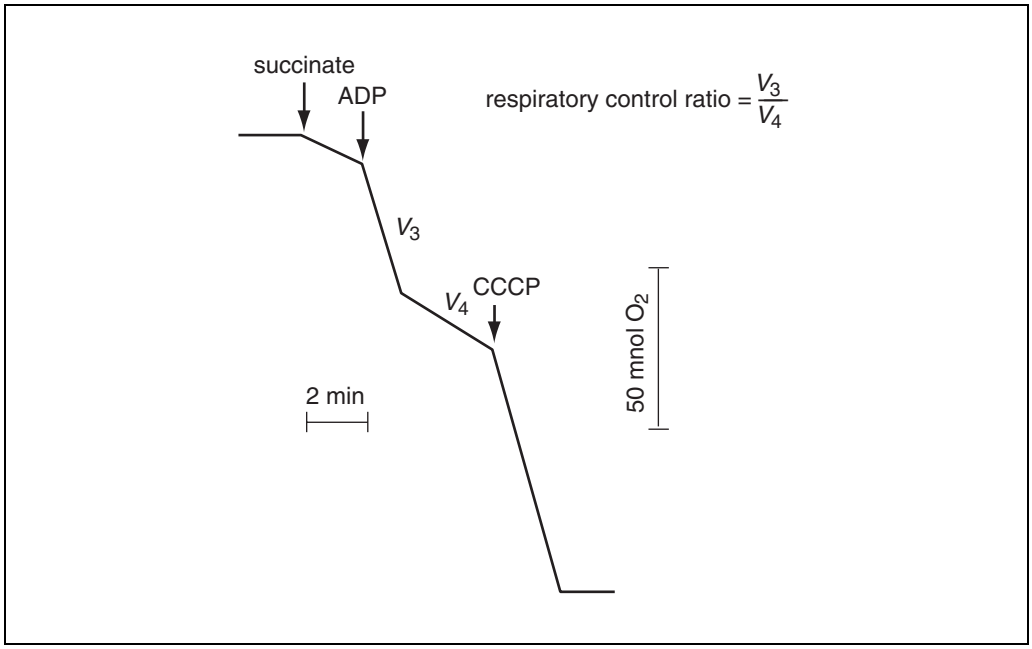

Figure 2.10.6 Estimation of mitochondrial respiration.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Buffer A for cultured cells

38.26 g/liter mannitol (210 mM final)
23.96 g/liter sucrose (70 mM final)
0.2g/liter $MgCl_2 \cdot 6\ H_2O$ (1 mM final)
1.2 g/liter HEPES (5 mM final)
0.38 g/liter EGTA (1 mM final)
Adjust pH to 7.5 with KOH
Store up to 3 to 4 days at 4°C

Buffer A for liver

38.26 g/liter mannitol (210 mM final)
23.96 g/liter sucrose (70 mM final)
1.2 g/liter HEPES (5 mM final)
2 ml/liter 0.5 M EDTA (1 mM final)
Adjust pH to 7.5 with KOH
Store up to 3 to 4 days at 4°C

Ficoll dilution buffer

0.25 M mannitol
60 mM sucrose
100 µM potassium EGTA
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Store up to 3 to 4 days at 4°C

Ficoll solutions, 3% and 6% (w/w)

Prepare 20% (w/v) Ficoll (Sigma) stock solution in Ficoll dilution buffer (see recipe). Store 3 to 4 days at 4°C. Before the experiment prepare 6% (v/v) and 3% (v/v) solutions by diluting 20% solution with Ficoll dilution buffer.

HEPES buffer

2.38 g/liter HEPES (10 mM final)
8.76 g/liter NaCl (150 mM final)
0.37 g/liter KCl (5 mM final)
0.2 g/liter $MgCl_2 \cdot 6H_2O$ (1 mM final)
Adjust pH to 7.4 with NaOH
Store up to 2 to 3 days at 4°C

Incubation buffer for calcium-sensitive electrode

1.11 g/100 ml KCl (150 mM final)
13.1 mg/100 ml KH_2PO_4 (1 mM final)
60 mg/100 ml Tris (5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

Incubation buffer for digitonin-permeabilized cells

150 mM KCl
5 mM KH_2PO_4
1 mM $MgCl_2$
5 mM sodium succinate
5 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 2 to 3 days at 4°C

Incubation buffer for swelling

1.11 g/100 ml KCl (150 mM final)
6.8 mg/100 ml KH_2PO_4 (0.5 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

Incubation buffer for testing mitochondrial quality

1.11 g/100 ml KCl (150 mM final)
13.1 mg/100 ml KH_2PO_4 (1 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
Adjust pH to 7.4 with HCl
Store up to 3 to 4 days at 4°C

Incubation buffer for TPP^+-sensitive electrode

1.11 g/100 ml KCl (150 mM final)
27 mg/100 ml KH_2PO_4 (2 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

Laemmli's loading buffer, 4×

3.125 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
4 ml glycerol
0.8 g sodium dodecyl sulfate
8 mg bromphenol blue
0.8 ml 2-mercaptoethanol
H_2O to 10 ml
Store up to several weeks at 4°C

MSH buffer

210 mM mannitol
70 mM sucrose
5 mM HEPES
Adjust pH to 7.4 with KOH
Store up to 2 to 3 days at 4°C

S100 buffer

20 mM HEPES, pH 7.5
10 mM KCl
1.5 mM $MgCl_2$
1 mM EGTA
1 mM EDTA
0.1 mM PMSF
10 mg/ml leupeptin
5 mg/ml pepstatin A
2 mg/ml aprotinin
25 mg/ml calpain I inhibitor
1 mM DTT
Store at 4°C; prepare weekly

SET buffer

8.58 g/100 ml sucrose (0.25 M final)
0.5 ml of 100 mM potassium EGTA stock solution/100 ml (0.5 mM final)
120 mg/100 ml Tris (free base; 10 mM final)
Adjust pH to 7.4 with HCl

COMMENTARY

Background Information

Mitochondrial function in apoptotic cells

Attempts to identify a common, unifying step in the apoptotic program, in response to various cytotoxic stimuli, have focused on the role of mitochondrial participation in this form of cell death (Petit et al., 1997). Specifically, the release of several proteins, normally located in the intermembrane space of mitochondria, has been observed during the early stages of apoptotic cell death (Green and Reed, 1998). Among these proteins are cytochrome *c* and other intermembrane-space proteins, including AIF (apoptosis-inducing factor), HSPs (heat shock proteins), DIABLO/Smac (direct IAP-binding protein with low pI/Second mitochondria-derived activator of caspase), AK-2 (adenylate kinase-2), several pro-caspases (Mancini et al., 1998; Köhler et al., 1999; Samali et al., 1999; Susin et al., 1999; Zhivotovsky et al., 1999; Du et al., 2000; Verhagen et al., 2000), endonuclease G, and sulfite oxidase. Although the role of many of these proteins in the apoptotic process is well characterized, the involvement of others (AK-2, sulfite oxidase) is still unclear. It is important to note that the function of the released proteins in the cytoplasm is different from their functions within mitochondria. The best-studied of these proteins is cytochrome *c*.

Cytochrome *c*, is a component of the electron transport chain that shuttles electrons between complexes III (bc1) and IV (cytochrome oxidase). Apo-cytochrome *c* is encoded by a nuclear gene, synthesized in the cytosol, and imported into the mitochondrial intermembrane space in an unfolded configuration where it receives its heme group. Covalent attachment of this heme group stimulates a conformational change, and holo-cytochrome *c* subsequently assumes its functional role as a component of the electron transport chain.

During the early phase of apoptosis, cytochrome *c* is released into the cytosol and interacts with Apaf-1 to form the apoptosome complex together with dATP and pro-caspase-9 (Li et al., 1997).

The mechanisms regulating cytochrome *c* release remain obscure. However, two distinct models for cytochrome *c* release have emerged, and these can be distinguished on the basis of whether Ca^{2+} is required for the event. In one instance, mitochondrial Ca^{2+} overload results

in opening of a pore in the inner mitochondrial membrane, with subsequent swelling and rupture of the outer membrane followed by the release of cytochrome *c* and other intermembrane space proteins (Crompton, 1999). The Ca^{2+}-independent model asserts that a more selective protein release occurs without changes in mitochondrial volume. This mechanism involves specific channels/pores in the outer mitochondrial membrane that may be opened and regulated by certain pro-apoptotic members of the Bcl-2 family of proteins, including Bax (Robertson and Orrenius, 2000). The precise manner in which Bax modulates cytochrome *c* release is controversial. In particular, the authors have reported recently that depending on the experimental conditions this protein can either act directly on mitochondria to stimulate the release of cytochrome *c* by forming a selective pore in the outer membrane, or it may facilitate opening of the permeability transition pore (Gogvadze et al., 2001). Recent evidence indicates that truncated Bid induces a conformational change in Bax that allows this protein to insert in the outer membrane, oligomerize, and stimulate cytochrome *c* release (Eskes et al., 2000).

Mitochondrial permeability transition

Energized mitochondria can take up and retain added Ca^{2+}. However this ability is not limitless. Mitochondria swell and become leaky; the membrane potential, which is the driving force for Ca^{2+} accumulation, drops, and accumulated Ca^{2+} is released. This process is called mitochondrial permeability transition (MPT). These changes are identified as a result of the opening of Ca^{2+}-dependent pore in the mitochondrial inner membrane.

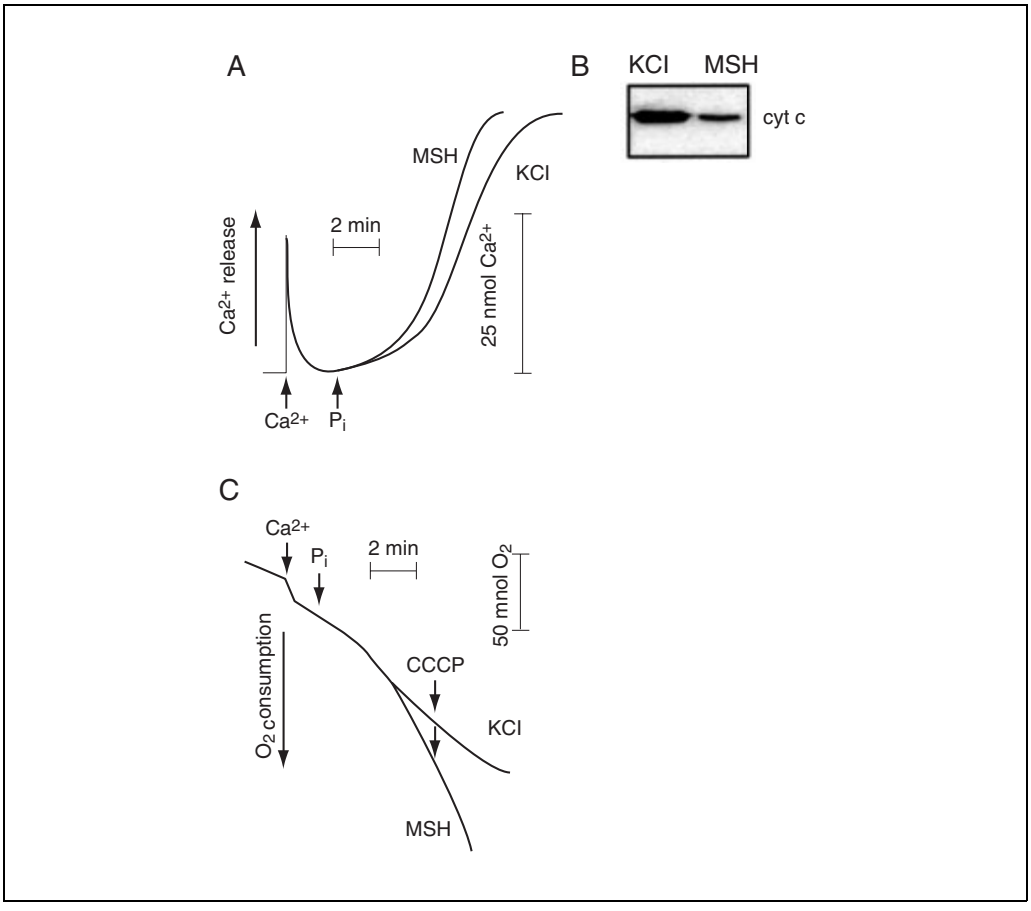

Figure 2.10.7 MPT-induced release of cytochrome *c* from mitochondria incubated in either MSH or KCl buffer. (**A**) Mitochondria were added to buffer at a concentration of 1 mg/ml. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+} (50 nmol/mg protein), and MPT was induced by adding 5 mM inorganic phosphate (P_i). (**B**) Mitochondrial suspensions from (A) were centrifuged and the resulting supernatants were separated by SDS-PAGE and immunoblotted as described in Basic Protocol 3. (**C**) Mitochondrial respiration following MPT induction in either MSH or KCl buffer was analyzed as described in Support Protocol 4. The concentration of CCCP was 1 μM.

MPT-dependent release of cytochrome c

Although the kinetics of MPT are unaffected by the composition of the incubation buffer (KCl versus MSH; Fig. 2.10.7A), the amount of cytochrome *c* released is much higher when mitochondria are incubated in the physiologically more relevant KCl buffer as compared to MSH buffer. Immunoblot analysis revealed that most cytochrome *c* was present in the supernatant fraction following MPT induction in KCl buffer, whereas only partial release of cytochrome *c* was observed in MSH buffer (Fig. 2.10.7B). Further evidence of this comes from the different effects that cytochrome *c* release has on mitochondrial respiration in the two buffers (Fig. 2.10.7C). Specifically, the induction of MPT in MSH buffer resulted in a time-dependent acceleration of oxygen consumption that persisted until all oxygen was consumed. In contrast, incubation of mitochondria in KCl buffer resulted in an initial acceleration of respiration that was followed by its suppression, and no additional stimulation of oxygen consumption was observed upon the addition of the uncoupler carbonyl cyanide *m*-chlorophenylhydrazone (CCCP). Taken together, these data indicate that while MPT-induced uncoupling of mitochondria occurs in both buffers, respiration is suppressed only in KCl buffer, an effect most likely due to a loss of cytochrome *c*.

It should be taken into account that mitochondrial preparations are heterogeneous. At a given concentration of Ca^{2+}, a certain subpopulation (more susceptible) of mitochondria have undergone permeability transition at a given time, while the released Ca^{2+} is accumulated by more resistant mitochondria, which thereby in-

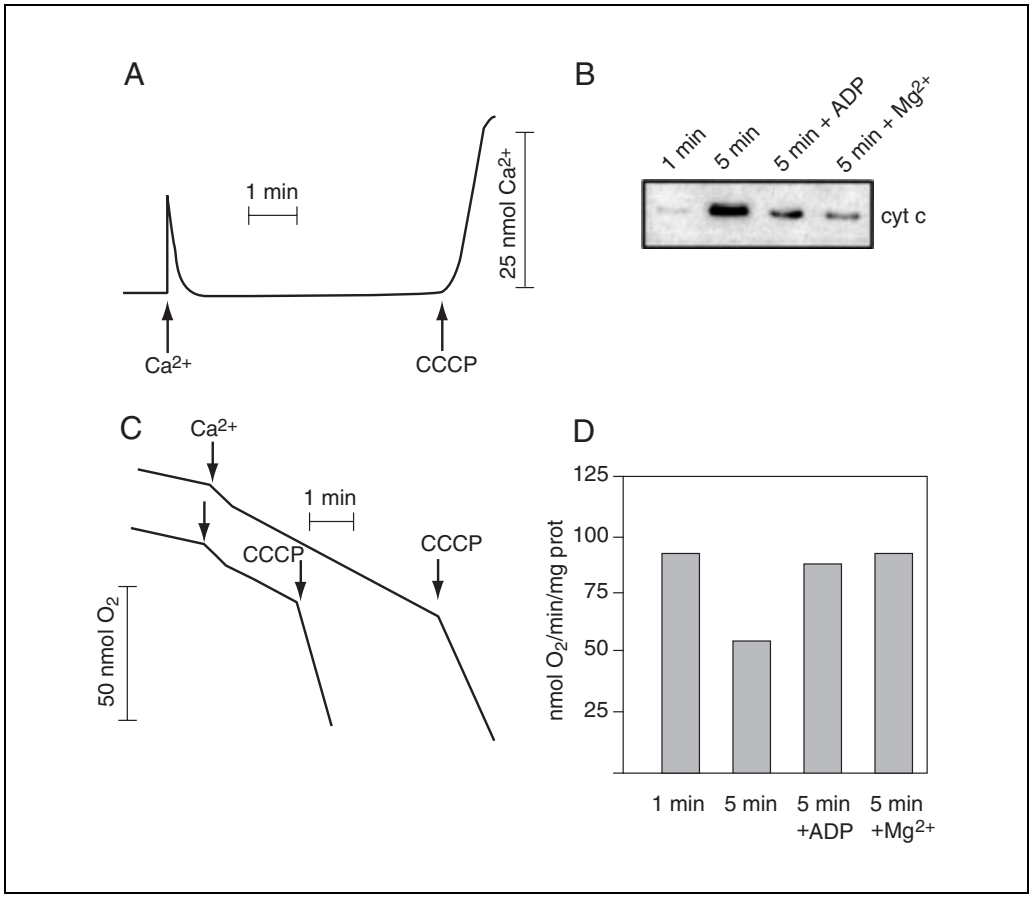

Figure 2.10.8 Ca^{2+}-induced release of cytochrome *c* from mitochondria in the absence of observable MPT. (**A**) Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+} (25 nmol/mg protein) prior to the addition of 1 μM carbonyl cyanide *m*-chlorophenyl hydrazone (CCCP) at 5 min. (**B**) The amount of cytochrome *c* released from mitochondria after 1 and 5 min of Ca^{2+} retention in the presence and absence of 0.5 mM ADP or 1 mM Mg^{2+}. (**C**) Samples incubated under the same conditions as (A) were used to evaluate the rate of uncoupled respiration after 1 and 5 min. (**D**) Samples incubated under the same conditions as conditions as (B) were used to determine the effect of inhibitors of MPT on the rate of uncoupled respiration of Ca^{2+}-loaded mitochondria.

crease their load until they also undergo permeabilization (Zoratti and Szabo, 1995).

In the aforementioned protocols, cytochrome *c* release was a consequence of MPT induction, accompanied by swelling of mitochondria and rupture of the outer membrane. When Ca^{2+} loading is insufficient to induce observable manifestations of MPT, the release of cytochrome *c* can still occur despite the absence of changes characteristic of MPT.

As seen in Figure 2.10.8A, moderate Ca^{2+} loading of mitochondria did not induce MPT, and this cation was retained by mitochondria unless the uncoupler CCCP was added. The accumulation of Ca^{2+} by mitochondria in the absence of observable MPT was nevertheless sufficient to stimulate a release of cytochrome *c*, an effect that was considerably more pronounced the longer mitochondria retained the accumulated Ca^{2+}. Inhibitors of MPT, such as Mg^{2+} and ADP, suppressed this release (Fig. 2.10.8B). In addition, Ca^{2+}-loaded mitochondria exhibited controlled respiration (Fig. 2.10.8C), although increasing the Ca^{2+} retention time from 1 to 5 min prominently diminished the rate of CCCP-directed uncoupled respiration (upper trace versus versus lower trace). Inhibitors of MPT, such as Mg^{2+} and ADP, suppressed this release (Fig. 2.10.8D) and restored the rate of uncoupled respiration.

Additional evidence of cytochrome *c* release in the absence of observable MPT is presented in Figure 2.10.9A, where the sequential addition of Ca^{2+} pulses to isolated mitochondria led to a step-wise decrease in the overall optical density without the large-amplitude swelling characteristic of MPT. Meanwhile, the amount of cytochrome *c* released from mitochondria was enhanced as Ca^{2+} loading increased (Fig. 2.10.9B). This release reflected MPT induction in a subpopulation of mitochondria, which was further supported by the fact that cotreatment of isolated mitochondria with 1 μM CsA (cyclosporin A) eliminated cytochrome *c* release induced by Ca^{2+} additions ranging between 20 to 80 nmol/mg protein (data not shown). Cytochrome *c* release ultimately reached a pinnacle at 80 nmol Ca^{2+}/mg protein (Fig. 2.10.9B, lanes 6 and 7) as all mitochondria underwent MPT (Fig. 2.10.9A).

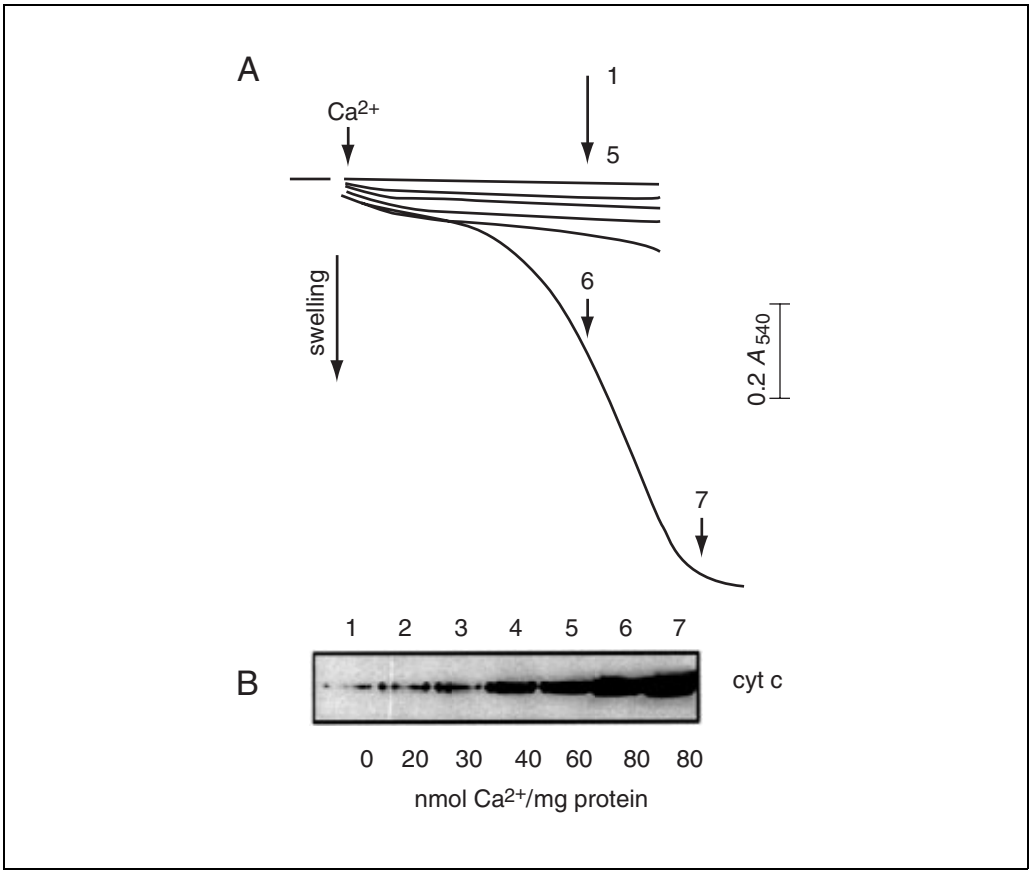

Figure 2.10.9 The effect of Ca^{2+} loading on mitochondrial swelling and the release of cytochrome *c*. Mitochondria (0.5 mg/ml) were incubated in 2 ml of KCl-based buffer. (**A**) Mitochondria were loaded sequentially with varied amounts of Ca^{2+} until MPT was induced. (**B**) Samples were taken after 5 min (lanes 1 to 6) or 8 min (lane 7) of incubation and the supernatants evaluated for cytochrome *c* content.

MPT-independent release of cytochrome c

Although it was originally believed that MPT induction was the root mechanism responsible for cytochrome *c* release in response to different cytotoxic stimuli, more recently this notion has been challenged and the precise mechanisms regulating the release of this protein are unclear. In fact, many of the early results on mechanisms of cytochrome *c* release were generated using cell-free systems wherein isolated mitochondria and nuclei were treated with different MPT pore activators, which, in turn, led to mitochondrial swelling, the release of cytochrome *c* (and other proteins), and subsequent changes in nuclear morphology that were characteristic of apoptosis. However, ample evidence from more recent studies suggests that, while MPT is likely to be a mechanism responsible for cytochrome *c* release, it is no longer regarded as *the* mechanism.

In case of MPT induction, mitochondrial swelling leads to a rupture of the outer membrane; without MPT, permeabilization can be achieved by Bcl-2 family proteins Bax or Bid that form pores in the outer membrane, leaving the inner mitochondrial membrane intact.

Discrimination between MPT-dependent and MPT-independent release of cytochrome c

While analyzing the release of cytochrome *c* from mitochondria, one should keep in mind that even without added Ca^{2+}, MPT may occur in a subpopulation of mitochondria if the trace amount of Ca^{2+} in buffers is enough to induce MPT in "susceptible" mitochondria. Therefore the release of cytochrome *c* observed in the absence of added Ca^{2+} can be mistaken for MPT-independent release of cytochrome *c*. In order to distinguish between the MPT-dependent and -independent release of cytochrome *c*, experiments should be performed in the presence of the Ca^{2+} chelator EGTA, which sequesters Ca^{2+} and therefore prevents MPT induction. Similar results can be achieved with CsA.

Critical Parameters and Troubleshooting

Collecting released proteins (Basic Protocols 1 and 2)

Separation of the mitochondria from the supernatant should be done thoroughly. Aliquots of supernatant should be taken without disturbing the pellet.

Immunoblot analysis of released proteins (Basic Protocol 3)

For immunoblot analysis, too many bands on the membrane may indicate too high a concentration of primary and/or secondary antibodies. If the background of nonspecific binding of immunological probes is unacceptably high, increase the length of the time of washing with PBS. If there is no band on the film, increase the duration of incubation with primary antibodies. If a white spot on the film makes it difficult to detect the protein band of interest, a bubble may have been introduced during blotting and the whole procedure must be repeated. If a band on the film is too strong, decrease exposure time of X-ray film to the ECL-stained membrane. If the gel runs too fast or too slow and poor resolution of protein occurs, decrease or increase voltage, respectively, or check the buffer recipe. If no prestained markers appear on the nitrocellulose filter, check the transfer buffer recipe, or reposition the location of gel towards the cathode and anode.

FACS analysis of TMRE-stained cells (Basic Protocol 4)

FACS analysis needs an appropriate gating of the cells—a selection of the population of interest, especially if the initial population is a mixture of different types of cells (for example when blood samples are analyzed).

Another critical parameter is time. The analysis of the membrane potential should be done shortly after staining of the cells. TMRE is only accumulated by mitochondria with high membrane potential and any delay in analysis may negatively affect the functional state of the mitochondria and therefore cause leakage of the dye.

Microscopy of apoptotic cells stained with MitoTracker Red (Basic Protocol 5)

To reduce potential artifacts from overloading, the concentration of dye should be kept as low as possible. However if cells are not sufficiently stained, the concentration of dye or time of incubation should be increased.

Measurement of calcium release and membrane potential (Basic Protocols 6 and 7)

The release of Ca^{2+} from mitochondria may result not from opening of the pore, but simply because of a drop of the membrane potential. This may happen, for instance, if the mitochondria consume all available oxygen. However at a mitochondrial protein concentration of 1 mg/ml

(or less), and with rapid stirring of the suspension, MPT usually occurs before the exhaustion of oxygen. If higher concentrations of mitochondrial suspension are used, possible anaerobiosis can be prevented by fine flow of oxygen blown onto the surface of the suspension.

Mitochondrial swelling (Basic Protocol 8)

Mitochondrial swelling assessed by a decrease in optical density of mitochondrial suspension represents one of the most reliable parameters of MPT induction in isolated mitochondria. However it should be kept in mind that anaerobiosis and subsequent release of accumulated Ca^{2+} due to the drop in membrane potential may prevent pore opening and terminate swelling. Anaerobiosis can be prevented by a fine flow of oxygen blown onto the surface of the suspension. On the other hand, a relatively low concentration of mitochondria (up to 1 mg/ml) should not lead to anaerobiosis.

Estimation of mitochondrial Ca^{2+} accumulation in digitonin-permeabilized cells (Basic Protocol 9)

Digitonin generally permeabilizes plasma membrane, which contains cholesterol; therefore, this detergent should be used with caution because relatively high concentrations of digitonin can affect also the outer mitochondrial membrane. The minimal concentration of digitonin that is necessary for the outer-membrane permeabilization can be detected with a Ca^{2+}-sensitive electrode. Cells do not accumulate added Ca^{2+}, since plasma membrane is permeable neither to Ca^{2+} nor to succinate, oxidation of which provides a driving force for Ca^{2+} accumulation. Upon addition of digitonin, the plasma membrane becomes permeable and the mitochondria start to accumulate Ca^{2+} from the incubation buffer.

Preparation of mitochondria (Support Protocols 1, 2, and 3)

The temperature during isolation should be kept around 4°C. Elevation of the temperature may result in activation of catabolic enzymes, in particular, mitochondrial phospholipase A_2, which leads to accumulation of free fatty acids in mitochondria. Free fatty acids are known as natural protonophores (agents that facilitate transport of protons through membrane); therefore, accumulation of fatty acids will decrease the mitochondrial membrane potential and destabilize mitochondria.

Anticipated Results

Analyzing functioning of isolated mitochondria and mitochondria in apoptotic cells: collection of released proteins and immunoblot analysis (Basic Protocols 1, 2, and 3)

Depending on the mechanisms involved in the release of cytochrome *c* or other proteins from mitochondria, the final result will be different. If the release was associated with mitochondrial swelling and the rupture of the outer membrane, most of the cytochrome *c* will be found in the supernatant after sedimentation of mitochondria. In such a situation, it would be informative also to present the data concerning changes in the content of cytochrome *c* in the pellet. Figure 2.10.10 represents a typical blot showing the release of cytochrome *c* from isolated liver mitochondria upon induction of MPT in KCl-based buffer.

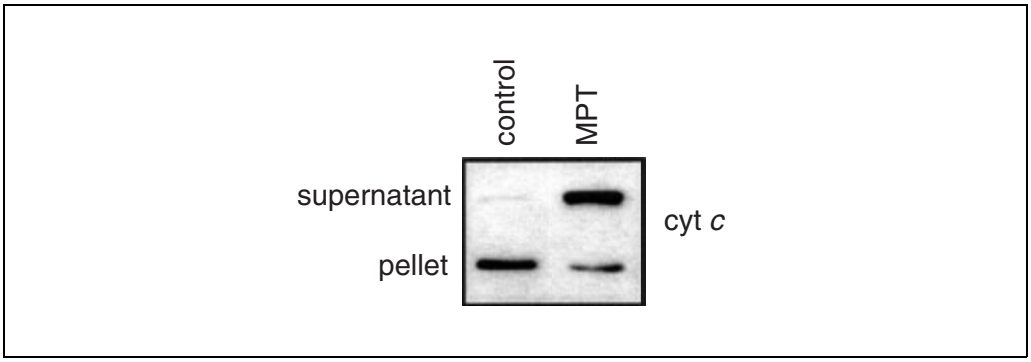

Figure 2.10.10 The release of cytochrome c from isolated rat liver mitochondria as a result of mitochondrial permeability transition (MPT). Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+}, and, when accumulation was complete, MPT was induced by 5 mM KH_2PO_4. A 200-µl aliquot of mitochondrial suspension was centrifuged and the resulting supernatant and pellet were separated by SDS-PAGE and immunoblotted as described under in Basic Protocol 3. Control mitochondria were incubated for the same time but without Ca^{2+} loading.

FACS analysis of TMRE-stained cells (Basic Protocol 4)

A typical image of FACS analysis of mitochondria in the cells undergoing apoptosis is present in Figure 2.10.1. The lower left quadrant contains living cells, the lower right, apoptotic cells, and upper right, necrotic cells.

Measurement of calcium release (Basic Protocol 6)

A typical response of mitochondria to Ca^{2+} is shown in Figure 2.10.2. Addition of Ca^{2+} to isolated mitochondria results in a quick rise in the basal level of Ca^{2+} in the incubation buffer, followed by restoration of the initial level due to accumulation of Ca^{2+} in mitochondria, whereupon a new steady state is reached. After addition of phosphate, mitochondria start releasing accumulated Ca^{2+}. The lag time before the onset of MPT induction, as well as the rate of release, depend on the Ca^{2+} load. If Ca^{2+} and other conditions are held constant, the effect of phosphate on MPT induction is dose-dependent. Therefore, the opening of the pore can be modulated either by varying the Ca^{2+} concentration while keeping the concentration of phosphate constant, or by varying the concentration of phosphate.

Both methods (spectrophotometric and ion-selective electrodes) are equally sensitive, and the choice is dictated by the availability of the equipment.

Measurement of membrane potential (Basic Protocol 7)

Energized mitochondria rapidly accumulate TPP^+ from the incubation buffer and release this cation as $\Delta\psi$ decays. A typical change in mitochondrial membrane potential upon MPT induction is shown on Figure 2.10.3. As can be seen in that figure, upon induction of MPT, two distinct phases of decrease in membrane potential occur. First, a relatively slow decrease starts when an MPT-inducing agent (P_i) is added, which is followed by a second, rapid phase, which reflects the induction of MPT in the whole population of mitochondria.

Measurement of mitochondrial swelling (Basic Protocol 8)

Figure 2.10.4 shows a typical example of results from measurement of mitochondrial swelling. When mitochondria are added to incubation buffer at a concentration of 0.5 mg/ml, the initial light absorption at 540 nm is about 1.3 to 1.4. Addition of Ca^{2+} to the mitochondria, followed by inorganic phosphate, results in a time-dependent decrease in the optical density (OD) of the mitochondrial suspension.

Estimation of mitochondrial Ca^{2+} accumulation in digitonin-permeabilized cells (Basic Protocol 9)

The addition of Ca^{2+} to a permeabilized cell suspension leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+} (Fig. 2.10.5); this is an effect that can be completely abrogated by 2 μg/ml antimycin, an inhibitor of mitochondrial respiratory chain (data not shown). Mitochondria accumulate sequential additions of Ca^{2+} until MPT is induced and the accumulated Ca^{2+} is released.

Preparation of mitochondria and assessing their quality (Support Protocols 1 to 4)

Isolation of mitochondria usually takes about 60 to 75 min. For liver the yield is about 20 to 25 mg protein of mitochondria per 1 g of tissue. High concentration of the final mitochondrial preparation is a prerequisite of mitochondrial stability.

A typical respiratory response of mitochondria and the method of calculating RCR are shown in Figure 2.10.6. Addition of CCCP when added ADP is phosphorylated and state 4 respiration is stabilized allows one to determine the rate of uncoupled respiration that represents the activity of the mitochondrial respiratory chain.

Time Considerations

The time of collecting samples and preparing for immunoblotting depends on the incubation conditions as well as the experience of a researcher. Basic Protocol 1 requires 45 to 60 min, Basic Protocol 2, 2 to 2.5 hr, and Basic Protocol 3, 2 days. TMRE (Basic Protocol 4) and MitoTracker Red (Basic Protocol 5) staining takes 1 hr and 1.5 hr, respectively. Measurement of the mitochondrial permeability transition (Basic Protocols 6, 7, 8, and 9 and Alternate Protocols 1 and 2) can be completed in 5 to 20 min.

Mitochondrial preparation (Support Protocols 1, 2, and 3) takes 60 to 80 min. Assessment of respiratory control ratio takes 20 to 35 min.

CHAPTER 3
Genetic Toxicology: Mutagenesis and Adduct Formation

INTRODUCTION

Hundreds of thousands of natural and man-made chemicals remain to be evaluated for mutagenic and carcinogenic activity. Because whole-animal studies of such activity are costly and time consuming, only a few chemicals have been tested in this fashion. A major advance in predictive toxicology was achieved when the in vitro testing procedure known as the *Salmonella* test (or Ames test, after its originator Bruce Ames) was developed to provide a sensitive and reliable method for evaluating mutagenicity (Ames, 1971; Ames et al., 1975; *UNIT 3.1*). This test has been applied quite extensively to build genotoxicity databases (Zeiger, 1997) through testing under various environmental conditions (Claxton, 1998).

The basis of the Ames test is a set of strains of *Salmonella* that each contain either a unique missense mutation or a frameshift mutation in the histidine operon. When the bacteria are treated with a chemical mutagen, some of the mutations that result will "reverse" the original mutation, restoring the cells' ability to synthesize their own histidine. Formation of such histidine-independent (his^+) revertants is evidenced by the growth of colonies on minimal agar plates with glucose. As described in *UNIT 3.1*, reversion levels in cultures treated with a putative mutagen are compared to those in untreated negative controls, with and without metabolic activation enzymes. Inclusion of positive controls (cultures treated with known mutagens) is also recommended. A desiccator assay for volatile liquids or gases and a reductive metabolism assay are also provided. Chemicals that are available only in small amounts can be assayed with a modified (Kado) microsuspension assay.

Measurement of DNA structural modifications is an important aspect of determining the consequences of chemical exposure, including exposure to reactive oxygen species that cause the formation of malondialdehyde via lipid peroxidation (*UNIT 2.4*). Assaying for malondialdehyde-DNA adducts, as described in *UNIT 3.2*, provides a true measure of the effective dose of a mutagen that can be correlated to biological changes. Although the procedures are fairly complicated and lengthy, they permit highly specific mass spectrometric quantitation of adduct with the use of a deuterated internal standard. Three protocols are included: (1) a gas chromatographic/negative chemical ionization–electron capture/mass spectrometry (GC/NCI EC/MS) assay for pyrimidopurinone (M_1G); (2) a method for HPLC quantification of nucleosides; and (3) preparation of anti-M_1G immunoaffinity gel (Sevilla et al., 1997).

Mutagenesis assays in mammalian cells complement the microbial assays in assessing genetic toxicology of potential mutagenic and carcinogenic properties of chemicals. Mammalian target genes include *hprt* (hypoxanthine-guanine phosphoribosyl transferase), *aprt* (adenine phosphoribosyltransferase), and *tk* (thymidine kinase). *UNIT 3.3* describes mutagenesis assays in the Chinese hamster V79 cell line and an analogous assay with the V79-derivative *hprt–/gpt*$^+$ G12 cell line. With the V79 cells, the toxic purine analog 6-thioguanine (6TG) is used to select *hprt* gene mutants. The G12 cell line contains an insertion of the *Escherichia coli* xanthine guanine phosphoribosyl transferase (*gpt*) gene that allows the detection of large deletions and epigenetic DNA methylation events

Current Protocols in Toxicology (2002) 3.0.1-3.0.4

as well as point and small intragenic mutations that can be detected in the standard V79 assays.

Cell transformation is widely used as a measure of the ability of chemical and physical agents to induce morphological changes, such as the loss of density-dependent growth regulation. Such changes include the formation of colonies with crisscrossed cells or foci of piled-up cells. Neoplastic characteristics of transformed cells resulting from exposure to carcinogens include the ability to form three-dimensional colonies in soft agar and the ability to induce tumor formation in immunosuppressed mice. Freshly isolated Syrian hamster embryo (SHE) cells, established cultured cells (mouse BALB/c-3T3), and C3H/10T1/2 cells are widely used for cell transformation assays. In *UNIT 3.4*, a basic cell transformation protocol is presented that utilizes SHE cells from pregnant Golden hamsters; secondary cell culture procedures applicable to Chinese hamster ovary (CHO) or baby hamster kidney 21 (BHK21) cells, used for an associated cytotoxicity assay, are also included. SHE cells are diploid and genetically stable, and possess the metabolic capability to bioactivate carcinogens. It should be noted that these (and indeed any) cell lines may already possess some properties characteristic of partial transformation, which will need to be considered in assessing the degree of morphological transformation caused by a putative carcinogen.

In a series of detailed steps, a number of protocols describe assays for DNA damage (*UNIT 3.5*). These protocols feature the measurement of single- and double-stranded breakage, DNA-DNA cross-links, and DNA-protein cross-links that can result from exposure to genotoxic chemicals or physical agents. Exposure to chemical and physical agents can be in vitro or in vivo. The assays for DNA damage include the "comet assay" by single-cell microgel electrophoresis (Singh, 1996) and filter elution (Kohn, 1991). K-SDS precipitation is the basis for an assay to reveal DNA-protein cross-links in cells (Zhitkovic and Costa, 1992). Other assays include measurement of repair activities such as unscheduled DNA synthesis following DNA damage. Oxidative DNA base modifications are detected by the use of exogenous bacterial repair enzymes to excise modified DNA bases.

DNA methylation has a role in mammalian development and tumorigenesis (Wolffe et al., 1999). The extent of DNA methylation can range from hypomethylation to hypermethylation, which in part may reflect the rates of methylation and demethylation. DNA methylation has even been suggested as a reversible biological signal (Ramchandani et al., 1999), and that DNA demethylase is a processive enzyme (Cervoni et al., 1999). These recent findings could be important in the analysis and interpretation of results obtained from the use of procedures described in *UNIT 3.6* on the measurement of DNA methylation. If detection of slight changes in gene methylation is desired, genomic sequencing following bisulfite-modification PCR (Clark et al., 1994) is recommended.This bisulfite mapping technique was used to determine that DNA demethylase is a processive enzyme (Cervoni et al., 1999). The first basic protocol in *UNIT 3.6* is the determination of the overall 5-methycytosine content in genomic DNA by the use of radiolabeled S-adenosylmethionine and a CpG methylase to artificially methylate DNA samples. A second basic protocol is the measurement of DNA:methyltransferase activity in the same manner as the first basic protocol but with the addition of an exogenous substrate, poly(dI-dC). Radiolabel incorporation is used as a measure of enzyme activity. A third basic protocol is based on the effect DNA methylation has on the activity of certain restriction enzymes; a measurement of gene-specific methylation. A fourth basic protocol is the measurement of deoxyribonuclease I sensitivity of active genes compared to inactive genes in chromatin with methylation causing gene inactivation by promoting chromatin condensation.

Alterations in the physical integrity of the chromosomes in toxicant-exposed cells, whether in culture, experimental animals or from humans, provides an additional experi-

mental approach to the determination of genotoxic damage. Assays for detecting chromosomal aberrations are described in *UNIT 3.7*. Visual assessment for the presence of micronuclei (Basic Protocol 1) is a measure of partial or whole chromosomes that have become separated from the main cellular nucleus. It can be used as an early marker for the identification of toxicant exposure. The state of the genome including rearrangements and translocations can be detected by Giemsa staining or trypsin/Giemsa banding (Basic Protocol 2). Fluorescent chromosome-specific painting probes are the basis for fluorescence in situ hybridization (FISH) probes that allow specificity in the evaluation of telomeric chromosomes of similar size as occurs in some mammalian species such as the mouse (Basic Protocol 3). A valuable approach to the utilization of Giemsa staining, Giemsa/trypsin banding, or FISH is the preparation of metaphase chromosome spreads on glass slides prior to staining (Support Protocol). A widely used assay, know as sister chromatid exchange, utilizes differential staining of chromatids so that each appears either dark or light after two cell cycles (Basic Protocol 4). Quantitation of toxicant-induced exchanges between sister chromatids provides the basis for genotoxic screening.

Methods for measuring DNA adducts are described in *UNIT 3.8*, Abasic Sites I: Isolation, Purification and Analysis of DNA Adducts in Intact DNA and *UNIT 3.9*, Abasic Sites II: Methods for Measurement of DNA Adducts. These two in depth units provide essential details for the analysis of DNA adducts. *UNIT 3.8* describes protocols for DNA isolation and hydrolysis for DNA adduct analyses and evaluation of abasic sites in DNA including low-temperature/antioxidant DNA isolation (Basic Protocol 1), measurement of apurinic/apyrimidinic sites (Basic protocol 2), immune slot-blot analysis of DNA adducts (Basic Protocol 3), immunohistochemical determination of DNA adducts (Basic Protocol 4) , and spectrophotometric quantification of DNA (Support Protocol).

UNIT 3.9 contains protocols for analyzing individual DNA adducts separated from the DNA backbone. Basic Protocol 1 describes HPLC methods for quantifying total guanine and Protocol 2 details similar techniques for total ribo- or deoxyribonucleosides. Other protocols describe methods to quantify individual DNA adducts with HPLC and electrochemical detection for 8-OH-dG (Basic Protocol 2), and N7-methylguanine (Basic Protocol 4). Basic Protocol 5 utilizes immunoaffinity chromatography to enrich for specific adducts that are subsequently analyzed by gas chromatography/electron capture negative chemical ionization/high resolution mass spectroscopy (GC/ECNCI/HRMS). Enzymatic DNA digestion (Support Protocol 1) preparation of immunoaffinity columns (Support Protocol 2) and determination of recovery (Support Protocol 3) are described. Other adduct purifications are described that utilize GC/ECNCI/HRMS isolation. Basic Protocol 7 utilizes liquid chromatography in combination with electrospray ionization/isotope dilution tandem mass spectrometry (LC/ESI/IDMS/MS for adduct purification and quantitation. Adduct quantification by ^{32}P postlabeling in combination with thin layer chromatography is described in Basic Protocol 8. Overall, *UNITS 3.8 & 3.9* provide a wide range of tools to determine the nature and extent of DNA modification by adduction; a critical issue in assessing the toxicology of chemicals.

The *Salmonella* (Ames) Test for Mutagenicity

The *Salmonella typhimurium*/mammalian microsome assay (Ames test) is a widely accepted short-term test for detecting chemicals that induce mutations in the DNA of organisms. This is a reverse mutation assay that employs histidine-dependent *Salmonella* bacteria with mutations at various genes in their histidine operon that render them incapable of synthesizing the amino acid histidine. When these histidine-dependent cells are grown on minimal medium agar plates containing a trace of histidine, only those cells that revert (mutate) to histidine independence (his^+) are able to form colonies. The small amount of histidine allows all the plated bacteria ($\sim 1 \times 10^8$ cells) to undergo a few cell divisions; in many cases, this growth is essential for mutagenesis to occur. The his^+ mutants are easily scored as colonies against the slight background growth of the his-dependent bacteria (bacterial lawn). The number of spontaneous mutant colonies per plate is relatively constant. However, when a mutagen is added to the plate, the number of revertant colonies is increased, usually in a dose-related manner.

Each of the basic *Salmonella* tester strains contains either a unique missense or a frameshift mutation in the histidine operon. These mutations result in a deficiency of an active enzyme or the production of an inactive enzyme in the histidine biosynthesis pathway. As a result, the cells cannot grow on minimal agar plates in the absence of histidine. A point mutation, induced by a chemical mutagen, will "reverse" the initial mutation and restore the cell's ability to synthesize its own histidine, thereby restoring its ability to grow in the absence of histidine. Such growth is evidenced by the formation of colonies (histidine revertant colonies) on minimal glucose agar plates (see Fig. 3.1.1).

Table 3.1.1 presents the genotypic characteristics of the eight most widely used *Salmonella* tester strains. Other strains that have been used for specialized testing purposes, such as for determining metabolic or genetic mechanisms, are those missing or with added nitroreductases, *O*-acetyl transferase, *N*-acetyl transferase, and glutathione-*S*-transferase (McCoy et al., 1981; Watanabe et al., 1987, 1990; Simula et al., 1993); strains to identify the specific point mutations induced (Gee et al., 1994); strains that also measure forward mutations (Ruiz-Rubio and Pueyo, 1982; Grant et al., 1992; Jurado et al., 1994); and DNA-repair proficient variants of the strains described in Table 3.1.1 (Maron and Ames, 1983).

The uniqueness of the mutation in each tester strain provides a "hot-spot" for different classes of mutagens. A chemical is considered a mutagen in the Ames test when a mutagenic response is obtained in at least one tester strain, either in the presence or absence of a metabolic activation system. There is no evidence to demonstrate that a chemical that is mutagenic in more than one strain is more potent or more mutagenic than a chemical that induces a mutation in only one strain.

There have been many test procedures developed that use histidine mutants of the *Salmonella* strains. These procedures include spot, plate, preincubation, vapor phase (chamber), and suspension tests (described by Ames et al., 1975; Maron and Ames, 1983), and other procedures such as the spiral plate assay (Houk et al., 1989, 1991) and the fluctuation test (Gatehouse and Delow, 1979). The most widely used of these procedures, which are described in this unit, are the plate test (see Basic Protocol) and preincubation test (see Alternate Protocol 1). Also described here are test procedures for highly volatile chemicals (see Alternate Protocol 2) and gases (see Alternate Protocol 3), chemicals that require reductive metabolism (see Alternate Protocol 4), and chemicals available only in

small amounts (see Alternate Protocol 5). Support protocols are included for toxicity testing to enable dose selection (see Support Protocol 1), strain maintenance and preservation (see Support Protocol 2), freezing permanent and working cultures (see Support Protocol 3), genetic analysis of strains (see Support Protocol 4), and preparation of the S-9 metabolic activation system (see Support Protocol 5).

The *Salmonella* assay is particularly well designed to detect chemically induced mutations (Ames et al., 1975). The primary impetus for its use is the high predictivity of a positive mutagenic response in *Salmonella* for rodent carcinogenicity (McCann et al., 1975; Sugimura et al., 1976; Tennant et al., 1987). The *Salmonella* test is also required or recommended by regulatory agencies prior to registration or acceptance of many chemicals, drugs, and biocides (Dearfield, et al., 1991; Kramers et al., 1991; Auletta et al., 1993; FDA, 1993; HPBGC, 1993; Kirkland, 1993; Sofuni, 1993).

ASEPTIC TECHNIQUE

The use of basic bacteriological laboratory procedures (see *APPENDIX 3*) are of utmost importance when performing the Ames assay. Aseptic procedures must be employed at all times; these include the use of sterile solutions and glassware. Contamination by bacteria or fungi will interfere with the test. Contaminated frozen permanent or working cultures of the *Salmonella* strains will render them unusable, as will contaminated

overnight cultures. Surface areas must be properly disinfected before and after use. All cultures and labware used to handle the cultures must be autoclaved before being discarded.

SAFETY CONSIDERATIONS

Because the purpose of the Ames assay is to ascertain a chemical's mutagenicity, and because of the known association of *Salmonella* mutagens with carcinogenicity, all test chemicals should be treated as potential mutagens or carcinogens, unless known to be otherwise. The positive control chemicals suggested for use consist of known rodent carcinogens and chemicals shown to be noncarcinogenic in rodent bioassays. All contaminated material (e.g., test tubes, pipets, and pipet tips) should be properly disposed of. In addition, all personnel performing the assay should wear protective clothing including safety glasses and gloves. Wearers of soft contact lenses should avoid wearing the lenses, or wear protective eye covering when performing mutagenicity testing, especially in the case of volatile chemicals. All handling of chemicals, as well as the test itself, should be performed in a chemical/biological safety hood.

Although the cell wall mutations (*gal* and *rfa*) in these *Salmonella* strains weaken their pathogenicity (Ames, 1971; Wilkinson et al., 1972), it is prudent to avoid direct contact with the cells. Gloves should be worn when handling the strains, and cultures should not be mouth-pipetted. Petri dishes and solutions containing *Salmonella* strains or colonies should not be discarded as is, but should be autoclaved or incinerated.

STANDARD PLATE INCORPORATION TEST

BASIC PROTOCOL

The standard plate incorporation assay consists of exposing the tester strain(s) to the test chemical directly on a glucose minimal agar plate (GM plate), usually in the presence and absence of a metabolic activation system. The components are first added to sterile test tubes containing 2 ml of molten top agar supplemented with limited histidine and biotin. The top agar should be maintained at a temperature between 43°C and 48°C. The contents of the tubes are mixed and poured on GM plates. After the top agar has hardened, the plates are incubated in an inverted orientation for 48 hr. Colonies are counted on all plates and the number of colonies on the test plates is compared to that on the negative solvent control plate. Figure 3.1.2 depicts the setup for performing the standard plate incorporation test.

Materials

Cultures of *Salmonella* tester strains (see Support Protocols 2 and 3)
Nutrient broth (see recipe), sterile
Glucose minimal agar plates (GM plates; 100 × 15 mm; see recipe)

continued

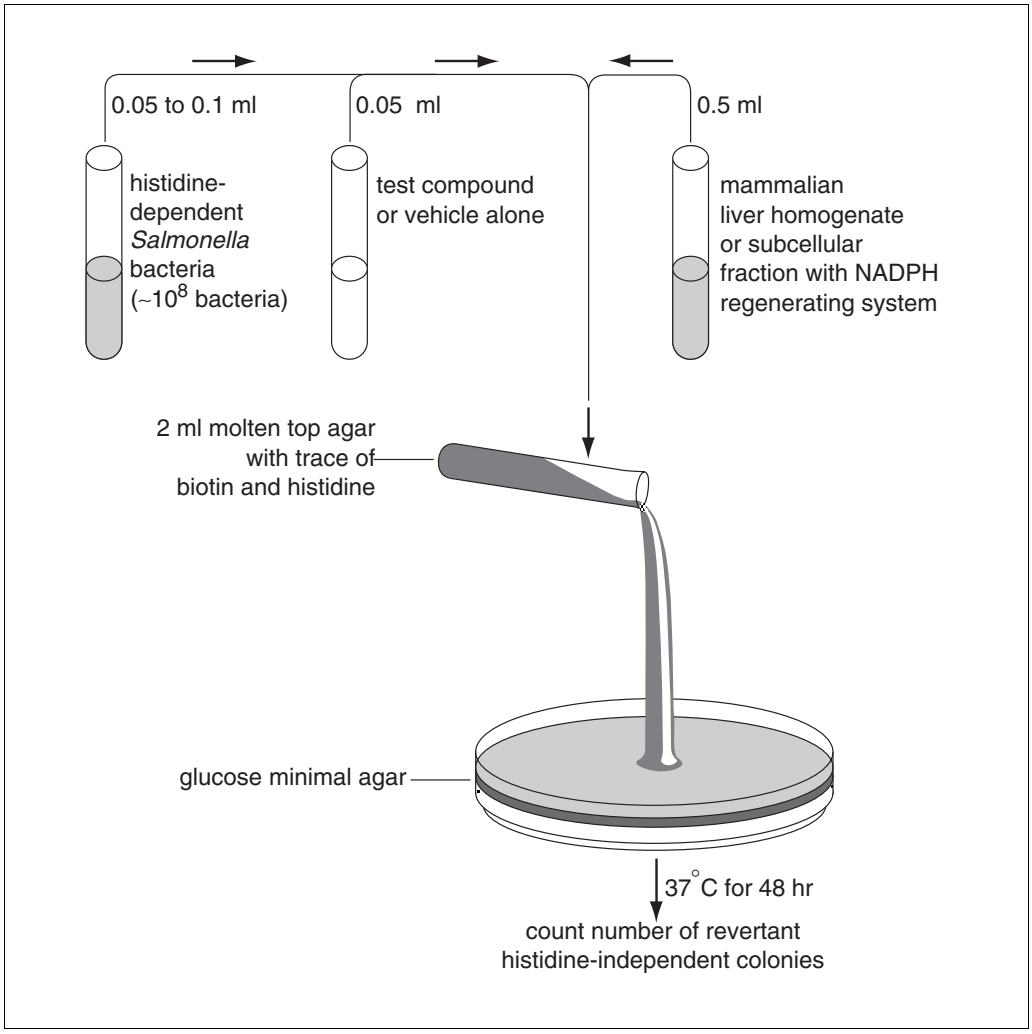

Figure 3.1.2 Standard plate incorporation assay.

Metabolic activation system (rat liver S-9 homogenate; see Support Protocol 5)
Cofactors for the S-9 mix (see recipe)
Test compound
Positive control chemicals (Table 3.1.2)
Negative control (solvent)
Top agar supplemented with biotin and limited histidine (see recipe), maintained at 43°C

37°C shaking incubator set at 100 to 120 rpm for cultivation of overnight cultures
Sterile glass test tubes (16 × 150–mm and 13 × 100–mm)
Boiling water or microwave oven to melt top agar
Oven, heating block, or water bath set at 43° to 48°C to maintain temperature of top agar
Bottle-top dispensers: 2-ml for delivering top agar and 0.5-ml for delivering buffer and S-9 mix to test tubes
Colony counter (optional)

Additional reagents and equipment for maintaining and growing bacterial stocks (*APPENDIX 3*), maintaining and growing *Salmonella* indicator strains (see Support Protocol 2), dose selection for *Salmonella* test (see Support Protocol 1), preparation of metabolic activation system for *Salmonella* test (see Support Protocol 5), and performing strain check for genetic integrity (see Support Protocol 4)

Table 3.1.2 Recommended Positive Control Chemicals and Test Concentrations[a]

Strain	Control	Chemical[b]
Without metabolic activation		
TA97	9-Aminoacridine	50 µg/plate
TA98	4-Nitro-*o*-phenylenediamine	2.5 µg/plate
TA100	Sodium azide	5 µg/plate
	Methyl methane sulfonate	250 µg/plate
TA102	Mitomycin C	0.5 µg/plate
TA104	Methyl methane sulfonate	250 µg/plate
TA1535	Sodium azide	5 µg/plate
	Methyl methane sulfonate	250 µg/plate
TA1537	9-Aminoacridine	50 µg/plate
TA1538	4-Nitro-*o*-phenylenediamine	2.5 µg/plate
With metabolic activation		
TA97	2-Aminoanthracene	1-5 µg/plate[c]
TA98	2-Aminoanthracene	1-5 µg/plate[c]
TA100	2-Aminoanthracene	1-5 µg/plate[c]
TA102	2-Aminoanthracene	5-10 µg/plate[c]
TA104	2-Aminoanthracene	5-10 µg/plate[c]
TA1535	2-Aminoanthracene	2-10 µg/plate[c]
TA1537	2-Aminoanthracene	2-10 µg/plate[c]
TA1538	2-Aminoanthracene	2-10 µg/plate[c]

[a]Other chemicals have been recommended for use as positive controls (Ames et al., 1975; Maron and Ames, 1983; Kier et al., 1986). For other strains, refer to the publications in which the strains are described.

[b]Concentrations based on 100 × 15–mm GM plates containing 20 to 25 ml agar (see Basic Protocol 1 and Reagents and Solutions).

[c]The optimum positive control concentration will depend on the source of S-9 and its concentration and must be determined empirically.

1. Inoculate *Salmonella* cultures into 16 × 150-mm sterile glass tubes containing 9 ml nutrient broth or 125-ml Ehrlenmeyer flasks containing 25 to 50 ml nutrient broth, 15 to 18 hr prior to performing the experiment. Grow overnight in a 37°C shaking incubator set to 100 to 120 rpm (see Support Protocol 2 and *APPENDIX 3*).

   The overnight culture should contain ~1–2 × 10^9 cfu/ml.

2. Label an appropriate number of GM plates and corresponding 13 × 100–mm sterile glass test tubes for each test chemical, taking into consideration that each experiment should contain a series of duplicate or triplicate plates for:

   Negative solvent control (bacteria only)
   Three or more concentrations of the test substance (diluted to at least half-log intervals), with the highest dose limited by toxicity or solubility (see Support Protocol 1)
   Positive control (see below and see Table 3.1.2).

   The positive control chemicals should be diagnostic for the unique mutation in each Salmonella strain, and a control that requires metabolic activation should be included. If a specific class of chemicals is being investigated, a positive control containing a mutagenic member of that class should be included in lieu of, or in addition to, the standard positive control chemical where ever possible.

Concurrent solvent and positive controls must be run with each trial. The positive controls and concentrations listed in Table 3.1.2 are recommended for general testing. The positive controls are designed to monitor the ability of the laboratory to obtain a positive response, to identify the tester strain, and to demonstrate the activity of the metabolic activation system. A negative control (no solvent or chemical) should be run if there is a question of the reactivity or toxicity of the solvent. Where a specific chemical class is being tested, or where the test chemical is known to be metabolized by a specific metabolic pathway, a related chemical, known to be mutagenic, should be used as the positive control. If more than one chemical is tested on the same day, only one set of positive-control chemicals need be tested. The negative solvent control is used as the base from which to determine the mutagenic activity of the test chemical.

3. Prepare metabolic activation system by mixing cofactors with S-9 at a concentration of either 5%, 10%, or 30% (v/v) of S-9 fraction. Calculate the total number of plates that will be needed and determine the volume of S-9 mix that will be needed by dividing the number of plates by 2 (since 0.5 ml of S-9 mix is added to each plate).

   Per 200 plates, a total of 100 ml of S-9 mix is needed, with the following v/v ratios of cofactors to S-9 fractions (total volume of 100 ml): for 5% S-9, 5 ml S-9 fraction/95 ml cofactors; for 10% S-9, 10 ml S-9 fraction/90 ml cofactors; for 30% S-9, 30 ml S-9 fraction/70 ml cofactors. If smaller volumes are needed, reduce the volumes of S-9 fraction and cofactors proportionally.

4. Prepare dilutions of test compound (see Support Protocol 1 for determination of dose range).

5. To the appropriately labeled sterile glass test tubes (see step 2), maintained at 43°C, add in the following order:

   2 ml of molten top agar (supplemented with 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C
   0.50 ml of metabolic activation (S-9) mix or buffer
   0.05 ml of appropriate test compound dilution or control.

   Mix contents of tubes after addition of the chemical, preferably by mild vortexing, then add:

   0.05 to 0.10 ml of overnight culture of the *Salmonella* strain (from step 1).

   Mix contents of the tubes again after addition of the bacteria, preferably by mild vortexing.

6. Pour contents of each test tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.

7. After the top agar has hardened (2 to 3 min), invert plates and place in a 37°C incubator for 48 hr.

   If growth retardation is seen at 48 hr, as evidenced by smaller than anticipated colony sizes, the plates are incubated for an additional 12 to 24 hr.

8. Count colonies either manually or by an electronic colony counter.

   If colonies cannot be counted immediately the plates should be refrigerated. The plates can be stored in a refrigerator for up to 2 days. All plates must be removed from the incubator and be counted at the same time.

   Histidine revertant colonies on the plates can be counted by machine or "by hand." It is important that electronic counting machines be calibrated by first comparing manual counts of a few plates containing different numbers of colonies, including high numbers, with the counts obtained by the electronic counter. If an electronic colony counter is not available, a measured section of the plate can be counted by hand when there is a high

density of colonies on the plate with an even distribution across the plate. The resulting colony count can then be extrapolated to the area of the entire plate.

If an electronic counter is available, plates are machine counted, unless precipitate is present, which could interfere with the count, or the color of the test chemical on the plate could reduce the contrast between the colonies and the agar. In such instances, the colonies are hand counted.

9. Express the test results as number of revertant colonies per plate.

A strain check for genetic integrity (see Support Protocol 4) should be performed with every experiment. For this strain check it is sufficient to monitor the rfa mutation (using crystal violet) and ampicillin and tetracycline resistance using disks impregnated with the appropriate concentration of each component (Zeiger et al., 1981).

Results should be reported as the individual plate counts, or the mean and standard deviations or standard error of the mean for each dose/activation combination. The results for the solvent and positive controls should be included. Additional calculations of the "mutation index" (often defined as the fold increase over the solvent control) or of his^+ revertants/unit weight or mass, can be performed as a method for comparing the responses of a series of test substances. These latter values should not be used by themselves, because they do not represent the actual responses and can exaggerate small differences among test samples.

PLATE ASSAY WITH PREINCUBATION PROCEDURE

ALTERNATE PROTOCOL 1

This assay involves exposing the tester strains for a short period (usually 20 min) in a suspension containing the test agent, with and without metabolic activation, prior to the addition of top agar and plating. It is believed that short-lived mutagenic metabolites have a better chance of reacting with the tester strains in the small volume of the preincubation mixture, as compared to the case described in Basic Protocol 1, where the incubation mixture is plated immediately on glucose minimal agar plates (Yahagi et al., 1975; Haworth et al., 1983). In addition, the smaller preincubation volume results in a higher effective concentration of the metabolic activation system (S-9) and cofactors (also see Alternate Protocol 5).

For materials and cross-referenced procedures, see Basic Protocol.

1. Prepare bacteria, plates and test tubes, metabolic activation system, and chemicals/controls to be tested (see Basic Protocol, steps 1 to 4).
2. To the appropriately labeled sterile glass tubes, maintained at 37°C, add in the following order:

   0.50 ml of metabolic activation mix or buffer
   0.05 ml of appropriate test chemical dilution or control.

   Mix contents of tubes after addition of the chemical, preferably by mild vortexing, then add:

   0.05 to 0.10 ml of overnight culture of the *Salmonella* strain.

   Mix contents of the tubes again after addition of the bacteria, preferably by mild vortexing.
3. Incubate mixture 20 min at 37°C without shaking.

   Chemicals known or suspected to be volatile should be incubated in capped tubes.
4. Add 2 ml of molten top agar (supplemented with 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C, to the incubation mixture and mix contents of each tube.

5. Pour contents of each test tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.
6. Incubate, count colonies, and interpret test results (see Basic Protocol, steps 7 to 9).

ALTERNATE PROTOCOL 2

DESICCATOR ASSAY FOR VOLATILE LIQUIDS

The use of a closed chamber is recommended for testing highly volatile chemicals and gases (Simmon et al., 1977; Zeiger et al., 1992). Procedures using plastic bags in lieu of desiccators have also been described (Hughes et al., 1987; Araki et al., 1994).

Figure 3.1.3 depicts a desiccator assay procedure for volatile liquids. This procedure should be used only if it is known that the test chemical will volatilize at 37°C and disperse throughout the desiccator. To aid dispersion, a magnetic stir bar is placed in the desiccator below the test chemical, and the desiccator is placed on a magnetic stir plate in the incubator. A 9-liter desiccator is recommended because it can hold up to 18 plates.

Additional Materials *(also see Basic Protocol)*

Volatile test chemical
Desiccator (9-liter) with perforated ceramic shelf
Glass petri plate (100 × 15–mm) or watch glass, sterile
Magnetic stir bar
Magnetic stirrer

1. Prepare bacteria, plates and test tubes, metabolic activation system, and chemicals/controls to be tested (see Basic Protocol, steps 1 to 4).

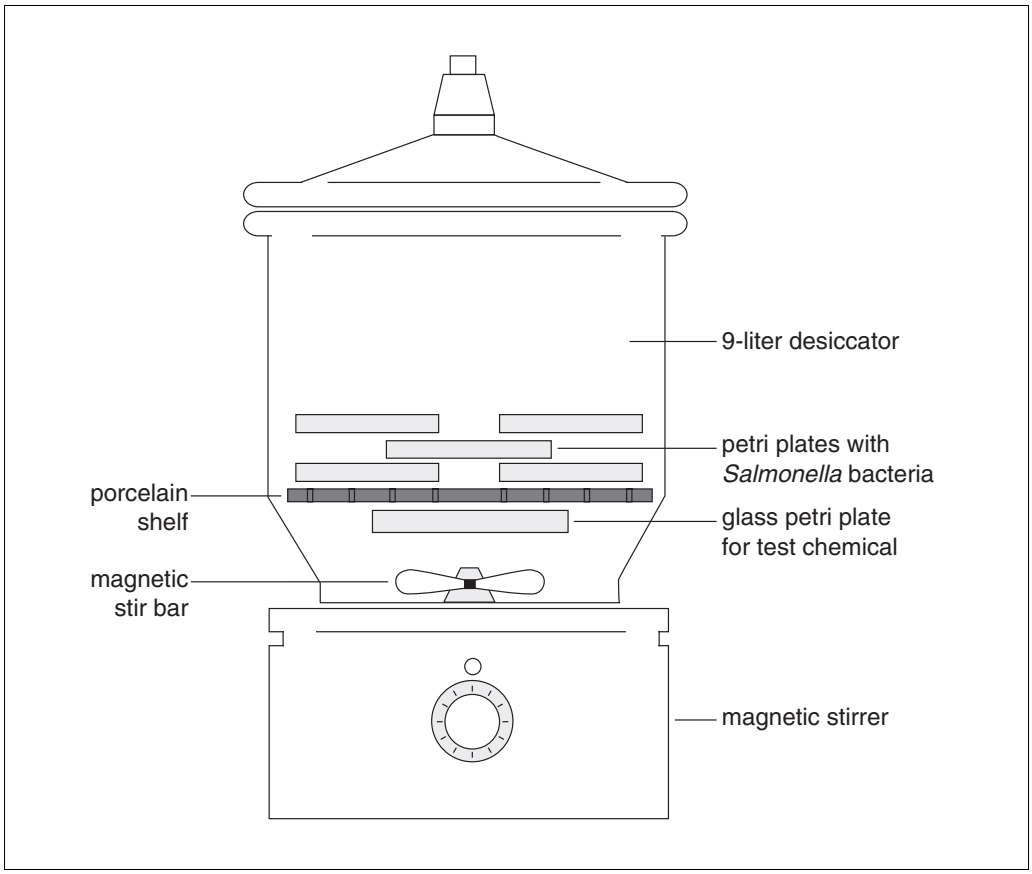

Figure 3.1.3 Desiccator assay using volatile liquids.

The plates should be labeled on their bottoms or sides because the lids will have to be removed prior to placing them in the desiccator.

The positive-control chemicals may be tested in the standard plate incorporation assay (see Basic Protocol).

2. To the appropriately labeled sterile glass tubes, maintained at 43°C, add in the following order:

   2 ml of molten top agar (supplemented with 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C
   0.50 ml of metabolic activation (S-9) mix or buffer
   0.05 to 0.10 ml of overnight culture of the *Salmonella* strain.

   Mix the contents of the tubes after addition of the bacteria, preferably by mild vortexing.

3. Pour contents of each test tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.
4. While the top agar is hardening, remove the perforated ceramic shelf of the desiccator for attachment of a sterile bottom or top lid of a glass petri dish (or a watch glass). Attach the bottom/top lid of the dish to the shelf using a self-adhesive labeling tap in a cross configuration to support it, using sufficient tape to extend all the way to the edge of the ceramic shelf with ~1 in. remaining for taping it over the edge on the top side of the shelf.
5. Place a magnetic stir bar in the bottom of the desiccator, then replace the ceramic shelf in the desiccator.
6. With a sterile pipet, transfer a predetermined volume (see Support Protocol 1 for preliminary toxicity assay) of the liquid test chemical to the petri dish.

   For nontoxic chemicals, volumes added are typically 1, 2, 3, 4, and 5 ml per desiccator. If toxicity is observed at the lowest dose (0.5 ml) used in the preliminary assay (see Support Protocol 1), dilute the chemical 10-fold (or more if needed) in a suitable solvent. The solvent should be tested first in a desiccator for toxicity.

7. Remove the lids of the petri plates containing the *Salmonella* bacteria and S-9 mix or buffer and loosely stack the plates in an inverted position on the ceramic shelf.
8. Seal the desiccator and place on a magnetic stirrer in a 37°C incubator or warm room for 24 hr.
9. After 24 hr, place the desiccator in a chemical safety hood, remove the plates, put the lids back on, and transfer to a 37°C incubator for 24 hr.

   If growth retardation is seen after the additional 24-hr incubation, as evidenced by smaller than anticipated colony sizes, the plates are incubated for an additional 12 to 24 hr.

10. Count colonies either manually or by an electronic colony counter.

    If colonies cannot be counted immediately the plates should be refrigerated. The plates can be stored in a refrigerator for up to 2 days. All plates must be removed from the incubator and be counted at the same time.

11. Express the test results as number of revertant colonies per plate based on volume added to each desiccator—i.e., number of revertants per volume (in ml) per desiccator.

    A strain check for genetic integrity (see Support Protocol 4) should be performed with every experiment. For this strain check it is sufficient to monitor the rfa (coeffective lipopolysaccharide) mutation (using crystal violet) and ampicillin and tetracycline resistance using disks impregnated with the appropriate concentration of each component (Zeiger et al., 1981).

ALTERNATE PROTOCOL 3

DESICCATOR ASSAY FOR GASES

The use of a closed chamber is recommended for testing highly volatile chemicals and gases (Simmon et al., 1977; Zeiger et al., 1992). Procedures using plastic bags in lieu of desiccators have also been described (Hughes et al., 1987; Araki et al., 1994).

The desiccator used for testing gases is similar to that shown in Figure 3.1.3, except that it contains a stopcock for inlet of gas. To aid dispersion of the gas, a stirring bar magnet is placed in the desiccator, and the desiccator is placed on a magnetic stir plate in the incubator. A 9-liter desiccator is recommended because it can hold up to 18 plates.

Additional Materials *(see also Basic Protocol)*

Gaseous test chemical
Desiccator (9-liter) with stopcock inlet (e.g., for use as vacuum desiccator) and perforated ceramic shelf
Glass petri plate (100 × 15–mm) or watch glass, sterile
Magnetic stir bar
Polyvinyl tubing
Pressure gauge
Vacuum pump
Magnetic stirrer

1. Prepare bacteria, plates and test tubes, metabolic activation system, and chemicals/controls to be tested (see Basic Protocol, steps 1 to 4).

   The plates should be labeled on their bottoms or sides because the lids will have to be removed prior to placing them in the desiccator.

   The positive-control chemicals may be tested in the standard plate incorporation assay.

2. To the appropriately labeled sterile glass tubes, maintained at 43°C, add in the following order:

   2 ml of molten top agar (supplemented with 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C
   0.50 ml metabolic activation (S-9) mix or buffer
   0.05 to 0.10 ml of overnight culture of the *Salmonella* strain.

   Mix the contents of the tubes after addition of the bacteria, preferably by mild vortexing.

3. Pour contents of each test tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.

4. Place a magnetic stir bar in the bottom of the desiccator and replace the ceramic shelf.

5. Remove the lids of the petri plates containing the *Salmonella* bacteria and S-9 mix or buffer and loosely stack the plates in an inverted position on the ceramic shelf.

6. Seal the desiccator and proceed with the following steps for each concentration of gas.

   a. Connect a polyvinyl tubing to a vacuum pump (or in-house vacuum) and to the stopcock of the desiccator.

      A vacuum gauge should be used to monitor the evacuation of air.

   b. Open the stopcock and partially evacuate the air from the desiccator.
   c. Close the stopcock, remove the vacuum tubing, connect the gas tubing to the stopcock, and connect the other end of the tubing to the cylinder containing the gaseous test chemical.

d. Slowly open the gas cylinder valve first, and then very slowly open the stopcock valve.

The gas will transfer to the desiccator very rapidly (within to 10 sec).

7. When atmospheric pressure is reached (after ~10 sec), close the stopcock first and then close the valve of the gas cylinder.

8. After removing the gas tubing from the desiccator stopcock, place the desiccator on a magnetic stirrer in a 37°C incubator or warm room for 24 hr.

Each laboratory performing a desiccator assay with gases should first determine how much air is removed from the desiccator at different levels of vacuum. This can be readily accomplished by using the procedure described above, but using water. The volume taken up by the agar plates should be taken into consideration when performing this procedure. The volume of water that has entered the desiccator is measured using a graduated cylinder. The procedure should be repeated for each level of vacuum that has been applied. Caution should be taken to remove no more than 50% of the air from the desiccator to prevent implosion.

9. After 24 hr, place the desiccator in a chemical safety hood, remove the plates, put the lids back on, and transfer to a 37°C incubator for 24 hr.

If growth retardation is seen after the additional 24-hr incubation, as evidenced by smaller than anticipated colony sizes, the plates are incubated for an additional 12 to 24 hr.

10. Count colonies either manually or with an electronic colony counter.

If colonies cannot be counted immediately the plates should be refrigerated. The plates can be stored in a refrigerator for up to 2 days. All plates must be removed from the incubator and be counted at the same time.

11. Express the test results as number of revertant colonies per plate based on moles of gas added to each desiccator. To calculate the moles of gas, use the formula $n = PV/RT$, where n is the number of moles, P is 1 atmosphere, V is volume in liters, R is the universal gas constant (0.0821 liter.atm/mol.°K) and T is temperature expressed in °K.

A strain check for genetic integrity (see Support Protocol 4) should be performed with every experiment. For this strain check it is sufficient to monitor the rfa mutation (using crystal violet) and ampicillin and tetracycline resistance using disks impregnated with the appropriate concentration of each component (Zeiger et al., 1981).

REDUCTIVE METABOLISM ASSAY

ALTERNATE PROTOCOL 4

This procedure is identical to that used for the preincubation assay (see Alternate Protocol 1) with the exception that a modified cofactor mix is used (Prival and Mitchell, 1982; Reid et al., 1984). This assay is recommended for testing chemicals that require reduction for their activation, such as azo dyes.

Additional Materials *(also see Basic Protocol)*

Cofactors for reductive metabolism (see recipe)
Metabolic activation system (uninduced hamster liver S-9 homogenate; see Support Protocol 5, but use hamsters and omit injection of Arochlor)
Flavin mononucleotide (FMN) solution (see recipe)

1. Prepare bacteria, plates, and test tubes (see Basic Protocol, steps 1 to 3).

2. Prepare reductive metabolic activation system by adding 30 ml of the hamster liver S-9 to 63 ml of the cofactors for reductive metabolism and keep on ice away from direct light (see Reagents and Solutions).

3. Prepare dilutions of the test compound (see Support Protocol 1 for determination of dose range).
4. Immediately before preparing the mix in step 5, add 7 ml of the flavin mononucleotide (FMN) solution to the 93 ml of the reductive metabolic activation system prepared in step 2 (also see Reagents and Solutions).
5. To the appropriately labeled sterile glass tubes, maintained at 37°C, add in the following order:

   0.50 ml of FMN-containing reductive metabolic activation mix (from step 4), or buffer
   0.05 ml of appropriate test chemical dilution or control.

   Mix contents of tubes after addition of the chemical, preferably by mild vortexing, then add:

   0.05 to 0.10 ml of overnight culture of the *Salmonella* strain.

   Mix contents of the tubes again after addition of the bacteria, preferably by mild vortexing.
6. Incubate mixture 20 min at 37°C without shaking.

   Chemicals known or suspected to be volatile should be incubated in capped tubes.
7. Add 2 ml of top agar (supplemented with 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C, to the incubation mixture, and mix contents of each tube.
8. Pour contents of each test tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.
9. Incubate, count colonies, and interpret test results (see Basic Protocol, steps 7 to 9).

ALTERNATE PROTOCOL 5

MODIFIED (KADO) MICROSUSPENSION ASSAY

This is a highly sensitive assay for testing the mutagenicity of pure chemicals, complex mixtures, and biological samples that are available only in small amounts (Kado et al., 1983). The procedure is a slight modification of the preincubation assay (see Alternate Protocol 1) and is performed as described below.

Additional Materials *(see also Basic Protocol)*

0.1 M sodium phospate buffer, pH 7.4 (see recipe)
Centrifuge and rotor
Sterile test tubes (10 × 70–mm), with sterile caps

1. Prepare overnight cultures of bacteria, plates, and test tubes (see Basic Protocol, steps 1 to 3; but use 10 × 70–mm test tubes).

   When testing urine samples, a deconjugating enzyme system is included in the assay (Kado et al., 1983).
2. Centrifuge *Salmonella* overnight culture(s) 15 min at 9000 × *g* (8700 rpm in a Sorvall SS-34 rotor), 4°C. Wash cells twice in 0.1 M sodium phosphate buffer, pH 7.4, each time centrifuging at 9000 × *g* and removing the supernatant. Resuspend pellet in 0.1 M sodium phosphate buffer, pH 7.4, at 1/10 the original volume (10-fold concentration).
3. Prepare metabolic activation system and keep on ice.
4. Prepare dilutions of the test compound (see Support Protocol 1 for determination of dose range).

5. To the appropriately labeled 10 × 70–mm test tubes, placed in an ice bath, add in the following order:

   0.1 ml of the 10-fold concentrated overnight *Salmonella* culture from step 3.
   0.1 ml of a metabolic activation system or buffer
   0.001, 0.0025, 0.005, or 0.01 ml of test compound.

   Adjust the volume of solvent so that each tube contains the same final volume of liquid.

6. Incubate mixtures 90 min at 37°C with shaking at 120 rpm.

7. Add 2 ml molten top agar (containing 0.05 mM histidine and 0.05 mM biotin), maintained at 43°C, to each incubation mixture. Mix contents of tubes.

8. Pour contents of each tube onto the surface of the corresponding GM plate and gently swirl to evenly distribute the molten top agar.

9. Incubate, count colonies, and interpret test results (see Basic Protocol, steps 7 to 9).

TOXICITY TEST FOR DOSE SELECTION

SUPPORT PROTOCOL 1

All chemicals are tested initially in a toxicity test to determine the appropriate dose range for the mutagenicity assay. When multiple chemicals with similar properties are to be tested, it may be sufficient to perform a toxicity test on one representative chemical and use these results to estimate the dose range to be used with the other chemicals. If more than one *Salmonella* strain is to be used for the mutagenicity test, the toxicity test should be performed using strain TA100. Otherwise, the test should be performed using the strain that will be used for the definitive mutagenicity test. Alternatively, the toxicity assay can be performed using the system developed by Waleh et al. (1982).

It is sufficient to perform the test using single plates for each test chemical concentration. The experiment should contain:

1. A solvent control (bacteria only).

2. A total of 8 concentrations, in half-log intervals, of the test substance, with the highest dose limited by solubility, or by an arbitrary value (this value is usually 5000 or 10,000 μg/plate). For volatile liquids or gases that are tested in desiccators, the preliminary toxicity assay uses a high and low concentration—5 and 0.5 ml for liquids and 4.5 and 0.5 liters for gases.

3. A positive control.

4. Dose selection for the definitive test of chemicals exhibiting toxicity should include at least four nontoxic doses with only the highest dose level exhibiting toxicity. Toxic concentrations are defined as those that produce a decrease in the number of histidine independent (his^+) colonies and/or clearing in the density of the background lawn (see Critical Parameters), or absence of a background lawn, under conditions of the test.

The preliminary toxicity test is also an opportunity to determine if the test substance is soluble under the conditions of the test, if it reacts with the solvent or test medium, or if it produces other effects than might interfere with the test.

The preliminary toxicity test should be performed in the presence and absence of the metabolic activation system, using the protocol that will be used for the definitive test.

SUPPORT PROTOCOL 2

STRAIN MAINTENANCE AND PRESERVATION

All indicator strains should be kept frozen (−80°C). Upon receipt of the new strains, up to five frozen permanent cultures should be prepared from one single colony isolate that has been checked for its genotypic characteristics (*his, rfa, uvrB-bio*) and for the presence of plasmids pKM101 and pAQ1, when appropriate. These cultures should be considered the frozen permanent strains which should be accessed only for the preparation of new frozen working cultures.

Materials

Salmonella strain (Table 3.1.1): available from Dr. Bruce Ames, Biochemistry Department, University of California, Berkeley, Calif. 94720
Nutrient agar plates (see recipe)
Nutrient broth (see recipe)
Glucose minimal agar plates (GM plates; see recipe)
Enriched GM agar plates (see recipe)
Cryogenic vials

Additional reagents and equipment for growth and manipulation of bacteria (*APPENDIX 3*)

Prepare permanent cultures

1. Upon receipt of the *Salmonella* tester strain(s), streak a loopful of the culture for individual colonies (*APPENDIX 3*) on nutrient agar plates and inoculate a small inoculum in 5 ml of nutrient broth. Incubate overnight.

   The broth culture serves as a backup in case no growth is observed on the agar plate.

   In case a disk containing the strain imbedded in nutrient agar is received, first streak the disc across the surface of a nutrient agar plate, and then transfer the disc to 5 ml of nutrient broth.

2. After overnight incubation, purify three colonies by streaking a small inoculum from each colony for individual colonies on enriched GM agar plates supplemented with an excess of biotin and histidine and as needed with ampicillin (for strains carrying plasmid pKM101) and tetracycline (for strains carrying plasmid pAQ1). Incubate 1 to 2 days at 37°C.

3. After incubation, pick three colonies from the plate and inoculate preassigned locations, labeled 1, 2, and 3, on an enriched GM agar plate supplemented with the appropriate nutrients/antibiotics, which should be the same as those used in step 2.

   Label the locations on the back of the plate. These plates will serve as the master agar plates.

   For steps 2 and 3, nutrient agar plates may also be used instead of appropriately supplemented GM agar plates, however the use of minimal defined medium reduces the risk of contamination.

4. At the same time inoculate a small inoculum from each of the three colonies, individually, in 5 ml of nutrient broth.

5. After incubation at 37°C for 1 or 2 days, perform a strain check analysis (see Support Protocol 4) on each of the triplicate liquid cultures.

6. Upon completion of the strain check, select the colony from the master plate that has given the best overall results in terms of phenotypic characteristics, including the best overall spontaneous mutation induction. Inoculate a small portion from this colony in 5 ml of nutrient broth and incubate the cultures overnight at 37°C with shaking at 100 to 120 rpm.

   For "Permanent Cultures" it is usually sufficient to freeze down five 1-ml aliquots.

7. When good growth (OD_{540} between 0.1 and 0.2) is obtained, label this culture as "Permanent Culture" and freeze the cells (see Support Protocol 3), storing them in a −80°C freezer or in liquid nitrogen.

   These permanent cultures should be accessed only when new working frozen cultures are needed.

   New frozen working cultures should be prepared every 12 months with an expiration date 1 year from the time the new frozen cultures were prepared. The following steps should be followed to prepare the working cultures.

Prepare working cultures

8. Take one permanent culture from the freezer and quickly remove a small inoculum by scraping the surface of the frozen culture with a sterile loop or needle. Transfer the inoculum to 5 ml nutrient broth and incubate overnight at 37°C with shaking at 100 to 120 rpm.
9. Streak the overnight culture for individual colonies on minimal medium agar plates supplemented with an excess of biotin and histidine and as needed with ampicillin (for strains carrying plasmid pKM101) and tetracycline (for strains carrying plasmid pAQ1). Incubate 1 to 2 days at 37°C.
10. After incubation, transfer a small inoculum from each of three single, healthy-looking colonies from the plate to preassigned locations, labeled 1, 2, and 3, on a glucose minimal medium agar master plate appropriately supplemented with biotin, histidine, ampicillin and/or tetracycline (i.e., the permanent plate).

    Nutrient agar plates may be used instead of the appropriately supplemented minimal agar plates, however the use of minimal defined medium reduces the risk of contamination.

11. At the same time inoculate a small inoculum from each of the three colonies, individually, in 5 ml of nutrient broth.
12. After incubation at 37°C for 1 or 2 days, perform a strain check analysis (see Support Protocol 4) on each of the triplicate liquid cultures prepared in step 11.
13. Upon completion of the strain check, select the colony from the permanent plate that has given the best overall results in terms of phenotypic characteristics, including the best overall spontaneous mutation induction. Add a small inoculum of nutrient broth and incubate the cultures overnight at 37°C with shaking at 100 to 120 rpm.

    The number of working cultures that are prepared depends on how many times during any given year fresh cultures will be grown up overnight. Frozen working cultures are usually maintained for up to 1 year. It is not unusual for laboratories that test at least once a week to prepare at least fifty 1-ml frozen aliquots. In that case, 50 ml of nutrient broth should be inoculated with the test organism for overnight growth.

14. When good growth is obtained (OD_{540} between 0.1 and 0.2), label the cultures as "Working Cultures" and freeze the cells (see Support Protocol 3) storing them in a −80°C freezer or in liquid nitrogen.

    At the time the experiment is to be performed, carry out the remaining steps.

Propagate working cultures

15. Thaw a 1-ml frozen culture at room temperature.
16. Transfer 0.1- to 0.5-ml aliquots into volumes of nutrient broth between 10 and 50 ml, to give an initial cell density between 1×10^6 and 1×10^7 colony forming units/ml (1:100 dilution). Discard remainder of working culture.

    Frequent thawing and refreezing of the frozen cultures can result in permanent injury to the bacteria.

An alternative procedure for inoculation of the overnight cultures is to use a sterile inoculation loop to scrape a small amount of the frozen culture from the surface of the frozen culture. This procedure should be done quickly to prevent thawing of the culture.

17. Grow the cultures at 37°C for 4 hr without shaking, then with gentle shaking (100 rpm) for 11 to 14 hr.

All strains should be analyzed for their genetic integrity (see Support Protocol 4) when each experiment is performed.

SUPPORT PROTOCOL 3

FREEZING OF PERMANENT AND WORKING CULTURES

After the strain check is performed, one of the three colony isolates that gave the best overall results in terms of genetic integrity is selected from the master plate for preservation (either as frozen permanent stock cultures or as frozen working cultures). The following procedure is used for freezing down the strains.

Materials

Permanent or working culture (see Support Protocol 2, step 7 or 14), with OD_{540} between 0.1 and 0.2)
Glycerol or DMSO, sterile
2-ml cryogenic vials, sterile

1. Add sterile glycerol (or DMSO) to the culture at a final concentration of 10% (v/v). Mix thoroughly, then dispense in 1-ml aliquots in sterile 2-ml cryogenic vials.

Each 1-ml sample should contain 1–2 × 10^9 cells. Make sure that the caps of the cryogenic vials are tightly secured.

2. Quickly freeze cultures by placing on dry ice.

3. Place the frozen cultures in a −80°C freezer or in liquid nitrogen.

One ampule of the frozen overnight culture should be saved for performing a strain check (see Support Protocol 4) to ensure that the new working cultures that were frozen down have maintained their genetic integrity.

SUPPORT PROTOCOL 4

GENETIC ANALYSIS OF STRAINS

After overnight incubation the cultures are analyzed for their genetic characteristics and for the number of spontaneous revertants as follows.

Materials

Overnight culture of *Salmonella* (see Support Protocol 2, step 5 or 12)
Enriched GM agar plates (see recipe) with the following additives:
An excess of biotin (B plates)
An excess of histidine (H plates)
An excess of biotin and histidine (BH plates)
An excess of biotin and histidine, and 24 µg/ml ampicillin (BHA plates)
An excess of biotin and histidine, and 2 µg/ml tetracycline (BHT plates)
0.1% (w/v) crystal violet solution (see recipe)
Sterile filter paper disk (6-mm)

1. *Biotin dependence (bio):* Streak a loopful of the culture across one GM plate supplemented with an excess of histidine. Incubate 1 to 2 days at 37°C.

Expected result: no growth.

Because a deletion mutation stretches across the bio-uvrB region of the chromosome, it is sufficient to show that the tester strains are biotin dependent to infer that they are also

defective in the accurate DNA repair pathway due to the uvrB deletion. The presence of a deletion of the uvrB gene, rather than an inactivating point mutation, ensures that the cell will not be able to mutate back to an effective uvrB gene.

2. *Histidine dependence (his):* Streak a loopful of the culture across one GM plate supplemented with an excess of biotin. Incubate 1 to 2 days at 37°C.

   Expected result: no growth.

3. *Biotin and histidine dependence (bio, his):* Streak a loopful of the culture across one GM plate supplemented with an excess of biotin and histidine. Incubate 1 to 2 days at 37°C.

   Expected result: growth.

4. *Ampicillin resistance:* Streak a loopful of the culture across one GM plate supplemented with an excess of histidine and biotin and 24 μg/ml ampicillin. Incubate 1 to 2 days at 37°C.

   Alternatively, a sterile 6-mm filter paper disk containing 10 μg ampicillin can be placed on a streak of the strain on a glucose minimal agar plate supplemented with an excess of histidine and biotin. A strain should be included that does not carry plasmid pKM101 as a control.

   Expected result: growth of only the pKM101 strains that are ampicillin resistant. The ampicillin disks can be prepared in advance and stored aseptically in the refrigerator.

5. *Tetracycline resistance:* Streak a loopful of the culture across a GM plate supplemented with an excess of histidine and biotin and 2 μg/ml tetracycline. Incubate 1 to 2 days at 37°C.

   Alternatively, a sterile 6-mm filter paper disk containing 1 μg tetracycline can be placed on a streak of the strain on a glucose minimal agar plate supplemented with an excess of histidine and biotin. Include a strain that does not carry plasmid pAQ1 as a control.

   Expected result: growth only of the (tetracycline-resistant) pAQ1 carrying strain.

6. *Presence of rfa marker (defective lipopolysaccharide):* Streak a loopful of the culture across a glucose minimal agar plate supplemented with an excess of biotin and histidine. Place a sterile filter paper disc in the center of the streak and apply 10 μl of a 0.1% crystal violet solution. Incubate 1 to 2 days at 37°C.

   Expected result: zone of growth inhibition surrounding the disc.

   The crystal violet disks can be prepared in advance and stored aseptically at room temperature.

PREPARATION OF METABOLIC ACTIVATION SYSTEM (S-9)

SUPPORT PROTOCOL 5

The *Salmonella* strains used for these tests are not capable of performing the cytochrome-based metabolic oxidations that act in mammalian systems to metabolize chemicals to their active forms. As a result, a 9000 × *g* supernatant fraction of a rodent (usually rat) liver homogenate (referred to as S-9), in the presence of NADP and an NADPH-generating system, is added to the test to simulate mammalian metabolism. To increase the enzyme activity, the animals are usually pretreated with the mixed-function oxidase inducer Aroclor 1254. The S-9 is added to the reaction mixture along with enzymic cofactors (the S-9 mix). The metabolism of different chemicals to their mutagenic forms requires different optimum concentrations of S-9. Generally, the concentrations used range from 4% to 30% in the S-9 mix (Ames et al., 1975; Maron and Ames, 1983). In general, fewer mutagens will be "missed" by using the higher concentrations of S-9. In the absence of specific information about the optimum S-9 concentration for the chemicals to be tested, it is recommended that 10% or 30% S-9 (v/v in the cofactor mix) be

used for the initial test. The S-9 concentration can also be calculated and standardized on protein content.

The procedure described in this protocol can also be followed when animals other than rats, e.g., hamsters, are used for preparing the metabolic activation system from livers. The preparation of hamster liver S-9, required for Alternate Protocol 4, would be done via the same procedure described below, with the exception that the animals would not be treated with Aroclor or any other inducer of liver enzymes. In this case, Golden Syrian hamsters weighing ~150 g each are the species that are usually used.

The S-9 can be prepared by the testing laboratory, and aliquots frozen at −80°C. It is recommended that more than one animal be used and the homogenates pooled so as to minimize animal-to-animal variation among batches. Alternatively, a number of vendors provide S-9 preparations, along with a characterization of their enzyme activities and effectiveness with standard mutagens.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Chemical inducer: e.g., polychlorinated biphenyl (Aroclor 1254) or phenobarbital
Corn oil
Male Sprague-Dawley rats weighing ~200 g each
0.15 M KCl

Syringes and 27-G needles
Sterile forceps and scissors
Potter-Elvehjem tissue homogenizer with loose Teflon pestle
1- or 5-ml cryogenic vials
Centrifuge with speeds up to 9000 × *g*

Induce liver enzymes

1. Dilute Aroclor 1254 in corn oil to a concentration of 200 mg/ml. Using a 27-G needle, give each animal a single intraperitoneal injection of 500 mg/kg (~0.5 ml of this mixture) 5 days before sacrifice.

   Be sure to use sterile corn oil and sterile syringes and needles.

   The solvent used, route of administration, and dose regimen will be different for different inducers. The route and regimen providing the maximum induction should be used.

2. Give the rats unrestricted access to drinking water and food until 12 hr prior to sacrifice. At that point, remove the food.

3. Stun the rat by a blow to the head and then decapitate it.

   IMPORTANT NOTE: *All subsequent steps should be performed at 0° to 4°C, using cold, sterile solutions and glassware.*

Prepare the S-9 fraction

4. Aseptically remove livers from rats and place in a preweighed beaker containing 0.15 M KCl.

   The volume of KCl should be ~1 ml/gram wet liver.

5. Weigh the beaker containing the livers and transfer to a sterile beaker containing 3 ml of 0.15 M KCl per g of wet liver (i.e., 3 vol).

6. Mince the livers with sterile scissors and homogenize using a Potter-Elvehjem homogenizer with a loose Teflon pestle.

   Other tissue homogenizers are acceptable.

7. Centrifuge homogenate 10 min at 9000 × *g*, 0° to 4°C.
8. Decant the supernatant (containing the S-9 fraction) into a sterile beaker that is kept on ice.
9. Dispense 1-ml aliquots of the S-9 fraction into sterile 1- or 5-ml cryogenic vials.

Store and test S-9 fraction

10. Quick freeze the homogenate in dry ice.
11. Store the S-9 homogenate in a −80°C freezer or in liquid nitrogen in appropriately labeled boxes.

    Typically, 1 ml of the S-9 fraction contains microsomes from ~250 mg of wet livers, with a protein concentration of ~40 mg/ml. Protein concentrations can be measured following the procedure described by Lowry et al. (1951).

12. Before being used for routine screening, test each batch of S-9 for sterility, as well as for effectiveness against the laboratory's standard positive control mutagens, or against the chemical class of interest.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent all recipes and all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX.***

Ampicillin solution, 8 mg/ml

To 100 ml of deionized water add 0.8 g ampicillin. Stir on magnetic stirrer until dissolved, then filter sterilize using a 0.45-µm filter. Store up to 1 year at 4°C.

Biotin/histidine solution for top agar, 0.5 mM

In a 4-liter flask, heat 1000 ml water to near boiling. Place flask with stir bar on a magnetic stirrer. Add 0.1 g of biotin and 0.1 g of histidine and stir until dissolved. Prepare only on the day top agar (see recipe) is to be made.

If filter sterilized, the solution can be stored up to 1 year at 4°C.

Biotin solution (0.01%)

Heat 100 ml of deionized water to a boil. Add 10 mg of D-biotin. Stir on magnetic stirrer until dissolved, then filter sterilize using a 0.45-µm filter. Store up to 1 year at 4°C.

Cofactors for reductive metabolism

Thaw 63 ml of standard S-9 cofactors for the S-9 mix (see recipe) and add the following:

423 mg D-glucose-6-phosphate

142 mg nicotine adenine dinucleotide, reduced form (NADH), disodium salt

Filter sterilize through a 0.45-µm filter. Aseptically add 280 U (2.8 U/ml final) of glucose-6-phosphate dehydrogenase, then add 30 ml of liver S-9 (see Support Protocol 5). Immediately before use add 7 ml flavin mononucleotide FMN solution (see recipe). Keep on ice at all times and away from direct light.

Cofactors for the S-9 mix

Sequentially dissolve by stirring each of the following components in 200 ml of deionized H_2O:

0.3 g D-glucose-6-phosphate

0.7 g nicotinamide adenine dinucleotide phosphate (NADP)

0.4 g magnesium chloride

continued

0.5 g potassium chloride
2.5 g sodium phosphate, dibasic
0.6 g sodium phosphate, monobasic
When dissolved filter sterilize through a 0.45-µm filter

Dispense in sterile tubes in aliquots of 7, 9, and 9.5 ml for convenient use when in need of 30%, 10%, or 5% S-9, respectively, in the S-9 mix (10 ml final volume). Store up to 1 year at –20°C.

Prior to each experiment, the cofactors are thawed at room temperature before the addition of the S-9 homogenate, which should be kept on ice throughout the day.

A 10% S-9 mix contains, per 100 ml: 10 ml (10% v/v) S-9 fraction (see Support Protocol 5), 0.5 mM glucose-6-phosphate, 0.4 mM NADP, 0.8 mmol $MgCl_2$, 3.3 mM KCl, and 10 mM sodium phosphate pH 7.4. Of course, these concentrations vary when a 5% or 30% S-9 mix is used. See Support Protocol 5 for preparation of the S-9 fraction; see Basic Protocol 1, step 3, for mixture of the cofactors and the S-9 fraction.

Crystal violet solution, 0.1% (w/v)

To 100 ml of water add 0.1 g crystal violet. Mix well and store up to 1 year at room temperature in light-proof glass container.

Enriched GM agar plates

Prior to pouring GM plates (see recipe), add the following item(s) as required for Support Protocol 4 to the 2 liters of medium, and mix thoroughly:

Biotin (B) plates: Add 16 ml of 0.01% biotin solution (see recipe).

Histidine (H) plates: Add 16 ml of 0.5% L-histidine solution (see recipe).

Biotin-histidine (BH) plates: add 16 ml of 0.01% biotin (see recipe) and 16 ml of 0.5% histidine (see recipe).

Biotin-histidine-ampicillin (BHA) plates: Add 16 ml of 0.01% biotin (see recipe), 16 ml of 0.5% histidine, and 6 ml of 8 mg/ml ampicillin (see recipe; final concentration of ampicillin, 24 µg/ml).

Biotin-histidine-tetracycline (BHT) plates: Add 16 ml of 0.01% biotin (see recipe), 16 ml of 0.5% histidine (see recipe), and 0.5 ml of 8 mg/ml tetracycline solution (see recipe; final concentration of tetracycline, 2 µg/ml).

Store plates up to 1 year at 4°C

Flavin mononucleotide (FMN) solution

To 7 ml of water add 96 mg of flavin mononucleotide (FMN). Filter sterilize through a 0.45-µm filter and keep on ice while preparing the remainder of the modified cofactors (see recipe for cofactors for reductive metabolism).

Glucose minimal agar plates (GM plates)

To 1800 ml of water in a 4-liter flask add 30 g of agar. Autoclave for 30 min and let cool ~45 min to ~60°C. Add 40 ml of sterile 50× VB salts (see recipe) and swirl until salts are in solution. Add 100 ml of sterile 10% glucose (see recipe) and swirl to mix thoroughly. Dispense 20 to 25 ml in sterile, 100 × 15–mm diameter petri plates. Store plates up to 1 year at 4°C.

GM agar medium is also known as Vogel-Bonner agar medium (Vogel and Bonner, 1956). Plates can be stored in a refrigerator for several months if placed in sealed, plastic bags. Prior to use make sure the surface of the solidified agar is dry; condensate will interfere with proper adherence of the top agar. One batch (2 liters) of GM bottom agar makes ~80 plates.

The agar should never be autoclaved together with the VB salts and 10% glucose. Bottom agar made this way will not fully support the growth of the Salmonella strains due to toxicity of the free radicals in the medium produced by the autoclaving.

Glucose solution, 10%

Heat 1500 ml water in a 4-liter flask on a magnetic stirrer. Add 200 g glucose (dextrose) and stir until the mixture is clear (~5 min). Adjust final volume to 2000 ml. Dispense in 100-ml aliquots in 250-ml bottles and autoclave for 30 min. Store up to 1 year at 4°C.

Histidine solution (0.5%)

To 100 ml of deionized water add 0.5 g mg of L-histidine hydrochloride. Stir on magnetic stirrer until dissolved, then filter sterilize using a 0.45-µm filter. Store up to 1 year at 4°C.

Nutrient agar plates

Prepare nutrient broth (see recipe), then add 15 g agar per liter and heat to dissolve. Autoclave, allow mix to cool to ~60°C, then pour plates.

Nutrient broth

If using Difco nutrient broth: To 1000 ml of deionized water add 8 g of nutrient broth powder (Difco). Stir to dissolve, then dispense in Erlenmeyer flasks or test tubes. Autoclave for 20 min. Store up to 1 year at room temperature in the dark.

If using Oxoid nutrient broth #2: To 1000 ml of deionized water add 25 g of nutrient broth powder (Oxoid). Stir to dissolve, then dispense in Erlenmeyer flasks or test tubes. Autoclave for 20 min. Store up to 1 year at room temperature in the dark.

Sodium phosphate buffer, 0.1 M, pH 7.4

Per 500 ml final volume add in the following order:

60 ml 0.1 M sodium phosphate, monobasic (add 13.8 g $NaH_2PO_4 \cdot H_2O$ to 1 liter H_2O)

440 ml 0.1 M sodium phosphate, dibasic (add 14.2 g Na_2HPO_4 to 1 liter distilled H_2O)

Adjust pH, as needed, using dibasic sodium phosphate

Mix well and dispense in 100-ml aliquots

Autoclave 20 min

Store up to 1 year at 4°C

Tetracycline solution, 8 mg/ml

Prepare 100 ml of 0.02 N sodium hydroxide. Add 800 mg tetracycline and stir on magnetic stirrer until dissolved, then filter sterilize using a 0.45-µm filter. Store protected from direct light up to 1 year at 4°C.

Top agar supplemented with biotin and limited histidine

To a 4-liter flask add:

1800 ml water

12 g agar

12 g sodium chloride

Melt agar by autoclaving for 10 min. Add 200 ml of 0.5 mM biotin/histidine (see recipe). Dispense in 300-ml aliquots in 500 ml-bottles and autoclave for 30 min. Store up to 6 months at room temperature.

For preparation of smaller volumes, reduce all ingredients proportionately. Prior to use, melt the top agar in boiling water or in a microwave oven.

Vogel-Bonner (VB) salts, 50×

To 650 ml warm water, add the following components in the order indicated, making sure that each chemical is dissolved thoroughly by stirring on a magnetic stirrer before adding the next chemical (it takes ~1 hr to dissolve all ingredients):

continued

10 g magnesium sulfat e ($MgSO_4 \cdot H_2O$)
100 g citric acid, monohydrate
500 g potassium phosphate, dibasic, anhydrous (K_2HPO_4)
175 g sodium ammonium phosphate ($Na_2NH_2PO_4 \cdot 4H_2O$)
Adjust volume to 1000 ml
Dispense in 40-ml aliquots and autoclave for 30 min
Store up to 1 year at room temperature in the dark

COMMENTARY

Background Information

During the developmental stages of the Ames *Salmonella* standard plate incorporation assay, Ames and colleagues constructed or selected five genetically altered tester strains that are differentially responsive to mutagen treatment. These strains are referred to as: TA1535, TA1537, TA1538, TA98, and TA100, and are considered the standard or traditional tester strains (Ames et al., 1975; Maron and Ames, 1983). The following three genetic alterations increased the sensitivity of these tester strains significantly.

1. Elimination of the accurate DNA repair pathway by a deletion mutation through the *uvrB* gene (all strains except TA102). This deletion also includes the biotin synthesis gene (*bio*), so that the cells require biotin for growth.

2. Increased cell wall permeability through selection for phage C21-resistant bacteria (*rfa* mutation, all strains).

3. Introduction of plasmid pKM101, which enhances error-prone DNA repair (in strains TA97, TA98, TA100, TA102, and TA104).

To mimic mammalian metabolism, the microsomal fraction (S-9) from rat liver, or from other species or tissues, is incorporated into the assay procedure. In the assay, the bacteria are exposed to the test chemical in the presence and absence of the metabolic activation system.

Although the standard plate incorporation assay with the five standard tester strains and inclusion of rat liver S-9 was highly effective in detecting chemical mutagens (Ames et al., 1975), several modifications to the assay procedure (Maron and Ames, 1983) and additional mutant strains (i.e., TA97, TA102, TA104) have made the assay more versatile and enhanced its overall sensitivity.

The protocols described here are designed to determine whether a chemical is mutagenic or nonmutagenic under the specific test conditions. The amount of chemical applied to the plate or introduced into the test chamber is known, but the actual dose to which the bacteria are exposed is affected by the chemical's stability, solubility, volatility, and ability to partition between solvent and aqueous phases.

Preincubation versus standard plate incorporation assay

The preincubation assay is the assay of choice for liquid chemicals, since many of these chemicals may be volatile. For all other chemicals except highly volatile chemicals and gases, either the preincubation or the standard plate incorporation assay may be used. It may be warranted to adopt one of these two assay procedures in a laboratory for general screening purposes. The use of one assay procedure for general screening aids in getting a solid historical database for the negative, solvent, and positive controls. The other assay procedure can then be used as a backup in case equivocal or negative results are obtained in the initial experiment.

Critical Parameters

Solvents

The solvent of choice is distilled water, followed by dimethylsulfoxide (DMSO). Other useful solvents are acetone, ethyl alcohol (75%), tetrahydrofuran, dimethylformamide, and methyl ethyl ketone (MEK). If other than the standard plate assay is to be performed, the toxicity of the solvent should be determined. It is also important to determine whether the solvent will interfere with the metabolic activation system at the concentrations used (Maron et al., 1981).

Dose selection

Each chemical should be tested initially at half-log dose intervals up to a dose that elicits toxicity, or up to a dose immediately below one that was toxic in the preliminary toxicity procedure. Subsequent trials can use narrower dose increments. Chemicals that are not toxic should be tested to a maximum dose of 5 to 10 mg/plate. Chemicals that are poorly soluble should be tested up to doses defined by their solubilities. At least five doses of each chemical should be tested in triplicate, and an independent repeat

experiment performed at least one week following the initial trial. Ideally, a new stock solution of the test chemical should be made with appropriate dilutions for each repeat experiment. A maximum of 0.05 ml organic solvent should be added to each plate when delivering the test chemical.

For volatile liquid chemicals tested in 9-liter desiccators, the high dose per desiccator should be 5 ml. For gases, the high dose should be the equivalent of 4.5 liters, which is 50% of the volume of the desiccator.

Metabolic activation

A rat liver S-9 fraction is customarily used for metabolic activation, but metabolic activation systems derived from different animal species and/or organs can be used instead (Zeiger, 1985). Mammalian intestinal flora (Reid et al., 1984) can also be used. Chemicals can be tested in the presence of more than one activation system, and more than one concentration of the metabolic activation system can be used, e.g., 30% and 10% (v/v). In addition, uninduced and induced microsomal enzymes can be selected by using different inducers such as phenobarbital, β-naphthoflavone, or Aroclor 1254.

An activation system can also be used for reductive metabolism. The use of reducing agents, such as flavin mononucleotide (FMN), has been recommended for testing certain classes of chemicals in the *Salmonella* assay. The most widely publicized of these classes are those containing azo and diazo compounds (Prival and Mitchell, 1982; Reid et al., 1984). Unless reduced, such compounds usually are not mutagenic. Reduction of chemical substances can occur in mammals, including humans, by anaerobic intestinal microflora and by reductases in the intestinal wall or the liver.

Salmonella strain selection

For general screening purposes, when the potential mutagenicity of the sample is unknown, it is recommended that a tiered approach be used, starting with an initial test using strains TA98 and TA100, with and without rat liver S-9. If a positive response is obtained in one or both strains, only the positive test condition(s) needs to be repeated. If an equivocal or weak positive response is obtained in one or both of these strains, the corresponding plasmid-free parent strain(s), TA1538 and TA1535, respectively, are used to determine whether a more definitive response could be obtained. If the results with TA98 and TA100 are negative, other strains, including TA97 or TA1537, and TA1535, are used with and without S-9. If a positive response is obtained in any of these strains, a confirmation test is run.

As a general rule, a chemical is not considered nonmutagenic if it has not been tested with the four most commonly used strains, TA97 (or TA1537), TA98, TA100, and TA1535, with and without S-9 mix.

Where there is advance information about the potential mutagenicity of the chemical or chemical class, the initial testing is performed in the strain(s) considered most likely to yield a positive response. If a negative response is obtained, testing is performed in additional strains.

Strains TA102 and/or TA104 are used if it is suspected that the test chemical would cause oxidative damage (e.g., free radical production) or be a DNA cross-linking agent. Strain TA102 is the strain of choice for the latter class of chemicals, because the presence of the wild-type *uvrB* gene makes the strain more responsive to this type of damage.

Background lawn

Except for the few histidine-independent bacteria that arose during the overnight incubation (pre-existing his^+) , the 1×10^8 cells put onto each plate are histidine dependent (his^-), and are not capable of growing or forming colonies in the absence of histidine. Sufficient histidine is added to the top agar to allow all the plated cells to undergo six to eight divisions before the histidine is exhausted. This limited number of divisions makes the cells more sensitive to mutagens, and allows for the fixation of mutational lesions. In the absence of exogenous histidine, only the mutant his^+ cells continue to grow and form macroscopic colonies. The limited growth of all the plated his^- bacteria leads to a "background lawn" of cells on the plate that generally gives the plates a hazy appearance. Under a dissecting microscope (40× to 100×), this lawn can be seen to be comprised of densely packed microcolonies of cells in the absence of toxicity. However, it should be noted that the presence of a normal-appearing background lawn is not evidence of an absence of toxicity.

The density of the background lawn is used as one indicator of chemical, or other, toxicity. A sparse lawn, usually referred to as "thinning," when compared to the negative or solvent control, is a sign of chemical toxicity, especially if it is dose-related. A total absence of bacterial background lawn is evidence of a high level of toxicity. Such a toxic dose should not be used. Occasionally, numerous small colonies, re-

Table 3.1.3 Spontaneous Control Values for the *Salmonella* Tester Strains[a]

Strain	Number of revertants	
	Without S-9	With S-9
TA97	75-200	100-200
TA98	20-50	20-50
TA100	75-200	75-200
TA102	100-300	200-400
TA104	200-300	300-400
TA1535	5-20	5-20
TA1537	5-20	5-20
TA1538	5-20	5-20

[a]Values are from the authors' laboratories.

ferred to as pinpoint colonies, will be present against such a clear lawn. These pinpoint colonies consist of his^- cells that survived the toxicity. The absence of competition for histidine from the nonsurviving his^- bacteria results in more histidine being available on a per-cell basis to support the growth of the surviving his^- cells. The surviving fraction of his^- cells will undergo additional cell divisions until the excess histidine is consumed, thereby forming small his^- colonies. The histidine requirement can be checked by spotting or streaking cells from these colonies onto histidine-deficient, but biotin-containing, glucose minimal agar plates in the absence of test chemical.

Table 3.1.3 presents a range of spontaneous (solvent/negative) control values per plate for each tester strain with and without S-9.

The values presented in Table 3.1.3 are ranges found in the authors' laboratories; they should not be taken as absolute values that must be achieved by all laboratories. Each laboratory performing routine testing should develop its own control ranges. However, the values in this table do depict the range of responses that could be seen. Extreme excursions from these values should be avoided. Different S-9 sources or concentrations, or different batches of agar and media, can result in changed values. Strains TA97, TA102, and TA104 are particularly sensitive to S-9 concentration, and will show increased spontaneous values with increasing S-9 concentrations.

Data evaluation

Because testing is usually performed with more than one strain and sometimes with more than one activation condition, the data have to be evaluated for each trial (strain/activation), for the tester strain, and for the chemical. There is no generally agreed upon approach to data evaluation. The data can be evaluated using a formal statistical procedure, by means of arbitrary rules, or using subjective criteria. Statistical treatments, if used, must be relevant for the data, and recognize that the data are not always Poisson distributed. Data evaluations must be made at both the individual trial level (i.e., strain/S-9 combination) and overall chemical levels.

A chemical is designated nonmutagenic only after being tested in strains TA98, TA100, TA1535, and TA97 and/or TA1537, in the presence and absence of at least one metabolic activation system with at least one concentration of the S-9 fraction. Other S-9 concentrations can be used to clarify equivocal or weak positive responses. Additional strains may be used (e.g., TA102, TA104) if, for example, a chemical is suspected of generating oxidative DNA damage.

Blind scoring is desirable to eliminate bias in the interpretation of the results. It can be accomplished by having all chemicals coded before testing and by maintaining the code during counting of the revertant colonies and during analysis of data.

Formal statistical procedure

The data can be evaluated for a positive trend, and/or the responses at the individual dose levels can be compared against the solvent control. A statistical analysis of the data is not required; however, a number of statistical procedures and approaches recommended for the assay have been compiled and reviewed by Vollmar and Edler (1990).

Table 3.1.4 Troubleshooting Guide for Ames Test

Problem	Possible cause(s)	Solution(s)
The revertant colonies are concentrated on one half of the plate	Bottom agar solidifies on a slant, or the top agar was allowed to solidify on a slant. When the top agar is not able to spread evenly over the plate, the section with the deepest agar will have the highest number of colonies.	The plates should be on a level surface when the bottom agar is poured, and during the experiment when the top agar is added and allowed to solidify.
There is no colony growth, or relatively few cells (including pinpoint colonies) are present, and there is a clear background lawn	This is an indication of toxicity to the bacteria. If the top agar is allowed to get above 50 ° C, it is toxic to the *Salmonella* bacteria. Where there is a high level of toxicity, the majority of the plated histidine-dependent bacteria are killed, and too few survive to form a visible background lawn. The pinpoint colonies usually arise from surviving *his*$^-$ cells. Because of the death of the other cells, there is more histidine available to the survivors, and they are able to form visible colonies.	It is important to keep the top agar ideally at a temperature of 43°C, with care taken not to exceed a temperature of 48°C. There may have been too much organic solvent added to the tubes. The toxicity of the solvent should be checked, or there may be a toxic chemical contaminant in the solutions or in the tubes. Alternatively, the top agar may contain inadequate buffering capacity for the test chemical.
The positive control "doesn't work"	No response, or an inadequate response, could result from many factors, the most common being: inactive S-9 or cofactors, use of the wrong bacterial strain, omission from the tubes of a necessary component of the S-9 mix, presence of something in the tube or on the plate that was toxic to the S-9, addition of the wrong amount of chemical, omission of the positive control chemical from the tube, improper storage of the positive control chemical, reduced biological activity resulting from solution.	New positive control solutions should be prepared when a decrease in activity is observed, or the physical appearance of the solution changes. Note that positive control solutions can be prepared in advance and stored at 4°C. 2-Anthramine is light-sensitive and should be stored in a dark container. Check the identity of the bacterial strain; if it is correct, then it may be necessary to reisolate the strain to select a culture that is responsive to the chemical.
Some of the colonies on the plate look different from the majority of the colonies	Colonies of contaminating bacteria or molds often have a different color or colony morphology than the *Salmonella* strains. This can be the result of contamination in the overnight *Salmonella* culture, contaminated solutions, or contamination present in the test chemical that was not killed by the solvent.	All solutions should be tested for contamination, and controls should be included to measure possible contamination in the S-9 mix and test chemical. It is recommended that a microbiologist be consulted if contamination is suspected.

continued

Arbitrary rules. The most often used arbitrary rule is the so-called two-fold rule. Using this rule, a positive response requires a dose-response that reaches 2-fold over the solvent control. Other laboratories use what is termed a "modified" two-fold rule. In this modified rule, the strains with low spontaneous frequencies (e.g., TA98, TA1535, TA1537) are required to reach 2.5- or 3-fold above spontaneous. Some laboratories require only one dose to reach the cutoff, others require two.

Subjective criteria. The data are evaluated as described by Zeiger et al. (1992). Individual trials are judged mutagenic (+), weakly mutagenic (+w), questionable (?), or nonmutagenic (−), depending on the magnitude of the increase in his$^+$ revertants, and the shape of the dose-response. A trial is judged questionable (?) if the dose-response is considered to be insufficiently high to support a call of "+w," if only a single dose is elevated over the control, or if a weak increase is not dose-related. Distinctions between a

Table 3.1.4 Troubleshooting Guide for Ames Test, continued

Problem	Possible cause(s)	Solution(s)
The spontaneous revertant count is too low	The wrong *Salmonella* strain was used. A lower than expected spontaneous response could also indicate a toxic effect on the cells introduced during handling, or from contamination of the agar or one of the reagents.	Check the identity of the *Salmonella* strain. If necessary, reisolate strain, selecting for a culture with a spontaneous revertant value in the desired range.
	There was too little histidine added to the top agar.	Prepare fresh solutions.
The spontaneous revertant count is too high	It is possible that the initial inoculum from the frozen culture contained an unusually high number of preexisting *his*$^+$ bacteria, which would lead to a higher than expected number of preexisting mutants in the overnight culture.	Check the identity of the *Salmonella* strain. If necessary, reisolate tester strain, selecting for a culture with a spontaneous revertant value in the desired range.
	Too much histidine may have been added to the top agar, or a larger amount of the *Salmonella* culture was added to the tube (resulting in additional histidine being carried over from the culture medium).	Redo experiment.
	Plates that had been sterilized with ethylene oxide (EtO) retain and outgas the EtO even after they are received by the laboratory. EtO outgassing from the plates is mutagenic to TA100 and TA1535.	Plates not sterilized with EtO should be obtained from the supplier. Alternatively, EtO should be allowed to out-gas for a couple of days in a fume hood before the bottom agar is poured.
There is unusually heavy growth of the background lawn, along with an increase in colonies on the minimal agar	There may be free histidine in the test sample. The increased histidine on the plate with increasing concentrations of test substance will lead to increased levels of growth of the his$^-$ cells, and a concomitant increase in the number of his$^+$ revertant colonies.	Substances that contain free histidine, or that could release histidine, cannot be adequately tested in the assay. An attempt should be made to remove the histidine using an ion-exchange resin column.
The response is not reproducible	The test chemical not stable.	The chemical cannot be adequately tested using this procedure.
	The test chemical is highly volatile	Use the desiccator procedure.
	Very low (marginal) responses are often not reproducible.	Repeat the test using a narrower dose range or a different protocol.

continued

questionable response and a nonmutagenic or weakly mutagenic response, and between a weak mutagenic response and mutagenic response, are highly subjective. When using this approach, it is not necessary for a response to reach a specific fold increase over background for a trial to be judged positive. The reproducibility of the response is important in making the overall evaluation.

Troubleshooting

Table 3.1.4 presents a troubleshooting guide for the Ames test.

Anticipated Results

Using these protocols, it is possible to identify compounds that are mutagenic for *Salmonella* and that have a high probability of being carcinogenic/mutagenic in other organisms.

Time Considerations

The experimental procedure, without the 48-hr incubation, takes ~4 hr to complete for one chemical when the following matrix is used:

Four *Salmonella* tester strains
Six dose levels (including the solvent control)
Triplicate plates per dose level

Table 3.1.4 Troubleshooting Guide for Ames Test, continued

Problem	Possible cause(s)	Solution(s)
The top agar doesn't solidify properly	Gelling of the agar is retarded at acid pH.	Add additional buffering capacity to the agar, or adjust the pH of the test chemical.
	The top agar concentration was too low.	The recommended agar concentration is 0.6% (w/v).
The agar slips out of the plate	Insufficient agar was used when the bottom agar was prepared.	The wrong agar concentration may have been used. The recommended bottom agar concentration is 1.5% (w/v).
Precipitate is present on the plates	The precipitate can be of the test substance, or be formed from a reaction of the test substance with a component of the test system such as the S-9 mix. In defining a dose range for testing, at least one dose should show some precipitate.	Determine if the precipitate would interfere with the automatic colony counter; if so, these plates must be counted by hand. For consistency, all plates in the series should be counted in a similar manner. The presence of precipitate should be noted on the data sheets. Note that there are chemicals that are mutagenic only at doses at which precipitate is present (Gatehouse et al., 1994).
A colored test chemical obscures colonies or reduces contrast	Automatic colony counters require contrast differences between the colonies and the background.	The automatic colony counter will not be effective, and the colonies must be counted by hand. For consistency, all plates in the series should be counted in a similar manner.
The test chemical appears to react with the solvent or other components of the test—e.g., it may produce fumes when it is added to the solvent	The test chemical is highly reactive.	The chemical may not be testable in vitro. The products of the reaction could be tested, but the results from this testing must carry the appropriate caveats.
		If the test chemical is known or believed to react with plastics, it can be tested using glass pipets, tubes, and petri dishes.

Metabolic activation system

Positive control chemicals for each strain

Sterility check for metabolic activation, buffer, and chemical.

This time schedule also includes, inoculation of overnight cultures, melting of top agar, labeling of plates, preparation of the metabolic activation system, and dilutions of the test chemical. An additional 4 hr is required for counting the plates, which includes inspection of the background lawn, and recording and analysis of the test results. Hand counting will take longer especially if a potent mutagen is being tested. In this case quadrants of the agar plates may be counted with appropriate extrapolation to the area of the entire plate.

Media preparation, weighing of the test chemicals, and maintenance of the laboratory, including safe disposition of the chemical, is estimated to take another 4 hr. Thus, overall, the testing of one chemical may take one individual between 12 and 16 hr. Testing of multiple chemical samples on one day will reduce the time it takes to complete the testing on a per-chemical basis, since only one set of positive controls are needed, and the time to set up the experiment in the laboratory is about the same, except for labeling of plates and test tubes, which is proportional to the number of additional samples.

Measurement of a Malondialdehyde-DNA Adduct

Determination of levels of various DNA adducts has become an essential tool in modern toxicology of carcinogens. Direct measurements of DNA adduct levels, the true biologically effective dose of a mutagen, can be correlated to biological outcomes or used to probe mechanisms of adduct formation. For each adduct to be measured, there must be a specific and sensitive assay developed.

Malondialdehyde is a carcinogenic and mutagenic electrophile that is endogenously produced during the peroxidation of polyunsaturated fatty acids. Reaction of malondialdehyde (MDA) with deoxyguanosine (dG) results in the fluorescent exocyclic pyrimidopurinone M_1G (Fig. 3.2.1). This unit describes a mass spectrometric assay for M_1G. This assay is highly specific and accounts for variable loss during sample preparation and analysis, unlike other currently used assays for M_1G. This unit includes three protocols: (1) a gas chromatographic/negative chemical ionization–electron capture/mass spectrometry (GC/NCI EC/MS) assay for M_1G (see Basic Protocol); (2) preparation of anti-M_1G immunoaffinity gel (see Support Protocol 1); and (3) a method for HPLC quantification of nucleosides (see Support Protocol 2). Sample preparation includes the use of an immunoaffinity column purification step to enrich for the M_1G adduct, which improves sensitivity over previously described methods.

GC/MS ASSAY FOR PYRIMIDOPURINONE

BASIC PROTOCOL

This protocol describes a procedure used to quantify M_1G in biological tissues starting with DNA isolation, continuing with sample preparation, and concluding with a brief description of M_1G analysis by GC/NCI EC/MS. In order to determine the ratio of M_1G adducts to normal nucleosides, a known quantity of dideuterated M_1G-deoxyribose internal standard ($[^2D_2]M_1G$-dR) is added to the dissolved DNA sample, and the sample

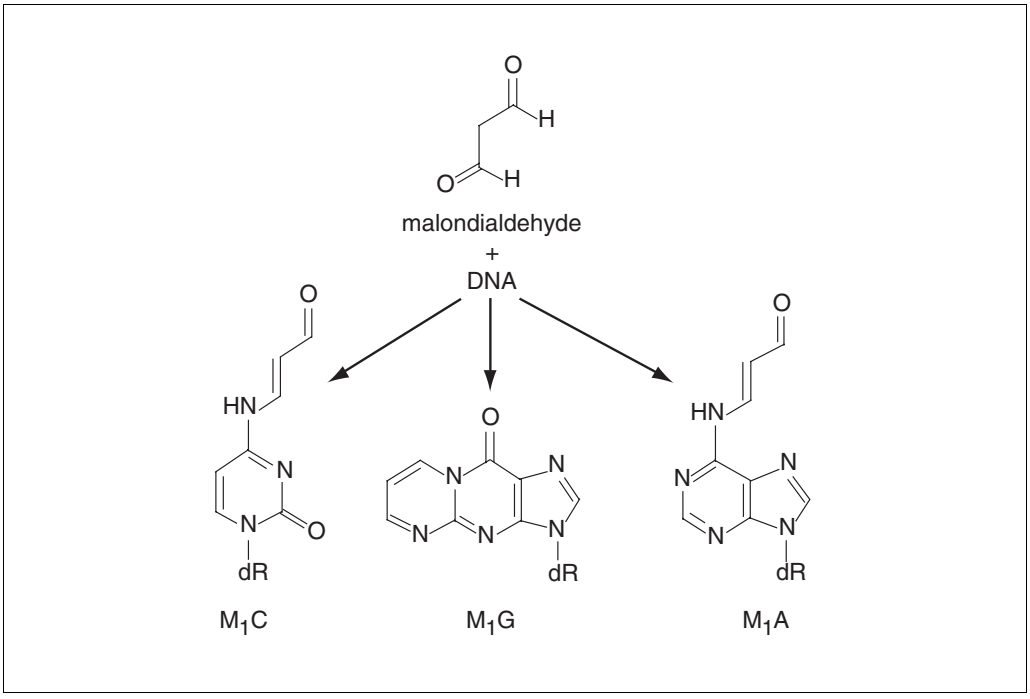

Figure 3.2.1 Structures of malondialdehyde-DNA adducts. The reaction with guanine residues yields the cyclized pyrimidopurinone M_1G.

Contributed by John P. Plastaras and Lawrence J. Marnett
Current Protocols in Toxicology (1999) 3.2.1-3.2.16

is enzymatically hydrolyzed to nucleosides. An aliquot is taken for HPLC analysis (see Support Protocol 2) to determine the total number of nucleosides. M_1G-dR is purified from the other nucleosides by immunoaffinity chromatography using Sepharose coupled to anti-M_1G monoclonal antibodies (see Support Protocol 1). The sugar is released from the nucleoside by formic acid hydrolysis to yield the M_1G base. M_1G is derivatized with pentafluorobenzyl bromide (PFB-Br), which will add a PFB group to either the N_7 or N_9 position of the base (Fig. 3.2.2). The products are subjected to solid-phase extraction with silica, and the analytes are subjected to GC/NCI EC/MS analysis.

Since the cleavage product of the internal standard, $[^2D_2]M_1G$, is two mass units heavier than M_1G, it is readily distinguished by MS (*m/z* of 188 vs. 186). By comparing the ratio of the peak area of $[^2D_2]M_1G$ to the peak area of M_1G, the quantity of M_1G in the sample before DNA hydrolysis can be determined.

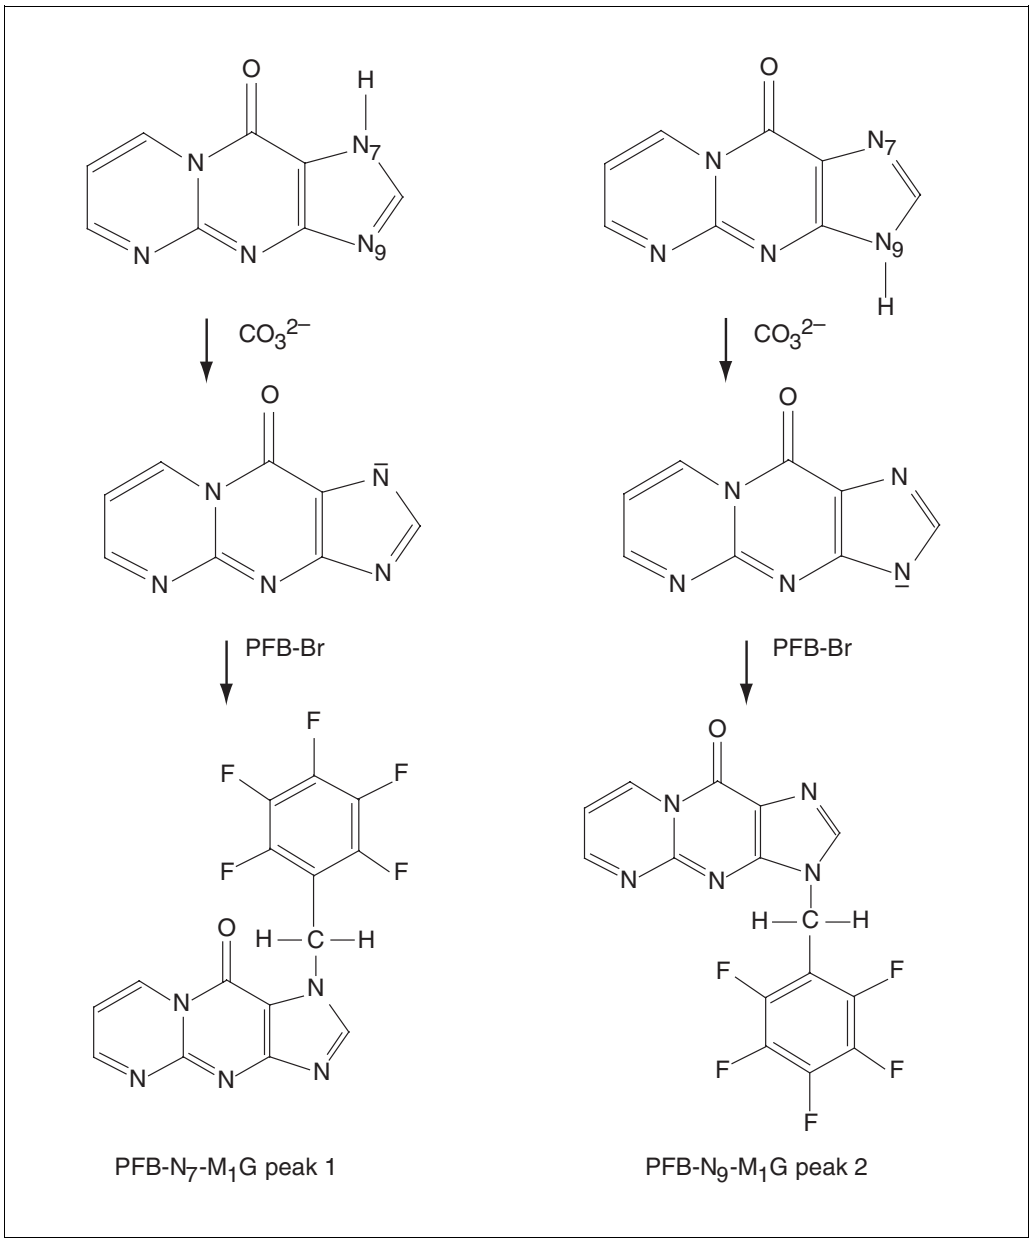

Figure 3.2.2 The M_1G base is derivatized by treatment with mild base to remove the N_7 or N_9 proton followed by reaction with pentafluorobenzyl bromide (PFB-Br) to yield two PFB-M_1G isomers. These isomers separate by gas chromatography.

NOTE: This assay takes several full days to complete, so appropriate stopping points have been mentioned in the procedure. As with any analytical method, consistency and careful attention to detail are required.

Materials

Tissue of interest
MOPS/sucrose buffer (see recipe), 4°C
2× lysis buffer (Applied Biosystems)
920 U/µl ribonuclease A (Sigma)
100,000 U/µl ribonuclease T_1 (Boehringer Mannheim)
10 to 20 U/µl proteinase K (Sigma)
Anti-oxidant MOPS buffer (see recipe)
Phenol/chloroform/water reagent (Applied Biosystems)
24:1 (v/v) chloroform/isoamyl alcohol
3 M sodium acetate (*APPENDIX 2A*)
100% and 70% (v/v) ethanol
10 mM MOPS/100 mM NaCl, pH 7.0
1.5 ng/ml [$^2D_2$]M_1G-dR standard (see Chaudhary et al., 1994b, for synthesis procedure, which is relatively straightforward)
Deoxyribonuclease (DNase) I stock solution (see recipe)
Nuclease P1 stock solution (see recipe)
25 mM $ZnCl_2$
0.4 M MOPS, pH 7.8
20 U/µl alkaline phosphatase (Sigma)
Anti-M_1G immunoaffinity gel (see Support Protocol 1)
PBS (*APPENDIX 2A*)
Nondeuterated M_1G-dR standard (see Chaudhary et al., 1994b)
Methanol
Nanopure water
Acetone
Concentrated formic acid (88% w/v)
PFB-Br derivatization solution (see recipe)
Methylene chloride
N,O-bis(Trimethylsilyl) trifluoroacetamide (BSTFA; Pierce)
Derivatized deuterated standard (see recipe)

Polytron homogenizer (Brinkmann)
Silica (Supelclean LC-Si, Supelco)
10-µl Hamilton syringe
Repeater pipetter and a range of disposable pipets
Ultrafree-Probind filters with modified PVDF membrane (Millipore)
End-over-end mixer
Solid-phase extraction vacuum manifold
6-ml glass columns with Teflon frits (Supelco)
5-ml glass conical tubes with screw caps
50-ml syringe with column attachment for positive pressure
60°C sand bath
Stills for drying solvents (see Fig. 3.2.3)
Vibrating shaker
Nitrogen evaporation chamber: N-Evap (Organomation) or equivalent
Mortar and pestle
0.5- or 1-ml glass pipet and pipet pump

Hewlett Packard MS Engine (model HP5989A) equipped with Series II Plus gas chromatograph (model HP5890), autoinjector (model 7673 GC/SFC injector), electronic pressure programming, and the negative chemical ionization option (or equivalent GC/MS equipment)
Sample vials and inserts
Vial caps
Vial cap crimper
50-µl micropipets
Micropipetter

Prepare tissue

1. If tissue is not to be processed immediately, snap freeze it by wrapping in aluminum foil and immersing in liquid nitrogen. Store at −80°C.

   The actual method used for homogenization and DNA extraction will vary depending on the tissue or cell source. This protocol has been used successfully to isolate DNA from liver, kidney, and brain for the purpose of analyzing nuclear DNA. High pH is avoided to prevent formation of the ring-opened oxopropenal form of M_1G, and MOPS buffer is used instead of Tris buffer to avoid forming a Schiff base adduct with M_1G.

2. Partially thaw tissue (~1 g/sample) and mince with a scalpel on a glass plate cooled over an ice bucket. Suspend minced tissue in cold MOPS/sucrose buffer (10 ml buffer/gram tissue).

   Avoid using Tris buffer or any other primary amine, which may react with M_1G to form a ring-opened Schiff base. MOPS buffer is a good alternative.

   Avoid pH >8.0 to prevent decomposition of the adduct.

3. Homogenize with a Polytron homogenizer on maximum setting for 20 sec, and filter through four layers of cheesecloth.

   Blood leukocytes or cells from tissue culture can be broken by suspension in MOPS/sucrose buffer followed by four freeze-thaw cycles.

Isolate nuclei

4. Centrifuge 5 min at 3000 × *g*, 4°C, to pellet nuclei. Carefully remove supernatant with pipet. Resuspend pellet in fresh MOPS/sucrose buffer (10 ml/gram tissue) and centrifuge again.

5. Remove supernatant as in step 4 and resuspend pellet in 3 ml fresh MOPS/sucrose buffer. Add 3 ml of 2× lysis buffer. Invert to mix.

Digest proteins and RNA

6. Add 400 U each per gram tissue of ribonuclease A and ribonuclease T_1. Incubate 1 hr at 37°C.

7. Add 10 mg proteinase K per gram tissue. Incubate 3 hr at 37°C.

Extract DNA

8. Add 2 ml anti-oxidant MOPS buffer. Add 8 ml phenol/chloroform/water reagent and mix thoroughly. Centrifuge 5 min at 3000 × *g*, 4°C.

9. Transfer aqueous layer to a new tube. Add 4 ml fresh anti-oxidant MOPS buffer to the organic layer, mix, and centrifuge 5 min at 3000 × *g*, 4°C.

10. Add the aqueous layer to the aqueous layer from the first extraction. Add 10 ml phenol/chloroform/water reagent to the combined aqueous layers, mix, and centrifuge for 5 min at 3000 × *g*, 4°C.

11. Transfer the aqueous layer to a new tube and add 10 ml of 24:1 (v/v) chloroform/isoamyl alcohol. Mix and centrifuge 5 min at 3000 × *g*, 4°C.

12. Transfer the aqueous layer to a new tube and add 0.1 vol of 3 M sodium acetate.

Precipitate DNA

13. Add 2 to 2.5 vol ice-cold 100% ethanol. Let the solution stand at least 2 hr at −20°C.

14. Using a glass hook, transfer DNA pellet to a microcentrifuge tube. Wash the DNA pellet twice with 70% ethanol. Allow pellet to air dry, and store at −20°C.

Resuspend DNA pellet

15. Weigh each 15-ml plastic conical tube, and transfer 1 to 2 mg dry DNA pellets to each tube. Add 2 ml of 10 mM MOPS/100 mM NaCl (pH 7.0) to each sample and let dissolve overnight on an end-over-end mixer at 4°C.

    If DNA is not completely dissolved, the sample can be treated with DNase I to finish solubilizing.

16. Vortex vigorously for 1 to 3 min to shear DNA.

17. Add 4 µl of 1.5 ng/ml [$^2D_2$]M_1G-dR standard to each sample using a dedicated 10-ml Hamilton syringe.

Digest DNA

18. Prepare fresh DNase I stock solution. Add 400 µl to each sample, and incubate 90 min in a 37°C water bath

    For running multiple samples, this addition and many of the following additions can be facilitated by using a repeater pipetter and disposable pipet.

19. Thaw an aliquot of nuclease P1 stock solution. Add 50 µl to each sample.

20. Add 100 µl of 25 mM $ZnCl_2$ to each sample. Incubate 2 hr in a 37°C water bath.

    While samples are incubating, the immunoaffinity gel may be prepared for use as in steps 22 to 25.

21. Add 1.0 ml of 0.4 M MOPS (pH 7.8) and 1.5 µl of 20 U/µl alkaline phosphatase (30 U) to each sample, and incubate 1 hr in a 37°C water bath.

    At the end of these enzymatic digestions, there will be a cloudy precipitate at bottom of each tube.

Prepare immunoaffinity gel

22. Label 15-ml conical plastic tubes. Swirl anti-M_1G immunoaffinity gel (see Support Protocol 1) and add 400 µl to each tube.

23. Add 5 ml PBS to each tube. Centrifuge 5 min at 1000 × *g*, 4°C, to pellet the gel.

24. Carefully remove and discard supernatant using a Pasteur pipet equipped with a dropper bulb.

25. Repeat steps 23 and 24. Store at 4°C until ready for use.

Recover hydrolyzed DNA

26. Dry and weigh each tube from step 21 to determine total hydrolysate volume.

    Volume is determined by subtracting the weight of the empty tube and assuming a density of 1 mg/ml. If tubes are finely graduated, the volume may be read directly.

27. Vortex samples and filter a 100-µl aliquot through a Probind filter. Store this sample at −20°C for later analysis by HPLC (see Support Protocol 2).

28. Pour DNA hydrolysate into tube with immunoaffinity gel. Wash hydrolysate tube with 3 ml PBS, then again with 2 ml PBS, each time transferring wash to tube with immunoaffinity gel. Also set up similar tubes without hydrolysate but containing a range of amounts of nondeuterated M_1G-dR (e.g., 25, 50, 100, 150, 200, and 500 pg, and possibly 1 ng).

    This will give a total volume of ~8 ml in the immunoaffinity tube.

    The nondeuterated standards are processed in parallel with the DNA tubes for the remainder of the procedure.

Purify DNA on immunoaffinity matrix

29. Cap tubes and mix on an end-over-end mixer for 30 min at room temperature.

    This incubation time can be extended without compromising results.

30. While samples are incubating, wash the 6-ml glass columns fitted with Teflon frits on a solid-phase extraction vacuum manifold attached to a side-arm faucet aspirator. Wash with at least two cycles of the following sequence: 5 ml each methanol, Nanopure water, acetone, and Nanopure water.

31. Just prior to use, wash columns with 5 ml methanol (added with glass pipet) and a final 5 ml PBS.

Pour immunoaffinity column

32. Mix the samples on an end-over-end mixer, uncap the tubes, and carefully pour the immunoaffinity gel suspension into the open column, allowing fluid to flow through.

33. Add 8 ml PBS to the immunoaffinity gel tubes. Recap, shake, and add to columns. Repeat.

34. Add 8 ml water to the immunoaffinity gel tubes. Recap, shake, and add to columns. Repeat.

Elute column

35. Add 4 ml water directly to columns. Apply vacuum to columns and allow to sit under vacuum at least 1 min until dry. Meanwhile, label 5-ml glass tubes and place in rack that fits in vacuum manifold.

36. Put rack of tubes into vacuum manifold, making sure column tips line up in tubes. With vacuum turned off, add 0.5 ml methanol with glass pipet, and wait 30 sec to allow methanol to denature IgG. Apply vacuum to elute.

    Turn off vacuum before adding each aliquot of methanol.

37. Add 0.5 ml methanol twice more to give 1.5 ml total eluent.

38. Remove columns from vacuum manifold. Either cap tubes and store at −20°C or continue with following step.

    Wash columns with water immediately to remove gel. They are difficult to clean after drying.

39. Dry samples by spinning under vacuum at ambient temperature for ~2 hr (using Speedvac evaporator). Cap and store at −20°C until ready for next step.

    Normally, no visible residue can be seen. However, when samples are dried extensively, a faint opaque residue, probably trace salt, may cloud the bottom of the tube. This will not adversely affect the results.

Acid hydrolyze base

40. Thaw samples, if stored, and set sand bath temperature to 60°C.

41. Immediately before use, add 142 µl concentrated formic acid (88% w/v) to 5 ml water to give a 2.5% (w/v) solution. Add 200 µl of 2.5% formic acid to each sample. Cap the tubes and vortex.

42. Incubate 45 min in sand bath at 60°C.

43. Immediately dry samples by spinning under vacuum at ambient temperature.

    This will take 90 min to 2 hr.

44. Cap and wrap tops of the tubes with Parafilm and freeze at −20°C, or proceed to the next step.

    IMPORTANT NOTE: *The derivatized product is sensitive to water. Therefore, this entire procedure should be performed under anhydrous conditions.*

Distill methanol

45. Set up still as illustrated in Figure 3.2.3.

46. Begin distilling 250 ml methanol and allow to reflux for 30 min to 1 hr. Heat to a low boil. In the meantime, remove samples from freezer and let warm to room temperature before removing Parafilm.

    CAUTION: *Do not allow solvent to completely evaporate.*

47. Ensure samples are dry by spinning under vacuum at ambient temperature for 15 to 20 min.

Derivatize pentafluorobenzyl-M_1G

48. Using a 0.5-ml pipet, add 0.15 ml of freshly prepared PFB-Br derivatization solution to each sample. Purge tubes with nitrogen, cap, and seal with Parafilm.

49. Vortex samples, and incubate 90 min at room temperature in a vibrating shaker.

    During this incubation, proceed with distillation of methylene chloride.

Prepare samples for chromatography

50. Evaporate samples to dryness under nitrogen in an N-Evap or similar device.

    Placing tube tips in a room temperature water bath facilitates drying. Complete dryness is indicated by appearance of a white residue; this will take ~90 min.

Distill methylene chloride

51. Set up still as illustrated in Figure 3.2.3.

52. Begin distilling 250 ml methylene chloride and allow to reflux for 30 min to 1 hr. Heat to a low boil.

    CAUTION: *Do not allow solvent to completely evaporate.*

Prepare silica columns

53. Wash 3-ml solid-phase extraction columns (tightly fitted with Teflon frits) with alternating cycles of methanol and acetone (3 ml each). Dry in oven for ~15 min at 70°C.

    These columns are reusable.

54. Place ~0.1 g silica (Supelclean LC-Si) in each column.

    This step can be done in advance and packed columns can be stored in a desiccator at room temperature.

Wash silica column

55. Set up silica columns in a tube rack over a reservoir in a fume hood.

56. Using a glass pipet, wash silica columns as follows:

Twice with 2.5 ml methanol
Twice with 2.5 ml of 20% (v/v) methanol in methylene chloride
Twice with 2.5 ml methylene chloride.

Keep columns moist with methylene chloride until samples are completely dry.

IMPORTANT NOTE: *All additions of dry organic solvents should be performed with glass pipets. Reusable pipets may be preferable because the solvent can wash the markings off disposable glass pipets, leaving flecks of ink in the samples. A syringe with column attachment may be used to improve flow rate by applying positive pressure when necessary.*

Load samples on column

57. When samples from step 50 are dry, add 1.0 ml dry methylene chloride to each.

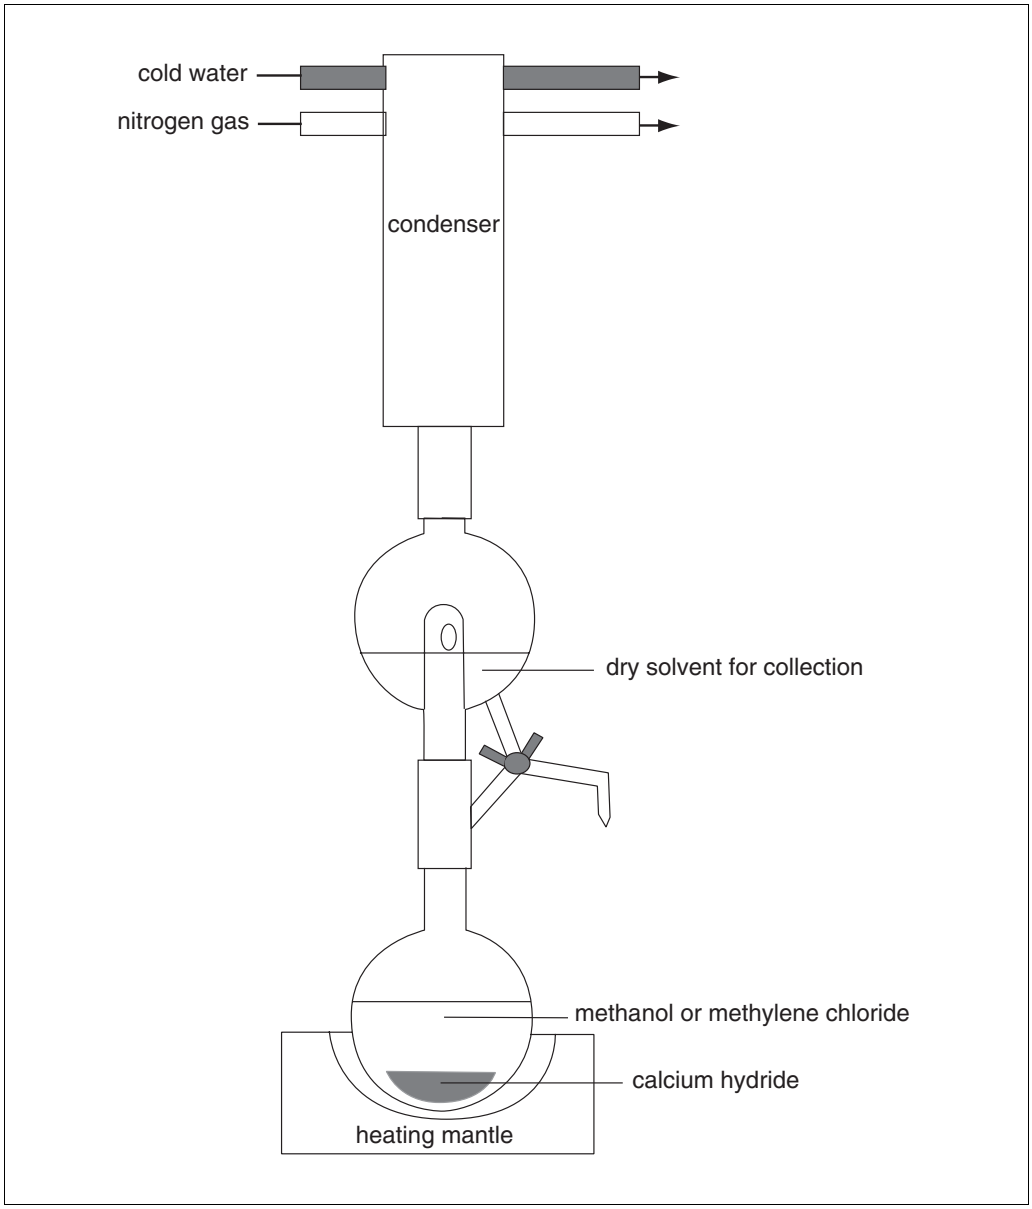

Figure 3.2.3 Distillation apparatus for drying solvents. Entire system is kept under dry nitrogen gas. Solvent is added to boiling flask with calcium hydride as a drying agent, and mantle set to keep at low boil. Dry solvent is collected in a trap equipped with drainage valve.

58. Using a Pasteur pipet, load samples onto columns carefully so as not to disturb silica bed. Leave this pipet in tube for next transfer.

59. When sample has completely entered the silica bed, add 1 ml of 1% (v/v) methanol in methylene chloride to sample tubes and transfer this wash to columns with the Pasteur pipets. Discard tubes and pipets.

60. Add 1 ml of 1% (v/v) methanol in methylene chloride directly to columns. While this is flowing, label 5-ml glass conical tubes and place them in positions in a tube rack corresponding to the columns.

61. After the wash has finished dripping, move entire rack of columns over the rack with the 5-ml glass conical tubes, being sure columns are lined up with tubes.

Elute column

62. Elute with 1 ml of 20% (v/v) methanol in methylene chloride without using positive pressure.

    Do not push any remaining liquid through with positive pressure, as this can push through some silica that will clog the gas chromatography column.

63. Evaporate samples to dryness under nitrogen. This will take ~1 hr. After samples are dry, cap the tubes, wrap in Parafilm, and store at −20°C.

    If silica columns were not sealed well, silica grains may be noticed in the sample tubes. These can clog the gas chromatography column.

Perform gas chromatography-mass spectrometry

NOTE: The following instructions work well with the Hewlett Packard MS Engine. Consult the manufacturer's instructions for other systems.

64. Use the following parameters for the gas chromatograph:

    Column: Rtx-50 (Restek) fused silica, 15 m long, 0.25 mm internal diameter
    Helium flow rate: 1.3 ml/min with a split ratio of 40:1
    Injector temperature, 280°C; transfer line temperature, 260°C
    Oven temperatures: initial 190°C, increase to 300°C at 25°C/min, maintain at 300°C or remainder of the run time (total time 10.7 min)
    Injector pressures: initial 16.0 psi, upon injection increase to 20.0 psi at 47 psi/min, hold at 20.0 psi for 0.99 min, decrease to 16 psi at 99.3 psi/min, hold at 16.0 psi for 0.25 min, increase to 30.0 psi at 3.5 psi/min, maintain at 30 psi for the remainder of the run time (total time 10.7 min)
    Splitless mode injection: volume of 2 µl.

65. Use the following parameters for the mass spectrometer:

    Negative chemical ionization with methane reagent gas at 2.6 to 3.1 Torr
    Source temperature, 270°C; quadrupole temperature, 100°C
    Selected ion monitoring at *m/z* of 186 and 188 after a 2-min solvent delay.

66. Freshly distill anhydrous methanol on day of analysis for reconstitution of samples.

67. Wash column two or three times with BSTFA prior to running samples.

68. Tune mass spectrometer to give optimum sensitivity for *m/z* of 186. Check sensitivity by injecting 2 µl of a stock solution of derivatized deuterated standard.

69. Set up data analysis to integrate peaks between 6 and 8 min for *m/z* of both 186 and 188.

    Because the PFB moiety can attach to M_1G at both the N_7 and N_9 positions, expect two peaks with retention times of between 6 and 8 min. Since the first peak (N_7) will be larger, use it for quantitation.

70. If sensitivity is adequate, reconstitute samples by adding 15 µl anhydrous methanol to each sample. Cap, vortex, and allow liquid to collect at the bottom, then transfer to sample vials using disposable micropipets. Crimp shut.

Let samples thaw before removing Parafilm

71. After injections of standard, inject pure methanol to wash injector apparatus. Make similar wash injections after every four or five samples that are analyzed.

72. Prepare a standard curve using the *m/z* 186/188 values obtained for the nondeuterated standards (see step 28). Determine the quantity of M_1G in samples by comparison to the standard curve (see Anticipated Results and Fig. 3.2.6).

SUPPORT PROTOCOL 1

PREPARATION OF ANTI-M_1G IMMUNOAFFINITY GEL

This reagent is required for the enrichment of the adducted deoxynucleoside from the sample, which will consist primarily of normal deoxynucleoside. The monoclonal anti-M_1G IgG antibody has been extensively characterized and is commercially available (Sevilla et al., 1997).

Materials

100 to 200 mg monoclonal anti-M_1G IgG antibody, protein A purified (Oxford)
CNBr-activated Sepharose 4B, freeze dried (Sigma)
1 mM HCl
Coupling buffer: 0.1 M $NaHCO_3$/0.5 M NaCl, pH 8.3
Blocking buffer: 0.1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
Storage buffer: 0.1 M Tris·Cl/0.02% (w/v) sodium azide, pH 8.0
0.1 M sodium acetate/0.5 M NaCl, pH 4.0
200-ml glass storage bottle

Couple antibody to Sepharose

1. Swell 15 g freeze-dried CNBr-activated Sepharose 4B gel in 1 liter of 1 mM HCl. Stir for 15 min.

2. Filter with 600-ml coarse Büchner funnel. Wash with 500 ml of 1 mM HCl four times in the funnel.

When filtering liquid from the gel in this procedure, be careful not to overdry.

3. Dilute 100 to 200 mg of antibody in 90 ml coupling buffer.

4. Divide antibody solution into three 50-ml plastic tubes. Divide washed gel into these tubes using a spatula.

5. Cap and mix for 1 hr at room temperatureon an end-over-end mixer.

Block and wash coupled gel

6. Pour the contents of the coupling reaction into the Büchner funnel and filter off liquid. Turn off vacuum.

7. Add 2 vol blocking buffer directly to Büchner funnel. Let sit at room temperature for 2 hr, occasionally stirring with glass stir rod. Filter off the liquid.

8. Wash the gel with three cycles of the following:

300 ml of 0.1 M sodium acetate/0.5 M NaCl, pH 4.0
300 ml blocking buffer.

9. Wash once with 300 ml storage buffer. Filter off until almost dry.

10. Transfer the nearly dry gel with a spatula to a 200-ml bottle for storage. Add 2 vol storage buffer and store at 4°C.

The gel volume should be ~50 ml.

HPLC QUANTIFICATION OF NUCLEOSIDES

SUPPORT PROTOCOL 2

This procedure is used to determine the total number of nucleosides in DNA samples. Taken together with the amount of M_1G in a DNA sample measured in Basic Protocol, the number of adducts per number of nucleosides can be determined. This method of DNA quantification is more accurate than simply relying on UV absorbance measurements. Additionally, the success of the enzymatic hydrolysis is monitored by HPLC analysis of the hydrolysate.

Materials

DNA hydrolysate (see Basic Protocol, step 27)
Solvent A: 50 mM ammonium acetate (pH 6.2), filtered and degassed
Solvent B: acetonitrile, filtered and degassed (solvents filtered with 0.2-µm GH-Polypro membrane; Gelman)
1 mM deoxyribonucleoside mix (see recipe)

4.6 mm × 25 cm octadecylsilyl (Ultrasphere ODS) HPLC column (Beckman)
HPLC system with ultraviolet detector

1. Set up HPLC with a 4.6 mm × 25 cm octadecylsilyl (Ultrasphere ODS) HPLC column.
2. Set up elution gradient with a flow rate of 1 ml/min as follows:

   Maintain at 94% solvent A/6% solvent B for 3 min
   Increase solvent B to 12% from 3 min to 9 min
   Maintain at 12% solvent B until 12 min
   Increase solvent B to 20% from 12 min to 15 min
   Maintain at 20% solvent B until 20 min
   Increase solvent B to 50% from 20 min to 25 min
   Monitor effluent at 254 nm with UV detector, and quantitate peaks

   The elution times for the deoxyribonucleosides should be ~4 min (deoxycytidine), 6 min (deoxyguanosine), 9 min (deoxythymidine), and 11 min (deoxyadenosine)
3. Inject 20 µl of hydrolysate collected in the Basic Protocol, step 27.
4. Make serial dilutions of the 1 mM deoxyribonucleoside mix (from 0.062 mM to 1.0 mM) in water. Repeat HPLC analysis using 20-µl injections of each dilution.

   Use this standard curve to quantify nucleosides in DNA samples.
5. Determine frequency of adducts per nucleoside:

   adducts (M_1G from GC/MS assay) ÷ number of nucleosides (from HPLC)

REAGENTS AND SOLUTIONS

*Use Nanopure water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Anti-oxidant MOPS buffer

Prepare 1 liter of 50 mM MOPS buffer, pH 7.8. Add 200 ml of 0.05 M butylated hydroxyanisole in ethanol. Add 4 ml of 10 mM indomethacin in ethanol. Store up to 1 month at at 4°C.

Deoxyribonucleoside mix, 1 mM each

Prepare ~10 mM solutions of each deoxynucleoside and determine actual concentrations by UV using the following extinction coefficients:

deoxycytidine (ε_{272} = 8300 $M^{-1}\cdot cm^{-1}$)
deoxyguanosine (ε_{254} = 13,600 $M^{-1}\cdot cm^{-1}$)
deoxythymidine (ε_{268} = 9700 $M^{-1}\cdot cm^{-1}$)
deoxyadenosine (ε_{260} = 14,900 $M^{-1}\cdot cm^{-1}$)

Prepare a solution containing 1 mM of all four nucleosides. Store up to 1 year at –20°C.

Derivatized deuterated standard

Derivatize 480 ng [$^2D_2$]M_1G-dR, as described in the Basic Protocol, starting with the formic acid hydrolysis step (see Basic Protocol, steps 40 to 44). Dissolve derivatized standard in 1.2 ml anhydrous methanol, vortex vigorously, and divide into 100-µl aliquots in microcentrifuge tubes. Evaporate under reduced pressure. Cap, wrap in Parafilm, and store at −20°C. On day of analysis, redissolve in 100 µl anhydrous methanol to obtain a 0.4 ng/ml solution of PFB-[$^2D_2$]M_1G (assuming 100% yield). Transfer to a sample vial and crimp shut.

Dried standards can be stored ~6 months at −20°C. The redissolved standard can be used for ~10 days if stored at −20°C between injections.

DNase I stock solution

Weigh out 0.0145 mg (1000 U) per sample of deoxyribonuclease I (lyophilized, from bovine pancreas; 68793 U/mg) and add to a 15-ml plastic conical tube (e.g., for <20 samples, use >0.29 mg). Dissolve in 10 mM MOPS/120 mM $MgCl_2$ (pH 7.0) to yield a 2.5 U/ml solution (27.5 ml buffer per mg DNase I). Mix by inversion. Prepare fresh each time.

MOPS/sucrose buffer

Dissolve 125 g of sucrose in anti-oxidant MOPS buffer (see recipe) up to a total volume of 500 ml. Store up to 1 month at 4°C.

Nuclease P1 stock solution

Add 4 ml of water to 5-mg vial of lyophilized nuclease P1 (640 U/mg; Sigma) in two separate aliquots. Transfer to a 15-ml tube. Wash vial with an additional 3 ml water and add this to the 15-ml tube. Divide into 1-ml aliquots and store at −20°C (stable >6 months).

This stock should be 5 mg nuclease P1 in 7 ml total.

PFB-Br derivatization solution

Crush a small amount of dry K_2CO_3 (kept in an oven) using a mortar and pestle. Weigh out 1 to 2 mg of crushed K_2CO_3 and add to a 5-ml glass conical tube. Add 5 ml dry methanol and vortex vigorously for 10 min. Transfer 4.75 ml of this methanol/K_2CO_3 to a 5-ml glass conical tube. Using a 0.5- or 1-ml glass pipet, add 0.25 ml of PFB-Br (Aldrich) to the methanol/K_2CO_3 to make a 5% solution. Use the same pipet to mix by pipetting up and down. Cover remaining PFB-Br with nitrogen, recap, and seal with Parafilm. Prepare fresh each time.

COMMENTARY

Background Information

Malondialdehyde (MDA) is carcinogenic in rats (Spalding, 1988) and mutagenic in bacterial and mammalian cells (Mukai and Goldstein, 1976; Basu and Marnett, 1983; Yau, 1979). It is endogenously produced from peroxidation of polyunsaturated fatty acids (Bernheim et al., 1948; Diczfalusy et al., 1977) and

has long been used as a marker of lipid peroxidation (Janero, 1990). MDA can react with DNA bases to form adducts with dA and dC, but the major product is formed with dG to yield the pyrimidopurinone nucleoside M_1G-dR (Fig. 3.2.1; Seto et al., 1983; Marnett et al., 1986). The M_1G adduct itself has been shown to be mutagenic (Fink et al., 1997). A double-stranded M13 viral vector with M_1G site-specifically incorporated was replicated in *E. coli* to study in vivo mutagenesis of M_1G (Fink et al., 1997). In these experiments M_1G partially blocked replication and had a mutation frequency of 18% when M_1G was used as template. These results show that MDA and its adducts with DNA are potential threats to genome stability and therefore justify experiments quantifying relative adduct levels.

Levels of M_1G have been measured by a variety of techniques, such as ^{32}P postlabeling (Vaca et al., 1995), HPLC/fluorescence detection (Agarwal and Draper, 1992), ELISA (Sevilla et al., 1997), and mass spectrometry (Chaudhary et al., 1994a,b). ^{32}P postlabeling and HPLC/fluorescence detection both rely on co-chromatography with synthetic standards. Measurement by ELISA relies solely on the specificity of the monoclonal antibody. In the GC/MS method described here, there is triple selectivity. First, the immunoaffinity purification step takes advantage of the monoclonal antibody's specificity for M_1G-dR and M_1G-ribose. Secondly, gas chromatography selects for the correct retention time. Finally, the mass spectrometer detects only ions of the correct molecular weight. The wide variety of DNA adducts that are being identified support the need for highly specific assays.

Another problem that potentially plagues ^{32}P postlabeling, HPLC/fluorescence detection, and ELISA is variability in sample loss during analysis. This problem is eliminated in mass spectrometric techniques by use of stable isotope dilution with $[^2D_2]M_1$G-dR (Fig. 3.2.4). At the start of an assay, DNA samples are spiked with a known amount of the stable isotope–labeled internal standard, which at the end can be differentiated by mass spectrometry. In this case, the PFB-M_1G derivative is ionized to M_1G^- (m/z = 186), and the PFB-$[^2D_2]M_1$G is ionized to $[^2D_2]M_1G^-$ (m/z = 188). The ratio of the peak areas will relate to the amount of M_1G-dR in the original sample (Fig. 3.2.5).

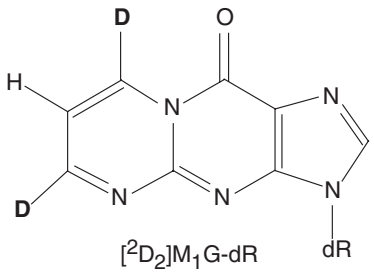
Because DNA adducts usually represent fewer than 1 in 10^6 normal bases, assays have to be exquisitely sensitive. Although ^{32}P postlabeling is more sensitive than the method presented here, the limit of detection with the GC/MS technique is 3 adducts per 10^8 bases in 1 mg of DNA or 100 fmol (Rouzere et al., 1997). GC/EC NCI/MS has been used to detect M_1G in human liver (90 adducts/10^8 bases; Chaudhary et al., 1994b), rat liver (50 adducts/10^8 bases; Chaudhary et al., 1994b), and human leukocytes (6 adducts/10^8 bases; Rouzer et al., 1997).

Critical Parameters

Reproducible standard curves, low background, and high signal-to-noise ratio depend on many factors in this fairly complicated assay. There are many steps and therefore many opportunities to compromise results.

The strict use of only glass after the immunoaffinity column step is imperative to keep background noise low. When organic solvents contact plastic, they can leach out trace quantities of plasticizers. These contaminants generate numerous fragments, one of which has a m/z of 186 and co-chromatographs with PFB-M_1G. Therefore, substitution of plastics in this procedure can significantly add to background noise.

One of the biggest threats to sample recovery is hydrolysis of PFB-M_1G by water. Careful



$[^2D_2]M_1$G-dR

Figure 3.2.4 Structure of stable isotope-labeled $[^2D_2]M_1$G-dR.

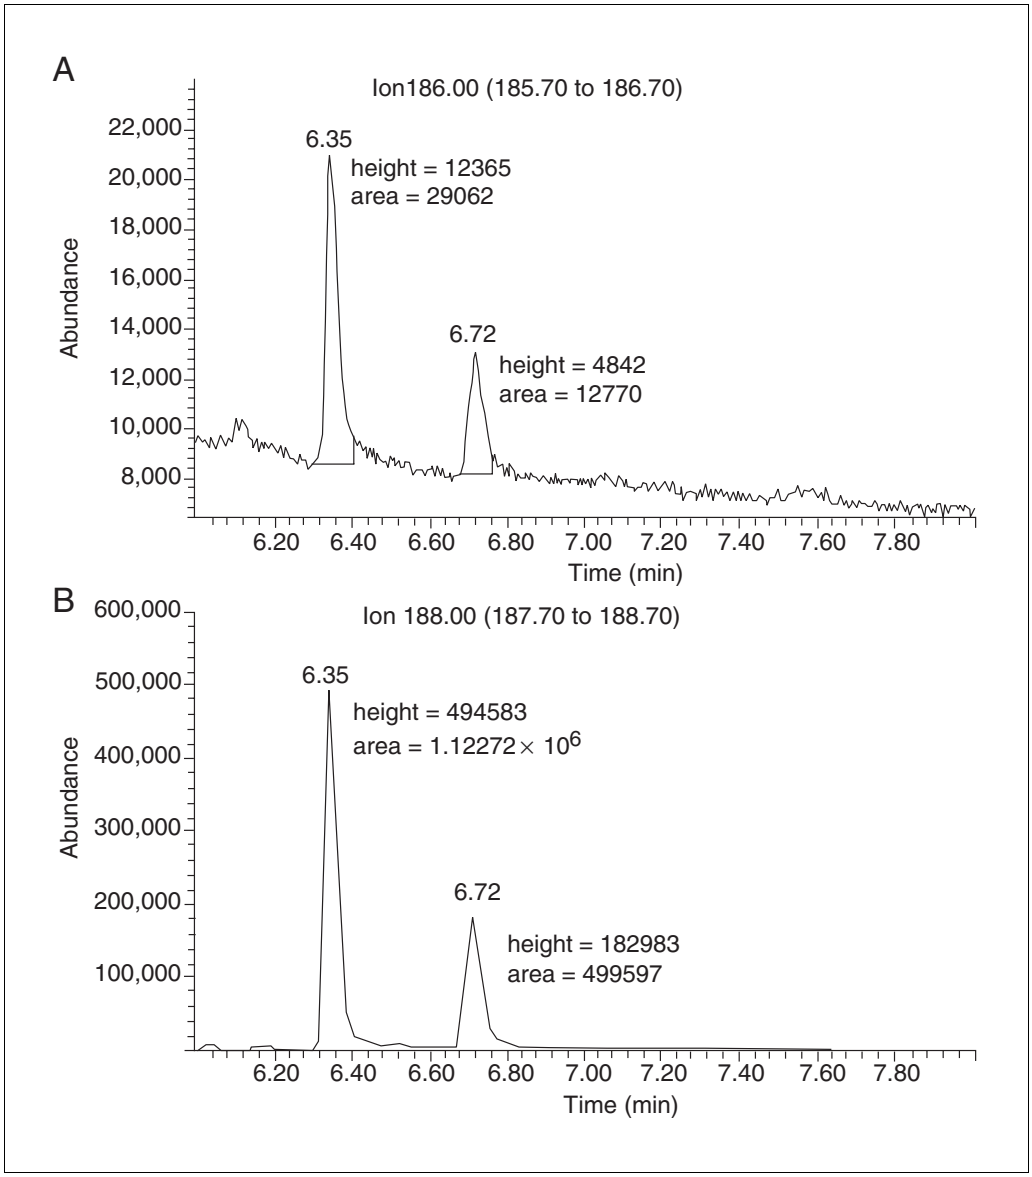


Figure 3.2.5 Selected ion monitoring at 186 for M_1G (**A**) and 188 [$^2D_2$]M_1G (**B**) during GC/MS run. Synthetic standards (340 fmol M_1G-dR and 15 pmol [$^2D_2$]M_1G-dR) were analyzed starting with the immunoaffinity gel purification step.

drying of solvents used during derivatization and solid-phase extraction is crucial in this respect. Furthermore, if samples must be stored as the PFB derivatives, they should be kept in a desiccator or covered with Parafilm.

The most critical step in maintaining high sensitivity and reproducibility is the performance of the GC/MS instrument. The authors have found that the response from stock solutions of derivatized standard varies considerably week to week. The GC interface and mass spectrometer can be very finicky, so regular maintenance is required to ensure optimum performance.

Troubleshooting

In order to ascertain the reliability and linearity of the assay, standard curves using synthetic M_1G-dR are required. If sensitivity is low or if the response is nonlinear, there are several aspects of the procedure that may require particular attention.

During the immunoaffinity step, washing with Nanopure water removes some of the bound analyte from the immunoaffinity gel. Excessive water washing should be avoided to maintain high recovery. In the derivatization step, inadequate nitrogen evaporation of the methanolic PFB-Br solution will yield unreliable results. Because columns and frits for the immunoaffinity and solid-phase extraction are

reused, they must be thoroughly washed between uses.

Poor sensitivity from the GC/MS can be the result of several potential causes. The most common problem is a dirty GC column. Clipping off the first 5 in. of the injector end often dramatically improves sensitivity, but sometimes switching to an entirely new column is warranted. Another common cause of low sensitivity is improper tuning for ions in the 180 mass range. Sensitivity is also highly dependent on the pressure of the chemical ionization

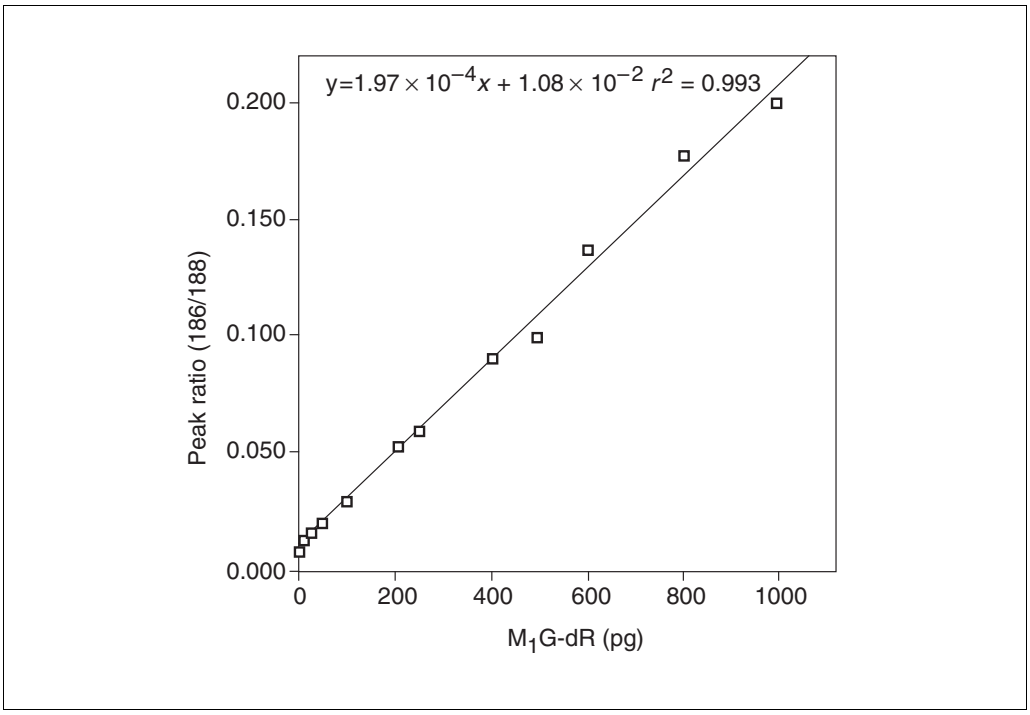

Figure 3.2.6 Standard curve generated by adding indicated amounts of M_1G-dR and a fixed amount of [$^2D_2$]M_1G-dR to immunoaffinity gel.

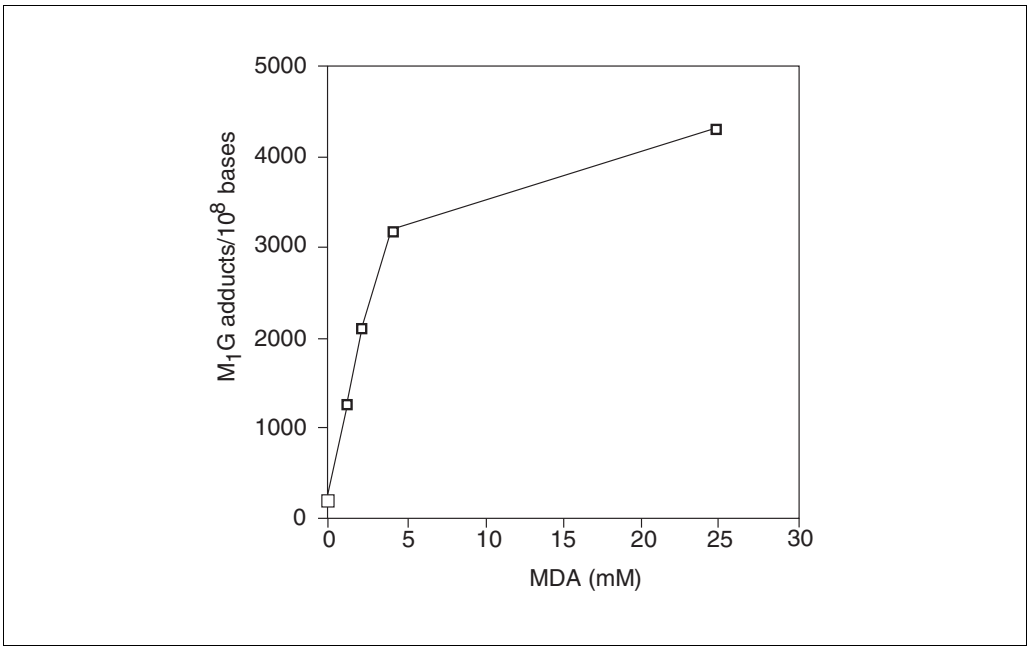

Figure 3.2.7 Calf thymus DNA was treated with indicated concentrations of malondialdehyde sodium salt and incubated at 37°C for 24 hr in 50 mM potassium phosphate buffer, pH 7.4. Adduct levels were determined by GC/MS assay and total number of bases was determined by HPLC/UV assay.

gas. Inefficient ionization can also result from a dirty or inadequately evacuated ion source. Often sensitivity improves when the instrument is allowed to equilibrate several hours to ensure thorough evacuation.

Anticipated Results

The GC/MS trace monitoring at *m/*z of 186 and 188 for an injection of 340 fmol M_1G-dR and 15 pmol [$^2D_2$]M_1G-dR taken through the derivatization procedure is shown in Fig. 3.2.5. If the signal-to-noise ratio is less than 5:1, results should be interpreted cautiously. A standard curve prepared by adding various amounts of M_1G-dR and a fixed amount of [$^2D_2$]M_1G-dR starting at the immunoaffinity step is shown in Figure 3.2.6. If calf thymus DNA is treated with various concentrations of MDA, the number of adducts per 10^8 normal bases is shown in Figure 3.2.7.

Time Considerations

Starting with isolated DNA, the overall assay takes 3 days. DNA hydrolysis and immunoaffinity column purification takes 12 to 14 hr. Formic acid hydrolysis and derivatization takes 10 to 12 hr. Setting up the instrument for the GC/MS analysis takes ~3 hr and each sample injection takes requires 12 to 15 min. Analysis of more than 24 samples in a batch becomes difficult.

Mutagenesis Assays in Mammalian Cells

Mutation assays using cultured mammalian cells can provide valuable information regarding the potential mutagenic and carcinogenic activities of chemicals. Due to the differences in genome organization and genetic complexity, mammalian cells are used to complement microbial assays in genetic toxicology studies (*UNIT 3.1*). A variety of mammalian target genes (e.g., *hprt, aprt, tk*) can be analyzed in several well validated assays (Aaron et al., 1994); however, one of the most commonly employed selective systems measures mutations in the *hprt* gene encoding the salvage pathway enzyme hypoxanthine-guanine phosphoribosyl transferase (HPRT). The toxic purine analog 6-thioguanine (6-TG), is used to select *hprt* gene mutants. The following protocol describes mutagenesis assays using the Chinese hamster V79 cell line, as well as an analogous assay using the V79 derivative *hgprt*$^-$/*gpt*$^+$ G12 cell line. The G12 cell line contains an insertion of the *E. coli* xanthine guanine phosphoribosyl transferase (*gpt*) gene, a functional equivalent of the mammalian *hprt* gene. The G12 assays detect large deletions and epigenetic DNA methylation events, as well as point and small intragenic mutations that can also be detected in the standard V79 assays.

MUTAGENESIS ASSAYS IN THE V79 AND DERIVED TRANSGENIC HPRT$^-$/GPT$^+$ V79 CELL LINES

BASIC PROTOCOL

In this assay, a large population of cells (V79 or G12) is exposed to the test substance for a defined period of time. After the treatment, the cells are cultured for 6 to 8 days for the depletion of residual HPRT or GPT protein and mRNA, which is referred to as the "expression period." The cells are then plated in medium containing a selective agent, 6-thioguanine (6-TG). Only cells that have inactive HPRT enzyme (V79 cells) or mutated/silenced *gpt* gene (G12 cells) will survive and give rise to 6-thioguanine–resistant colonies. For routine mutagenesis assays, use of V79 is sufficient. For test chemicals that may affect DNA methylation and lead to gene silencing, the G12 line is specifically informative because this cell line detects both mutagenic (e.g., mutations and deletions) and epigenetic (DNA methylation) changes.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

V79 cells (ATCC CCl-93) *or* G12 cells (C. Klein, NYU School of Medicine)
F-12 medium/5% FBS (see recipe)
F-12/HAT medium (see recipe)
Physiological buffer, 37°C: Earle's balanced salt solution (EBSS; Life Technologies), phosphate-buffered saline (PBS; *APPENDIX 2A*), or HEPES-buffered saline (Life Technologies)
Substance to be tested for mutagenicity
F-12 medium/5% FBS (see recipe) containing 10 μg/ml 6-thioguanine (6-TG; freshly added)

80-cm^2 tissue culture flasks
100-mm and 60-mm tissue culture dishes

Additional reagents and equipment for toxicity assay (see Support Protocol 1) and Giemsa staining (see Support Protocol 2)

Contributed by Catherine B. Klein, Limor Broday, and Max Costa
Current Protocols in Toxicology (1999) 3.3.1-3.3.7

Grow the cells

1. Grow G12 or V79 cells in F-12 medium/5% FBS in 80-cm^2 tissue culture clasks, passaging every 3 to 5 days.

   Fresh cell cultures are initiated from frozen stocks every 6 weeks.

For G12 cells

2a. Three to four days before the mutagen treatment, seed 5×10^5 G12 cells in a 80-cm^2 tissue culture flask with 10 ml F-12/HAT medium.

   The G12 cultures are supplemented with HAT to maintain a low spontaneous mutant frequency.

3a. At least 24 hr before the mutagen treatment, remove the HAT medium (do not trypsinize the cells), wash the G12 cells with suitable 37°C physiological buffer (EBSS, PBS, HEPES-buffed saline), and feed with complete F-12 medium/5% FBS.

   The cells are removed from HAT selection one day prior to the beginning of each G12 mutagenesis experiment, and HAT is never present during mutagen treatment, or during mutant expression and selection.

For V79 cells

2b. Do not passage in F-12/HAT medium; continue growing in F-12 medium/5% FBS.

   V79 cells are not routinely pretreated with HAT, due to their inherent low spontaneous-mutant frequency.

3b. Feed V79 cells with fresh F-12/5% FBS 24 hr before mutagen treatment.

Mutagenize V79 or G12 cells with the desired test agent

4. At least 3 to 4 hr before the treatment, trypsinize the V79 or G12 cells and seed them for attachment at a density of 10^5 cells per 100-mm dish in F-12 medium/5% FBS. Use two dishes per mutagenic treatment. Incubate at 37°C for 3 to 4 hr to allow cell attachment. Establish a concurrent toxicity assay at this time (see Support Protocol 1).

   Trypsinization should be kept as short as possible (1 to 3 min at room temperature), until it is observed that the cells are detached from the vessel. Overtrypsinization will make the cells sticky.

5. After V79 or G12 cell attachment, remove the medium and gently rinse the cells with physiological buffer to remove adherent medium/serum.

   Be careful not to dislodge the weakly attached cells.

6. Add the test agent to the V79 or G12 cells in any appropriate buffer or medium, for the time and concentration determined by the preliminary toxicity assay (see Support Protocol 1).

7. At the end of the treatment, rinse the cells gently again with physiological buffer, and overlay with 10 ml fresh F-12 medium/5% FBS.

   Be careful not to aspirate agents of environmental concern into the general-use vacuum flasks. Radioactive or carcinogenic solutions must be removed to isolated containers or bottles for regulated disposal. Treatment pipets and tips must also be separated for proper disposal.

8. Allow cells to grow for 7 days ("expression period"), supplying the cells with fresh F-12/5% FBS every three days.

Select for 6-TG-resistant cells

9. Following the 7-day expression period, reseed 2×10^6 mutagenized V79 or G12 cells per treatment into F-12 medium/5% FBS containing 10 µg/ml 6-thioguanine (6-TG), at a maximum cell density of 2×10^5 cells/100-mm dish (usually 10 dishes/dose). Incubate 10 to 14 days, allowing the 6-TG-resistant mutant clones to become macroscopic. During this period, supply the cells with fresh F-12/5% FBS/6-TG every 3 to 4 days.
10. In addition, seed 300 mutagenized cells per treatment, in triplicate, in 60-mm dishes with 4 to 5 ml nonselective (plain) F-12 medium/5% FBS. Incubate these reseeding plating efficiency dishes for 1 week. Score the plates by staining with Giemsa (see Support Protocol 2) and determine the plating efficiency.

    The reseeding plating efficiency in nonselective medium (F-12) is determined for use in the mutant frequency calculations.

11. Giemsa stain (see Support Protocol 2) and score the mutant cells from the plates prepared in step 9. Alternatively, isolate individual (unstained) mutant colonies for molecular characterization of the mutations that occurred.

    If it is desirable to isolate numerous 6-TG-resistant cells for further molecular analysis, a modified cell treatment and reseeding protocol is followed to ensure that the subsequently isolated mutant colonies originated from separate populations of mutagenized parental cells. In order to collect a large number of independent mutants, 30 replicate cultures are seeded in a 6-well plate format, and each well is treated and reseeded individually (as per Klein et al., 1997). This ensures the exclusion of sibling mutants in the molecular studies.

12. Calculate mutant frequency (MF) as the total number of mutants counted on all mutation plates divided by the number of cells seeded (usually 2×10^6 cells) corrected by the reseeding plating efficiency.

TOXICITY ASSAY

SUPPORT PROTOCOL 1

Prior to mutagenicity assays toxicity/cell viability tests should be conducted. In the following assay, attached cells are exposed in situ to the test agent and then screened for clonal survival.

For reagents and equipment, see Basic Protocol.

1. Prepare V79 or G12 cells (see Basic Protocol, steps 1 to 3, a or b).
2. At least 3 to 4 hr before treatment, seed dispersed single-cell suspensions of V79 or G12 cells for attachment into labeled tissue culture dishes, three dishes per dose or control (also see Basic Protocol, step 4).

    Typical seeding densities can be 200 to 300 cells per 60-mm dish or 500 to 1000 cells per 100-mm dish. Cells can be seeded at different densities according to estimated toxicity. Always include untreated and solvent controls.

3. After cell attachment, remove the medium and gently rinse the cells with buffer to remove adherent medium/serum.
4. Add the toxicant in any appropriate buffer or medium for a given period of time, depending upon the mode and efficiency of cellular uptake.

    Short treatments in buffer are preferred, but these cannot successfully exceed 3 hr in length because the cells will detach. For studies requiring stringent pH levels during treatment, HEPES-buffered saline is preferred. For longer treatments, serum-free medium is appropriate for up to 24 hr. Initial testing is suggested to cover several orders of magnitude in dose (e.g., 10^{-4} to 10^{-7} M).

5. At the end of the treatment, rinse the cells gently again with buffer and overlay with fresh F-12 medium/5% FBS (usually 4 to 5 ml per 60-mm dish and 7 to 10 ml per 100-mm dish).

   See Basic Protocol, step 7, for disposal precautions.

6. Incubate plates at 37°C for 1 week, and stain plates with Giemsa on the seventh day (see Support Protocol 2).
7. Count the clones on all plates and average for each triplicate dose set. Determine the cloning efficiency (average number of colonies scored per number of cells seeded) and percent survival relative to the control.

SUPPORT PROTOCOL 2

GIEMSA STAINING

The V79 and V79-derived G12 cells stain very well in a one-step protocol with a working solution of 50% Giemsa/50:50 (v/v) methanol.

Materials

Plates to be stained (Basic Protocol or Support Protocol 1)
Giemsa stain (see recipe)

1. Remove medium from plates. Add ~5 ml/100-mm dish or ~3 ml/60-mm dish of Giemsa stain and wait 5 to 10 min.

   The cells are fixed by the methanol and stained simultaneously. Since the working stain solution is reutilized for several weeks, be sure that the staining solution has adequate methanol content by testing one dish in advance. If the methanol content has become inadequate, the cell clones will not be fixed to the dish and will be lost by the rinsing procedure. The working stain solution can occasionally be resupplemented with methanol (e.g., every 2 to 4 weeks) to compensate for depletion of the methanol that occurs by evaporation during use.

2. Pour the staining solution back into the bottle.

   The staining solution may be reused for 2 to 3 months, until the Giemsa stain becomes depleted. Giemsa stain depletion will become evident by lightening of the stained cell clones over several weeks of recycled stain use.

3. Rinse the stained plates gently by dipping the plates into a water-filled container. Invert the plates to dry.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

F-12/HAT medium

F/12 medium/5% FBS (see recipe below) supplemented with:
100 µM hypoxanthine
1 µM aminopterin
100 µM thymidine
Prepare fresh as needed

F-12 medium/5% FBS

F-12 medium (Life Technologies) containing:
5% (v/v) fetal bovine serum
2 mM glutamine
1% (w/v) 10,000 U penicillin G/10,000 µg/ml streptomycin (Life Technologies)
Store up to 2 to 3 weeks at 4°C

Unsupplemented F-12 medium (i.e., without FBS, antiobiotics, and glutamine) can be stored 4 to 6 months at 4°C. Typically, FBS, antibiotics, and glutamine are added to one or more bottles of F-12 medium to make enough complete medium for use in a given week. It is useful to aliquot a 500-ml bottle of FBS into ten 50-ml aliquots that are stored frozen until use.

Giemsa stain

2 g Giemsa stain
132 ml methanol
138 ml glycerol

Keep in dark for 3 days, then filter through Whatman no. 1 filter paper and carefully pour into a new dark bottle. Store at room temperature.

COMMENTARY

Background Information

Mammalian systems for studying gene mutations include a variety of well characterized rodent cell assays to evaluate endogenous (e.g., *hprt, tk, aprt*) or transgenic gene targets in vitro and in vivo (Li et al., 1991; Aaron et al., 1994). A mammalian cell mutagenicity assay that measures the mutation rate of the *hprt* gene, which encodes the salvage-pathway enzyme hypoxanthine-guanine phosphoribosyl transferase (HPRT), is frequently employed. This enzyme catalyzes the formation of inosine or guanosine monophosphate from hypoxanthine or guanine, using 5-phosphoribosyl-1-pyrophosphate as the phosphate donor. Since the *hprt* gene is carried on the X chromosome, a single copy of the gene is present in males and expressed in females, thus greatly facilitating the detection of those cells that have an inactivating mutation in the gene (Caskey and Kruh, 1979). This allows *hprt* mutagenesis assays to also be applied to human cells. The experimental cell lines most widely used for *hprt* mutation assays are female Chinese hamster ovary (CHO) cells and male Chinese hamster lung fibroblasts (V79). After treatment of the cultured cells with a potential chemical mutagen, the cells are subcultured for 6 to 8 days so that depletion of residual HPRT protein and mRNA occurs. The cells are then plated in medium containing a selective agent, 6-thioguanine (6-TG). The HPRT enzyme forms a toxic metabolite, 6-thioguanine monophosphate from this substrate; thus only cells that have inactivated HPRT will survive and form colonies. Since a functional enzyme is not essential for DNA synthesis, 6-TG-resistant mutants may arise through base-pair substitution, frameshift mutation, or deletion in the *hprt* gene.

In order to enhance the sensitivity of this system, derivative V79 cell lines (G12 and G10) were developed (Klein and Rossman, 1990; Klein et al., 1994). These cell lines are *hprt*$^-$ mutant cell lines that contain an insertion of the functionally analogous *E. coli gpt* gene. An analogous *gpt*$^+$ transgenic cell line, CHO-AS52, has also been derived from *hprt*$^-$ CHO cells (Tindall et al., 1986; Aaron and Stankowski, 1989). The *gpt* transgenic G12 and G10 cell lines have the same phenotype (6-TG sensitivity) as the parental V79 wild-type cells and can be used to measure forward mutations yielding 6-TG resistance in the standard V79 protocol. In contrast to the mammalian *hprt* gene, the bacterial *gpt* gene target is uninterrupted by introns, and therefore is easier to examine for molecular alterations. Like the V79 *hprt* assay, the G12 and G10 assays detect a broad spectrum of gene deletions, frameshift mutations, and point mutations. However, the mutant frequency observed for the G12 and G10 cell lines is significantly higher than that at the *hprt* gene in V79 cells (Klein and Rossman, 1990; Klein et al., 1994, 1997). An added advantage of the G12 cell line is its well characterized ability to score epigenetic gene-silencing events that can occur by hypermethylation of the promotor and proximal *gpt* sequence following treatment with some test agents (Lee et al., 1995; Klein and Costa, 1997).

The V79 cells and V79-derived *gpt*$^+$ transgenic cell lines, G12 and G10, are anchorage-dependent, fetal male Chinese hamster lung fibroblast cells. The doubling time of these cell lines is between 12 to 13 hr. A stable *gpt* locus is carried at a single integration site in the Chinese hamster genome in G12 and G10 cells. The integration site is different in the G12 and G10 cell lines, and therefore the mutability of their target gene (*gpt*) is not identical. This permits the study of genome location–dependent mutagenesis from a mechanistic point of view (Kargacin et al., 1993; Klein et al., 1994, 1997; Lee et al., 1995).

The mutagenesis protocols described above are according to Klein and Rossman (1990) and

Klein at al. (1994). 6-TG-resistant mutants are isolated according to a modified replating technique published by Chang et al. (1978). Mutant frequency is expressed as 6-TG-resistant mutants per 10^6 viable cells. This is calculated by dividing the number of mutant colonies (per 10^6 cells plated) by the reseeding cloning efficiency of each treated population. The reseeding cloning efficiency is the number of colonies formed per 300 cells plated in nonselective medium.

When individual mutant clones are isolated, it is also possible to perform reversion assays using either the V79 or G12 cells (described in Stone-Wolf et al., 1985; Lee et al., 1995). Reversion assays, which detect re-expression of the previously mutated or silenced gene in HAT selection media, are especially useful for the detection of epigenetic mutations using the G12 cells.

Critical Parameters

Prior to commencing any mutagenesis assay, the toxicity of the agent must be assessed. Although several toxicity assay protocols are available, the in situ exposure of attached cells followed by clonal growth for a week is usually sufficiently informative. It is then possible to choose the experimental doses and conditions for the mutagenesis assay. The usual working doses in mammalian mutagenesis assays are chosen to yield a cell survival range of 30% to 80%.

The V79 and derived transgenic cell lines proliferate with a typical growth curve that exhibits a growth delay (lag time) after trypsinization or manipulation, followed by log phase growth for several generations and a growth plateau as the growth area becomes limited. The V79 and derived cells will, however, pack very tightly in the growth vessel and will often overgrow each other, forming sporadic foci. The cells are not sensitive to low seeding density and will eventually grow back with time from any diluted culture (even as low as a 1:20 split of a confluent flask). The cells are never trypsinized two days consecutively. Because of the regular and predictable growth of these cells, it is easy to plan ahead so that trypsinization the day before a planned experiment is avoided. It is essential that the trypsinized cells not be clumped at the time of experimental seeding, since individual single cells must be treated. V79 cells are prone to clumping under two conditions: if kept for more than a few minutes at $>10^6$ cells/ml suspension, or if made sticky by excessive trypsinization. The cells are also not sensitive to minor changes in temperature. The anchored growth of these cells is, however, sensitive to pH, atmospheric CO_2, and certain test agents, including some metals.

Anticipated Results

In the preliminary toxicity assay, the examined doses, length of treatment, and medium of treatment should include conditions ranging from the "no effect" dose level up to 10% cell viability.

If the chemical tested induced a mutagenic response, the mutation frequencies following the mutagenesis assay will be higher than the spontaneous levels. For the endogenous *hprt* gene, the spontaneous mutant frequency is ~1 $\times$ 10^{-6} surviving cells. For the V79-derived transgenic cell lines, the spontaneous mutant frequencies are 30×10^{-6} and 100×10^{-6} for G12 and G10 cells, respectively (Klein and Rossman, 1990, Klein et al., 1994). There should be an absolute increase in the number of mutants at least at some doses of the examined agent. One criterion for defining a positive mutagenic response (Cole and Arlett, 1984) is a statistically significant, reproducible dose-response curve with increases in the calculated mutant frequency per survivor of >10× the control value at one or more doses. Smaller increases in mutant frequency can be equally valid pending appropriate statistical testing (e.g., χ^2 analysis).

Time Considerations

The time required to complete one full V79 or G12 toxicity/mutagenesis assay is 4 weeks: one week for the initial toxicity assay and 3 weeks for the complete mutagenesis assay. From a practical perspective, individual concurrent experiments are initiated on a staggered weekly or biweekly schedule, if sufficient incubator space and technical support is available.

Cell Transformation Assays

In vitro mammalian cell transformation assays have been widely used to test chemical and physical agents for the ability to induce morphological transformation (IARC/NCI/EPA Working Group, 1985; Kerckaert et al., 1996a). Morphologically transformed cells are characterized by the loss of density-dependent regulation of growth and the formation of colonies with crisscrossed cells or foci of piled-up cells that are not observed in untreated controls (Evans and DiPaulo, 1981). Because of the biological similarities between in vitro cell transformation and in vivo carcinogenesis, cell transformation assays are used routinely to screen chemicals for carcinogenic potential and to study the mechanisms of known carcinogens. Morphologically transformed cells are further tested for neoplastic characteristics, including the ability to form three-dimensional colonies in soft agar and/or the ability to induce tumor formation in immunosuppressed (e.g., "nude") mice (Costa, 1980).

Cell transformation assays most frequently employ freshly isolated cells from rodents, such as Syrian hamster embryos (SHE; Berwald and Sachs, 1965), or use established cultured cell lines, such as the mouse BALB/c-3T3 (Kakunaga, 1973) or C3H/10T1/2 (Reznikoff et al., 1973) cell lines. The Basic Protocol describes the establishment of primary SHE cell cultures and their use in a cell transformation assay for testing putative carcinogens. The methods are based upon those described by Costa (1980). SHE cells are diploid and genetically stable, have a finite lifespan, and are capable of metabolizing many procarcinogens to their ultimate carcinogenic form (Kerckaert et al., 1996a). They also have a low spontaneous rate of transformation. Cell lines are sometimes preferred because they are convenient and because scoring morphological transformation is often easier than with SHE cells (Rundell, 1984). However, investigators should be aware that cell lines are immortal and, as such, may already partially exhibit transformed characteristics, whereas untreated SHE cells normally do not (Costa, 1980). Guidelines regarding the use of SHE, C3H/10T1/2, and BALB/c-3T3 cells have been reviewed by Dunkel et al. (1991).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Pregnant Golden Syrian hamsters
Chinese hamster ovary (CHO; ATCC)
Disinfectant solution: e.g., 2% (v/v) Orsyl
95% (v/v) ethanol
Serum-free Dulbecco's minimal essential medium (DMEM)
0.5% (w/v) trypsin solution in normal saline A
Fetal bovine serum (FBS; tested in cell culture)
Complete DMEM supplemented with 10% (v/v) FBS
Normal saline A (see recipe)
Dimethyl sulfoxide (DMSO) or glycerol
Complete DMEM supplemented with 20% (v/v) FBS
F-12 medium supplemented with 10% (v/v) FBS

Contributed by Max Costa and Jessica E. Sutherland
Current Protocols in Toxicology (1999) 3.4.1-3.4.9

Test agent
0.5% (w/v) crystal violet solution in 95% ethanol
Positive and negative control agents
Serum-free F-12 medium

Absorbant cloth, sterile
Laminar flow hood
Dissecting instruments
100-mm tissue culture plates, sterile
10-ml pipets, sterile
Freezing vials for storing cells
150-ml beakers
Inverted tissue culture microscope

Additional reagents and equipment for sacrificing animals (*APPENDIX 3*), for counting cells with a Coulter counter or hemacytometer (*APPENDIX 3*), and for trypan blue exclusion (*APPENDIX 3*)

Harvest hamster embryos

1. Obtain pregnant Golden Syrian hamsters on day 13 of gestation.

   The Syrian hamster embryo system is the preferred system because it has been claimed that these cells have a low incidence of spontaneous transformation (Trott et al., 1995).

   The 13th day of gestation is the optimal time to harvest embryos; however, cells from 12-or 14-day-old embryos can also be isolated for tissue culture.

   Pregnant hamsters can be obtained from commercial sources. Alternatively, they can be bred, but this is not recommended unless one has experience with breeding hamsters.

2. Sacrifice the hamster by CO_2 asphyxiation and immediately immerse in a disinfectant solution for a few seconds.

   Animals can be sacrificed by CO_2 asphyxiation by placing them in a glass dessicator (or large glass jar with lid) connected to a CO_2 tank by a hose or tubing.

3. Place the animal on an absorbent sterile cloth in a sterile laminar flow hood.

4. Sterilize the dissection tools by dipping them in a 150-ml beaker containing 95% ethanol and igniting the residual alcohol by passing them through a Bunsen burner flame.

5. Lay the hamster on its dorsal side and make an incision in the uterus to expose the embryonic sacs.

6. Using forceps and scissors, carefully remove the embryonic sacs and place them into a sterile 100-mm tissue culture dish.

7. Remove the embryo from each sac, and use the alive ones (as gauged by body movement) for isolation of cells.

   To prevent contamination of the cultures, remove the hamster carcass and dead embryos from the sterile area.

Isolate embryonic cells

8. Wash the embryos twice with 10 ml serum-free DMEM.

9. Transfer the embryos to a fresh 100-mm tissue culture dish containing 10 ml of 0.5% trypsin solution in normal saline A. Mince the embryos with sterile scissors.

10. Disperse into individual cells by repeatedly passing the mixture up and down through a 10-ml sterile pipet. Incubate the cells in the 0.5% trypsin solution for ~30 min.

    After this step, the embryos are reduced either to individual cells or to small clumps of cells.

11. Terminate the action of trypsin by adding 1 ml FBS.

12. Seed 5×10^6 to 1×10^7 cells in 10 ml of complete DMEM-10% FBS into 100-mm tissue culture plates.

    Cellular transformation levels can vary greatly depending upon the source and/or lot of FBS.

Establish a primary cell culture

13. Place the plates in a 37°C incubator with an atmosphere containing 5% CO_2. Incubate for 2 days.

    Cells will attach to the bottom of the plate and form a monolayer.

14. Aspirate the medium and wash cells with fresh complete DMEM-10% FBS.

15. Return plates to the incubator for 1 additional day.

    At this point, the cultures are known as primary cell cultures.

Establish a secondary cell culture

16. Wash the monolayer twice with 10 ml sterile normal saline A and disrupt the monolayer by adding 10 ml of 0.5% trypsin solution in normal saline A. Expose cells to trypsin for ~5 min. Centrifuge the cells for 10 minutes at 500*g*. Aspirate the supernatant and resuspend the cell pellet in 10 ml of fresh complete DMEM-10% FBS.

17. Replate at a density of 5×10^6 cells/100 mm plate in 10 ml complete DMEM-10% FBS. Freeze unused cells (see Step 18).

    At this point, the cells are known as secondary or second-passage cultures. Tertiary or third-passage cultures are prepared by trypsinizing cells from the secondary cultures. All subsequent trypsinization procedures are numbered by the passage giving rise to each culture.

Prepare frozen cell stocks

18. Suspend cells in 20% (v/v) DMSO or 10% (v/v) glycerol in complete DMEM-20% FBS and dispense aliquots into freezing vials. Place the freezing vials in a styrofoam holder and place in a −70°C freezer.

    This allows the cells to freeze slowly. Slow freezing yields high cell viability.

    Third- or fourth-passage cells are probably best for use in testing the carcinogenic activity of a chemical. Freezing a large batch of early passage cells is recommended so that the same batch can be used repeatedly, affording consistency in the cell transformation assay. This also prevents having to isolate cells fresh from experimental animals.

19. When frozen, transfer the vials to liquid nitrogen.

Determine cytotoxicity of test agent

20. Plate 1×10^6 CHO cells in 10 ml complete F12-10% FBS and allow to attach overnight.

The plating efficiency of primary cultures is so low that they are not optimal for determining cytotoxicity. Thus, an established cell line of hamster cells (e.g., CHO cells) should be used to obtain an approximate level of cytotoxicity of the chemical.

21. Expose these cells to the test agent using a broad range of dosages (e.g., 0.1, 0.2, 0.5, 1.0, 5, and 10 µg/ml) in order to establish an appropriate dosing regimen (i.e., low dose yields 90% to 100% plating efficiency; high dose yields 50% plating efficiency) for the cell transformation assay.

    Cells of the appropriate passage are exposed to carcinogens using one or multiple exposures. In some cases, a single 24-hr exposure will suffice, but for other agents, a longer exposure period may be necessary. The use of multiple exposures is important since the half-lives of many carcinogens are short, and multiple exposures allow the cells to be exposed to fresh carcinogens as long as possible. Long intervals of exposure are also important since this allows the cells to be exposed to the carcinogens during several rounds of proliferation. For example, in cell transformation assays with carcinogenic metals, the authors employ a 5-day exposure period with replacement of the spent medium with freshly prepared metal solution and fresh medium every 24 hr.

    If organic chemicals are tested, benzo(a)pyrene can be used as a positive control and acetone as the negative control.

22. Following treatment, remove the chemicals from the culture plates and wash cells twice with normal saline A.

    CAUTION: *The medium may contain toxic and/or carcinogenic chemicals and should be disposed of in an appropriate manner.*

23. Trypsinize the monolayer with 0.5% trypsin and count cells with a Coulter counter. Determine cell viability by trypan blue exclusion using 0.4% (w/v) trypan or hemacytometer blue solution (Life Technologies).

24. Plate 100 to 1000 cells into 100-mm tissue culture plates in 10 ml complete DMEM-10% FBS (use 6 plates per dose).

25. Incubate for 2 weeks at 37°C in 5% CO_2. Change the medium twice weekly during this period.

26. Wash the cells with normal saline A and fix in 95% ethanol for 5 min. Stain with 0.5% crystal violet solution in 95% ethanol for 5 min.

27. Wash the excess stain by holding the plate by hand and allowing water from the tap to trickle over the hand.

    The overflow will trickle onto the plate and wash away the stain, eliminating all stain not bound to the cellular material.

28. Count the number of colonies and calculate the plating efficiency. Plating efficiency = (number of colonies/number of cells plated) × 100.

    Plating efficiency refers to the percentage of cells that are initially plated that give rise to colonies. This information is used in the cell transformation assay to determine the starting number of cells to plate in order to obtain a sufficiently large number (e.g., 25-50) of surviving colonies per dish.

    It should be noted that the cytotoxicity in this particular cell line may not be exactly the same as that in SHE cells; therefore, adjustment to the dose is sometimes needed. Generally, a dose that is toxic to one hamster cell line will also be toxic to another hamster cell line.

Determine cell transformation

29. Trypsinize unexposed SHE cells (as in step 16) and neutralize the trypsin with an equal volume of fresh complete DMEM-10% FBS.

30. Seed 1000 to 5000 cells into 100-mm tissue culture plates and allow to attach for 1 or 2 days. Treat with the test compound or a positive or negative control. Use 6 dishes for each exposure level.

    Cell numbers may vary depending upon the experiment. At higher exposure levels, 5000 to 20,000 cells may be plated to counteract the low plating efficiency of these cells.

31. Place cells in a 37°C, 5% CO_2 humidified incubator for ~2 weeks or until visible colonies are formed. Replenish the medium twice weekly during this incubation period.

    Care must be taken not to shake or agitate the plates during this procedure, because this may dislodge cells from colonies. This would result in the formation of new colonies, artificially increasing or decreasing the apparent incidence of transformation by giving birth to more than one colony from one cell at risk.

32. Aspirate the medium and wash cells twice with normal saline A. Fix with 95% ethanol for 5 min.

    CAUTION: *The medium may contain potentially carcinogenic compounds and should be disposed of in an appropriate manner.*

33. Stain with 0.5% crystal violet solution in 95% ethanol for 5 min.

34. Wash off excess stain as described in step 27.

Assess the degree of morphological transformation

35. Count the number of surviving colonies in each plate and examine them for morphological transformation. Observe each colony under an inverted tissue culture microscope for cell crisscrossing and overlapping as shown in Figure 3.4.1 (normal colony) and Figures 3.4.2, 3.4.3, and 3.4.4 (transformed colonies). Circle the transformed colonies on the bottom surface of the plate with an indelible black marker. Calculate the morphological transformation frequency as the (number of transformed colonies/total number of colonies) × 100.

    At least a good portion of the colony must have cells exhibiting disorderly growth at the border as well as in the middle of the colony. Additional scoring criteria are described in detail by Dunkel et al. (1991).

    It is best that the person evaluating the plates be unaware of the specific treatment regimens employed in order to avoid bias. The evaluation of morphological transformation requires a great deal of practice, patience, and care.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Normal saline A

3.3 mM $NaHCO_3$
5 mM KCl
130 mM NaCl
5 mM glucose
Filter sterilize
Store up to 6 months at 4°C

COMMENTARY

Background Information

Since it very expensive to test a carcinogenic substance in experimental animals, it has become necessary to develop cheaper, more rapid in vitro assays to assess the potential carcinogenicity of chemicals. These assays, while useful, are somewhat limited in their ability to assess the complete carcinogenic properties of a compound. The assays can be divided into two types based on the cells used. The first type of cell transformation assay uses established cell lines that lack one or more cancer-related endpoints, and the acquisition of these various cancer-related properties are measured. For example, many cell lines do not exhibit anchorage-independent cell growth and acquire such properties following exposure to carcinogens. The second and perhaps better system uses primary cell lines. Such cells have a limited life span in culture, are not immortalized, and are

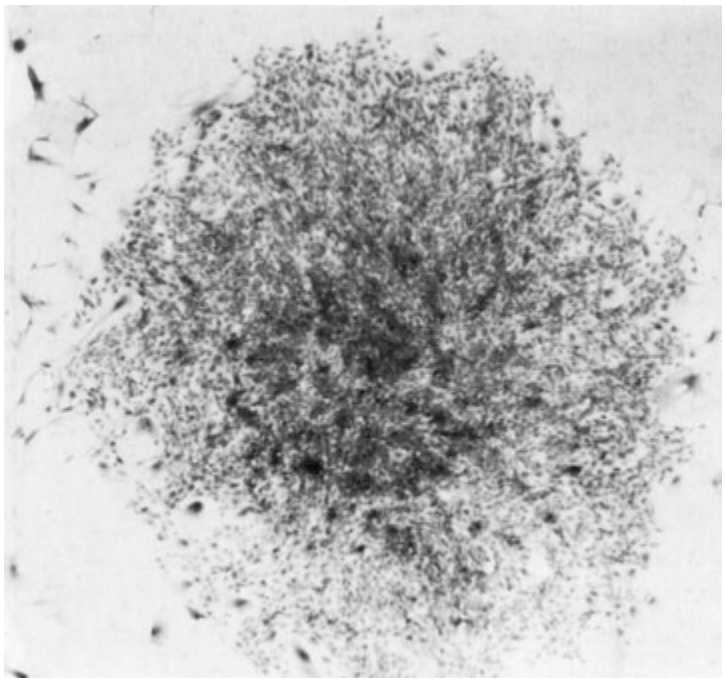

Figure 3.4.1 Normal colony of Syrian hamster embryo cells. From Costa (1980), reprinted with permission from Humana Press.

useful for studying the acquisition of a number of cancerous properties following exposure to carcinogens.

The most common properties that have been used to examine cell transformation of primary cultures are the pattern of growth and the morphological transformation of cells. Cells are exposed to a test substance, plated to form colonies, and the growth properties of the colonies after treatment are studied. A very dense and crisscross pattern of growth is indicative of the induction of morphological transformation.

		1.0	5.8	
		5.0	8.9	
Sodium nitrite	24	0	0.3	Kerckaert et al. (1996a)
		500	1.7	
		750	1.5	

[a]SHE cells were exposed twice to the concentrations listed. Each exposure was with fresh medium and compound for a period of 2 days.

One can then confirm that these transformed cells are in fact tumorigenic by cloning the cells and testing them for their ability to grow in soft agar or to form tumors in nude mice; however, cells exhibiting morphological transformation usually have acquired these other cancer-related properties. Cloning and growing the cells is an additional step that is more expensive and time-consuming, but may be required to establish the carcinogenic properties of the test chemical.

Assays involving embryonic cultures plated fresh from animals have advantages over cell lines in the sense that the starting point is a cell that has not been immortalized and one can study immortalization. In contrast to established cell lines, the primary cell culture exhibits mostly normal properties.

The establishment of primary cultures from Syrian hamsters is preferred over other rodents because these have much lower rates of spontaneous immortalization. Trott et al. (1995) reported that the rates of spontaneous transformation are 10^{-5}, 10^{-6}, 10^{-6}, and less than 10^{-9} for rat, mouse, Chinese hamster, and Syrian hamster fibroblasts, respectively. In addition, SHE cells have been used extensively in carcinogenesis testing therefore data is available for a large number of test agents.

Critical Parameters

The importance of obtaining a good source of fetal bovine serum cannot be sufficiently emphasized. The authors have found that fetal bovine serum obtained from certain sources yields consistent results. Once a good batch is identified, a large number of bottles from that lot should be obtained. This assures optimal growth and consistency in the level of transformation. A different lot of fetal bovine serum may give a different level of transformation for that carcinogen. It has been reported that the serum variability problem is diminished if assays are conducted at pH 6.7 instead of the typical pH (7.1 to 7.3; Kerckaert et al., 1996b). This reduced-pH assay has also been reported to increase the frequency of morphologial transformation. A comprehensive protocol for this approach has been published by Kerckaert et al. (1996b).

Cells may be used beyond the third or fourth passage; however, splitting the cells several times ensures the elimination of many of the nonproliferating cells present in the primary cultures of mixed embryo cells. This greatly improves the evaluation of morphological transformation, since the stained plates can be easily read if nonproliferating cells and other debris are removed during the early passages. Mixed cell populations are always a problem when culturing any type of embryo-derived cell. If the cells are passaged too many times (six to seven) prior to exposure to the carcinogen, the assay does not respond as well, which may be related to the fact that the cells have a limited capacity for proliferation. Additionally,

chromosomal and/or genetic changes frequently increase with passage number and these changes could potentially impact cell transformation assays. The best results are obtained with third- or fourth-passage cells.

Anticipated Results

This assay will yield information on the toxicity and transforming capabilities of test agents and, as such, is a useful screen of potential carcinogens. A positive compound in this assay will cause morphological transformation of cells similar to that depicted in Figures 3.4.2, 3.4.3, and 3.4.4. In Table 3.4.1, some previously reported morphological transformation frequencies have been listed for a few selected chemicals.

Time Considerations

Establishment of third- or fourth-passage cell cultures takes 1.5 to 2 weeks. Exposure to the test agent and subsequent viability and transformation assays require an additional 2 to 3 weeks.

Assays for DNA Damage

Single- and double-strand breakage, DNA-DNA cross-links, DNA-protein cross-links, and DNA adducts are types of DNA damage that can result from exposure to genotoxic chemicals or physical agents. If not repaired, these DNA lesions are involved in teratogenesis, mutagenesis, and carcinogenesis.

Most assays detect DNA damage directly; however, damage can also be indirectly assessed by measuring DNA repair activity following the genotoxic insult. This unit describes assays that detect DNA strand breakage—e.g., by single-cell microgel electrophoresis (see Basic Protocol 1 and Alternate Protocol 1) and filter elution (see Basic Protocol 2 and Alternate Protocols 5, 6, and 7); DNA-DNA interstrand cross-links—e.g., by filter elution (see Basic Protocol 2 and Alternate Protocol 2); DNA-protein cross-links—e.g., by filter elution (see Alternate Protocol 3) or K-SDS precipitation (see Basic Protocol 3 and Alternate Protocols 8 and 9); oxidative DNA base modifications (see Alternate Protocol 4); and repair activities following DNA damage—e.g., unscheduled DNA synthesis (see Basic Protocol 4). Assays to detect DNA adduct formation can be found in *UNIT 3.2*.

These assays can be applied in vitro to cultured cells following exposure to the test agent. In addition, most of these assays can also be conducted using DNA obtained from animals or humans that were exposed to the test agent in vivo. Accordingly, some of these assays may prove valuable for ascertaining whether or not certain types of DNA damage can serve as biomarkers for assessment of human exposure to certain genotoxic agents.

DETECTION OF SINGLE-STRANDED DNA BREAKS USING THE SINGLE-CELL MICROGEL ELECTROPHORESIS ASSAY (COMET ASSAY) UNDER ALKALINE CONDITIONS

BASIC PROTOCOL 1

The single-cell microgel electrophoresis assay (SCGE or "comet assay") is a valuable tool for investigating cellular DNA damage. This assay is amenable to most cell types and thus can be used to assess DNA damage in cultured cells or in cells isolated from treated animals, including humans. Moreover, both double-strand DNA breakage (dsb) and single-strand DNA breakage (ssb) can be identified; for identification of dsb via the neutral assay, see Alternate Protocol 1. In addition, alkali-labile apurinic sites are converted to single-strand breaks at high pH and therefore can be detected in comet assays, particularly when lesion-specific repair endonucleases are used following cell lysis. This procedure describes electrophoresis of single cells following lysis in alkaline pH conditions to detect ssb. Following electrophoresis, the cells are stained with a fluorescent dye and examined microscopically. The appearance of a characteristic DNA "comet" is evidence of DNA damage. The procedures outlined here are adapted from those previously described by Singh (1996).

Materials

Cells of interest
Phosphate-buffered saline (PBS; see recipe)
Test chemical
Normal-melting-point (NMP) agarose
Low-melting-point (LMP) agarose
Alkaline lysis solution, pH 10 (see recipe), 4°C
Alkaline electrophoresis buffer (see recipe)
400 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
20 µg/ml ethidium bromide (or other fluorescent DNA stain; e.g., propidium iodide, ethidium bromide, YOYO-1, TOTO-1)

Contributed by Jessica E. Sutherland and Max Costa
Current Protocols in Toxicology (1999) 3.5.1-3.5.36

Metal baking tray
Microscope slides, fully frosted
24 × 50–mm no. 1 coverslips
45°C water bath
200-µl pipet tips with 5 mm cut off the small end
Coplin jars or slide staining apparatus
Horizontal electrophoresis unit
Power supply capable of delivering 300 mA of current at 25 V
Fluorescence microscope with excitation and barrier filters appropriate for the selected DNA stain, and camera
Eyepiece micrometer
Digital calipers
Transparencies with mm^2 grids
Image analysis software (optional)

Prepare single-cell suspensions and treat with test chemical

1. Prepare a cell suspension at 2,000 to 200,000 cells/µl in PBS.

   Cultured cells, cells isolated from animal tissues, or lymphocytes from human blood are suitable.

2. Treat the cells with the test chemical.

   There are several approaches for treating cultured cells. The test agent can be added directly to the growth medium as long as it is freely soluble and will not form complexes with constituents of the medium. Alternatively, cells can be treated after they are embedded in agarose and mounted on the microscope slide. If embedded cells are to be treated for more than a few minutes, the agarose should contain the growth medium. McKelvey-Martin et al. (1993) reported that control lymphocytes in standard agarose (i.e., dissolved in PBS) developed comets after 1 hr of incubation time. Finally, Singh (1997) described a technique to grow human CFNF-2 fibroblasts directly on frosted slides.

   Examples of previously reported assays are provided in Table 3.5.1. In addition, Henderson et al. (1998) lists agents that have been screened with the comet assay.

   To prevent DNA repair, keep cells on ice during treatment.

Precoat slides with agarose layer (optional)

3. Warm slides (50°C) and label with pencil. Place them on a metal baking tray.

4. Prepare 3 ml of 0.5% (w/v) NMP agarose in PBS by boiling. Cool by placing into 45°C water bath. Using a cut-off pipet tip, apply 100 µl agarose to each of the (fully frosted) slides that are to be used. Gently lower a 24 × 50–mm coverslip onto the agarose, using care to avoid air bubbles. When agarose has been applied to all the

Table 3.5.1 Examples of Previously Reported Single-Cell Microgel Electrophoresis Assays

Test agent	Dose	Exposure time	Cell type	Reference
Acetaldehyde	0-100 mM	1 hr	Human peripheral lymphocytes	Singh (1996)
Dimethyl sulfate	0, 0.5 mM	10 min	Human VH10 fibroblasts	Klaude et al. (1996)
Hydrogen peroxide	0-15 mM	0.5 hr	Mouse 707 Friend erythroleukemia (FEL) cells	McCarthy et al. (1997)
Methylmethane sulfonate	0-4 mM	0.5 hr	Human HeLa (transformed epithelial) cells	Collins et al. (1997)
X-ray	0-25.6 rads	100 rads/min	Human peripheral lymphocytes	Singh (1996)

slides, place the baking tray over ice for 10 min to allow agarose to set. Remove the coverslips.

This is an optional step but pretreatment of slides lessens loss of the microgels during lysis, electrophoresis, fixation, or staining.

Embed cells in agarose, mount onto slides, and lyse cells

5. Prepare 0.5% (w/v) LMP agarose in PBS. Mix 5 µl of cell suspension in 75 µl of the 0.5% LMP agarose, maintained at 37°C.
6. Pipet 30 µl of this mixture onto a fully frosted microscope slide (optionally precoated as in step 4) and cover with a glass 24 × 50–mm coverslip.
7. Cool for 60 sec by placing the slide on a metal tray kept on ice.

   Alternatively, slides can be cooled briefly in a 4°C refrigerator.

8. Remove the coverslip and layer an additional 100 µl of 0.5% LMP agarose on top of the gel and replace the coverslip. Cool as before, and remove coverslip.
9. Place slides in a Coplin jar filled with 4°C alkaline lysis solution, pH 10, and incubate 1 hr at 4°C to lyse cells.

   IMPORTANT NOTE: *Lysis and subsequent steps should be conducted in dim light to avoid introduction of additional DNA damage.*

   Alternatively, the slides can be placed on edge in a staining rack and lowered slowly into a staining trough containing cold lysis solution.

10. (Optional) Treat slides with 1 mg/ml proteinase K in lysis solution without Triton X-100, pH 7.4, for 2 hr at 37°C.

    Alternatively, the proteinase K can be added directly to the agarose.

    This step is often performed to improve assay sensitivity.

Equilibrate slides with electrophoresis buffer and perform electrophoresis

11. Place slides onto horizontal slab of electrophoretic apparatus and carefully cover with alkaline (ssb) electrophoresis buffer. Position the slides as close as possible to the anode and close to one other. Place blank slides in empty spaces.

    The volume of buffer will depend on the size of the electrophoresis apparatus. Add enough buffer to cover gels by ~5 mm. Make sure that the gel box is horizontally level so that the volume of buffer over each slide is the same.

    Among runs, consistent temperature of the electrophoretic buffer should be maintained. A variety of temperatures (4° to 25°C) have been reported for this procedure. Sensitivity of the assay is improved at higher temperatures; however, background rates of comet formation are also increased. For this reason, Green et al. (1996) recommend a maximum temperature of 15°C.

    Singh (1997) describes a slide-holding tray that can be used for lysis and subsequent electrophoresis.

12. Allow gels to equilibrate with buffer for 20 min.

    This also allows for DNA unwinding to occur. Twenty minutes represents the minimum time for equilibration. The time may be increased to 40 min. Prolonged equilibration time (i.e., >40 min) may result in comet formation in controls (Green et al., 1996). Preelectrophoretic equilibration also ensures that the salt concentrations in the buffer and the gel will be equivalent. High salt concentrations in the gel would retard DNA migration (Fairbairn et al., 1995).

13. Begin electrophoresis using a voltage gradient of 0.4 V/cm for 60 min (usually this corresponds to 25 V). Adjust the current to 300 mA by adjusting the volume of the alkaline electrophoresis buffer.

Each experiment should be conducted at the same current. Current magnitude and electrophoresis time is highly variable among laboratories. Using the same voltage, buffer volume, and gel box should yield the same current each time.

Neutralize the alkaline buffer and stain the DNA

14. Remove slides from the alkaline electrophoresis buffer and place them in a Coplin jar (or staining trough) containing 400 mM Tris·Cl, pH 7.4, for 30 min at room temperature.

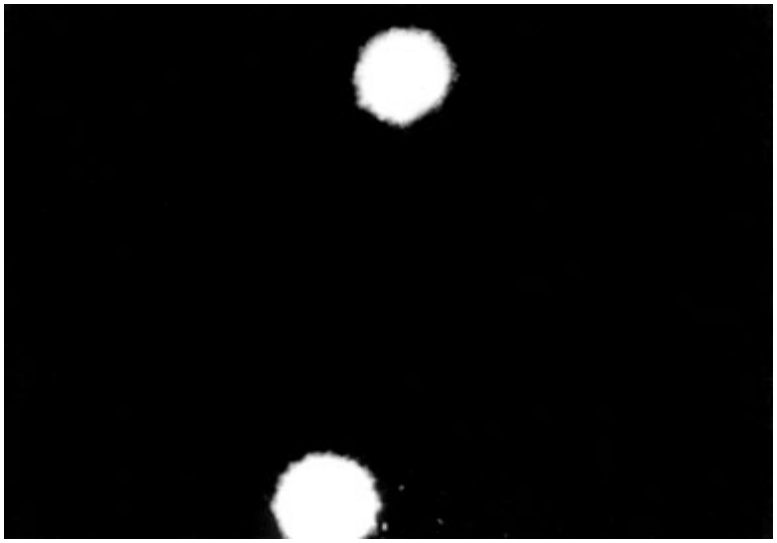

Figure 3.5.1 Untreated lymphocytes processed as controls in the comet assay. From McKelvey-Martin et al. (1993); reprinted with permission from Elsevier Science Publishers.

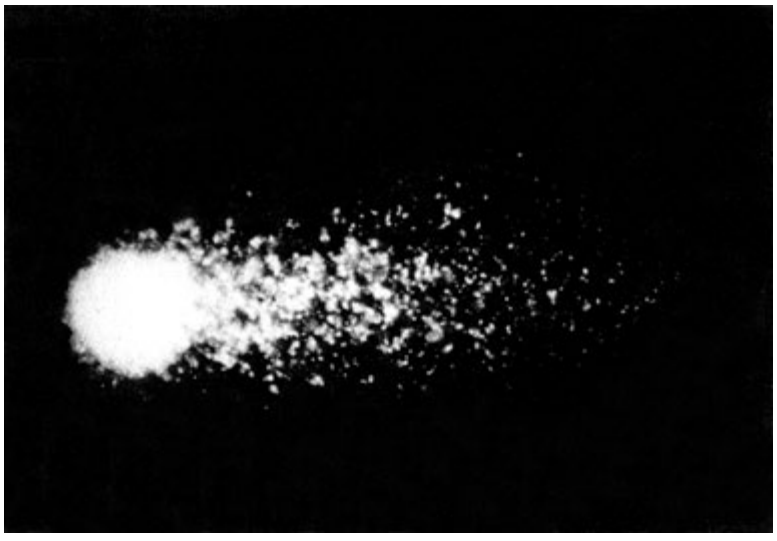

Figure 3.5.2 Human lymphocyte following treatment with 172.5 μM H_2O_2 for 1 hr at 4°C and processed in the comet assay. From McKelvey-Martin et al. (1993); reprinted with permission from Elsevier Science Publishers.

15. Transfer to fresh 400 mM Tris·Cl, pH 7.4 for additional 15 min. Repeat once.

Neutralization can also be performed by placing the slides flat on a staining tray and then rinsing with 1 ml of 400 mM Tris·Cl, pH 7.4, dropwise. This process is then repeated one more time.

16. Stain DNA with 60 µl of 20 µg/ml ethidium bromide. Cover gels with a new coverslip.

Alternatively, gels can be dehydrated and the DNA can also be fixed. To do this, immerse slides (two per Coplin jar) in absolute ethanol for 10 min at room temperature. Repeat with 70% ethanol, then dry slides at room temperature.

Other stains that have been used in comet assays are: DAPI (5 µg/ml), propidium iodide (2.5 to 5 µg/ml), TOTO-1, and YOYO-1. YOYO-1 and TOTO-1 are the most sensitive and should be used at the minimal concentration that will give good DNA staining and low background (1 to 100 µM). All of these dyes bind to nucleic acids and hence should be used with appropriate care. Continue to work in dim light to avoid photobleaching.

If desired, gels can be stored for a few days in a light-proof box. Keep moist with PBS-soaked gauze.

Examine slides with fluorescent microscope and quantitate DNA damage manually or via automated image analysis

17. Equip microscope with a filter combination appropriate for the DNA stain that was used.

For example, for ethidium bromide, an excitation filter of 515 to 560 nm and a barrier filter of 590 nm are required.

See Figure 3.5.1 and Figure 3.5.2 of control and hydrogen peroxide–treated cells, respectively, that were processed using the comet assay.

For manual quantitation

18a. Score damage empirically using a numerical rating system (0 for no damage and 4 for maximal damage). Count at least 50 comets per treatment.

19a. Measure DNA migration with an eyepiece micrometer.

20a. Use digital calipers (0 to 150 mm) to measure nuclear DNA and migrated DNA (i.e., head diameter and comet length) on negative photomicrographs.

21a. Measure comet area by placing a transparency with a mm^2 grid between a light box and a negative photomicrograph. Record the total number of squares encompassing each comet.

For quantitation by automated image analysis

18b. Quantify % head DNA, % tail DNA, tail length, comet area, and tail moment—i.e., the product of tail length and the fraction of total DNA in the tail (Olive et al., 1990)—using a computerized image analysis system.

Many other measurements are also possible with image analysis systems. Some of these are: the comet moment (Kent et al., 1995), ratio of head diameter to tail length (Olive, 1989), and ratio of overall intensities within the tail and the head (Böcker et al., 1997).

ALTERNATE PROTOCOL 1

DETECTION OF DOUBLE-STRANDED DNA BREAKS USING THE SINGLE-CELL MICROGEL ELECTROPHORESIS ASSAY UNDER NEUTRAL CONDITIONS

Neutral electrophoresis conditions allow the detection of double-strand breaks.

Additional Materials *(also see Basic Protocol 1)*

Neutral lysis solution, pH 8.3 (see recipe), *or* alkaline lysis solution, pH 10 (see recipe)
10 µg/ml RNase A in alkaline lysis solution (see recipe for the alkaline lysis solution; omit Triton X-100 and adjust pH to 7)
1 mg/ml proteinase K in alkaline lysis solution (see recipe for the alkaline lysis solution; omit Triton X-100 and adjust pH to 7)
Neutral electrophoresis buffer: 300 mM sodium acetate/100 mM Tris·Cl, pH 8.5 (see *APPENDIX 2A* for Tris·Cl)
300 mM NaOH

1. Prepare cell suspension, treat cells with test chemical, precoat slides with agarose, and embed cells in agarose (see Basic Protocol 1, steps 1 to 8).
2. Lyse cells in neutral or alkaline lysis solution at 4°C for 1 hr by placing slides in a Coplin jar filled with lysis solution.

   IMPORTANT NOTE: *Lysis and subsequent steps should be conducted in dim light to avoid introduction of additional DNA damage.*

   In an attempt to enhance migration of DNA fragments in the comet tail, many investigators have used the alkaline lysis solution followed by neutral electrophoresis when conducting neutral comet assays.

Remove RNA and protein

3. Treat slides with 10 µg/ml ribonuclease A at 37°C for 2 hr.
4. Treat slides overnight with 1 mg/ml proteinase K at 37°C in lysis solution without Triton X-100 and adjusted to pH 7.

   Alternatively, the proteinase K can be added directly to the agarose (Singh, 1997).

5. Rinse slides for 5 min with neutral electrophoresis buffer at room temperature.
6. Perform electrophoresis [see Basic Protocol 1, steps 11 and 13; substitute neutral electrophoresis buffer where alkaline electrophoresis buffer is called for and omit buffer equilibration/DNA unwinding step (Basic Protocol, step 12)].
7. Place slides in a Coplin jar (or staining trough) filled with 300 mM NaOH and incubate at room temperature for 10 min to degrade remaining RNA.
8. Neutralize NaOH, stain DNA, examine slides, and quantitate DNA damage manually or by image analysis (see Basic Protocol 1, steps 14 to 21a or 18b).

BASIC PROTOCOL 2

DETECTION OF DNA DAMAGE WITH FILTER ELUTION

Filter elution is a commonly used technique for measuring DNA stand breakage. The assay uses a filter to mechanically impede passage of long (unbroken) DNA strands during elution. Most often, this assay has been employed in alkaline conditions to measure single-strand DNA breakage (ssb). With modification, the assay has also been used to detect alkali-labile sites, DNA-protein cross-links, DNA interstrand cross-links, and double-strand DNA breakage (dsb). The assay described here is modified from the

protocol of Kohn et al. (1981) and outlines detection of single-strand DNA breakage. The alternate protocols describe modifications for the other types of DNA damage.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Materials

Cells of interest
[Methyl ^{3}H]thymidine (20 Ci/mmol) or [2-^{14}C]thymidine (50 mCi/mmol) for radioactive determination *or* Hoechst 33258 (bis-benzamide; for fluorometric determination)
Unlabeled thymidine
Appropriate growth medium for cells
Test compound
Phosphate-buffered saline (PBS; see recipe), ice-cold
Cell lysis solution, pH 9.7 (see recipe)
Cell lysis solution (see recipe) containing 0.5 mg/ml proteinase K
Alkaline elution solution, pH 12.3 (see recipe)
1 N HCl
0.4 N NaOH
Scintillation fluid (e.g., Ecolume, ICN Biomedicals) containing 0.7% (v/v) acetic acid
0.2 M tetrasodium EDTA, pH 10 (pH adjusted with 1 N NaOH)
1 M potassium dihydrogen phosphate
17 mM KH_2PO_4
150 µM Hoechst 33258 stock solution

Tabletop centrifuge
2.0-µm polycarbonate filter (25-mm diameter; Nucleopore, Whatman)
1-liter vacuum flask
Alkaline elution funnel apparatus (e.g., Millipore)
Aluminum foil or black paper cylinder
Multichannel peristaltic pump and suitable Tygon tubing
Fraction collector
Glass scintillation vials
60°C oven or water bath
Liquid scintillation counter or fluorometer

Additional reagents and equipment for assessing cell viability by trypan blue exclusion (*APPENDIX 3B*)

Label cells with [^{14}C] or [^{3}H]thymidine

1. Expose 10^5 cells/ml in suspension or a monolayer culture of ~10^6 cells to 0.1 µCi/ml [methyl ^{3}H]-thymidine plus 10^{-5} M unlabeled thymidine or 0.01 to 0.02 µCi/ml of [2-^{14}C]-thymidine for 24 hr. Follow with a chase period of 24 hr so that cells are uniformly labeled (i.e., not just the newly replicated DNA). Grow and label an adequate number of cells (i.e., several flasks or plates may be necessary) for the experimental protocol (see step 3).

   Radiolabeling is not required. Alternatively, DNA can be quantitated fluorometrically (see steps 15b to 22b). In this case, omit step 1. Fluorometric quantitation must be used for nonreplicating cells (e.g., peripheral lymphocytes).

2. Recover cells in suspension by centrifuging 5 min at 200 × *g*, 4°C and remove the supernatant. Or if monolayer cells are used, rinse twice with ice-cold PBS, gently scrape cells with a rubber policeman, and use a sterile pipet to transfer them into a sterile centrifuge tube. Centrifuge 5 min at 200 × *g*, 4°C and remove the supernatant. Rinse pellets with ice-cold PBS, centrifuge again, remove the supernatant and transfer an appropriate number of cells into the appropriate medium for treatment with test agent (either as suspended cells or as re-attached cells on a plate).

   If monolayer cells are used, avoid excess trypsinization or scraping as this can result in significant DNA damage.

3. Treat cells with test agent, using at least four different concentrations of the agent, a vehicle control, and a positive control, all in triplicate. Conduct cell viability tests (trypan blue exclusion; see *APPENDIX 3B*) concurrently.

   Alternatively, cells can be removed ex vivo from tissues of treated laboratory animals. Typically, nuclear suspensions are prepared and nuclei are applied to the filter. Sensitivity of the assay will depend on the degree of damage incurred by the nuclear DNA during the isolation procedure (Kohn, 1991). For biomonitoring purposes, the assay can also be applied to lymphocytes obtained from exposed and nonexposed human subjects.

Assemble and prepare filter apparatus

4. Secure the filter within the funnel apparatus and attach to a suction flask that is in turn connected to a vacuum line.

5. Add ~20 ml of ice-cold PBS to the funnel. Use a pipet to slowly add fluid while allowing air bubbles in the solution to escape. Apply a full vacuum for a few seconds to expel air from the filter. Adjust vacuum to a slow flow rate.

   Always keep enough buffer in the funnel to cover the filter, so as not to suck air into the filter. Air pockets can cause spurious elution of DNA strands.

Apply cells to filter

6. Add 0.5–2 × 10^6 cells, diluted in 20 ml ice-cold PBS, to the funnel. Continue to apply a gentle vacuum to pull the cells onto the filter.

   The number of cells to be loaded onto the filter depends upon cell size and the degree to which the cells impede the solution flow rates through the filter.

   An internal standard can be added to control for elution anomalies or variability between individual elution columns. These are cells that are labeled in a different manner than the test cells (e.g., with ^{14}C rather than ^{3}H) and that have been irradiated with X rays in order to introduce a known frequency of single-strand breaks. Elution curves of the test cells are normalized with respect to the internal standards (Kohn et al., 1981). Additionally, the frequency of single-strand breaks caused by the test agent can be calculated. The mathematical formulas are detailed by Kohn et al. (1981).

7. Just before the solution level reaches the filter, add 5 to 10 ml of additional ice-cold PBS to wash the cells. Repeat twice. During the last wash, turn off the vacuum when the fluid is ~1 cm above the filter and allow the last of the solution to flow through the filter by gravity.

8. Cover the funnel apparatus, if transparent, with foil or a black paper cylinder to shield from light.

   All subsequent steps should be performed in dim light to avoid further DNA damage.

Lyse the cells

9. Disconnect the funnel/filter apparatus from the suction flask and move to a support rack.

10. Fill the upper chamber of the filter holder with cell lysis solution, pH 9.7, by using a pipettor with a plastic tip that will fit through the filter orifice. Withdraw the tip slightly to allow for air bubbles to escape from the upper chamber. Pipet 1 ml at a time, slowly. Add a total of 5 ml of cell lysis solution. Allow the lysis solution to drip by gravity into a scintillation vial.

    Air pockets in the filter chamber may cause spurious DNA elutions.

Digest protein

11. Connect the outflow tubes to tubing leading to a peristaltic pump (with the pump turned off at this point).

12. Fill the upper chamber of the filter holder with 2 ml of cell lysis solution containing 0.5 mg/ml of proteinase K, using the procedure described above for adding the cell lysis solution. Pump through the filter at 0.035 ml/min. Turn off the pump.

    It is important to properly adjust the pump so that no retrograde flow pulsations occur. These can cause DNA breakage (Kohn, 1991).

    For the fluorometric procedure (see steps 15b to 22b, below), if DNA is to be quantitated with Hoechst 33258 fluorochrome, it is important to wash out SDS from the cell lysis solution to eliminate background fluorescence from the SDS. To accomplish this, wash the lysate with 10 ml of 0.02 M disodium EDTA buffer, pH 10, prior to the elution step (Sterzel et al., 1985).

Elute damaged DNA

13. Aspirate excess proteinase K solution from the filter funnel and add 5 ml of alkaline elution solution, pH 12.3, by slowly running the solution down the wall of the funnel. Pour an additional 30 to 40 ml of the solution into the funnel.

14. Turn on the pump at a speed of 0.035 ml per min and collect fractions into scintillation vials at 90- or 180-min intervals for 15 hr. Turn pump off.

Quantitate DNA using scintillation counting of radiolabeled DNA or fluorometry

Using radiolabeled DNA

15a. Pour off any remaining elution solution.

16a. Turn pump on to maximum speed to empty solution remaining in the line and filter holder. Collect this fraction into a scintillation vial.

17a. Turn off the pump and remove the filter. Place it in a scintillation vial containing 0.4 ml of 1 N HCl. Cap the vial and heat at 60°C in oven or water bath for 1 hr to depurinate the DNA.

18a. Add 2.5 ml of 0.4 N NaOH and shake vigorously. Allow to stand for 1 hr at room temperature. Shake again.

19a. Flush the filter holder and line tubing with 10 ml of 0.4 N NaOH by pumping at high speed. Collect into another scintillation vial. Wash again with 2.5 ml 0.4 N NaOH and count to check if all radioactivity has been removed.

20a. Add 10 ml of scintillation fluid (e.g., Ecolume, ICN Biomedicals) containing 0.7% (v/v) acetic acid to each scintillation vial.

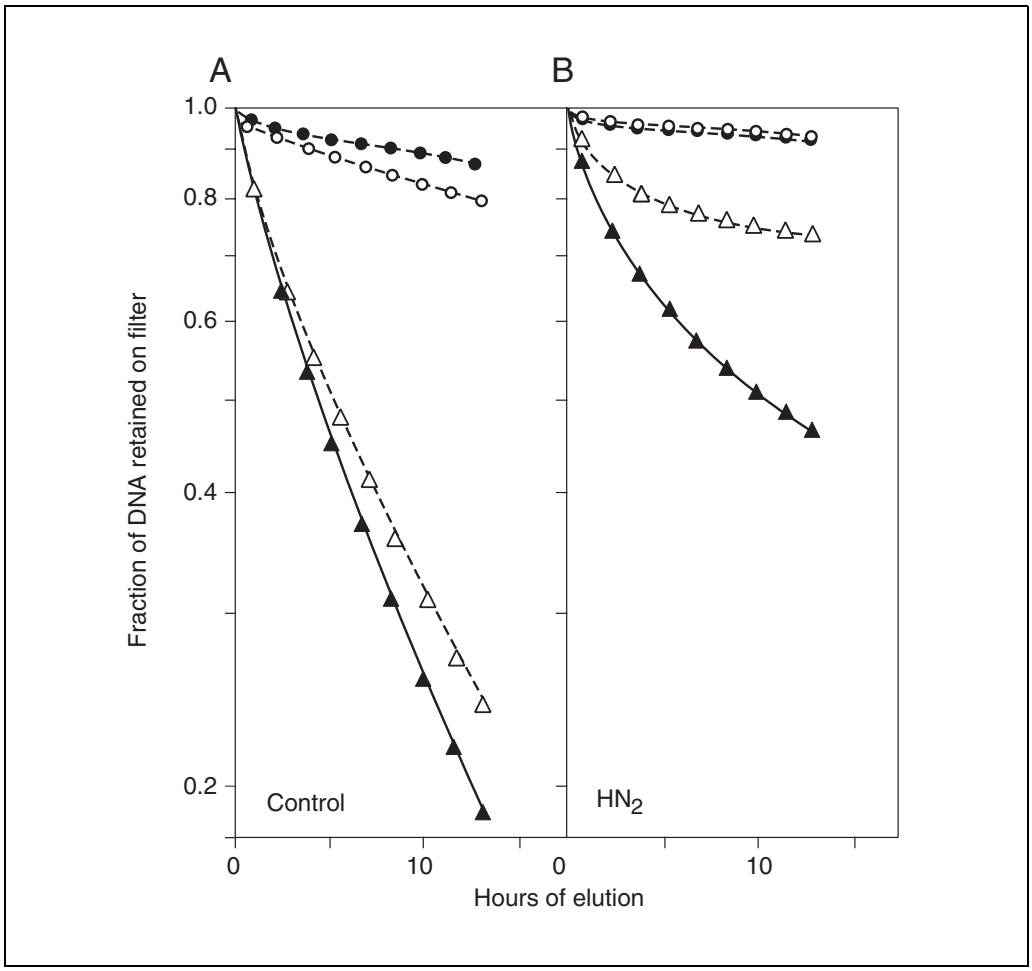

Figure 3.5.3 Protein-dependent (**A**) and protein-independent (**B**) DNA cross-linking in L 1210 cells by bis (2-chloroethyl) methyl amine (HN_2). Cells, prelabeled with [^{14}C]thymidine (20 hr) were treated with 0.1 μM HN_2 (0.5 hr). Tests were conducted with and without proteinase K and with and without 300 red of X ray. Symbols: open circles, no X ray or proteinase K; open triangle, X ray, no proteinase K; filled circle, no X ray with proteinase K; filled triangle, X ray with proteinase K. From Ewig and Kohn (1977); reprinted with permission from American Association for Cancer Research (AACR).

21a. Count the radioactivity in each of the vials containing the filters, rinse solution, and eluted fractions.

22a. Calculate results by adding the radioactivity (cpm) from the filter to the radioactivity measured in the wash of the filter holder. Add this amount to the cumulative amount of radioactivity in the fractions.

This sum will represent the total amount of labeled DNA in the assay.

23a. Plot data on a semilogarithmic plot of DNA retention [i.e., the fraction of total DNA retained on the filter (log scale)] versus elution time (arithmetic scale; see Fig. 3.5.3).

Using fluorometry (i.e., cells have not been radiolabeled; step 1 has been omitted)

15b. Wash the lysate with 10 ml of 0.02 M disodium EDTA buffer, pH 10, prior to the elution step (see step 12 above; Sterzel et al., 1985).

If DNA is to be quantitated with Hoechst 33258 fluorochrome, it is important to wash out SDS from the cell lysis solution to eliminate background fluorescence from the SDS.

16b. Conduct elution of damaged DNA (see step 13 above). Collect 3-ml fractions at rate of 30 μl/min.

17b. To recover the DNA on the membrane, transfer the membrane to a small plastic petri dish and cut into small pieces with a scalpel blade. Place the pieces in a 20-ml scintillation vial and add 5 ml of the alkaline elution solution (pH 12.3). Vortex for 1 min. Collect the wash fraction and replace with an additional 5 ml of buffer and vortex. Pool the two wash fractions.

18b. Dilute 1 ml of the pooled wash fraction with 2 ml of alkaline elution buffer.

19b. Adjust pH of each 3-ml fraction (eluant and wash fractions) to 6.8 to 7.0 by adding 175 µl of 17 mM KH_2PO_4.

20b. Add 0.8 ml 2.25 µM Hoechst 33258 dissolved in 0.15 M sodium chloride/0.015 M sodium citrate. Incubate in the dark for 30 min.

21b. Measure fluorescence with fluorometer set at an excitation wavelength of 360 nm and an emission wavelength of 450 nm.

Alternatively, DNA can be quantitated fluorometrically using an automated method. This technique requires a continuous-flow analyzer manifold with a sample carousel, proportioning pump, and fluorometer (Sterzel et al., 1985).

22b. Plot data on a semi-logarithmic plot of DNA retention [i.e., the fraction of total DNA retained on the filter (log scale) versus elution time (arithmetic scale; see Figure 3.5.3)].

DETECTION OF INTERSTRAND CROSS-LINKS

ALTERNATE PROTOCOL 2

The elution rate (see Basic Protocol 2) of broken fragments of DNA (introduced by X irradiation) is decreased if interstrand cross-links are present. After treatment with the test agent or vehicle control, irradiate cells with an X-ray dose of 300 rad at 0°C. Alternatively, hydrogen peroxide can be used as a DNA fragmenting agent (Szmigiero and Studzian, 1988). Perform alkaline elution assay as above (see Basic Protocol 2) except use a 0.8-µM polycarbonate filter (Nucleopore, Whatman). If the test agent caused interstrand linkage, a greater fraction of DNA (quantitated with radiolabeling or by fluorescence) will be retained on the filter over time as compared to the vehicle control.

DETECTION OF DNA-PROTEIN CROSS-LINKS

ALTERNATE PROTOCOL 3

After treatment with test agent as in steps 1 to 3 in Basic Protocol 2, cells are irradiated with 300 rad of X ray at 0°C to introduce DNA strand breakage. A 0.8-µm polyvinyl chloride filter (Gelman) is used instead of polycarbonate because polyvinyl chloride retains more protein. The lysis solution consists of 0.2% (w/v) sodium dodecylsarkosine/2 M NaCl/0.04 M EDTA, pH 10.0. The proteinase K treatment before alkaline elution is omitted. If the test agent has induced significant DNA-protein cross-linkage, more DNA (as quantitated by radiolabeling or fluorescence) will be retained on the filter over time as compared to the vehicle control. To better quantitate the amount of DNA-protein cross-linkage that has occurred, the results from assays conducted with and without proteinase K can be compared (see Fig. 3.5.3).

ALTERNATE PROTOCOL 4

DETECTION OF OXIDATIVE DNA BASE MODIFICATIONS

Oxidation-induced DNA lesions undergo excision repair by cellular endonucleases. This assay uses exogenous bacterial repair enzymes—e.g., 1 μg/ml foramidopyrimidine-DNA glycosylase E, 10 ng/ml endonuclease IV (Boehringer Mannheim), 30 ng/ml TY endonuclease V, 0.3 ng/ml exonuclease III—to excise modified DNA bases following cell lysis. The resulting single-stranded DNA fragments are quantified with alkaline elution (see Basic Protocol 2) and this is compared to the number of single-strand breaks detected without added repair enzymes (Pflaum et al., 1997).

ALTERNATE PROTOCOL 5

DETECTION OF DOUBLE-STRAND DNA BREAKAGE

Double-strand DNA breaks are detected with "neutral" filter elution (performed at pH 9.6). This pH is nondenaturing thus no DNA strand unwinding occurs.

Polycarbonate filters are preferred because they retain less protein than polyvinyl chloride filters. A lysis solution containing 2% (w/v) sodium dodecyl sulfate and 0.5 mg/ml proteinase K, pH 9.6, is used for 30 min (Elia et al., 1991). The eluting solution is composed of 0.05 M Tris·Cl/0.05 M glycine/0.025 M EDTA (disodium salt)/2% (w/v) sodium dodecyl sulfate. The pH of the eluting solution is adjusted to pH 9.6 with 10 N NaOH (Bradley and Kohn, 1979). DNA quantitation is conducted as above (see Basic Protocol 2) by prelabeling cells with radiolabeled thymidine or by using fluorometry.

ALTERNATE PROTOCOL 6

SIMULTANEOUS DETECTION OF DNA DOUBLE- AND SINGLE-STRAND BREAKS

Lu et al. (1996) introduced a filter-elution assay that simultaneously detected single- and double-strand DNA breaks. Double-strand breaks are estimated by measuring the DNA in the eluate following neutral cell lysis (pH 10) and proteinase K digestion. This step is followed by alkaline elution (pH 12.3) and the degree of single-strand breakage is estimated by quantitating the amount of DNA in the alkaline eluate.

ALTERNATE PROTOCOL 7

ALKALINE ELUTION USING 96-WELL PLATES

Anard et al. (1997) used the Millipore Multiscreen Assay System for alkaline elution. The system included disposable 96-well plates with hydrophobic polyvinylidenefluoride (PVDF) membranes (0.65 mm pore size) and a vacuum manifold. Eluates were collected in a standard 96-well plate placed below the vacuum manifold. The advantages of this technique included its rapidity and the fact that a large number of tests could be run in a single experiment.

BASIC PROTOCOL 3

DETECTION OF DNA-PROTEIN CROSS-LINKS BY K-SDS PRECIPITATION

This assay uses detergent and high temperatures to disrupt noncovalent DNA-protein binding. Covalent DNA-protein complexes are selectively precipitated by the addition of potassium chloride. This protocol was introduced by Zhitkovich and Costa (1992).

Materials

Culture of monolayer cells
Phosphate-buffered saline (PBS; see recipe), ice-cold
K-SDS cell lysis solution (see recipe)
4 mg/ml bovine serum albumin (BSA; molecular biology grade)
Precipitation/washing solution (see recipe)
Proteinase K solution (see recipe)
1 mg/ml Hoechst 33258 dye (freshly prepared 1:20 dilution gives A_{338} = 1.12)
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
λ DNA of known concentration

3-ml syringe with 21-G needle
50° and 65°C water baths
Centrifuge with swinging-bucket rotor capable of 3300 × *g* with adapters for 1.5-ml microcentrifuge tubes (optional)
15-ml polystyrene centrifuge tubes with caps, sterile
12 × 75–mm borosilicate glass culture tubes of size appropriate for fluorometer
Centrifuge with swinging-bucket rotor capable of 1500 × *g* with adapters for 15-ml tubes
Fluorometer

Treat and lyse cells

1. Treat cultured monolayer cells with test agent or vehicle control. Scrape with a rubber policeman and wash twice with ice-cold PBS. Centrifuge at 600 × *g* for 5 min and resuspend pellet in PBS at 1–2 × 10^7 cells/ml.

   For biomonitoring purposes, this assay can be used on white blood cells or lymphocytes isolated from human blood samples (Costa et al., 1993; Taioli et al., 1995). The assay can also be applied to cells isolated from tissues of treated laboratory animals (Zhitkovich and Costa, 1992).

   Optimal density will depend on cell type. Use a cell density that yields 8 to 15 μg of total DNA per cell preparation. Starting cell densities should be the same for treated and control preparations.

2. From each plate, prepare three lysates as follows. Pipet 0.5 ml K-SDS cell lysis solution into a 1.5-ml microcentrifuge tube and then add 100 μl of cell suspension. Vortex for 5 sec at maximum speed. Spin briefly to collect lysate in bottom of tube. Freeze lysates at −70°C until analysis.

   Freeze-thawing of lysates is necessary in order to lower the background. At least 1 hr of freezing is required. Lysates can be stored frozen for at least 1 month.

3. Prepare three blank tubes as follows. To a 1.5-ml microcentrifuge tube, add 50 μl of 4 mg/ml BSA and 0.5 ml of K-SDS cell lysis solution. Vortex 5 sec at maximum speed, then microcentrifuge briefly to collect solution at bottom of tube. Freeze blanks at −70°C until analysis.

   Throughout the remaining steps of the assay, blanks and lysates should be treated in an identical manner.

Thaw lysates, shear DNA, and separate the protein-bound from the free DNA by precipitation

4. Thaw lysates in 37°C water bath and shear the DNA by passing the cell lysate four times through a 21-G needle, using a 3-ml syringe.

   Shearing of DNA assures uniform background measurements of DNA-protein cross-links. When performing this step, apply medium pressure to the syringe and avoid excess foaming of the lysate.

5. Add 0.5 ml of precipitation/washing solution. Vortex the tube at maximum speed for 5 sec, then heat in a 65°C water bath for 10 min.

   The optimal temperature of the water bath depends upon the test agent. Some DNA-protein cross-links formed by organic compounds are labile at higher temperatures (Costa et al., 1997).

6. Remove tubes from water bath and mix by inversion three times. Place on ice for 5 min to form potassium dodecyl sulfate (K-SDS) precipitates.

7. Collect the precipitate by centrifuging 6 min at 3300 × *g*, 4°C. Remove the supernatant by gently aspirating with a pipet and save in a sterile 15-ml centrifuge tube for future DNA quantitation.

   A swinging-bucket rotor is preferred for this step because it lowers background and improves the overall recovery of K-SDS precipitates. However, a fixed-angle rotor, spun at 6000 × g is satisfactory.

   Pouring off of the supernatant results in higher background during detection; hence aspiration is preferred.

Resuspend and wash the K-SDS precipitate

8. Resuspend the pellet in 1 ml of precipitation/washing solution and vortex at maximum speed for 3 sec.
9. Repeat the heating, tube inversion, and centrifugation, as described in steps 5 to 8, three times.
10. Pool the supernatants with that of step 7 above and store at 4°C.

    Final volume will be ~4 ml.

Release the protein-bound DNA from the K-SDS precipitate

11. Add 0.5 ml of proteinase K solution to the pellet.
12. Incubate the samples at 50°C for a minimum of 3 hr with occasional shaking.

    Overnight incubation is acceptable.

Reduce the SDS content of the solution by precipitation

13. Place samples on ice until precipitate forms (1 to 5 min). Add 50 µl of 4 mg/ml BSA to each tube, vortex, and place samples on ice for 30 min.
14. Centrifuge the tubes in a swinging bucket rotor 20 min at 3300 × *g*, at 4°C

    Alternatively, centrifugation may be performed for 10 min in a fixed-angle rotor at 12,000 × g, 4°C.

15. Gently aspirate 500 µl of the supernatant with a pipet, being careful not to disturb the K-SDS pellet, and transfer to a 12 × 75–mm borosilicate glass tube or to a tube or cuvette appropriate for the fluorometer.

    SDS interferes with the Hoechst 33258 assay.

Determine DNA concentrations of pooled supernatants from wash steps (total free DNA)

16. Prepare a 0.312 mg/ml solution of Hoechst 33258 dye by diluting a 1 mg/ml dye stock solution in 20 mM Tris·Cl, pH 7.5.

    Protect Hoechst dye from direct light. Perform all subsequent steps in dim light. Measure pH carefully; pH 7.5 is optimal.

17. Using a λ DNA solution of known concentration, prepare DNA standards (250, 500, 1000, 2500, 5000, and 10,000 ng/ml) in 20 mM Tris·Cl, pH 7.5.

    Choice of DNA is important. Always use standard DNA from the same source in each assay.

18. Centrifuge the tube containing the pooled supernatant 15 min at 1500 × *g* in a swinging-bucket rotor, 4°C.

    Centrifugation helps to remove residual SDS.

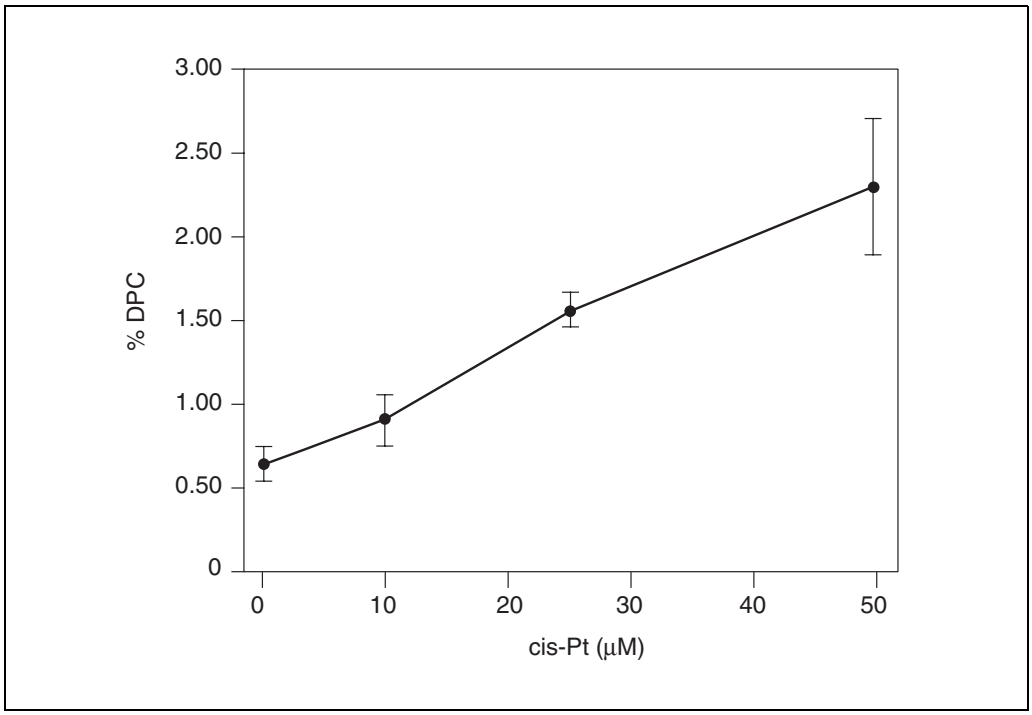

Figure 3.5.4 DNA-protein cross-links (mean ± std. dev.) induced by cis-platinum (cis-Pt; 16 hr) in EBV-transformed human Burkitt's lymphoma cells. From Costa et al. (1996). Reprinted with permission from Elsevier Science Publishers.

19. Mix (in duplicate) a 200-µl aliquot of the pooled supernatant with 0.8 ml of the Hoechst dye solution prepared in step 16. Also mix duplicate 200-µl aliquots of the BSA blanks and each of the standards with 0.8 ml of the Hoechst dye solution. Incubate 10 min in the dark.

    The final DNA concentration of the standards will be 50, 100, 200, 500, 1000, and 2000 ng/ml.

    In practice, the authors have found that it is possible to combine the pooled supernatants from all three triplicates (~12 ml) for total DNA determination. Do this only when it has been ascertained that the total amount of DNA among triplicates is similar. Perform total DNA determination in duplicate.

20. Set the excitation wavelength of the fluorometer to 365 nm and the emission wavelength to 450 to 460 nm. Read the fluorescence of the DNA standards, supernatant aliquots, and BSA blanks. Use the DNA standard curve to calculate the DNA concentration of the supernatant aliquot.

    A 96-well microtiter plate reader with appropriate filters also works well.

21. Calculate the amount of total DNA by multiplying the DNA concentration by the total volume of the pooled supernatant (~4 ml).

Determine DNA concentration in supernatant from proteinase K digest [DNA formerly cross-linked with protein (DPC)]

22. Prepare 300 ng/ml Hoechst dye in 20 mM Tris·Cl, pH 7.5.

23. Using a λ DNA solution of known concentration, prepare 100, 200, 400, 1000, 2000, and 4000 ng/ml DNA standards by diluting a 1 mg/ml stock in 20 mM Tris·Cl, pH 7.5.

24. Determine the amount of DNA formerly cross-linked to protein (DPC) by combining 0.5 ml of the supernatant from the proteinase K digestion step (step 15) with 0.5 ml

of the 300 ng/ml Hoechst fluorochrome solution. Incubate 10 min in dark. Treat blanks in an identical manner.

25. Add 0.5 ml of DNA standard to 0.5 ml of the 300 ng/ml Hoechst dye and incubate 10 min in the dark.

    The final DNA concentration of the standards will be 50, 100, 200, 500, 1000, and 2000 ng/ml.

26. Determine fluorescence, DNA concentration, and amount of cross-linked DNA as described previously for total DNA in steps 20 and 21. Correct for background fluorescence by subtracting blank measurements.

    If the standard curve is nonlinear at the high DNA concentrations or if the DPC samples exceed the highest DNA standard, repeat the DNA measurements the following day using a 250 ng/ml Hoechst dye concentration. Store the DNA samples at 4°C without light protection to quench the previously added Hoechst dye.

Calculate the DNA-protein cross-link (DPC) percentage

27. Calculate the percentage of the total DNA that was cross-linked with protein by dividing the amount of DPC DNA by the amount of total DNA and multiplying this quotient by 100.

    It is often appropriate to graphically express DPC percentage versus test agent dosage (see Fig. 3.5.4).

ALTERNATE PROTOCOL 8

USING A 96-WELL PLATE TO DETERMINE DNA CONCENTRATIONS FOR K-SDS PRECIPITATIONS

Using techniques similar to those in Basic Protocol 3, the DNA can also be quantified using Pico green dye in a 96-well plate assay.

Additional Materials *(also see Basic Protocol 3)*

Pico green (Molecular Probes)
TE buffer, pH 7.5: 10 mM Tris·Cl (*APPENDIX 2A*) containing 1 mM EDTA
1 mg/ml DNA stock solution

Polystyrene 96-well plates (Corning Costar no. 3603)
Phosphorimager or microtiter plate reader

1. Conduct the lysis, precipitation, washing, and proteinase digestion (see Basic Protocol 3, steps 1 to 15).
2. Prepare a 1:200 dilution of stock Pico green (Molecular Probes) dye in TE buffer, pH 7.5.

   Work in dim light.

   CAUTION: *Pico green is a DNA-binding agent and should be used with appropriate care.*

3. Prepare 0 to 50 ng/well λ DNA standards in 50 µl in a 96-well polystyrene plate.

   50 µl of a 1 µg/ml DNA stock solution equals 50 ng of DNA.

4. Pipet 5 µl of total DNA, or 50 µl DPC DNA or blank, into the appropriate wells of the plate.
5. Add 50 µl of Pico green dye (diluted as in step 2) to each well. Incubate at room temperature in dark for 10 min.
6. Use a phosphorimager or a microtiter plate reader to quantitate fluorescence.

   The excitation wavelength is 498 nm and the emission wavelength is 520 nm.

USING SLOT BLOTTING TO DETERMINE DNA AMOUNTS

The sensitivity of this technique for DNA-protein cross-link detection is greater than the aforementioned methods. Hence, it is useful when cell numbers are limited (1000 to 2000 cells) (Zhitkovich et al., 1998). The disadvantages are that radioactivity is used and that this method requires more time than the previously described methods.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the investigator and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Additional Materials *(also see Basic Protocol 3)*

5 M NaCl
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (prepared with buffered phenol; *UNIT 2.2*)
24:1 chloroform/isoamyl alcohol
DNA from test species
TE buffer, pH 8: 10 mM Tris·Cl, pH 8 (*APPENDIX 2A*) containing 1 mM EDTA
3 M NaOH
2 M ammonium acetate, pH 7
6× SSPE (see recipe for 10×)
Human Alu DNA or purified DNA from other species for use as a probe
Random priming kit (e.g., Prime-A-Gene Labeling System; Promega)
Prehybridization solution (see recipe)
2× and 0.1× SSC (see recipe for 20×)
2× SSC (see recipe for 20×) containing 1% (w/v) SDS

45° 65°, and 70°C water bath
Slot blot apparatus
UV transilluminator
Sephadex G-50 spin column
X-ray film

Additional reagents and equipment for DNA labeling with ^{32}P, purification of DNA probes, and autoradiography (*APPENDIX 3*)

1. Conduct cellular lysis, DNA shearing, K-SDS precipitation, proteinase K digestion, and removal of SDS (see Basic Protocol 3, steps 1 to 15).

   If the total cell number is <2 × 10^5 add 50 µl of BSA (2 mg BSA/ml) to the lysate, after shearing (step 4) but prior to K-SDS precipitation step (step 5).

Extract the DPC DNA

2. Transfer the supernatant from the proteinase K digestion step (0.5 ml) to a 1.5-ml microcentrifuge tube.

3. Add 25 µl of 5 M NaCl to 0.5 ml of the supernatant (200 mM NaCl, final). Add 0.5 ml of 25:24:1 phenol/chloroform/isoamyl alcohol. Do not shake. Heat 5 min at 45°C in water bath. Mix gently by inversion twice, then vortex. Micocentrifuge 5 min at maximum speed (≥10,000 rpm).

   CAUTION: *Phenol causes severe burns; use appropriate caution. Perform work in a fume hood and dispose of used phenol in a glass receptacle. Chloroform is a suspected human carcinogen.*

4. Collect aqueous (top) phase.

5. Add equal volume of 24:1 chloroform/isoamyl alcohol. Vortex. Microcentrifuge 5 min at maximum speed.
6. Collect aqueous phase.

   Final volumes from each sample should be consistent. Henceforth, this fraction will be referred to as DPC DNA.

Denature and neutralize DPC DNA and DNA standards

7. Prepare DNA standards at 2, 4, 10, 20, 40, 100, and 200 ng DNA/ml.

   The source of the DNA should match that of the test species.

8. Mix 50 µl of DPC DNA or DNA standard with 130 µl of TE buffer, pH 8, and 20 µl of 3 M NaOH.

   More DPC DNA (up to 100 µl) can be loaded if the hybridization signal is too weak. Conversely, less DPC DNA should be loaded if the signal is too strong. Final total reaction volume should always equal 200 µl.

9. Heat in 70°C water bath for 1 hr.
10. Add an equal volume (i.e., 200 µl) of 2 M ammonium acetate, pH 7.

Load samples into slot blot apparatus

11. Follow manufacturer's protocol for loading samples into slot blot apparatus.

    The authors have found that a Nytran 0.45-µm membrane (Schleicher and Schuell) works well.

12. Cross-link the DNA to the membrane with UV radiation.
13. Soak membrane in 6× SSPE 15 min at room temperature.

Make DNA probe

14. If human DNA is tested, label *Alu* DNA with ^{32}P, using a random-priming kit. For other species, label purified DNA for use as a probe. Purify the probe from the unincorporated labeled deoxynucleotide using a Sephadex G-50 spin column.

    Purification of the probe with a Sephadex G-50 spin column is required.

Hybridize probe and DPC DNA

15. Prehybridize the membrane in prehybridization solution for 2 hr at 65°C.
16. Denature probe by boiling for 10 min.
17. Keep membrane in prehybridization solution and add probe to a final concentration of 2×10^6 cpm/ml.
18. Hybridize overnight at 65°C.
19. Wash membrane with 2× SSC for 5 min at 65°C. Repeat once. Wash membrane once with 2× SSC/1% SDS for 30 min at 65°C. Wash membrane once with 0.1× SSC for 15 min at room temperature.

Quantify the amount of DPC DNA

20. Dry membrane and expose to X-ray film (autoradiography; *APPENDIX 3*).

    Exposure time will depend upon the amount of DNA on the filter and the strength of the probe.

21. Quantify the bands with densitometry.

Determine the amount of total DNA in the cell lysates

22. Remove 0.5 ml of the pooled supernatants from the wash steps (see Basic Protocol 3, step 10) and extract the DNA with phenol/chloroform as described above for DPC DNA (steps 3 to 6 in this protocol).

    In practice, the authors have found that it is possible to combine the pooled supernatants from all three triplicates (~12 ml) for total DNA determination. Do this only when it has been ascertained that the total amount of DNA among triplicates is similar. Perform total DNA determination in duplicate.

23. Mix 5 µl of purified total DNA with 175 µl of TE buffer, pH 8, and 20 µl of 3 M NaOH. Mix 50 µl of DNA standard with 130 µl of TE buffer, pH 8, and 20 µl of 3 M NaOH.

24. Heat in 70°C water bath for 1 hr.

25. Repeat steps 10 to 21, except use supernatant DNA.

26. Determine the DPC coefficient by dividing the amount of DPC DNA by the amount of total DNA. Express as a percentage.

DETECTION OF DNA REPAIR USING THE UNSCHEDULED DNA SYNTHESIS (UDS) ASSAY

BASIC PROTOCOL 4

This assay indirectly measures DNA damage by quantitating the amount of DNA synthesis that occurs in cells that are not undergoing normal S-phase DNA replication. This type of DNA synthesis has been termed "unscheduled DNA synthesis" (UDS) and is a component of DNA repair. This protocol describes how to prepare a primary hepatocyte culture and measure UDS by determining the degree of [^{3}H]thymidine incorporation into nuclear DNA following treatment with test agents. Williams (1976) was the first to describe this assay for screening xenobiotics, and it has been subsequently modified by others. This protocol is based upon that of Dean (1995).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male 200 to 250 g Fisher 344 rats (Charles River Laboratories, Harlan Sprague-Dawley)
General anesthetic (e.g., sodium pentobarbital)
70% and 90% (v/v) and absolute ethanol
Liver perfusion buffer 1 (see recipe)
Liver perfusion buffer 2 (see recipe)
Collagenase A
769 mM $CaCl_2$
Williams medium E-complete medium (WE-C medium; see recipe)
Williams medium E-incomplete medium (WE-I medium; see recipe)
0.4% (w/v) trypan blue stain
1 mCi/ml [^{3}H]thymidine
Phosphate-buffered saline (PBS; see recipe)
1:3 (v/v) glacial acetic acid/absolute ethanol, freshly prepared
Permount mounting medium (Fisher)
Glycerol
Kodak NTB-2 autoradiography emulsion

continued

Desiccant (e.g., silica gel or Drierite)
Kodak D19 developer
Kodak Fixer
Mayers hemalum stain (see recipe)
1% (w/v) aqueous eosin Y
Xylene

Sterile cotton surgical gauze
Dissection scissors
Suture thread
18-G and 14-G catheters
Surgical tubing ~3 mm o.d. (suitable for a peristaltic pump, e.g., high-pressure tubing with male and female Luer-Lok connectors; Harvard Apparatus)
Variable-flow peristaltic pump
6-well multi-well plates or 30-mm Petri dishes, sterile
Cheesecloth or gauze, sterile
50-ml plastic centrifuge tubes, sterile
Sterile glass beaker
Hemacytometer
Microscope with 100× objective interfaced to a colony counter
25-mm-diameter round plastic coverslips, sterile (e.g., Thermanox; Fisher)
Microscope slides
50-ml plastic graduated cylinders cut to 30-ml mark
43°C water bath
Plastic teaspoons
Light-proof slide boxes
Staining troughs
22 × 50–mm glass coverslips

Additional reagents and equipment for counting cells and assessing viability with trypan blue (*APPENDIX 3B*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Anesthetize rat and perfuse the liver

1. Anesthetize rat with a dose of general anesthetic that is incompatible with recovery (e.g., 60 mg/kg sodium pentobarbital administered by intraperitoneal injection). Check reflex actions of rat (i.e., tail and toe pinch) before beginning surgery.
2. Disinfect the abdominal surface by swabbing with 70% ethanol.

   Perform perfusion as aseptically as possible.
3. Make a V-shaped incision through skin and muscle from the center of lower abdomen to the lateral aspects of the rib cage.
4. Clamp the inferior vena cava proximal to the renal vein.
5. Secure a loose ligature around the hepatic portal vein and cannulate the vein with a 18-G catheter. After the catheter is in place, remove the inner needle and tighten the ligature.

6. Cut through the diaphragm muscle and remove the ventral portion of the rib cage. Locate the superior vena cava distal to the heart and tie a loose ligature. Cannulate the vena cava with a 14-G catheter, remove the inner needle, and tighten the ligature.
7. Sterilize the surgical tubing by flushing twice with 70% ethanol, followed by sterile water. Connect the tubing to the portal vein catheter, taking care to avoid air bubbles.
8. Connect the portal vein catheter to a peristaltic pump. Connect the superior vena cava catheter to a waste line.

   It is useful to outfit the line with a three-way valve so that perfusion buffers can be switched. This way separate reservoirs for buffer 1 and buffer 2 can be used.
9. Perfuse the liver for 10 min with 400 ml of liver perfusion buffer 1 at 40 ml/min. Keep the perfusion buffer in a 37°C water bath.

   As the blood drains, the liver should turn tan in color and lobes should clear equally. If not, gently massage the liver or reposition the portal vein catheter.
10. Place 400 ml of perfusion buffer 2 in the reservoir attached to the perfusion pump. Perfuse the liver for 5 min with liver perfusion buffer 2 at 40 ml/min, until 200 ml of the buffer has been pumped. Keep the perfusion buffer 2 in a 37°C water bath.
11. While the perfusion in step 10 is in progress, dissolve 75 U (50 mg) of collagenase A in 1 ml of 769 mM $CaCl_2$, sterile filter, and add to 10 ml of liver perfusion buffer 2. Pour this solution into the remaining 200 ml of liver perfusion buffer 2 in the reservoir and perfuse the liver for ~1 min. When the dark red color of the collagenase preparation reaches the liver, move the waste line to the buffer 2 reservoir so that the solution recirculates. Reduce the flow rate of the pump to ~20 ml/min.
12. When the liver becomes spongy (10 to 15 min), stop the perfusion. Remove the liver from the body cavity and place it in a beaker containing 10 ml of the recirculated buffer 2.

Prepare primary hepatocyte culture

13. Warm WE-C medium in a 37°C water bath.

    Continue to work aseptically and prepare the primary hepatocyte culture under a laminar flow hood.
14. Move the liver to a sterile, plastic Petri dish and cut open the capsule. Gently tease out the hepatocytes with a forceps or round-tooth stainless steel comb.
15. Filter the hepatocytes through several layers of sterile cheesecloth or a four-ply layer of sterile gauze into a sterile glass beaker. Wash the residue with 120 ml of WE-C. Decant 40 ml of filtrate into three sterile 50-ml centrifuge tubes.
16. Centrifuge at 40 × *g* for 3 min at room temperature to bring down the hepatocytes. Aspirate the supernatant and resuspend the pellets in 20 ml of WE-C.
17. Centrifuge at 40 × *g* for 3 min at room temperature. Repeat the resuspension and centrifugation steps once more.
18. Combine the three pellets in 50 ml of WE-C.
19. Pipet 0.5 ml of the hepatocyte preparation into a 1.5-ml microcentrifuge tube. Add 0.5 ml of 0.4% trypan blue stain (*APPENDIX 3B*).
20. Apply 10 µl to a hemacytometer and count the viable (yellow) and non-viable (blue) cells. Calculate the viability percentage.

    Viability should be >70%.

21. Place a 25-mm sterile round plastic coverslip in each well or dish for cell attachment. Plate the hepatocytes into 6-well plates or 30-mm dishes at a density of 1.5×10^5 viable cells/ml at 3 ml of culture per well or dish. Press down gently on the coverslip. Stir cells gently to evenly distribute them over the coverslip.

    Thermanox coverslips are treated on one side for cell attachment. Be sure to place the coverslips in the correct orientation (i.e., coated-side-up) in the wells.

    Prepare three coverslips per dose, and for the negative and positive controls. Also prepare an additional three coverslips for each treatment for cell viability testing.

22. Place the plates in a 5% CO_2 incubator at 37°C. Allow cells to attach for 1.5 hr, then aspirate unattached cells and add 2 ml of 37°C WE-I medium to each of the plates or wells.

    Incubate for an additional 24 hr to allow for recovery of membrane function and cellular glutathione levels (Parton et al., 1995).

Treat hepatocyte culture with test agent and label cells with ^3H

23. Prepare test agent in appropriate solvent.

    Culture medium is appropriate for water-soluble agents unless they bind to components of the medium. Dimethy sulfoxide (DMSO) is often used for water-insoluble compounds. Solvent concentration should be ≤1% (v/v) of the growth medium to avoid cytotoxicity or induction of UDS by the solvent (Mitchell et al., 1983).

    Dosages are based upon cytotoxicity. Use the lowest cytotoxic dose (or the highest soluble concentration if nontoxic) and scale down. Test at least five concentrations, encompassing at least a 2-log range (Mitchell et al., 1983).

    2-Acetamidofluorene (2-AAF; 0.25 and 0.50 mg/ml) is frequently used as a positive control test agent.

24. Add sufficient 1 mCi/ml [^{3}H]thymidine stock solution to the medium containing the test agent to achieve a final concentration of 10 μCi/ml.

    When preparing mixtures, use normal radiochemical safety precautions.

25. Remove medium from hepatocyte cultures. Wash each cell monolayer with 2 ml of 37°C WE-I.

26. Dispense 2 ml of each test agent/[^{3}H] thymidine mixture into the corresponding plate or well. Treat the cultures designated for viability testing with the test agent only (i.e., no [^{3}H]-thymidine).

27. Incubate cultures for ≥16 hr at 37°C.

    If cytoplasmic background counts are unacceptably high, shorten the incubation period.

Assess cell viability using trypan blue exclusion test

28. From each plate or well that was designated for cell viability testing, remove 1 ml of medium. Add 1 ml of 0.4% trypan blue to the plate. Incubate for 5 min.

29. Aspirate the trypan blue/medium mixture and replace with 2 ml of PBS. Aspirate PBS to rinse plate.

30. Use an inverted microscope fitted with a graticule to view slides. Score four areas for viable (unstained) and nonviable cells (stained blue). Calculate the viability percentage for each dose and compare to the vehicle control.

    A rapid and easy alternative is the neutral red (NR) assay described by Fautz et al. (1991).

Fix cells and attach coverslips to microscope slides

31. Remove medium from wells/dishes (and dispose of radioactive waste properly). Rinse coverslips with 2 ml PBS. Add 2 ml of a freshly prepared 1:3 glacial acetic acid/absolute ethanol to each and wait 10 min. Repeat the application of the acetic acid/ethanol mixture twice more.

    Before fixation, the cells can be chased overnight with unlabeled 0.25 mM thymidine in WE-I (Hamilton and Mirsalis, 1987).

    Alternatively, one 30-min fixation step (with 1:3 glacial acetic acid/absolute ethanol) can be substituted to lessen loss of attached cells due to washing.

    Before fixation, 1% (w/v) sodium citrate can be applied to the cells to enhance swelling of the hepatocytes, which facilitates scoring of UDS (Hamilton and Mirsalis, 1987). However, Parton et al. (1995) reported that this practice ruptured large hepatocytes and contributed to high background grain counts.

32. Wash wells/dishes with distilled or deionized water four times. Retrieve the coverslips and air dry.

33. When dry, mount the coverslips (cell-side-up) onto labeled microscope slides ~1 cm from one edge, using Permount mounting medium.

34. Leave slides flat for a few hours (or overnight) in a dust-free area (e.g., plastic box with lid) until mounting medium sets.

Apply photoemulsion to slides

35. Dispense 12 ml of deionized or distilled water into 50-ml graduated cylinder cut off at the 30-ml mark. Add 0.5 ml of glycerol and place the cylinder in a 43°C water bath.

    IMPORTANT NOTE: *Perform this and all following steps in a darkroom under safelight conditions (Kodak safelight filter no. 2).*

36. Into a second cut-off cylinder, use a plastic teaspoon to transfer enough NTB-2 emulsion to reach the 20-ml mark.

    Fresh emulsion (not older than 3 months) gives the best results.

37. Place this cylinder in the 43°C water bath for 10 min to melt the emulsion. Stir occasionally with a plastic utensil, avoiding air bubbles.

38. Pour the molten emulsion into the cylinder containing the water/glycerol mixture until the 25-ml mark is reached. Return the cylinder to the water bath for 2 min and stir gently with a plastic implement. Remove air bubbles, if present, by skimming the surface with a glass microscope slide.

39. Remove emulsion from water bath. Keeping slides vertical, dip into emulsion and withdraw slowly and steadily to achieve an even coating. Hold the slides vertically for 2 sec and blot the emulsion off of the bottom of the slides.

40. Place each slide on a metal tray set on ice for 10 min to solidify emulsion.

41. Place slides in light-proof slide boxes and dry for at least 90 min at room temperature.

42. Add a dessicant (e.g., silica gel or Drierite) to each box. Seal the edges of the box with black electrical tape and wrap each box in aluminum foil. Label the box with name and date.

    A false-bottomed box containing Drierite works well. Alternatively, silica gel can be smeared on a clean microscope slide and placed at the end of the slide box.

Develop and stain exposed slides

43. Immerse each slide successively for the time indicated in staining troughs containing the following solutions:

    5 min in 1:1 (v/v) Kodak D19 developer/distilled water (19° to 21°C)
    1 min in distilled water
    5 min in 1:3 (v/v) Kodak fixer/distilled water
    10 min in tap water
    3 min in Mayer's hemalum stain (or until nuclei are pale blue)
    1 min in tap water until nuclei are pale blue
    1.5 min in 1% aqueous eosin Y
    2 min in tap water
    2 min in 70% ethanol
    2 min in 90% ethanol
    2 min in absolute ethanol
    2 min in (fresh) absolute ethanol
    3 min in xylene
    3 min in (fresh) xylene

    Other stains that have been used are methyl green Pyronin Y, or Giesma.

    Use a razor blade to scrape stain/emulsion off bottom of slides if necessary.

44. Mount coverslips onto the cell preparations using Permount mounting medium.

Score slides for UDS

45. Place the slide under a microscope. Score only morphologically normal cells. Do not score the heavily labeled S-phase cells. Do not score the same cell more than once.

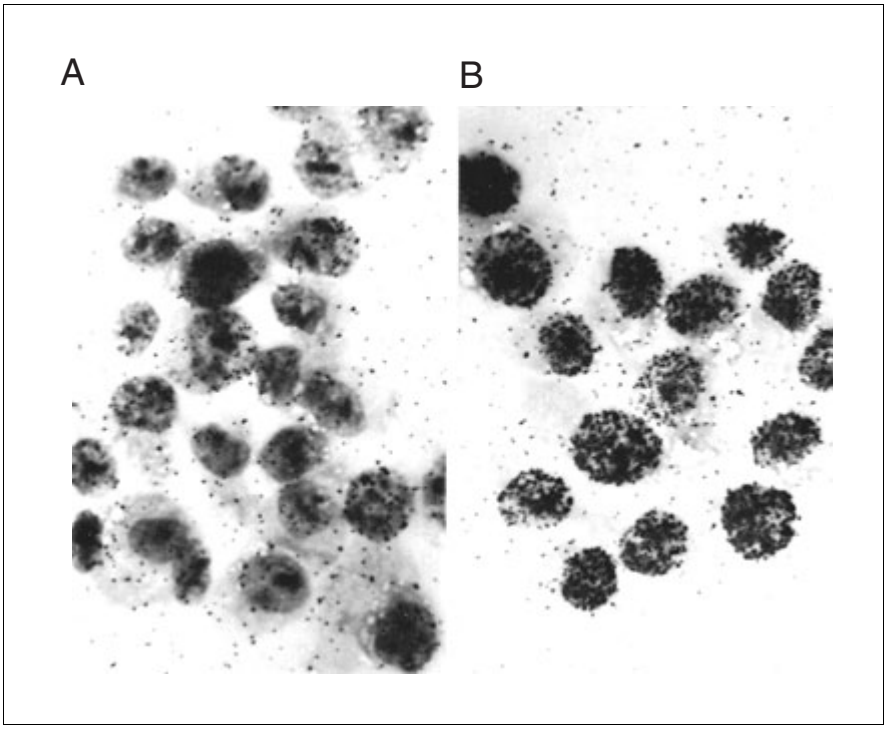

Figure 3.5.5 Unscheduled DNA synthesis (UDS) in human amnion (AV_3) cells following culture in arginine-deficient medium, treatment with 5 mM hydroxyurea (1 hr), irradiation with 254 nm ultraviolet light and exposure to [^{3}H]TdR (5 μCi/ml medium; 2 or 4 hr). (**A**) Control (unirradiated) cells pulsed for 4 hr. (**B**) Cells irradiated with 15 ergs/mm^2 and pulsed for 2 hr. From Trosko and Yager (1974); reprinted with permission from Academic Press.

Perform grain counting manually using an appropriate graticule; this is greatly facilitated by use of an automated system (e.g., a colony counter interfaced to the microscope). Count the number of grains over the nucleus and over one or more nuclear-sized areas of adjacent cytoplasm. Score 50 cells on each of the three slides for each treatment/concentration in a blind manner (see Fig 3.5.5).

Harbach et al. (1991) evaluated four different scoring methods for UDS. Hill et al. (1989) described a whole-cell counting method designed to eliminate the subjectivity of choosing the areas to be quantitated for cytoplasmic grain counts.

46. Calculate the net nuclear grain count by subtracting the mean cytoplasmic grain count from the total nuclear grain count.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline electrophoresis buffer

0.1% (w/v) 8-hydroxyquinoline
10 mM disodium EDTA, pH 10
2% (v/v) dimethyl sulfoxide (DMSO)
300 mM NaOH
Store up to 3 months at room temperature

The pH of the alkaline electrophoretic buffer is highly variable (pH 9 to 13) among laboratories.

Alkaline elution solution, pH 12.3

0.1% (w/v) sodium dodecyl sulfate
20 mM tetrasodium EDTA
0.8% tetrapropylammonium hydroxide
Adjust pH to 12.3 with 20% (w/v) tetrapropylammonium hydroxide in water
Store up to 3 months at room temperature

Alkaline lysis solution, pH 10

2.5 M NaCl
100 mM disodium EDTA
10 mM Tris·Cl, pH 10
1% (v/v) Triton X-100
1% (w/v) laurylsarcosine, sodium salt (optional)
10% (v/v) dimethylsulfoxide, (add just before use; optional)
Store up to 6 months at room temperature

Cell lysis solution, pH 9.7

2% (w/v) sodium dodecyl sulfate (SDS)
0.025 M disodium EDTA
0.1 M glycine (optional)
Adjust pH to 9.7 with 1 N NaOH
Store up to 6 months at room temperature

K-SDS cell lysis solution

1% (w/v) SDS
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM PMSF (add just before use)
Store up to 6 months at room temperature

Liver perfusion buffer 1

150 mM NaCl
3.73 mM $NaHCO_3$
4.84 mM Na_2HPO_4
4.97 mM KCl
1.24 mM KH_2PO_4
0.62 mM $MgSO_4$
0.62 mM $MgCl_2$
10 µg/ml phenol red
Sterile filter
Store up to 3 months at 4°C

Liver perfusion buffer 2

142 mM NaCl
24 mM $NaHCO_3$
4.37 mM KCl
1.24 mM KH_2PO_4
0.62 mM $MgSO_4$
0.62 mM $MgCl_2$
10 µg/ml phenol red
Sterile filter
Store up to 3 months at 4°C

Mayer's hemalum stain

1 g hematoxylin (dissolve with warming in 800 ml distilled H_2O)
50 g aluminum ammonium dodecahydrate (ammonium alum)
0.2 g sodium iodate
1 g citric acid
50 g chloral hydrate
H_2O to 1 liter
Store up to 6 months at room temperature

Neutral lysis solution, pH 8.3

0.5% (w/v) sodium dodecyl sulfate (SDS)
30 mM EDTA
Adjust pH to 8.3 with 1 N NaOH
Store up to 6 months at room temperature

Phosphate-buffered saline (PBS)

137 mM NaCl
2.7 mM KCl
4.3 mM $Na_2HPO_4 \cdot 7H_2O$
1.4 mM KH_2PO_4
Store up to 1 month at 4°C

Precipitation/washing solution

100 mM KCl
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Store up to 6 months at room temperature

Prehybridization solution

6× SSPE (see recipe) containing:
1% (w/v) SDS
100 µg/ml salmon sperm DNA (boiled for 10 min and added just before use)
Prepare fresh

Proteinase K solution (for Basic Protocol 3)

100 mM KCl
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM EDTA
0.2 mg/ml proteinase K
Prepare fresh

SSC, 20×

3 M NaCl
0.3 M trisodium citrate·dihydrate
Store up to 6 months at room temperature

SSPE, 10×

1.8 M NaCl
100 mM NaH_2PO_4
100 mM disodium EDTA
Adjust to pH 7.4 with 1 N NaOH
Store up to 6 months at room temperature

Williams medium E-complete (WE-C)

Prepare Williams medium E-incomplete (see recipe) containing 10% fetal bovine serum. Store up to 6 months at 4°C.

Williams medium E-incomplete (WE-I)

Williams medium E (Life Technologies) containing
4 mM L-glutamine
100 µg/ml gentamycin
Store up to 6 months at 4°C.

COMMENTARY

Background Information

Microgel electrophoresis assay

Single-cell microgel electrophoresis (i.e., the comet assay; see Basic Protocol 1 and Alternate Protocol 1) is a simple, rapid, and sensitive technique for quantitating DNA strand breakage in individual cells. Cells are embedded in agarose on a microscope slide and are then permeabilized with detergent and treated with high salt to extract cellular proteins. The resulting "nucleoids" contain supercoiled DNA. If the DNA has been damaged, relaxation of the supercoiled DNA occurs, and, upon electrophoresis, the relaxed loops and broken DNA fragments will migrate toward the anode. Undamaged DNA remains trapped within the nucleoid. This creates a comet-like pattern of DNA when visualized with fluorescence microscopy.

This technique was first introduced by Ostling and Johanson (1984) who assessed DNA damage in irradiated cells. Their work was conducted at near-neutral pH. Because neutral pH does not permit much DNA strand separation, the assay was more sensitive to double rather than single DNA strand damage. Singh et al. (1988) modified the assay by using alkaline (pH 13) electrophoretic conditions, which disrupted base pairing and allowed for DNA strand separation (unwinding) and hence more sensitive detection of single-strand breakage. As a result, alkaline comet assays are sensitive to both double- and single-strand breakage, including the indirect single-strand breaks produced at alkaline-labile apurinic (AP) sites. Moreover, DNA strand breakage that occurs during DNA excision repair can be detected.

Since its introduction, numerous refinements to the assay have been published. Major adaptations have included the use of increasingly sensitive fluorescent DNA stains (Singh et al. 1994); addition of free-radical scavengers to the electrophoresis solution (Singh et al., 1994); inclusion of DNA repair enzymes (Collins et al., 1997); use of repair-deficient cell lines (Helbig and Speit, 1997) or repair inhibi-

tors; design of cell-free assays (Kasamatsu et al., 1996); and improved quantitation of DNA damage (Olive, 1989; Olive et al., 1990) via use of image analysis software (McKelvey-Martin et al., 1993).

Many other techniques exist for detecting DNA strand breakage. In the nucleoid sedimentation assay, the extent of DNA unwinding, reflecting the amount of strand breakage, is measured by the rate of sedimentation (Cook and Brazell, 1975). Sucrose sedimentation separates different sizes of DNA fragments along a sucrose gradient (McGrath and Williams, 1966). Pulsed-gel electrophoresis is based upon the assumption that intact mammalian chromosomes are too large to enter a gel. The amount of DNA that enters the gel will reflect the degree of DNA double-strand breakage (Elia et al., 1994). DNA precipitation assays rely upon the centrifugal separation of intact and broken DNA (Olive et al., 1988). Filter elution assays measure the rate of DNA elution through a filter; elution rates are proportional to the number of strand breaks (Kohn et al., 1981). In these procedures, neutral and alkaline pH conditions are employed for the detection of double- and single-strand breaks, respectively.

The comet assay has several advantages over those above. Data are collected for individual cells; therefore variability within a given cell population can be evaluated. In contrast, the other techniques only provide information regarding the average number of DNA strand breaks per cell. In addition, the comet assay requires viable cells, but because no radioactive labeling is required, cell growth is not required. Hence, the comet assay can be applied to most eukaryotic cell populations and only a few thousand cells are required. Moreover, the sensitivity of the comet assay is comparable to or greater than the sensitivity of other assays for DNA strand breakage (Olive et al., 1990; Singh et al., 1994; Singh, 1996). However, the sensitivity of the assay for detection of double-strand breaks has been questioned (Helbig and Speit, 1997).

The use of the comet assay for genotoxicity testing has increased steadily since its introduction in 1988. Henderson et al. (1998) provide a current list of agents that have been evaluated with the comet assay during genotoxicity screening. A particular strength of this assay for genotoxicity assessment is that it can be employed both in vitro and ex vivo. The latter route is especially useful because genotoxicty in a variety of target organs can be assessed. In addition to agents that directly damage DNA, other lesions such as DNA-DNA and DNA-protein cross-links can be detected using the comet assay. Pfuhler and Wolf (1996) reported that cis-platinum, mitomycin C, and formaldehyde reduced the migration of methyl methanesulfonate–damaged DNA in the comet assay, presumably because cross-linking retarded DNA migration.

A major drawback of using the comet assay for genotoxicity testing is that it lacks rigorous validation. Each investigator who has performed the assay has used a unique set of experimental conditions and scoring criteria. The effects of different protocol factors (cell type, lysis and electrophoretic conditions, and exposure times) on the overall outcome of the assay are poorly understood. Several investigators have pointed out the need for further validation in this area (Ross et al., 1995; Anderson and Plewa, 1998; Henderson et al., 1998). It is also imperative that investigators clearly detail their experimental conditions so that the results of assays can be reproduced and compared between laboratories (Ross et al., 1995).

Results from comet assays must also be cautiously interpreted both in terms of the nature of the DNA breakage that is revealed and the relationship of that damage to mutagenesis. Single-strand breakage occurs transiently during base or nucleotide excision repair. Accordingly, Collins et al. (1997) suggested that high levels of DNA strand breakage in the comet assay indicate either high damage or efficient DNA repair processes. For example, Speit et al. (1996) reported that the mutagen, benzo[a]pyrene and its reactive metabolite, (+)-anti-benzo[a] pyrene-7,8-diol 9,10-oxide were genotoxic in the comet assay, yet were only marginally mutagenic to the HPRT gene in human (MRC5CV1) cells presumably because most of the detected strand breakage represented excision repair activity.

On the other hand, the comet assay has been modified in order to exploit the process of DNA repair to reveal DNA lesions that would have gone undetected in traditional comet assays. Exogenous lesion-specific repair enzymes have been used to detect AP sites formed following DNA alkylation damage (Fortini et al., 1996), 8-0H, dG, and UV radiation-induced cyclobutane pyrimidine dimers (Collins et al., 1997). In a somewhat analogous approach, DNA repair synthesis inhibitors have been added to impede DNA ligation following excision (Gedik et al., 1992).

A final caveat to consider when interpreting comet assay results is the effect of cytotoxicity or apoptosis on the assay. DNA strand breakage occurs in necrotic and apoptotic cells. It is, therefore, important to distinguish between direct genotoxicity and DNA damage secondary to cytotoxicity or apoptosis.

Filter elution assay

The alkaline elution technique, introduced by Kohn and Ewig (1973), measures DNA single-strand breakage. Cells treated with the test agent are placed on a polycarbonate filter and lysed with detergent and proteinase. The lysate is then eluted with an alkaline buffer (pH = 12). At this pH, the double-stranded DNA molecules denature, and short broken fragments of single-stranded DNA are eluted whereas the intact longer fragments are retained on the filter. The DNA in the eluted fractions and that retained on the filter are quantified by scintillation counting if cells have been labeled prior to the experiment, or by fluorometry. To control for anomalies in the procedure, an internal standard, composed of cells labeled differently than the test cells, is often included. Most often, a defined number of single-strand breaks are introduced into the internal standard cells by X-irradiation and the elution profiles of the test cells and the standard cells are compared (Kohn et al., 1981).

The assay has been modified to detect other types of DNA damage. Interstrand linkage impedes passage of DNA through the filter. Treated and control cells are X-irradiated and then alkaline eluted. If significant interstrand linkage has been caused by the test agent, more DNA will be retained on the filter than in the control cells (Kohn, 1991).

In a similar manner, DNA-protein cross-links impede passage of DNA through a filter and can be measured using the technique described above for interstrand linkage, with the following modifications. Proteinase K digestion is omitted from the assay, and a polyvinyl chloride filter (better at retaining protein than polycarbonate) is used (Kohn, 1981). It is also instructive to run assays with and without proteinase K and compare the elution profiles.

Another lesion that can be detected with a modified alkaline elution assay is oxidative DNA base damage. These lesions are normally removed by intracellular repair endonucleases via excision repair, which results in transient single-strand breakage. To measure the formation of these damaged bases, exogenous bacterial repair enzymes are added to the assay following lysis. If the test agent has caused significant oxidative base damage, more strand breakage should result and hence less DNA should be retained on the filter compared to cells that did not undergo endonuclease treatment (Pflaum et al., 1997).

Finally, the technique has been adapted to detect primarily double-strand DNA breakage. Even though this assay is conducted at alkaline pH (9.6), it is referred to as "neutral" filter elution because this pH is nondenaturing to DNA molecules. Hence, the DNA present in the eluted fractions must have arisen from double-stranded DNA breakage (Elia et al., 1991). Bradley and Kohn (1979) first used neutral filter elution to measure double-strand breaks in mouse cells treated with X rays, bleomycin, and hydrogen peroxide (H_2O_2). Elia et al. (1991) provides a list of agents tested with the neutral elution filter method.

Advantages of the filter DNA elution are experimental reproducibility, sensitivity, and simplicity. The primary disadvantage is that populations of cells are tested, so intercell susceptibility to the test agent cannot be assessed. If the traditional method is used, only a limited number of samples can be processed effectively in one assay. Additionally, the assay is fairly time consuming.

K-SDS precipitation assay

A number of agents (e.g., γ and UV radiation, formaldehyde, cis-platinum, chromate, and nickel) induce covalent DNA-protein cross-linking (Costa, 1990). Such damage may be genotoxic if DNA replication is impaired resulting in deletions, and/or carcinogenesis if these deletions occur in tumor suppressor genes.

The K-SDS precipitation assay described here is a simple, sensitive, rapid, and inexpensive method for detecting DNA-protein cross-links. It was introduced by Muller (1983) and Liu et al. (1983) to examine DNA-topoisomerase complexes and modified by Zhitkovich and Costa (1992). SDS-resistant DNA/protein complexes form insoluble precipitates with potassium and can be separated from free DNA by low-speed centrifugation. By measurement of the free DNA in the supernatant, the total amount of DNA in the lysed cells can be quantified. The amount of DNA cross-linked to protein is determined by measuring the DNA liberated from the K-SDS/protein/DNA precipitate following proteinase K digestion. The

assay has been validated in several independent laboratories (Costa et al., 1996), and normal values of DNA-protein cross-links in lymphocytes of healthy human controls have been established (Taioli et al., 1995). The detection limit for DNA-protein cross-links is ~1 lesion per 1 to 2×10^7 bases (Zhitkovich et al., 1998).

Other approaches exist for detection of DNA-protein cross-links. Alkaline filter elution assays have been frequently used (Kohn et al., 1981). This method only indirectly measures DNA-protein cross-links by quantitating the reduction in elution rates of DNA fragments caused by cross-linkage with protein. It is also time-consuming, and a limited number of samples can be processed at one time. Another potential disadvantage is that the cell lysis conditions employed may not be sufficiently stringent to dissociate all non-covalent protein/DNA complexes (Zhitkovich and Costa, 1992). The filter-binding technique (Chiu et al., 1984) also may be impaired by insufficient stringency of lysis solutions. In addition, sensitivity is relatively low (i.e., high doses of cross-linking agents are necessary), and the biochemical nature of the interaction between the filter and the DNA/protein complexes is not well understood (Zhitkovich and Costa, 1992). Other investigators have used time-consuming ultracentrifugation to isolate DNA/protein complexes (Wedrychowski et al., 1985). It is also possible to raise antibodies against DNA/protein complexes and then use immunological assays to detect these complexes in cell lysates (Wedrychowski et al., 1985; Miller and Costa, 1989; see *UNIT 2.3*). This method is both time and labor intensive and is not generally applicable because the proteins that complex with DNA are dependent upon the test agent used, thus affecting the antigenicity of the DNA/protein complexes.

K-SDS precipitation can be used for genotoxicity testing in vitro, ex vivo, or for biomonitoring purposes in human populations. This assay has been used to measure DNA protein cross-links in leukocytes of rats and mice exposed to intraperitoneal chromate; in leukocytes of humans following chromate ingestion; in peripheral lymphocytes from cancer patients treated with cis-platinum; in residents of a chromium-contaminated area; in welders; and in chrome platers. Cultured cells exposed to chromate, cis-platinum, copper, lead, cadmium, or arsenic, or to acetaldehyde, acrolein, diepoxybutane, paraformaldehyde, 2-furaldehyde, propionaldehyde, chloroacetaldehyde, sodium arsenite, or tris(hydroxymethyl) nitromethane have also been assayed for DNA-protein cross-links with this assay (reviewed by Zhitkovich et al., 1998).

Unscheduled DNA synthesis assay

Rasmussen and Painter (1966) demonstrated that mammalian cells that were not undergoing normal S-phase DNA synthesis incorporated thymidine following ultraviolet irradiation. Accordingly, this event has been termed unscheduled DNA synthesis (UDS) and is a component of excision repair of damaged DNA. Hence, UDS assays detect DNA repair following damage by a physical or chemical agent; these assays have been used to assess the genotoxicity of a number of chemicals (Mitchell et al., 1983; Williams et al., 1989), and there are several published guidelines for genotoxicity screening (Mitchell et al., 1983; Swierenga et al., 1991; Madle et al., 1994).

There are two approaches to assessing UDS. The first is to conduct the assay solely in vitro with cultured cells. Alternatively, animals can be dosed in vivo and UDS subsequently measured in cells collected from the tissue of choice. Madle et al. (1994) provide guidelines concerning in vivo assays and a list of compounds that have been evaluated with this approach.

Hepatocytes are the cells usually chosen for in vitro UDS assays, for several reasons. These cells are easy to obtain and to culture and also retain the metabolic enzymes that activate most pro-carcinogenic and pro-mutagenic precursors into their ultimately DNA-damaging forms. Moreover, drug-metabolizing enzymes are also present; therefore, hepatocytes are an appropriate model for processes that occur in the liver in vivo. This is particularly true for males, so hepatocytes from male (particularly Fischer-344) rats have been the most frequently used in in vitro UDS assays. However, tests with females are sometimes more appropriate, depending upon the nature of the test agent. An additional advantage is that in primary hepatocyte cultures, only a small proportion of the cells undergo S-phase DNA synthesis, making the detection of UDS a relatively simple process. Recently, UDS assays have been conducted on hepatocytes obtained from human surgical samples (Brambilla and Martelli, 1995).

Other cell types are sometimes used for in vitro UDS assays, particularly when tissues other than liver are the primary targets of a chemical agent. Moreover, human liver samples are difficult to obtain, so the use of the HepG2 human liver cell line in UDS assays has

been explored (Naji-Ali et al., 1994). Results from these assays are often difficult to interpret because of several potentially confounding factors. Because S-phase cells interfere with measurement of UDS, cell division needs to be inhibited. This is accomplished by adding hydroxyurea and depleting the cultures of serum and/or arginine (Mitchell et al., 1983). In Chinese hamster V79 cells, 10 mM hydroxyurea caused DNA damage (Rueff et al., 1996). Furthermore, expression of some metabolic enzymes may be reduced in quiescent cells. Rueff et al. (1996) reported that expression of a transfected cytochrome P-450 1A2 gene in V79 Chinese hamster cells was decreased 10-fold in nonproliferating cells. This latter difficulty can be overcome by adding an exogenous metabolic activating system (e.g., liver S9 fraction; see *UNIT 3.1*) to the cultures during treatment. It should be noted, however, that the results of the assay sometimes differ depending upon the activating system used. Moreover, compounds activated by such systems may differ from those ultimately formed in vivo, and the metabolites generated exogenously may not reach the target DNA (Rueff et al., 1996).

Both autoradiography and liquid scintillation counting (LSC) have been used to quantitate the amount of [^{3}H]thymidine incorporation during UDS (Mitchell et al., 1983). Although more time-consuming than LSC, autoradiography is preferred because S-phase cells are not counted in the assay, and abnormal and dead cells can also be excluded (Madle et al., 1994). As an alternative to using radioactivity, UDS can be quantitated by measuring the incorporation of bromodeoxyuridine (BrdU) into DNA by staining with a fluorescein isothiocyanate (FITC)–tagged anti-BrdU antibody and quantitating with flow cytometry (Selden et al., 1994).

Critical Parameters

Microgel electrophoresis assay

Careful preparation of a single-cell suspension is necessary in order to avoid high background levels of comet formation. Trypsinization may cause unacceptable amounts of damage. Green et al. (1996) suggested that a "short, sharp shock" of trypsin/EDTA causes less damage than trypsin alone. In their hands, they also obtained better results with recently plated cells. Finally, they also suggested that some background damage can be ameliorated if the cells are allowed to recover on the slide for 30 to 60 min before treatment.

The type of cell used will also affect the background rates of controls. For example, human sperm cells have higher background rates of comet formation than do human lymphocytes (Anderson and Plewa, 1998). If cells are obtained ex vivo, it is also likely that background rates may vary among tissue types. Previous research with human lymphocytes has also indicated that there is inter- and intra-individual variation (Ross et al., 1995). In humans, confounding factors are age, tobacco use, physical activity, and seasonal variation (Anderson and Plewa, 1988).

McKelvey-Martin et al. (1993) recommended that a minimum genotoxicity testing protocol should include four doses of the test agent, solvent controls, and positive controls. Moreover, they suggested that each determination be made in triplicate in two independent experiments and that cell viability experiments should be conducted concurrently. For statistical purposes, comets should be chosen randomly (i.e., avoiding observer bias), and a large enough number of comets (≥50) should be scored so to provide adequate sample sizes.

The choice of scoring criterion will depend upon the equipment available to the investigator. As described previously, it is possible to numerically score damage and to measure tail length, head diameter, and total comet area without an image-analysis system. Many additional densitometric and geometric measurements of comets are attainable with image analysis, and the choice of which comet parameter best defines the degree of DNA damage is contentious (Olive et al., 1990; Kent et al., 1995; Böcker et al., 1997; McCarthy et al., 1997). The advantages of automated image analysis are that it can measure differences in fluorescence intensity (a gauge of the amount of DNA present) and that it can rapidly deliver quantitative results. It is the best method for large-scale comet analysis. On the other hand, researchers without access to such equipment can still obtain reliable results via manual methods, albeit not as rapidly (Olive et al., 1990; McCarthy et al., 1997).

The sensitivity of the assay can be adjusted by varying the lysis temperature (Ross et al., 1995), NaOH concentration in the electrophoresis buffer (Klaude et al., 1996), and the voltage, temperature, and/or duration of electrophoresis (Green et al., 1996). It is important to evaluate assay modifications in terms of whether the enhanced sensitivity outweighs increases in background comet formation in controls.

Finally, when designing experiments, it is important to remember that the amount of DNA that migrates during electrophoresis will be a function of both damage and of repair. Conducting the assay at 4°C or in the presence of repair inhibitors increases the sensitivity of detecting direct DNA strand breakage. Conversely, using exogenous endonucleases involved in excision repair increases the sensitivity of the assay for detecting DNA damage that is not due to direct inducers of DNA breakage.

Filter elution assay

When conducting filter elution, it is important not to introduce additional DNA damage because of poor technique. Following lysis, all remaining procedures should be conducted in dim light. Treatment of the cells with the test agent or X irradiation should be conducted at 0°C to prevent DNA repair. Solutions should be slowly eluted through the filter to avoid spurious DNA damage, and care should be taken to avoid air-pocket formation during all steps of the procedure.

The choice of filter and lysis conditions will determine how much protein is retained on the filter. If detection of DNA breakage is the primary goal, then deproteinizing conditions should be used. On the other hand, if the major objective is quantitation of DNA-protein cross-linkage, experimental conditions should be adjusted so that protein is retained on the filter by omitting proteinase K treatment and using polyvinyl chloride filters.

When quantifying DNA, the DNA retained on the filter should be completely hydrolyzed so as to increase the counting efficiency. All elution fractions, washes, and filters should be counted with the same counting efficiency (Elia et al., 1991).

It is also necessary to gauge the cytotoxicity of the test agent. DNA strand breakage occurs during necrotic and apoptotic cell death, and these events can confound the interpretation of results from filter elution assays (Elia et al., 1994). In other words, a genotoxic response in alkaline elution is defined as one in which DNA damage occurs at concentrations that produce low levels of immediate cytotoxicity (Elia et al., 1994).

K-SDS precipitation assay

The sensitivity and reproducibility of the K-SDS precipitation assay depends upon uniform mechanical fragmentation of DNA. Disparate precipitation of DNA/protein complexes can occur if DNA fragments vary greatly in length. Shearing of the DNA following lysis also reduces the background level of DNA/protein complexes.

Inclusion of internal standards to control for potential inter-assay variability is recommended (Zhitkovich et al., 1996). Cells designated as the internal standard should be lysed and frozen in aliquots at −70°C and assayed concurrently with the test cells.

During in vitro genotoxicity testing, it is important to assess cytotoxicity of the test agent. Many compounds have tested positive for DNA/protein cross-link formation only at cytotoxic levels (Costa et al., 1996, 1997).

Finally, some DNA-protein cross-links are thermolabile (Costa et al., 1997). The temperature of the water bath during the precipitation/washing steps may have to be adjusted accordingly.

Unscheduled DNA synthesis

It is important to monitor cell viability following hepatocyte isolation. This is most often accomplished by using the trypan blue exclusion test, which assesses membrane integrity. Depending upon the nature of the test agent, other cell-viability tests may be more appropriate. The collagenase perfusion procedure used to isolate hepatocytes can result in loss of membrane receptors and decreased activity of some membrane enzymes (Parton et al., 1995). Moreover, cytochrome P-450 activities and cellular glutathione levels may decrease during the establishment of primary hepatocyte cultures, and cell polarity is disrupted because the natural matrix is not maintained (Parton et al., 1995). Accordingly, Parton et al. (1995) reported that these potential problems could be partially alleviated by allowing a 24-hr recovery period in serum-free medium following plating and prior to treatment; they also use a collagen-fibronectin-laminin-coated matrix for hepatocyte attachment. These modifications resulted in improved sensitivity of the in vitro UDS assay.

The suitability of different scoring criteria for the UDS assay is currently a matter of debate. Many investigators have scored the results of UDS assays as positive or negative based upon a threshold value or percentage of cells undergoing repair. For example, Dean (1995) recommends scoring cells as positive for repair if their net nuclear grain counts are ≥5 and a test agent as positive if the mean net nuclear grain count is ≥5 and ≥20% of cells

were undergoing repair. Negative test agents had a mean nuclear grain count of ≤0 and <20% of the cells were in repair. Edler (1994) provided details regarding the statistical analyses of this type of data.

Madle et al. (1994) recommended that net nuclear grain values (i.e., gross nuclear grain counts minus gross cytoplasmic grain counts) should be the primary index of UDS, although gross nuclear and cytoplasmic grain counts should also be reported. Increases in net nuclear grain counts that result from decreased cytoplasmic grain counts should be cautiously interpreted because these may indicate cytotoxicity or inhibition of mitochondrial DNA synthesis. The absolute value of the net nuclear grain count can vary with the methodology used; therefore Madle et al. (1994) suggest that threshold values for distinguishing positive and negative values are unreliable indices. As an alternative, they recommended that test agents be scored as positive if they elicit a dose-dependent increase in net nuclear grain counts over at least two consecutive concentrations.

Experiments should be rejected if the positive controls are lower than the vehicle controls, if negative or solvent controls yield positive results, if cytoplasmic background grain counts are unacceptably high, or if there is low cell viability and/or poor cell attachment (Swierenga et al., 1991).

Anticipated Results

Microgel electrophoresis assay

The negative control treatments should result in no discernible comet formation (Fig. 3.5.1) If the test agent caused single or double DNA strand breaks, then comets will be visible following electrophoresis and staining (Fig. 3.5.2). The alkaline assay can detect one single-stranded break per 2×10^{10} Da of DNA (Singh et al., 1994). The neutral assay is able to detect about 200 double-stranded breaks per cell (Olive et al., 1991).

Filter elution assay

Depending upon the protocol used, this assay will yield elution profiles for single- or double-strand breaks (see Fig. 3.5.3). With modification, the influence of interstrand or DNA-protein cross-linking may also be examined. In addition, the frequency of single- or double-strand DNA breaks can be calculated if an internal standard is included. Details regarding these calculations can be obtained in Kohn et al., (1981) and Kohn (1991). Filter elution assays can detect 1 DNA lesion per 10^7 nucleotides (Kohn et al., 1981).

K-SDS precipitation assay

This assay will reveal the presence of DNA/protein cross-links in cultured cells, cells obtained ex vivo, or in lymphocytes from human subjects. Comparison of control and treated cells will indicate if the test agent induced significant levels of DNA/protein cross-links (Fig. 3.5.4). This assay can detect one adduct per $1–2 \times 10^7$ bases (Zhitkovich et al., 1998).

Unscheduled DNA synthesis assay

Treatment of primary hepatocyte cultures with a positive control agent (e.g., 2-AAF) for at least 16 hr will yield detectable UDS (Fig. 3.5.5). Note the nuclear and cytoplasmic grains and the heavily-labeled S-phase cells.

Time Considerations

Microgel electrophoresis assay

Preparation of slides, treatment of cells, and embedding takes ≤1 hr. An additional hour is required for lysis. Equilibration and electrophoresis can be completed in 1.5 hr. Neutralization, rinsing, and staining of slides requires 1 hr. The time needed for scoring of comets depends on whether or not manual or semiautomated image analysis is used. If the latter system of scoring is available, the assay can be fully completed within 8 hr. Neutral assays take longer because of additional procedural steps (e.g., an overnight incubation with proteinase K and RNase treatment).

Filter elution assay

Not counting the time required to grow the cells or treat the animals, this assay takes at least 4 days if radiolabeled cells are used. If the DNA is instead quantitated via fluorometry, allow 2 days for the assay.

K-SDS precipitation assay

The assay can be completed within 1 day. However, it is often convenient to conduct the lysis, K-SDS precipitation and wash, followed by an overnight incubation during the proteinase K digestion phase. Subsequent steps are performed the following day. An additional 1 to 2 days are required for film exposure (Alternate Protocol 9).

Unscheduled DNA synthesis assay

Not counting the time needed to house the rats, this assay takes 2 to 3 weeks to perform.

Detecting Epigenetic Changes: DNA Methylation

Epigenetic changes refer to alterations in gene expression without a change in nucleotide sequence. One of the best understood epigenetic mechanisms is DNA methylation. The protocols in this unit describe some basic methods of DNA methylation analysis: determination of the overall genomic DNA methylation levels (see Basic Protocol 1), measurement of DNA methyltransferase (Mtase) activity (see Basic Protocol 2), and determination of gene-specific methylation (see Basic Protocol 3) and chromatin condensation patterns (see Basic Protocol 4). These protocols may be used immediately after treatment with toxicant or after a suitable recovery or selection period.

DETERMINING THE OVERALL 5-METHYLCYTOSINE CONTENT IN GENOMIC DNA

BASIC PROTOCOL 1

In this protocol, which is used to detect changes in overall DNA methylation, the bacterial enzyme *Sss*I (a CpG methylase), is used to artificially methylate a DNA sample, using radioactive *S*-adenosylmethionine (SAM). Higher amounts of *S*-adenosyl-L-[methyl-^{3}H]methyl incorporation into DNA indicate lower levels of genomic DNA methylation, while less [^{3}H]methyl incorporation is indicative of higher levels of genomic DNA methylation.

Materials

Genomic DNA purified from treated and control cells
*Sss*I methylase (New England Biolabs)
60 to 85 Ci/mmol *S*-adenosyl-L-[methyl-^{3}H]methionine (Amersham Pharmacia)
15 mM nonradioactive *S*-adenosylmethionine (SAM; prepare fresh)
*Sss*I reaction buffer (see recipe or use as supplied by manufacturer)
5% (w/v) trichloroacetic acid
70% (v/v) ethanol
Scintillation cocktail

Millipore Ultrafree-MC 100,000 NMWL filter unit (polysulfone membrane)
Scintillation vials
Liquid scintillation counter

1. Combine 200 ng genomic DNA sample with 4 U *Sss*I methylase, 1.5 µM *S*-adenosyl-L-[methyl-^{3}H]methionine, and 1.5 µM nonradioactive *S*-adenosylmethionine, in *Sss*I reaction buffer (25 µl total volume). Incubate reaction mixture 4 hr at 37°C.

   It is also possible to use HpaII or HhaI methylases for comparison.

   Include control reactions without DNA and without enzyme to determine background levels.

   5-Azacytidine will decrease DNA methylation and is suitable as a positive control treatment.

2. Stop the reaction by adding 25 µl of 1 mM nonradioactive *S*-adenosylmethionine.

3. Wash the filter unit once with water and then load the reaction mixture onto the filter. Wash with 0.3 ml of 5% trichloroacetic acid and 0.3 ml of 70% ethanol.

   The unincorporated S-adenosyl-L-[methyl-^{3}H]methionine should be washed away. High background levels are a common problem in this assay, because of nonspecific binding to the filter; therefore ascertain that controls have low levels of ^{3}H incorporation. Use of the polysulfone filter unit (Ultrafree from Millipore) eliminates this problem.

Contributed by Limor Broday and Max Costa
Current Protocols in Toxicology (2000) 3.6.1-3.6.8

4. Transfer the filter unit to a scintillation vial containing 10 ml of scintillation cocktail and determine the ^3H incorporation with a liquid scintillation counter.

   Relatively higher levels of [^3H]methyl incorporation are an indication of lower levels of genomic DNA methylation, and vice versa.

5. Calculate methylation levels as dpm/ng DNA, and DNA methylation levels as percent of control.

   This protocol should detect changes in the overall level of DNA methylation.

BASIC PROTOCOL 2

MEASURING DNA: METHYLTRANSFERASE ACTIVITY ASSAY

This assay measures the methyltransferase activity in cell extracts. The assay is based upon the same principle as Basic Protocol 1, but an exogenous substrate, poly(dI-dC), is added to the reaction. The level of *S*-adenosyl-L-[methyl-^3H]methionine incorporation measured is proportional to the enzyme activity.

Materials

$\sim 1 \times 10^7$ treated and control cells to be tested
PBS (*APPENDIX 2A*)
Methyltransferase lysis buffer (see recipe)
Polydeoxyinosinic-deoxycytidylic acid [poly (dI-dC)]
60 to 85 Ci/mmol *S*-adenosyl-L-[methyl-^3H]methionine (Amerham Pharmacia)
Methyltransferase stop solution (see recipe)
1:1 (v/v) phenol/chloroform
100% ethanol, ice-cold
0.3 M NaOH
5% (w/v) trichloroacetic acid
70% ethanol
0.5 M perchloric acid
Scintillation cocktail

Syringe and 25-G needle
GF/C Whatman filter discs
Fitration unit (e.g., Millipore)
Liquid scintillation counter

Additional reagents and equipment for protein assay and phenyl/chloroform extraction/ethanol precipitation (*APPENDIX 3*).

1. Scrape 1×10^7 cells from plates with a rubber policeman, pool into 5 to 10 ml ice-cold PBS, and collect by centrifuging 10 min at $1850 \times g$, 4°C.
2. Resuspend the cells in 0.5 ml methyltransferase lysis buffer. Pass the suspension once through a 25-G needle and submit to four cycles of freeze (dry ice) and thaw (37°C).
3. Determine the protein concentration in the samples (*APPENDIX 3*).
4. Combine lysate containing 5 µg protein with 0.5 µg poly(dI-dC), 1.5 µM *S*-adenosyl-L-[methyl-^3H]methionine, and methyltransferase lysis buffer in a total volume of 20 µl. Incubate at 37°C for 2 hr.

   Also prepare control reactions lacking poly(dI-dC).

5. Stop the reaction by adding 300 µl methyltransferase stop solution and incubating 1 hr at 37°C.

   The protease incubation is necessary to obtain complete recovery of DNA, which may be complexed with protein.

6. Extract the DNA with phenol/chloroform and precipitate with 2 vol ice-cold 100% ethanol (*APPENDIX 3*).
7. Dissolve the recovered DNA in 30 µl of 0.3 M NaOH and incubate 30 min at 37°C.

   This step is done to remove any residual RNA, which might be labeled.
8. Spot the 10 µl DNA on duplicate GF/C Whatman filter discs and air dry. Transfer the filters to a filtration unit and wash the DNA five times with 10 ml of 5% trichloroacetic acid and then five times with 10 ml of 70% ethanol.
9. Transfer the dried filter to a counting vial with 0.5 ml of 0.5 M perchloric acid, and heat 1 hr at 60°C.

   The DNA is solubilized during the incubation. Perchloric acid depurinates the DNA.
10. Add 5 ml scintillation cocktail and determine the ^{3}H incorporation with a liquid scintillation counter.
11. Calculate the Mtase enzyme activity as dpm/µg of protein.

    Results are usually expressed as percent of control values (mean ± SEM).

MEASURING GENE-SPECIFIC METHYLATION: MODIFICATION-SENSITIVE RESTRICTION ENDONUCLEASES ASSAY

BASIC PROTOCOL 3

The modification-sensitive restriction endonucleases (MSREs) assay is based upon the principle that DNA methylation will affect certain restriction enzymes. As a control, comparison of digestion patterns by methylation-sensitive and methylation-insensitive isoschizomers (e.g., *Hpa*II and *Msp*I) is performed. Following digestion of the examined DNA sample, the analysis may be done by Southern blot hybridization or PCR (*APPENDIX 3*).

Materials

Genomic DNA from treated and control cells to be tested, from tissue culture cells or tissues

Methylation-insensitive restriction enzyme (with recognition sites located within the borders of the tested DNA region) and buffer

Methylation-sensitive restriction enzyme (such as the 4 cutters *HpaII* and *HaeI*, 6 cutters *EagI* and *SacII,* or 8 cutter *NotI*) and buffer

Appropriate PCR primers designed for the target region *or* appropriate probe for Southern blot hybridization analysis

Additional reagents and equipment for ethanol precipitation of DNA (*APPENDIX 3*), PCR amplification (*APPENDIX 3C*) or Southern blot hybridization (Ausubel et al., 1992), and agarose gel electrophoresis (*UNIT 2.2*)

1. *For Southern blot hybridization analysis:* Digest 10 µg genomic DNA with 5 U/µg DNA of a methylation-insensitive restriction enzyme that releases a fragment of the genomic region to be examined. Incubate 16 hr at 37°C.

   If PCR analysis is performed start this experiment at step 2, below.

   The size of the test fragment depends on the physical map of the genomic target and also on the frequency of sites and size of fragments released following digestion with the methylation-sensitive restriction enzyme.
2. Precipitate the DNA by ethanol (*APPENDIX 3*), recover pellet, and digest (again, if step 1 was carried out for Southern blotting) with 5 U/µg DNA of a cytosine methylation-sensitive restriction enzyme for an additional 16 hr at 37°C.

   When PCR is to be performed, digest a much smaller sample of DNA (0.5 µg) than that recommended in step 1.

3a. *For Southern blot hybridization analysis:* Separate the digested samples (10 μg) by electrophoresis on 1% agarose gels (*UNIT 2.2*), transfer to a nylon membrane, and hybridize according to standard procedures (Ausubel et al., 1992).

In Southern blot hybridization, the percent methylation is calculated as the intensity of the band(s) representing DNA that is not digested by the methylation-sensitive enzyme (and which is therefore methylated) relative to the combined intensity of all bands in the lane (see Background Information and Critical Parameters).

3b. *For PCR*: Use ~50 ng digested DNA per PCR reaction (*APPENDIX 3C*). Compare the PCR product to a PCR product of an uncut control DNA.

Quantitative PCR conditions should be established empirically for each gene and cell type.

Absence of the expected DNA product indicates methylation of this site. The fraction of resistant DNA equals the fraction of cells that contain this modified site (see Background Information and Critical Parameters).

BASIC PROTOCOL 4

MEASURING DEOXYRIBONUCLEASE I SENSITIVITY

This assay is based on the principle that active genes are often more prone to deoxyribonuclease I (DNase I) digestion than inactive genes in which the chromatin is much more compact and condensed, and that methylation can inactivate genes and cause this condensation. Isolated nuclei from the treated cell line are digested with different amounts of DNase I and then the specific target gene is analyzed either by PCR or Southern-blot hybridization.

Materials

Cell line to be examined, treated and control
DNase I buffer (see recipe)
DNase I
DNase I stop solution (see recipe)
1:1 (v/v) phenol/chloroform
100% ethanol, ice-cold
25° and 55°C water baths

Additional reagents and equipment for phenol/chloroform extraction and ethanol precipitation of DNA (*APPENDIX 3*), Southern blot hybridization (Ausubel et al., 1992), and PCR (*APPENDIX 3C*)

1. Isolate nuclei from the examined cell lines.
2. Resuspend 5×10^5 nuclei for each treatment in 200 µl DNase I buffer.

   All the steps should be done on ice, except where otherwise indicated.

   This amount of nuclei is appropriate for PCR analysis. For Southern blot hybridization use at least 120 times more nuclei. The volume of the reaction and amount of enzyme, should be adjusted proportionally when using higher quantities of nuclei.

3. Prepare samples with increasing amounts of DNase I (0, 0.5, 1, 2, 10 U). Incubate 30 min at 25°C.
4. Terminate the reactions by adding 200 µl DNase I stop solution to each. Incubate 4 to 20 hr at 55°C.
5. Extract the DNA with phenol/chloroform and precipitate with ethanol (*APPENDIX 3*).

6a. *For PCR:* Amplify ~50 ng of the samples using primers designed for the target region. Using quantitative PCR conditions as established empirically for each gene and cell type.

See APPENDIX 3C for PCR protocols.

6b. *For Southern blot hybridization analysis:* Digest 10 µg DNase I–digested DNA per sample with a restriction enzyme that produces fragments of the analyzed region, as done in the MSREs assay (see Basic Protocol 2, step 1).

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and in all protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

DNase I buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
10 mM NaCl
3 mM $MgCl_2$
100 mM $CaCl_2$
Store up to 1 month at 4°C

DNase I stop solution

1% (w/v) SDS
0.1 M NaCl
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
10 mM EDTA (*APPENDIX 2A*)
Store 1 month at 4°C
Add 1 mg/ml proteinase K just before use

Methyltransferase lysis buffer

50 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
1 mM EDTA (*APPENDIX 2A*)
1 mM DTT
0.01% NaN_3
10% (v/v) glycerol
1% (v/v) polyoxyethylenesorbitan monooleate (closed up on Tween 80)
0.35 mM PMSF (add fresh)
100 mg/ml RNase A (add fresh)
Prepare just before use

Methyltransferase stop solution

1% (w/v) SDS
2 mM EDTA (*APPENDIX 2A*)
5% (v/v) isopropanol
125 mM NaCl
1 mg/ml proteinase K (add fresh)
0.25 mg/ml carrier DNA
Prepare fresh

SssI reaction buffer

50 mM NaCl
10 mM Tris·Cl, pH 7.9 (*APPENDIX 2A*)
10 mM $MgCl_2$
1 mM DTT
Store at −20°C

This buffer is usually supplied with the enzyme.

COMMENTARY

Background Information

Epigenetic agents heritably alter the DNA structure without altering the DNA sequence per se. DNA methylation is one of the best understood epigenetic mechanisms. DNA methylation levels of promoter regions are inversely correlated with gene expression. Increased levels of DNA methylation (hypermethylation) could potentially be a nonmutational mechanism to disrupt tumor-suppressor gene function, while reduction in DNA methylation (hypomethylation) of proto-oncogenes could facilitate their increased expression (Gonzalgo and Jones, 1997).

The first two protocols describe measurement of the overall methylation levels and DNA methyltransferase activity in the cells. The basis of the overall methylation assay is that fewer methyl groups from SAM will be transferred by *Sss*I methylase to cytosine in DNA that has relatively greater 5-methyl cytosine content, and vice versa (Wu et al., 1993). *Sss*I methylates cytosine in 5'-CpG-3' sequences, and thus it has the same recognition sequence as eukaryotic DNA methyltransferase. Since its purification (Renbaum et al., 1990), this enzyme has been widely used to artificially methylate DNA. *Sss*I has been preferred to other cytosine methylases such as *Hpa*II or *Hha*I, whose recognition sequences (CCGG and GCGC, respectively) are only a subset of all CpGs present in genomic DNA. The measurement of DNA methyltransferase activity from cell extracts is based on the same principle, but in this assay a DNA substrate is added to the reaction (Adams et al., 1991). This method is applicable to enzyme extracted from cultured cells and small pieces of tissue, where the cells have been disrupted by freeze thawing.

The remaining protocols describe gene-specific analysis of DNA methylation and chromatin condensation. The modification-sensitive restriction endonucleases (MSREs) assay uses methylation-sensitive restriction enzymes to distinguish between methylated and nonmethylated states of a specific gene or other genomic region. This is a relatively simple method for identifying modified bases at specific restriction-endonuclease sites. It requires only the map of restriction sites in the region of interest. The limitation of the method is that the methylation status can be determined only at restriction sites. Therefore, it is frequently applied as a first indication of whether or not modified bases are found in the examined genomic region.

Two techniques are used to determine the extent of DNA digestion. The first is fractionation of the digested DNA by gel electrophoresis and Southern blot hybridization (Bird and Southern, 1978). Absence of the expected DNA product indicates methylation of this site. The fraction of resistant DNA equals the fraction of cells that contain this modified site (Rein et al., 1998). As a control, comparison of digestion patterns by methylation-sensitive and methylation-insensitive isoschizomers (e.g., *HpaII* and *MspI*) is performed.

A more sensitive technique for the MSRE employs the polymerase chain reaction (PCR). After digestion, the DNA is amplified using specific primers for the genomic target. The amount of product will be proportional to the level of methylated DNA in the sites examined. However, it is necessary to calibrate the reaction conditions to achieve a linear response between input DNA and amplified product. In addition, the DNA must be completely digested. Inefficient DNA cleavage is the principle artifact of the MSRE method. Thus, small differences in methylation levels will not be detected using PCR. More sensitive methods have included quantitative PCR (Singer-Sam et al., 1990), ligation-mediated PCR (LMPCR; McGrew and Rosenthal, 1993), and genomic sequencing methods such as differential base modification by hydrazine, based on the Maxam and Gilbert sequencing reactions (Pfeifer et al., 1989), or bisulfite genomic sequencing (Clark et al., 1994). Although many alkylating agents have been identified, only a few compounds have been shown to affect CpG methylation levels directly. For example, 5-azacytidine decreased cytosine DNA methylation. It has also been shown that treatment with nickel increased methylation of a reporter gene and caused silencing (Lee et al., 1995).

Southern blot hybridization can also be used to determine the overall methylation level. The DNA is digested with methylation-sensitive restriction enzyme (e.g., a 4 cutter such as *Hpa*II), separated by electrophoresis, and hybridized with satellite sequences.

The final protocol describes a DNase I protection assay (Weintraub, 1985). Endonucleases have been widely employed to detect alterations in chromosomal states based on the accessibility of chromatin to restriction enzymes, DNase I, or micrococcal nuclease. In higher eukaryotes, heterochromatin-mediated gene silencing is accompanied by demonstra-

ble DNA hypermethylation. Methylated 5'-CpG dinucleotides within promoter regions may block transcription via the assembly of the methylated sequences into a condensed heterochromatic state (Nan et al., 1998; Bestor, 1998). In this assay, condensed, transcriptionally inactive areas will be more protected from DNase I digestion than transcriptionally active, euchromatic regions of the genome. As in the previous protocol the analysis may be done by Southern blot hybridization or by PCR.

Critical Parameters

For the determination of the overall methylation levels and methyltransferase activity, all reaction samples should be analyzed in duplicate. In addition, genomic DNA samples or cell extracts should be analyzed in triplicate. Values are obtained as dpm/ng of DNA for methylation levels or dpm/mg protein for methyltransferase activity.

Careful washing of the GF/C Whatman filter discs is crucial in Basic Protocol 2. Background problems may be overcome by washing the filters with cold SAM (1 mM) before applying the radioactive sample, adding cold SAM to the 5% TCA during the washing steps, and by using large volumes of 5% TCA. Use of the Ultrafree-MC filter unit also helps eliminate the high background levels.

In the MSREs assay (Basic Protocol 3), the use of highly purified DNA is the most critical parameter. Incomplete digestion will produce artifacts.

When performing PCR analysis for the MSREs assay or the DNase I sensitivity assay, it is always necessary to perform preliminary experiments in order to determine the appropriate conditions for quantitative PCR (e.g., amount of template DNA, number of cycles). See *APPENDIX 3C* for optimizing PCR.

Anticipated Results

In the overall methylation assay, it will be easy to distinguish between highly methylated (less ^{3}H-methyl incorporation) and nonmethylated samples (more ^{3}H-methyl incorporation), but rather difficult to elucidate differences when small changes in the genomic methylation levels have occurred. In the methyltransferase assay, higher amounts of ^{3}H-methyl incorporation into poly(dI-dC) indicate high methyltransferase activities in the tested lysates.

In the gene-specific methylation and condensation assays, highly methylated genes will yield clearly different Southern blots than controls. If PCR analysis is performed, highly methylated genes (i.e., those that are uncut by methylation-sensitive enzymes) will be amplified to a greater extent than unmethylated genes. For slight changes in gene methylation, genomic sequencing following bisulfite-modification PCR (Clark et al., 1994) is recommended.

Time Considerations

The overall methylation level protocol (see Basic Protocol 1) requires a 4-hr incubation, and ~1 hr to load, wash, and read the samples using the scintillation counter (depending on the number of samples).

The methyltransferase assay (see Basic Protocol 2) requires ~7 hr including two periods of incubation (2 hr and 1 hr), but this also depends on the number of samples examined.

For the MSREs assay (see Basic Protocol 3), 2 to 3 days are required to perform the PCR analysis if the conditions for the quantitative PCR are already established, and an additional 2 to 3 days if Southern blot hybridization is performed.

The DNase I sensitivity assay (see Basic Protocol 4), requires 1 to 2 hr of work (starting with nuclei), 4 to 20 hr incubation with the stop buffer, and 1 hr for phenol/chloroform extraction and DNA precipitation. An additional 4 to 6 hr for PCR analysis, or 2 to 3 days for Southern blot hybridization are required.

Assays for Detecting Chromosomal Aberrations

Genotoxicity can be evaluated by studying the physical integrity of the chromosomes in toxicant-exposed cultured cells, experimental animals, or even in cells derived from humans exposed in vivo. Chromosome preparations can be initiated from any dividing cell population and can even be prepared from nondividing cells, such as peripheral blood lymphocytes, that can be stimulated by mitogens to divide for a brief period of time.

In contrast to mutagenesis assays that can identify genetic alterations related to specific gene expression, or to the identification of specific DNA base mutations by the use of molecular-biology techniques, the employment of various chromosome assays allows for direct visualization of the structural integrity of the genome. This visual assessment can be made by evaluating cells for the presence of micronuclei (see Basic Protocol 1), which are small chromatin-containing bodies containing partial or whole chromosomes that have become separated from the main cellular nucleus as a result of toxicant insult. The state of the genome can be visually observed by routine Giemsa staining or trypsin/Giemsa banding (see Basic Protocol 2) of each individual chromosome to look for any aberrations in the typical chromosome size, form, and number known for each species. Missing, misshapen, or broken chromosomes can be readily noted. Rearrangements and translocations between chromosomes can also be detected by routine Giemsa staining, or can be colorfully highlighted by the use of fluorescent chromosome-specific painting probes (see Basic Protocol 3). Toxicant-induced exchanges between sister chromatids of each chromosome can be quantitated by differentially staining the chromatids so that each appears either dark or light (see Basic Protocol 4). Overall, the visual assessment of the genome's integrity can be a useful companion to many of the other assays described in this chapter. In some cases, visible disruption of the chromosomes can signify genotoxic damage to the cell, even in the absence of detectable gene-specific mutations. Whereas the cytogenetic assays are limited by the power of visual magnification, they have the advantage of offering a broad cellular target for investigating genotoxic effects. This unit also includes a protocol for preparation of metaphase chromosome spreads (see Support Protocol).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

MICRONUCLEUS ASSAY FOR CHROMOSOMAL ABERRATIONS

BASIC PROTOCOL 1

Micronuclei (MN) originate from acentric chromosome fragments or whole chromosomes that are not included in the main nuclei following DNA replication and nuclear division. The in vitro cytokinesis-blocked micronucleus (CBMN) technique described here uses cytochalasin B (Cyt-B), which, at appropriate concentrations, prevents cytoplasmic, but not nuclear, division. Thus, cells after one mitotic division can be recognized by their typical binucleate interphase appearance and the micronuclei can be scored in the binucleate interphase cells. The MN test is a valid tool for the detection of chromosome-damaging agents and can be used as an initial screening assay for the identification of putative carcinogenic and other environmental exposure hazards.

Current Protocols in Toxicology (2000) 3.7.1-3.7.16

Materials

Cells to be tested, in exponential growth phase or PHA-stimulated lymphocytes
Medium and supplements appropriate for the cell line studied (*APPENDIX 3B*)
Agent to be tested for toxicity, in appropriate solvent
1 mg/ml cytochalasin B (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Hypotonic solution: 0.075 M KCl
80% to 100% ice-cold methanol, freshly prepared
5% (w/v) Giemsa solution (prepare fresh): dilute Giemsa stain (see recipe) 1:19 (v/v) in Sorenson's phosphate buffer, pH 6.8 (see recipe)

60-mm petri dishes
Microscope slides, –20°C

Additional reagents and equipment for culturing and trypsinizing cells (*APPENDIX 3B*), mutagenesis assays in cells (*UNIT 3.3*), and slide preparation by dropping (see Support Protocol) or cytospinning (*UNIT 2.2*)

Grow cells and treat with test agent

1. Seed 0.5 to 2 × 10^5 cells per 60-mm petri dish in 5 ml medium (four dishes are suggested for each dose of putative genotoxic agent).

   For a detailed description of mutagenicity testing, see UNIT 3.3.

2. After cell attachment, add the test agent to the dishes and incubate cells for the appropriate exposure time previously shown to yield genotoxic effects at 37°C.

   Dosage levels of the test agent are selected based on toxicity or solubility limits. If the chemical is dissolved in DMSO or other organic solvent, pure DMSO or solvent should be used as a negative control. Solvent concentration should not exceed 1%.

Inhibit cytokinesis

3. Add cytochalasin B to the cultures (from 1 mg/ml stock) to a final concentration of ~3 μg/ml. Incubate cells 24 to 72 hr at 37°C.

   This treatment blocks cytokinesis. Preliminary experiments should be performed to determine the optimal cytochalasin B concentration (0.5 to 6.0 μg/ml) and duration of exposure that yields the highest proportion of binucleated cells for each cell line tested.

Fix cells and score for micronuclei

4. Harvest the cells by washing twice with PBS and then trypsinizing (*APPENDIX 3B*).
5. Resuspend the cells in 1 ml hypotonic solution (0.075 M KCl) and incubate for 5 to 10 min in a 37°C water bath. Centrifuge 10 min at 155 × *g*, 4°C.
6. Fix the cells in freshly prepared 80% to 100% methanol for ≥90 min at 4°C.
7. Centrifuge 10 min at 155 × *g*, 4°C. Remove supernatant.
8. Repeat step 6 for 30 min and centrifuge again 10 min at 155 × *g*, 4°C.
9. Remove most of the supernatant (retain ~0.2 ml). Resuspend the cells, and spread the cell suspension on cold (–20°C) slides by dropping (see Support Protocol) or cytospinning (*UNIT 2.2*).
10. After drying, stain the slides 10 to 15 min with 5% Giemsa solution.
11. Examine the cells for micronuclei at 1000× magnification. Score the number of MN in ≥1000 binucleated cells for each independent experiment. Code and score all slides without any knowledge of the treatment condition.

The cytokinesis-blocked cells scored for MN should have two nuclei of approximately equal size. The criteria for identifying micronuclei are: (1) MN have a diameter between 1/16 and 1/3 that of either of the main nuclei; (2) MN are round or oval with the same color as the main nuclei; (3) MN are not linked to a main nuclei via a nucleoplasmic bridge; and (4) MN may sometimes overlap the boundaries of the main nuclei (Fenech, 1993). Statistical significance of MN levels can be evaluated by the T-test, and the scoring of MN can be automated (Streffer et al., 1998).

12. Calculate the mean number of micronuclei and the standard deviation in a total of three to four independent experiments.

Statistical analysis of the number of micronuclei may be done. It is also recommended that the distribution of MN among binucleate cells be determined, because the sensitivity to a particular clastogen may depend on cell-cycle status when heterogeneous cell populations are treated.

The proportion of binucleate cells should also be noted, since this can provide an index of cytotoxicity and responsiveness to the examined agent in conjunction with cytochalasin B (for an advanced statistical analysis see Johnston et al., 1997).

GIEMSA OR GIEMSA/TRYPSIN STAINING TO EVALUATE CHROMOSOME ABERRATIONS

BASIC PROTOCOL 2

From a genetic toxicology perspective, chromosome aberrations involving gains or losses of whole or partial chromosomes (aneuploidy), as well as breaks, gaps, rearrangements, translocations, ring chromosomes, dicentric chromosomes, and acentric chromosome fragments, can be analyzed in metaphase spreads of cultured mammalian cells following toxicant exposure in vitro. Chromosome aberrations can also be readily evaluated in short-term cultures of cells derived from various animal tissues (e.g., peripheral blood lymphocytes) following in vivo toxicant exposures, as well as in cell cultures of tumor-derived cells. Conventional staining or chromosome banding techniques can be used to visualize and characterize these aberrations. Staining with Giemsa will produce homogeneously stained purple chromosomes. For more enhanced visualization of chromosome rearrangements and translocations, the slides can alternatively be treated with trypsin then stained with Giemsa to produce characteristic G-banding patterns on each chromosome.

Materials

Slides containing metaphase spreads (see Support Protocol) from treated and control cells

10% (w/v) Giemsa solution (for Giemsa staining) *or* 5% (w/v) Giemsa solution (for trypsin/Giemsa staining): dilute Giemsa stain (see recipe) 1:9 (for 10%) or 1:19 (for 5%) in Sorenson's phosphate buffer, pH 6.8 (see recipe), prepare diluted stains fresh

0.05% (w/v) trypsin: dilute 2.5% (w/v) stock in PBS or other physiological saline solution

PBS (*APPENDIX 2A*) or saline solution

Permount (Fisher Scientific)

22 × 44–mm coverslips

ASA 100 color film

Stain chromosomes with Giemsa or with trypsin/Giemsa

For Giemsa staining

1a. Stain chromosomes on slides for 3 to 5 min with 10% Giemsa solution.

2a. Proceed to coverslipping (step 3).

For trypsin/Giemsa staining to produce G-banded chromosomes

1b. Incubate slides in 0.05% working solution of trypsin in PBS or other physiological saline solution, for 5 to 60 sec depending on the cell type and the age of the slides.

The duration of exposure to the trypsin should be optimized for each set of slides by evaluating the outcome of the banding process on the first test slide (faint banding will be detected even without the Giemsa staining step). If the trypsinization is insufficient, the slide can be placed into the trypsin again. Occasionally, the trypsinization step will have to be increased to 1 to 2 min. It is always better to undertrypsinize the chromosomes than to overexpose them, since the overtrypsinized situation cannot be corrected. In the case of overtrypsinization, the chromosomes will lose morphology, becoming bloated ghosts with no evident banding. Aged slides, whether air dried for ~1 week, or mechanically "aged" by placing in a drying oven for several hours, seem to yield the best G bands.

2b. Rinse slides two to three times in PBS or saline, then stain 1 to 3 min in 5% Giemsa solution.

Score chromosome aberrations (CA)

3. Coverslip slides by adding a drop of Permount to the non-frosted farthest edge of the slide. Place the edge of a 22 × 44–mm glass coverslip into the Permount at a 45° angle, then gently lower the coverslip over the viewing area of the slide letting the Permount spread evenly beneath the coverslip. Gently tease out any large bubbles and excess mounting fluid, and let the Permount dry for 15 min at room temperature.

Permounted, Giemsa-stained slides are permanently preserved, allowing for viewing at any convenient time as well as archival storage of the slides.

4. Score ≥100 well spread, intact metaphase cells for each treatment at 1000× magnification. Document representative metaphase cells (Giemsa-stained or G-banded) by routine color photography (ASA 100 film).

In addition to counting the number of chromosomes per metaphase spread, aberrant chromosomes should be classified according to standard cytogenetic definitions: chromatid gaps, chromatid breaks, chromatid deletions, chromosome gaps, chromosome breaks, chromosome deletions, acentric fragments, dicentric, rings (centric or acentric), quadriradials, and triradials. The frequency of each type of aberration should be tallied (as per Keshava et al., 1998). For banded chromosomes, translocations may also be tallied.

Mitotic index (MI), a measure of cytotoxicity, can also be calculated for each treatment by counting the number of metaphases per 1000 cells.

BASIC PROTOCOL 3

EVALUATION OF CHROMOSOME ABERRATIONS BY PAINTING WITH FLUORESCENCE IN SITU HYBRIDIZATION (FISH) PROBES

For some mammalian species such as the mouse, the karyotype consists of 40 telomeric chromosomes of similar size. This makes evaluation of complex rearrangements and translocations very difficult. The use of differently colored fluorescence in situ hybridization (FISH) probes specific for any two representative chromosomes, such as chromosomes 2 or 8 (Spruill et al., 1996), allows for rapid, accurate scoring of symmetrical and asymmetrical exchanges between painted and unpainted chromosomes. Thus, a translocation between any of the four fluorescent biotinylated chromosomes with any of the unpainted chromosomes can be easily seen as a bicolored (e.g., red/yellow) product. FISH techniques using chromosome-specific painting probes have increased the sensitivity and ease of detecting stable chromosome aberrations in both in vitro and in vivo studies in humans and other species (Tucker et al., 1995).

Materials

Chromosome-specific DNA painting probes (2 chromosomes) for the species of interest, labeled with biotin or digoxigenin (Vysis, Inc.)
Hybridization solution (see recipe)
Metaphase spreads (see Support Protocol) from test-agent-treated cells
70% (v/v) formamide/2× SSC and 50% (v/v) formamide/2× SSC (see recipe for SSC)
70%, 80%, and 100% ethanol
Rubber cement
2× SSC (see recipe)/1% (v/v) NP-40 (Ventana Medical Systems)
Sodium phosphate (PN) buffer (see recipe)
3% (w/v) powdered non-fat milk in PN buffer
5 µg/ml FITC-avidin in PN buffer
12 µg/ml biotinylated anti-avidin in PN buffer (optional)
200 µg/ml stock DAPI stain (store up to 1 year at −20°C; dilute to 0.5 µg/ml in antifade solution just before use)
200 µg/ml stock propidium iodide stain (store up to 1 year at −20°C; dilute to 1 µg/ml in antifade solution just before use)
Antifade solution (Vysis, Inc., Molecular Probes, Ventana Medical Systems)

Coplin jars
Humidified chamber (container with lid and lined with moist paper towels)
22-mm^2 coverslips
Kodak Ektachrome 400 film

1. Mix chromosome-specific biotinylated or digoxigenen-labeled probe DNA(s) with hybridization solution at 10 ng/ml in a final volume of 15 µl per slide. Denature at 70°C for 5 min and keep on ice until use.

   Human and mouse chromosome-specific fluorescent painting probes are commercially available (Vysis, Inc.). The probes are supplied in aqueous solution, or may be pre-mixed with hybridization buffer as indicated by the supplier. Alternatively, the investigator may make his own chromosome probes by PCR of microdissected chromosomes of any species (Christian et al., 1999).

2. Denature the metaphase cell slides 5 min at 70°C in 70% formamide/2× SSC, pH 7.0. Use 2 to 4 slides per test.

   CAUTION: *Care should be exercised when handling formamide and only glass Coplin jars should be used as a vessels for all formamide solutions.*

   Metaphase slides are best for FISH when well dried, either air-dried for several days, or oven-dried (1 to 2 hr at 65°C). Some FISH protocols recommend a brief protein digestion step (10% pepsin, 37°C, 10 min) prior to denaturation.

3. Dehydrate the slide(s) through a series of 5-min 70% ethanol, 80% ethanol, and 100% ethanol washes at room temperature in Coplin jars.

4. Apply 15 µl of the denatured probe/hybridization mix to the surface of each slide, cover with clean 22-mm^2 coverslip and seal edges with rubber cement. Incubate 24 to 48 hr at 37°C in a humidified chamber.

   Alternatively, Parafilm coverslips can be used in place of glass coverslips, thus eliminating the need for rubber cement. Hybridization time may vary depending on the size and sequence specificity of the fluorescent probe.

5. Remove unbound probe by rinsing the slides in three 5-min washes at 45°C of 50% formamide/2× SSC, pH 7.0, in Coplin jars.

Do not forcibly remove the coverslips after hybridization, since the chromosome spreads can easily become mechanically sheared. The coverslips will loosen and slip off into the first wash. To promote this, the slides can be very gently agitated by hand in the Coplin jar.

6. Follow with 5-min washes successively in 2× SSC at 45°C, in 2× SSC with 1% NP-40 at 45°C, and in PN buffer at room temperature.

7. Block slides 5 min with 3% powdered non-fat milk in PN buffer at room temperature.

   The blocking step will reduce the background that can result from nonspecific binding of the FITC-avidin.

8. Stain slides with 5 µg/ml FITC-avidin applied to the surface of each slide. Incubate 30 min at room temperature.

   The visualization of the fluorescent probe can be enhanced by sequential overstaining with biotinylated anti-avidin/FITC-avidin (Spruill et al., 1996).

9. Counterstain the chromosomes with 2 to 3 drops of a mixture of DAPI at 0.5 µg/ml and propidium iodide at 1 µg/ml in antifade solution. Cover the slide with a clean coverslip.

10. Visualize the fluorescent-stained chromosome under 1000× magnification using an epifluorescent photomicroscope with halogen (75-W mercury lamp) illumination.

    A DAPI filter set will allow the viewer to locate blue stained metaphases for further analysis with other UV filter sets, such as a dual red/green filter set that allows simultaneous visualization of red propidium iodide stained chromosome, contrasted with the bright yellow-green FITC stained hybridized probe regions for translocation analysis.

    FISH slides can be covered with foil or stored in any light-tight container at 4°C, for several days without fading to permit subsequent visualization at a later time.

Score chromosome aberrations (CA)

11. Score chromosome rearrangements in the equivalent of ≥200 intact metaphase cells per treatment (therefore 1000 cells, see rationale below), using the following criteria: the centromeres of all chromosomes including the four painted chromosomes must be visible, and the FITC label must be bright enough to differentiate between painted and unpainted chromosomes.

    Since chromosome painting with two chromosome-specific probes detects only a fraction of the total exchanges possible within each metaphase, five metaphase cell equivalents must be scored in order to obtain the same amount of information as obtainable from one G-banded cell (Spruill et al., 1996).

12. Document abnormal metaphases by fluorescent photomicroscopy using Kodak Ektachrome 400 film.

    Various camera set-ups can be installed for standard photomicroscopy or for digital image analysis of informative chromosome spreads. Record the position of any photographed or analyzed metaphase spread using the calibrated horizontal and vertical locators on the microscope stage.

SUPPORT PROTOCOL

PREPARATION OF METAPHASE CHROMOSOME SPREADS

Metaphase chromosome spreads are required to evaluate cells for chromosomal aberrations by Giemsa staining, Giemsa/trypsin banding, or fluorescence in situ hybridization (FISH). Cells are cultured, treated, harvested, incubated in hypotonic medium, fixed, and dropped onto glass slides to provide chromosomal spreads for staining.

Materials

Cells to be studied
Medium and supplements appropriate for the cells being studied
Agent to be tested in appropriate solvent
10 μg/ml colchicine or Colcemid
Hypotonic solution: 0.075 M KCl, 37°C
Carnoy's fixative: 3:1 (v/v) methanol/glacial acetic acid, freshly prepared (ice-cold)

60-mm petri dishes
Microscope slides, cleaned and chilled

Grow and treat cells

1. Seed 2.5×10^4 cells per 60-mm petri dish in 5 ml medium (four dishes are required for each dose of putative genotoxic agent). Incubate cells 16 to 20 hr at 37°C.

   The chemical treatment should be performed while cells are in exponential growth.

2. Add the test agent to the dishes and incubate cells at 37°C for the appropriate exposure time found previously to generate genotoxic effects.

   Dosage levels are selected based on toxicity or solubility limits. If the chemical is dissolved in DMSO or other organic solvent, pure DMSO or solvent should be used as negative control. Solvent concentration should not exceed 1%.

Harvest and fix cells

3. Before harvesting the cells, add Colcemid (from 10 μg/ml stock) to a final concentration of 0.1μg/ml. Leave the Colcemid on the cells for 1 to 2 hr.

   The duration of Colcemid exposure depends on the proportion of metaphases that are collected as determined by occasional observation under an inverted cell culture microscope. Colcemid added to actively dividing cells arrests the cells during metaphase to produce the classic chromosome morphology that is most often visualized in cytogenetic preparations. The dose and duration of Colcemid exposure should be optimized for each cell type studied. The timing of the Colcemid treatment should be kept as short as possible, since prolonged exposure to the drug will progressively shorten the metaphase chromosomes, making their evaluation more difficult.

   Colchine can be used interchangeably with Colcemid.

4. Collect the cells by trypsinization (*APPENDIX 3B*), gentle scraping, or mitotic shake-off, depending on the type of cells being used. Collect both the Colcemid-containing medium prior to trypsinization and the trypsinized cell suspension in a15-ml centrifuge tube. Centrifuge 5 min at $600 \times g$, room temperature.

   Certain mammalian cells such as those derived from Chinese hamster (V79, CHO) are amenable to mitotic shake off, thus allowing the elimination of the trypsinization step if desired.

   Retention of the medium from the Colcemid treatment will allow collection of additional metaphase cells that have become detached during the metaphase blocking step and will also facilitate inactivation of the trypsin when the trypsinized cell suspension is added to the centrifuge tube that already holds the Colcemid-containing medium.

5. Decant all but 1 ml of the supernatant, then gently resuspend the cell pellet. Add 4 ml prewarmed 0.075 M KCl hypotonic solution and incubate 5 to 10 min in a 37°C water bath.

   The optimal duration of hypotonic treatment may vary for different cell types.

   During exposure to the hypotonic salt solution, the cells expand in volume and metaphase chromosomes are distributed throughout the cytoplasm. Upon dropping the cells onto the

slides, the cells split open, thus spreading the metaphase chromosomes. This allows the examination and identification of individual chromosomes on microscopic slide preparations. Due to their fragility, hypotonically swelled cells must be handled gently to avoid cell rupture prior to fixation and slide preparation. Narrow-tipped pipets and excessive centrifugation or vortexing should be avoided.

6. Add 5 drops of ice-cold, fresh Carnoy's fixative to the 37°C cell suspension and swirl the tube gently. Collect cells from the hypotonic treatment by gently centrifuging 10 min at 200 × *g*, room temperature.

7. Aspirate the supernatant carefully with a clean glass Pasteur pipet without disrupting the loose cell pellet.

   After the hypotonic treatment and centrifugation, the cells will be clearly visible as a loose pellet. Following centrifugation, the supernatant should not be decanted by inversion, since the cell pellet is loose and in danger of being lost.

   In this and all subsequent steps, mechanical pipetting devices are usually avoided in favor of using Pasteur pipets and bulbs. This allows for more gentle handling of the cells and facilitates the dropwise additions of the fixative.

8. Add 5 ml of fresh, ice-cold Carnoy's fixative to the cell pellet in a dropwise manner.

   To avoid problems with cell clumping, the first fixation step should follow a meticulous drop-by-drop method that includes a gentle swirling of the tube in between each drop of added fixative. The fixative should be freshly prepared on the day of its use, should be iced in a −20°C freezer prior to use, and should be kept on ice during use. To reduce the evaporation of the methanol, the fixative bottle should not be left uncapped while working.

9. Refrigerate the centrifuge tubes 30 min at 4°C. Centrifuge 10 min at 300 × *g*, 4°C. Aspirate the fixative using a Pasteur pipet, as above.

   The previously visible swelled cell pellet will become significantly reduced in size during the fixation procedure. This does not indicate a loss of cells.

10. Repeat steps 8 and 9 at least two more times to ensure adequate fixation of the cells.

    After the first fixation, the dropwise addition of the Carnoy's fixative is only necessary until the cells are resuspended (first 1 ml added). The remainder of the fixative should be added slowly with gentle bubbling or swirling to mix the cells. For some cell types, fixed metaphase cells can be stored at 4°C in the final fix for several weeks or even months prior to slide preparation.

11. Centrifuge the fixed cells 10 min at 300 × *g* and decant the fixative using a pipet.

12. Add a minimal amount (0.5 to 1.5 ml) of fresh, ice-cold fixative and resuspend the cells for slide preparation.

    The amount of final fixative used for slide preparation will depend on the concentration of cells observed in each tube but should be kept to a minimum.

13. Take up a small amount (<0.5 ml) of this concentrated cell suspension into the narrow neck of a fresh Pasteur pipet, and drop 3 to 4 drops across a clean, cold microscope slide. Prepare multiple slides as permitted by the volume of the cell suspension. Air dry the slides.

    Various methods for chromosome slide preparation can be found in the literature, and individual preference should be applied. The slides for metaphase preparations can be iced/dry, iced/wet, or cold/wet. Many investigators prefer to drop the cell suspension onto the slide from a height of 1 to 2 feet to promote cell breakage. The slides can be passed over a flame, or gently blown upon to enhance metaphase spreading. Visual inspection of the first slide prepared from each tube will determine whether the cell preparation would benefit from another overnight fixation step to further weaken the cell membrane and

enhance metaphase spreading. Some cell types or staining procedures may require drying the slides on a hot plate (60°C, 2 to 5 min) or aging the slides several days at room temperature.

DETECTION OF SISTER CHROMATID EXCHANGES

BASIC PROTOCOL 4

In this assay, cells are treated with the test agent, then the thymidine analog 5-bromodeoxyuridine (BrdU) is incorporated into the DNA during two cell cycles. Metaphase chromosomes are accumulated at the second metaphase after the addition of BrdU and then stained by the 33258 Hoechst/Giemsa technique. The objective is to obtain cells containing differentially stained chromatids, in which exchanges between sister chromatids can be observed. The sister chromatid exchange (SCE) assay is a widely used assay in genotoxicity screening.

Materials

Cells to be studied
Medium and supplements appropriate for the cell line studied (*APPENDIX 3B*)
Agent to be tested
0.5 mM 5-bromodeoxyuridine (BrdU), filter sterilized, (store up to 2 to 3 weeks in the dark at −20°C)
10 μg/ml colchicine or Colcemid
Hypotonic solution: 0.075 M KCl
Carnoy's fixative 3:1 (v/v) methanol/glacial acetic acid (freshly prepared), ice-cold
2 mg/ml Hoechst 33258 in water (store several months in the dark at −20°C)
0.5× and 2× SSC (see recipe)
3% (v/v) Giemsa solution (prepare fresh): dilute Giemsa stain (see recipe) 3:97 (v/v) in Sorenson's phosphate buffer, pH 6.8 (see recipe)

60- and 100-mm petri dishes
Microscope slides, cleaned and chilled
UV light source (Philips MWL 160 W lamp)

Additional reagents and equipment for mutagenesis of cells (*UNIT 3.3*), trypsinization of cultures (*APPENDIX 3B*), and preparation of metaphase spreads (see Support Protocol)

Grow and treat cells

1. Seed ~2.5×10^4 cells per 60-mm petri dish in 5 ml medium (four dishes are suggested for each dose of putative genotoxic agent). Incubate 16 to 20 hr at 37°C.

   For a detailed description of mutagenicity testing, see UNIT 3.3. The chemical treatment should be performed while cells are in exponential growth. In addition, the initial cell number should be adjusted so that the culture will not reach confluence during the additional two cell cycles in the presence of BrdU required to perform the assay.

2. Add the test agent to the dishes and incubate cells at 37°C for any exposure time found previously to generate genotoxic effects.

   This step allows interaction of the test substance with cells before addition of BrdU. Longer exposure periods may be necessary for agents which have an effect only during DNA synthesis.

   If the chemical is dissolved in DMSO or other organic solvent, pure DMSO or solvent should be used as negative control. Solvent concentration in contact with the cells should not exceed 1%.

Incorporate BrdU into DNA

3. Wash the cells twice with PBS, and add 5 ml fresh medium containing 10 to 20 µM BrdU. Incubate cells at 37°C for the time appropriate to span two cell cycles.

   This time span differs among cell types, but may typically be 24 to 30 hr.

   The optimal concentration of BrdU varies with cell type. The final BrdU concentration should not significantly inhibit cell replication but should allow differential staining to enable scoring for SCEs. BrdU itself increases the frequency of SCE, so it is important to include a BrdU control treatment (cells that have not been treated with the test agent) in the experiment.

   All manipulation of cultures containing BrdU must be carried out in the absence of direct light because exposure to light degrades BrdU-substituted DNA.

4. Two hours before harvesting the cells, add Colcemid (from 10 µg/ml stock) to a final concentration of 0.1 µg/ml.

   Colcemid or colchicine added to mitotic cells during metaphase and anaphase disrupts spindle-fiber formation, preventing the separation of chromatids after the centromere is split.

Harvest and fix cells

5. Collect the cells by trypsinization (*APPENDIX 3B*) or gentle scraping. Centrifuge 7 min at 600 × *g*, room temperature.

6. Resuspend the cells in 1 ml hypotonic solution (0.075 M KCl) for 5 to 10 min in a 37°C water bath.

   Due to the fragility of the swollen cells, the optimal duration of hypotonic treatment may vary for different cell types.

7. Fix the cells as described for metaphase spreads (see Support Protocol, steps 6 to 10), drop the cell suspension onto clean, cold microscope slides (see Support Protocol, step 13), and air dry the slides.

   During exposure to hypotonic salt solution, the cells expand in volume and metaphase chromosomes are distributed throughout the cytoplasm. Upon dropping the cells onto the slides, the cells split open, spreading the metaphase chromosomes. This allows the examination and identification of individual chromosomes in microscopic slide preparations.

   Hypotonically swelled cells must be handled gently to avoid cell rupture prior to fixation and slide preparation. Narrow-tipped pipets should be avoided.

Stain the cells

8. Stain the slides 45 min in 50 ml of 0.5× SSC containing 50 µl of 2 mg/ml Hoechst 33258 in a Coplin jar.

9. Wash the slides 5 min in 2× SSC.

10. Immerse the slides in 5 ml of 0.5× SSC in a 100-mm tissue culture dish and expose them to UV light (Philips MWL 160-W lamp) at a distance of 10 cm for 1 hr. Do not allow the slides to dry out.

11. Incubate the slides 1 hr in fresh 0.5× SSC in a Coplin jar at 60°C and overstain 15 min with 3% Giemsa solution, pH 6.8. Add Permount and a coverslip. View at 400 to 1000× magnification.

    Differential staining of chromatids by BrdU/Giemsa (purple/white) will highlight the frequency of crossing over between the two chromatids, and thus enable scoring of SCEs.

Score for SCE

12. Count the number of SCEs in at least 50 differentially stained metaphase spreads from each treatment. Also record the number of chromosomes analyzed in each cell. Determine both the frequency of SCE per chromosome and total SCEs per cell.

    While scoring the SCEs, it is important to select an area of the slide where the metaphase chromosomes are well spread to allow screening of individual metaphase chromosomes. Each chromatid exchange is counted as a single event.

    Usually the mean and standard deviation values of the SCE per chromosome are presented for each dose (from at least three independent experiments), and are compared to the SCE values of the solvent controls, using appropriate statistical procedures.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytochalasin-B stock solution, 1 mg/ml

Dissolve 1 mg of cytochalasin B in 1 ml of dimethyl sulfoxide (DMSO). Store up to 2 to 3 months at −20°C.

Giemsa stain

Mix 7 g Giemsa powder with 482 ml glycerol, warm 2 hr in a 60°C water bath. Allow to cool to room temperature and add 462 ml methanol. Filter through Whatman no. 1 filter paper, store up to 6 months at room temperature in a dark glass bottle.

Some precipitation will be noted with time.

Hybridization solution

50% (v/v) formamide
2× SSC (see recipe)
10% (w/v) dextran sulfate
1.5 µl of 1µg/µl herring sperm DNA
2.0 µg species-specific COT-1 DNA (Life Technologies, Vysis, Inc.)
Store up to 6 months at −20°C in 100- to 200-µl aliquots

This solution is also commercially available from Vysis, Inc. and Ventana Medical Systems or comes supplied with the probe.

Sodium phosphate (PN) buffer for FISH

0.1 M $NaPO_4$, pH 8.0 (*APPENDIX 2A*)
0.1% (v/v) NP-40 (Ventana Medical Systems)
Store 2 to 3 months at 4°C

Sorenson's phosphate buffer

9.4 g/liter $NaHPO_4$
9.08 g/liter KH_2PO_4
Store 6 months at 4°C

2× SSC solution

0.30 M NaCl
30 mM sodium citrate
Adjust pH to 7.0 with 1 M HCl
Store 6 months at room temperature

COMMENTARY

Background Information

The micronucleus (MN) assay determines the clastogenic or chromosome-breaking effects of particular agents and examines the relative sensitivities of eukaryotic cells to such clastogens. Micronuclei are chromatin-containing bodies that represent acentric chromosomal fragments or whole chromosomes that were not incorporated into a nucleus during mitosis (Fenech, 1998). Micronuclei can be examined for the presence of a centromere by staining with anti-kinetichore antibodies. This method differentiates between whole chromosomes (with kinetichores) and acentric fragments (without kinetichores) in the micronuclei (Hermine et al., 1997).

Although the number of micronuclei within a cell is not a precise measure of chromosome breakage or gap formation (since multiple fragments may reside within a single micronucleus), it is possible to demonstrate a dose-response relationship between clastogen exposure and MN frequency, as well as a relationship between long-term survival and MN frequency.

Micronuclei assays may be conducted in vivo or in cultured cells. The in vivo assays are most often performed by counting micronuclei in immature polychromatic erythrocytes (PCE) from the bone marrow of treated mice or in peripheral blood smears (Fenech, 1998). MN remain in the cells when the nucleus is extruded during the maturation of erythroblasts.

MN assays in cultured cells have been greatly improved by the cytokinesis-block micronucleus (CBMN) technique, in which cytoplasmic division is inhibited by the fungal metabolite cytochalasin B, resulting in binucleate and multinucleate cells (Fenech and Morley, 1985; Fenech, 1993; Kirsch-Volders, 1997). In this assay, cells are exposed to the test agent and cytochalasin B is added for the last part of the culture period. Micronuclei are counted only in the binucleate cells to ensure that the cells have undergone a single nuclear division. The assay allows parallel estimation of mitotic delay (frequencies of binucleated cells), apoptosis (frequencies of condensed nuclei), chromosome breakage/chromosome loss (frequencies of micronuclei), and chromosome non-disjunction (requires FISH analysis).

For detailed analysis of chromosomal rearrangements and translocations, the production of G-bands is worthwhile. In comparison to other chromosome banding methods, such as those using fluorochromes like quinicrine, trypsin-Giemsa banding is the most convenient and reproducible and does not require the use of a fluorescent microscope. In addition, the Giemsa staining of trypsin-banded chromosomes provides a permanent record of the banding patterns, allowing historical reevaluation of slides long after the fluorescent bands would have faded. The principle behind trypsin/G-banding is that the trypsin digestion removes chromosomal proteins in distinct regions along each chromosome arm. The trypsin banding patterns are therefore characteristic for each chromosome of every species. G-banded reference karyotypes are available in the literature for virtually all species that can be used in genetic toxicology. Enlarged pitcographs of all G-banded human chromosomes are depicted in Verma and Babu (1989) with the primary nomenclature references cited therein. Various methods for optimization of G-banding procedures, as well as Q-, C-, R-banding and numerous other chromosome banding methods are also well described by Verma and Babu (1989). Only the most basic trypsin banding protocol has been included in this unit.

As an adjunct to conventional banding techniques, fluorescent in situ hybridization (FISH) has numerous research and clinical applications including but not limited to the characterization of complex structural abnormalities, chromosome enumeration using alpha-satellite probes, and gene mapping. Depending on the availability of multi-band fluorescence microscopy filters, two or three differentially colored fluorescent chromosome paints can be incorporated into these assays using a variety of fluorescent dyes. Spectral karyotyping (SKY), in which each chromosome homolog is depicted in a different color shade facilitates the identification of otherwise cryptic, complex, or very small chromosomal rearrangements (Schröck et al., 1996; Veldman et al., 1997). However, specialized costly equipment is required for SKY analyses, which may limit the routine use of this procedure in genetic toxicology studies.

Sister chromatid exchanges (SCEs) are a consequence of the interchange of replicating DNA between chromatids at apparently homologous loci. The process involves DNA breakage and reunion. A wide variety of physical and chemical mutagens induce SCEs in cultured cells and in mammals in vivo (Tucker et al., 1993). Each separate chromatid exchange

is visible cytologically after differential staining of the individual chromatids. The nature of the initial DNA damage and the mechanism of formation of SCE is still unknown; however, it appears that SCEs are produced at or near DNA replication forks. SCE frequency is increased after DNA damage by agents that inhibit or block the progression of the replication fork of a replicon (Painter, 1980). In order to screen for SCE induction, the cells are treated with the test agent, and then BrdU is added to the medium for two successive cell cycles (BrdU replaces thymidine in the newly synthesized DNA). Metaphase spreads are prepared by standard methods and the chromosomes are then stained with Hoechst 33258. This dye fluoresces at a lower intensity when bound to DNA substituted with BrdU than when bound to unsubstituted DNA. Following photosensitization which leads to degradation of highly BrdU- substituted chromatids, and staining with Giemsa, the chromatids appear differentially stained (Perry and Wolff, 1974). This process distinguishes hybrid chromosomes with one BrdU-containing strand and one darkly stained original strand from those in which both strands contain BrdU (no Giemsa stain). The sister chromatid exchanges generate the so-called "harlequin chromosomes."

Because cell lines have limited endogenous capacity for metabolic activation, it is possible to use exogenous sources of liver-derived microsomal S9 mixes (*UNIT 3.1*), when the above chromosomal aberration assays are performed (treatment of cells with S9 mix should be performed in serum-free or reduced serum medium). Alternatives to the use of S9 mixes include cocultivation, where target cells are treated in the presence of cells which are proficient for metabolic activation (Gulati et al., 1989).

Critical Parameters

The induction of chromosomal aberrations in cell culture may lead to artifacts associated with extreme culture conditions. For example, at high chemical concentrations, high osmolarity may cause apparent genotoxic effects. Highly cytotoxic doses and pH extremes may activate metabolic systems that may also be genotoxic. On the other hand, it is critical that sufficiently high doses be examined, therefore testing should be extended to doses at which some cytotoxicity is observed, as gauged by a reduction in the mitotic index (the proportion of cells in division).

A key factor in the design of cytogenetic assays in vitro is obtaining appropriate cell populations for treatment and analysis. Cells with stable, defined karyotypes, short generation times, low chromosome numbers, and large chromosomes are recommended. For this reason, Chinese hamster ovary (CHO) cells have been used extensively. Additional critical factors in cytogenetic assays are the growth conditions, controls, doses, treatment conditions, and the time intervals between treatment and the sampling of cells for analysis. In all the assays described above, it is essential that a sufficient number of cells be scored and that three to four independent experiments are performed for each toxicant dose.

While performing the MN assay, it is important to follow the criteria for scoring micronuclei as described in the protocol. Micronuclei are counted only in binucleate cells, in which two distinct nuclei are surrounded by a recognizable independent cell membrane. Only morphologically integrated cells are scored. Cells undergoing cell death, mitosis, or containing more than two nuclei, are excluded from MN scores, but included in calculations of total cell number.

By far, the most critical parameter in obtaining useful cytogenetics information from Giemsa stained, G-banded, fluorescent probe–hybridized, or SCE chromosome slides is the preparation of the metaphase spreads (also see Bangs and Donlon, 1994). These assays all require that the chromosome slides be coated with well spread non-overlapping metaphases that have not lost any chromosomes due to rough mechanical handling. A maximal number of metaphases per slide can be obtained by optimizing the Colcemid arrest timing and by not over-diluting the final cell suspension immediately prior to making the slides. During the metaphase preparations, excessive hypotonic swelling of the cells can lead to premature cell breakage, resulting in the chromosomes from many cells being mixed together in the test tube. Ideally, the swelled cells should burst at the moment of impact with the slide, allowing the chromosomes to spread out within a small radius. On the other hand, if the hypotonic treatment was insufficient, or the fixative steps did not fully weaken the cell membrane, the cells may not burst open on the slide. In this case, tightly packed poorly-stained chromosomes will be seen within ghost cells whose cytoplasm is still faintly visible. Such cells are not adequate for scoring chromosome aberrations, translocations, or SCE. Over-condensation of the chromosomes by Colcemid treatment that is too concentrated or too long will

also impact on staining and analysis in all protocols discussed above. Based on these considerations, it is essential that new investigators familiarize themselves with hands-on experience in metaphase spread preparations prior to commencing any treatment experiments. In addition, the specific parameters for Colcemid arrest, hypotonic swelling, fixation and slide preparation should also be optimized in advance for the particular cell type that will be used, since species and tissue of origin of the cells can have profound effects on these variables.

Lastly, it should be noted that the protocols specified herein are general protocols that may be standardized to include very narrow windows of timing and other processing parameters when the assays are being applied to industrial genotoxicity testing settings or when comparing data between laboratories, especially in human exposure biomarker situations (Fenech, 1998).

Anticipated Results

Clastogenic activity may be measured as an increase of MN and SCE frequencies. If the tested agent has a clastogenic potential it is expected to induce MN and SCE in a dose responsive manner. MN assays provide a measurable index of chromosome breakage or loss, but cannot replace the detailed analysis of chromosome damage obtained on Giemsa stained, banded, or FISH-painted metaphase spreads.

Baseline levels of the various cytogenetic outcomes discussed in this unit have been reported for humans and experimental animal studies for each of the specific assays discussed above. A brief review of some of those data will be presented here, with the caveat that a broad range of interpopulation, intraindividual, interlaboratory, and species differences in these values can be found in the literature. As noted above, ongoing international standardization of each of the cytogenetic assays currently used for regulatory and research purposes will undoubtedly lead to more clearly defined acceptable baseline values, test protocols, and toxicity limits for each specific assay (Kirkland, 1998). Therefore the data presented here will only serve to orient the reader to general baseline and genotoxicant exposure levels observed for some of the different cytogenetic assays that we have discussed.

With any exposure to genotoxicants, the mean MN values could increase dramatically. This was shown, for example, in a CBMN micronucleus study in which mouse liver cells were exposed to X-rays and vinblastine (Salassidis et al., 1992). Compared to the background level of MN (35/1000 cells scored) exposure of these cells to 3 Gy of X-rays induced 385 MN/1000 cells, and 0.6 μM vinblastine induced 154 MN/1000 cells. Human population studies often yield much lower values for MN frequency. As summarized recently by Fenech (1998), the CBMN assay generates mean baseline MN values of about 10 MN per 1000 binucleated (BN) cells in unexposed human lymphocytes from 20- to 45-year-old donors, with age and gender being the most important demographic variables. A large age-related variability in this value is evident, with 20 to 29 year olds showing 7.9 ± 3.3 MN/1000 BN cells, compared to 70 to 89 years olds showing 22.3 ± 7.6 MN/1000 BN cells. In contrast, variability related to different tissue culture media was not found. However, the mean MN value in the unexposed lymphocytes as determined by two independent scorers (9.2 ± 0.4 versus 11.4 ± 0.5) varied by at least 34%.

In normal human lymphocytes, the general level of chromosome aberrations is on the order of 0.5% to 1% of cells with any aberration. In a study of X-ray exposures of human lymphocytes, the frequency of cells with aberrations increased to about 26% and 72%, following 100Gy and 300Gy exposures to X-rays (Grigorova and Natarajan, 1998). In human lymphocytes, the total number of aberrant chromosomes observed in one FISH study of X-ray-induced chromosome interchanges involving chromosome 1 was even lower than the level of general aberrations, about 2.5/1000 cells scored (Boei et al., 1998). Following in vitro exposure of these cells to 3 Gy of X-rays, the level of chromosome aberrations involving rearrangements with chromosome 1 rose to near 700/1000 cells. In Chinese hamster V79 cells, background levels of SCE were reported to be about 5.5/100 cells scored, whereas the SCE levels increased to 20/100 cells following exposure to UVB light and to even higher levels of about 55/100 cells when the UVB light was combined with a topoisomerase II inhibitor (Ikushima et al., 1998).

Time Considerations

In the MN assay, the seeding of the cells and adding of the test agent will take ~9 hr (including the incubation periods). The cells are then incubated in the presence of cytochalasin B for 20 to 24 hr. Cell fixation and staining require 4 to 6 hr, and scoring of MN will take several hours, depending upon the number of inde-

pendent experiments performed and the skill of the observer. In the SCE assay, the seeding of the cells requires 1 to 2 hr and then the cells are incubated for 16 to 20 hr. The cells are then treated with the test agent for 4 hr followed by incubation with BrdU for 24 to 48 hr. Cell fixation and staining require 7 to 9 hr, and the scoring process requires an additional several hours. Following desired exposure to a genotoxicant, routine chromosome harvest and trypsin/Giemsa banding can be accomplished in a total of 6 to 8 hr; however, the banding procedure is optimal when the slides have been aged at least overnight prior to staining. FISH analysis of fluorescent painted chromosomes requires the cell exposure, then the usual 6 to 8 hr for chromosome harvest. This is followed by 2 to 4 hr for the initial prehybridization handling, 24 to 48 hr for hybridization of the painting probes, and another 2 to 4 hr of post-hybridization washing and staining. For all cytogenetic procedures, microscopic analysis of the results requires several hours to several days, depending on the number of treatments and slides to be evaluated, as well as the skill of the investigator.

Methods for Measuring DNA Adducts and Abasic Sites I: Isolation, Purification, and Analysis of DNA Adducts in Intact DNA

The major event involved in the formation of mutations and the initiation and progression of cancer is the induction of DNA damage by reactive intermediates arising from exposure to exogenous or endogenous chemicals. Many electrophilic metabolites of chemicals covalently bind to the bases of DNA, causing specific DNA adducts. A classic reference for these interactions is the book by Singer and Grunburger (1983). More recent reviews include several chapters in Volume 12 of *Comprehensive Toxicology* (Sipes et al., 1997) and the paper by La and Swenberg (1996). In addition to these reviews that include sections on DNA adducts arising from exogenous agents, there are numerous reviews on oxidative DNA damage that arises from endogenous and exogenous sources and from lipid peroxidation (Marnett and Burcham, 1993; Chung et al., 1996).

There are several features of DNA damage that need to be understood to place the results of such research in proper perspective. The first is that different DNA adducts have different efficiencies for causing mutations. To date, the most efficient adduct reported is O^4-methylthymine, which causes a base-pair substitution ~80% of the time DNA polymerase transcribes the adduct. Other promutagenic adducts cause mutations anywhere from 1% to 20% of the time. Most of these adducts are located in the base-pairing region of the DNA, although others cause the adducted base to flip out, so that different parts of the base are involved with base-pairing. Still other DNA adducts do not appear to cause mispairing and are relatively inefficient in causing mutations. Some of these, like the N-7 alkyguanine and N-3 alkyladenine adducts, are repaired rapidly or chemically depurinated causing abasic sites. Second, DNA adducts are repaired by a variety of pathways. These repair pathways can be error prone or essentially error free. They can also be saturated (i.e., the DNA repair pathways are working at maximum speed and efficiency, but cannot keep up with the damage being done) or induced. This points out an important caveat, that the number of DNA adducts may differ in single-dose studies compared to multiple-dose studies. DNA adducts are like other toxicokinetic parameters: under conditions of continuous exposure they will reach a steady state, where the number of DNA adducts formed on a given day will equal the number that are lost from repair and depurination. Finally, it is important to remember that loss of a DNA adduct does not necessarily mean that the lesion has returned to its normal state with a correct base inserted in a normal strand of DNA. In the case of base excision repair, there are five steps including removal of the base by the glycosylase, 5′-incision of the abasic site by AP endonuclease, single nucleotide insertion by β polymerase, subsequent release of the deoxyribose fragment, and ligation of the repaired strand. If any of the steps that follow removal by glycosylase are not completed, the resulting lesion may still have genetic consequences.

This unit contains protocols for DNA isolation and hydrolysis that are suitable for the most common types of DNA adduct analyses and for the evaluation of abasic sites in DNA: low-temperature/antioxidant DNA isolation (see Basic Protocol 1), room temperature/antioxidant DNA isolation (see Alternate Protocol), measurement of apurinic/apyrimidinic sites (see Basic Protocol 2), immune slot-blot analysis of DNA adducts (see Basic Protocol 3), immunohistochemical determination of DNA adducts (see Basic Protocol 4), and spectrophotometric quantification of DNA (see Support Protocol).

Current Protocols in Toxicology (2002) 3.8.1-3.8.18

DNA ISOLATION METHODS

The approach to DNA isolation for DNA adduct studies is generally similar to those for other endpoints. The main considerations are the purity of the DNA and the amount of DNA needed for the assay. DNA for adduct studies should be devoid of RNA and free of protein as possible. This can be accomplished through the use of RNase incubation and extensive extraction with phenol and chloroform. The amount of DNA required for measuring some DNA adducts is typically much higher than amounts required for biotechnological assays. Some of these assays require up to 300 μg DNA. Most of the DNA isolation in the authors' laboratory is done through manual extraction using phenol and chloroform.

Alternative approaches to DNA isolation involve commercially available kits that significantly reduce the amount of time involved and do not require the use of phenol or chloroform. Many DNA isolation kits are designed to produce very small amounts of DNA for molecular biology studies; however, some kits can be scaled up to produce larger amounts of DNA from cell and tissue samples. Two such kits are the Puregene system of DNA isolation (Gentra Systems) and isolation using DNAzol genomic DNA isolation reagent (Molecular Research Center).

DNA adducts are usually quantified by comparing the number of adducted bases to the total number of the same base in the DNA sample, the number of total nucleotides, or the amount of DNA. For example, when measuring N^2,3-ethenoguanine (εGua) adducts, one must first measure the amount of guanine in the sample to produce useful data (*UNIT 3.9*). One could also give the data as the number of εGua per milligram DNA or per 1×10^6 nucleotides. Before treating the isolated DNA, an aliquot (typically 10 to 20 μl) of the DNA solution should be removed for measurement of the base, nucleoside, nucleotide, or DNA content. This is typically done using an HPLC-based assay and a calibration curve (see *UNIT 3.9*).

The protocols presented in this section detail two methods of DNA isolation that are based on phenol/chloroform extraction. The main differences between the two protocols involve incubation temperatures and times. Some DNA adducts are sensitive to the effects of heat and oxidation while others are not. This variable must be determined for the adduct studied before deciding which method to use. The low-temperature/antioxidation DNA isolation method (see Basic Protocol 1), should be used if there is any question that heat may alter the assay measurement. The room-temperature/antioxidation DNA isolation method (see Alternate Protocol) can be used if it is known that heat will not alter the assay measurement. Regardless of the DNA isolation method used, the authors have found that the addition of antioxidants—i.e., 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) and butylated hydroxytoluene (BHT)—to the protocol has resulted in a reduction of artifactual production of oxidative DNA damage. Spectrophotometric quantification of DNA (see Support Protocol) can be used to estimate DNA content with any isolation method.

BASIC PROTOCOL 1

Low-Temperature/Antioxidation DNA Isolation

This protocol is particularly useful when dealing with assays that are sensitive to the effects of heat and oxidation (i.e., aldehyde reactive probe slot-blot assay and 8-hydroxy-2′-deoxyguanosine assay).

Materials

10 mg/ml proteinase K, nucleic acid purification grade (PE Biosystems): store powder up to 1 year at 4°C and solution up to 1 year at −20°C

1× lysis buffer/20 mM 2,2,6,6-tetramethyl-1-piperidinyloxy (lysis buffer/TEMPO; see recipe)

1× phosphate buffered saline without Ca^{2+} or Mg^{2+} (CMF-PBS; see recipe)/20 mM TEMPO

20 mg/ml butylated hydroxytoluene (BHT; Sigma-Aldrich) in isopropanol: store up to 1 month at −20°C

Tissue

70% phenol/chloroform/water (Applied Biosystems): store up to 6 months at 4°C

Sevag mixture (Applied Biosystems): store up to 6 months in a brown bottle at room temperature

2 M and 1 mM TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy; Sigma-Aldrich)

4 M NaCl: store up to 4 weeks at room temperature

100% and 70% ethanol, −20°C

30 mg/ml (~3000 Kunitz units/ml) ribonuclease A (Sigma-Aldrich)

5000 U/ml ribonuclease T_1 (Roche or Sigma-Aldrich): boil 15 min to inactivate DNases and store up to 6 months at 4°C

15- and 50-ml polypropylene centrifuge tubes

Tissue homogenizer with a glass tube and loose-fitting Teflon pestle with >0.1 to 0.15 mm tolerance

10-ml pipets

Additional reagents and equipment for determining DNA concentration (see Support Protocol)

CAUTION: TEMPO is a hazardous chemical that is corrosive, combustible, and readily absorbed through the skin. Use only in a chemical fume hood and wear suitable protection. Refer to the material safety data sheet (MSDS) for more information.

DAY 1

1. Turn on tabletop centrifuge and cool to 4°C.
2. Place stock solutions of 10 mg/ml nucleic-acid-purification-grade proteinase K, 1× lysis buffer/20 mM 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO), and 1× phosphate buffered saline without Ca^{2+} or Mg^{2+} (CMF-PBS)/20 mM TEMPO in a bucket of ice.
3. Label microcentrifuge tubes (1 per sample), 50- (1 per sample), and 15-ml (3 per sample) polypropylene centrifuge tubes.

   CAUTION: *Use only polypropylene centrifuge tubes when working with phenol, chloroform, or other organic solvents, as polystyrene tubes will dissolve. Polypropylene tubes are usually slightly opaque, while polystyrene tubes are clear.*

Start DNA isolation

To prepare tissue/cells from fresh or frozen whole tissue

4a. Add 20 ml ice-cold CMF-PBS/20 mM TEMPO and 25 µl of 20 mg/ml butylated hydroxytoluene (BHT) in isopropanol to 1000 mg tissue in a glass homogenizer tube. Homogenize using a loose-fitting Teflon pestle, with a tolerance >0.1 to 0.15 mm. Apply as few strokes as possible.

   Typically, 5 to 10 strokes are required for complete homogenization.

5a. Transfer liquid to previously labeled 50-ml centrifuge tube and obtain a nuclear pellet by centrifuging in a tabletop centrifuge 10 min at 1500 × *g*, 4°C.

6a. Discard the supernatant and resuspend the pellet in 10 ml ice-cold lysis buffer/20 mM TEMPO.

To prepare fresh or frozen cell fractions

4b. Prepare cell fractions in microcentrifuge tubes and place on ice.

5b. Add 0.5 to 1 ml cold lysis buffer/20 mM TEMPO and 25 µl of BHT in isopropanol, and resuspend.

6b. Transfer to a labeled 15-ml centrifuge tube. Using a 10-ml pipet, add cold lysis buffer/20 mM TEMPO to reach a total volume of 4 ml.

For both tissue/cell preparations and fragments

7. Add 100 µl ice-cold proteinase K solution using a micropipet.

8. Mix by inversion for 12 to 24 hr (i.e., overnight) at 4°C.

DAY 2

9. Turn on tabletop centrifuge and cool to 4°C.

10. Place 70% phenol/chloroform/water mixture and Sevag mixture on ice at least 30 min prior to use. Add 2 M TEMPO to each to a final concentration of 20 mM (100-fold dilution of TEMPO).

    70% phenol/water/chloroform is 68% phenol/18% water/14% chloroform.

Extract DNA

11. Add 10 ml of 70% phenol/chloroform/water mixture to the sample.

    CAUTION: *Phenol is a caustic chemical and contact with skin should be avoided. Perform this step under a fume hood using only glass pipets, as chloroform/phenol will melt some plastics. Insert only the tip of the pipet into solution as the numbers and lines may be removed by the organic solvents.*

12. Mix 5 min, inverting by hand.

13. Centrifuge in a tabletop centrifuge 10 min at 1800 × *g*, 4°C.

    Centrifugation should result in the separation of the aqueous DNA (water/DNA) portion from the phenol/chloroform portion (Fig. 3.8.1).

14. Place sample tubes on ice and remove the upper phase (water/DNA layer) using a hand-held micropipettor. Transfer to a fresh labeled 15-ml centrifuge tube.

    Be sure to take the entire water/DNA layer.

15. Repeat steps 9 through 12, except reduce centrifugation time to 5 min.

16. Add 10 ml Sevag mixture (step 8) to sample.

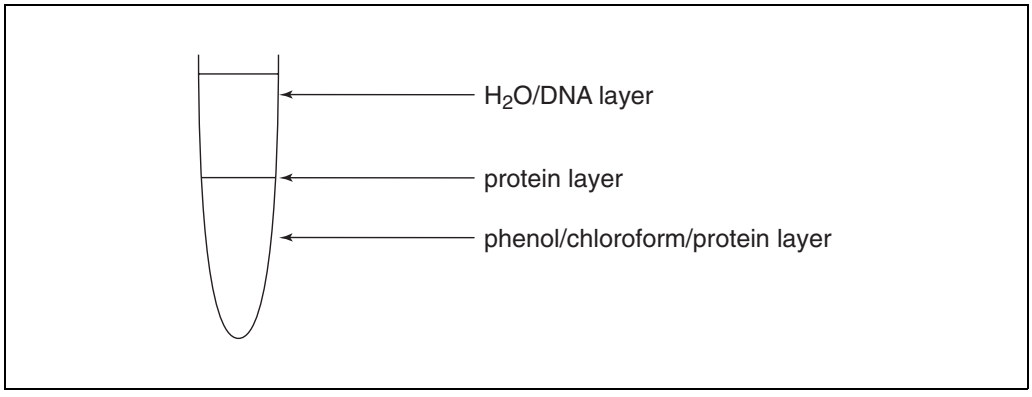

Figure 3.8.1 Centrifugation results in a distinct separation of the H_2O/DNA portion from the phenol/chloroform portion.

17. Mix 5 min, inverting by hand.
18. Centrifuge in a tabletop centrifuge 5 min at 1800 × *g*, 4°C.
19. Place sample tubes on ice and remove the upper phase (water/DNA layer) using a hand-held micropipettor. Transfer to a new, previously labeled centrifuge tube.
20. Add 750 µl of 4 M NaCl to each sample and mix by hand ten times.

    This step is useful when there is a concern about low concentrations of DNA, since salt enhances DNA precipitation. The total amount of 4 M NaCl added is 7.5% the volume water/DNA—i.e., for 3 ml, add 225 µl of 4 M NaCl (3 ml × 0.075 = 225 µl).

Precipitate DNA

21. To each sample, add 3 vol of 100% ethanol, −20°C.
22. Mix by hand and incubate the sample tubes at −80°C for 15 to 20 min.

    This step is useful for greater recovery of DNA in small samples.

23. Centrifuge sample tubes in a tabletop centrifuge 15 min at 2200 × *g*, 4°C.
24. Discard the supernatant, wash DNA pellet with 5 to 10 ml of 70% ethanol, −20°C, and mix gently.
25. Centrifuge sample tubes in a tabletop centrifuge 5 min at 1800 × *g*, 4°C.
26. Resuspend DNA in 0.75 to 3 ml CMF-PBS/20 mM TEMPO. Incubate 1 to 4 hr at 4°C.

    The amount of CMF-PBS/TEMPO will vary with DNA pellet size. Use 750 µl for a very small pellet, 1.5 ml for an average pellet, and 3 ml for a very large pellet.

Treat with RNase A

27. Add 12 µl of 30 mg/ml ribonuclease A and 12 µl of 5000 U/ml ribonuclease T_1 solutions.
28. Incubate 1 hr at 37°C, mixing continuously to generate a homogenous DNA solution.
29. *Optional:* Repeat steps 16 to 19.

    To reduce residual TEMPO and RNase, an additional Sevag extraction is useful after RNase incubation.

30. Add 1.5 ml water and 225 µl of 4 M NaCl (i.e., 7.5% total volume; see step 18) to each sample.

Precipitate DNA

31. Add 3 vol of 100% ethanol, −20°C, to each sample and invert several times by hand.
32. Using a pipet tip or spatula, transfer the DNA fiber to a new previously labeled centrifuge tube.

    The extracted DNA will appear as a white cloud or fiber structure floating in the ethanol.

33. Wash the DNA fiber with 2 to 4 ml of 70% ethanol, −20°C.
34. Centrifuge the DNA solution in a tabletop centrifuge 10 to 15 min at 1800 × *g*, 4°C.
35. Remove supernatant (ethanol) by inverting tube and allowing to dry 1 min.
36. Resuspend DNA in 1 ml of 1 mM TEMPO for 1 to 4 hr or overnight, 4°C.
37. Store resuspended DNA product up to 1 year or more at −80°C.

ALTERNATE PROTOCOL

Room Temperature/Antioxidation DNA Isolation

For many other DNA adduct assays, room temperature and heated incubations do not pose a threat to the assay measurement; therefore, an alternate shorter protocol is available. This method is used in the authors' laboratory to isolate DNA from cells or tissues prior to ethenoguanine adduct quantification. The purity of the DNA obtained by this method is not especially high, but protein contamination does not interfere with these assays. The short procedure is also thought to help minimize artifactual adduct formation.

Additional Materials *(also see Basic Protocol 1)*

Tissue or pelleted sample
1× phosphate-buffered saline without Ca^{2+} or Mg^{2+} (CMF-PBS; see recipe)
1× lysis buffer/BHT: add 1 ml of 20 mg/ml BHT (Sigma-Aldrich) in isopropanol per 450-ml bottle of 1× lysis buffer (Applied Biosystems)
RNase solution (see recipe)
70% phenol/water/chloroform containing BHT: add 1 ml of 20 mg/ml BHT in isopropanol per 450-ml bottle of 70% phenol/water/chloroform (Applied Biosystems)
Chloroform/BHT (see recipe)
3 M sodium acetate trihydrate (Mallinckrodt; *APPENDIX 2A*)
95% ethanol, −20°C
Isopropanol (Mallinckrodt)
Alumina (Sigma-Aldrich): store up to 6 months in a 60°C oven

Wheaton overhead mixer
Gel-loading tips
3-ml syringes and 22-G needles

CAUTION: Phenol is a caustic chemical and contact with skin should be avoided. Perform this step under a fume hood using only glass pipets as chloroform/phenol will melt some plastic pipets. Insert only the tip of the pipet into solution as the numbers and lines may be removed by the organic solvents.

Prepare tissue

1. Suspend tissue (typically 0.5 to 1.0 g) or pelleted cell sample in 10 ml of 1× CMF-PBS and add 25 µl of 20 mg/ml BHT in isopropanol.
2. Homogenize each sample by making 4 to 5 passes with a Wheaton overhead mixer. Transfer to a 15-ml polypropylene centrifuge tube.
3. Centrifuge the samples 10 min at 1000 × *g*, 4°C.
4. Resuspend pellet in 5 ml of 1× lysis buffer/BHT.
5. Add 40 µl RNase solution to each sample and incubate 2 hr at 37°C, mixing continuously.
6. Add 125 µl of 10 mg/ml nucleic-acid-purification-grade proteinase K solution to each sample and incubate an additional 2 hr.

Extract DNA

7. Add 5 ml 70% phenol/water/chloroform containing BHT to each sample and mix for 5 min.

   CAUTION: *Phenol is a caustic chemical and contact with skin should be avoided. Perform this step under a fume hood using only glass pipets as chloroform/phenol will melt some plastic pipets. Insert only the tip of the pipet into solution as the numbers and lines may be removed by the organic solvents.*

8. Centrifuge 10 min at 1000 × *g*, 4°C.

9. Carefully transfer the upper (aqueous) phase of each sample to a clean 15-ml centrifuge tube using a transfer pipet.
10. Repeat steps 7 through 9.
11. Add 5 ml chloroform/BHT to each sample and mix 5 min.
12. Repeat steps 8 and 9.

Precipitate DNA

13. Place samples on ice and add 0.5 ml of 3 M sodium acetate trihydrate to each sample.
14. Add 10 ml of 95% ethanol, −20°C, and mix 15 min at 4°C.
15. Centrifuge 3 min at 1000 × *g*, 4°C.
16. Pour off the supernatant and resuspend the pellet in 5 ml of 70% ethanol, −20°C.
17. Repeat the centrifugation (step 15) and discard the supernatant.
18. Remove the remaining ethanol by pipetting with gel-loading tips. Allow any residual solution to evaporate 15 min at room temperature.
19. Resuspend DNA in enough water to yield a 1 mg/ml solution (typically ~1 ml; see Support Protocol) and store overnight at 4°C.

Shear the DNA

20. Pull each sample into a 3-ml syringe though a 22-G needle until the solution flows easily and uniformly.
21. Transfer each sample to a labeled 1.7-ml microcentrifuge tube.
22. Store DNA samples up to 1 year or more at −80°C.

Spectrophotometric Quantitation of DNA

SUPPORT PROTOCOL

For each of the above isolation methods (see Basic Protocol 1 and Alternate Protocol), quantification of DNA can be performed using the following protocol.

Materials

DNA samples (see Basic Protocol 1 or Alternate Protocol)
Spectrophotometer with reference and sample slots
Quartz cuvettes with 1 cm path length

1. Prepare the spectrophotometer with reference and sample slots for photometric measurements. Set the measurement wavelength to 320 nm and press the autozero function. Correct the baseline after placing sample cuvettes filled with water in reference and sample locations. Set measurement parameters to record at 230, 260, and 280 nm.

   The 230 nm wavelength is used as a zero baseline. The 260 nm wavelength is used to quantify DNA, while both the 230 and 280 nm wavelengths are used to estimate protein contamination.

2. Make 1:20 or 1:200 dilutions of the DNA samples in water to give a final volume of 1 ml.

   Add 50 µl DNA sample to 950 µl water to make a 1:20 dilution or 1:200 dilutions if the sample size is very small.

3. For each diluted DNA sample, place the DNA sample in a quartz cuvette with 1-cm path length in the sample location. Measure the absorbance of each sample against the water reference cuvette at 260 nm and 280 nm.

   Begin with water as a sample. These measurements should be zero.

4. Calculate DNA yield:

   DNA (mg) = (A_{260}/20 mg^{-1}) × volume of DNA solution (ml) × (dilution factor)

   The dilution factor for a 1:20 dilution is 20.

   The extinction coefficient of DNA at wavelength 260 is 20 $(mg/ml)^{-1}$ cm^{-1}.

5. To estimate possible protein contamination, divide A_{260} by A_{280} and divide A_{230} by A_{260}.

   The ratio A_{260}/A_{280} should be ≥1.7; however, ratios of 1.5 and 1.6 are common. The ratio of A_{230}/A_{260} should be ≥2.3. If protein contamination is high, the DNA can be extracted again from the sample using phenol.

ANALYSIS OF DNA ADDUCTS IN INTACT DNA

Apurinic/apyrimidinic (AP) sites are base-loss lesions in nucleic acids. These lesions are introduced in DNA by spontaneous depurination and by DNA glycosylases. In addition, oxidative stress directly causes AP sites through sugar damage. It is believed that the formation of AP sites is one of the most frequent and deleterious events in genomic DNA. The AP sites need to be repaired efficiently because they introduce mutations and block DNA replication.

A sensitive assay to measure the number of AP sites in genomic DNA is essential to better understand the efficiency of base excision repair (BER). The most common AP sites (regular AP sites) are derived from simple hydrolysis of the *N*-glycosylic bond. These regular AP sites are in equilibrium with an aldehydic ring-opened form. The aldehyde-reactive probe (ARP), a specific biotin-tagged aldehydic probe, reacts with aldehydic ring-opened AP sites (Kubo et al., 1992). The number of biotin-tagged AP sites can then be determined colorimetrically by an ELISA-like assay.

BASIC PROTOCOL 2

Measurement of Apurinic/Apyrimidinic Sites

The protocol described here is a convenient and sensitive assay to measure the number of AP sites in genomic DNA by a combination of ARP and the slot-blot technique (Nakamura et al., 1998; Nakamura and Swenberg, 1999). Quantitation is based on comparisons to internal standard DNA containing known amounts of AP sites.

Materials

One primary (e.g., Dojindo) and three secondary (e.g., Dojindo or equivalent) internal DNA standards (100 and 30 AP sites/1 × 10^6 nucleotides, respectively)
Unknown DNA samples
10× PBS, pH 7.4 (see recipe)
10 mM aldehyde-reactive probe (ARP; Dojindo Molecular Technologies): store up to 1 year at −80°C
100% and 70% ethanol, −20°C
1× TE buffer, pH 7.5 (see recipe for 10×)
Calf thymus DNA (Sigma-Aldrich)
1 and 2 M ammonium acetate
5× SSC (see recipe)

Hybridization mix (see recipe)
Streptavidin-conjugated horseradish peroxidase (HRP; BioGenex Laboratories)
Washing buffer (see recipe)
ECL reagent (Amersham)

Minifold II dot/slot blotting manifold (Schleicher & Schuell)
Blotting paper (Schleicher & Schuell)
Nitrocellulose (NC) membrane—e.g., Hybond C-Super (Amersham), BA 85 (Schleicher & Schuell)
37°C environmental shaker
80°C vacuum oven
Bottle rotator
Scanning densitometer
Temperature-controlling device (e.g., thermocycler, water bath, etc.)

Additional reagents and equipment for measurement of DNA concentration (see Support Protocol)

Prepare samples

1. In a 600-µl microcentrifuge tube on ice, add ~16 µl of the following 0.5 µg/µl solutions:

   One primary standard containing 100 AP sites/1×10^6 nucleotides
   Three secondary standards containing 30 AP sites/1×10^6 nucleotides
   Unknown samples (up to 25).

   Add 15 µl of 10× PBS and adjust the volume to 135 µl with water.

2. Add 15 µl of 10 mM ARP into the tube on ice.
3. Incubate 10 min at 37°C.
4. Precipitate DNA by adding 3 vol of 100% ethanol, −20°C, and incubating 20 min at −80°C.
5. Microcentrifuge 15 min at maximum speed, 4°C.
6. Wash DNA pellet with 70% ethanol, −20°C, and microcentrifuge 5 min at maximum speed, 4°C.
7. After discarding the supernatant, add 250 µl of 1× TE buffer, pH 7.5, and mix vigorously 1 hr at room temperature by mixer, or overnight in the refrigerator.

Prepare denatured DNA solution

8. Measure DNA concentration using a spectrophotometer at 260 nm (see Support Protocol).
9. Prepare 0.5 to 1.1 µg DNA mixture in 220 µl of 1× TE buffer and ~2 ml calf thymus (blank) DNA in of 1× TE buffer at a concentration of 0.5 to 1.1 µg/220 µl.
10. Denature DNA at 100°C for 10 min.
11. During denaturation of DNA set up Minifold II dot/slot blotting manifold:
    a. Place two sheets of blotting paper on the plate of the Minifold II.
    b. Immerse blotting paper in 1 M ammonium acetate.
    c. Place one sheet of nitrocellulose (NC) membrane on the blotting paper.
    d. Immerse the NC membrane in 1 M ammonium acetate.
    e. Place the top plate on the filter and clamp.

f. Aspirate residual ammonium acetate by vacuum.

g. Add 200 µl of 1 M ammonium acetate to each slot.

h. Aspirate 1 M ammonium acetate by vacuum.

12. Transfer denatured DNA from 100°C to ice and wait ~2 min.

13. After cooling, serially dilute primary standard DNA with blank DNA containing equal concentrations (e.g., 100, 30, 10, 3, 1, 0.3, 1, and 0 AP sites/1×10^6 nucleotides).

14. Add 220 µl of 2 M ammonium acetate to the DNA solution.

Load samples

15. Load DNA onto the NC membrane in duplicate random locations using 200 µl/slot.

16. Aspirate DNA solution by vacuum.

17. Add 200 µl of 1 M ammonium acetate to each slot.

18. Aspirate ammonium acetate by vacuum.

Hybridize filter

19. Transfer the filter into 150 ml of 5× SSC and wash 15 min in a 37°C environmental shaker.

20. Bake the NC membrane 30 min in an 80°C vacuum oven.

21. Incubate the membrane 15 min with 20 ml hybridization mix in a plastic bottle at room temperature using a bottle rotator.

Visualize adducts

22. Add 2 µl streptavidin-conjugated horseradish peroxidase (HRP) and incubate the membrane 45 min at room temperature.

23. Wash the NC membrane three times with washing buffer at 37°C, 5 min each.

24. Incubate the filter 30 sec in ECL reagent at room temperature and wrap the membrane with plastic wrap.

25. Expose the NC membrane to X-ray film 30 sec to 2 min. Develop the film.

Quantify AP sites

26. After drying the X-ray film, scan the density using a scanning densitometer.

27. Using the standard curve, quantitate the number of AP sites for duplicate secondary standard samples and unknown samples.

28. Calculate the mean numbers of AP sites for triplicate secondary standard samples.

29. Calculate a factor to adjust the mean to 30 AP sites/1×10^6 nucleotides.

30. Adjust the number of AP sites for unknown samples by the same factor used for the secondary standards.

Measurement of DNA Adducts by Immuno-Slot Blot (ISB)

A number of specific antibodies against base lesions have been established to measure DNA adducts in genomic DNA (Farmer and Shuker, 1999). One of the most convenient and relatively sensitive assays to determine the number of DNA adducts is the immuno-slot blot (ISB) assay using these antibodies (Farmer and Shuker, 1999). This ISB method, which is a noncompetitive immunoassay, can quantify the number of any heat- or alkaline-stable DNA lesions. The typical detection limit of the ISB assay is 0.3 to 1 lesion/1×10^7 nucleotides. The amount of DNA needed for this assay is between 0.1 to 3 µg, making this technique suitable for determining the number of DNA lesions in the small amounts of DNA associated with epidemiological samples.

The protocol described here is a noncompetitive immunoassay used to determine the number of lesions in DNA immobilized on a nitrocellulose (NC) membrane. Quantitation of specific lesions is performed by comparing the signals of slots loaded with unknown samples to those loaded with internal standard samples.

Materials

Internal standard containing 30 DNA lesions/1×10^6 nucleotides
Unknown DNA samples
1× TE buffer, pH 7.5 (see recipe for 10×)
Calf thymus DNA (Sigma-Aldrich)
1 and 2 M ammonium acetate
5× SSC (see recipe)
Antibody blocking buffer (see recipe)
Primary antibody against specific DNA lesions (e.g., R & D Systems)
Washing buffer (see recipe)
Hybridization mix (see recipe)
Biotinylated secondary antibody (BioGenex Laboratories)
Streptavidin-conjugated HRP (BioGenex Laboratories)
ECL reagent (Amersham western kit)

37°C environmental shaker
80°C vacuum oven
Bottle rotator

Additional reagents and equipment for set up of Minifold dot/slot blotting manifold (see Basic Protocol 2, step 11)

Prepare denatured DNA samples

1. In a 600-µl centrifuge tube on ice, prepare 3 µg DNA/sample in 220 µl of 1× TE buffer, pH 7.5, containing:

   Internal standard containing 30 DNA lesions/1×10^6 nucleotides
   Unknown DNA samples (up to 30 samples).

2. Serially dilute standard DNA by a factor of ~3 using calf thymus (blank) DNA (e.g., 30, 10, 3, 1, 0.3, 0.1, 0.03, and 0 lesions/1×10^6 nucleotides).

3. Denature DNA 10 min at 100°C, and immediately place the tubes on ice.

4. During denaturation of DNA, set up Minifold II dot/slot blotting manifold (see Basic Protocol 2, step 11).

5. Add 220 µl of 2 M ammonium acetate to the DNA solution.

Load samples

6. Load DNA on the membrane in duplicate at random locations using 200 µl/slot.
7. Aspirate DNA solution by vacuum.
8. Add 200 µl of 1 M ammonium acetate to each slot.
9. Aspirate ammonium acetate by vacuum.
10. Transfer the NC membrane into 150 ml of 5× SSC and soak 15 min in a 37°C environmental shaker.
11. Bake the membrane 30 to 120 min at 80°C in a vacuum oven.
12. Incubate the NC membrane 2 hr in 20 ml blocking reagent in a plastic bottle at room temperature using a bottle rotator.

Probe membrane with antibody

13. Add the primary antibody against the specific DNA lesion and incubate the filter 2 hr at room temperature or overnight at 4°C.
14. Wash the NC membrane three times with washing buffer in a 37°C environmental shaker for 5 min each.
15. Incubate the membrane in a plastic bottle containing 20 ml hybridization mix and 10 µl biotinylated secondary antibody, using a bottle rotator for 1.5 to 2 hr at room temperature, or overnight at 4°C.
16. Wash the NC membrane three times with washing buffer 5 min at 37°C, each.

Visualize AP sites

17. Incubate the membrane 45 min at room temperature in 20 ml hybridization mix containing 2 µl streptavidin-conjugated HRP in a plastic bottle using a bottle rotator.
18. Wash the NC membrane three times with washing buffer for 5 min at 37°C, each.
19. Incubate the membrane 30 sec with ECL reagent at room temperature, and wrap the membrane in plastic wrap.
20. Expose the NC membrane to X-ray film for 30 sec to 2 min. Develop the film.
21. After drying the X-ray film, scan the density using a scanning densitometer.
22. Using the standard curve generated by peak area of slot, quantitate the number of AP sites for unknown samples.

BASIC PROTOCOL 4

Immunohistochemical Demonstration of DNA Adducts

Immunohistochemistry (IHC) is a method utilizing a primary antibody against a specific target, in this case a DNA adduct, which uses a secondary labeled antibody that can be reacted enzymatically to produce a colored or fluorescent end product which can be visualized by microscopy. The advantage of IHC is that the DNA adducts can be identified by cell type and location within the organ of interest.

Materials

Slides with tissue sections, treated and control
Xylene
100%, 95%, and 70% ethanol
1× PBS (see recipe for 10×)/1% (v/v) Tween 20

DAKO Envision Kit for HRP (Dako):
  Blocking reagent: 0.3% H_2O_2 in methanol
  Polymer-labeled secondary antibody
  DAB
  Substrate buffer
Primary antibody
Quick DAB enhancer solution (Innovex Biosciences)
Aqua Hematoxyin (Innovex Biosciences)
Permount (Fisher Scientific)

NOTE: Other manufacturers' reagents can be substituted; however, incubation times in the following procedure would have to be changed according to their directions.

NOTE: All of the following steps are performed at room temperature.

Prepare slides

1. Hydrate slides with treated and control tissue sections through three changes of xylene, three changes of 100% ethanol, two changes of 95% ethanol, and 1 change of 70% ethanol, for 4 min each.
2. Rinse the slides with two changes of water each time for 1 min.
3. Rinse slides twice with 250 µl PBS/1% (v/v) Tween 20 each time for 3 min.
4. Incubate slides 5 min in 250 µl blocking reagent from the DAKO Envision kit.
5. Repeat rinse (step 3).

Expose slides to antibody

6. Incubate slides 10 min in 250 µl diluted primary antibody.

   As most of the primary antibodies against DNA adducts are not commercially available the actual dilution factor for the primary antibody used in this step will have to be determined through a set of serial dilutions (e.g., 1:50, 1:100, 1:500, 1:1000).

7. Repeat rinse (step 3).
8. Incubate slides in 250 µl polymer-labeled secondary antibody from the Envision kit for 10 min.
9. Repeat rinse (step 3).

Visualize bound antibody

10. Add one drop DAB per milliliter substrate buffer to make working DAB solution. Incubate slides 8 min in the dark with 250 µl working DAB solution.
11. Rinse well with water.
12. Incubate slides 5 min with 250 µl DAB Enhancer solution.
13. Rinse well with water.
14. Stain with aqua hematoxylin for 25 sec and rinse with tap water.
15. Incubate 5 min in tap water.
16. Dehydrate the slides through two changes of 95% ethanol, two changes of 100% ethanol, and clear in two changes of xylene, 4 min each.
17. Coverslip the slides out of xylene using Permount to mount the coverslips.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibody blocking buffer

10 ml 1× TBES (see recipe) containing 0.1% (w/v) deoxycholate (DOC)
0.5% (w/v) casein
0.1% (v/v) Tween-20
Store up to 2 weeks at 4°C

Chloroform/BHT

Plug a 2.5-cm diameter column with glass wool and pour alumina to a height of 10 cm. Discard the first column volume (~50 ml) of chloroform (J.T. Baker) and collect the next 450 ml. Add 1 ml BHT stock solution (Sigma) to the chloroform and store at 4°C.

Hybridization mix

10 ml 1× TBES (see recipe) containing 0.5% (w/v) casein
0.25% (w/v) BSA
0.1% (v/v) Tween-20
Store up to 2 weeks at 4°C

Lysis buffer, 1×/2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO), 20 mM

Dilute nucleic acid–purification grade lysis buffer to 1× from a 2× stock (Applied Biosystems). Store up to the expiration date in a brown glass bottle at 4°C. Add 2 M TEMPO free-radical reagent (Sigma-Aldrich) in methanol (store up to ~1 year at −80°C) to 20 mM. Store up to 2 months at −80°C.

PBS, 10×, pH 7.4

1.37 M NaCl
2.68 mM KCl
101 mM Na_2HPO_4
17.6 mM KH_2PO_4
Adjust pH to 7.4

RNase solution

Prepare RNase solution by adding 8 µl RNase T_1 (~800 U) and 30 µl RNase A (~80 U) to 614 µl water. This is enough for 16 samples. Scale the volume up or down as needed.

SSC, 20×, 5×

For 20× solution:
3 M NaCl
0.3 M trisodium citrate
Store up to 1 month at room temperature
Dilute to 5× with H_2O
Store up to 1 month at room temperature

TBES, 10×, 1×

160 mM Tris hydrochloride
40 mM Tris base
1 M NaCl
10 mM EDTA
Dilute to 1× with H_2O
Store up to 1 month at room temperature

TE buffer, 10×

80 mM Tris hydrochloride
20 mM Tris base
10 mM EDTA
Store up to 1 month at room temperature

Washing buffer

1× TBES (see recipe) containing 4 M NaCl
0.1% (v/v) Tween-20
Store up to 1 month at room temperature

COMMENTARY

Background Information

Apurinic/apyrimidinic sites

Various DNA base adducts are produced by alkylation, deamination, and oxidation. Many of these base lesions are believed to be repaired by the base excision repair (BER) pathway. During the first process of BER, DNA glycosylase cleaves a modified DNA base at the *N*-glycosylic bond, resulting in the formation of an AP site. AP sites can also be caused spontaneously by chemical depurination of labile DNA adducts and directly by oxidative stress. Formation of apurinic/apyrimidinic (AP) sites is one of the most frequent events in chromosomal DNA under physiological conditions (Lindahl, 1993; Nakamura et al., 1998). AP sites inhibit DNA replication and result in base substitution mutations and loss of genetic integrity (Loeb and Preston, 1986).

Several methods are currently available to detect AP sites (Brent et al., 1978; Kohn et al., 1981; Weinfeld et al., 1990; Kubo et al., 1992; Maulik et al., 1999). The present unit describes one of the aldehydic reactive reagents (ARP) and a slot-blot technique to improve the sensitivity of AP site assay (see Basic Protocol 2).

Immuno-slot blots

The ISB method is a noncompetitive immunoassay, which was originally established for the quantification of ethylated base adducts such as mutagenic O^6-ethyldeoxyguanosine and O^4-ethylthymidine as described by Nehls et al. (1984). Using this technique, the number of O^6-methyldeoxyguanosine (LeDoux et al., 1996), O^2-ethylthymidine (Dragan et al., 1994), aflatoxin B1 adducts (Phillips et al., 1999), thymine glycol (Greferath and Nehls, 1997), thymine dimer (Kriste et al., 1996), and malondialdehyde-derived guanine adducts (M_1G; Leuratti et al., 1998) have been quantitated in DNA. Basically, the number of base adducts in DNA immobilized on a NC membrane are quantified colorimetrically using a combination of monoclonal antibodies specific to adducts, biotinylated secondary antibodies, avidin/streptavidin-conjugated enzymes (e.g., horseradish peroxidase or alkaline phosphatase), and suitable substrates. This assay requires a small amount of DNA and provides relatively high sensitivity. The most significant advantage of this method is its convenience. Thirty different samples are applicable in duplicate on one NC membrane and can be measured within 2 days.

Immunohistory

Immunohistochemistry uses the affinity of monoclonal and polyclonal antibodies to locate specific epitopes which can then be visualized by an enzymatic chromogenic or fluorescent reaction visualized microscopically. This technique demonstrates not only the cell type to be identified but also the location of the cell in relation to other cells within the tissues of the organ of interest.

Critical Parameters

Apurinic/apyrimidinic sites

Spontaneous depurination and oxidation during DNA extraction may artifactually introduce an increase in the number of AP sites. DNA extraction steps should be performed at ~4°C except for the RNA digestion (Nakamura and Swenberg, 1999). Antioxidant or radical trapping agents such as TEMPO should be included in the DNA extraction solution to prevent artifactual induction of AP sites by oxidative stress during DNA extraction.

Standard DNA can be prepared by incubation of DNA in a heat/acid buffer (Nakamura et al., 1998); however, the rate of depurination may vary depending on the DNA concentration. The standard DNA should be calibrated by others who routinely measure the number of AP sites.

After denaturation, the DNA sample should be loaded onto the NC membrane as quickly as possible to diminish unnecessary renaturation. In addition, the DNA should be loaded randomly and at least in duplicate to avoid reaction variation within the membrane.

The concentration of streptavidin conjugated with HRP is one of the critical parameters in this assay. Usually, lower concentrations of streptavidin conjugated with HRP work better.

Immuno-slot blots

The essential material is a specific antibody against a particular base adduct. Cross reactivity of antibodies with unmodified bases and structurally similar base adducts may introduce high background and cause inaccurate measurement of target DNA lesions. Even highly sensitive antibodies may work inefficiently. If a couple of antibodies are available, the best antibody should be selected using the ISB assay.

The ISB assay typically detects 0.3 to 1 lesion/1×10^7 nucleotides. If this detection limit is not sensitive enough to measure the target DNA lesion, it is recommended to use other methods.

The number of adducts in standard DNA has to be quantified before measuring unknown samples by the ISB assay. The ratio of modified nucleosides to either unmodified nucleosides (e.g., picomole O^6-ethyldeoxyguanosine/μmole deoxyguanosine) or to total nucleotides (e.g., O^6-ethyldeoxyguanosine/1×10^6 nucleotides) in the standard DNA is a prerequisite and has to be characterized by another method.

To quantitate the number of DNA lesions, an equal amount of DNA should be loaded on each slot including serially diluted standard DNA. The amount of DNA applicable on each slot has previously been examined (Nehls et al., 1984). Based on ^{3}H-thymidine-labeled DNA, 3 to 4 μg DNA per slot are efficiently immobilized on the NC membrane.

DNA denaturation is also essential for the immobilization of DNA onto the NC membrane. Heating at high temperature (100°C for 10 min) or incubating in an alkaline solution can achieve this immobilization. During heat denaturation, the *N*-glycosylic bonds between heat-labile base lesions and deoxyriboses are easily cleaved; therefore, the ISB assay is not suitable for the measurement of heat-labile base adducts such as *N*7-alkylguanine and *N*3-alkyladenine. In addition, these N-alkylpurine adducts are also alkaline-labile. This ISB assay may not be appropriate for the measurement of these adducts. Before measuring target adducts by this assay, the stability of the adducts under thermal or alkaline conditions should be checked.

Immunohistochemistry

Tissue fixation and trimming are two of the most important factors involved when doing IHC. Tissues should be trimmed so that they are between 2 and 3 mm thick and fixed in 10% neutral buffered formalin (NBF) for a minimum of 24 hr and a maximum of 72 hr. A change to fresh NBF should be made within the first 6 hr. The tissues should then be placed in 70% ethyl alcohol prior to paraffin processing and subsequent microtomy. During microtomy the sections should be mounted on Fisher+ slides or equivalent. After microtomy the slides should be allowed to dry overnight at room temperature. The slides should not be exposed to heat in excess of 50°C at any time prior to performing IHC. The only exception to this would be if an antigen retrieval method needed to be used.

Troubleshooting

DNA isolation

Some problems that may be encountered using these isolation protocols include lower than expected yields and/or purity. If yields are low, be sure to thoroughly homogenize the tissue and attain homogenous solutions at all incubations through gentle pipetting. If purity is low (i.e., $A_{260}/A_{280} < 1.6$), the DNA sample can be cleaned using an additional phenol extraction. Also, be sure not to aspirate the cloudy white protein layer when collecting the DNA/water portion following extraction with the 70% phenol/chloroform/water mixture. If the DNA sample is contaminated with RNA, extend the incubation time of the RNase step.

Apurinic/apyrimidinic sites

High background on the entire NC membrane may be introduced by an inappropriate membrane (e.g., different brand of NC membrane), low SSC concentration, or short incubation and baking times. Different lots of NC membranes may work differently. To improve the background problem, it is recommended to increase incubation and baking times at first. High background in the slot including blank DNA may be due to over-incubation in HRP with streptavidin. Try to reduce the concentration of HRP and incubation time. In addition, it is also important to check the temperature of the surrounding environment when incubating the NC membrane.

If the difference in the number of AP sites between groups is relatively small, it is highly recommended to react DNA in duplicate or triplicate with ARP and determine the value by using an average of the three data points.

Immuno-slot blots

The problem regarding high background in the entire NC membrane may be introduced by inappropriate membrane (e.g., different brand of NC membrane), low SSC concentration, short incubation and baking time, insufficient washing, and high antibody and enzyme concentrations. The process conditions should be optimized by using a couple of smaller sheets of the NC membrane prepared under different conditions.

If the DNA slot is not sharp and the DNA migrates from the slot area, it is recommended that the lot or brand of NC membrane be changed; however, this type of problem has rarely happened in the authors' laboratory. Once an appropriate NC membrane is found, try to stock the same lot of membranes for consistency in future studies.

The variation in the number of adducts between membranes can be avoided by using a secondary internal standard. The secondary internal standard should contain a similar level of adducts as the real samples. These standards should be loaded in duplicate or triplicate on every NC membrane and used to adjust intermembrane variation.

Immunohistochemistry

The hematoxylin solution should always be filtered (No.1 Whatman) prior to use as bacteria grow in the stock solutions. If the tissue sections are allowed to air dry at any time during the procedure, false negative or positive staining will result. Not all antibodies will work on formalin-fixed, paraffin-embedded tissue. It is sometimes necessary to use frozen sections. If the working DAB solution turns a dark brown it should not be used. Instead, discard and make fresh. It is important to note that DAB is light sensitive and the working solution should be prepared just prior to use (i.e., ~10 min). Antibody-antigen reactions are also adversely affected by exposure to light; therefore, all incubations should be done in the dark.

Anticipated Results

DNA isolation

The yield and purity using either isolation protocol will depend on the tissue used for isolation. Most parenchymal organs (liver and kidney for example) isolated using these protocols will yield ~1.5 μg DNA/milligram tissue used for isolation. Brain, lung, and other tissue will yield ~1 μg DNA/milligram tissue used for isolation. DNA purity (A_{260}/A_{280} ratios) should be between 1.5 and 1.9.

Apurinic/apyrimidinic sites

The number of endogenous AP sites are ~5 lesions/1 × 10^6 nucleotides in either HeLa S3 suspension cells (Nakamura et al., 2000) or H2E1 cells, human lymphoblastoid cells (Nakamura et al., 1998). In tissue samples, ~9 AP sites/1 × 10^6 nucleotides were detected in rat and human liver (Nakamura and Swenberg, 1999).

Immuno-slot blots

To confirm the accuracy of the ISB assay, it is recommended that the number of base adducts measured using this assay be compared to data obtained by other quantitative methods such as HPLC, LC/MS, or GC/MS.

Time Considerations

DNA isolation

The time required for low-temperature isolation is ~24 to 40 hr (including overnight incubations and DNA solubilization). Room-temperature isolation can be performed in ~8 hr (24 hr including overnight DNA solubilization). Spectrophotometric quantification can be performed in ~30 min depending on how many samples are processed.

Apurinic/apyrimidinic sites

The entire process of sample preparation and analysis for 24 unknown samples can be performed in 1 or 2 days. Sample preparation requires ~1 hr. The ARP reaction, DNA precipitation, and resuspension take ~3 hr. DNA concentration measurement and sample loading require ~2 hr. Baking and incubating the NC membrane in buffer with enzymes takes ~1.5 hr.

Immuno-slot blots

The entire process for preparing and analyzing 24 unknown samples can be performed in 2 days. Sample preparation requires ~1 hr. Denaturing and sample loading takes another 1 hr. Baking and incubating the NC membrane in buffer with antibodies or enzymes requires ~9 hr.

Immunohistochemistry

Most immunohistochemical procedures on 20 samples (slides) can be completed in 4 to 7

hr, depending on the primary and secondary antibody incubation times. Slides can usually be examined the same day.

Methods for Measuring DNA Adducts and Abasic Sites II: Methods for Measurement of DNA Adducts

The first unit of this series of protocols (*UNIT 3.8*) dealt with the isolation of DNA and methods for analysis that utilize intact DNA.

This unit contains protocols for analyzing individual DNA adducts separated from the DNA backbone. The first two protocols describe HPLC methods for quantifying total guanine (see Basic Protocol 1) and ribo- or deoxyribonucleosides (see Basic Protocol 2). The remaining protocols describe a variety of methods used to quantify individual DNA adducts. HPLC with electrochemical detection is used to determine 8-OH-dG (see Basic Protocol 3) and N7-methylguanine (see Basic Protocol 4). Immunoaffinity chromatography is used to enrich for specific adducts which are then analyzed using gas chromatography/electron capture negative chemical ionization/high-resolution mass spectroscopy (GC/ECNCI/HRMS; see Basic Protocol 5). Enzymatic DNA digestion (see Support Protocol 1) preparation of immunoaffinity columns (see Support Protocol 2), and determination of recovery (see Support Protocol 3) are also described. There is also a protocol for GC/ECNCI/HRMS isolation that can be used with adducts purified by other means (see Basic Protocol 6). Liquid chromatography in combination with electrospray ionization/isotope dilution tandem mass spectrometry (LC/ESI/IDMS/MS) can also be used to purify adducts for quantification (see Basic Protocol 7). Finally, ^{32}P postlabeling in combination with thin layer chromatography (TLC; see Basic Protocol 8) can be used for adduct quantification.

CAUTION: Extremely high voltage is present when a mass spectrometer is turned on from the instrument, and various components of GC and MS are at very high temperatures during operation. Operators are advised to refer to the respective instrument manuals for operation and safety (also see Critical Parameters).

NOTE: All methanol used in this unit must be HPLC grade.

MEASUREMENT OF NUCLEIC ACIDS BY HPLC

An important part of every DNA adduct analysis is to quantitate, in some way, the amount of DNA used in the assay. While spectrophotometric absorbance (*UNIT 3.8*) is useful as a reliable estimate, the most accurate method for determining DNA content is HPLC analysis of the components of DNA. In the authors' laboratories, the most common methods for DNA quantitation are the HPLC measurement of guanine (and adenine) and/or the measurement of deoxyguanosine, depending on the method of DNA hydrolysis. The choice of methodology is in the measurement of the adduct itself. If the DNA adduct is measured as a base, then guanine or the appropriate base should be measured. If the DNA adduct is measured as a nucleoside, then the measurement of the normal nucleoside must be accomplished.

HPLC Determination of Purine Bases

BASIC PROTOCOL 1

The determination of purine bases involves shearing the DNA, hydrolysis by mild acid, and heating before analysis by HPLC.

Contributed by James A. Swenberg, Amy-Joan L. Ham, Hasan Koc, David K. La, Eric J. Morinello, Brian F. Pachkowski, Asoka Ranasinghe, and Patricia B. Upton
Current Protocols in Toxicology (2002) 3.9.1-3.9.35

Materials

Hydrated DNA solution
0.1 N HCl
Mobile phase: 0.1 M ACS-grade ammonium formate (pH 2.8)/10% HPLC-grade methanol
Guanine (or adenine) standard for calibration curve

22-G needle
70°C water bath or equivalent
0.45-µm filter
HPLC system:
Isocratic HPLC pump
500-µl injection loop
10-µm × 25-cm × 0.46-cm Whatman Partisil 10 SCX analytical column
Single-wavelength UV detector set to 254 nm
Syringe and 22-G needle

Additional reagents and equipment for determination of DNA concentration by spectrophotometric absorption (*UNIT 3.8*)

1. Shear the hydrated DNA solution by pulling up and out ~5 times with a 22-G needle to ensure a homogenous solution.
2. Estimate the concentration of this solution by spectrophotometric absorption at 260 nm (where 50 µg = 1 AU; *UNIT 3.8*).
3. Dilute an aliquot of this solution with 0.1 vol of 1 N HCl.
4. Heat the acidic DNA solution 30 min in a 70°C water bath or equivalent. Place the samples on ice.

   This mild acid hydrolysis serves to effectively depurinate the DNA, releasing guanine and adenine nucleic acid bases.

5. Filter mobile phase through a 0.45-µm filter and degas by vacuum.

   Filtering and degassing helps to prevent the formation of interfering bubbles as the water and methanol mix.

6. Run mobile phase at 1.8 ml/min through the HPLC system, including a 10-µm × 25-cm × 0.46-cm Whatman Partisil 10 SCX analytical column. Equilibrate ~30 min or until the warming single-wavelength UV detector shows a stable baseline at 254 nm.
7. Set the HPLC run time as 8 min.
8. Prepare a guanine (or adenine) standard stock by dissolving a known amount in 0.1 N HCl. Dilute this stock 1:100 in 0.1 N HCl (~0.05 nmol/µl). Build a guanine standard curve by injecting and analyzing increasing amounts of dilute stock:

First injection:	5 µl (0.25 nmol standard)
Second injection:	50 µl (2.5 nmol standard)
Third injection:	100 µl (5.0 nmol standard)
Fourth injection:	200 µl (10.0 nmol standard)

   The standard curve is built by plotting the area under the guanine (or adenine) peak versus amount of guanine (or adenine) injected. The guanine standard curve is linear across a very wide range of concentrations, but be careful not to saturate the detector.

9. Inject 100 µl hydrolyzed DNA samples to be assayed for guanine (or adenine).

   The amount of sample that should be injected will depend on the estimated concentration (A_{260}; UNIT 3.8) and the dilution of the sample for mild acid hydrolysis.

10. Between injections, rinse syringe with several volumes of 100% methanol.

11. Determine the quantity of guanine by comparison of the sample peak area with the standard curve of peak area versus volume standard injected. Multiply this amount by the injection volume, divide by the dilution factor, and divide by the average amount of guanine (or adenine) in the species DNA (0.22 for rat, 0.28 for mouse, 0.20 for human and calf thymus; Fasman, 1976). Multiply by the average molecular weight of a nucleotide (320) to obtain the concentration of DNA in the sample in micrograms/milliliter.

    For a 100-µl injection of rat DNA diluted 1:10, determined to have a guanine concentration of 1.07 nmol from the standard curve, the concentration in the original sample is 156 µg/ml—i.e., 1.07 nmol × 100/1000/0.22 × 520 = 156 µg/ml.

HPLC of Ribonucleoside and Deoxynucleoside Digests

BASIC PROTOCOL 2

Following digestion of DNA to nucleosides, HPLC analysis of the digest gives a denominator to adduct analysis. This is also the way to quantify RNA contamination of the DNA solution (i.e., to give a correction factor).

Materials

Mobile phase A: 50 mM NaH_2PO_4 (pH 5.5)/10% methanol
Mobile phase B: 90% methanol
Deoxyguanosine (dGuo), deoxyadenosine (dAdo), guanosine (rGuo), and adenosine (rAdo)
50 mM NaH_2PO_4, pH 7.4 (optional)
100 mM Bis-Tris (pH 7.1)/100 mM $MgCl_2$
100 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*)
Sample digest (see Support Protocol 1)

0.45-µm filter
HPLC system:
  500-µl injection loop
  5-µm × 25-cm × 0.46-cm reversed-phase column
  Single-wavelength UV detector set to 254 nm
  Isocratic HPLC pump

Set up HPLC

1. Filter mobile phases A and B through a 0.45-µm filter and degas by vacuum.

    Filtering/degassing helps to prevent the formation of interfering bubbles as the water and methanol mix.

2. Run mobile phase A at 1.8 ml/min through the HPLC system, including the 5-µm × 25-cm × 0.46-cm reversed-phase column. Equilibrate ~30 min or until the warming single-wavelength UV detector shows a stable baseline at 254 nm.

Prepare standards

3. Make 4 mM stock solutions of nucleoside standards in water—i.e., deoxyguanosine (dGuo), deoxyadenosine (dAdo), guanosine (rGuo), and adenosine (rAdo).

4. Use water or 50 mM NaH_2PO_4, pH 7.4, to dilute stock solutions of dGuo and dAdo to 0.4 mM, and stock solutions of rGuo and rAdo to 0.025 mM for use in an HPLC standard curve. Aliquot and freeze extra up to 1 year at −20°C.

5. Mix dGuo and dAdo dilutions 1:1.

    Final concentration of each is now 0.2 nmol/µl.

Table 3.9.1 Deoxyguanosine (dGuo) and Deoxyadenosine (dAdo) Standard Mixture

Standard no.	0.2 nmol/µl dAdo/dGuo mix (µl)	100 mM Bis-Tris (pH 7.1)/100 mM $MgCl_2$ (µl)	100 mM Tris·Cl, pH 8.5 (µl)	H_2O (µl)
1	20 (4 nmol)	10	3	167
2	40 (8 nmol)	10	3	147
3	80 (16 nmol)	10	3	107
4	160 (32 nmol)	10	3	27

Table 3.9.2 Guanosine (rGuo) and Adenosine (rAdo) Standard Mixture

Standard no.	0.0125 nmol/µl dAdo/dGuo mix (µl)	100 mM Bis-Tris, pH 7.1/100 mM $MgCl_2$ (µl)	100 mM Tris·Cl, pH 8.5 (µl)	Water (µl)
1	20 (0.25 nmol)	10	3	167
2	40 (0.5 nmol)	10	3	147
3	80 (1 nmol)	10	3	107
4	160 (2 nmol)	10	3	27

6. Add 100 mM Bis-Tris (pH 7.1)/100 mM $MgCl_2$ to dGuo/dAdo standards to yield approximately the same buffer concentrations as the samples (Table 3.9.1).
7. Mix the rGuo and rAdo 1:1.

   Final concentration of each is now 0.0125 nmol/µl.
8. Add 100 mM Bis-Tris (pH 7.1)/100 mM $MgCl_2$ to rGuo/rAdo standards to yield approximately the same buffer concentrations as the samples (Table 3.9.2).
9. Set the HPLC run time as 30 min with a flow rate of 1 ml/min.
10. Build a standard curve of each nucleoside by injecting and analyzing 200 µl increasing concentrations (Tables 3.9.1 and 3.9.2) and plotting the area under the peak versus the amount of standard injected.

Analyze sample

11. Inject 50 µl of each sample digest.
12. Determine quantities of dGuo/dAdo and rGuo/rAdo based on comparison with the standard curve.

QUANTIFYING DNA ADDUCTS: HPLC WITH ELECTROCHEMICAL DETECTION

Since its advent, HPLC with electrochemical detection (HPLC-ECD) has been utilized for a number of applications (Krien et al., 1992; Leung and Tsao, 1992; Achilli et al., 1993). Combining the separatory capability of HPLC with the sensitivity and selectivity of ECD makes for efficient and accurate analysis of complex samples with low analyte concentration. A popular use of HPLC-ECD is in the investigation of DNA adducts. The formation and persistence of these adducts in the genome has been linked to aging and cancer (Halliwell and Gutteridge, 1989; Swenberg et al., 1985). Quantitative analysis of

specific adducts can reveal the relationship between chemical exposure and toxicological response.

Two major types of DNA adducts analyzed by HPLC-ECD are those induced by either oxidative damage or base alkylations. Oxidative DNA damage caused by reactive oxygen species (ROS) has been associated with cancer and other degenerative diseases (Harman, 1981; Ames, 1983). The major oxidative damage product in DNA, 8-hydroxy-2′-deoxyguanosine (8-OH-dG; see Basic Protocol 3), is used as a biomarker of oxidative stress (Kasai, 1997) and in studies regarding base excision repair (BER; Nakamura et al., 2000).

The N7 position of guanine is a major site for electrophilic modification. While not promutagenic, N7-methylguanine (N7-MG) can spontaneously depurinate leaving an apurinic/apyrimidinic site (AP site) which can lead to mutagenicity. N7-MG quantification (see Basic Protocol 4) is useful in understanding the molecular dosimetry of alkylating agents (de Groot et al., 1994) and the efficiency of BER (Calléja et al., 1999).

HPLC-ECD Analysis of 8-OH-dG

BASIC PROTOCOL 3

The protocol described below for the determination of 8-OH-dG is a modification of a method described by Richter et al. (1988). Isolated DNA is subjected to enzymatic digestion to yield deoxyribonucleosides, which are then separated chromatographically and detected coulometrically.

Materials

DNA sample (see Support Protocol 1)
Mobile phase: 50 mM KH_2PO_4, (pH 5.5)/10% HPLC-grade methanol
8-OH-dG standard (see recipe)

HPLC system:
- 100-µl injection loop
- Electrochemical detector (i.e., E.S.A. Model 5600 CoulArray and Model 5040 cell with platinum target)
- 25-cm × 4.6-mm Beckman Ultrasphere (or equivalent) C_{18} column with 5-µm particle size, room temperature

37°C incubator

Additional reagents and equipment for HPLC determination of deoxyguanosine (see Basic Protocol 1)

NOTE: All water used must be distilled and deionized.

Analyze the sample

1. Set potentials of the electrochemical detector to 200, 300, 375, 450, 525, 600, 700, and 1000 mV.

   These potentials were selected in order to oxidize any interfering compounds with oxidation potentials below that of the analyte, to measure the analyte, and to oxidize any interfering compounds with oxidation potential below deoxyguanosine, which is usually monitored at 1000 mV.

2. Equilibrate the HPLC system for at least 1 hr by running mobile phase at 1 ml/min, including 25-cm × 4.6-mm C_{18} column with 5-µm particle size.

   Keep the 1 ml/min flow rate for the duration of the analysis (see Critical Parameters).

3. Run three or four standards within the likely range that 8-OH-dG will be measured.

   The standard curve for 8-OH-dG is prepared by running 3 to 4 standards within the likely range that 8-OH-dG will be measured (this can range from 10 fmol of 8-OH-dG on column

and upwards). An example of a range of standards may include 10, 30, 90, and 180 fmol 8-OH-dG on column. Using the suggested array of potentials, standards are run and 8-OH-dG is measured at 300 mV. Also see Troubleshooting.

4. Run a water blank. Make 50-µl injections at 0 and 5 min, then allow the blank to run 30 min.

   The purpose of this step is to determine if there is any standard carryover that could interfere with the analyte measurement.

5. Inject 50-µl sample into the HPLC system.

   Keep samples at storage temperature and thaw just prior to analysis.

6. Allow the sample to run at least 15 min.

   Depending on the age of the column, retention times may vary, but should be ~10 min.

7. Determine the concentration of 8-OH-dG by comparing peak areas of samples with those of a series of standards.

8. To take into account the extent of digestion, normalize the concentration of 8-OH-dG to the amount of deoxyguanosine (dG), determined by either ECD or UV detection (see Basic Protocol 2).

   The concentration of 8-OH-dG can also be normalized to the amount of DNA determined by UV analysis (UNIT 3.8).

SUPPORT PROTOCOL 1

Enzymatic DNA Digestion

The support protocol described below is used to enzymatically digest DNA to yield deoxyribonucleosides.

Materials

Digestion enzymes:
200 U/0.1ml deoxyribonuclease I (Sigma-Aldrich)
0.1 U/0.1 ml spleen phosphodiesterase (Sigma-Aldrich)
0.5 U/0.1 ml snake venom phosphodiesterase (Worthington Biochemicals)
10 U/0.1 ml alkaline phosphatase (Sigma-Aldrich)
10× digestion buffer: 400 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*)/100 mM $MgCl_2$; store up to 1 month at 4°C
DNA sample

Digest DNA sample

1. Add 10 µl each digestion enzyme (i.e., deoxyribonuclease I, spleen phosphodiesterase, snake venom phosphodiesterase, and alkaline phosphatase) to 15 µl of 10× digestion buffer and keep on ice.

   The resulting 55 µl is enough for one sample of 100 µg DNA in 100 µl water.

2. Adjust the volume of isolated DNA sample (100 µg) to 100 µl with water and keep on ice.

   If the concentration of DNA is <1 mg/ml, dry the sample (i.e., in a SpeedVac; Savant) and then adjust the volume to 100 µl with water.

3. Add 55 µl digestion buffer/enzyme mixture to each sample.

4. Incubate 2 hr at 37°C.

5. Proceed to analyze immediately or store sample up to 3 months at −80°C.

HPLC-ECD Analysis of N7-Methylguanine

The protocol described below is a modified procedure for measuring the amount of N7-MG present in an exposed sample (Park and Ames, 1988a,b). Isolated DNA is heated to release labile bases (N7-MG) from the DNA backbone. The liberated bases are prepared for analysis, separated chromatographically, and detected coulometrically.

Materials

DNA sample
1 M HCl, ice cold
Mobile phase, cold: 50 mM KH_2PO_4 (pH 5.5)/2% (v/v) HPLC-grade methanol
1 M NaOH
N7-MG standards (see recipe)

HPLC system:
- 100-µl injection loop
- Electrochemical detector (E.S.A. Model 5600 CoulArray and Model 5040 cell with platinum target)
- 25 cm × 4.6–mm C_{18} column with 5-µm particle size, room temperature

100°C water bath or equivalent

NOTE: All water used must be distilled and deionized.

Prepare DNA

1. Adjust the volume of an isolated 100-µg DNA sample to 100 µl with water. Store on ice.
2. Wrap the tops of the tubes with Parafilm and subject samples to neutral thermal hydrolysis 30 min in a 100°C water bath or equivalent.

   Securing the tops of tubes is necessary, since steam generated can pop them open and contamination of the sample can occur.

3. Precipitate DNA by placing samples on ice and adding 10 µl ice-cold 1 M HCl. Vortex briefly.

   The solution should become hazy as the DNA falls out of solution.

4. Microcentrifuge 30 min at 14,000 × *g*, 4°C.

   A pellet should be observed depending on the amount of DNA used. If no pellet is visible either continue centrifugation, use a filtration device (i.e., Centricon), or proceed with preparation, keeping in mind excess DNA may clog HPLC plumbing.

5. Transfer 100 µl supernatant to a new microcentrifuge tube. Keep the new tubes on ice.
6. Add 100 µl cold mobile phase to each sample.

   This will buffer the hydrolysate solution and depending on injection volume, will allow for duplicate analysis of the sample.

7. Add 9 µl room-temperature 1 M NaOH.

   Even though alkaline conditions induce imidazole ring opening, the amount here is used to adjust the pH and does not approach the pH at which ring opening occurs (Chetsanga et al., 1981).

8. Vortex sample and either analyze immediately or store up to 6 months at −80°C.

HPLC-ECD Analysis

9. Set potentials of the HPLC system's electrochemical detector to 200, 300, 400, 500, 600, 700, 800, and 900 mV.

   The above range is a suggestion for a system with an eight-channel array detector (see Critical Parameters; also see Basic Protocol 3, step 1).

10. Equilibrate system, including 25-cm × 4.6-mm C_{18} column with 5-µm particle size, for at least 1 hr by running mobile phase at 1 ml/min. Maintain the 1 ml/min flow rate for the remainder of the analysis (see Critical Parameters).

11. Run three or four standard concentrations within the likely range that N7-MG will be measured (see Troubleshooting).

    The standard curve for N7-MG is prepared by running 3 to 4 standards within the likely range that N7-MG will be measured (this can range from 1 pmol N7-MG standard on column and upward). An example of a range of standards may include 1, 10, and 100 pmol N7-MG on column. Using the suggested array of potentials, standards are run and N7-MG is measured at 700 mV.

12. Run a water blank, making injections at 0 and 5 min. Allow the blank to run 30 min.

13. Inject 50-µl sample into HPLC system.

    Keep samples at storage temperature and thaw just prior to analysis.

14. Allow sample to run 25 min.

    Depending on the age of the column, retention times may vary but should be ~18 min.

15. Determine the concentration of N7-MG by comparing the peak areas of samples with those of a series of standards.

    Normalize the concentration of N7-MG to the amount of DNA analyzed.

BASIC PROTOCOL 5

Quantification of N^2, 3-Ethenoguanine by IA/GC/ECNCI/HRMS

The DNA adduct, N^2,3-ethenoguanine (N^2,3-εGua), is formed from a number of carcinogens, including vinyl chloride (Bartsch et al., 1994), as well as from lipid peroxidation by-products (Ham et al., 2000). The formation of this adduct occurs from the reaction of guanine with electrophiles that are produced from carcinogens as well as from endogenous sources. The method described here for the quantification of N^2,3-εGua uses immunoaffinity chromatography to purify the adduct, followed by derivatization, to increase the volatility of the adduct, and GC/ECNCI/HRMS analysis. This method is used to determine the amount of the promutagenic DNA adduct N^2,3-εGua relative to the amount of unmodified guanine bases in a sample of isolated DNA (Ham et al., 1999).

Materials

DNA sample
1 N HCl: dilute 3.3 ml concentrated HCl to 40 ml with water; store up to 6 months at room temperature
~2 fmol/ml [$^{13}C_4$,$^{15}N_2$]N^2,3-εGua internal standard
~1 fmol/ml N^2,3-εGua standard
500 mM sodium phosphate buffer, pH 7.2 (see recipe; also see *APPENDIX 2A*)
Immunoaffinity (IA) columns made with polyclonal antibodies to N^2,3-εGua (see Support Protocol 2)
5% (v/v) and 100% HPLC-grade methanol
PBS/azide (see recipe)
0.1 M formic acid

Potassium carbonate: grind to a fine powder with mortar and pestle and store at 60°C
Acetone, HPLC-grade (≥99.9%)
5% PFBBr (see recipe)
Hexane
Silica gel slurry: silica gel 60, 70-230 mesh (Fisher) in hexane
Ethyl acetate, GC/GC-MS grade
Dichloromethane, ACS or HPLC grade
5% (v/v) ethyl acetate in hexane
99.8% toluene
Helium gas
Methane gas

22-G needle
70°C water bath or heating block with H_2O in the test-tube holes
Centricon 10 concentrators
13 × 100–mm silanized, disposable, borosilicate culture tubes
5.75-in. silanized Pasteur pipets
Silanized glass wool
200-µl genomic and 100-µl gel-loading aerosol-resistant pipet tips
1.8-ml GC autosampler vials with inserts and caps
Silanized culture tubes with caps
Transfer pipets
GC-MS system:
Electron capture negative chemical ionization detector
DB-5MS 30-m × 0.32-mm × 0.1-mm film column or equivalent
Uniliner HP injection sleeve, 4.0 mm i.d. × 6.3 mm o.d. × 78.5 mm (Restek)

Additional reagents and equipment for quantifying DNA by UV spectroscopy (*UNIT 3.8*) and measurement of guanine by HPLC (see Basic Protocol 1)

NOTE: All hexane used in the protocol must be capillary GC/GC-MS grade.

Hydrolyze DNA

1. Suspend DNA sample in water and shear by passing through a 22-G needle until homogeneous. Quantify by UV spectrophotometry ($A_{260\,nm} = 20$ ml/mg cm^{-1} in water) prior to use (*UNIT 3.8*).
2. Add the following to a 1.7-ml microcentrifuge tube:

   100 ml 1 N HCl
   60 ml ~2 fmol/ml [$^{13}C_4$,$^{15}N_2$]*N*^{2},3-εGua internal standard
   Adjust to 1 ml final volume (after sample or standard is added; see step 4) with water.

3. Add 100 to 400 mg DNA (step 1) or 0, 5, 10, 25, 50, 100, and 200 ml of ~1 fmol/ml N^2,3-εGua standard to a microcentrifuge tube, cap, and mix using a vortex mixer. Incubate 30 min in a 70°C water bath or heating block with water in the test-tube holes.

   The amount of DNA required will vary depending on the anticipated amount of εGua *in the sample. Larger amounts of DNA are required for endogenous* εGua *samples, while smaller amounts can be used for carcinogen-treated samples. As little as 5 to 10 mg has been used for quantitation of in vitro samples that produce* εGua *from direct reaction.*

   During this step is a good time to cool the centrifuge rotor to 4°C if it has not been cooled already.

4. After incubation, place tubes on ice 10 min prior to hydrolysate purification.

Purify hydrolysate

5. Transfer samples and standards to sample reservoirs of Centricon 10 concentrators.

   The Centricon concentrators are used to separate the DNA backbone from the depurinated adducts and normal nucleobases.

6. Centrifuge 60 min at 5000 × *g*, 4°C.

7. Remove a 100-ml aliquot of the filtrate from each sample (not the standards) for guanine analysis (see Basic Protocol 1).

   The aliquot taken for guanine analysis will vary depending upon the amount of DNA used. For example, if 200 mg DNA is used, generally a 100-ml aliquot is taken and that aliquot is diluted 5-fold (e.g., 400 ml water is added) before guanine analysis. If small quantities of DNA are used (i.e., 5 to 10 mg), a larger aliquot may be taken and no dilution will be necessary before guanine analysis.

8. Rinse microcentrifuge tubes that contained the samples or standards with 1 ml of 500 mM sodium phosphate buffer, pH 7.2, and transfer to sample reservoirs of the same Centricon 10 concentrators. Add an additional 1 ml of 500 mM sodium phosphate buffer directly to the reservoir.

9. Centrifuge samples 75 min at 5000 × *g*, 4°C, or until only a small fraction of the retentate remains.

   The filters should be allowed to dry.

   The length of time for this centrifugation step may vary depending on the batch of Centricon filters and the amount of DNA. Generally, more DNA requires more time to complete the transfer of liquid to the filtrate reservoirs.

10. Dilute samples 2-fold with water. Check the pH of the filtrate for neutrality using pH paper.

    The pH of the filtrate should be 7.0 to 7.2 using short-range pH paper, prior to immunoaffinity chromatography. See Immunoaffinity Purification (below), for a discussion on the importance of neutrality prior to this method of chromatography.

Purify adduct

11. Precondition immunoaffinity (IA) columns made with polyclonal antibodies to N^2,3-εGua, at 4°C, by draining and sequentially adding 5 ml water, 10 ml of 100% methanol, 10 ml water, and 10 ml PBS/azide.

    Immunoaffinity columns are constructed using 500 ml polyclonal antiserum for each of four columns (see Support Protocol 2) and tested accordingly (see Support Protocol 3). The production of polyclonal antibodies for this adduct is described by Ham et al. (1999). Columns are stable for at least one year and may be reused multiple times.

12. At room temperature, transfer filtrate from Centricon filtrate reservoir to IA column.

13. Drain and wash the IA column sequentially with 5 ml PBS/azide, 5 ml water, and 10 ml of 5% methanol.

14. Elute the sample at room temperature with 3 ml of 100% methanol. Collect eluate in a 13 × 100–mm silanized, disposable, borosilicate culture tube.

    The columns and solvents were kept refrigerated during preconditioning (step 11), largely because this process takes a considerable amount of time. (It is unlikely that the columns behave differently at room temperature.) Sample application, wash, and elution (steps 12 to 14) were done at room temperature largely because it is inconvenient to apply the samples in the refrigerator. The wash solvents (i.e., PBS, water, and 5% methanol) are stored in the refrigerator and should still be cold when applied to the columns. The elution solvent (i.e.,

methanol) should be stored on the bench, and should be at room temperature when applied to the columns. In the authors' laboratory, the temperature change was not noted to induce bubble formation, but the mixing of methanol and water certainly did. It was occasionally necessary to force some solvent through the space between the frits that contained the resin when these bubbles became large enough to obstruct the flow.

15. Dry samples in a SpeedVac evaporator using low-medium heat.

16. Recondition IA columns at 4°C by sequentially adding: 5 ml 100% methanol, 5 ml water, 10 ml of 0.1 M formic acid, 10 ml water, and 10 ml PBS/azide. Store columns at 4°C in 5 ml PBS/azide.

    The recovery of the columns should be checked periodically by adding (unlabeled) analyte standard to the columns, and (labeled) internal standard to the collection tubes. New columns should be made when the calculated recovery no longer provides the required sensitivity.

Derivatize samples

17. To each dried sample tube, add a spatula tip (~25 mg) potassium carbonate, 500 µl HPLC-grade acetone, and 35 µl of 5% PFBBr. Cap and mix continuously 75 min at 50°C using a vortex mixer.

    A derivatization step is necessary to make the adduct volatile so it is suitable for gas chromatography.

18. While samples are incubating, prepare silica gel chromatography columns as follows:

    a. Plug silanized 5.75-in. Pasteur pipets with silanized glass wool.
    b. Wet plug with hexane and add silica gel slurry to a height of 1.5 to 2.0 cm.
    c. Condition columns by sequentially adding 2 ml hexane, 4 ml GC/GC-MS-grade ethyl acetate, and 6 ml hexane.

    The headspace of the column when prepared as described is ~2 ml.

19. After incubation is complete, evaporate samples to dryness using a SpeedVac evaporator without heating.

20. Resuspend the dried samples in 100 µl A.C.S.-HPLC-grade dichloromethane and transfer to silica gel columns using 200-µl genomic aerosol-resistant tips. Add an additional 100 µl dichloromethane to the sample tube to rinse and transfer the rinse to silica gel columns.

21. Wash the silica columns with 4 ml hexane and 6 ml of 5% HPLC-grade ethyl acetate in hexane.

22. Elute the samples into clean silanized culture tubes with 3 ml GC/GC-MS-grade ethyl acetate and dry in the SpeedVac evaporator using medium heat.

23. Resuspend samples in 15 to 50 µl of 99.8% toluene (depending on the anticipated amount of the adduct), vortex, and centrifuge at low speed just long enough to get toluene off the sides of the tube (i.e., to recover as much sample as possible).

24. Transfer samples to GC vial inserts with 100-µl gel-loading tips, place inserts in 1.8-ml GC autosampler vials, cap the vials, and store samples at −80°C until analysis (up to 6 months).

Perform GC/ECNCI/HRMS analysis

25. Analyze sample using GC/ECNCI/HRMS system with the following conditions:

Column:	DB-5MS 30 m × 0.32 mm × 0.1 mm film or equivalent
Injection liner:	HP 4.0 mm i.d. × 6.3 mm o.d. × 78.5 mm
Carrier gas:	Helium
Injection volume:	2 ml
Injector temperature:	290°C
Temperature program:	0.5 min at 100.0°C 20.0°C/min increase to 290°C 3 min at 290°C 50°C/min increase to 300°C 2 min at 300°C
Reagent gas:	Methane
Mode:	High-resolution, negative ion
Mass channels:	354.0413 (analyte) 360.0489 (internal standard)

These are the conditions specific to the analysis of ε*Gua by GC/ECNCI/HRMS. More detailed description of the analysis of this adduct and general considerations and troubleshooting for the analysis of DNA adducts using this technique are described below (see Basic Protocol 6).*

IMMUNOAFFINITY PURIFICATION

Because many DNA adducts are present in a very low proportion relative to unmodified bases, and because the chemical properties of adducts are often very similar to the original base, enrichment can be the biggest obstacle to quantification of adducts formed in vivo. Immunoaffinity chromatography is an approach to adduct purification that is efficient, highly selective, and less labor intensive than most traditional chromatography techniques. Here, a 1-day protocol for producing (see Support Protocol 2) and testing (see Support Protocol 3) immunoaffinity columns is described that has been successfully applied to both monoclonal and polyclonal antibodies without any requirement for antibody purification. Similar protocols have been used to quantify the vinyl chloride-induced adduct N^2,3-ethenoguanine from DNA (Ham et al., 1999), and 3-methyladenine from urine (Friesen et al., 1991).

SUPPORT PROTOCOL 2

Preparation of Immunoaffinity (IA) Columns for DNA Adduct Purification

This method is based on that originally described by Schneider et al. (1982) and later adapted by Friesen et al. (1991) for DNA adduct purification. It is designed to covalently bind an antibody raised against the adduct of interest to a Sepharose support through specific binding to Protein A.

NOTE: All procedures should be done at 4°C except when specified otherwise.

Materials

Protein A–Sepharose CL4B (Amersham Pharmacia Biotech)
100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Purified antibody, hybridoma cell supernatant, or antiserum against adduct of interest
200 mM triethanolamine, pH 8.2: 13.3 ml in 500 ml (total) water; store up to 1 month at 4°C

20 mM dimethylpimelidate (DMP; Pierce Chemical) in 200 mM triethanolamine, pH 8.2, fresh
20 mM ethanolamine (Fisher Scientific) in 200 mM triethanolamine, pH 8.2
PBS/azide (see recipe)
100% HPLC-grade methanol (J.T. Baker or equivalent)

12-ml polyethylene minisorb tubes (Nunc) or 15-ml centrifuge tubes
End-over-end mixer
Four 5-ml disposable polystyrene columns with two frits each (Pierce Chemical)

1. Suspend Protein A–Sepharose CL4B by stirring with the blunt end of a Pasteur pipet. To prepare four immunoaffinity columns, transfer 1 ml of the suspension to a rinsed 12-ml polyethylene minisorb or 15-ml centrifuge tube.
2. Add 5 ml of 100 mM Tris·Cl, pH 7.4, and mix well. Centrifuge 5 min at 1000 × *g*, and discard supernatant. Repeat once.
3. Add an appropriate volume of purified antibody, hybridoma cell supernatant, or antiserum against the adduct of interest.

   Antibody is present in hybridoma cell supernatant or antiserum. The volume added is dependent on antibody concentration and may be optimized through trial-and-error. As little as 250 µl polyclonal antiserum or as much as 10 ml monoclonal hybridoma cell culture supernatant has proven adequate. Smaller volumes of purified antibody may be used depending upon antibody concentration.

4. Bring the volume to 10 ml with 200 mM Tris·Cl, pH 7.4.

   If the total volume is greater than 10 ml, do not use the full volume. Only use 10 ml or less.

5. Mix suspension end-over-end for 30 min at room temperature. Centrifuge as before (step 2) and discard supernatant.
6. Wash gel twice with 4 ml of 200 mM Tris·Cl, pH 7.4, centrifuge, and discard supernatant.
7. Wash gel twice with 4 ml of 200 mM triethanolamine, pH 8.2, centrifuge, and discard supernatant.
8. Add 10 ml of 20 mM freshly-prepared dimethylpimelidate (DMP) in 200 mM triethanolamine, pH 8.2. Mix end-over-end for 45 min at room temperature. Centrifuge and discard supernatant.
9. Add 10 ml of 20 mM ethanolamine solution and mix end-over-end for 5 min at room temperature. Centrifuge and discard supernatant.
10. Add 5 ml PBS/azide, mix, centrifuge, and discard supernatant. Repeat once.
11. Soak frits in PBS/azide for at least 1 hr, preferably overnight. Insert in the bottom of each of four disposable polystyrene columns using the blunt end of a Pasteur pipet. Plug the column.
12. Resuspend the resin in 4 ml PBS/azide and carefully transfer 1 ml to each column.
13. Rinse the tube with 4 ml PBS/azide and transfer 1 ml to each column.
14. Add 3 ml PBS/azide to each column and allow resin to settle at least 1 hr.
15. Insert a second frit into each column ~1 cm above the top of the gel bed. Remove plugs and allow columns to drain.

16. Wash columns by sequentially adding 5 ml PBS/azide, 5 ml water, 25 ml of 100% HPLC-grade methanol, 10 ml water, and 10 ml PBS/azide.

17. Cap columns and store at 4°C in PBS/azide when not in use.

    Columns can be stored indefinitely as long as the recommended storage conditions are followed.

SUPPORT PROTOCOL 3

Determination of Recovery and Adduct Purification

A crude sample is applied to the column, and a highly-purified adduct is eluted after several washes. The adduct may then be quantified by the method of choice without any need for desalting. The columns should be kept refrigerated whenever possible, but the sample application and elution steps may be done at room temperature if this is more convenient. The following procedure has been developed for the use of IA purification of the DNA adduct N^2,3-ethenoguanine (Ham et al., 1999).

Materials

IA columns (see Support Protocol 2)
5% (v/v) and 100% methanol
PBS/azide (see recipe)
Neutralized standard (e.g., ~1 fmol/ml N^2,3-εGua, pH 7.0) or sample DNA sample
0.1 M formic acid
Internal standard (optional)

Additional reagents and equipment for quantifying samples by HPLC (see Basic Protocol 1)

1. Drain IA columns and precondition by sequentially adding 5 ml water, 10 ml of 100% methanol, 10 ml water, and 10 ml PBS/azide.
2. Transfer a known amount of neutralized standard (to determine recovery) or DNA sample to column.

   The sample or standard must be loaded on an IA column at neutral pH. If pH is not neutral, the adduct will not bind to the antibody.

3. Wash the columns by adding 5 ml PBS/azide, 5 ml water, and 10 ml of 5% methanol.

   Exact washing conditions may need to be determined, depending on the stability of the antibody on the immunoaffinity column and the affinity of the IA column for contaminating substances (i.e., normal bases, nucleosides, or nucleotides).

4. Elute the sample with 3 ml of 100% methanol or mild acid (e.g., 0.1 M formic acid) at room temperature.

   The choice of eluting solvent depends upon the stability of the antibody and/or adduct and the affinity of the antibody for the IA column. Stronger affinity of the IA column for the analyte may require a stronger eluting solvent (i.e., acid). Less stable IA columns may require a milder eluting solvent (i.e., methanol).

5. If determining recovery, add a known amount of internal standard to the collection tube.
6. Dry the eluent in a rotary evaporator and quantify the standard or sample by method of choice (e.g., *UNIT 3.8*).
7. Recondition columns by adding 5 ml of 100% methanol, 5 ml water, 10 ml of 0.1 M formic acid, 10 ml water, and 10 ml PBS/azide.
8. Cap columns and store in 5 ml PBS/azide at 4°C.

QUANTIFICATION OF DNA ADDUCTS: GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Various gas chromatographs made by different instrument manufacturers (e.g., Hewlett Packard, Varian Analytical Instruments, Thermoquest) interfaced with quadrupole and sector mass analyzers are typically used for quantitative GC/MS analyses. While quadrupole mass analyzers (e.g., Finnigan 70, 700, and 7000 series, HP engines, Micromass, VG Trio series) are used in low-resolution (unit-resolving-power) mass spectrometry, sectors (e.g., VG 70 series, VG AutoSpecs, and Jeol instruments) and recently time-of-flight (e.g., Micromass, Leco) analyzers are used at both unit and high-mass resolving powers. Although functional description of each GC/MS can be quite different, GC/MS quantification using isotopic dilution mass spectrometry follows basic underlying principles irrespective of the type of GC and mass analyzer used. Thus, the protocol must have guidelines for GC separation using a suitable column and temperature program, tuning and mass calibration using a reference compound, and mass measurements of the analyte and the corresponding internal standard (preferably a stable isotope of the analyte); however, one important consideration in choosing the mass spectrometer is its ability to operate under ECNCI mode because most of the bench-top MS machines may not be equipped with an ECNCI source and appropriate detector.

GC/ECNCI/HRMS Analysis of N^2, 3-ethenoguanine (εGua), 7-(hydroxyethyl) Guanine (7-HEG), and 7-(hydroxypropyl) Guanine (7-HPG) Using a VG 70-250SEQ Mass Spectrometer

BASIC PROTOCOL 6

The following protocol describes the steps that should be followed in order to analyze derivatized DNA adducts dissolved in toluene. Prior to GC/MS analysis, the biological samples are presumably cleaned and concentrated by various affinity and low-pressure chromatographic methods. Please refer to the respective methods for preparation of these samples prior to GC/ECNCI/HRMS analysis. The analyst is advised to read the paper entitled "Application of Gas Chromatography/Electron Capture Negative Chemical Ionization High-Resolution Mass Spectrometry for Analysis of DNA and Protein Adducts" by Ranasinghe et al. (1998). Although not required, basic understanding of quadrupole and sector mass spectrometers and general mass spectrometry principles can be useful for troubleshooting purposes. The method involves tuning of the MS and quantification using isotopic dilution mass spectrometry (Garland and Powell, 1981). This typically involves area measurement of two ion chromatographic peaks due to the analyte and the corresponding internal standard (IS). Note that the same method with slight modifications can be applied if the mass analysis is performed at a low (unit) resolving power (RP 1000). For example, tuning the mass spectrometer for high resolving power is not required (skip steps 5, 6, and 7 below). Also, a reference compound (PFK or FC43) is not introduced during the mass analysis (skip step 10, the needle valve is closed); therefore, no lock-mass or a check-mass is measured (skip first two rows in Tables 3.9.3, 3.9.4, and 3.9.5).

Materials

99.999% helium (Sunox)
Perflurokerosine (PFK; PCR) or perfluorotributylamine (FC43; PCR)
Sample in toluene
