through a sulcus. The selection of the entry site is aided by intraoperative ultrasound images and the frameless image-guided stereotactic system. Self-retaining retractors are placed to retract gently both sides of the cortical incision (generally approximately 3 cm in length), and then the operating microscope is brought in for the approach through the subcortical white matter to the tumor. The tumor is resected with suction, two-point coagulation forceps, grasping instruments, the CO<sub>2</sub> laser, or the CUSA, the resection proceeding from the inside out, so that surrounding normal white matter is disturbed minimally. The glistening peritumoral white matter is seen easily through the microscope as each of the tumor's margins are reached, and it is at this interface that the resection is stopped. Hemostasis is sometimes difficult but must be perfect. Hemispheric tumor cysts can be drained and, when possible, fenestrated into an adjacent ventricle to prevent reaccumulation. Tumors not amenable to resection because of their location or their diffuseness should be biopsied stereotactically. Again, there is no indication for a craniotomy when the purpose is merely to biopsy (and not resect) a tumor.

The introduction of cortical mapping procedures into brain tumor surgery has made feasible the extensive resection of tumors in functionally critical areas. By use of intraoperative cortical stimulation, motor- and speech-associated cortex can be mapped, and safe routes to deep-lying tumors and safe resection limits determined.<sup>31</sup> A principal disadvantage of surgery that incorporates mapping of speech is that the patient cannot be given general anesthesia, and the surgeon must, therefore, anticipate unexpected patient movement and possibly inferior brain relaxation during the operation.

## REOPERATION FOR CEREBRAL ASTROCYTOMAS

Evidence is accumulating that reoperation for resection of cerebral astrocytomas at the time of their recurrence can be efficacious.<sup>80,86,87</sup> The rationale cited earlier for the aggressive initial resection of cerebral astrocytomas seems to fit equally well the prospect for resection at recurrence. This is only true, however, if there is some treatment modality (e.g., chemotherapy and brachytherapy) that the patient can receive after the reoperation, and most often there is.

Salzman proposes from experience with reoperation of all patients who were to receive further therapy for recurrence of malignant glioma that a relatively nonselective approach might be rational, given that reoperation is safe and of potential benefit despite the patient's age, performance status, tumor grade, or interval between initial surgery and recurrence.<sup>80</sup> Young and coworkers argue for more rigid selection criteria when choosing candidates for reoperation on recurrent malignant gliomas.<sup>86</sup> They found that patients with a Karnofsky performance score (KPS) higher than 60 and an interval between the initial surgery and recurrence of at least 6 months had the longest survival times after reoperation. Harsh and associates looked at the effect of reoperation on the subsequent high-quality survival (KPS of at least 70) of patients with recurrent malignant gliomas.<sup>87</sup> Age and preoperative KPS have effects on the duration of high-quality survival in this study, with relative youth and high performance scores being advantageous. Because their data suggest that reoperation can significantly enhance the effects of chemotherapy on recurrent brain tumors, Harsh and associates would not suggest confining reoperation to young patients in excellent condition, but would suggest instead simply using these factors as guidelines in the broader therapeutic picture. Barker and his coworkers updated the experience from the same institution [University of California, San Francisco (UCSF)] and found that while the number of patients with *high quality* survival after reoperation had increased, the overall survival remained poor.<sup>472</sup> In this series the KPS was the single significant determinant for longer survival after reoperation.

## RADIATION THERAPY

### *Astrocytoma*

Differentiated or low-grade astrocytomas constitute a heterogeneous group of tumors. Median survival times may vary from 1 to 12 years depending on the patient's age, performance status, and the presence or absence of tumor enhancement on neuroimaging studies.<sup>88</sup> The variability in their behavior has led to uncertainties regarding their therapy and prognosis. Fortunately, randomized trials are being performed to clarify many of the issues surrounding the treatment of these tumors.

Approximately 10% to 35% of astrocytomas are amenable to total surgical resection.<sup>89</sup> The local control rate for completely resected cystic cerebellar astrocytomas approaches 100%, and postoperative irradiation is not recommended.<sup>90</sup> Similarly, the 5- and 10-year survival rates for patients with juvenile pilocytic astrocytomas are almost 100% after complete or *radical subtotal* resection and radiation.<sup>89,91</sup> Wallner and coworkers reported 10- and 20-year progression-free survival rates of 74% and 41%, respectively, for incompletely resected and irradiated juvenile pilocytic astrocytomas.<sup>91</sup> The authors had no data relative to incompletely resected and nonirradiated lesions. Shaw and associates found that patients with supratentorial pilocytic astrocytomas who underwent subtotal resection or biopsy and irradiation survived longer than nonirradiated patients.<sup>89</sup> However, the number of patients treated with surgery alone was small, and, therefore, the efficacy of radiotherapy for this tumor is uncertain. Based on these data, postoperative irradiation is not indicated for pilocytic astrocytomas when a complete or near complete resection has been performed. After subtotal resection, either immediate irradiation or close follow-up, reserving treatment for those patients with symptomatic, progressive, nonresectable tumors may be recommended.<sup>92</sup>

The 5-year recurrence-free survival rates of patients with infiltrative (nonpilocytic) astrocytomas or mixed oligoastrocytomas who undergo total or radical subtotal tumor resection range from 52% to 95%.<sup>93</sup> The variation in outcome may reflect prognostic differences related to age, the inclusion of patients with radical subtotal resections, and the reliance on retrospective evaluations of operative reports to determine the completeness of resection in the era before CT and MRI studies. Because recurrences are infrequent in children with completely resected astrocytomas, postoperative irradiation is generally not recommended. The outcome of adult patients after total or radical subtotal resection, has been found in some series to be similar to that of patients undergoing less extensive surgery.<sup>93</sup> Thus, in adults, postoperative irradiation has been recommended after complete resection by some authors,<sup>93</sup> whereas others advise that radiation therapy be withheld until there is evidence of tumor recurrence.<sup>94</sup>

Retrospective reviews published between 1956 and 1990 suggested that postoperative irradiation is beneficial for incompletely resected infiltrative low-grade astrocytomas. For irradiated patients, 5-year survival rates varied from 36% and 55%, and 10-year rates ranged from 26% to 43%. In contrast, 5-year survival rates for subtotally resected, nonirradiated tumors varied from 19% to 32% and 10-year rates were approximately 10%.<sup>92,93</sup> Many series that report the outcome of irradiated patients do not include a comparable control group, whereas others have presented results for selected groups of irradiated and nonirradiated patients. Further, marked changes in the quality of surgery, radiation therapy, and patient management occurred over the long time intervals spanned by these studies. Indeed, survival rates in these reports increase directly as a function of the time period in which the patients were treated.<sup>95</sup> Most of these data precede the era of modern neuroimaging techniques. The outcome of patients diagnosed and treated in the CT/MRI era is notably better than that reported in the older literature. Median survival times in more recent series are in the range of 7.2 to 10.0 years,<sup>95,96</sup> raising concerns over the value of the older literature in making treatment decisions today. The improved outcome appears to be related to the earlier diagnosis of tumors in neurologically intact patients who exhibit only seizures at the time of diagnosis.<sup>96</sup> In addition, CT and MRI may assist in operative planning, allowing a greater percentage of patients to undergo complete resections.<sup>94,97</sup>

The earlier diagnosis of patients with low-grade astrocytomas raised new questions regarding the timing of therapeutic intervention. Is it better to intervene early, or to wait until there is disease progression? Recht and colleagues<sup>95</sup> reported 26 patients with suspected low-grade supratentorial gliomas (based on clinical and radiologic features only) who were monitored without other treatment except anticonvulsants. Of these patients, 58% subsequently required intervention (surgery alone or with radiotherapy) within a median of 29 months (range, 4 to 123 months) because of increased size of the radiographic abnormality, refractory seizures, new symptoms, or malignant transformation. When compared with 20 patients who had similar characteristics but in whom the decision was made for immediate intervention, there was no difference in the outcome of patients who received immediate or deferred treatment and no difference in the time to neoplastic transformation. Arguments for performing an immediate biopsy are to confirm the diagnosis and to identify patients with nonenhancing anaplastic tumors. Further, complete surgical resection may improve survival, obviate the need for irradiation, and decrease the risk of malignant transformation, the most common cause of death in low-grade astrocytoma patients,<sup>95,96</sup> and <sup>97</sup> by reducing the tumor burden.<sup>97</sup>

The timing of postoperative irradiation is another area of controversy. Although it is generally agreed that patients with unfavorable astrocytomas with radiographic evidence of tumor growth, intractable seizures, progressive neurologic impairment, or malignant transformation of the tumor should undergo radiotherapy, this treatment is commonly deferred in patients with well-controlled seizures who present with asymptomatic, indolent tumors. Proponents of this approach argue that with CT and MRI, the disease is diagnosed much earlier in its natural history than in the past and that it is unclear whether early irradiation provides an outcome advantage over delayed irradiation, can delay or prevent tumor dedifferentiation, or whether radiation therapy even alters the prognosis.<sup>92</sup>

This issue was clarified in a randomized trial conducted by the EORTC and British Medical Research Council Brain Tumor Working Party. Patients with low-grade astrocytomas (65%), oligodendrogliomas (25%), or mixed tumors (10%) were randomized to receive immediate postoperative irradiation to a dose of 54 Gy or no further treatment until neurologic and CT scan evidence of disease progression. Among those in the control arm, 65% of patients received subsequent radiotherapy, 19% underwent surgery, chemotherapy, or both, and the remainder received only supportive care. A preliminary analysis of the study demonstrated that although

immediate irradiation improved the 5-year progression-free survival (44% vs. 37%,  $P = .02$ ), there was no improvement in overall 5-year survival (63% vs. 66%).<sup>98</sup> The outcome of patients with astrocytomas strongly correlates with the proliferative potential of the tumor as measured by bromodeoxyuridine (BUdR) and Ki67. The use of immunohistochemical and molecular markers may provide an opportunity for earlier intervention and improvement in the outcome for the prognostically more unfavorable subsets of patients.

Because radiotherapy is likely to lead to unacceptable sequelae in children younger than 3 to 5 years of age, treatment in this age group is postponed for as long as possible, provided that no significant neurologic deficits and no neuroimaging changes indicative of rapid tumor progression are present. Management decisions are also individualized in older children with incompletely resected astrocytomas who, compared with adults, have a better prognosis, a less pronounced survival improvement with postoperative irradiation, and a greater risk of late radiation sequelae.<sup>93</sup>

Limited radiation fields are used in the treatment of low-grade astrocytomas. The lesion defined by CT scan is encompassed with a 2-cm margin of normal tissue, whereas the T2-weighted MRI abnormality, which tends to be larger than the CT-defined lesion is given a margin of 1 to 2 cm. Complex treatment planning should be used whenever appropriate to minimize the risk of long-term sequelae. The standard dose is 54 Gy, administered using daily fractions of 1.8 to 2.0 Gy. The dose is reduced to 50.4 Gy for children younger than 5 years of age.

Two studies indicate that higher radiation doses do not improve the outcome (at least at 5 years) and suggest that lower doses may be preferable. In a trial conducted by the EORTC, patients were randomized to receive 45 Gy in 25 fractions or 59.4 Gy in 33 fractions. No difference in survival was observed between the two dose levels. The 5-year survival rates were 58% for 45 Gy and 59% for 59.4 Gy. Progression-free rates were also similar (47% vs. 50%). Minimal surgery, poor neurologic status, large tumors, advanced age, and unfavorable histologic features were adverse prognostic factors.<sup>95</sup> Similarly, a combined North Central Cancer Treatment Group, RTOG, and Eastern Cooperative Oncology Group trial randomized adult patients with supratentorial astrocytomas to receive 50.4 Gy in 28 fractions or 64.8 Gy in 36 fractions. As in the EORTC study, the 5-year survival rates were similar for the two dose levels studied, 73% for 50.4 Gy and 68% for 64.8 Gy ( $P = .57$ ). Age 40 or older and astrocytoma-dominant histology were poor prognostic features.<sup>100</sup> An increase in functional sequelae<sup>101</sup> and radiation necrosis<sup>100</sup> was observed in patients treated in the high dose arms of these studies.

There have been few studies evaluating combined chemotherapy and radiation therapy for low-grade astrocytomas. In a Southwest Oncology Group trial, adult patients with incompletely excised low-grade gliomas were randomized to receive radiation therapy alone or radiation therapy and CCNU. The median survival time for all patients was 4.45 years with no difference between the two treatment arms.<sup>102</sup> A trial by the RTOG is studying whether the addition of PCV to radiotherapy improves the outcome over radiotherapy alone.

Levin and coworkers<sup>103</sup> treated 22 adult patients with contrast-enhancing astrocytomas with the halopyrimidine analogue BUdR and radiation therapy. BUdR was given in weekly 96-hour infusions throughout the course of irradiation. This was followed by 1 year of PCV chemotherapy. The estimated 6-year progression-free and overall survival rates were 63% and 79%, respectively, comparing favorably with survival rates for enhancing low-grade gliomas reported by others.<sup>97</sup> These results require further confirmation.

### **Malignant Gliomas**

Prospective clinical trials conducted by the Brain Tumor Cooperative Group provided seminal evidence supporting the efficacy of radiation therapy in the treatment of malignant gliomas. The Brain Tumor Cooperative Group trial demonstrated a significant survival advantage for patients who received radiotherapy alone or with BCNU, as compared with those treated with resection and supportive care or with BCNU alone. The median survival time for patients receiving supportive care alone was 14 weeks, whereas those treated with radiation therapy had a median survival time of 36 weeks ( $F = .001$ ).<sup>104</sup> Patients with anaplastic astrocytomas and glioblastoma multiforme were treated to a dose of 60 Gy in single daily fractions of 1.8 to 2.0 Gy, five times per week. With this schedule, 25% of patients with glioblastoma multiforme and 50% of those with anaplastic astrocytoma exhibit a significant radiographic response by the completion of radiation therapy. Only 5% of patients have a complete tumor response, and a delayed response after irradiation is uncommon.<sup>105</sup>

Partial brain fields (also called *limited field*), defined by the extent of tumor on neuroimaging studies, are used for the treatment of malignant gliomas.<sup>106</sup> The target volume is defined as a 2- to 3-cm margin of tissue surrounding the perimeter of the CT- and MRI-defined contrast-enhancing lesion. RTOG protocols use a shrinking field approach. Initially, the treatment volume includes the contrast-enhancing lesion and surrounding edema on the preoperative CT or MRI study with a 2-cm margin. Subsequently (after 46 Gy of a 60-Gy course), the target volume is reduced to include the enhancing lesion only (without edema) with a 2.5-cm margin.

With conventional radiation therapy the median survival time for patients with anaplastic astrocytoma is 36 months, and the 3-year survival rate is approximately 55%.<sup>107</sup> In contrast, the median survival time for patients with glioblastoma multiforme is 10 months, whereas the 3-year survival rate is only 6%.<sup>106</sup> The response of malignant gliomas to standard radiation therapy techniques is limited by their striking inherent radioresistance and the radiosensitivity of the surrounding normal brain tissue. Thus, research in the treatment of malignant gliomas has been directed at improving the efficacy of radiotherapy. In addition to pursuing more effective chemotherapy programs (see [Chemotherapy](#) section), areas of investigation have included the use of chemical modifiers of the radiation response, altered fractionation schemes, dose escalation with interstitial brachytherapy, radiosurgery and three-dimensional conformal radiotherapy, and the use of heavy particle irradiation.

Two different classes of radiation-sensitizing agents have been investigated in malignant gliomas. The combination of the hypoxic cell radiation sensitizer, misonidazole, and radiation was compared with radiation alone in ten randomized trials. No survival improvement was observed in any of the dose-fractionation or drug schedules tested.<sup>108</sup> In addition, two halopyrimidine analogues, BUdR<sup>103,109,110</sup> and iododeoxyuridine,<sup>111</sup> have been tested. In a phase II study conducted by the Northern California Oncology Group, patients with malignant gliomas received BUdR in six weekly 96-hour infusions during the course of radiation therapy. This was followed by 1 year of PCV chemotherapy. The median survival times for patients with glioblastoma multiforme and anaplastic astrocytoma were 64 and 272 weeks, respectively.<sup>103,109</sup> Compared with historical controls, the survival of patients with anaplastic astrocytoma using this regimen was particularly encouraging. Based on these results, a randomized trial comparing radiotherapy alone or with BUdR plus PCV chemotherapy in patients with anaplastic astrocytoma was conducted by the RTOG, North Central Cancer Treatment Group, and Southwest Oncology Group. Enrollment into the study was discontinued before it reached its full accrual when it was estimated that there would be no difference between the two treatment arms.<sup>110</sup>

Hyperfractionated irradiation is the use of two or more treatments per day with fraction sizes smaller than conventional dose fractions to deliver a higher dose in the same overall treatment time as conventionally fractionated therapy. With hyperfractionation, tumor control probabilities should improve without increasing the risk of late complications. Further, with a 6-hour interval between doses, there is greater probability that rapidly proliferating tumor cells will be irradiated during more radiosensitive phases of the cell cycle and become *self-sensitized* by redistribution. Target cells for late sequelae proliferate slowly, and, therefore, for these tissues little redistribution or self-sensitization occurs.

The RTOG conducted a randomized phase II dose-escalation study in which patients were given 64.8, 72.0, 76.8, or 81.6 Gy in 1.2-Gy twice-daily fractions. Patients receiving 72 Gy had the longest median survival time, and no further improvement in outcome was observed at the higher dose levels.<sup>112</sup> A randomized trial comparing 72-Gy hyperfractionated irradiation with conventionally fractionated 60-Gy radiotherapy (BCNU given in both arms) was subsequently conducted by the RTOG. The median survival times for patients with glioblastoma multiforme were similar (10.2 months with hyperfractionation and 11.2 months with conventional fractionation). Likewise, for patients with anaplastic astrocytoma, the median survival was 44 months with hyperfractionation and 50 months with conventional fractionation ( $F = .81$ ).<sup>113</sup>

Another fractionation option, accelerated fractionation, attempts to reduce the overall treatment time by giving conventional sized dose fractions two or three times daily. This treatment schedule may improve the therapeutic ratio by reducing the opportunity for tumor cell repopulation during treatment, thereby increasing the probability of tumor control for a given dose level. Several trials using accelerated regimens have been conducted, but none has shown a survival benefit over conventional irradiation.<sup>114</sup> These studies indicated that although rapid regeneration does not appear to explain the radioresistance of malignant gliomas, the overall treatment time can be shortened. Altered fractionation schedules also provide an opportunity to integrate chemosensitizers and hypoxic cell sensitizers in a novel fashion. Trials applying this approach, however, have yet to demonstrate a benefit.<sup>115</sup> On the other hand, the use of accelerated fractionation and other short-course fractionation schemes may be especially appropriate in patients with relatively short survival expectancies.

Most gliomas are localized to a single area of the brain,<sup>62,63</sup> and they should be controllable if sufficiently high radiation doses can be delivered without damaging the surrounding normal brain tissue. One approach to augmenting the radiation dose is with interstitial brachytherapy. Iodine 125 and iridium 192 sources have been

used in clinical practice, and stereotactic techniques have been devised for the placement of afterloading catheters that are removed after the prescribed dose has been accrued. Well-circumscribed, peripheral, solitary supratentorial lesions measuring as large as 5 cm are best suited for implantation. Further, candidates must have good neurologic function and a KPS of at least 70. Based on these criteria, approximately one-third of patients with newly diagnosed malignant gliomas are candidates for this procedure.<sup>116</sup>

Several phase II studies have demonstrated survival improvements in patients with glioblastoma multiforme when external irradiation is combined with brachytherapy. Gutin and coworkers evaluated brachytherapy as an adjunct to external irradiation and chemotherapy in patients with newly diagnosed supratentorial malignant gliomas.<sup>117</sup> Patients received involved field external irradiation to 60 Gy with concomitant hydroxyurea (300 mg/m<sup>2</sup> orally every other day) followed by an iodine 125 implant to deliver an additional minimum tumor dose of 50 to 60 Gy. Following removal of the implants, they were given PCV chemotherapy every 6 to 8 weeks for 1 year. Although the median survival time of patients with glioblastoma multiforme (22 months) compared favorably with that of historical controls, there was no apparent gain observed in performing implantation at diagnosis in patients with anaplastic gliomas (median survival time, 39 months). Loeffler and associates reported the outcome of 35 patients with glioblastoma multiforme who underwent partial brain external irradiation (59.4 Gy in 33 fractions) followed by an additional 50 Gy given by interstitial implantation.<sup>118</sup> Survival rates at 1 and 2 years were 87% and 57%, respectively, for patients receiving brachytherapy compared with 40% and 12%, respectively, for a control group matched by radiographic and patient characteristics ( $P > .001$ ). Reoperation for brachytherapy-induced symptomatic radiation injury is required in approximately 40% of patients.<sup>117,118</sup>

The Brain Tumor Cooperative Group compared interstitial implantation (60 Gy at 10 Gy/d) preceding external irradiation (60.2 Gy at 1.72 Gy per fraction) and BCNU with external irradiation and BCNU alone in a randomized trial. Implanted patients experienced improvement in median survival (16 months vs. 13 months) and 18-month survival (47% vs. 32%) compared with those who did not receive brachytherapy.<sup>119</sup> However, in another randomized trial, Laperriere and colleagues found no difference in outcome in patients randomized to receive external beam irradiation alone to 50 Gy (median survival, 14 months) or external beam irradiation and an iodine 125 implant delivering a minimum tumor dose of 60 Gy (13 months).<sup>120</sup> A randomized trial testing the addition of interstitial microwave hyperthermia to the brachytherapy boost after external irradiation in newly diagnosed patients with glioblastoma multiforme was conducted at the UCSF. Median survival was 85 weeks versus 76 weeks and the 2-year survival was 31% versus 15%, favoring patients receiving hyperthermia compared with those treated with external beam irradiation and brachytherapy alone ( $P = .045$  and  $P = .02$ , respectively).<sup>121</sup> Brachytherapy has also been shown to improve the survival and quality of life of patients with recurrent malignant gliomas who meet the criteria of implantation.<sup>122</sup>

Stereotactic radiosurgery has also been used to augment the dose of external beam irradiation in initial treatment of patients with malignant gliomas. Shrieve and colleagues<sup>123</sup> used radiosurgery as a boost after standard external beam irradiation (59.4 Gy) in 78 patients with newly diagnosed glioblastoma multiforme. Patients with discrete, geometrically spherical lesions measuring 4 cm or less in diameter and a KPS of 70 or higher were selected for radiosurgery. The median minimum tumor dose was 12 Gy. The median survival was 20 months, and the 1- and 2-year survival rates were 88% and 36%, respectively. Similar to brachytherapy, 50% of the patients required reoperation for symptomatic radiation necrosis or recurrent tumor. Based on tumor size, geometry and functional status guidelines proposed for radiosurgery, only 12% of patients with malignant gliomas met the criteria for radiosurgery. The median survival time for radiosurgery-eligible glioblastoma multiforme patients was 12.5 months, compared with 10.5 months for ineligible patients ( $P = .07$ ).<sup>124</sup> A comparison of these data with those cited previously suggests that for glioblastoma multiforme a survival advantage of approximately 7 months is conferred when radiosurgery is actually given. Unfortunately, the benefit of radiosurgery diminishes when broader selection criteria are used.<sup>125</sup>

Radiosurgery may also be used to retreat patients with small previously irradiated tumors. In one series the median survival time of 86 patients with recurrent glioblastoma multiforme was 10 months from the time of radiosurgery, similar to the published experience for brachytherapy at recurrence.<sup>126,127</sup>

Three-dimensional conformal photon radiation therapy is a mode of treatment planning and delivery designed to enhance the conformation of the radiation dose to the target volume, while maximally restricting the dose delivered to the normal tissue outside the treatment volume. Conformal treatment planning techniques when applied to cerebral tumors have permitted a 30% to 50% reduction in the volume of normal brain tissue irradiated to high doses.<sup>128</sup> This new approach to treatment planning may not only decrease the risk of normal tissue injury, but also allow higher than traditional radiation doses to be safely administered to patients with malignant gliomas. In an ongoing study at the University of Michigan, doses as high as 80 Gy have been administered using three-dimensional techniques, and escalation to higher dose levels is planned.<sup>129</sup> Fitzek and colleagues used conformal techniques to plan combined treatment with photons and proton beams using an accelerated fractionation regimen to escalate the tumor dose to 90 cobalt gray equivalent (CGE). Twenty-three patients were treated with this approach. The median survival time was 20 months (a 5- to 11-month improvement compared with patients with comparable risk factors treated with conventional radiotherapy) and the 2- and 3-year actuarial survival rates were 34% and 18%, respectively. Tumor regrowth, demonstrated by histologic tissue examination, occurred most commonly in areas that received 70 CGE or less, whereas tumor was found in the 90 CGE volume in only one case.<sup>130</sup>

## CHEMOTHERAPY

The era of controlled clinical trials for malignant astrocytomas began with the inception of the Brain Tumor Study Group in 1967. The European Organization for Research on Treatment of Cancer then established a comparable group. In addition, other national and regional cooperative groups have conducted controlled chemotherapy trials. [Table 43.2-12](#) and [Table 43.2-13](#)<sup>103,131,132</sup> and <sup>133</sup> summarize selected data from some of these groups. Differences in reports are sometimes confusing, for instance, some groups report survival or time to tumor progression (TTP) from initiation of therapy, whereas others use the original surgery date for untreated patients. Some groups define histologic groups and separate glioblastoma multiforme from anaplastic astrocytoma, and others combine the two groups under the heading of malignant glioma. For more detail, see a published review of chemotherapy for gliomas in the 1990s.<sup>134</sup>

In addition to histology, other factors influence the likelihood and duration of response. Major known factors are age, performance status, and extent of surgical resection at onset of therapy. For instance, younger patients are more likely to respond and for a longer period; better performance status patients do best; and patients who have more extensive surgical resection do better than those who do not have surgery or who have biopsy only.<sup>80,135</sup>

With consideration for these covariates, it is still clear that adjuvant chemotherapy after surgery and radiation therapy for glioblastoma and anaplastic astrocytomas increases both TTP and survival, more so for the patients with anaplastic gliomas than for glioblastoma. There is less precise information with respect to response because of differing criteria used by the various groups. However, most investigators agree on the definition of deterioration or tumor progression: TTP and survival are more universal measures for controlled clinical trials. TTP is a more pure measure of efficacy, because at time of initial progression, many patients receive other forms of therapy. Survival, however, is a better measure of the social usefulness of the life attained by the therapy.

Clinical trials have demonstrated the efficacy of a number of drugs when combined with irradiation as adjuvant therapy for patients with glioblastoma multiforme and anaplastic astrocytoma. [Table 43.2-15](#) summarizes some of the trials of adjuvant chemotherapy for glioblastoma.<sup>126,128,131,136,137,138,139,140,141,142,143,144,145,146,147,148</sup> and <sup>149</sup> The data are disappointing in that evidence-based survival gains for adjuvant chemotherapy have not occurred over the past 25 years. Chemotherapy appears to benefit modestly those patients that are in the 25th percentile of survivors. This is reasonable, because *in vitro* tumor drug-sensitivity assays suggest that approximately 60% of patients are resistant to the cytotoxic anticancer drugs used in those studies.<sup>150,151</sup> From [Table 43.2-15](#) it would appear that nitrosourea-based drug combinations may be modestly superior to monotherapy<sup>131,132,149</sup> in that the 25% survival for BCNU is 71 weeks, whereas it is 91 to 120 weeks for drug combinations.

For anaplastic astrocytoma and other anaplastic gliomas, the benefits of combination chemotherapy appear to be greater and better accepted. The first study to open this door was the randomized study of postradiation BCNU to the PCV combination. In that study the survival at the 50th percentile was 157 weeks for PCV compared with only 82 weeks for BCNU-treated patients ( $P = .009$ ). Even better was the 25th percentile survival, which was greater than 7.7 years for PCV patients compared with 4.1 years for BCNU patients. Jeremic and coauthors found similar results with their combination of CCNU, procarbazine, and vincristine.<sup>132</sup> The study with bromodeoxyuridine together with irradiation and then followed by PCV appears similar for anaplastic astrocytoma patients in whom the median survival is actually higher (4 years vs. 3 years), although it offers no advantage for glioblastoma patients.<sup>103,109</sup> Another nitrosourea combination, 6-thioguanine and BCNU, appears to be at least as active against anaplastic astrocytoma (and other anaplastic gliomas) with an anticipated median survival of more than 5 years.<sup>149</sup>

More approaches need to be considered to improve the results cited in [Table 43.2-15](#) and [Table 43.2-16](#). The status of phase II chemotherapy trials is summarized in [Table 43.2-17](#). These studies are disappointing and show that response rate (response plus stable disease) does not correlate with durability of response. [Table 43.2-17](#)<sup>67,128,145,152,153,154,155,156,157,158,159,160,161,162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179</sup> and <sup>180</sup> shows that even though the number of patients benefiting from chemotherapy is high in some studies, nevertheless, among the response and stable tumor patients, the duration of benefit has shown only modest gains during the

last decade. This failure of chemotherapy is probably a function of *de novo* and emergent resistance of tumor cell subclones. It is disappointing that drugs designed specifically for gliomas, such as diaziquone and spiromustine, were only mediocre agents in the clinic. [158,159](#) and [160,162](#)

**TABLE 43.2-16.** Survival for Adult Anaplastic Glioma Patients with Karnofsky Performance Scores Greater Than or Equal to 60 Treated on Protocols Published Since 1990

**TABLE 43.2-17.** Chemotherapy of Recurrent and Progressive Supratentorial Astrocytomas

The use of the combination of polyamine inhibitors for anaplastic astrocytomas was somewhat encouraging, and one of the authors has spent many years in pursuit of better drug combinations with little positive gain to date. Alpha-difluoromethyl ornithine (eflornithine; DFMO) has been studied alone, [181](#) with methyl-bisguanylhydrazine, [175](#) with BCNU, [174](#) and most recently with PCV (glioblastoma multiforme [GBM] study submitted). As a single agent, DFMO appears to have similar activity to the DFMO–methyl-bisguanylhydrazine combination. In both instances, the median time to progression (MTP) for recurrent anaplastic gliomas achieving response and stable disease was almost 1 year. The difference in response rates (72% vs. 46%) may reflect too lenient entry requirements for the DFMO patients and a subsequent high number of patients who went off therapy before the first evaluation at 8 weeks. [182](#)

It has long been known that some alkylating agents such as the nitrosoureas have their DNA damage repaired by an alkyltransferase. Tumors with high alkyltransferase levels are able to repair nitrosourea-inflicted DNA damage and are thus considered *resistant* to the chemotherapy. This can reflect itself in decreased survival. [183,184](#) We have conducted some uncontrolled phase II studies in an attempt to overcome tumor resistance to nitrosoureas. In one study, 6-thioguanine, dibromodulcitol, and procarbazine were given before CCNU to enhance tumor cell kill by interfering with DNA repair. [176](#) The results were dramatic for the anaplastic gliomas, when 95% of patients who had failed radiation therapy responded or stabilized for an MTP of 15 months, and 25% did not fail until 33 months; 61% of glioblastoma patients with response or stable disease had an MTP of 9.3 months. Of those who failed earlier nitrosourea therapies, 38% of anaplastic glioma patients and 58% of glioblastoma patients benefited, with MTPs of 10.6 and 5.1 months, respectively. Using a modification of this protocol, we combined 6-thioguanine, procarbazine, CCNU, and hydroxyurea and found that in the anaplastic glioma group, 23% of patients had a partial response and 53% had stable disease. This included 77% of 30 patients who had not received prior chemotherapy and 76% of 17 who had undergone previous chemotherapy. The median time to disease progression was 50 weeks for patients responding who had not undergone previous chemotherapy and 25 weeks for those who had undergone previous chemotherapy. More careful controlled studies with drugs that block alkyltransferase levels are indicated, but expectations should not be too high as these early data remain discouraging.

Intravenous cisplatin and carboplatin have shown only modest activity with respect to TTP, although response and stable rates appear high. [163,185](#) This may reflect poor tumor and adjacent brain penetration of these drugs and their inability to kill tumor cells at a distance from the main tumor mass. Compounding this pharmacokinetic disadvantage is recent experimental data in rodent tumors that show that dexamethasone can reduce cisplatin penetration into the brain adjacent to tumor where infiltrative tumor cells reside. [186](#)

Paclitaxel studies have shown acceptable toxicity but only modest antitumor activity in the treatment of recurrent malignant gliomas. Against recurrent anaplastic astrocytoma, Chamberlain and Kormanik found a remarkable 80% response and stabilization rate for a median of 7.5 months. [187](#) Experience with paclitaxel was summarized in a review article where it was shown to have modest activity. [188](#) Evaluation of paclitaxel has been complicated by accelerated plasma clearance in patients on anticonvulsants. [189](#)

The newest alkylating agent to be approved by the European and American regulatory authorities is temozolomide. It has been approved for anaplastic astrocytoma in the United States and also for glioblastoma multiforme in Europe. The drug has been shown to be modestly active in glioblastoma and moderately active against anaplastic astrocytoma. [190,191](#) Temozolomide is oral, better tolerated than procarbazine by patients, and has a predictable and short nadir period. These features make it a popular choice for drug combination regimens. Currently, trials have been completed or are underway to evaluate temozolomide with interferon- $\alpha$ , *cis*-retinoic acid, BCNU, and Marimastat to name a few trials.

Betaseron, an interferon- $\beta$ , attained 50% response and stable rates in a cooperative study; however, the duration of benefit is low, with MTPs of 16 to 18 weeks. [165](#) Tamoxifen, an antiestrogen with the ability to reduce protein kinase C levels and possibly interfere with angiogenesis, has taken on almost cult status as a brain tumor agent. [192,193,194](#) and [195](#)

Autologous bone marrow transplantation has had few practitioners, generally because of a low rate of observed complete responses to any form of chemotherapy. Single-agent BCNU was used years ago with no definable gains over conventional dose nitrosourea therapy. [196](#) Other researchers have used thiotepa [236](#) and etoposide. [197,198](#) Although neither thiotepa nor etoposide alone has shown remarkable activity against gliomas, various combinations of the three agents are being evaluated. [199,200](#) It is currently unclear whether autologous bone marrow transplantation has a place in the management of cerebral gliomas.

## BRAIN STEM GLIOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Tumor involvement of the brain stem is caused by, in order of decreasing frequency, astrocytoma, glioblastoma, and ependymoma. These tumors can be primarily central, diffuse, and infiltrative or focally infiltrative with or without an exophytic; the latter carry a better prognosis. Cranial nerve involvement can be at the nuclear level or of the cranial nerve as it leaves the brain stem. The initial manifestations of a brain stem glioma are unilateral palsies of cranial nerves VI and VII in

approximately 90% of patients. Cranial nerve involvement is usually followed by long tract signs, such as hemiplegia, unilateral limb ataxia, ataxia of gait, paraplegia, hemisensory syndromes, gaze disorders, and, occasionally, hiccups. Less commonly, long tract signs precede the cranial nerve abnormalities; this is more likely with confined central intrinsic lesions.

If the tumor is a well differentiated or an anaplastic astrocytoma, it is likely to involve the midbrain and produce hydrocephalus, vomiting, drowsiness, and cerebellar signs; if the tumor is a glioblastoma, it more often involves the medulla. Children with glioblastoma characteristically have a rapidly progressive course and are likely to have deficits in cranial nerves VI, VII, IX, and X, and dysarthria, personality change, and head tilt. Unlike expansive posterior fossa tumors, headache, vomiting, and papilledema occur late.

As a group, the prognosis is poor, with 5-year survival rates varying between 0% and 38% and a median survival of less than 1 year in most series. <sup>201,202 and 203</sup> Certain patients do better than others. For instance, patients with type II tumors do better than those with infiltrative type I tumors. Moderately anaplastic exophytic tumors do better than higher grade anaplastic tumors. Landolfi and others reported a small series of 19 brain stem glioma patients between 17 and 70 years of age with a median survival of 54 months.<sup>204</sup> In their group were 2 tectal, 4 cervicomedullary, and 13 pontine gliomas; three pontine tumors had an exophytic component. Surprisingly, only 12 were treated initially with radiotherapy and 3 were treated at recurrence.

## SURGERY

Modern imaging of the CNS with MRI has improved the capability for definitive diagnosis of brain stem tumors. Lesions previously difficult to distinguish from brain stem glioma (e.g., clivus tumors, foramen magnum meningiomas, multiple sclerosis, occult arteriovenous malformations, and brain stem abscesses) usually can now be excluded. Still, biopsy of brain stem gliomas for confirmation of the diagnosis and for definite tumor grading should be performed when possible. Biopsy of brain stem gliomas accessible through the floor of the fourth ventricle or presenting on the lateral surface of the pons can be accomplished safely, and associated symptomatic cysts can be drained. Attempt at complete resection of these tumors is contraindicated. Stereotactic needle biopsy of brain stem gliomas using CT and MRI guidance seems to have a low complication rate, so this method is being used increasingly, with the consequence that fewer patients are being treated without a tissue diagnosis.<sup>205</sup>

## RADIATION THERAPY

Radiation therapy, the primary treatment for brain stem tumors, improves survival and can stabilize or reverse neurologic dysfunction in 75% to 90% of patients. <sup>203</sup> Traditionally, brain stem gliomas have been treated with doses of 54 Gy, administered in daily fractions of 1.8 Gy, through parallel opposed portals with the tumor dose calculated at the midline on the central axis of the beam. According to a multiinstitutional survey by Freeman and Suissa, <sup>202</sup> the 1-, 2-, and 5-year survival rates of children treated with conventional radiation therapy techniques were 50%, 29%, and 23%, respectively.

Because of the relatively poor results obtained with conventional radiation dose-fractionation schedules and the observation that these tumors recur locally, hyperfractionated irradiation, designed to deliver higher tumor doses, was evaluated by several investigators. <sup>206,207,208 and 209</sup> Early reports demonstrating consistent, although modest, improvements in outcome have been observed when patients treated with hyperfractionation regimens of up to doses of 70.2 to 72.0 Gy (1.0 to 1.17 Gy twice daily) were compared with historical control patients treated with conventional or low-dose hyperfractionated irradiation. <sup>250,253</sup> There was no outcome improvement when the dose was increased to 75.6 Gy and 78 Gy,<sup>208</sup> but considerable morbidity was observed at these higher dose levels. <sup>210</sup> The Pediatric Oncology Group (POG) conducted a dose-escalation trial of 66.0, 70.2, and 75.6 Gy in twice-daily fractions of 1.1, 1.17, and 1.26 Gy, respectively, in children with diffuse brain stem gliomas. No difference in the median time to progression (7 to 8 months) and median survival time (10 months) between the three dose schedules was found. The highest dose was associated with steroid dependency in 62% of patients and a 45% incidence of intralesional necrosis. <sup>209</sup> Thus, the 70.2-Gy dose level was considered to have the best therapeutic ratio, and was tested by POG in a randomized trial comparing hyperfractionated radiotherapy with 54 Gy given with conventional fractionation. Children in both treatment arms received cisplatin during radiotherapy. <sup>209</sup> Hyperfractionation did not improve event-free survival ( $P = .96$ ) or overall survival ( $P = .65$ ) over that of the conventional dose fractionation regimen. For patients receiving the conventional fractionation regimen, the median time to progression was 6 months, the median survival time was 8.5 months, and the 1- and 2- year survival rates were 30.9% and 7.1%, respectively. For those receiving the hyperfractionated irradiation regimen, the median time to progression was 5 months, the median survival time was 8 months, and the 1- and 2- year survival rates were 27% and 6.7%, respectively.<sup>211</sup>

Based on the results of the POG trial, the current standard for the treatment of diffuse intrinsic brain stem gliomas consists of conventionally fractionated radiotherapy given to a dose of 54.0 to 59.4 Gy. The availability of MRI and three-dimensional conformal radiotherapy treatment planning approaches offers improved target definition and allows the high-dose radiation volume to be better tailored to the contour of the lesion. The irradiated volume includes a margin of normal tissue of approximately 2 cm around the tumor. Smaller margins may be used for more focal lesions. <sup>210</sup> Dorsal exophytic and cervicomedullary tumors that are completely resected do not require routine postoperative irradiation. <sup>210</sup>

## CHEMOTHERAPY

As with cerebral astrocytomas, chemotherapy is primarily nitrosourea based. <sup>212</sup> The use of chemotherapy, adjuvant to irradiation, has been infrequent. The Children's Cancer Group (CCG) randomly compared radiation therapy with radiation therapy followed by CCNU, PCV, and prednisone. <sup>170</sup> The mean survival was 11 months, and there was no difference between the two groups. In another trial, 5-fluorouracil and CCNU before radiation therapy and hydroxyurea and misonidazole during radiation therapy were evaluated<sup>258</sup>; in that study, TTP (32 weeks) and survival (44 weeks) were not better than the initial CCG study. A pilot study evaluating oral etoposide during and after radiotherapy was closed to accrual by the CCG; analysis of the data has not yet been reported.

For recurrent or progressive brain stem gliomas, few therapies have been evaluated. <sup>213</sup> Some benefit has been demonstrated, but the extent of benefit has not been well established. In one study, 5-fluorouracil, CCNU, hydroxyurea, and 6-mercaptopurine were used to treat children and adults with recurrent or progressive brain stem gliomas.<sup>214</sup> Sixty-nine percent of 13 patients had response or stabilization, with a relapse-free survival of 25 weeks; the overall survival was 27 weeks. This finding is somewhat worse than would be expected for supratentorial gliomas. These authors conducted a phase II study of recurrent malignant gliomas with a combination of BCNU and DFMO. In that study, three of five patients benefited, with the three continuing to benefit at 1 to 3 years. <sup>174</sup> Although not curative, some of these chemotherapeutic leads should be exploited.

## CEREBELLAR ASTROCYTOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Astrocytomas arising in the cerebellum are considered separately, because their prognosis is consistently better than astrocytomas arising in the cerebrum or brain stem. These tumors, which occur most often during the first two decades of life, arise in the vermis or more laterally in a cerebellar hemisphere. Cerebellar astrocytomas usually are well circumscribed; they can be cystic, solid, or an admixture of polycystic and solid.

Histologically, most astrocytomas are low grade and lack features commonly associated with anaplasia; many are pilocytic in appearance and, histologically, some are juvenile pilocytic astrocytomas. In a series on 451 children reported from the Hospital for Sick Children of Toronto, cerebellar astrocytomas accounted for 25% of all posterior fossa tumors; 99 of 111 (89%) of the cerebellar astrocytomas were low grade, with nearly all vermian in origin. <sup>215</sup> Approximately 75% of these tumors are located only in the cerebellum, with the remainder involving the brain stem as well. <sup>216</sup>

Because most of these tumors arise in the vermis, the clinical presentation is similar to medulloblastoma, with truncal ataxia, headache, nausea and vomiting, and in the young, split cranial sutures and head enlargement from increased intracranial pressure.

## SURGERY

Cystic cerebellar astrocytomas are exposed through a posterior fossa craniectomy. The cyst is located with ultrasound, cannulated, and then exposed by an incision through the cerebellar folia. Self-retaining retractors are placed into the cyst and then, with the aid of the operating microscope, the cyst is examined and the vascular,

Routine postoperative irradiation is not indicated for most gliomas confined to the optic nerve.<sup>227</sup> In contrast, radiation therapy can prevent tumor progression, improve disease-free survival, and stabilize or improve vision in patients with chiasmal lesions. Wong and colleagues reported that 6 of 27 (22%) chiasmal gliomas that did not receive radiation therapy progressed locally, whereas 9 of 20 (45%) that received radiation therapy failed.<sup>226</sup> Three of these recurrences were seen in the adults with extremely aggressive, nonresponsive tumors. Further, 87% of the irradiated patients who received a dose of 50 to 55 Gy were controlled compared with 55% of those who received 46 Gy or less. Radiation therapy significantly improved the relapse-free survival but not the overall survival. Tao and colleagues concluded that radiotherapy was effective in the majority of patients with progressive chiasmal gliomas. The 10-year progression-free and overall survival rates after radiotherapy were 89% and 100%, respectively. Stabilization or improvement in vision was achieved in 81% of the evaluable treated patients. The authors drew attention to the fact that the median time for a radiographic response of 50% or more was 62 months. Hypopituitarism was common after radiotherapy, underscoring the need for life-long endocrine follow-up with appropriate replacement after treatment.<sup>228</sup> Jenkin and colleagues<sup>227</sup> found that for posterior optic gliomas irradiation was more effective in preventing subsequent relapse than subtotal resection alone. The 10-year relapse-free survival rate was 70% for irradiated patients, compared with 41% for those who did not receive primary radiotherapy ( $F = .03$ ). However, there was no difference in overall survival between these two patient groups due largely to the efficacy of radiation therapy in previously nonirradiated relapsed patients. Erkal and colleagues also reported a progression-free survival rate of 77% in children irradiated for optic nerve and chiasmal hypothalamic gliomas.<sup>229</sup> The prognosis for patients with optic pathway tumors and chiasmatic hypothalamic lesions was similar. In a series collected from the literature, local control was achieved in 154 of 189 (81%) irradiated anterior chiasmal tumors, whereas 92 of 142 (65%) posterior tumors were controlled. Vision improved in 61 of 210 (29%) evaluable patients and remained stable in 118 of 210 (56%) patients.<sup>225</sup> For hypothalamic tumors, radiation therapy produced radiographic improvement in 11 of 24 (46%) with a median progression-free survival of 70 months compared with 30 months for those patients who did not receive radiation therapy.<sup>230</sup>

Although some clinicians advocate deferring irradiation in asymptomatic patients or in those with lesser visual disturbance until there are signs of disease progression,<sup>227</sup> others recommend that radiation therapy be given early in the course of the disease to minimize the risk of visual deterioration.<sup>226</sup> The radiation portals are tailored to the tumor volume and designed to avoid irradiation of the lens of the eye. Three-dimensional conformal, intensity-modulated radiotherapy and stereotactic radiotherapy techniques are used to minimize the dose to adjacent structures. A dose of 50 to 54 Gy in daily 1.8-Gy fractions is recommended.

## CHEMOTHERAPY

The published chemotherapy trials for this group of patients represent small series. Chemotherapy has been used successfully to delay the initiation of radiation therapy in young children.<sup>231,232</sup> Packer and associates treated 24 children (median age, 1.6 years) with a combination of dactinomycin and vincristine.<sup>233</sup> Six of the cases involved the chiasm, eight involved the chiasm and hypothalamus, and ten involved the chiasm and visual pathways. At a median follow-up period of 4.3 years, 38% of patients had disease that progressed.

Petronio and coworkers reported on 19 infants or children with chiasmatic and hypothalamic gliomas treated with chemotherapy after diagnosis.<sup>234</sup> Of the 12 tumors in which a biopsy was obtained, there were 7 juvenile pilocytic astrocytomas, 2 astrocytomas, 2 anaplastic astrocytomas, and 1 subependymal giant cell astrocytoma. The children were between 3 months and 15 years of age when treated. The chemotherapy included one of three regimens: one with dactinomycin and vincristine; one with the combination of BCNU, 5-fluorouracil, hydroxyurea, and 6-mercaptopurine; and 15 with the combination of 6-thioguanine, procarbazine, dibromodulcitol, CCNU, and vincristine (BTRC 8422 protocol). Fifteen of 18 initially treated with chemotherapy responded or stabilized; the median follow-up period exceeded 1.5 years (range, 1.4 months to 5.8 years). Rodriguez and colleagues reported a series of 33 patients with hypothalamic gliomas,<sup>230</sup> some of whom were included in the Petronio series.<sup>234</sup> Chemotherapy at presentation or recurrence was beneficial in 10 of 16 (62%) patients.

In another study, Prados and colleagues treated 42 children with low-grade gliomas who had either progressive neurologic symptoms or radiographic tumor enlargement with a combination of 6-thioguanine, procarbazine, dibromodulcitol, CCNU, and vincristine (TPDCV).<sup>235</sup> In that group were 33 patients with hypothalamic chiasmatic gliomas. Multivariate analysis demonstrated no difference between this group and those with low-grade gliomas elsewhere; for the entire group of 42 patients the median progression-free survival was 2.5 years and the 5-year median survival was 78%, reflecting the value of secondary chemotherapy regimens and radiotherapy.

## OLIGODENDROGLIOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Oligodendrogliomas have a relatively flat peak incidence between 25 and 49 years. Although they are most common (80%) in the cerebral hemispheres, approximately 15% occur in the third or lateral ventricles or protrude into a ventricle from the thalamus.<sup>236</sup> Grossly, these tumors are often well demarcated, and in 20% they are cystic. They have a 10% likelihood of spreading through the CSF pathways. Like astrocytomas, they vary in malignancy. Attempts have been made to grade oligodendrogliomas on an A through D scale<sup>236</sup>; however, grades A through C vary little, and B and C are virtually identical with respect to survival such that these subdivisions seem unnecessary; a designation of differentiated or highly anaplastic may be sufficient. These tumors often have both astrocytic or ependymal elements seen at biopsy; such tumors are called *mixed gliomas*.

Clinically, these tumors present in the typical fashion of hemispherical astrocytomas. However, two features distinguish them from astrocytomas: the antecedent history, averaging 7 to 8 years, tends to be longer, and seizures are more common, occurring in 70% to 90% of patients by the time of diagnosis. Provisional diagnosis may be made by MRI or CT neuroimaging, but histologic confirmation is necessary and almost always possible. Approximately 50% of oligodendrogliomas have scattered calcification, usually related to intrinsic blood vessels, which are evident by CT scan.

At recurrence or autopsy, approximately 60% of oligodendroglioma and most mixed oligoastrocytoma patients demonstrate histologically an anaplastic astrocytoma or glioblastoma multiforme. This may belie a common origin of both types of tumors to the O2A progenitor cell.

## SURGERY

The surgical resection of hemispheric oligodendrogliomas follows the same principles as discussed earlier for [cerebral astrocytomas](#), with gross total removal being the goal when this is consistent with good neurologic outcome. The margins of oligodendrogliomas can appear to be more distinct than those of astrocytomas, but generally they are infiltrative. Because of this, surgical cure remains unlikely; but the indolent course of these tumors allows for a long progression-free interval after an aggressive resection in some patients. Oligodendrogliomas often recur in the previous operative site. Under these circumstances, reoperation may be advisable, particularly when followed by chemotherapy.

## RADIATION THERAPY

The infrequency of oligodendrogliomas and their variable and often long prediagnosis and posttreatment natural history make it difficult to evaluate the effect of radiation therapy in patients with differentiated oligodendrogliomas. Data from Mirk and colleagues<sup>237</sup> indicate that the behavior of these tumors may be more unpredictable and their prognosis less favorable than previously believed. The problems in evaluating retrospective reports for oligodendrogliomas are similar to those previously discussed for low-grade astrocytomas. Conclusions regarding the value of radiotherapy are contradictory, and the lack of randomized trials precludes the statement of firm recommendations. Five-year survival rates for irradiated patients range from 36% and 83% and 10-year rates vary from 30% to 46%. In contrast, 5-year survival rates for subtotally resected, nonirradiated tumors range from 25% to 55% and 10-year rates vary from 13% to 25%.<sup>92,93,238,239,240,241</sup> and <sup>241</sup> Some authors recommend immediate postoperative irradiation for patients with incompletely resected lesions,<sup>238,239,240</sup> and <sup>241</sup> whereas others have been unable to show that postoperative irradiation is of benefit.<sup>242</sup> It has also been suggested that radiation therapy be deferred until there is evidence of tumor progression or recurrence or that only patients with anaplastic tumors or mixed oligoastrocytomas should receive treatment.<sup>92</sup>

Most retrospective studies comparing surgery alone with surgery and radiation therapy do not contain analyses to ensure that the distribution of patients in the two treatment groups are comparable with respect to prognostic variables such as age,<sup>242</sup> completeness of resection,<sup>237,243</sup> neurologic signs and symptoms,<sup>239,242</sup> and histopathologic features.<sup>236,239,242,243</sup> Furthermore, treatment selection criteria are either not stated or unknown.<sup>241</sup> It is likely that many retrospective studies in which the pathology material was not independently reviewed contain patients with both differentiated and anaplastic oligodendrogliomas. This has been considered to be an important distinction because on average patients with low-grade oligodendroglioma tumors survive 9 years, as compared with 2.2 years for those with high-grade

tumors.<sup>93,236,244</sup> Our own data compiled at the University of Texas M. D. Anderson Cancer Center and the University of California Brain Tumor Center (San Francisco) found that median survival was comparable and greater than 7 years.

Although there is some controversy, most neurooncology specialists find that the outcome of patients with pure oligodendroglioma is significantly better than those with mixed oligoastrocytomas. Shaw and colleagues found that the 5- and 10-year survival rates for patients with oligodendrogliomas were 72% and 46%, respectively, whereas for mixed oligoastrocytomas the survival rates were 63% and 33%.<sup>244</sup>

Taken together, the data suggest that there may be a benefit to radiation therapy for patients with incompletely resected tumors during the first 5 years after treatment, but this effect appears to diminish over time. Gannett and colleagues found a significant improvement in survival with postoperative irradiation. Patients treated with surgery alone had 5- and 10-year survival rates of 51% and 36%, respectively, compared to 83% and 46% for irradiated patients ( $P = .032$ ). Lindegaard and colleagues found that radiation therapy prolonged the median survival time (38 months vs. 26.5 months,  $P = .039$ ) but did not influence the overall cure rate when given after subtotal resection, whereas it did not appear to be indicated after total resection.<sup>241</sup> Wallner and associates reviewed the outcome of 42 patients and observed 5- and 10-year survival rates of 61% and 33%, respectively; relapse-free survival rates were only 33% and 25%.<sup>240</sup> The 10-year survival rate for patients with pure oligodendrogliomas who received at least 45 Gy was 56% compared with 18% for nonirradiated patients ( $P = .092$ ). Wallner and coworkers concluded that adjunctive radiation therapy increased the time to tumor recurrence and the number of long-term survivors.<sup>240</sup> Shaw and colleagues<sup>244</sup> also found a survival advantage in irradiated patients with incompletely resected tumors who received at least 50 Gy. However, the survival differences between the irradiated and the nonirradiated groups did not reach statistical significance. The 10-year survival rate for patients treated with subtotal resection alone was 25%, compared with 31% for those treated with surgery and radiation therapy to at least 50 Gy. Shimizu and colleagues performed a metaanalysis on reports from the current literature and concluded that postoperative irradiation conferred a 14% improvement in 5-year survival ( $P < .01$ ).<sup>238</sup> The data presented in these studies suggest that more effective therapies are needed to improve the long-term outcome of patients with oligodendrogliomas.

As in the case in low-grade astrocytomas, it is difficult to take a categorical position regarding the role of radiation therapy in the treatment of low-grade oligodendrogliomas.<sup>92</sup> Some small asymptomatic (except for controlled seizures) tumors can be carefully observed, delaying surgical or radiotherapeutic intervention until there is tumor progression or uncontrolled neurologic symptoms. If feasible, large, symptomatic or progressive tumors should be resected. Patients with completely resected or small asymptomatic incompletely resected low-grade oligodendrogliomas can be observed, delaying radiotherapy until the time of recurrence.<sup>92</sup> Because of the poor long-term prognosis associated with some of these tumors and data that suggest that radiotherapy may improve survival, at least up to 5 years, patients with large, symptomatic unresectable or incompletely resected tumors should receive radiation therapy.<sup>92</sup> As in the case of low-grade astrocytomas, proliferation markers such as the MIB-1 labeling index may help to distinguish patients who require aggressive treatment from those who can be observed.

Radiation therapy is given using fields that encompass the tumor volume with a 2-cm margin. A dose of 54 to 60 Gy is used in adults, and the dose is reduced to 50 Gy in children. PCV chemotherapy (see following [Chemotherapy](#) section) may be useful in some patients as initial treatment, as combined therapy or to reduce the size of large tumors before beginning radiotherapy.<sup>245,246</sup> In the latter situation, reducing the volume of brain irradiated may decrease risk of treatment-related adverse effects.

Patients with pure or mixed anaplastic oligodendrogliomas have a poorer outcome than those with low-grade tumors. Winger and colleagues reported median survival times of 1.3 years and 5.3 years, respectively, for patients with mixed anaplastic oligoastrocytomas and pure anaplastic oligodendrogliomas treated with radiotherapy and chemotherapy.<sup>83</sup> Shaw and coworkers found that patients with high-grade mixed oligoastrocytomas and oligodendrogliomas (based on the St. Anne-Mayo system) had similar outcomes with a median survival of 4.5 years, and 5- and 10-year survival rates of 45% and 25%, respectively.<sup>247</sup> Patients with pure and mixed anaplastic oligodendrogliomas receive postoperative irradiation to a dose of 60 Gy in conventional daily fractions of 1.8 to 2.0 Gy using an approach similar to that used for malignant gliomas. Clinical trials are currently testing whether the combination of PCV with radiotherapy improves the outcome of anaplastic lesions.<sup>248</sup> Others are using high-dose chemotherapy with stem cell rescue to defer radiotherapy until there is evidence of tumor progression.

## CHEMOTHERAPY

Prospective clinical chemotherapy trials of oligodendroglioma patients are underway; until they are completed and reported, we have two sources of information: individual patients reported within trials for malignant astrocytomas and some PCV trials that led up to the randomized studies currently in progress. In those reports, chemotherapy was limited to the treatment of recurrent, well-differentiated, and moderately anaplastic oligodendrogliomas and the primary treatment of the highly anaplastic oligodendrogliomas with surgery, radiation therapy, and chemotherapy. Adjuvant chemotherapy following surgery and irradiation yields 58% 5-year survival for oligodendroglioma patients, a 50% 3-year survival for anaplastic oligodendroglioma patients, and an 80% 2-year relapse-free survival for oligoastrocytoma patients.

[Table 43.2-19](#) summarizes the status of PCV chemotherapy for recurrent oligodendroglioma from three contemporary publications. The complete response rate was 19% for a MTP of 31 months, the partial response rate was 45% for a MTP of 14 months, and the stable disease rate was 22% for a MTP of 8 weeks. Thus, the majority (86%) of patients treated with PCV at recurrence are expected to either respond or stabilize for a period in excess of 1 year.

Reference	Complete Response % (MTP, mo)	Partial Response % (MTP, mo)	Stable Disease % (MTP, mo)
466	17 (25)	46 (12)	19 (7)
467	12 (45)	50 (24)	31 (32)
468	33 (25)	40 (16)	20 (7)
Total	18 (31)*	46 (16)*	25 (14)*

\*Weighted mean of three medians.

**TABLE 43.2-19.** Status of Phase II Studies of Lomustine, Procarbazine, and Vincristine for Recurrent Oligodendroglioma and Oligoastrocytoma

For anaplastic oligodendrogliomas, Kyritsis and coworkers found a median 1.3 years relapse-free survival after chemotherapy (mostly PCV therapy).<sup>249</sup> For recurrent oligoastrocytoma, the median relapse-free survival is 1.0 to 1.2 years.<sup>249,250</sup> To test the efficacy of this chemotherapy regimen in newly diagnosed patients, the RTOG is coordinating an intergroup randomized trial that compares neoadjuvant intensive PCV chemotherapy followed by radiation therapy with radiation therapy alone.

## EPENDYMOMA

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Ependymoma tumors arise from cells of ependymal lineage and, therefore, have a propensity for occurring in the obliterated central canal of the spinal cord, the filum terminale, and white matter adjacent to a ventricular surface (usually a highly angulated surface).<sup>28</sup> Sixty percent of intracranial ependymomas are infratentorial, and 40% are supratentorial.<sup>251</sup> Of infratentorial sites, the fourth ventricle is the most common site. Extension into the subarachnoid space occurs in 50% of these cases, and encasement of the medulla and upper cervical cord can occur. Of supratentorial ependymomas, 50% are primarily intraventricular, and the remainder are parenchymal, arising from ependymal rests. Most of the intraventricular tumors arise in the lateral ventricles, and fewer (25%) occur in the third ventricle.

Ependymomas can be classified in various ways. Ependymomas are either differentiated (ependymoma or myxopapillary ependymoma) and, therefore, low-grade or,

less commonly, they are anaplastic and higher grade and more likely to disseminate through the CSF pathways.

Clinical presentations are dependent on the location of tumor. Intraventricular tumors often cause increased intracranial pressure and hydrocephalus. As a result, headache, nausea and vomiting, papilledema, ataxia, and vertigo are found in most patients at presentation. Focal neurologic signs and symptoms are more often seen with extraventricular supratentorial ependymomas.

Either MRI or CT scanning is sufficient to make the anatomic diagnosis before surgery. The presence of calcium in a fourth ventricular tumor is highly suggestive but not diagnostic of an ependymoma. Surgical exploration and biopsy are essential for the selection of appropriate treatment. For anaplastic ependymomas, staging myelography and examination of the CSF for cytologic evidence of malignancy are essential.

The inclusion of ependymoblastomas, which are known for their propensity to disseminate throughout the CNS, tends to overestimate the risk of seeding.<sup>252,253</sup> In a literature review, Vanuystel and Brada found that the overall incidence of spinal seeding was 6.9%.<sup>254</sup> It was 1.6% for supratentorial tumors, 9.7% for infratentorial lesions, 8.4% for high-grade tumors, and 4.5% for low-grade lesions. No patient with high-grade supratentorial lesions developed spinal seeding, whereas 15.7% of those with high-grade infratentorial tumors developed spinal dissemination. For low-grade tumors, 2.7% of patients with supratentorial lesions developed seeding compared with 5.5% for those with infratentorial lesions. The incidence of spinal seeding was related directly to local tumor control, regardless of tumor grade. The incidence of spinal dissemination was 3.3% in locally controlled patients and 9.5% in those with uncontrolled primary lesions ( $P < .05$ ).

## SURGERY

Approximately one-half of hemispheric ependymomas arise from the wall of the lateral ventricle, and one-half appear to be intraparenchymal, arising perhaps from remote fetal ependymal cell rests.<sup>255</sup> Hemispheric ependymomas tend to be cystic and, even when not, are often well circumscribed from surrounding brain, allowing gross total resection. A wide craniotomy permits a transcortical exposure of the tumor through a cortical incision placed to avoid injury to vital brain tissue. The tumor is removed using the operating microscope, and every effort is made to minimize bleeding into the ventricular cavity. At the end of the resection, the ventricular system is gently irrigated free of blood and blood clots to prevent mechanical obstruction to CSF flow, to prevent the blockage of the CSF absorptive bed (arachnoid granulations), and to reduce the irritation of bloody CSF to the brain.

Ependymomas arising from the floor of the fourth ventricle are approached through a wide bilateral suboccipital craniectomy and laminectomy of C-1. The tumor is exposed by retracting the cerebellar tonsils laterally and splitting the inferior aspect of the vermis, although often a tongue of tumor is visible over the dorsal aspect of the medulla and upper cervical spinal cord before the tonsils are retracted. The dorsal convexity of the tumor comes into view as the cerebellar vermis is divided, and its attachment to the floor of the fourth ventricle can then be exposed progressively and evaluated. Firm attachment precludes a complete resection, as does infiltration of the tumor into the cranial nerves of the cerebellopontine angle through the foramen of Luschka. Tumor is removed to the extent possible using illumination and magnification afforded by the operating microscope.

There would appear to be a relation between residual ependymoma left by the surgeon and a poorer outcome after radiation therapy.<sup>256</sup> In ependymomas, as in most of the gliomas, a maximal surgical resection should be carried out when possible.

## RADIATION THERAPY

It is well established that postoperative irradiation improves the survival of patients with intracranial ependymomas, and 5-year survival rates with doses of 45 Gy or more range from 40% to 87%.<sup>45</sup> Tumor grade has been considered to be the most important determinant of tumor behavior and prognosis. The 5-year survival for patients with low-grade tumors ranges from 60% to 80%, whereas for anaplastic ependymomas it is only 10% to 47%.<sup>45</sup> Most series fail to distinguish patients with malignant ependymomas from those with ependymoblastomas that are classified as primitive neuroectodermal tumors and have an especially poor prognosis. Analysis of these data when these lesions are excluded suggested that tumor grade may have less prognostic value.<sup>252</sup>

The amount of normal CNS tissues to include in the treatment volume and the need for prophylactic irradiation to the entire craniospinal axis are major areas of controversy. The differences of opinion are based on the potential for ependymomas to spread into the ventricular system and to disseminate into the spinal subarachnoid space. In their literature review, Vanuystel and Brada found that risk of seeding was independent of whether prophylactic spinal irradiation was given.<sup>254</sup> For high-grade lesions, spinal dissemination occurred in 9.4% of patients receiving craniospinal irradiation and in 6.7% of those treated with local radiation therapy only. Similarly, for low-grade tumors, spinal seeding occurred in 9.3% after craniospinal irradiation, whereas 2.2% developed seeding without prophylactic treatment.

The treatment volumes recommended for low-grade supratentorial ependymomas vary from generous local fields to fields encompassing the whole brain, whereas for low-grade infratentorial tumors they include local fields, the whole brain with cervical spine extension, and the craniospinal axis. Wallner and coworkers reviewed the outcome of 20 patients with supratentorial and infratentorial low-grade ependymomas treated with partial or whole brain irradiation after surgery; only 1 in 16 patients, who was eventually found to have a local recurrence, developed spinal dissemination.<sup>257</sup> The 5- and 10-year survival rates for those who received more than 45 Gy (approximately 50 Gy in most instances) were 67% and 57%, respectively. As nearly all recurrences were limited to the original primary tumor site, it was concluded that treatment of the whole brain was unnecessary. Based on this series and data from others<sup>253,254,258</sup> and the greater precision in determining tumor extent currently available through high-quality diagnostic imaging, low-grade supratentorial ependymomas are treated using partial brain fields with a dose of at least 54 Gy. Spinal MRI and CSF evaluation are not obtained unless there is evidence of ventricular involvement or signs of subarachnoid metastases. Low-grade infratentorial ependymomas are also treated with limited fields. The craniospinal axis is irradiated only if pretreatment CSF cytology studies reveal malignant cells or if radiographic studies show evidence of tumor spread.

Many authors recommend inclusion of the entire craniospinal axis in the treatment of anaplastic ependymomas<sup>257,259,260</sup>; the entire craniospinal axis should be treated, although some recommend whole brain irradiation with an additional boost for high-grade supratentorial lesions located away from the CSF pathways, if there is no evidence of leptomeningeal spread.<sup>253</sup> A dose of 54 Gy is given to the primary tumor site and 36 Gy to the remainder of the axis. If spread within the brain is demonstrated, the entire brain receives 54 Gy. Spinal imaging studies are routinely performed, and any area of gross involvement is boosted to 50 Gy. However, despite the apparent superiority of craniospinal irradiation in some series,<sup>259</sup> local recurrence is the primary pattern of failure with high-grade ependymomas,<sup>253,257,258,261</sup> and subarachnoid seeding is uncommon in the absence of local recurrence.<sup>45</sup> Furthermore, the patterns of failure are similar in patients treated with local fields or with craniospinal axis irradiation,<sup>253,258,260</sup> and prophylactic treatment may not prevent spinal metastases.<sup>253,254</sup> Merchant and colleagues reviewed the outcome of 28 patients with anaplastic ependymomas.<sup>261</sup> Twelve patients received craniospinal irradiation, 2 were treated to the whole brain, and 14 received treatment to limited fields. The actuarial 5- and 10-year survival rates were 56% and 38%, respectively. All 19 patients who failed radiotherapy had relapses at the primary site, and one of these also developed subarachnoid dissemination. A benefit from craniospinal irradiation could not be demonstrated. Based on these data and the findings in other reported series, craniospinal irradiation is generally not recommended for patients with anaplastic (high-grade) ependymomas unless evidence of leptomeningeal spread is pathologically or radiographically documented.<sup>253,258,261</sup> Others, however, suggest that prophylactic craniospinal irradiation be reserved for those with infratentorial high-grade lesions.<sup>258</sup>

Because the inability to eradicate the primary tumor remains the single most important factor leading to treatment failure,<sup>260</sup> clinical trials are examining more aggressive local therapies to improve local tumor control, both in low- and high-grade ependymomas. These include the use of boosts with stereotactic radiotherapy or conformal radiotherapy techniques as well as hyperfractionated dose schedules.<sup>258</sup> There is no evidence thus far that the addition of chemotherapy to radiotherapy improves the outcome.<sup>262</sup>

## CHEMOTHERAPY

Because ependymomas are uncommon tumors and before MRI these tumors were difficult to assess, there are few chemotherapeutic trials. For instance, the only trial for initial treatment of anaplastic ependymomas is one the authors started in 1984. It combined craniospinal axis irradiation with oral hydroxyurea followed by six courses of polydrug chemotherapy TPDCV.<sup>263</sup> Since 1984 17 consecutive children and adults were treated. At publication 11 of 17 patients had failed with an MTP of 141 weeks; the median follow-up for the eight who had not died was 469 weeks, whereas nine patients who died had a median survival of 183 weeks.

[Table 43.2-20](#)<sup>163,264,265,266</sup> and [267](#) summarizes some published and unpublished series of chemotherapy for recurrent differentiated or anaplastic ependymomas. The therapies range from single-agent therapies to the five-drug protocol, TPDCV. The best single agents were BCNU and dibromodulcitol, with combined response plus

stable disease rates of 75% to 78% and MTP of 13 to 16 months.<sup>264</sup> Results are somewhat better than those achieved for anaplastic astrocytomas. With a variety of drug combinations the best response plus stable disease rate was 82% with an MTP of 21 months for TPDCV.

Treatment	No.	Responding and Stable (%)	Median Time to Progression (mo)
Bichloroethylnitrosourea*	14	78	13
Dibromodulcitol <sup>††</sup>	12	75	16
AZQ <sup>‡‡</sup>	12	42	10
Carboplatin <sup>§§</sup>	14	38	14
Cisplatin <sup>¶¶</sup>	8	75	3.8
VCR-CDDP-CCNU-PCB-VP16-IFSO combinations <sup>   </sup>	16	92	9
6TG-PCB-DBD-CCNU-VCR*	11	82	21.6
			16

AZQ, azetidinobenzosquinone; CCNU, lomustine; CDDP, cisplatin; DBD, dibromodulcitol; IFSO, ifosfamide; PCB, procarbazine; 6TG, 6-thioguanine; VCR, vincristine; VP16, etoposide.

TABLE 43.2-20. Chemotherapy for Recurrent Ependymoma and Anaplastic Ependymomas

Goldwein and colleagues retrospectively analyzed 16 recurrent ependymoma patients treated with a variety of agents alone and in combination (VCR, cisplatin, CCNU, procarbazine, VP-16, and ifosfamide).<sup>267</sup> Approximately 20% of patient trials led to a partial response or stable disease (more common 7:1), for an approximate median of 6 to 10 months.

Gaynon and associates of the CCG used carboplatin every 4 weeks and found a response and stable disease rate of 28% (4 in 14) with a duration of 6+, 17+, 12, and 15 months.<sup>266</sup> Those who did not receive prior cisplatin were more likely to respond to carboplatin. Bertolone and coworkers evaluated cisplatin and found 6 of 8 (75%) benefiting, with an MTP of 3.8 months.<sup>163</sup> Ettinger and colleagues, also of the CCG, used diaziquone on a 5-day schedule every 3 weeks in 12 children with recurrent or metastatic disease. One response more than 35 months was reported.<sup>265</sup>

If the 87 patients cited in the studies presented in Table 43.2-20 are weighted for the number of patients in each trial, the mean TTP was 16 months.

## MENINGIOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Meningiomas arise from arachnoidal cells in the meninges, especially in areas of the arachnoid villi. In some series, meningiomas constitute 39% of primary CNS tumors.<sup>24</sup> The most frequent locations of these tumors are along the sagittal sinus and over the cerebral convexity. Table 43.2-21 summarizes the frequency of these tumors according to location.<sup>268</sup> Meningiomas are extraaxial, intracranial (and sometimes spinal) tumors that produce symptoms and signs through compression of adjacent brain tissue and cranial nerves. They often also produce hyperostosis. Table 43.2-22 summarizes the symptoms and signs associated with these tumors.

Site	No.
Parasagittal	65
Convexity	54
Sphenoidal ridge	53
Olfactory groove	29
Suprasellar	28
Posterior fossa	25
Spinal	18
Periorbital	12
Temporal fossa	8

(From ref. 268, with permission.)

TABLE 43.2-21. Sites of Predilections of Meningiomas within the Intracranial Regions

Site	Presentation
Sphenoidal ridge	Nonpulsating, painless unilateral exophthalmos; unilateral vision loss; ophthalmoplegia; ICP
Cerebral convexity	Altered mentation; ICP; seizures
Intraventricular	Hydrocephalus; headache; mental changes; visual field abnormalities
Olfactory groove	Central scotomas; ipsilateral optic atrophy; contralateral papilloedema; ipsilateral loss of smell; altered sensation; facial motor abnormalities
Tuberculum sellae	Loss of vision; bitemporal hemianopsia; papilloedema or optic atrophy
Other basilar sites	See Table 43.2-5
Cerebellar convexity	ICP; cerebellar findings
Cerebellar-pontine angle	Cerebellar findings; hearing loss
Foramen magnum	No findings; spastic paresis and sensory findings in upper extremities

ICP, increased intracranial pressure.

TABLE 43.2-22. Neurologic Findings Associated with Meningiomas as a Function of Their Location

Histologically, most meningiomas are differentiated, with low proliferative capacity and limited invasiveness. Less commonly, meningiomas are more anaplastic with a higher proliferative capacity and are invasive. Even though the difference in the 30-minute bromodeoxyuridine labeling index *in situ* for the differentiated meningiomas may be less than 1% versus 3% to 4% for anaplastic meningiomas,<sup>269</sup> biologically, the anaplastic meningiomas behave considerably differently than the more differentiated meningiomas. MIB-1, an antibody to the Ki-67 protein, has been used as a proliferative marker in meningioma patients and found to correlate closely with the bromodeoxyuridine labeling index.<sup>315</sup>

## SURGERY

The perception that meningiomas are surgically resectable gives these tumors an undeserved reputation of benignity. Although meningiomas usually are well circumscribed and do not invade adjacent brain, they can occur virtually anywhere in the CNS, and access is sometimes only by deep retraction. In addition, these tumors may be extremely vascular and can surround important structures such as cranial nerves and major arteries at the skull base. Such characteristics can preclude a smooth operation, and a total removal is commonly not possible. Simpson reported on a large series of surgically resected meningiomas and documented that even when there was a perceived total resection, the recurrence rate was 9%.<sup>270</sup> A more modern series from Massachusetts General Hospital shows that a *total resection* is followed by 7% recurrence rate at 5 years, 20% at 10 years, and 32% at 15 years.<sup>271</sup>

Since many meningiomas are surgically resectable, the neurosurgeon is usually more favorably disposed toward operating on them than another glioma. The neurosurgeon's zeal must be tempered, however, with an understanding of the risks of removing a meningioma in a particular location and an understanding of the

effect of this meningioma on the well-being of the patient, because these tumors are often exceedingly slow growing and the patients are often elderly. When surgery is undertaken in an elderly patient, partial removal is sometimes adequate.

### **Preoperative Planning**

The preoperative preparation of the patient, surgical planning, and intraoperative anesthetic management are as described in the earlier [Surgery](#) section. However, the planning of surgery for meningiomas must be extremely assiduous, because a detailed knowledge of surgical anatomy is necessary in these tumors. A preoperative angiogram to assess overall tumor vascularity and to identify arterial feeders is often important. In many instances, the angiography procedure is combined with embolization of the tumor's blood supply. The angiogram is done within 24 to 96 hours of the operative procedure, so that alternative vascular routes to the tumor do not have time to develop.

### **Surgical Principles**

Those feeding arteries that could not be occluded by embolization are addressed first at the operation, if they are accessible. These arteries are meningeal and cerebral in origin. The tumor is retracted from surrounding normal brain progressively as the tumor bulk is reduced by the use of the CUSA or, for extremely vascular tumors, the cutting loop of the electrocoagulation unit or the CO<sub>2</sub> laser. Meningiomas at individual sites pose special surgical problems.

At the cerebral convexity, a large bone flap is made around the tumor, a dural incision circumscribes the tumor, and the dura attached to the tumor is used to retract the tumor from the brain as microdissection frees the adhesions between the tumor and surrounding brain.

Parasagittal meningiomas about the midline; difficulties in removal are related to critical draining veins, to involvement of the sagittal sinus with tumor, and to the occasionally massive overlying bony erosion or hyperostosis or both. A patent sagittal sinus cannot be transected for a complete tumor removal except in its anterior one-third, so a careful study of the preoperative arteriogram looking for the patency of the sinus and for the position of the draining veins in the region is critical. Some clinicians advocate opening the sagittal sinus for removal of tumor that has grown through its wall, and others advocate resecting and grafting the involved sagittal sinus wall. In the authors' opinion, these dangerous maneuvers are not usually indicated, because recurrence-free survivals after subtotal resection of these lesions are extended,<sup>271</sup> and because the tumor may grow to occlude the sinus completely, thereby making complete resection possible later with a lesser risk to life.

Falx meningiomas do not involve the sagittal sinus but occupy the falx below the sinus, often becoming bilateral. Major complications of resection of falx meningiomas relate to interruption of draining veins and consequent cerebral edema and venous infarction.

Olfactory groove meningiomas grow extremely large before their neurologic sequelae lead to their discovery. Surgery is carried out through a large frontal bone flap based low on the forehead. The broad sessile base of the tumor is attacked first so that its blood supply can be interrupted. The tumor's bulk is then reduced by internal coring and dissection, with attention to protection of the optic nerves, carotid artery, and anterior cerebral arteries on the tumor's posterior aspect.

Tuberculum sellae meningiomas are smaller at presentation because of their proximity to the optic apparatus. Attention to the safety of the optic apparatus and the anterior cerebral and carotid arteries is equally critical.

The approach to sphenoid ridge meningiomas varies according to whether they occupy the outer, middle, or inner third of the sphenoid bone. Outer third tumors can be a problem purely of tumor mass, purely of massive temporal hypertosis from an plaque tumor invading bone, or a combination of both. When it is present, the tumor mass insinuates itself in the sylvian tissue, and its removal through a frontotemporal craniotomy is complicated by the tumor's adherence (on its medial aspect) to sylvian veins. Surgical cure is not possible. Middle third tumors grow into both the frontal and temporal fossae in a globular fashion. The approach is through a frontotemporal craniotomy, with the base of the tumor approached first to eliminate the blood supply. Surgical cure is likely. Inner third tumors arise from the anterior clinoid process and compress the optic nerve and encase the carotid and middle cerebral arteries. In addition, medial sphenoid ridge meningiomas can grow diffusely into the cavernous sinus and optic canal. Only in those situations in which the tumor presents early because of optic nerve compression is total removal feasible, with the surgeon stopping when the risk of the surgery exceeds potential benefits.

Tentorial meningiomas arise from the broad surface or free edge of the tentorium and are approached under the temporal lobe or under the occipital lobe, depending on their placement. In all instances, the principle of removal is incision of the tentorium around the tumor and gradual bulk reduction and separation of the tumor from surrounding brain. Venous sinuses and critical draining veins, particularly the vein of Labbe, must be protected.

Cerebellopontine angle meningiomas arise from the petrous bone and if small and dorsolaterally situated are exposed through a posterior fossa craniectomy by retracting the cerebellum medially. More ventrally situated tumors arising at the junction of the petrous bone and the clivus or from the clivus itself are exposed through a combined approach above and below the tentorium, which allows a better angle to work medially and more generous exposure with less brain retraction.<sup>272</sup> Posterior fossa meningiomas may engulf critical blood vessels and cranial nerves and may be characterized by extreme adherence to the brain stem, so attempts at complete removal must proceed cautiously. In younger patients, particularly, these tumors should be completely resected during the first attempt if possible as subsequent operations are complicated by scarring, with obliteration of surgical planes and increased adherence to the brain stem.

### **Radiation Therapy**

The need for adjunctive radiation therapy is determined by the extent of surgical resection and the histopathologic features of the tumor (benign vs. malignant). The risk of recurrence for completely resected benign meningiomas is small, and postoperative irradiation is not usually recommended. In contrast, the risk of relapse after subtotal resection ranges from 33% to 60% at 5 years to more than 90% at 15 years.<sup>271,273,274</sup> Several reports provide evidence that postoperative irradiation prolongs the interval to recurrence, prevents tumor regrowth in some patients, and improves the survival of patients with incompletely resected meningiomas. Barbaro and associates compared the outcome of 54 patients who were treated with subtotal resection and radiation therapy with a group of 30 patients who underwent subtotal resection alone.<sup>275</sup> Sixty percent of the nonirradiated patients developed recurrence, whereas 32% of the irradiated patients recurred. The median time to recurrence was 10.4 years for the irradiated patients compared with 5.5 years for the nonirradiated group ( $P < .05$ ). Irradiated patients had a more favorable outcome than nonirradiated patients, despite the fact that they more frequently had tumors located in surgically unfavorable sites. This series was recently updated by Goldsmith and colleagues who reported the results of 140 patients (117 benign and 23 malignant) treated at UCSF with subtotal resection and postoperative irradiation. The median tumor dose was 54 Gy.<sup>276</sup> For patients with benign meningiomas, the 5- and 10-year progression-free survival rates were 89% and 77%, respectively. Patients who received at least 52 Gy had a 20-year progression-free survival of more than 90%. The 5-year progression-free survival of patients treated after 1980 was 98%, compared with 77% of those treated before 1980. This improvement was attributed to the availability of CT scanning and MRI for tumor localization and treatment planning.

A multivariate analysis identified that for benign meningiomas, improved progression-free survival was not related to tumor size but was associated with younger age ( $P = .01$ ) and treatment after 1980 with innovative technologies ( $P = .002$ ).<sup>277</sup> Condra and coworkers found that at 15 years 70% of their patients relapsed after subtotal excision alone, whereas only 13% of those treated with subtotal excision and postoperative irradiation recurred ( $P = .0001$ ). The 15-year cause-specific survival rate was 86% for patients treated with combined therapy compared with 51% for nonirradiated patients ( $P = .0003$ ). For patients undergoing complete resection, 24% relapsed after 15 years, and the 15-year cause-specific survival was 88%.<sup>278</sup> The actuarial 5-, 10-, and 15-year relapse-free survival rates for patients undergoing subtotal resection and irradiation reported by Grahm and colleagues were 78%, 67%, and 56%, respectively.<sup>279</sup> These results and those of Goldsmith and coworkers<sup>276</sup> compare favorably with the relapse-free survival rates of 63%, 45%, and 9% reported by Mirimanoff and associates for incompletely resected, nonirradiated patients.<sup>271</sup>

The size of the residual meningioma affects the outcome of radiotherapy. Connell and colleagues showed that for tumors of 5 cm or larger, the 5-year progression-free survival rate was 40%, significantly less than the 93% observed for smaller tumors.<sup>280</sup> Among patients irradiated for unresectable tumors and in those with residual disease, the volume of visible tumor on imaging studies rarely decreases by more than 15% and often only after many years.<sup>277</sup>

It is controversial whether patients should be treated with radiation therapy after their initial subtotal resection or when signs of disease progression appear. Some clinicians have found that patients with benign meningiomas do equally well with either approach<sup>281</sup>; others suggest that initial postoperative irradiation is preferable,<sup>277</sup> because recurrence has an adverse influence on outcome, and many patients who recur after initial subtotal excision alone may not be salvaged by subsequent treatment.<sup>278</sup> Postoperative irradiation often is deferred in elderly patients and in those in poor medical condition until there is evidence of symptomatic

progression. When a surgical resection is not feasible, radiation therapy may relieve symptoms and substantially decrease the rate of tumor progression. <sup>279</sup>

Malignant meningiomas behave in a more aggressive manner than their benign counterparts. Chan and Thompson found that the median survival of six patients treated with surgery alone was only 7.2 months, compared with 5.1 years for 12 patients treated with surgery and postoperative irradiation. <sup>282</sup> Six of the nine patients with malignant histology reported by Grahm and coworkers died within 5 years. <sup>279</sup> Goldsmith and colleagues reported a 5-year progression-free survival of 48% for 23 patients treated by subtotal resection and irradiation. <sup>277</sup> The recurrence rate among 53 patients with malignant meningiomas collected from six series in the literature was 49%. The recurrence rates were 33% for patients treated with complete resection alone, 12% for those undergoing complete resection and radiation therapy, 55% for patients treated by subtotal resection and irradiation, and 100% for those treated by subtotal resection alone. <sup>273</sup> These data support the recommendation that all patients with atypical and malignant meningiomas should be offered postoperative irradiation, regardless of the extent of resection. <sup>277,283</sup>

For benign meningiomas, the planning target volume consists of the residual tumor with a 1 to 2 cm margin of normal tissue, defined by CT scan or MRI and modified by the neurosurgeon's description of the site of residual disease. Extensive tumors of the base of the skull and malignant meningiomas require more generous margins. The preoperative tumor volume is used for planning completely resected malignant lesions. A dose of 54 Gy in daily fractions of 1.8 to 2.0 Gy is recommended for benign meningiomas, whereas the dose is increased to 60 Gy for atypical and malignant tumors. Complex three-dimensional conformal treatment planning and delivery techniques and intensity modulated radiotherapy are used to restrict the dose to normal tissues.

Radiosurgery is another option for the treatment of meningiomas. Kondziolka and colleagues reported that 93% of their patients treated with radiosurgery and followed for 5 to 10 years required no further therapy for their tumors. <sup>284</sup> Nearly 85% of patients treated by Hakim and coworkers were controlled with a median follow-up time of 22.9 months. <sup>285</sup> Complications, including cranial neuropathies, transient neurologic deficits, radiation necrosis, and malignant edema, have been reported 6% to 42% of radiosurgically treated patients. <sup>286,287</sup> Complications have been observed most frequently in patients with large or deep-seated tumors and those treated with high single doses. <sup>288</sup> These data suggest that treatment with radiosurgery should be limited to small lesions, whereas fractionated radiotherapy may be preferable for other subsets of tumors. Although tumor control rates for small meningiomas appear promising, several more years of patient accrual and follow-up will be required to fully evaluate the efficacy of radiosurgery in comparison with surgery and conventional radiotherapy.

## CHEMOTHERAPY

There is currently no defined role for chemotherapy for newly diagnosed and nonirradiated meningiomas. Chemotherapy has been used for the most intransigent recurrences. For patients with histologically malignant meningiomas or recurrent, surgically inaccessible, more differentiated meningiomas, the situation is only slightly different. Because of the potentially lethal consequences of these two situations, the authors have been treating with aggressive surgery, focal irradiation, and chemotherapy.

The authors have evaluated primarily sarcoma regimens such as the combinations of cyclophosphamide, doxorubicin, and vincristine (VCR) (nine patients); dacarbazine (DTIC) and doxorubicin (five patients); and high-dose ifosfamide with mesna (two patients). Little objective activity was noted for the first, one in five responses in the second, and one in two in the third. Grunberg and colleagues reported on the use of mifepristone, an antiprogestone, in 14 patients with recurrent meningiomas; 5 in 14 showed objective response after 6 to 12 months of daily oral therapy. <sup>289</sup> A randomized trial for incompletely resected meningiomas is active through Southwest Oncology Group to better determine the efficacy of mifepristone (RU-486).

Kaba and colleagues reported on six patients with either a recurrent malignant meningioma or an unresectable meningioma who were treated with interferon- $\alpha$  at a dosage of 4 mU/m<sup>2</sup>/d, 5 days per week. <sup>290</sup> Five of six patients exhibited positive response to treatment with stabilization of the size of the tumor in four patients and slight regression in one for 6 to 14 months. A larger study has been opened at the University of Texas M. D. Anderson Cancer Center.

Lastly, there are preliminary data suggesting that hydroxyurea may provide treatment in patients with unresectable and recurrent meningiomas. <sup>291</sup>

## PRIMITIVE NEUROEPITHELIAL TUMORS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

The treatment of primitive neuroepithelial tumors is controversial and complex. Much of the controversy is based on the failure to understand that there are multiple entities included within this pathologic diagnosis. Controversy surrounds the classification of these tumors. <sup>292</sup> Primitive cells that remain undifferentiated or exhibit varying degrees of neuronal or glial differentiation, or both, are the hallmark of these tumors. Conceptually, these tumors can be viewed as developmentally aberrant brain cells. Therefore, primitive neuroepithelial tumors can be divided into the following classification schema: medulloepithelioma, neuroblastoma, spongioblastoma, ependymblastoma, pineoblastoma, and medulloblastoma. With the exception of medulloblastoma, primitive neuroepithelial tumors are rare.

It has been proposed that all neoplasms showing primitive poorly differentiated neuroepithelial cells be called primitive neuroectodermal tumors, regardless of location or cell type. Because of the infrequency of these tumors and the controversy surrounding an all-inclusive classification schema currently, it is best to refer to each histiotype separately.

Clinically, however, these tumors share some common and disquieting features. Primarily, they are proliferative and malignant tumors that tend to spread throughout the neuraxis like medulloblastoma. As a result, a complete evaluation of the CNS, including contrast-enhanced CT scans of the entire brain, CSF cytology, and metrizamide myelography, must be performed before the initiation of treatment.

## SURGERY

The initial therapy for primitive neuroectodermal tumors is surgical bulk reduction whenever feasible. Surgical principles are the same as those for [cerebral astrocytoma](#) described earlier.

## RADIATION THERAPY

There is general consensus that patients with primitive neuroectodermal tumors should receive postoperative irradiation. Although radiation therapy appears to improve survival time, the outcome is generally poor, and most patients develop local or regional recurrences. Because of their propensity to spread throughout the subarachnoid space, primitive neuroectodermal tumors are treated with craniospinal axis irradiation. The primary tumor is given 54 to 56 Gy and the remainder of the axis receives 36 Gy. The dose is reduced in very young children. Chemotherapy is usually a part of the treatment program. Primitive neuroectodermal tumors are less radiocurable than medulloblastomas. Whereas in some series 1-year survival rates are as low as 10%, <sup>293</sup> others report 5-year survival rates of 20% to 25%. <sup>294</sup> The disparity in outcome data reflects the heterogeneity of malignancies that are classified under the term of primitive neuroectodermal tumors. <sup>295</sup> For example, in a series of 14 patients reported by Gaffney and coworkers the 3-year survival rate was 29%. None of the patients with tumors containing more than 90% undifferentiated elements were alive at 3 years, whereas 60% of those with less primitive tumors survived 3 years. <sup>296</sup> In another study, Mikaeloff and colleagues reported on 30 patients with CNS primitive neuroectodermal tumors other than medulloblastoma treated with gross tumor resection (16 of 30) who were considered good risk who had a 37% 3-year survival. <sup>297</sup> In a more recent series, Paulino and Melian reported a 5-year survival rate of 47% in a small group of patients treated for supratentorial primitive neuroectodermal tumors. <sup>298</sup>

Cerebral neuroblastomas are biologically distinct from other primitive neuroectodermal tumors. They tend to be less malignant, have a better outcome, and are less likely to disseminate throughout the craniospinal axis. <sup>299</sup> These tumors may present as a cystic lesion with a peripheral nodule or as a solid mass, and their morphologic appearance is related to prognosis. Berger and colleagues found that 7 of the 11 patients treated with local irradiation to an average of 52 Gy were alive with no evidence of tumor progression. <sup>300</sup> Of the six patients with cystic tumors, none had recurrent disease, whereas four of the five patients with solid tumors had recurrences. The only patient with a solid lesion who did not have a recurrence received adjuvant chemotherapy. Although subarachnoid dissemination is found in autopsied cases, <sup>301</sup> this pattern of spread does not represent a significant clinical problem. Thus, localized cerebral neuroblastomas are treated with involved field irradiation to 54 Gy. The craniospinal axis is included only if there is evidence of tumor dissemination beyond the site of origin by imaging studies or CSF cytology.

## CHEMOTHERAPY

Because primitive neuroectodermal tumors are an uncommon type of tumor, there are no controlled chemotherapy trials. Reports of isolated cases and small series indicate that drugs active against medulloblastoma have activity in primitive neuroectodermal tumors (see [Medulloblastoma Chemotherapy](#) section, later in this chapter).

## MEDULLOBLASTOMA

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Medulloblastoma appears more similar to the primitive neuroectodermal tumors of childhood than to the gliomas. Although the cell of origin of these tumors is controversial, it is probable that medulloblastoma takes its origin from germinative neuroepithelial cells in the roof of the fourth ventricle.<sup>28</sup> Consistent with its embryonal nature is the fact that the peak incidence occurs in the first decade of life; 50% to 60% of medulloblastomas occur in the first decade, with a peak between 5 and 9 years. A second but lesser peak occurs between 20 and 30 years. The typical location for childhood medulloblastoma is in the cerebellum, mostly in the midline and posterior vermis ([Fig. 43.2-5](#)); many encroach on the cisterna magna and the fourth ventricle. In adolescents and adults, there is an increasing tendency for tumors to be laterally placed in the cerebellar hemispheres. Regardless of where in the cerebellum they occur, the tendency for metastatic spread (within craniospinal intradural axis) of medulloblastoma is relatively high. At presentation, as many as 30% of patients have positive cytology or myelographic evidence of spinal metastasis.<sup>302,303</sup> Extra-CNS metastasis is less common and occurs in fewer than 5% of patients; most metastases are to long bones.<sup>302</sup>

**FIGURE 43.2-5.** This young girl presented with headache and gait ataxia. A T1-weighted sagittal magnetic resonance imaging scan (TR 600, TE 20) demonstrated a large, low-intensity mass involving the inferior aspect of the cerebellum in the midline and extending to and filling the fourth ventricle. There is arcuate stretching and displacement of the medulla and secondary hydrocephalus. The well-circumscribed nature and location of the tumor is fairly characteristic for medulloblastoma.

Based on bromodeoxyuridine 30-minute labeling indices, medulloblastoma would be considered a highly proliferative tumor because its labeling index is approximately 14%, as opposed to gliomas, which range between less than 1% to 10%.<sup>269</sup>

The overall disease-free 5-year survival for medulloblastoma is approximately 50%.<sup>212,302,304,305,306, and 307</sup> However, the extent of disease at initial diagnosis defines risk. When risk factors are considered, survival is altered dramatically. Poor risk is defined as less than a 75% resection (probably greater than 1 cc residual); invasion of the brain stem (less clearly established); metastasis to the spinal cord, cerebrum, and leptomeninges or seeding of the cerebellum; positive CSF cytology 2 weeks after surgery; and age younger than 4 years.<sup>212,304,305</sup> Of the poor risk factors, two need explanation. Resection of less than 75% is an imprecise measure of remaining tumor; CT and MRI measurement of residual tumor volume would be better. However, in most patients, if the surgeon can remove more than 75% of tumor, the resection is usually a gross total resection. Poor risk associated with age 4 years and younger may relate more to the restricted irradiation to the developing CNS and its negative effect on tumor control. Most radiation therapists do not treat with full doses of craniospinal irradiation at 4 years of age.

The disease-free survival of poor-risk patients with craniospinal irradiation with or without chemotherapy is approximately 25% to 30%.<sup>306</sup> Good-risk patients, on the other hand, have 5-year disease-free survivals of 66% to 70%.<sup>307,308</sup>

At relapse, the major site of first recurrence is the posterior fossa in more than 50% of patients, the frontal lobe in nearly 20%, bone in 10% to 15%, and other cerebral and suprasellar regions in 10% to 15%.<sup>302,308</sup>

The incidence of systemic metastasis varies between 10% and 30%,<sup>305,306</sup> although the 10% incidence is most similar to the authors' experience. Most extra-CNS metastases are to long bones and ribs, with lymph nodes being a distant second site. In the series by Park and associates<sup>305</sup> and Lowery and colleagues,<sup>306</sup> the median time to the development of extra-CNS metastasis was 10 to 12 months; in the authors' more recent study, it was 18 months.<sup>309</sup> In the Park study, 17% of ventriculoperitoneal-shunted patients developed systemic metastases, whereas only 4% in unshunted patients did so. In Lowery's series, 30% of patients developed systemic metastases, and none had been shunted previously. These authors' experience is that, except in patients with rampant disease, they did not find an association between ventriculoatrial or ventriculoperitoneal shunting, with or without an in-line filter, and systemic metastases. Bone metastases can occur as the only evidence of recurrence in unshunted patients years after their initial presentation with CNS disease.

## SURGERY

Although hydrocephalus associated with medulloblastoma obstructing the fourth ventricle can be relieved with a preresection CSF shunt, it is more usual to defer shunting and control increased intracranial pressure with corticosteroids. In as many as 60% of patients, aggressive resection of the tumor relieves hydrocephalus. An occipital burr hole is commonly placed at surgery, before the posterior fossa exposure is done, to allow cannulation of the ventricles for drainage of CSF to lower the increased intracranial pressure so that the dura can be opened safely.

Surgery for medulloblastoma is carried out in the prone or the sitting position. The prone position is preferred, especially in children. The incision and bony exposure are usually in the midline, but a paramedian incision and unilateral bony removal are done when the tumor is limited to one hemisphere, particularly in adults. The more commonly used midline craniectomy extends down through the foramen magnum, and a laminectomy of C-1 (and rarely, C-2) is performed to decompress herniated cerebellar tonsils or to remove a caudally extending tongue of tumor over the dorsum of the spinal cord.

After the dura is opened, the cerebellar tonsils are retracted laterally, and it is in the foramen of Magendie that the purplish-gray tumor usually is first seen. The floor of the fourth ventricle is separated from the tumor by a cottonoid pledget. The pledget is advanced to protect the floor of the fourth ventricle as the tumor is resected.

The thinned cerebellar vermis is progressively incised in the midline until the dorsum of the tumor is exposed. The tumor is usually soft and moderately vascular and is readily removed with suction irrigation, the CUSA, or laser, using the operating microscope for magnification and illumination. Clinical studies of cooperative groups show that an aggressive (gross total) removal is associated with an improved prognosis for the patient.<sup>305</sup> Dissection is continued laterally to remove tumor from the cerebellar hemispheres and ventrally to remove tumor from the fourth ventricle. When the obstructive hydrocephalus has been relieved, the CSF can be seen flowing from the aqueduct of Sylvius superiorly. It is rare for medulloblastoma to invade the floor of the fourth ventricle. Closure is carried out in multiple layers, with particular attention to a tight dural closure to decrease the risk for pseudomeningocele (bulging wound) formation and the risk for aseptic meningitis and consequent communicating hydrocephalus from spilled blood products. Postoperative CSF shunting for hydrocephalus remains necessary in approximately 30% to 40% of patients.

## RADIATION THERAPY

Medulloblastomas commonly infiltrate the subarachnoid space and have a striking propensity to spread throughout the CSF. As many as 25% to 30% of patients have clinically unsuspected cytologic and radiographic evidence of CNS dissemination at the time of diagnosis,<sup>303</sup> and for this reason, radiation therapy is directed to the entire craniospinal axis. Doses of 54 to 55 Gy to the primary tumor site and 35 to 36 Gy to the remainder of the craniospinal axis are generally recommended. These doses usually are reduced by approximately 10 Gy for children younger than 2 or 3 years of age. Five-year survival rates in more recent series range from 50% to 65% or higher.<sup>45</sup> The prognosis is affected by local tumor extent, completeness of surgical resection, presence of CSF dissemination, and age at diagnosis.<sup>307</sup> Survival and patterns of relapse in adults with medulloblastoma are similar to those reported for children.<sup>310</sup> Although medulloblastoma is considered to be one of the most radiosensitive tumors of the CNS, local recurrence remains the primary cause of failure.<sup>311,312</sup>

Although modern radiation therapy techniques have greatly improved the prognosis for patients with medulloblastoma, the maximum benefit that can be achieved with conventional radiation therapy has probably been reached. Adjunctive chemotherapy programs are being pursued actively to further improve the outcome. Randomized trials have been conducted by the International Society of Pediatric Oncology<sup>307</sup> and the CCG.<sup>308</sup> Each study compared radiation therapy plus chemotherapy with radiation therapy alone. The International Society of Pediatric Oncology study used a regimen of weekly VCR during radiation therapy followed by eight courses of VCR and CCNU, cycled every 6 weeks. Patients in the CCG study received similar chemotherapy plus prednisone. Neither trial demonstrated an overall improvement in outcome with the addition of chemotherapy. The 5-year disease-free survival rates in the CCG and International Society of Pediatric Oncology studies were 59% and 55%, respectively, for radiation therapy plus chemotherapy, and 50% and 43%, respectively, for radiation therapy alone. Chemotherapy did, however, appear to benefit certain patients with more advanced stages of disease, including those having only partial or subtotal tumor excision, those with brain stem involvement, and those with advanced T (T3 and T4) and M (M1 to M3) stages. Based on these findings, patients with medulloblastoma have been separated into low-stage or good-risk and high-stage or poor-risk subgroups, and different study questions are being examined in each group.

Clinical studies in good-risk patients have been directed at decreasing treatment-related morbidity, including neuropsychological dysfunction, impaired growth of the spine, and hypothalamic-pituitary dysfunction, by reducing the dose of prophylactic irradiation to areas remote from the primary tumor site. A randomized trial conducted by CCG and POG, which compared 23.4 Gy with the standard 36 Gy craniospinal prophylactic dose in good-risk patients, demonstrated an excessive number of overall treatment failures and isolated neuraxis recurrences in the low-dose arm.<sup>313</sup> In a pilot study conducted by the CCG, the survival rates of patients treated with a combination of low-dose craniospinal axis irradiation and chemotherapy in the form of VCR, CCNU, and cisplatin were found to compare favorably with those in studies of full-dose radiotherapy alone or conventional radiation therapy and chemotherapy.<sup>314</sup>

Studies are also being directed at improving local tumor control. Wara and colleagues used a hyperfractionation schedule (1.0 Gy twice a day) to treat the craniospinal axis to 30 Gy and to boost the posterior fossa to 72 Gy.<sup>315</sup> Poor-risk patients also received chemotherapy. An excess of failures occurred outside of the primary site in good-risk patients, and there was no improvement in survival over that observed with conventional regimens in either risk group.<sup>316</sup> Investigators are currently exploring the use of stereotactic radiosurgery and three-dimensional conformal radiotherapy techniques to deliver an incremental increase in dose to the primary tumor site.<sup>312,315</sup>

## CHEMOTHERAPY

Medulloblastomas are responsive to a variety of antineoplastic agents, including VCR, nitrosoureas, procarbazine, dibromodulcitol, cyclophosphamide, methotrexate, platinum compounds, and various drug combinations. Table 43.2-23<sup>128,152,160,167,201,264,266,299,317,318,319,320,321,322,323,324,325,326,327,328,329,330,331,332,333,334,335,336,337</sup> and <sup>338</sup> summarizes some of the single agents and their observed response rates for CNS medulloblastoma when treated at recurrence or for progressive disease. For extra-CNS disease, these same agents have activity, although drugs such as cyclophosphamide, methotrexate, doxorubicin, and VCR may be more active than the nitrosoureas and procarbazine.

Treatment (Reference)	No.	Response Rate* (%)
Doxorubicin <sup>317</sup>	6	0
PCNU <sup>152</sup>	4	0
Etoposide <sup>318</sup>	4	0
AZQ <sup>319</sup>	21	38
Bischloroethylnitrosourea <sup>320,321</sup>	6	33
Cyclophosphamide <sup>322</sup>	34	35

TABLE 43.2-23. Efficacy of Single-Agent Chemotherapy for Recurrent and Progressive Central Nervous System Medulloblastoma

Table 43.2-24<sup>339,340,341,342,343,344,345,346</sup> and <sup>347,406</sup> summarizes some of the drug combinations that have been used for recurrent or progressive CNS medulloblastoma. It is not possible to compare the durability of these responses, because some reports pool the primitive neuroectodermal tumor patients with medulloblastoma, whereas others do not provide individual lengths of response, an MTP, or Kaplan-Meier curves. This is unfortunate, because those studies suggest an MTP range of 10 to 19 months among the better single agent and combination chemotherapy programs.<sup>346</sup> It is clear, however, that better treatments are needed for recurrent and progressive disease. Whether well-founded or not, current emphasis appears to be with drug combinations such as cyclophosphamide, teniposide, and cisplatin or CCNU, VCR, and cisplatin. Whether these approaches provide long-standing benefit or short-term gain awaits more careful adjuvant studies. Problems with drug delivery of these agents to the CNS and inherent drug resistance may compromise long-term benefits and ultimate cure.

Treatment (Reference)	No.	Response Rate* (%)
Vincristine-prednisone-procarbazine <sup>339</sup>	12	25

TABLE 43.2-24. Efficacy of Combination Chemotherapy for Recurrent and Progressive Central Nervous System Medulloblastoma

As adjuvant therapy to surgery and irradiation, chemotherapy has shown inconsistent but sometimes dramatic benefit. Part of the problem resides with an agreement for the definition of good and poor risk and the tendency of some investigators to pool data from medulloblastoma with other primitive neuroectodermal tumors. Another constraint is that patients who receive craniospinal irradiation do not tolerate high-dose aggressive chemotherapy protocols well because of reduced bone marrow reserves. In an attempt to improve the tolerance to cytotoxic agents, these authors and others conducted trials to evaluate reduced craniospinal radiation therapy doses. Packer et al. 1994<sup>348,473</sup> reported a 10-year experience with medulloblastoma treated with craniospinal local-boost radiotherapy and adjuvant

chemotherapy with vincristine weekly during radiotherapy followed by eight 6-week cycles of cisplatin, lomustine, and vincristine. To be eligible, children had to have a subtotal resection, evidence of metastatic disease, brain stem involvement, or all three. Of the 63 eligible patients, 42 had brain stem involvement, 15 had metastatic disease at the time of diagnosis, and 19 had a subtotal resection. Progression-free survival for the entire group at 5 years was 85%. Progression-free survival was not adversely affected by younger age at diagnosis, brain stem involvement, or subtotal resection. Patients with metastatic disease at the time of diagnosis had a 5-year progression-free survival rate of 67%, as compared with 90% for those children with localized disease at the time of diagnosis ( $P = .037$ ).

The authors conducted a nonrandomized trial of preradiation procarbazine and hydroxyurea during reduced craniospinal irradiation.<sup>304</sup> In that study they found that after 2 weeks of oral procarbazine and irradiation with hydroxyurea, reducing the craniospinal radiation dose to 25 Gy to the spinal axis and 25 to 35 Gy to the whole brain was not detrimental with respect to disease-free survival or recurrence patterns in good- and poor-risk patients. When this group was compared with historical controls treated with conventional doses, Halberg and associates<sup>349</sup> found no increase in tumor recurrence in the brain or spinal axis. The 5-year disease-free survival rates for good- and poor-risk patients were 77% and 39%, respectively. In both groups, 70% of recurrences were in the posterior fossa only.

A randomized postoperative trial with postirradiation nitrogen mustard, PCV, procarbazine, and prednisone versus radiation therapy alone for newly diagnosed medulloblastoma found that patients treated with irradiation plus nitrogen mustard, PCV, procarbazine, and prednisone had a statistically significant increase in overall survival rate at 5 years compared with patients treated with radiation therapy alone (74% vs. 56%;  $P = .06$ ).<sup>350</sup>

The authors presented preliminary results of a study that opened in 1984.<sup>232</sup> In that study, they gave combination chemotherapy with TPDCV before and for as many as eight cycles every 6 weeks after radiation therapy in children and adults with high-risk (more than 25% residual tumor, brain stem invasion, positive CSF cytology, positive myelogram) medulloblastoma. Radiation therapy consisted of 54 Gy to the posterior fossa and 24 Gy to the craniospinal axis. Of the 30 patients evaluable (25 children and 5 adults), there were 17 failures, a 5-year disease-free survival of 30%, and an MTP of 4.3 years. Seven pineoblastomas were also treated, with four failures to date, an MTP of 1.6 years, and 38% 5-year disease-free survival.

Hyperfractionated radiation therapy regimens, although potentially less damaging to the CNS, may lead to more bone marrow damage and less tolerance to systemic chemotherapy. One approach that is being evaluated consists of aggressive preradiation therapy chemotherapy. The advantage of this approach is that it unequivocally defines response; the disadvantage is that some drugs may fail to achieve adequate levels in patients with poor risk due to CSF spread of tumor cells.

*Eight-in-1-day* therapy has also been evaluated before radiation therapy.<sup>343</sup> Of 21 eligible medulloblastoma patients who received at least two courses of chemotherapy, 12 (57%) responded (including three complete responses and three partial responses). The MTP for the combined medulloblastoma primitive neuroectodermal tumor group was 2 years.

In another study, Kovnar and associates treated 11 newly diagnosed children with measurable residual disease and characteristics indicative of poor prognosis with preradiation therapy cisplatin and etoposide.<sup>474</sup> There were 2 of 11 complete responses, 8 partial responses, and 1 stable disease determined radiographically in the series.

For extracranial metastases, the best results appear with aggressive combination chemotherapy. In this situation, issues of CNS drug delivery are not important, and many drugs are active. Initially, these authors evaluated the combination of cyclophosphamide, doxorubicin, and VCR; seven patients treated responded for a median duration of 17 months, and two continue at 34 and 62 months without evidence of disease.<sup>308</sup> Other combinations with good activity are cyclophosphamide and VCR<sup>351</sup>; VCR, dactinomycin, and cyclophosphamide<sup>352</sup>; cisplatin, cyclophosphamide, and VP-16; and DTIC and doxorubicin.<sup>181</sup>

## PINEAL REGION TUMORS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

The pineal gland is located in the posterior portion of the third ventricle. Tumors in this region are rare, accounting for fewer than 1% of intracranial tumors, although in children they constitute 3% to 8% of intracranial tumors.<sup>353</sup> The peak incidence of germ cell tumors is the second decade, and few present after the third decade.<sup>354</sup> Table 43.2-25 summarizes the types of tumors found in the pineal region and their tumor markers.<sup>355,356</sup> In all series, germinomas are the most common histology, accounting for 33% to 50% of pineal tumors (the higher frequencies are seen in Japan). Gliomas are the second most common, accounting for approximately 25% of pineal tumors; astrocytomas are the most common of the glial neoplasms arising at this site.

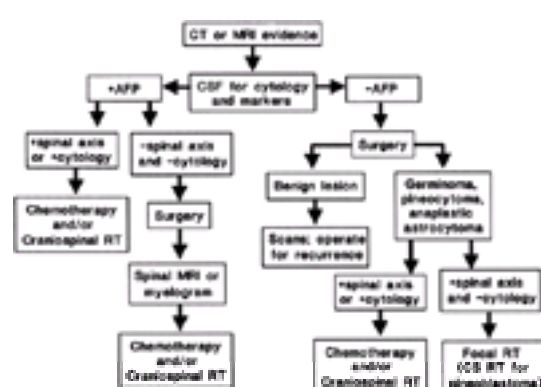

Tumor	$\alpha$ -Fetoprotein	Human Chorionic Gonadotropin $\beta$	Luteal Inhibin/Inhibin	Pineal Inhibin/Inhibin
<b>TUMORS OF GERM CELL ORIGIN</b>				
Germinoma (digital testis, dysgerminoma, seminoma)		+	++	++
Embryonal carcinoma				
Teratocarcinoma				
Embryonal stem tumor (all cell types)	+			
Choriocarcinoma	+++	+++		
Embryonal carcinoma, seminoma, and/or teratocarcinoma (all types) mixture				
Mixed germ cell				
<b>TUMORS OF NON-GERM CELL ORIGIN</b>				
<b>Pinealoma</b>				
<b>Pineocytoma</b>				
<b>TUMORS OF GLIAL AND OTHER CELL ORIGIN</b>				
<b>NON-PLASTIC CELLS UNNAMED</b>				

(Data from refs. 351 and 354.)

**TABLE 43.2-25.** Classification of Pineal Region Tumors and Tumor Markers

Neurologic signs and symptoms are caused by obstructive hydrocephalus and involvement of ocular pathways. Major symptoms are headache, nausea and vomiting, lethargy, and diplopia. Signs are primarily ocular but can include ataxia and hemiparesis. The major ocular manifestation is paralysis of conjugate upward gaze (Parinaud's syndrome), although pupillary and convergence abnormalities are seen, as are skew deviation and papilledema.

Determination of tumor histology, tumor cell markers, and extent of disease is critical for optimal management of pineal region tumors. Figure 43.2-6 is a schema the authors use to evaluate end-stage patients with pineal region tumors.

**FIGURE 43.2-6.** Treatment and evaluation schema for pineal region tumors. AFP, a-fetoprotein; CS, ; CT, computed tomography; MRI, magnetic resonance imaging; RT, radiation therapy. (Modified from Edwards MSB, Huggins RJ, Wilson CB, et al. Pineal region tumors in children. *J Neurosurg* 1988;68:689.)

The prognosis for these tumors varies depending on the histology and size of tumor and the extent of disease at presentation. Typically, patients with mature teratomas do well with surgery alone; germinomas do best with radiation, although preradiation therapy chemotherapy may increase the cure rate and reduce the total radiation dose; gliomas respond to therapy in a manner discussed in earlier sections; and the remaining tumors respond variably to chemotherapy and radiation therapy, leading to survivals ranging from months to years before recurrence.

## SURGERY

Because pineal tumors are near the center of the brain, they are among the most difficult brain tumors to remove, and it is this factor that has created some controversy in their management. However, the application of modern surgical technology, with superb illumination, magnification, surgical guidance, and neuroanesthesia to microsurgical approaches to the pineal region have made this region much more accessible. Surgeons choose from several accepted approaches depending on personal preference and the tumor's position and extent.<sup>357</sup> The current recommendation is to obtain a tissue diagnosis when a diagnosis is not forthcoming from CSF markers, cytology, or both. When possible a gross total resection of the tumor is performed. Resection is particularly important for pineal masses that are relatively radioresistant or that do not require radiation therapy, such as teratomas, arachnoid cysts, and meningiomas.

Many surgical approaches to the pineal region have been described: (1) through the dilated lateral ventricle; (2) through the posterior corpus callosum; (3) under the occipital lobe; and (4) through the posterior fossa over the cerebellum.<sup>358</sup> The most commonly used microsurgical approaches are currently the infratentorial supracerebellar approach described first by Horsley, later by Krause, and resurrected and modernized by Stein, and the supratentorial approach under the occipital lobe described by Poppen and popularized by Clark.<sup>358</sup> Both have been associated with low morbidity and mortality in experienced hands.

The place of image-guided (stereotactic) biopsy in the diagnosis of pineal region tumors is unclear. Although such biopsies have been described as relatively safe, particularly in large tumors, there is a risk that tissue sampling of these heterogenous tumors may not depict accurately the correct histologic nature of the tumor.<sup>359</sup> Without an accurate histologic diagnosis, treatment planning may be erroneous or inadequate. In its favor is the advantage of rapid tissue diagnosis and shortened hospital stay.

## RADIATION THERAPY

With certain exceptions, such as benign teratomas, radiation therapy has an established role in the treatment of pineal and suprasellar tumors of pineal parenchymal or germ cell origin. Because of their location and infiltrative nature, complete surgical extirpation often is not possible. In the past, high mortality and morbidity associated with biopsy or attempted resection, especially with older surgical techniques, often led to the use of radiation therapy without histologic confirmation. In such instances, response to low-dose radiation therapy, measurement of AFP and b-HCG, and CSF cytology were used to provide diagnostic information. There has been a tendency to increase the use of biopsy and attempted resection. Although surgery theoretically might be expected to increase the incidence of CSF seeding, there is no proof that this will occur. A review of older literature suggests that the incidence of spinal seeding increased from 3% for tumors in which biopsy was not obtained to 23% when biopsy was obtained from the tumors.<sup>45</sup> However, Linstadt and associates found no instances of failure in the spinal axis in 13 patients with biopsy-proved germinomas, only one of whom received prophylactic spinal irradiation.<sup>360</sup>

Five-year survival rates with radiation therapy range from 44% to 78% and vary with histology and extent of disease, age, radiation volume, and dose to the primary site.<sup>45</sup> According to a multiinstitutional survey by Wara and coworkers, the survival of patients with pineal parenchymal cell tumors or malignant teratomas was 21% (3 of 14) compared with 72% (26 of 36) for those with germinomas.<sup>361</sup> More recently, Wolden and colleagues reported 5-year disease-free survival rates of 91% for germinomas, 63% for unbiopsied tumors and 60% for nongerminoma germ cell tumors irradiated to doses of 50 to 54 Gy to the local tumor site with or without additional treatment to the whole brain or ventricular system.<sup>362</sup> Patients younger than 25 to 30 years of age have survival rates of 65% to 80% compared with 35% to 40% for older patients.<sup>361,363</sup> This finding may reflect the increased incidence of true germinomas in younger patients.

Germinomas are infiltrative tumors that tend to spread along the ventricular walls or throughout the leptomeninges. The incidence of CSF seeding ranges from 7% to 12%. Because of these features, the use of fields encompassing the entire ventricular system, the whole brain, and even the entire craniospinal axis has been recommended. In a literature review, Salazar and colleagues found a recurrence-free survival rate of 76% for patients with whole brain irradiation compared with 61% for irradiation to the ventricular system and 51% for smaller volumes.<sup>364</sup> Further analysis of those data showed a 90% survival rate for patients treated with whole brain irradiation and a tumor dose of at least 50 Gy. If smaller fields were used or the dose to the primary tumor site was less than 50 Gy, the survival was 33%. With less than whole brain irradiation, recurrences at the margin of the irradiated volume were reported in the older literature. However, the frequency of such recurrences has been reduced with the availability of CT and MRI for treatment planning. Linstadt and associates concluded that the risk for spinal metastases from germinomas was too small to justify routine prophylactic spinal irradiation, but recommended its use when there is tumor spill at surgery or in those patients with malignant CSF cytology or known subependymal or leptomeningeal metastases.<sup>360</sup>

The paradigm described by Edwards and Levin for management of pineal region tumors differs somewhat from the approach just discussed and is outlined in [Figure 43.2-6](#).<sup>365</sup> If hydrocephalus is present, patients are placed on corticosteroids. A shunt is placed only if corticosteroids fail to relieve the symptoms of increased intracranial pressure. An open operation with the goal to resect the tumor is preferred to a stereotactic biopsy. Occasionally, in a patient with widely disseminated disease, a stereotactic biopsy may be indicated. The approach (supratentorial vs. infratentorial) is planned on the basis of the MRI scan. At the time of craniotomy, an external ventricular drain with an intracranial pressure monitor is placed in the lateral ventricle and CSF is removed to lower intracranial pressure and measure CSF tumor markers (b-HCG and AFP). A tumor biopsy is obtained, and, based on the findings at operation and the histologic diagnosis, a decision is reached regarding the aggressiveness of tumor resection.

Additional therapy is planned based on the histology, CSF markers, staging CT and MRI, and myelography; localized germinomas are treated with 20 Gy to the ventricular system and an additional 30 Gy to the tumor with a 1.5- to 2.0-cm margin for a total of 50 Gy.<sup>362</sup> Treatment with neoadjuvant chemotherapy and low-dose (30 to 40 Gy) focal irradiation is being studied in some centers.<sup>366,367</sup> If the germinoma is disseminated or if multiple midline tumors are present, systemic chemotherapy or craniospinal irradiation is administered. Doses of 20 to 35 Gy to the craniospinal axis have been recommended when tumor cells are detected in the CSF.<sup>368</sup> Patients given chemotherapy as their primary treatment but who have an incomplete response or subsequently recur can be successfully treated with radiotherapy.<sup>369</sup>

Nongerminomatous malignant germ cell tumors, whether localized or disseminated, are treated with systemic chemotherapy (for six courses), followed by restaging studies. After restaging, localized tumors receive focal radiation therapy (20 to 24 Gy to the ventricular system with a tumor boost to 54 to 60 Gy), and disseminated tumors receive craniospinal irradiation (54 to 60 Gy to the primary tumor, 45 Gy to the ventricular system, 35 Gy to the spinal cord, and 45 Gy to any localized spinal cord lesions).<sup>362</sup>

Biopsy-verified tumors with little or no tendency to metastasize to the spinal cord, such as teratomas, pineocytomas, and low-grade gliomas, are treated by resection or with local field irradiation.<sup>370</sup> Craniospinal axis irradiation is reserved for tumors that have a strong tendency toward cord involvement (such as pineoblastoma), for those with positive CSF cytology, or for those with radiographic evidence of spinal cord involvement.

## CHEMOTHERAPY

Chemotherapy for glial neoplasms is similar to that covered in earlier sections. The chemotherapy for germ cell tumors is in flux but is encouraging. Adjuvant multidrug therapy with agents such as cisplatin, etoposide, and bleomycin together with high-dose radiotherapy have produced encouraging disease-free and overall survival rates.<sup>371</sup> Finally and coworkers have used high-dose chemotherapy alone (carboplatin, etoposide, and bleomycin) with deferral of radiotherapy.<sup>372</sup> These results also appear promising.

For germinomas, complete responses before radiation therapy or at recurrence have been observed with cisplatin and bleomycin<sup>373</sup>; carboplatin<sup>374</sup>; cyclophosphamide<sup>375,376</sup>; the combination of cyclophosphamide, vinblastine, and bleomycin<sup>375</sup>; the combination of cisplatin and etoposide<sup>377</sup>; and dactinomycin, methotrexate, vinblastine, and cisplatin.<sup>354,365</sup> This has led to attempts to reduce or defer radiotherapy.<sup>378</sup> Following surgical diagnosis of germinoma, two courses of high-dose cyclophosphamide produced complete response in 91%.<sup>375</sup> Because of this, Allen and coworkers reduced the radiation dose and volume. Of the 10 complete response patients treated with reduced radiation, only 10% of patients have failed 5 years later. A comparable approach using carboplatin produced an 88%

response rate and a radiation dose-reduction in five of eight patients.<sup>374</sup> More recently, Bouffet and colleagues reported on a Societe Francaise d'Oncologie Pediatrique study of four courses of alternating etoposide-carboplatin and etoposide-ifosfamide followed by 40 Gy localized radiation therapy for nonmetastatic cases and craniospinal radiation therapy for metastatic cases.<sup>366</sup> Of the 57 patients registered, 47 had biopsy proof of germinoma. Median follow-up was 42 months. The estimated 3-year event-free survival was 96%.

For nongerminoma malignant germ cell tumors (e.g., embryonal, endodermal sinus, and mixed tumors), the benefits of chemotherapy are far less impressive, with partial rather than complete responses and recurrence within months to years being the norm. Chemotherapies with activity include combinations of cyclophosphamide, vinblastine, and bleomycin<sup>375</sup>; cisplatin, VCR, and bleomycin<sup>379</sup>; cisplatin and etoposide<sup>380</sup>; and cisplatin, bleomycin, and teniposide.<sup>381</sup> Occasional patients with recurrent germ cell tumors who have failed the combination of cisplatin, bleomycin, and vinblastine therapies have responded to chemotherapy with TPDCV.

The results with chemotherapy have appeared paradoxical, because patients with systemic seminoma treated with cisplatin, bleomycin, and vinblastine have developed brain metastases while receiving chemotherapy. Using nonseminomatous testicular germ cell lines, Pera and colleagues found that temozolomide was quite cytotoxic and they predict that temozolomide will be active against intracranial metastases from testicular seminomas as well as primary germ cell tumors in the CNS.<sup>382</sup>

Given the rarity of CNS germ cell tumors and the similarity of small trials reported in the literature, it is obvious that cooperative group trials are necessary to determine which of the existing chemotherapy combinations are most active. Second-generation studies could then address modifications based on a reasonable database rather than the few anecdotal studies in the literature. Much study needs to be done to elucidate the best drug combinations and use of chemotherapy in these patients.

## PITUITARY ADENOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Pituitary gland tumors tend to produce neuroendocrine or neurologic symptoms and signs. Anatomically, tumors arising from the pituitary gland can compress the pituitary, grow out of the sella to compress and invade the optic chiasm, and, if growth is unabated, extend into the temporal lobe, third ventricle, and the posterior fossa. The chief finding in most patients is vision loss initially characterized by a bitemporal hemianopia. Headache occurs in approximately 20%. Less frequent are ocular palsies due to compression or invasion of the cavernous sinus.

Neuroendocrine abnormalities can be associated with tumor compression of the pituitary gland or hypersecretion of hormones, or both. [Table 43.2-6](#) summarizes some of the more common syndromes and their endocrine abnormalities. Sexual impotence in men and amenorrhea and galactorrhea in women are commonly associated with hyperprolactinemia. Growth hormone hypersecretion is associated with acromegaly or gigantism, depending on the age of the patient. Corticotropin hypersecretion results in Cushing's disease. Elements of hypothyroidism, adrenal insufficiency, and growth hormone deficiency may follow compression of the pituitary gland by growth of an adenoma.

The diagnosis of a pituitary tumor is based on sensitive radioimmunoassays, CT scans, and, most recently, MRI. [Figure 43.2-3](#) shows an MRI scan of a pituitary adenoma before surgery. Pituitary adenomas are classified as endocrine inactive or endocrine active. Most secrete one or, occasionally, two hormones. The reported incidence of the various types of pituitary adenomas depends on the institution's referral patterns. Of 800 patients operated on at UCSF between 1970 and 1981, 630 of 800 (79%) were endocrine active; of these, 331 of 630 (52%) were prolactin secreting, 27% growth hormone secreting, 20% corticotropin secreting, and only 0.3% were thyroid-stimulating hormone secreting.<sup>383</sup> Undifferentiated cell adenomas are considered to be nononcocytic (null) or oncocytic (oncocyoma) tumors.

Of prognostic importance are the functional status of the tumor and how large or invasive it is. [Table 43.2-6](#) is the grading and staging system used at UCSF.<sup>383</sup>

### SURGERY

The goal of surgery for the larger (usually, but not always, endocrine inactive) pituitary tumors is to decompress the visual pathways and reduce tumor bulk, whereas the goal for hypersecreting adenomas is normalization of the hypersecretion with preservation of remaining normal pituitary function. For larger nonsecreting pituitary adenomas, surgical cure is often not possible or even necessary, because radiation therapy adjuvant to surgery is usually curative. However, radiation therapy is often withheld until regrowth is suspected on postoperative surveillance scans. In contrast, the hypersecreting adenoma should be resected in its entirety, whenever possible, because the effects of hypersecretion can be devastating, and response to radiation therapy is slow and less predictable.

The operative approach of choice for most pituitary tumors is transsphenoidal, because it is safer and better tolerated than the alternative transcranial (frontal craniotomy) approach.<sup>384</sup> The transsphenoidal approach is possible for tumors occupying the sella turcica and even in those with generous suprasellar extension as long as the tumor is soft (the usual case) and can drop into the sella with progressive resection. Tough, woody suprasellar tumors and those with extension laterally into the middle fossa or anteriorly beneath the frontal lobes must be resected by craniotomy.

### RADIATION THERAPY

Microadenomas of the pituitary, usually diagnosed because of endocrine hypersecretion, may be totally resected. There is no indication for radiation therapy, unless there is persistent hormone elevation. Radiation therapy is also indicated for hormone-secreting adenomas that are refractory to pharmacologic management. Macroadenomas, particularly the endocrine inactive lesions, may invade into adjacent structures, such as the cavernous sinus, the optic chiasm, or the third ventricle. Subtotal resection and postoperative irradiation can relieve mass effect, shrink the remaining tumor, prevent regrowth, and lower hormone levels. Further, radiation therapy alone or medical treatment for patients with hormone-secreting tumors are effective alternatives to resection for patients who are medically inoperable or who refuse surgery.

Breen and colleagues found that for irradiated nonfunctioning adenomas the actuarial tumor control rate was 87.5% at 10 years, 77.6% at 20 years, and 64.7% at 30 years. The oncocytic variant of pituitary adenoma appears to be less sensitive to control by radiotherapy than the nononcocytic form of undifferentiated cell adenoma.<sup>385</sup> Sheline demonstrated that patients with large, nonfunctioning adenomas or prolactin-secreting adenomas associated with visual field deficits had a 60% recurrence rate (using visual field changes as an end point) within 5 years after incomplete resection alone.<sup>386</sup> The recurrence rate was reduced to approximately 4% by the addition of radiation therapy, whereas 7% treated with radiation therapy alone recurred. Approximately two-thirds of patients who presented with modest visual field defects, involving not more than one quadrant, who were treated by surgery or radiation therapy alone had return of normal vision in the involved eyes. With larger visual field defects, restoration of vision was better in patients who received preirradiation therapy and surgical decompression than in those treated by radiation therapy alone. Normal vision was achieved by irradiation alone in approximately two-thirds of patients with acromegaly and visual field defects.

Radiation therapy is less effective in controlling endocrine hypersecretion than in controlling the growth of pituitary adenomas. Radiation therapy decreases serum growth hormone concentrations to normal levels (defined as basal growth hormone levels of less than 5 ng/mL and glucose-suppressed growth hormone levels of less than 2 ng/mL) in 80% to 85% of acromegalic patients.<sup>387</sup> Growth hormone levels decrease at a rate of 10% to 30% per year. Thus, several years may be required for the levels to normalize.<sup>387</sup> The probability of normalization is related to the pretreatment growth hormone level. Radiation therapy is most effective in tumors with relatively small preradiation therapy growth hormone elevations (30 to 50 ng/mL), whereas the response is less predictable with higher growth hormone levels.<sup>386</sup> In contrast, serum insulin-like growth factor-1 levels remain elevated after radiotherapy,<sup>388</sup> and long-term treatment with somatostatin or its analogues may be required.<sup>389</sup> Radiation therapy controls hypercortisolism in 50% to 75% of adults and 80% of children with Cushing's disease. Response occurs within 6 to 9 months of treatment.<sup>390</sup>

Data on control of prolactin secretion by conventional radiation therapy are difficult to interpret. When radiation therapy is used as primary treatment or after incomplete surgical resection, the rate of prolactin normalization varies from 30% to 70%.<sup>391,392</sup> The response occurs over several years, and the probability of cure (defined as prolactin less than 25 ng/mL) is inversely related to the baseline prolactin level. In some cases persistent hyperprolactinemia after treatment may be caused by damage to the hypothalamic prolactin inhibitory pathway.<sup>393</sup> Dopamine agonist therapy with agents such as cabergoline is often part of the initial

management of prolactinomas.<sup>394</sup> Radiation therapy in such cases is reserved for patients who fail to respond to this treatment.

Pituitary adenomas may be treated using several different techniques. One approach is to use bilateral coronal arcs with moving wedge filters. The usual treatment plan includes two 110-degree arcs with 30-degree wedge filters. The field size is chosen to include the target volume in the 95% isodose line. The neck is placed in the flexed position so that the plane of rotation is behind the eyes. During simulation, markers are placed on the eyelids. Three tattoo marks are placed on the skin and used for alignment with laser beams to ensure daily positional reproducibility. For large tumors, a three-field technique with lateral opposed wedged portals and a superior or vertex field may be used. Three-dimensional conformal radiotherapy approaches as well as stereotactic radiosurgery and radiotherapy and charged particle beams have also been advocated.<sup>395,396</sup> With conventional radiotherapy techniques, the total dose is carried to 45 Gy in 25 fractions of 1.8 Gy, calculated at the 95% isodose line. This combination of fraction size and total dose controls tumor growth in 90% of cases at 10 years, and, therefore, a larger dose is not indicated.<sup>397,398</sup> and <sup>399</sup> Further, radiation-induced injury to optic apparatus or adjacent brain with this dose-fractionation scheme is rare, whereas larger fractions or greater total doses lead to a higher incidence of injury. The optic chiasm appears especially sensitive to radiation injury in patients with acromegaly.<sup>39</sup> Hypopituitarism, however, may develop as a late complication years after completion of radiation therapy.<sup>397</sup> It is more likely to occur in patients who have had surgery and postoperative radiation therapy than in those who have been treated by radiation therapy or surgery alone.<sup>397</sup> Because hypopituitarism is largely correctable by hormone replacement therapy, patients treated for pituitary adenomas should be observed by an endocrinologist for the remainder of their lives. The risk of developing a radiation-induced brain tumor after treatment is 1.3% to 2.7% at 10 years and 2.7% at 30 years.<sup>385,400</sup>

Reirradiation can be considered for patients with recurrent pituitary adenomas when there has been a long interval after the first course of radiotherapy and when other therapeutic methods have been unsuccessful. Schoenthaler and colleagues reported the outcome of 15 patients who were retreated (median dose, 42 Gy) after a median of 9 years from their initial course of radiation therapy (median dose, 40.8 Gy). With a median follow-up time of 10 years, 80% of patients were locally controlled. Although no visual complications were observed, all patients developed hypopituitarism and two sustained temporal lobe injury.<sup>401</sup>

## CRANIOPHARYNGIOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Craniopharyngiomas occur primarily in children. These tumors arise from cell rests that are remnants of Rathke's pouch at the juncture of the infundibular stalk and the pituitary gland. Most of these tumors become symptomatic only after they have attained a diameter of approximately 3 cm. They are usually cystic at the time of presentation. They may compress the optic chiasm or pituitary gland and extend up into the third ventricle. The cyst is high in proteinaceous material and calcium and is seen easily by CT scan or MRI.

Clinically, craniopharyngiomas produce increased intracranial pressure and hypopituitary-hypothalamic-chiasmal dysfunction. Symptoms vary and, in children, may include obesity, delayed development, decreased vision and optic atrophy, field defects, and papilledema.

### SURGERY

Craniopharyngiomas usually are approached by a microsurgical procedure done through a frontal or frontotemporal craniotomy. Large craniopharyngioma cysts that enter and enlarge the sella turcica can be drained and resected through a transsphenoidal procedure.

The goal of most surgeons in the surgery of craniopharyngioma is total removal, but some do a more conservative operation and depend on the excellent results with radiation therapy. Aggressive removal nearly guarantees some injury to the pituitary stalk, with subsequent temporary or permanent diabetes insipidus and elements of hypopituitarism. Patients injured in this manner must take replacement hormones and use inhaled desmopressin acetate spray for the control of diabetes insipidus for life. However, patients whose vision was affected by the craniopharyngioma can expect improvement after surgery. The mortality of craniopharyngioma resection should be extremely low.

In Europe, a few centers are treating craniopharyngioma cysts with stereotactic puncture and the instillation of colloidal therapeutic radioisotopes, particularly yttrium 90.<sup>402</sup> Such treatments are being tried in this country also with colloidal phosphorus 32.<sup>403</sup> Intracystic therapy may be a good treatment for craniopharyngioma cysts recurring after conventional external beam irradiation.

### RADIATION THERAPY

Although debate exists regarding the extent to which total excision should be attempted, numerous reports demonstrate that local tumor control and survival after subtotal removal, consisting of extensive resection or of limited biopsy and cyst aspiration and irradiation, is comparable with that achieved by radical excision.<sup>404,405</sup> and <sup>406</sup> The local control rates after complete resection, subtotal resection alone, and incomplete resection and postoperative irradiation are 70%, 26%, and 75%, respectively.<sup>406</sup> Ten-year survival rates range from 24% to 100% for complete resection, 31% to 52% for subtotal resection, 62% to 86% for incomplete resection and irradiation,<sup>404,405,407</sup> and 100% after radiotherapy alone.<sup>407</sup> The latter group are comprised of patients with small tumors at presentation. Patients undergoing conservative treatment including biopsy and cyst drainage and irradiation appear to enjoy a better quality of life and demonstrate less psychosocial impairment than those initially treated with more extensive resections.<sup>405</sup> Further, conservative therapy is associated with less hypothalamic and pituitary dysfunction and a lower incidence of persistent diabetes insipidus than when a total or near total excision is attempted.<sup>408</sup> More extensive resections using a subfrontal approach may be associated with frontal lobe and visual perceptual dysfunction.<sup>409</sup>

The radiation therapy target volume is based largely on CT and MRI scanning using relatively small margins around demonstrated tumor. The technique varies according to size and location of residual tumor, but most patients are treated by bicoronal arcs with moving wedge filters, similar to the method used for pituitary adenomas. More sophisticated three-dimensional conformal radiotherapy and intensity-modulated radiotherapy approaches and stereotactic radiotherapy techniques using relocatable immobilization devices may further spare surrounding normal tissues.<sup>407</sup> The use of radiosurgery is limited because of the proximity of most lesions to the optic chiasm and brain stem. The total dose is 50 to 55 Gy, given in daily 1.8-Gy increments. In children younger than 3 years of age, it is recommended that, if possible, irradiation be delayed until the child is older.

## CEREBELLOPONTINE VESTIBULAR SCHWANNOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

The major tumors occurring in this region are the acoustic nerve tumors and meningiomas. Meningiomas have been discussed previously (see [Meningiomas](#), earlier in this chapter); therefore, the discussion that follows is limited to vestibular schwannomas (acoustic neuromas). These tumors originate on cranial nerve VIII, almost always on the vestibular division, at the point where the nerve acquires its reticulin and Schwann cell investment. Within the skull, this transition zone occurs in the internal auditory foramen and causes local erosion of the internal auditory meatus. Slow growth characterizes these tumors; therefore, they can grow to substantial size before clinical symptoms lead to diagnosis. They often occupy the posterior fossa at the angle between the cerebellum and the pons. By compression, they can affect cranial nerves VII, V, and, less often, IX and X, alone or in various combinations. When large enough, they can compress the medulla and obstruct the CSF, leading to hydrocephalus.

Vestibular schwannomas are most common in the fifth decade and can be associated with familial neurofibromatosis. In the latter instance they occur earlier, in late childhood and adolescence, and may be bilateral.

In a series from the Massachusetts General Hospital, auditory and vestibular branch involvement was found to occur in 98% of patients, facial weakness with disturbances of taste in 56%, sensory loss over the face in 56%, gait abnormality in 41%, and appendicular ataxia in 20%.<sup>29</sup> Diagnosis by skull radiographic examination is suggestive, but definitive diagnosis is most effectively made with MRI or CT scan done in conjunction with the CSF administration of metrizamide contrast.

### SURGERY

The aim of surgery for vestibular schwannomas is complete resection, with the surgical approach chosen after consideration of the patient's age, residual hearing, and the size and location of the tumor.<sup>410</sup> When useful hearing is present, the suboccipital approach is taken because of the possibility of hearing preservation postoperatively, particularly in smaller tumors. In patients with poor hearing, the translabyrinthine approach, which produces deafness in the ear operated on, is used for its lower overall morbidity. Occasionally, tumors that reside purely within lateral portions of the internal acoustic canal are approached through the middle cranial fossa.<sup>410</sup>

The translabyrinthine route requires only a small incision behind the ear through which the petrous bone is gradually removed with a high-speed drill until the facial nerve is identified and exposed to the point where it can be separated from the tumor and protected. The dura of the posterior fossa is seen easily and can be opened to gain access to the intradural component of the tumor.

The transoccipital approach requires a unilateral posterior fossa craniectomy, after which the dura is opened and the cerebellum is retracted medially to expose the cerebellopontine angle. The lower cranial nerves are protected while tumor is removed, and the porus acusticus is unroofed in an effort to identify the facial nerve, and in smaller tumors, the acoustic nerve as well. Once the facial nerve is identified, the remainder of the tumor is removed in a usually lengthy and involved operation that fully exploits the surgeon's microsurgical skill.

Complete removal of vestibular schwannomas through the posterior fossa can be predicted in almost every instance, and life-threatening complications are rare except in patients with extremely large tumors. While preservation of the acoustic nerve is uncommon in even small tumors, the facial nerve is in continuity at the end of most acoustic tumor resections. Therefore, any postoperative paresis or paralysis tends to be temporary. When the facial nerve is divided during surgery, it is sutured together when possible, or a nerve graft is placed between the stumps. Facial paralysis with no evidence of recovery within a few months is treated by surgical reinnervation, wherein another cranial nerve, usually the hypoglossal nerve, is joined to the facial nerve peripherally. Bilateral acoustic tumors are seen with neurofibromatosis type 2 and present difficult problems in surgical decision making.<sup>411</sup> In general, a conservative approach is taken, treating the largest tumor when symptoms absolutely require it. Bilateral aggressive tumor resections lead to complete deafness and confer the possibility of bilateral facial nerve paralysis, a cosmetic and functional problem.

## RADIATION THERAPY

There have been few reports on the role of conventional radiation therapy for treatment of acoustic neurilemmomas. A review by Wallner and colleagues disclosed 62 patients who were thought to have had a total resection and did not receive irradiation.<sup>412</sup> The recurrence rate in this group was only 3% (2 of 62). The 15-year actuarial survival and relapse-free survival rates were 98% and 94%, respectively. Thirty patients underwent subtotal resection, defined as removal of less than 90% of the tumor. Six of the 13 (46%) patients with subtotally resected lesions recurred, whereas only 1 of 17 (6%) of those treated with subtotal resection and postoperative irradiation to a dose higher than 45 Gy relapsed. The 15-year relapse-free survival rate for patients treated with subtotal resection and radiation therapy (greater than 45 Gy) was 94% compared with 41% for nonirradiated patients ( $P = .01$ ); the corresponding 15-year survival rates were 100% and 67%, respectively ( $P = .016$ ). There were no recurrences among three patients in whom biopsy was obtained at the time of surgery that was followed by irradiation. On the other hand, four of seven patients who were irradiated for disease progression after having had resection alone subsequently developed a second recurrence. Based on these data, it was concluded that postoperative irradiation should be given after subtotal resection to reduce the risk of local tumor progression. The target volume includes a narrow margin around the residual tumor. Maire and colleagues reported a local control rate of 88% among 24 patients with large tumors, the majority of whom were irradiated without initial surgical resection. Hearing was maintained in three of five patients with bilateral neurilemmomas after contralateral tumor resection. No patient developed facial or trigeminal neuropathy.<sup>413</sup> Treatment is given using a homolateral pair of angled beams with wedge filters in daily increments of 1.8 to 2.0 Gy to a total of 50 to 55 Gy.

Stereotactic radiosurgery and stereotactic radiotherapy have been used as an alternative to surgery in selected patients with small acoustic neurilemmomas. In a long-term follow-up study Kondziolka and colleagues reported that 98% of 162 patients treated to a median dose of 16 Gy were controlled.<sup>414</sup> Only four patients required subsequent surgical treatment. Normal facial function was preserved in 79% of patients after 5 years, and normal trigeminal function was preserved in 73%. Patients may develop new incomplete trigeminal and facial cranial neuropathies within a median of 6 to 7 months after radiosurgery. These tend to be mild and usually improve within 8 to 13 months of onset. Approximately, 45% to 50% of patients with useful hearing before radiosurgery maintain their pretreatment hearing level, whereas patients with hearing deficits before treatment generally do not improve after radiosurgery.<sup>393,414,415</sup> The risk of treatment-induced cranial neuropathy is directly related to the volume of the lesion, the dose administered, and the length of nerve irradiated.<sup>416</sup> Efforts are being directed at decreasing the complication rates while maintaining the high control rates with more sophisticated planning and treatment techniques and reducing dose levels.<sup>417</sup>

## GLOMUS JUGULARE TUMORS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Glomus jugulare tumors arise from glomus tissue in the adventitia of the jugular bulb (glomus jugulare) or along Jacobson's nerve in the temporal bone, sometimes multifocally. The tumor invades temporal bone diffusely, but growth is characteristically slow. Sometimes they are endocrine active, with a carcinoid or pheochromocytoma-like syndrome.<sup>418</sup> Because glomus jugulare tumors occur in the jugular foramen, they commonly cause lower cranial nerve palsies and early symptoms of hoarseness and difficulty swallowing. Later, facial weakness, hearing loss, and atrophy of the tongue become prominent. Pulsating tinnitus also may be a presenting symptom, and a pulsating mass can sometimes be seen behind the eardrum. A presumptive radiologic diagnosis of glomus tumor can be made by CT or MRI scanning, with jugular neurilemmoma being the main differential diagnosis. Because glomus tumors incite a tremendous blood supply, particularly by way of the ascending pharyngeal artery, cerebral angiography provides the definitive diagnosis. Because preoperative tumor embolization is essential to surgical removal of glomus tumors, the diagnostic angiogram should be performed just before surgery when possible.

Histopathologically, numerous vascular channels are distinctive. The background is composed of clear cells clumped in a fibrous matrix. A small percentage of glomus tumors are malignant.

### SURGERY

The treatment of glomus jugulare tumors is controversial, with advocates for radiation,<sup>419</sup> surgery, and the combination.<sup>420</sup> Most clinicians would agree that a resection should be attempted and that in most instances gross surgical resection, if not a cure, is a realistic goal. Surgery on glomus tumors is most often performed by a neurosurgeon and a head and neck surgeon together after preoperative embolization. The base of the skull in the region of the jugular foramen is first exposed, and neurovascular structures are identified and mobilized through a high transverse cervical incision. When the incision is extended behind the pinna and a mastoidectomy is completed, the facial nerve can be protected, and the entire tumor bulb, jugular bulb, and internal jugular vein can be seen passing through the base of the skull. Finally, after a suboccipital craniectomy, the sigmoid sinus above and the jugular vein below can be ligated, and the segment between them excised with the attached tumor. Complications of this procedure include CSF leak and cranial nerve (particularly facial) palsy.

### RADIATION THERAPY

Even though glomus tumors are histologically benign, radiation therapy is effective and has been recommended for symptomatic lesions that cannot be totally resected or as primary treatment.<sup>421,422</sup> These tumors regress slowly after irradiation, and the success of radiation therapy is measured by the amelioration of symptoms and the absence of disease progression. In their review of the literature, Springate and Weichselbaum found a 94% local control rate for temporal bone glomus tumors treated with radiotherapy alone and a 91% local control rate for glomus tympanicum and jugulare tumors treated with radiotherapy alone or with preoperative or postoperative irradiation.<sup>421</sup> The dose required for control is relatively modest. Kim and associates reported a series of 40 patients with such lesions and added a literature survey.<sup>423</sup> The control rate with subtotal resection and postoperative irradiation was 85%. When radiation therapy only was used for inoperable or recurrent tumors, control was achieved in 88%. Their composite data, including cases from the literature, showed a 25% recurrence rate for doses lower than 40 Gy, whereas only 1.4% recurred with doses of 40 Gy or higher.

Based on these data, a dose of 45 Gy in 5 weeks is recommended. Although a dose of 50 Gy has been advocated for more advanced tumors, there is no evidence that such lesions require higher doses.<sup>422</sup> Treatment is usually delivered through a homolateral pair of angled, wedged portals, depending on the precise location of

the lesion. More sophisticated three-dimensional conformal techniques may be used to reduce the dose to surrounding normal tissue structures.

## CHORDOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Chordomas occur along the pathway of the primitive notochord, which extends, in human embryos, from the tip of the dorsum sellae to the coccyx. Chordomas are extradural, multilobulated tumors, varying in consistency from extremely soft to woody and cartilaginous. They are pseudoencapsulated and may invade through the basal dura.

The typical chordoma is composed of cord-like rows of distended, vacuolated (physaliferous) cells. A variant, the chondroid chordoma, has distinctly chondroid elements and may be less aggressive.<sup>424</sup> None of the histopathologic characteristics of tumor aggressiveness (cellularity, pleomorphism, and mitoses) seems to be predictive in chordoma.

The diagnosis of clivus chordomas cannot be made without radiologic tests and often is delayed because symptoms are nonspecific and vague. At onset there is usually headache and intermittent diplopia. These vague symptoms often are not reported, allowing the tumor to grow to an enormous size before the diagnosis is made. Gradually, headache (upper clivus tumors) and neck pain (lower clivus tumors) worsen. Superiorly placed tumors proceed to cause diplopia and facial numbness as the cavernous sinus and Meckel's cave are invaded. Lower clivus tumors compress the lower cranial nerves and later the brain stem.

The differential diagnosis of cranial chordoma includes basal meningioma, neurilemmoma (schwannoma), nasopharyngeal carcinoma, pituitary adenoma, and craniopharyngioma. MRI scanning usually results in a working diagnosis of chordoma, but surgical biopsy (and resection) is mandatory.

### SURGERY

Surgery for cranial chordomas is obligatory to obtain diagnostic tissue, to enhance the effectiveness of subsequent radiation therapy, and to improve the patient's clinical condition. With an aggressive surgical resection, a favorable effect on the severe headaches and neurologic deficits associated with chordomas can be anticipated.

Intracranial chordomas occur at the base of the skull, a region relatively remote from surgical access. Consequently, a variety of innovative approaches have been developed by neurosurgeons and head and neck surgeons, and these procedures are commonly done with both types of specialist in attendance.

For midline lesions of the upper clivus that extend into the sella or sphenoid sinus, or both, a transseptal, transsphenoidal approach (as for pituitary tumors) is best. Large, compressive, transdural extensions of these upper clivus tumors into the interpeduncular cistern must be removed through a transcranial, subtemporal, intradural approach. For the more lateralized upper clival tumor and some lateralized midclival tumors, an approach through a sphenoidectomy (to which may be added a maxillectomy) is useful. For midline tumors of the midclivus and lower clivus, a transoral resection is commonly used. A combination of exposures sometimes is necessary for extremely large tumors.

A potentially serious complication of the transsphenoidal, transsphenoid, and transoral approaches is CSF leakage and consequent meningitis. Therefore, every attempt must be made to keep the dura intact during these procedures. Because dural invasion by cranial chordomas may occur 50% of the time, inadvertent entry of the dura during tumor resection is sometimes unavoidable. Careful intraoperative patching of the leak with fat and muscle grafts followed by postoperative spinal CSF drainage is essential.

Cranial chordomas often recur after surgery and radiation therapy. In this situation, reoperation directed toward symptomatic improvement is the only treatment option. Reoperations are complicated by surgical scarring and tissue compromise from irradiation.

### RADIATION THERAPY

Chordomas and low-grade chondrosarcomas of the base of skull, clivus, and axial skeleton are not amenable to complete surgical resection. With conventional megavoltage irradiation (median dose of 50 Gy), the local control rate for these lesions is only 27%.<sup>425</sup> Although higher doses appear to improve the local control rate, the proximity of dose-limiting critical structures, such as the optic nerves, chiasm, other cranial nerves, brain stem, temporal lobes, and spinal cord, limit the dose that can be delivered safely to these lesions. Charged particle beams such as protons and helium ions, which feature sharp lateral beam edges and a finite range in tissue, may be used to deliver higher doses than are possible with conventional photon irradiation while keeping the dose to neighboring critical structures at a safe level. The depth of penetration can be tailored to the clinical situation by varying the energy of the beam or by interposing bolus material in the beam path. Charged particle beams can be made to stop in front of a critical structure, such as the spinal cord, and in combination with other lateral or oblique beams, a target volume may be *wrapped* around a critical structure. Precise tumor and normal tissue identification and beam delivery techniques, highly reproducible patient positioning, and accurate compensation for tissue inhomogeneities in the beam path are required.

Available data suggest that the higher doses that are achievable with charged particle irradiation result in higher local control rates than have been observed with conventional radiation therapy techniques. Munzenrider and coworkers reported the outcome of 132 patients with nonchondroid and chondroid skull base chordomas treated postoperatively at the Harvard Cyclotron Laboratory at Massachusetts General Hospital with a 160-MeV proton beam. Patients received a median dose of 69 cobalt Gy equivalent (CGE; the dose in proton Gy multiplied by 1.1, the relative biologic effectiveness for protons compared with cobalt 60), with a range of 36 to 79 CGE, and 95% received 67 CGE (70% to 100% of dose given with proton beam). Follow-up ranged from 2 to 158 months (median, 46 months). Local control was achieved in 70% of patients (93 of 132). Local control was more common in men than women (77% vs. 40%) and more frequent in those with chondroid chordomas than in nonchondroid tumors (83% vs. 66%). The 5-year actuarial local control and disease-specific survival rates were 59% and 80%, respectively.<sup>426</sup> Treatment was complicated by functional and anatomic abnormalities in the brain and brain stem, visual and auditory deficits, and pituitary insufficiency requiring hormone replacement. Skull base chondrosarcomas treated with proton therapy have a better prognosis than chordomas. Rosenberg and colleagues reported a 5- and 10-year local control rate of 99% and 98%, respectively, whereas the disease-specific survival rates at 5 and 10 years were both 99%.<sup>427</sup>

Berson and colleagues reviewed the results of 45 patients with chordomas and chondrosarcomas of the base of skull and cervical spine treated at the University of California Lawrence Berkeley Laboratory with helium ion or neon beams.<sup>428</sup> Total doses ranged from 59.4 to 80.0 Gy equivalent (the physical dose multiplied by the relative biologic effectiveness; 1.2 to 1.3 for helium and 2.0 to 3.3 for neon). After initial subtotal resection, 23 patients were treated with charged particles alone, and 13 were treated with photons and particles combined. Nine patients were treated for recurrent disease. Similar to the findings of Munzenrider and coworkers,<sup>426</sup> the 5-year actuarial local control and survival rates were 59% and 62%, respectively. The 2-year actuarial local control rate for patients treated at initial diagnosis was 78% compared with 33% for those with recurrent tumors ( $P < .01$ ). The 2-year local control rate for tumor volumes of less than 20 mL was 80%, whereas it was 33% for larger lesions ( $P < .05$ ). Complications included unilateral or bilateral blindness in five patients, and four patients developed brain stem injury.

## HEMANGIOBLASTOMAS AND HEMANGIOMAS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Hemangioblastoma accounts for approximately 2% of intracranial tumors, arising most often in the cerebellar hemispheres and vermis. Usually solitary, these tumors can be multiple and may also occur in the brain stem, spinal cord, and supratentorial compartment. Cerebellar hemangioblastoma can be sporadic or occur as a familial disorder as part of the von Hippel-Lindau complex that is transmitted as an autosomal dominant disorder with varying degrees of penetrance. Other entities associated with familial hemangioblastoma are hypernephroma, polycystic kidneys, pancreatic cysts, pheochromocytoma, and erythrocytosis.

Cerebellar hemangioblastomas usually are recognized in the third decade, causing symptoms of increased intracranial pressure and symptoms and signs of cerebellar dysfunction. Gait disturbance and imbalance are particularly common. Clinical progression is slow because these tumors enlarge extremely slowly.

The hemangioblastoma probably arises during embryonic life from primitive endothelial cells around the fourth ventricle. The tumor is composed of numerous capillary and sinusoidal channels lined with endothelial cells. Interspersed are nests of lipid-laden pseudoxanthoma cells. The tumor is usually cystic and contains

proteinaceous, xanthochromic fluid. The cyst contains a red (vascular) firm mural nodule, the apparent source of the fluid. The cyst wall is a glial nonneoplastic reaction to the secreted fluid. Occasional hemangioblastomas (brain stem and spinal cord, particularly) are without cysts.

## **SURGERY**

In most instances, the diagnosis can be made by CT scan or MRI. Angiography, to confirm the diagnosis and map the tumor's blood supply, is usually done before surgery. Cerebellar hemangioblastoma tumors are readily approached and excised, with the cyst drained and the entire solid portion carefully dissected and removed. Solid hemangioblastomas of the brain stem are exceedingly vascular, and their removal is associated with high mortality. Such tumors are sometimes irradiated with or without a confirmatory biopsy.

## **RADIATION THERAPY**

Radiation therapy is recommended for patients with unresectable, incompletely excised, and recurrent hemangioblastomas and for those patients who are medically inoperable. Smalley and associates reported the outcome of 25 patients treated with radiation therapy for hemangioblastoma.<sup>429</sup> Nineteen patients had gross residual disease after initial surgery or recurrent tumors, whereas six had only microscopic disease. The overall 5-, 10-, and 15-year survival rates were 85%, 58%, and 58%, respectively, and the recurrence-free survival rates were 76%, 52%, and 42%, respectively. Eight of the 19 patients with gross disease were locally controlled. In-field disease control rates were significantly higher in patients who received at least 50 Gy ( $P = .06$ ) than in those who received lower doses. Five of the six patients treated for microscopic disease had the disease controlled. Based on these data, doses of at least 50 to 55 Gy in 5.5 to 6.0 weeks appear to be warranted.

Radiosurgery has also been applied to the treatment of hemangioblastomas. Patrice and colleagues summarized the outcome of 38 lesions in 22 patients (eight patients with multifocal tumors) who received radiosurgery as definitive treatment or in relapsed patients after surgery or surgery and conventional radiotherapy. The median tumor volume was 0.97 cc (range, 0.05 to 12.0 cc), and the median dose was 15.4 Gy (range, 12 to 20 Gy). With a median follow-up time of 24.5 months (range, 6 to 77 months), 31 of 36 evaluable tumors (86%), including all tumors treated definitively with radiosurgery, remained locally controlled. All five lesions that relapsed after radiosurgery were among the tumors that were treated for recurrence after initial surgery. Better control rates were associated with higher doses and smaller tumor volumes. The 3-year actuarial progression-free survival rate was 86%, and the 2-year actuarial survival rate was 88%.<sup>430</sup> Among 29 hemangioblastomas treated by Chang and coworkers, only one (3%) progressed. Five tumors (17%) regressed completely, 16 (55%) partially regressed, and 7 (24%) remained unchanged in size.<sup>431</sup> Radiosurgery should be considered for surgically unresectable hemangioblastomas, as adjuvant treatment for incompletely excised tumors, as definitive treatment of multifocal disease, and for salvage therapy for discrete recurrences after surgical relapse.<sup>430,431</sup>

## **CHOROID PLEXUS PAPILLOMA AND CARCINOMA**

### **CLINICAL AND PATHOLOGIC CONSIDERATIONS**

Choroid plexus papilloma and carcinoma are rare tumors that occur most often in children younger than 12 years of age, although they can occur at any age. Nearly one-half of these tumors are found in patients younger than 20 years of age. The tumor is an irregularly lobulated reddish mass, which on histopathologic examination is apparently normal choroid plexus. Rarely, these tumors show malignant features and are then classified as choroid plexus carcinoma.

In children, choroid plexus papillomas most often occur in the lateral ventricles. In adults, the fourth ventricular papilloma is most common. Third ventricle tumors are exceedingly rare. Because papillomas tend to grow slowly within ventricles, they expand to fill the ventricle and block CSF flow. In addition, papillomas are thought to secrete CSF. Choroid plexus papillomas (and carcinomas) can produce hydrocephalus secondary to obstruction of the CSF; by CSF overproduction by the tumor; or by damage to the CSF resorptive bed from recurrent hemorrhages. As a result, increased intracranial pressure without focal findings is the most common presentation; fourth ventricular tumors can also be associated with focal findings of ataxia and nystagmus.

Although choroid plexus papillomas and carcinomas extensively seed throughout the ventricular and subarachnoid spaces, seeding from papillomas is usually subclinical, whereas that from carcinomas is frequent and dramatically symptomatic. These tumors are seen easily by CT scan and MRI. For patients with anaplastic changes, the authors advocate staging by myelography and examination of the CSF.

Therapy for anaplastic tumors should be approached in a manner similar to medulloblastoma and malignant ependymomas. Because of the aggressive nature of the more anaplastic tumors, therapy must be equally aggressive, requiring radiation therapy and, in some instances, intraventricular chemotherapy.

## **SURGERY**

The treatment of choroid plexus papillomas is total surgical excision. Choroid plexus tumors of the lateral ventricle are approached through a high parietal cortical incision and transcortical approach to the ventricular trigone. The predilection of these tumors for the left (often dominant) side makes this approach worrisome. Hydrocephalus is the rule and simplifies the exposure when retraction into the ventricle is established. Tumor arteries and veins are identified by use of the operating microscope and then coagulated, after which smaller tumors are removed intact and larger tumors are removed piecemeal. In one-half of the patients, hydrocephalus is relieved by tumor resection, but persistent hydrocephalus requires shunting.

Choroid plexus papillomas of the third ventricle are exceedingly rare but can be approached through various surgical exposures of the third ventricle. The problems of removal of fourth ventricular choroid plexus tumors are similar to those associated with suboccipital removal of [medulloblastomas](#) or ependymomas, as discussed in surgery sections for those tumors.

## **RADIATION THERAPY**

Because choroid plexus papillomas are often cured by complete surgical resection, there is little information regarding their response to radiation.<sup>299</sup> The studies that are available do not provide sufficient detail to allow an assessment of the value of radiotherapy for these tumors. Pathology specimens from patients who received low-dose preoperative radiation therapy (approximately 30 Gy) demonstrated a marked reduction in tumor size, obliteration of the capillary bed, and necrosis, although at this dose level there was little change in the neoplastic choroidal cells. Naguib and coworkers reported a case of an inoperable choroid plexus papilloma with extensive involvement of the mastoid bone.<sup>432</sup> This patient received 49.5 Gy in 32 treatments during a 33-day period. Serial CT scans showed that 16 months after completion of the radiation therapy, the mass was markedly reduced in size. Such anecdotal reports suggest that it is reasonable to offer local radiation therapy to patients with inoperable or recurrent choroid plexus papillomas.<sup>299</sup>

Radiation therapy may be beneficial in patients with choroid plexus carcinomas even after gross total resection.<sup>433,434</sup> Because ventricular and subarachnoid tumor seeding may occur in up to 44% of cases,<sup>435</sup> consideration must be given to treating the entire craniospinal axis. However, data to support this approach are unavailable. Chow and colleagues recommend that patients with completely excised localized choroid plexus carcinomas be treated with either chemotherapy or limited field irradiation if their spinal MRI and CSF cytology study results are negative. They advise both chemotherapy and craniospinal axis irradiation for those with incompletely excised tumors or evidence of leptomeningeal spread.<sup>434</sup> Infants and young children may be successfully treated initially with postoperative chemotherapy and delayed radiation.<sup>436</sup>

## **CHEMOTHERAPY**

Usually, chemotherapy is not used for choroid plexus papillomas. For the more anaplastic tumors, however, the authors have increasingly used chemotherapy adjuvant to surgery and irradiation to prevent the inevitable recurrence and CSF dissemination common to the choroid plexus carcinomas. As with many of the less common tumors discussed, there are no chemotherapeutic guidelines and few reports to guide the therapist.

Initially, the authors used chemotherapy only for recurrent disease. They have used combinations of cyclophosphamide, doxorubicin, and VCR and nitrosourea-based combinations. They have seen transient responses and disease control with both. They have also used intraventricular chemotherapy with low-dose methotrexate (2 to 3 mg/d for 5 days) or cytosine arabinoside (30 mg/d for 3 days), or both, to stave subarachnoid spread. As a result of this experience, the authors currently advocate the use of adjuvant chemotherapy with a nitrosourea-based combination after irradiation and the use of concomitant intraventricular chemotherapy. During

irradiation, they have used intraventricular cytosine arabinoside and methotrexate after irradiation. Further study and additional approaches should be considered.

## SPINAL AXIS TUMORS

### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Some of the clinical features of spinal axis tumor localization and diagnosis have been discussed previously. Most primary spinal axis tumors produce symptoms and signs as a result of spinal cord and nerve root compression rather than because of parenchymal invasion.

The reported frequency of primary spinal cord tumors is between 10% and 19% of all primary CNS tumors.<sup>437</sup> Although most spinal axis tumors are extradural, most primary spinal axis tumors are intradural. Of intradural tumors, the intradural extramedullary neurilemmomas and meningiomas are the most common (see [Table 43.2-3](#)). Neurilemmomas and meningiomas are normally intradural, but occasionally they may present as extradural tumors. Other intradural extramedullary tumors are vascular tumors, chordomas, and epidermoids.

Intramedullary tumors have the same cellular origins as the other CNS tumors discussed previously. In terms of frequency, ependymomas occur in approximately 40% of patients with intramedullary tumors; next most common are the astrocytomas of low- and mid-anaplasia. These are followed in frequency by less common histologies such as oligodendroglioma, ganglioglioma, medulloblastoma, and various hemangiomas and hemangioblastomas.

[Table 43.2-26](#) classifies spinal axis tumors by location. Although different tumor types exhibit a predilection for certain spinal regions, taken altogether, spinal tumors are distributed almost evenly along the spinal axis. Approximately 50% of spinal tumors involve the thoracic spinal canal, 30% involve the lumbosacral spine, and the remainder involve the cervical spine, including the foramen magnum. Some tumors, such as the neurilemmomas, occur with greatest frequency in the thoracic region, although they can be found throughout the spine and often extend through an intervertebral foramen to acquire a dumbbell configuration.

Location	Usual Tumor Histologies
Extradural	Metastatic (carcinoma, lymphoma, melanoma, sarcoma), chordoma
Intradural	
Extramedullary	Schwannoma,* meningioma <sup>a</sup>
Intramedullary	Astrocytoma, ependymoma <sup>b</sup>

<sup>a</sup>May extend along nerve root into extradural and extraspinal spaces.  
<sup>b</sup>Ependymomas originating from the filum terminale and involving the cauda equina, not intramedullary in the strictest sense, are included here by custom.

**TABLE 43.2-26.** Classification of Spinal Tumors by Their Location in Relation to the Spinal Cord and Dura Mater

Meningiomas are dural based and arise preferentially at the foramen magnum and in the thoracic spine. Astrocytomas are distributed throughout the spinal cord, and most ependymomas involve the conus medullaris and the cauda equina. Spinal chordomas are characteristically sacral.

Clinically, patients with spinal axis tumors present with a sensorimotor spinal tract syndrome, a painful radicular spinal cord syndrome, or a central syringomyelic syndrome. In the sensorimotor presentation, symptoms and signs are in response to compression of the spinal cord. The onset is gradual over weeks to months, initial presentation is asymmetric, and motor weakness predominates. The level of impairment determines the muscle groups involved. Because of external compression, dorsal column involvement occurs with paresthesia and abnormalities of pain and temperature on the side contralateral to the motor weakness.

Radicular spinal cord syndromes occur because of external compression and infiltration of spinal cord roots. The main symptom is sharp, knife-like pain in the distribution of a sensory nerve root. The intense pain is often of short duration, with pain that is more aching in nature persisting for longer periods. The pain typically is exacerbated by coughing and sneezing or other maneuvers that increase intracranial pressure. Local paresthesia and impairment of sensations of pain and touch are common, as are weakness and muscle wasting. These findings commonly antedate cord compression by months.

Spinal tumors, particularly intramedullary tumors, can produce syringomyelic dysfunction by destruction and cavitation within the central gray matter of the cord. This produces lower motor neuron destruction and attendant segmental muscle weakness, wasting, and loss of reflexes. There is also a dissociated sensory loss of pain and temperature sensation with preservation of touch. With extension of the lesion, however, touch, vibration, and position sense are affected.

Finally, many patients with spinal axis tumors or supratentorial tumors that show a tendency toward drop metastases tend to lead to leptomeningeal neoplasia. Choucair and colleagues found that 1.2% of glioblastomas and 1.5% of anaplastic gliomas had metastatic spread of their supratentorial tumors to the spinal cord at some time during the course of their disease.<sup>62</sup>

## SURGERY

### General Considerations

The use of the operating microscope is as essential for spinal cord tumor surgery as it is for brain tumor surgery. In addition, other surgical adjuncts, such as intraoperative ultrasound, the CO<sub>2</sub> laser, and the CUSA, are equally valuable for the resection of spinal cord tumors. The ultrasound is particularly useful for examining the spinal cord through an intact or open dura to assess the level of maximum tumor involvement or to differentiate tumor cysts from solid tumor masses.

### Surgical Planning

MRI scanning is invaluable for the diagnosis, localization, and characterization of spinal tumors (see [Fig. 43.2-4](#)). In all but vascular tumors (e.g., hemangioblastoma), in which angiography is needed, or tumors that cause extensive bony destruction (e.g., metastasis), where CT scanning might be helpful, a technically excellent MRI scan is most often sufficient for preoperative planning for spinal tumors. Determination of the spinal level of the tumor and its exact relation to the spinal cord is important in localization. Corticosteroids are given before, during, and after spinal cord tumor surgery to help control spinal cord edema.

### Removal of Intradural Extramedullary Tumors

Meningiomas and neurilemmomas (schwannomas) occur in the intradural extramedullary spinal compartment. Most of these tumors can be completely resected (cured), because through a laminectomy exposure they can be easily separated and rotated away from the spinal cord, which is already displaced, but not invaded, by tumor.

Neurilemmomas arise from spinal rootlets (most often dorsal rootlets), and their removal includes sections of those rootlets involved. Neurilemmomas can grow along the nerve root in a dumbbell fashion through a neural foramen; and although some of these extraspinal tumor extensions can be removed by extending the initial laminectomy exposure laterally, some must be resected at a separate operation through a thoracotomy, a costotransversectomy, or a retroperitoneal approach.

Meningiomas in most patients can be removed through a posterior (laminectomy) approach, because they are commonly lateral or anterolateral, and even the more anteriorly placed tumors cause enough lateral displacement of the spinal cord to allow access for resection without traction on the spinal cord. The uncommon tumor directly anterior to the spinal cord must sometimes be approached anteriorly, anterolaterally, or posterolaterally. Anteriorly situated meningiomas at the foramen

magnum are sometimes unresectable because of their encasement of the vertebral artery.

### Removal of Intramedullary Tumors

The most common intramedullary tumors are ependymoma and astrocytoma. Hemangioblastoma is another (infrequent) tumor occurring in the spinal intramedullary compartment. Surgery is the principal treatment for all these tumors, with the exception of anaplastic astrocytomas.

Intramedullary tumors are approached through a laminectomy exposure, and after the dura is opened, a longitudinal myelotomy is made over the widened region of spinal cord and the incision deepened several millimeters to the tumor surface. Dissection planes around the tumor are sought microsurgically and, in the case of ependymomas, usually found and extended gradually around the tumor's surface, because removal of the central tumor bulk (by CO<sub>2</sub> laser or CUSA) causes the tumor to collapse. Usually, such tumors are completely removed. Tumors with indefinite dissection planes (usually low-grade astrocytomas) cannot be removed completely, but bulk reduction can cause long-term palliation. If frozen section shows a tumor to be malignant, surgery is aborted, and radiation therapy is the treatment.

Hemangioblastomas are extremely vascular tumors, so the tumor margins are addressed first where feeding arteries are coagulated, and the tumor is dissected and removed *en bloc*. The dorsal location of most of these tumors and the commonly associated cyst simplifies the removal to some extent.

### RADIATION THERAPY

Radiation therapy is recommended for unresectable and incompletely resected neoplasms of the spinal axis. As a rule, doses of 50 to 54 Gy are used so that the risk of radiation injury to the cord is less than that from the neoplasm itself. Low-grade tumors and meningiomas are treated at the lower dose level and malignant tumors to the higher level.<sup>438</sup> For lesions involving only the cauda equina and in situations in which irreversible and complete transverse myelopathy already has occurred, higher doses are permissible. The tumor usually is treated with a margin of 2 to 3 cm or two vertebral bodies above and below the lesion. Extension of the portals to include the thecal sac has been suggested for ependymomas that are removed piecemeal<sup>439</sup> and for those arising in the distal spinal canal.<sup>440</sup> Ependymomas of the cord have a longer natural history than astrocytomas. Although most astrocytomas that recur do so within 3 years of treatment, recurrence of ependymomas may be delayed for as long as 12 years.<sup>440,441</sup>

Adjunctive radiation therapy is not necessary when ependymomas are removed completely in an *en bloc* fashion. However, 75% of patients (three of four) reported by Wen and associates recurred locally or with spread to the thecal sac after complete resection alone when the tumor was excised piecemeal.<sup>439</sup> All seven nonirradiated patients with incompletely excised lesions reported by Barone and Elvidge<sup>442</sup> and Schuman and coworkers<sup>443</sup> recurred. In contrast, postoperative radiation therapy appears to improve tumor control and disease-free survival in patients with incompletely resected ependymomas. Sloof and colleagues found their irradiated patients survived nearly twice as long as those who were not irradiated.<sup>2</sup> Five- and 10-year survival rates in irradiated patients with localized ependymomas range from 60% to 100% and 68% to 95%, respectively, whereas 10-year relapse-free survival rates vary from 43% to 61%.<sup>440,444</sup> Tumor grade has a significant effect on outcome. Waldron and colleagues found that for well-differentiated tumors the 5-year cause-specific survival was 97% as compared with 71% for intermediate or poorly differentiated tumors ( $P = .005$ ).<sup>440</sup> Myxopapillary ependymomas that arise exclusively in the conus medullaris have a better prognosis than the cellular ependymomas that arise in the cord.<sup>439</sup> Local recurrence is the predominate pattern of treatment failure, occurring in 25% of irradiated patients.<sup>440</sup>

The 5- and 10-year survival rates for irradiated patients with low-grade astrocytomas of the spinal cord vary from 60% to 90% and 40% to 90%, respectively; 5- and 10-year relapse-free survival rates range from 66% to 83% and 53% to 83%, respectively.<sup>438,441</sup> Approximately 50% to 65% of astrocytomas are controlled locally. Patients with malignant gliomas have a much poorer prognosis; none of the patients with anaplastic astrocytoma or glioblastoma multiforme reported by Linstadt and colleagues survived longer than 8 months.<sup>441</sup>

### CHEMOTHERAPY

There have been no reports of controlled clinical trials of chemotherapy for primary spinal axis tumors. Drugs active against intracranial astrocytomas, oligodendrogliomas, ependymomas, medulloblastoma, and germ cell tumors logically may be assumed to be equally efficacious against these same histologies in the spinal cord. Along with reports of chemotherapy activity against intracranial tumors, anecdotal patient reports have been included.

The authors' experience suggests that palliation is possible for astrocytomas using nitrosourea-based chemotherapy regimens. No therapy is clearly superior. For drop metastases from ependymomas, they have used BCNU and dibromodulcitol as single agents and various combinations with some benefit.<sup>181,445</sup> For drop metastases from medulloblastoma, various drugs have been found to be beneficial. Specifically, cyclophosphamide, carboplatin, methotrexate, procarbazine, teniposide, and VCR have been used alone or in various combinations. These drugs would be expected to produce palliation for weeks to many months.

Although leptomeningeal spread is a common complication of primary spinal axis tumors, the use of intraventricular and intrathecal chemotherapy is limited to the treatment of microscopic deposits. Biodistribution in the subarachnoid CSF can be limited in the face of intradural extramedullary tumors. In addition, deposits of 5 mm in diameter or larger are not likely to benefit because of limitations in diffusion coupled with transcapillary loss of drug in the tumor.<sup>446</sup>

## INTRODUCTION

The biologic nature of tumors of childhood is clinically, histopathologically, and biologically distinct from that of adult-onset malignancies. Childhood cancers tend to have short latency periods, are often rapidly growing and aggressively invasive, are rarely associated with exposure to carcinogens implicated in adult-onset cancers, and are generally more responsive to standard modalities of treatment, in particular chemotherapy. Most childhood tumors occur sporadically in families with at most a weak history of cancer. In approximately 10% to 15% of cases,<sup>1,2</sup> however, a strong familial association is recognized, or the child has a congenital or genetic disorder that imparts a higher likelihood of specific cancer types. Examples of genetic disorders that render a child at increased risk of tumor development include xeroderma pigmentosa, Bloom's syndrome, or ataxia-telangiectasia, which predispose to skin cancers, leukemias, or lymphoid malignancies, respectively. In all three cases, constitutional gene alterations that disrupt normal mechanisms of genomic DNA repair are blamed for the propensity to cell transformation. Other hereditary disorders including Beckwith-Wiedemann syndrome (BWS) and the multiple endocrine neoplasias types 1 and 2 are thought to be associated with their respective tumor spectra through constitutional activation of molecular pathways of deregulated cellular growth and proliferation. The cancers that occur in these syndromes are generally secondary phenotypic manifestations of disorders that have distinctive recognizable physical stigmata. On the other hand, some cancer predisposition syndromes are recognized only by their malignant manifestations, with nonmalignant characteristics being virtually absent. These include hereditary retinoblastoma, the Li-Fraumeni syndrome (LFS), familial Wilms' tumor (WT), and familial adenomatous polyposis coli. Each of these presents with distinct cancer phenotypes, and for each the identified molecular defect is unique ([Table 44.1-1](#)).

Hereditary Syndrome	Predominant Pediatric Neoplasms
Hereditary retinoblastoma	Retinoblastoma, osteosarcoma
Familial Wilms' tumor	Wilms' tumor
Beckwith-Wiedemann syndrome	Wilms' tumor, hepatoblastoma, duodenopancreatic carcinoma, adrenocortical carcinoma
Li-Fraumeni syndrome	Sarcoma, brain tumor, leukemia, adrenocortical carcinoma, choroid plexus carcinoma
Ataxia-telangiectasia	Lymphoma, brain tumor, leukemia
Neurofibromatosis type 1	Sarcoma, glioma
Neurofibromatosis type 2	Meningioma, acoustic neuroma
Multiple endocrine neoplasia, types 1 and 2	Adenoma/carcinoma of endocrine organs
Familial polyposis coli	Intestinal polyps, colon carcinoma, hepatoblastoma
Gorlin syndrome	Medulloblastoma, basal cell nevus
Bloom's syndrome	Leukemia

**TABLE 44.1-1.** Hereditary Syndromes Associated with Childhood Cancers

The study of pediatric cancer and rare hereditary cancer syndromes and associations has led to the identification of numerous cancer genes including dominant oncogenes and tumor suppressor genes. These have proved to be important not only in hereditary predisposition, but also as major players in the normal growth, differentiation, and proliferation pathways of all cells. Alterations of these genes have been consistently found in numerous sporadic tumors of childhood and led to studies of their functional role in carcinogenesis. The numerous properties of transformed malignant cells in culture or *in vivo* can be explained by the complex abnormal interaction of numerous positive and negative growth regulatory genes. Pediatric cancers offer unique models in which to study these pathways in that they are less likely to be disrupted by nongenetic factors. The embryonic ontogeny of many childhood cancers suggests that better understanding of the nature of the genetic events leading to these cancers will also augment the understanding of normal embryologic growth and development. This chapter begins with an outline of tumor suppressor genes, the most frequently implicated class of cancer genes in childhood malignancy. This leads into discussion of molecular features of retinoblastoma, the paradigm of cancer genetics, followed by analysis of the molecular understanding of other common pediatric cancers. Evaluation of the importance of molecular alterations in familial cancers, as well as new approaches in molecular therapeutics, are also addressed.

## TUMOR SUPPRESSOR GENES

Faulty regulation of cellular growth and differentiation leads to neoplastic transformation and tumor initiation. Many inappropriately activated growth-potentiating genes, or *oncogenes*, have been identified through the study of RNA tumor viruses and the transforming effects of DNA isolated from malignant cells. However, activated dominant oncogenes themselves do not readily explain a variety of phenomena related to transformation and tumor formation. Among these is the suppression of tumorigenicity by fusion of malignant cells with their normal counterparts. If these malignant cells carried an activated dominant oncogene, it would be expected that such a gene would initiate transformation of the normal cells, likely leading to either embryonic or fetal death. The observation is more readily explained by postulating the existence of a factor in the normal cell that acts to suppress growth of the fused malignant cells. Malignant cells commonly exhibit specific chromosomal deletions ([Table 44.1-2](#)). The best example of this occurs in retinoblastoma, a rare pediatric eye tumor in which a small region of the long arm of chromosome 13 is frequently missing.<sup>3,4</sup> The presumed loss of genes in specific chromosomal regions argues strongly against the concept of a dominantly acting gene being implicated in the development of the tumor. Hereditary forms of cancer are also not readily explained by altered growth-potentiating genes. Comparisons between the frequencies of familial tumors and their sporadic counterparts led Knudson to suggest that the familial forms of some tumors could be explained by constitutional mutations in growth-limiting genes.<sup>5</sup> The resulting inactivation of these genes would facilitate cellular transformation.<sup>6</sup> Such growth-limiting genes were termed *tumor suppressor genes*.

Solid Tumor	Cytogenetic Rearrangement
Wilms' tumor	t(11;22)(p13;p11), 4
Neuroblastoma	del(1p36), double-minute chromosomes, homogeneously staining region, +17q21-qter
Retinoblastoma	del(13q)4
Wilms' tumor	del(1p)3, t(3;7)
Sexual precocity	t(8;11)(p11;q11)
Osteogenic sarcoma	del(13q)4
Rhabdomyosarcoma	t(2;13)(q11;q11), t(1;13)(q21;q11), 11p-
Peripheral neuroepithelioma	t(11;22)(q13;q11), 4
Anticoagulant	t(17p)
Meningioma	del(22) 22
Angioma/teratoid/blastoid tumor	del(22) 11
Germ cell tumor	t(17p)

**TABLE 44.1-2.** Common Cytogenetic Rearrangements in Solid Tumors of Childhood

Unlike dominant oncogenes, mutant tumor suppressor genes may be found either in germ cells or somatic cells. In the former, they may arise *de novo* or be transmitted from generation to generation within a family. Despite many similarities among the various cloned tumor suppressors, it has become evident that this family of genes is heterogeneous in many respects. The diversity of functions, cellular locations, and tissue-specific expression of the tumor suppressor genes suggests the existence of a complex, yet coordinated, cellular pathway that limits cell growth by linking nuclear processes with the intracytoplasmic and extracytoplasmic environment. This discussion is limited to those genes for which pediatric tumors are frequently associated.

## RETINOBLASTOMA: THE PARADIGM

Retinoblastoma is the prototype cancer caused by mutations of a tumor suppressor gene. It is a malignant tumor of the retina that occurs in infants and young children, with an incidence of approximately 1 in 20,000.<sup>7</sup> Approximately 40% of retinoblastoma cases are of the heritable form<sup>8</sup> in which the child inherits one mutant allele at the retinoblastoma susceptibility locus (RB1) through the germline. A somatic mutation in a single retinal cell causes loss of function of the remaining normal allele, leading to tumor formation. Tumors are often bilateral and multifocal. The disease is inherited as an autosomal dominant trait, with a penetrance approaching 100%.<sup>9</sup> The remaining 60% of retinoblastoma cases are sporadic (nonheritable).<sup>10</sup> Both RB1 alleles in a single retinal cell have been inactivated by somatic mutations. As one can imagine, such an event is rare, and these patients usually have only one tumor that presents later than in infants with the heritable form. Fifteen percent of unilateral retinoblastoma is heritable,<sup>9</sup> but by chance develops in only one eye. Survivors of heritable retinoblastoma have a several-hundred-fold increased risk of developing mesenchymal tumors such as osteogenic sarcoma, fibrosarcomas, and melanomas later in life.<sup>10,11</sup> It is thought that several genetic mechanisms may be involved in elimination of the second wild-type RB1 allele in an evolving tumor. These include chromosomal duplication or nondisjunction, mitotic recombination, or gene conversion.<sup>12</sup>

The RB1 gene was eventually mapped to chromosome 13q14.<sup>13</sup> Using Southern blot analysis, it was then possible to demonstrate that the second target gene that led to disease was actually the second copy of the RB1 locus. Reduction to homozygosity of the mutant allele [or loss of heterozygosity (LOH) of the wild-type allele] would lead to the loss of functional RB1 and account for tumor development.

Using classic cloning techniques, a 4.7-kb cDNA fragment was isolated from retinal cells.<sup>14</sup> This gene, RB1, consisted of 27 exons and encoded a 105-kD nuclear phosphoprotein. As well as being altered in retinoblastoma, this gene and its protein product have also been found to be altered in osteosarcomas, small cell lung carcinomas, and bladder, breast, and prostate carcinomas.<sup>14,15</sup>

Although it is clear that RB1 and its protein product play some role in growth regulation, the precise nature of this role remains obscure. In the developing retina, inactivation of the RB1 gene is both necessary and sufficient for tumor formation.<sup>16</sup> Although the RB1 gene is expressed in virtually all mammalian tissues, only in the retina is its inactivation sufficient for tumor initiation. Outside the retina, RB1 inactivation is often a rate-limiting step in tumorigenesis generated by multiple genetic events. The molecular characteristics and potential functional activities of RB1 are outlined in detail elsewhere in this volume.

The patterns of inheritance and presentation of retinoblastoma have been well described, and the responsible gene identified. Although the basic mechanisms by which the gene is inactivated are understood, much still remains to be determined about the biologic function of the gene and its protein product.

## WILMS' TUMOR: THREE DISTINCT LOCI

WT, or nephroblastoma, is an embryonal malignancy of the kidney that arises from remnants of immature kidney. It affects approximately 1 in 10,000 children, usually before the age of 6 years (median age at diagnosis, 3.5 years). Some 5% to 10% of children present with either synchronous or metachronous bilateral tumors.<sup>17</sup> A peculiar feature of WT is its association with nephrogenic rests, foci of primitive but nonmalignant cells whose persistence suggests a defect in kidney development. These precursor lesions are found within the normal kidney tissue of 30% to 40% of children with WT. Nephrogenic rests may persist, regress spontaneously, or grow into a large mass that simulates a true WT and presents a difficult diagnostic challenge.<sup>18</sup> Another interesting feature of this neoplasm is its association with specific congenital abnormalities, including genitourinary anomalies, sporadic aniridia, mental retardation, and hemihypertrophy. The WT1 tumor suppressor gene is homozygously deleted, at least in part, in a small but highly informative set of sporadic WTs. In addition, both sporadic and hereditary WTs have been described in which WT1 is specifically altered.

A genetic predisposition to WT is observed in two distinct disease syndromes with urogenital system malformations (the WAGR syndrome and the Denys-Drash syndrome)<sup>19</sup> as well as in an overgrowth syndrome characterized by visceromegaly, macroglossia, and hyperinsulinemic hypoglycemia (BWS).<sup>20</sup> These congenital disorders have now been linked to abnormalities at specific genetic loci implicated in Wilms' tumorigenesis.

The WAGR syndrome, the association of WT (W) with congenital aniridia (A), genitourinary malformations (G), and mental retardation (R), has been correlated with constitutional deletions of band q3 of chromosome 11.<sup>21</sup> Whereas it is now known that the WAGR deletion encompasses a number of contiguous genes, including the aniridia gene *Pax6*,<sup>22</sup> the cytogenetic observation in patients with WAGR was also important in the cloning of WT1 at chromosome 11p13.<sup>23,24</sup> and<sup>25</sup> Characterization of WT1 demonstrated that this gene spans approximately 50 kb of DNA and contains 10 exons. The WT1 protein is a transcription factor.<sup>26</sup> However, the identity of the gene(s) targeted by WT1 during normal kidney development is not known.

The second syndrome closely associated with this locus was initially described by Denys in 1967 and recognized as a syndrome by Drash 3 years later.<sup>27,28</sup> Denys-Drash syndrome is a rare association of WT, intersex disorders, and progressive renal failure.<sup>28</sup> It has been demonstrated that virtually all patients with Denys-Drash syndrome carry WT1 point mutations in the germline.<sup>29</sup>

WT1 is altered in only 10% of WTs. This observation implies the existence of alternative loci in the etiology of this childhood renal malignancy. One such locus also resides on the short arm of chromosome 11, telomeric of WT1, at 11p15. This gene, designated WT2, is associated with BWS. Patients with BWS are at increased risk of developing WT, as well as other embryonic malignancies including rhabdomyosarcoma (RMS), neuroblastoma, and hepatoblastoma. The putative BWS gene maps to chromosome 11p15<sup>30,31</sup> and is tightly linked to the Ha-*ras* oncogene homologue *HRAS-1* and the insulin growth factor-2 gene (*IGF-2*). Whether the BWS gene and WT2 are one and the same or two distinct yet closely linked genes remains to be determined.

Although linkage studies have indicated that the gene for familial WT must be distinct from WT1 and WT2, and from the gene that predisposes to BWS, to date, this gene has been neither cytogenetically localized nor isolated. Whether, of course, the gene for familial WT interacts with the gene product of either of the two WT suppressor genes has yet to be determined.

Finally, loss of the long arm of chromosome 16 has been observed in approximately 20% of WT specimens.<sup>32</sup> This observation implicates yet another genetic locus in WT. Since linkage studies have also excluded this locus as the *familial* WT gene,<sup>33</sup> a total of four loci have thus far been associated with this pediatric malignancy.

However, it is not known whether alterations at 16q can initiate tumorigenesis or simply reflect subsequent steps in the progression of malignancy.

It is apparent that the influence of the genetic alterations in WT is quite different from those of the retinoblastoma gene. In the latter, there is strong evidence that a single gene is involved, whereas a series of genetic alterations, or at least distinct genetic events, is required for Wilms' tumorigenesis.

## NEUROFIBROMATOSSES

The neurofibromatoses (NF) comprise two similar entities. NF1 is one of the most common autosomal dominantly inherited disorders, affecting approximately 1 in 3500 people,<sup>34</sup> one-half of which arise from new spontaneous mutations. Carriers of mutant NF1 are predisposed to a variety of tumors including optic nerve glioma, neurofibroma and neurofibrosarcoma, malignant schwannoma, astrocytoma, and pheochromocytoma.<sup>35,36</sup> Occurring with less frequency are leukemias, osteosarcoma, RMS, and WT.

Using standard linkage analysis, the NF1 gene was mapped to chromosomal band 17q11 and subsequently cloned.<sup>37,38</sup> The NF1 gene is unusual in that it contains three embedded genes, OMGP, EV12A, and EV12B, in a single intron.<sup>39</sup> This gene encodes a 2818 amino acid protein, termed *neurofibromin*, that is ubiquitously expressed. One region of the gene shows extensive structural homology to the GTPase activating domain of mammalian guanosine triphosphatase-activating proteins: Loss of the protein's activity results in failure of hydrolysis of guanosine triphosphate to guanosine diphosphate by the ras oncoprotein. Loss of neurofibromin function usually results from mutations in one allele of the gene leading to premature truncation of the protein, followed by absence or mutations of the second allele in tumors. This loss of function is thought to lead to elevated levels of the guanosine triphosphate-bound RAS protein that transduces signals for cell division. There appears to be more than one mechanism whereby malignant tumors develop in NF patients. In addition to structural alterations of both alleles of the NF1 gene, alternative splicing leading to dysregulation at the level of transcription has also been demonstrated. It appears that the two types of resulting protein may modify the modulation of RAS-regulated signal transduction.

NF2 is much less frequent than NF1, occurring in only 1 in 1 million persons. Although it is also inherited as an autosomal dominant disorder with high penetrance, the new mutation rate in NF2 is low.<sup>40</sup> It is clinically characterized by bilateral acoustic neuromas, spinal nerve root tumors, and meningiomas.

The NF2 locus was mapped to chromosome 22, band q12,<sup>41</sup> and its 69-kD encoded protein, termed *merlin*, has been shown to be expressed in various tissues, including brain, although not as ubiquitously as NF1.<sup>42,43</sup> The mechanism of tumor formation in NF2 appears to be in concordance with the Knudson two-hit model, although the mechanism of action of the NF2 protein has not yet been elucidated. It is, however, postulated that a defect in such a molecule may dysregulate normal cell growth by disrupting a signal transduction pathway, anchorage dependence, or cell-cycle regulation.<sup>43</sup>

## NEUROBLASTOMA

Nonrandom chromosomal abnormalities are observed in more than 75% of neuroblastomas,<sup>44</sup> and many of these are also found in neuroblastoma-derived cell lines. The most common of these is deletion or rearrangement of the short arm of chromosome 1, although loss, gain, and rearrangements of chromosomes 10, 14, 17, and 19 have also been reported. The allelic losses indicate loss of function of as yet unknown tumor suppressor genes in these regions. It is believed that a tumor suppressor gene that lies on band p36 of chromosome 1 is critically important in the pathogenesis and aggressive nature of neuroblastoma. It has been shown that the loss of chromosome 1p is a strong prognostic factor in patients with neuroblastoma, independent of age and stage.<sup>45,46</sup> Two other unique cytogenetic rearrangements are highly characteristic of neuroblastoma.<sup>47,48</sup> These structures, homogeneous staining regions and double-minute chromosomes, contain regions of gene amplification. The N-myc gene, an oncogene with considerable homology to the cellular protooncogene c-myc, is amplified within homogeneous staining regions and double-minute chromosomes. Virtually all neuroblastoma tumor cell lines demonstrate amplified and highly expressed N-myc,<sup>49</sup> and N-myc amplification is thought to be associated with rapid tumor progression. Expression of N-myc is increased in undifferentiated tumor cells compared with much lower (or single copy) levels in more differentiated cells (ganglioneuroblastoma and ganglioneuroma). N-myc expression is diminished in association with the *in vitro* differentiation of neuroblastoma cell lines.<sup>50</sup> This observation formed the basis for current therapeutic trials demonstrating a survival advantage to patients treated with cis-retinoic acid.<sup>51</sup> Furthermore, a close correlation exists between N-myc amplification and advanced clinical stage.<sup>52</sup>

Although it is clear that altered expression of N-myc contributes to the development of malignancy, it is not yet apparent which cellular functions are altered. The molecular mechanisms underlying regulation of neuroblastoma differentiation may be explained in part through the contribution of other genes and proteins.

Neuroblastoma cells that express the high-affinity nerve growth factor receptor trkA<sup>53</sup> can be terminally differentiated by nerve growth factor and may demonstrate morphologic changes typical of ganglionic differentiation. Tumors showing ganglionic differentiation and trk gene activation have a favorable prognosis.<sup>53</sup> As noted previously, resistance to multidrug chemotherapeutic regimens (multidrug resistance) is characteristic of aggressive, poorly responsive N-myc amplified neuroblastomas. It is interesting to note that expression of the multidrug-resistance-associated protein, found to confer multidrug resistance *in vitro*, is increased in neuroblastomas with N-myc amplification and decreased after differentiation of tumor cells *in vitro*.<sup>54</sup> It has been demonstrated in fact that high levels of multidrug-resistance-associated protein expression are significantly associated with poor outcome, independent of N-myc amplification.<sup>54</sup> Gain of chromosome segment 17q21-qter has been shown to be the most powerful prognostic factor yet.<sup>55</sup> However, no gene has yet been implicated at this site.

Finally, insulin growth factor-2 (IGF-2) is a developmentally regulated gene that may play a role in the pathogenesis of neuroblastoma. IGF-2 is expressed in embryonic adrenal cortex, as well as adult adrenal medulla. It is a stimulatory ligand for neuroblastoma cell growth. IGF-2 is highly expressed in tumor cell lines that express a pattern of developmentally regulated genes found late in the chromaffin lineage and functions in an autocrine growth pathway.<sup>56</sup> Cell lines that express markers corresponding to more immature cells are responsive to IGF-2, but do not produce the mitogen itself. This paracrine growth-mediating effect is consistent with observations of IGF-2 expression in infiltrating tumor specimens and adjacent normal tissues.<sup>57</sup>

## EWING'S SARCOMA FAMILY OF TUMORS

Ewing's sarcoma is one of the first examples in which the application of molecular diagnostics led to improved tumor classification. Ewing's sarcoma was first described by James Ewing as a bone tumor characterized by small blue round cells and minimal mitotic activity.<sup>58</sup> Turc-Carel identified a recurring reciprocal t(11;22) chromosomal translocation in these tumors in 1983.<sup>59</sup> Investigators subsequently demonstrated a cytogenetically identical t(11;22) in adult neuroblastoma or peripheral primitive neuroectodermal tumor, so named because of its histologic similarity to neuroblastoma.<sup>60</sup> Based on the presence of the identical translocation, it was hypothesized that peripheral primitive neuroectodermal tumor was related to Ewing's sarcoma. This translocation breakpoint has been molecularly characterized as an in-frame fusion between a new Ewing's sarcoma gene, EWS, on chromosome 22 and an ETS transcription family member, FLI-1, on chromosome 22.<sup>61,62 and 63</sup>

In addition to this fusion transcript being identified in peripheral primitive neuroectodermal tumor, other variants, notably the chest wall Askin's tumor and soft tissue Ewing's sarcoma, previously treated as a RMS because of its location in soft tissue, were also shown to bear the identical fusion transcript. Several variant translocations have also been identified, invariably fusing the EWS gene to an ETS family member.<sup>64,65</sup> Greater than 90% of Ewing's sarcoma family of tumors carry the EWS-ETS fusion gene, and a search for EWS-ETS by either reverse transcriptase polymerase chain reaction or fluorescence *in situ* hybridization should be considered standard practice in the diagnostic evaluation of suspected Ewing's sarcoma family of tumors. The nature of the novel fusion transcription factor and its downstream targets are currently under intense investigation. Interestingly, it has been suggested that the specific fusion protein expressed in the Ewing's sarcoma family of tumors has prognostic significance.<sup>66,67</sup>

## RHABDOMYOSARCOMA

The two major histologic subtypes of RMS, embryonal and alveolar, have both unique histologic appearance as well as distinctive molecular genetic abnormalities, while sharing a common myogenic lineage. Embryonal tumors make up two-thirds of all RMS and are histologically characterized by a stroma-rich, spindle-cell appearance. Alveolar tumors make up approximately one-third of RMS and are histologically characterized by densely packed small round cells often lining a septation reminiscent of a pulmonary alveolus, giving rise to its name. Both histologic subtypes express muscle-specific proteins including  $\alpha$ -actin, myosin, desmin, and MyoD,<sup>68,69 and 70</sup> and they virtually always express high levels of IGF-2.<sup>71,72</sup>

At the molecular level, embryonal tumors are characterized by LOH at the 11p15 locus, which is of particular interest since this region harbors the IGF-2 gene.<sup>73,74</sup>

The loss of heterozygosity (LOH) at 11p15 occurs by loss of maternal and duplication of paternal chromosomal material.<sup>75</sup> While LOH is normally associated with loss of tumor suppressor gene activity, in this instance LOH with paternal duplication may result in activation of IGF-2. This occurs because IGF-2 is now known to be normally imprinted (i.e., this gene is normally transcriptionally silent at the maternal allele, with only the paternal allele being transcriptionally active).<sup>76,77</sup> Thus, LOH with paternal duplication potentially leads to a twofold gene-dosage effect of the IGF-2 locus. Furthermore, in alveolar tumors where LOH does not occur, the normally imprinted maternal allele has been shown to be reexpressed.<sup>78,79</sup> Thus, LOH and loss of imprinting may in this case lead to the same functional result, namely, biallelic expression of the normally monoallelically expressed IGF-2. However, loss of an as yet unidentified tumor suppressor gene due to LOH also remains a possibility.

Alveolar RMS is characterized by a t(2;13)(q35;q14) chromosomal translocation.<sup>80,81</sup> Molecular cloning of this translocation has identified the generation of a fusion transcription factor, fusing the 5' DNA-binding region of PAX-3 on chromosome 2 to the 3' transactivation domain region of FKHR gene on chromosome 13.<sup>82,83</sup> A variant t(1;13)(q36;q14) has been identified in a small number of alveolar RMS tumors that fuses the 5' DNA-binding region of the PAX 7 gene on chromosome 1 with the identical 3' transactivation domain of the FKHR gene.<sup>84</sup> Fluorescence *in situ* hybridization or reverse transcriptase polymerase chain reaction can be used to identify these PAX-FKHR fusions in approximately 90% of tumors and are diagnostic of alveolar RMS. As noted previously, the fusion protein generated by the translocation leads to a novel transcription factor. The nature of this transcription factor and its downstream targets are the subject of active investigation. Of particular interest is the association of the PAX3-FKHR fusion with increased expression of c-met.<sup>85,86</sup> Met is the receptor tyrosine kinase for hepatocyte growth factor/scatter factor and is overexpressed in both embryonal and alveolar RMS.<sup>87</sup> It has also been suggested that, like the Ewing's sarcoma family of tumors, where the specific expressed fusion transcript has prognostic significance, the PAX3-FKHR and the PAX7-FKHR fusions lead to distinct clinicopathologic entities.<sup>88</sup>

Other frequently reported genetic alterations that may be common to both embryonal and alveolar RMS include activated forms of N-RAS and K-RAS,<sup>89,90</sup> inactivating p53 mutations,<sup>91</sup> as well as amplification and overexpression of MDM2, CDK4, and N-MTC.<sup>92</sup>

## HEREDITARY SYNDROMES ASSOCIATED WITH TUMORS OF CHILDHOOD

### LI-FRAUMENI SYNDROME

A few hereditary cancer syndromes are associated with the occurrence of both childhood and adult-onset neoplasms. The paradigm Li-Fraumeni familial cancer syndrome was originally described in 1969 from an epidemiologic evaluation of more than 600 medical and family history records of childhood sarcoma patients.<sup>93,94</sup> The original description of kindred with a spectrum of tumors that includes soft tissue sarcomas, osteosarcomas, breast cancer, brain tumors, leukemia, and adrenocortical carcinoma has been overwhelmingly substantiated by numerous subsequent studies,<sup>95</sup> although other cancers are also observed. Germline alterations of the p53 tumor suppressor gene are associated with LFS.<sup>96,97</sup> and<sup>98</sup> These are primarily missense mutations that yield a stabilized mutant protein. The spectrum of mutations of p53 in the germline are indistinct from somatic mutations found in a wide variety of tumors. Carriers are heterozygous for the mutation, and in tumors derived from these individuals, the second (wild-type) allele is frequently deleted or mutated, leading to functional inactivation.<sup>99,100</sup> and<sup>101</sup> Only 60% to 80% of *classic* LFS families have detectable alterations of the gene. It is not yet determined whether the remainder are associated with the presence of modifier genes, promoter defects yielding abnormalities of p53 expression, or simply the result of weak genotype-phenotype correlations. Other candidate predisposition genes, such as p16, p15, p21, BRCA1, BRCA2, and PTEN, associated with multisite cancer associations have generally been ruled out as potential targets.

Germline p53 alterations have also been reported in some patients with cancer phenotypes that resemble the classic LFS phenotype. Between 3% and 10% of children with apparently sporadic RMS or osteosarcoma have been shown to carry germline p53 mutations.<sup>102,103</sup> These patients tend to be younger than those who harbor wild-type p53. It appears as well that more than 75% of children with apparently sporadic adrenocortical carcinoma carry germline p53 mutations, although in some of these cases, a family history develops that is not substantially distinct from LFS.<sup>104,105</sup> These observations suggest that germline p53 alterations may be associated with early-onset development of the childhood component tumors of the syndrome. It is not clear what clinical significance these findings have in that no studies of prognostic significance or potential impact on anticancer treatment modalities are reported. Nevertheless, in light of the critical role played by p53 in the initiation and potentiation of gamma irradiation or chemotherapy-induced DNA damage repair, studies into the effect of such germline mutations on the potentiation of tumor development related to therapeutic interventions would be important.

### BECKWITH-WIEDEMANN SYNDROME

BWS occurs with a frequency of 1 in 13,700 births. More than 450 cases have been documented since the original reported associations of exomphalos, macroglossia, gigantism, and other congenital anomalies. With increasing age, phenotypic features of BWS become less pronounced. Laboratory findings may include, at birth, hypoglycemia (extremely common), polycythemia, hypocalcemia, hypertriglyceridemia, hypercholesterolemia, and high serum a-fetoprotein levels. Early diagnosis of the condition is crucial to avoid deleterious neurologic effects of neonatal hypoglycemia and to initiate an appropriate screening protocol for tumor development. The increased risk for tumor formation in BWS patients is estimated at 7.5% and is further increased to 10% if hemihyperplasia is present. Tumors occurring with the highest frequency include WT, hepatoblastoma, neuroblastoma, and adrenocortical carcinoma.<sup>20,106</sup>

The genetic basis of BWS is complex. Various 11p15 chromosomal or molecular alterations have been associated with the BWS phenotype and its tumors.<sup>107</sup> It is unlikely that a single gene is responsible for the BWS phenotype. Because it appears that abnormalities in the region affect imprinted domain, it is more likely that normal gene regulation in this part of chromosome 11p15 occurs in a regional manner and may depend on various interdependent factors or genes. Chromosomal abnormalities associated with BWS are extremely rare, with only 20 cases having been associated with 11p15 translocations or inversions. The chromosomal breakpoint in each of these cases is always found on the maternally derived chromosome 11.<sup>108</sup> This parent-of-origin dependence in BWS suggests that the chromosome translocations disrupt imprinting of a gene in the 11p15 region. On the other hand, BWS-associated 11p15 duplications (approximately 30 reported cases) are always paternally derived, and the duplication breakpoints are heterogeneous.<sup>109</sup> Paternal uniparental disomy, in which there are two alleles inherited from one parent (the father), has been reported in approximately 15% of sporadic BWS patients.<sup>110</sup> It is interesting that the insulin/IGF-2 region is always represented in the uniparental disomy, although the extent of chromosomal involvement is highly variable. Alterations in allele-specific DNA methylation of IGF-2 and H19 reflect this paternal imprinting phenomenon.<sup>111</sup> Although there are associated cytogenetic and molecular findings for some patients, no single diagnostic test exists for BWS. This observation is not unlike that described for LFS, or perhaps for other multisite cancer phenotypes, in which the clarity of the phenotype is often weak, making the genetic link cloudy and the likelihood of multiple pathways to tumor formation strong.

### GORLIN SYNDROME

Nevoid basal cell carcinoma syndrome, or Gorlin syndrome, is a rare autosomal dominant disorder characterized by multiple basal cell carcinomas, developmental defects including bifid ribs and other spine and rib abnormalities, palmar and plantar pits, odontogenic keratocysts, as well as generalized overgrowth.<sup>112</sup> This syndrome appears to be caused by germline mutations of the tumor suppressor gene PTCH, a receptor for sonic hedgehog.<sup>113,114</sup> Approximately 5% of patients with Gorlin syndrome develop medulloblastoma. Furthermore, approximately 10% of patients diagnosed with medulloblastoma by the age of 2 years are found to have other phenotypic features consistent with Gorlin syndrome and also harbor germline PTCH mutations.<sup>115</sup> Of further note, mice with heterozygous PTC deletions develop RMS.<sup>116</sup> Although RMS is not associated with Gorlin syndrome, the mouse studies suggest a possible link between PTC signaling and RMS.<sup>117</sup>

### MALIGNANT RHABDOID TUMORS

These unusual pediatric tumors occur as primary renal tumors, but have also been described in lung, liver, soft tissues, and the CNS, where it is often termed *atypical and teratoid rhabdoid tumor*.<sup>118,119</sup> Recurrent chromosomal translocations of chromosome 22 involving a breakpoint at 22q11.2, as well as complete or partial monosomy 22, have been observed, strongly suggesting the presence of a tumor suppressor gene in this area. The hSNF5/INI1 gene has been isolated and shown to be the target for biallelic, recurrent, inactivating mutations.<sup>120</sup> The encoded gene product is thought to be involved in chromatin remodeling. Studies have not only demonstrated the presence of inactivating mutations in the majority of malignant rhabdoid tumors (renal or extrarenal), but also in chronic myeloid leukemia,<sup>121</sup> as well as in a wide variety of other childhood and adult-onset malignancies.<sup>122,123</sup> An intriguing feature in some individuals with malignant rhabdoid tumors is the observation of germline mutations, suggesting that this family of tumors may occur as a result of a primary inherited defect in one allele of the INI1 gene.<sup>124</sup> Further studies of the function of this gene will be important in determining its role in tumorigenesis of this wide spectrum of neoplasms.

## PREDICTIVE TESTING FOR GERMLINE MUTATIONS AND CHILDHOOD CANCERS

Several important issues have arisen as a result of the identification of germline mutations of tumor suppressor genes in cancer-prone individuals and families. These include ethical questions of predictive testing in such families and in unaffected relatives, and selection of patients to be tested, as well as the development of practical and accurate laboratory techniques, development of pilot testing programs, and the role of clinical intervention based on test results. This chapter was not meant to discuss these problems in detail, but one would be remiss to ignore their significance.

For several reasons, testing cannot as yet be offered to the general pediatric population, particularly in light of the demonstrably low carrier rate of the abnormal tumor suppressor genes and the general lack of standardized methods of preclinical screening of carriers. Exceptions to these limitations include screening of gene carriers in RB, BWS, multiple endocrine neoplasia, and multiple melanoma families. Whether predictive testing studies are initiated in high-risk families or surveys are carried out in cancer populations likely to harbor germline mutations in tumor suppressor genes, the investigations should be undertaken in a research setting involving expertise in oncology, psychiatry, psychology, genetics and genetic counseling, medical ethics, and molecular genetics. The development of screening programs should address aspects of cost, informed consent (particularly where it affects children), socioeconomic impact on the individual tested, consistency in providing results, and counseling. [125,126](#)

## MOLECULAR THERAPEUTICS

With the identification of alterations in a variety of molecular signaling pathways, including activated growth factor signaling pathways (e.g., IGF-2) and altered tumor suppressor pathways (e.g., RB), it has become increasingly apparent that these alterations may potentially represent the Achilles heel for these tumors. New agents targeting the tyrosine kinase enzymes that transduce growth factor signals are at various stages of development in early clinical studies. Agents blocking the growth hormone IGF-1 pathway are currently being tested in clinical trials in osteosarcoma and breast cancer. Farnesyl transferase inhibitors, blockers of the RAS pathway, have been developed and are also currently in clinical testing. Of note, the activity of farnesyl transferase inhibitors against NF is under investigation, since activation of RAS signaling has been observed in NF-associated tumors (see previous discussion). As targets of mutant transcription factors generated are identified, it is hoped that they may represent additional targets for therapeutic intervention.

Finally, fusion proteins derived from tumor-specific translocations may themselves represent potential neoantigens that could be targeted by cytotoxic T cells. It is likely that the molecular characterization of pediatric tumors will lead to novel and perhaps more effective treatment approaches in the near future. It is likely that some of these innovative approaches will at least initially be integrated into standard therapeutic protocols.

## INTRODUCTION

Malignant solid tumors account for 30% of all cases of childhood cancer. Collaborative, multimodality treatment efforts undertaken in the context of pediatric cooperative group clinical trials have produced a remarkable improvement in survival since the 1970s. In addition to improvements in survival and functional outcome, the cooperative group studies have also facilitated a rapid growth in our understanding of cancer genetics and tumor biology. Prospective studies are currently underway to validate new risk group stratification schemes that integrate classical tumor staging information with prognostically significant features of tumor biology detectable with molecular diagnostics. We review the epidemiology, pathology, clinical presentation, evaluation, treatment, and prognosis of the common malignant solid tumors of children and adolescents.

## EPIDEMIOLOGY

Approximately 12,400 children and adolescents younger than 20 years of age were diagnosed with cancer in 1998.<sup>1</sup> Malignant neoplasms are a major cause of

mortality in children between 1 and 14 years of age. In 1998, the most recent year for which statistics are available, accidents, congenital anomalies, and homicide were responsible for more deaths in the age group 1 to 4 years, whereas only accidents were a more frequent cause of death in the age group 5 to 14 years. <sup>2</sup>

The most common malignant neoplasms diagnosed in pediatric patients are acute leukemia, non-Hodgkin's lymphoma, Hodgkin's disease, and primary tumors of the central nervous system. The most common malignant solid tumors are neuroblastoma, Wilms' tumor, rhabdomyosarcoma (RMS), and retinoblastoma (Table 44.2-1).<sup>1</sup>

Disease	Incidence <sup>a</sup>	
	White	African American
Acute lymphoblastic leukemia	32.9 (23.6%)	16.9 (15.6%)
Astrocytoma	17.9 (12.8%)	14.5 (13.2%)
Neuroblastoma	10.2 (7.3%)	7.8 (7.2%)
Non-Hodgkin's lymphoma	9.1 (6.5%)	5.4 (5.0%)
Wilms' tumor	8.5 (5.9%)	9.4 (8.7%)
Hodgkin's disease	7.3 (5.2%)	4.7 (4.3%)
Primitive neuroectodermal	6.8 (4.9%)	5.9 (5.4%)
Acute myeloid leukemia	5.8 (4.2%)	4.8 (4.4%)
Rhabdomyosarcoma	4.7 (3.4%)	4.1 (3.8%)
Retinoblastoma	3.9 (2.8%)	4.5 (4.1%)
Osteosarcoma	3.4 (2.4%)	3.9 (3.6%)
Ewing's sarcoma	3.3 (2.4%)	0.5 (0.5%)
All histologic types	139.5 (100.0%)	108.3 (100.0%)

<sup>a</sup>Per million children younger than 15 years of age.

**TABLE 44.2-1.** Annual Incidence Rates and Percentage Distribution of Malignant Diseases in U.S. Children

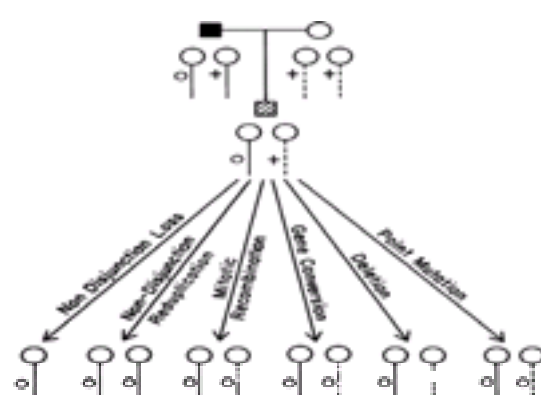

Insights into the etiology of malignant solid tumors of childhood have been suggested by well-designed case-control studies ( Table 44.2-2).<sup>3,4,5,6,7,8,9,10,11,12 and 13</sup>

Tumor	Father		Mother	
	Exposed	Relative Risk	Exposed	Relative Risk
Wilms' tumor	Hair coloring products	35	Nicholas, vitamin	13
Neuroblastoma	Dietary, high blood pressure	41		
	Trampolines, swings	32		
	Asphalt (baby)	13		
Retinoblastoma	Working clothes, radiation	23		
Epithelioma	Work	21	Work	18
	Paracetamol products	17		
	Dates or grapes	17		
Rhabdomyosarcoma	Herbicides or	18	Herbicides or	18
	Oral contraceptives	11	Oral contraceptives	11

**TABLE 44.2-2.** Risk of Solid Tumors Following Parental Preconception Exposures

Some childhood solid tumors occur in association with well-recognized single gene defects. Examples of these include the association of Wilms' tumor with Denys-Drash syndrome [Wilms' tumor suppressor gene (WT1) mutation],<sup>13</sup> bilateral retinoblastoma [retinoblastoma tumor suppressor gene (RB1) mutation],<sup>14</sup> hepatoblastoma and adenomatous polyposis coli (APC gene mutation),<sup>15</sup> RMS or malignant peripheral nerve sheath tumor and neurofibromatosis type 1 (NF1 gene mutation),<sup>16</sup> RMS and Li-Fraumeni syndrome (p53 gene mutation).<sup>17,18</sup>

The etiology of most childhood tumors is unknown. Knudson proposed the two-event model to explain the pattern of retinoblastoma, in which approximately 10% of patients with sporadic unilateral tumors and all patients with bilateral tumors carry a germline mutation of RB1. <sup>19</sup> This mutation could be either a new germinal mutation transmitted from the father<sup>20</sup> or a mutation transmitted from a carrier or affected parent.<sup>21</sup> The interstitial deletion occurs preferentially in the paternally derived allele of RB1,<sup>22</sup> as is the case for new germinal mutations of WT1,<sup>23</sup> resulting in the loss of function of one of the alleles of the RB1 or WT1 gene. A tumor arises only if a second event occurs, resulting in the loss of function of the remaining normal allele. This loss occurs via one of several mechanisms ( Fig. 44.2-1), recognized by loss of heterozygosity for markers of specific chromosomal regions, all of which result in complete absence of the normal gene product. <sup>21</sup> This mechanism has been demonstrated in tumor tissue derived from embryonal RMS, hepatoblastoma, retinoblastoma, and Wilms' tumor. <sup>24</sup>

**FIGURE 44.2-1.** Loss of heterozygosity may occur by a variety of mechanisms. (From Cavenee WK, Dryja TP, Phillips RA, et al. Expression of recessive alleles by chromosomal mechanisms in retinoblastoma. *Nature* 1983;305:779, with permission.)

The genetics of some childhood solid tumors may be more complex. Analysis of the epidemiologic and clinicopathologic features suggest, for example, some cases of bilateral and multicentric Wilms' tumor may arise from somatic mosaicism rather than germline mutation. <sup>25,26</sup>

## MANAGEMENT OF CHILDHOOD CANCER

Childhood malignant solid tumors are unique due to their responsiveness to many chemotherapeutic agents. Effective combination chemotherapy regimens have been identified and evaluated through cooperative group multiinstitutional trials. The cooperative groups' membership includes multidisciplinary treatment teams consisting of pediatric oncologists, radiologists, surgeons, and surgical subspecialists, as well as pediatric pathologists, pediatric radiation oncologists, and allied pediatric health professionals. The dramatic improvements in survival of pediatric patients with cancer are the result of treatment by such teams with experience in the evaluation, staging, surgical management, radiation treatment, and administration of intensive chemotherapy regimens to these children.

Surgery plays two roles in the management of solid tumors. The first role is establishing a histologic diagnosis and staging the tumor; the second is resection of the primary site of disease. It is increasingly important that the surgeon work in a collaborative fashion with the pediatric oncologist and radiation oncologist, since resection may be best accomplished after initial chemotherapy and radiotherapy. These initial treatments may decrease both the potential risks of resection and the long-term morbidity. Similarly, it is critical that the surgeon be involved from the outset in the care of a child presenting with a solid tumor since an inappropriately performed biopsy of the tumor may complicate later resection efforts. Questions regarding timing and feasibility of resection should only be considered by surgeons who are facile in reconciling the sometimes competing demands of durable local control and optimal functional outcome in a growing child. In light of the exquisite

radiosensitivity of most pediatric solid tumors, all deliberations concerning timing and extent of resection efforts must recognize the importance of radiotherapy as an effective adjunct in efforts to secure local control.

Advances in anesthetic management of infants and children have contributed greatly to the surgical resection of solid tumors. Procedures that were performed in the past with a significant mortality, such as hepatectomy and extensive retroperitoneal resections, are now accomplished on a routine basis with limited risk. The duration of a procedure with modern anesthetic techniques is also rarely a consideration. Although the length of anesthesia was once a major determinant of operative morbidity and mortality, duration of a procedure is now rarely an issue.

Significant advances have also been achieved in postoperative pain management. Epidural catheters and continuous intravenous infusions of narcotics by mechanical pumps have greatly limited the severity of pain following extensive resections. Improvements in pain management have permitted more rapid mobilization of postoperative patients, with a corresponding decrease in the risk of pneumonia.

These advances in surgical management have been complemented by substantial improvements in radiation planning and delivery. Conformal radiotherapy using three-dimensional treatment planning to spare normal tissues has had a salutary effect on functional outcome. Advances in our knowledge of radiation dosing and planning techniques are discussed separately under each specific tumor type.

## WILMS' TUMOR

Wilms' tumor is the most common primary malignant renal tumor of childhood. The striking success of national cooperative studies in improving survival and decreasing treatment-related morbidity mark this disease as the paradigm for multimodal treatment of a pediatric malignant solid tumor.

### EPIDEMIOLOGY AND GENETICS

The incidence rate of Wilms' tumor is 7.9 cases per 1 million in white children younger than 15 years of age.<sup>1</sup> The incidence rate is approximately three times higher for African Americans in the United States and blacks in Africa than for East Asians, with rates for white populations in Europe and North America between these extremes.<sup>27</sup>

Wilms' tumor in the United States is slightly less frequent in boys than in girls. The tumor presents at an earlier age among boys, with the mean age at diagnosis for those with unilateral tumors being 41.5 months compared with 46.9 months among girls. The mean age at diagnosis for those who present with bilateral tumors is 29.5 months for boys and 32.6 months for girls.<sup>28</sup>

Children with Wilms' tumor may have associated anomalies, including aniridia, hemihypertrophy (as an isolated abnormality, or as a component of the Beckwith-Wiedemann syndrome), cryptorchidism, and hypospadias.<sup>29,30</sup> and <sup>31</sup> Children with pseudohermaphroditism and renal disease (glomerulonephritis or nephrotic syndrome) who develop Wilms' tumor may have the Denys-Drash syndrome,<sup>32,33</sup> which is associated with mutations within the same gene implicated in the Wilms' tumor, aniridia, genitourinary malformations, mental retardation (WAGR) syndrome.<sup>34</sup>

Wilms' tumor has become an important model for the study of fundamental mechanisms of tumorigenesis. The etiology of Wilms' tumor was thought to follow the two-event model proposed by Knudson to explain the pattern of retinoblastoma. Case reports of the familial occurrence of Wilms' tumor, however, remain uncommon. Approximately 1.5% of National Wilms' Tumor Study Group (NWTSG) cases have one or more family members with the disease.<sup>26,35</sup> In the absence of a history of parental consanguinity in such families, the mode of inheritance is generally thought to be autosomal dominant, with variable penetrance and expressivity. The rate of synchronous and metachronous bilaterality among NWTSG familial cases is significantly higher than for the NWTSG population as a whole. In addition, the mean age at diagnosis for familial unilateral or familial bilateral cases is significantly lower than the corresponding group of sporadic cases.<sup>35</sup>

Predicting the outcome in multicentric disease is likely to be more complex than previously imagined because of the emerging evidence for genetic heterogeneity. Mechanisms other than an inherited mutation may account for at least some of the bilateral and multicentric cases. Analysis of the epidemiologic and clinicopathologic features of Wilms' tumor patients led NWTSG investigators to suggest that some bilateral and multicentric tumors may arise from somatic mosaicism rather than germline mutation.<sup>25,26</sup> They also suggested that the disease comprises at least two pathogenetic entities that are identifiable on the basis of distinct precursor lesions.<sup>36</sup>

### PATHOLOGY

Wilms' tumor is characterized by tremendous histologic diversity and is thought to be composed of, or derived from, primitive metanephric blastema. Most Wilms' tumors are unicentric lesions, although a substantial number arise multifocally in the kidney. Among 1905 NWTSG cases, approximately 5% involved both kidneys either at initial presentation or subsequent to diagnosis. An additional 7% of reported cases were multicentric unilateral tumors.<sup>26</sup> There is no predilection for either side. The tumor may arise anywhere within the kidney, which is usually markedly distorted by the neoplasm.

The most distinctive microscopic feature of Wilms' tumor is its structural diversity. The classic nephroblastoma is made up of varying proportions of three cell types (i.e., blastemal, stromal, and epithelial), but they are not all present in every case.<sup>37</sup> Anaplasia is marked by the presence of gigantic polyploid nuclei within the tumor sample. The new definition of focal anaplasia emphasizes distribution, requiring that cells with anaplastic nuclear changes be confined to sharply restricted foci within the primary tumor. By definition, focally anaplastic disease must not be identifiable in any site outside the renal parenchyma.<sup>38</sup>

Clear cell sarcoma of the kidney is an important primary renal tumor associated with a significantly higher rate of relapse and death than favorable histology Wilms' tumor.<sup>39,40</sup> Clear cell sarcoma of the kidney has a wider distribution of metastases than favorable histology Wilms' tumor. Most clear cell sarcomas of the kidney specimens have a distinct histologic appearance, although a number of variant patterns, such as epithelioid, spindling, myxoid, and cystic patterns, invite confusion with Wilms' tumor or other tumor types.<sup>41,42</sup>

Rhabdoid tumor of the kidney was identified for the first time in 1978 by NWTSG pathologists.<sup>39</sup> The neoplasm, previously confused with Wilms' tumor, is a monomorphous tumor like clear cell sarcoma of the kidney. The cell of origin for this distinctive tumor remains unknown.<sup>43</sup> Rhabdoid tumor of the kidney tends to metastasize to the lung and brain. Several studies have reported that separate primary neuroectodermal tumors of the brain have apparently developed in children with this neoplasm.<sup>44</sup> Primary rhabdoid tumors of the kidney and brain (atypical teratoid/rhabdoid tumors) share deletions of chromosome band 22q11.2.<sup>45</sup> This deleted locus appears to be the site of INI1, a putative tumor suppressor gene.<sup>46,47</sup>

The existence of precursor lesions to Wilms' tumor has been recognized for many years.<sup>48,49</sup> They take the form of small, usually microscopic clusters of blastemal cells, tubules, or stromal cells that are generally situated at the periphery of the renal lobe. The lesion that occurs within the deeper cortex of medulla has been termed an *intralobar nephrogenic rest* in contrast with the more commonly encountered *perilobar nephrogenic rest*. One or both of these variants are encountered in the renal parenchyma of approximately 30% of Wilms' tumor cases.<sup>36</sup> These nephrogenic rests are present in approximately 1% of random perinatal postmortem examinations.<sup>49</sup>

Congenital mesoblastic nephroma is important to recognize since it is usually curable by nephrectomy alone.<sup>50</sup> These tumors are typically identified in the first months of life, with a median age at diagnosis of 2 months.

### CLINICAL PRESENTATION AND NATURAL HISTORY

Most children with Wilms' tumor come to medical attention because of abdominal swelling or the presence of an abdominal mass. This feature is usually noticed by a parent while bathing or dressing the child. Abdominal pain, gross hematuria, and fever may be present at diagnosis. Hypertension, present in approximately 25% of cases, has been attributed to an increase in renin activity.<sup>51</sup>

During the physical examination, it is important to note the location and size of the abdominal mass and its movement with respiration. A varicocele secondary to

obstruction of the spermatic vein may be associated with the presence of a tumor thrombus in the renal vein or inferior vena cava. It is also important to note specifically any signs of the Wilms' tumor-associated syndromes marked by the presence of aniridia, partial or complete hemihypertrophy, and genitourinary abnormalities, such as hypospadias and cryptorchidism.

## STAGING

The staging system currently employed by the NWTSG is shown in [Table 44.2-3](#).

Stage	Description
I	When histologic examination of the histology reveals a completely unencapsulated tumor which is limited to the renal parenchyma and does not extend beyond the renal capsule, the tumor is staged as stage I. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated.
II	When histologic examination of the histology reveals a completely unencapsulated tumor which is limited to the renal parenchyma and does not extend beyond the renal capsule, the tumor is staged as stage II. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated.
III	When histologic examination of the histology reveals a completely unencapsulated tumor which is limited to the renal parenchyma and does not extend beyond the renal capsule, the tumor is staged as stage III. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated.
IV	When histologic examination of the histology reveals a completely unencapsulated tumor which is limited to the renal parenchyma and does not extend beyond the renal capsule, the tumor is staged as stage IV. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated. The tumor may be completely unencapsulated, or it may be partially encapsulated, or it may be completely encapsulated.

**TABLE 44.2-3.** National Wilms' Tumor Study Group Staging System for Renal Tumors

## EVALUATION

Laboratory evaluation should include a complete blood cell count, differential white blood cell count, platelet count, liver function tests, renal function tests, serum calcium, and urinalysis. Elevation of the serum calcium may occur in children with rhabdoid tumor of the kidney or congenital mesoblastic nephroma. <sup>52</sup>

## DIAGNOSTIC IMAGING

Imaging studies initially should be restricted to those necessary to establish the presence of an intrarenal space-occupying lesion. These studies should also be directed at identifying the presence of a contralateral kidney, which must be assessed for possible tumor involvement. In addition, imaging of the affected kidney must look for evidence of tumor thrombus in the renal vein and measure its proximal extent.

The initial radiographic study often selected is an abdominal ultrasound examination. This demonstrates whether the abdominal mass is solid or cystic and may allow identification of the mass's organ of origin and measurement of the maximum diameter of the mass. Contrast-enhanced computed tomography (CT) of the abdomen, performed to further evaluate the nature and extent of the mass, may suggest apparent extension of the tumor into adjacent structures such as the liver, spleen, and colon ([Fig. 44.2-2](#)). However, most children believed to have invasion of the liver on CT are found to have hepatic compression at the time of surgery, rather than hepatic invasion. <sup>53</sup> The examination also may demonstrate small lesions that may be nephrogenic rests or Wilms' tumor in the opposite kidney. Small superficial or intrarenal lesions are frequently not identified even when CT is employed. <sup>54</sup>

**FIGURE 44.2-2.** Computed tomography scan of abdomen demonstrating bilateral renal tumors (*arrows*).

The patency of the inferior vena cava may be demonstrated relatively inexpensively using real-time ultrasonography. When tumor is identified within that vessel, the proximal extent of the thrombus must be established before operation. Extension of the thrombus to the right atrium may produce few, if any, clinical signs and may not be suspected preoperatively. <sup>55,56</sup>

The results of the radiographic studies and real-time ultrasonography provide sufficient information to support proceeding with a laparotomy in most children, although no imaging study unequivocally establishes the histologic diagnosis of Wilms' tumor.

Plain chest radiographs should be obtained to determine if pulmonary metastases are present. Insufficient data are currently available to firmly establish the need for CT of the chest in the initial evaluation of children with Wilms' tumor. Substantial interobserver variation exists in the interpretation of chest CT scans of children with Wilms tumor. <sup>57</sup> The available data suggest that, in many cases, nodules identified are not metastatic tumor. Thus, at least one nodule should be biopsied to confirm the stage.

A radionuclide bone scan and skeletal survey should be obtained postoperatively on all children with clear cell sarcoma of the kidney and all children, regardless of histologic type, with pulmonary or hepatic metastases who have suggestive symptomatology. Both studies are necessary due to the potential of clear cell sarcoma of the kidney to cause lytic bony lesions, which may be evident on plain radiographs but undetectable on bone scan. <sup>58,59</sup>

In light of the association of intracranial metastases with both clear cell sarcoma and rhabdoid tumor of the kidney, children with either of these histologies should undergo brain imaging. <sup>43,60</sup>

## TREATMENT

### Surgery

Resection is the primary means of achieving local control in Wilms' tumor, with radiotherapy reserved for locally advanced or metastatic disease. Accurate surgical staging is critical as it determines subsequent requirements for chemotherapy and radiotherapy based on penetration of renal capsule by tumor, regional lymph node involvement, and residual tumor. These factors cannot be determined radiographically with sufficient sensitivity for treatment planning. A review of children treated in NWTSG-4 demonstrated an increased incidence of local recurrence in those cases in which lymph node biopsies were not obtained. <sup>61</sup> Presumably, these children were understaged and thus, undertreated. The increased incidence of local recurrence in these cases highlights the need for complete surgical staging.

Initial resection of the tumor has been the policy supported by the NWTSG through all of its protocols. Despite the presentation of most Wilms' tumors as a large mass, resection is generally feasible. In contrast to neuroblastoma, attempted resections of Wilms' tumors are less likely to be complicated by tumor invasion of surrounding organs. Close surveillance of children undergoing initial nephrectomy in the NWTSG-3 cohort demonstrated an operative complication rate of 19.8% in a group closely followed and evaluated.<sup>62</sup> The most frequent complication was intestinal obstruction, occurring in 6.9%, followed by extensive intraoperative hemorrhage in 5.8% of cases.<sup>63</sup> Injuries to other visceral organs (1%) and extensive vascular injuries (1.4%) were much less frequent. Factors that correlated with increased risk of surgical complications included advanced local stage, intravascular extension of the tumor, and resection of other organs. Resected adjacent organs were often found to be merely compressed or distorted by the tumor rather than directly infiltrated. Extensive resection involving removal of other organs or procedures that may carry a high risk of morbidity or mortality should be avoided. In such cases of extensive disease, initial surgery should be limited to a biopsy, followed by administration of chemotherapy. Resection can be more readily performed after the tumor has regressed.

The International Society of Pediatric Oncology (SIOP) has promoted the use of preoperative treatment of children with Wilms' tumor with radiotherapy or chemotherapy, without histologic confirmation of the diagnosis before therapy is initiated. They report a lower surgical complication rate of 8% by following this policy.<sup>64</sup> This approach has several risks, including (1) the potential for administration of chemotherapy for benign disease; (2) modification of the tumor histology; (3) loss of staging information; and (4) delivering treatment that is inappropriate for a particular histology (e.g., rhabdoid tumor of the kidney). Treatment without an initial diagnosis is difficult to support when NWTSG and SIOP studies have both demonstrated a 7.6% to 9.9% rate of benign or other malignant diagnosis in children with a pre-nephrectomy diagnosis of Wilms' tumor.<sup>65,66</sup>

A major driving factor for the use by SIOP of preoperative therapy was the high rate of operative tumor rupture in their early series. This rate decreased from 33% to 4% in the SIOP series when pre-nephrectomy abdominal radiation was given. However, 33% is an extremely high frequency of this complication.<sup>66</sup> Operative rupture occurred in NWTSG-1 and NWTSG-2 in 22% and 12% of children, respectively. In NWTSG-4, operative rupture occurred in 14% of cases.<sup>65,67,68</sup> A subsequent randomized SIOP study reported that the rate of rupture was essentially the same for children receiving abdominal radiation and dactinomycin (8%) and those receiving vincristine and dactinomycin (6%).<sup>69,70</sup> In two consecutive nonrandomized studies, the proportion of stage II lymph node-negative children versus stage II lymph node-positive and stage III changed from 45% to 32% and 33% to 19%, suggesting that the preoperative treatments significantly decreased the apparent stage of the children's disease.<sup>71</sup> Evaluation of NWTSG-4 clearly demonstrates that operative rupture, whether localized to the renal fossa or diffuse in the peritoneal cavity, is associated with an increased incidence of local recurrence.<sup>68</sup> This supports the need to avoid rupture by use of an adequate abdominal or thoracoabdominal incision to safely remove the tumor.

Adequate biopsy of lymph nodes in the renal hilum and along the vena cava or aorta is critical for staging. The surgeon must always consider the possibility of stage III disease, and obtain adequate tissue for its diagnosis. While grossly involved lymph nodes are generally resected, this approach should not be extrapolated into a recommendation for an extensive retroperitoneal lymph node dissection since this has not been shown to improve local control.<sup>72</sup>

The histologic diagnosis following preoperative treatment in a group of children followed by the NWTSG did not appear to have been distorted by treatment. It is less certain, however, that the pathologic findings that would determine staging were not altered by preoperative therapy.<sup>73</sup> A SIOP study randomized the use of local radiotherapy (20 Gy) in children treated preoperatively with chemotherapy who had stage II node-negative disease at resection. The study was terminated after randomization of 123 children because of an increased incidence of abdominal recurrence during the first year of follow-up in the children not receiving radiation (six vs. zero).<sup>74</sup> This difference in outcome suggested that pre-nephrectomy treatment altered the pathologic findings that would otherwise have led to a diagnosis of stage III disease (i.e., lymph node involvement or capsular penetration) and inclusion of local radiation.

Preoperative treatment of Wilms' tumor is generally accepted in certain circumstances. These include the occurrence of Wilms' tumor in children with a solitary kidney, bilateral renal tumors, tumor in a horseshoe kidney, and respiratory distress from extensive pulmonary metastases. In most instances, pretreatment biopsy should be obtained. In children with bilateral disease or involvement of a solitary kidney, preoperative chemotherapy is intended to permit maximal conservation of uninvolved renal parenchyma. Studies on pretreatment of children with unilateral tumors have demonstrated that in most instances a complete nephrectomy is still required due to extensive involvement with the kidney at presentation.<sup>74</sup>

In the bilateral cases, preservation of normal renal tissue is a more critical issue. In these children the contralateral tumor often is smaller and more amenable to a partial nephrectomy after treatment with chemotherapy. Concerns about long-term renal impairment following removal of more than one-half of the renal parenchyma have resulted in a less radical surgical approach to the treatment of these children.<sup>75</sup>

The goal of therapy in bilateral cases is first, to eradicate all tumor, and second, to preserve as much renal tissue as possible to minimize the frequency of chronic renal failure.<sup>76,77</sup> The management presently recommended is initial bilateral renal biopsy and staging. Children then receive combination chemotherapy based on the stage and histology. A reevaluation is performed after 5 weeks to determine if there has been sufficient response of the tumors to allow tumor resection, with preservation of a substantial amount of normal renal tissue. Additional chemotherapeutic agents, such as doxorubicin, with or without radiation therapy, may be necessary for the management of children whose tumors respond poorly to the combination of vincristine and dactinomycin.

The absence of radiographic response or evidence of radiographic progression does not always imply lack of histologic response. Fetal rhabdomyomatous nephroblastoma is being recognized with increasing frequency as an entity with a favorable prognosis that may be misinterpreted as chemotherapy-resistant tumor in the absence of histologic confirmation.<sup>78,79</sup> This potential lack of concordance between radiographic and histologic response mandates that changes in chemotherapy, the addition of radiation therapy, or both in the management of children with bilateral or inoperable tumors should only be made after evaluation of a posttreatment biopsy.

In the most recent NWTSG series (NWTSG-4), 98 children with bilateral Wilms' tumors underwent a partial nephrectomy.<sup>80</sup> One hundred thirty-four kidneys were managed with renal salvage procedures (120 partial nephrectomies and 14 enucleations). Definitive surgical resection was performed at initial operation in 58 kidneys (34 were salvage procedures). Complete resection of gross disease was accomplished in 118 (88%) of the 134 kidneys. The higher incidence of positive surgical margins (21%) and local tumor recurrence (8.2%) seen in this group of children compared with children with unilateral tumors was justified by the attempts to maximize renal preservation. Local recurrence occurred in only one of the children with gross residual disease or positive margins. Overall, 72% of the kidneys were preserved, and the 4-year survival rate was 81.7%. In a similar effort, the United Kingdom Children's Cancer Study Group reported on 70 children with bilateral Wilms' tumor.<sup>81</sup> The majority (57) had initial biopsy and chemotherapy with delayed resection, whereas the rest had initial surgical resection. Overall survival of 69% was similar in both groups (initial vs. delayed resection), as was the 80% incidence of normal renal function. Only the estimated mean preserved renal mass differed between the two groups, with 45% preservation when surgery was delayed versus 35% in patients with surgery at initial diagnosis.

Intracaval or intraatrial extension of a tumor thrombus is an uncommon event, occurring in 4% of children with Wilms' tumor. Identification of vascular extension by preoperative radiographic studies or by palpation early in the surgical exploration is critical to avoid embolization during mobilization of the kidney. Traditionally, vascular extension has been managed by resection during nephrectomy. Cardiopulmonary bypass is used for atrial extension. This approach has been associated with a significant risk of complications. In one NWTSG report, 23 children with vascular extension were treated initially with chemotherapy after biopsy of the renal mass. Complete resolution of the tumor thrombus occurred in seven children, and all lesions except one decreased in size.<sup>56</sup> Of the 14 children with tumor initially extending into the atrium, only 4 had residual atrial involvement at resection requiring sternotomy and bypass. Tumor embolism did not occur during chemotherapy. This study suggests that children with atrial or caval involvement generally require less extensive resection after preliminary treatment with combination chemotherapy.

Gross hematuria in children with Wilms' tumor is infrequent, but should lead to suspicion of extensive involvement of the renal pelvis with possible extension into the ureter. Cystoscopy should be considered in these children to identify extension of the tumor into the bladder and avoid transection of the tumor with division of the ureter. Ureteral extension that is recognized and entirely resected does not increase the stage of the tumor.

Exploration of the contralateral kidney has been recommended by the NWTSG based on the 5% occurrence of synchronous lesions. Exploration of the renal fossa by opening Gerota's fascia to directly examine the anterior and posterior aspects of the kidney is suggested. A review of children with bilateral tumors treated on NWTSG-4 identified 9 of 122 children in whom the diagnosis of bilateral disease was missed by the preoperative imaging studies [CT, ultrasonography, or magnetic resonance imaging (MRI)].<sup>54</sup> All but one of these lesions were small, with five being less than 1 cm and three being 1 to 3 cm in diameter. CT was found to be more sensitive for diagnosing contralateral disease than ultrasonography. Thus, 7% of the 5% of children presenting with bilateral disease would have been missed if exploration had not been performed, or an incidence of 0.35% among children with Wilms' tumor. This low frequency explains why more recent studies with smaller

numbers of children have reached other conclusions.

The role of surgery in the treatment of pulmonary relapse has been evaluated by the NWTSG in 211 patients. While diagnostic confirmation of relapse may be required, there was no therapeutic benefit identified to resection of a solitary pulmonary metastasis in addition to pulmonary radiotherapy and chemotherapy alone.<sup>82</sup> Four-year survival rates were identical in the two groups.

### **Radiation Therapy**

Pioneering radiation oncologists noted that Wilms' tumors were responsive to radiation therapy. This modality then became routine postoperative treatment at Children's Hospital, Boston, where many of the initial observations concerning the management of these children were made.<sup>83</sup> First, the treatment volume was extended across the midline to include the entire circumference of the implicated vertebral bodies.<sup>84</sup> This was done to equalize the growth suppression; irradiation of only one side of a vertebra had been shown to lead to an obligatory scoliosis convex away from the irradiated side.

The original radiation therapy concepts have been modified as the result of the clinical trials conducted by the NWTSG. For example, the age-adjusted dosages were shown to be unnecessary in tumors of favorable histology. The advent of effective drugs had a profound effect, not only on the general management of these children, but also on the indications for the administration of postnephrectomy abdominal irradiation. Presumed microscopic residual disease in the tumor bed of children with stage I favorable histology Wilms' tumor can be successfully treated with combination chemotherapy rather than flank irradiation. This was demonstrated in the first two NWTSG randomized clinical trials that indicated the overall relapse-free survival rate in all patients, regardless of age, was similar to that of irradiated patients in NWTSG-1 who had received chemotherapy with only dactinomycin. Retrospective analyses of the data accumulated in NWTSG-1 and NWTSG-2 were conducted to determine the patterns of relapse and to evaluate the relationship between abdominal radiation therapy dose and intraabdominal tumor recurrence.<sup>85,86 and 87</sup> In NWTSG-3, the unirradiated and the irradiated (20 Gy) stage II, favorable histology patients had similar relapse-free survival percentages, as did those with stage III, favorable histology, who received nominal doses of 10 versus 20 Gy. Meanwhile, excellent results continued to be recorded for stage I, favorable histology patients, none of whom received radiation therapy.<sup>88</sup> In summary, NWTSG-1, NWTSG-2, and NWTSG-3 demonstrated that stage I and II patients with favorable histology tumors who receive vincristine and dactinomycin do not require postoperative irradiation. A dose of 1000 cGy is sufficient for local control in stage III, favorable histology patients if they also received chemotherapy with vincristine, dactinomycin, and doxorubicin.<sup>89</sup>

Whole lung irradiation (12 Gy) is recommended for patients who present with pulmonary metastases visible on plain chest radiography. Chemotherapy doses given immediately after the completion of whole lung irradiation are decreased by 50%.

A pilot study conducted by investigators from SIOP produced results similar to those of the NWTSG in stage IV, favorable histology patients following treatment with nephrectomy and chemotherapy only.<sup>90</sup> Patients with persistent or recurrent lung nodules received whole lung radiation therapy or surgical removal of the metastatic lesions or both. Using a similar approach, the United Kingdom Children's Cancer Study Group reported results inferior to those of the NWTSG in this group of patients.<sup>91</sup>

The potential adverse effects of whole lung irradiation and chemotherapy (which includes vincristine, dactinomycin, and doxorubicin as employed in the NWTSG treatment regimens) include radiation pneumonitis or *Pneumocystis carini* pneumonitis, or both. These complications are an important cause of morbidity and mortality in patients with stage IV Wilms' tumor.<sup>92</sup>

Patients with pulmonary lesions identified only on CT of the chest should undergo biopsy of one or more lesions to confirm that they are due to metastatic Wilms' tumor if treatment with whole lung irradiation and doxorubicin is planned. A report from St. Jude Children's Research Hospital suggested that such patients have an increased risk of pulmonary recurrence following treatment with chemotherapy only.<sup>93</sup> A review of the experience with such patients treated on NWTSG-3 and NWTSG-4 did not demonstrate a clear benefit of whole lung irradiation for such patients. The 4-year relapse-free survival rate was 89% among 53 irradiated patients and 80% among 37 unirradiated patients.<sup>94,95</sup> This improvement in relapse-free survival must be balanced against the increase in potential side effects of therapy, leaving the use of whole lung irradiation as a continued source of debate.

### **Chemotherapy**

Wilms' tumor was the first pediatric malignant solid tumor found to be responsive to the systemic chemotherapeutic agent dactinomycin.<sup>96</sup> Other active agents were subsequently identified, including vincristine, doxorubicin, and cyclophosphamide.<sup>51</sup>

## **FAVORABLE HISTOLOGY WILMS' TUMOR**

### **NATIONAL WILMS' TUMOR STUDY-3**

Patients with stage I Wilms' tumor were successfully treated using an 11-week regimen composed of vincristine and dactinomycin without abdominal irradiation. The 4-year relapse-free percentage and overall survival percentage with this regimen were 89.0% and 95.6%, respectively.<sup>88</sup>

Patients with stage II Wilms' tumor were randomized to receive vincristine and dactinomycin or these two drugs and doxorubicin. They were also randomized to receive tumor bed irradiation (20 Gy) or no radiation therapy. The 4-year relapse-free percentage and overall survival percentage for patients who were treated with vincristine and dactinomycin and no abdominal irradiation were 87.4% and 91.1%, respectively. There was no statistically significant difference between these results and those for the remaining three treatment regimens for patients with stage II, favorable histology tumors.<sup>88</sup>

Patients with stage III Wilms' tumor were randomized to treatment with vincristine and dactinomycin or these two drugs and doxorubicin. They were also randomized to receive 10 or 20 Gy of abdominal irradiation. This study demonstrated that these patients benefited from the addition of doxorubicin to the two-drug combination of vincristine and dactinomycin. There was no statistically significant difference in the frequency of intraabdominal relapse among those treated with 10 Gy compared with 20 Gy. Although there was no statistically significant difference in the frequency of intraabdominal relapse in any of the subgroups, there appeared to be a higher frequency among those treated with vincristine and dactinomycin with 10 Gy (7 of 61), compared with those receiving vincristine and dactinomycin with 20 Gy (3 of 68) or vincristine, dactinomycin, and doxorubicin with 10 Gy (3 of 70).<sup>89</sup> The 4-year relapse-free percentage and overall survival percentage of those children treated with vincristine, dactinomycin, doxorubicin, and 10 Gy of abdominal irradiation were 82.0% and 90.9%, respectively.<sup>88</sup>

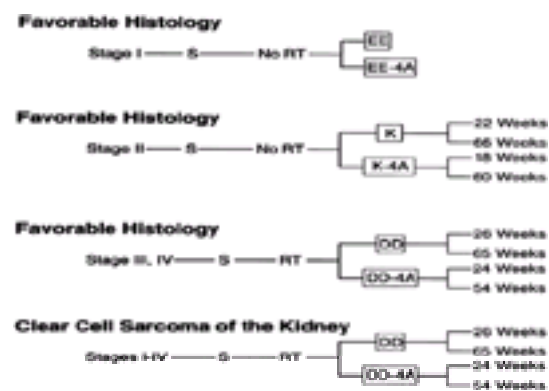

Patients with stage IV Wilms' tumor were randomized to receive vincristine, dactinomycin, and doxorubicin or these three drugs and cyclophosphamide. All underwent immediate nephrectomy, and all received abdominal irradiation (20 Gy) and whole lung irradiation (12 Gy). The 4-year relapse-free percentage and overall survival percentage for the patients treated with vincristine, dactinomycin, and doxorubicin were 79.0% and 80.9%, respectively. There was no statistically significant improvement in the 4-year relapse-free percentage or overall survival percentage from the addition of cyclophosphamide to the three-drug regimen.<sup>88</sup>

### **NATIONAL WILMS' TUMOR STUDY-4**

Previous success in treatment strategies allowed the design of a unique study, NWTSG-4, with the primary aims of continuing to improve treatment results while decreasing the cost of therapy through modification of the schedule of drug administration. This study was based on experimental and clinical data<sup>97,98</sup> demonstrating the safety and efficacy of dactinomycin when administered in a single, moderately high dose.

The design of NWTSG-4 (Fig. 44.2-3) allowed the results of pulse-intensive chemotherapy regimens employing single doses of dactinomycin and doxorubicin to be compared with treatment regimens using divided dose regimens of each drug. In addition, treatment durations of 6 and 15 months were compared in patients with stages II to IV, favorable histology tumors.

**FIGURE 44.2-3.** Treatment randomization for patients entered on National Wilms' Tumor Study-4. Doxorubicin and radiation therapy (RT) are included in the treatment regimen only for patients with stage III or IV Wilms' tumor. EE, K, and DD are regimen designations; RT, radiotherapy; S, surgery.

Toxicity analyses confirmed that the pulse-intensive regimens produce less hematologic toxicity than the standard regimens, and the administered drug dose intensity is greater on the pulse-intensive regimens.<sup>99</sup> Also, an analysis of the cost of chemotherapy treatment suggested that at least \$728,000 per year could be saved if all U.S. children with stages I to IV, favorable histology Wilms' tumor were treated using the pulse-intensive regimens.<sup>100</sup> In addition, there were no statistically significant differences in the 2-year or 4-year relapse-free percentages or overall survival percentage of patients treated with pulse-intensive, compared with standard, modes of chemotherapy administration.<sup>101</sup>

## TREATMENT

These recommendations are based on the results of the NWTSG, which advocates early surgery without preoperative therapy and modulates therapy according to stage and histology. For stage I, favorable or anaplastic histology, stage II, favorable histology, combination chemotherapy with vincristine and dactinomycin is recommended; no abdominal radiation therapy is necessary. For stage III, favorable histology, combination chemotherapy with vincristine, dactinomycin, and doxorubicin and postnephrectomy abdominal radiation therapy are recommended. For stage IV, favorable histology, combination chemotherapy with vincristine, dactinomycin, and doxorubicin and postnephrectomy abdominal radiation therapy if renal tumor is stage III are recommended; all patients with pulmonary metastases receive whole lung radiation therapy. For stages II through IV, anaplastic histology, combination chemotherapy with dactinomycin, vincristine, doxorubicin, and cyclophosphamide is recommended; all patients receive abdominal radiation therapy; and all patients with pulmonary metastases receive whole lung radiation therapy. For stages I through IV, clear cell sarcoma of the kidney, combination chemotherapy with vincristine, dactinomycin, and doxorubicin is recommended; all patients receive abdominal radiation therapy; and all patients with pulmonary metastases receive whole lung radiation therapy.

## Prognostic Factors

Tumor size, age of the patient, histology, lymph node metastases, and local features of the tumor, such as capsular or vascular invasion, have been predictive of outcome. Modern treatments have been so successful that some of these factors no longer pertain.

The results of the first three NWTS were evaluated using logistic regression analysis. Children entered on NWTS-1 who were younger than 24 months of age had a significantly better prognosis than those who were older. The relapse rate was 14.8% for those younger than 2 years of age, compared with 34.7% for those between 2 and 4 years old, and 27.6% for those older than 4 years.<sup>102</sup>

The histology of Wilms' tumor was identified as the most important determinant of prognosis. More recent analyses have confirmed the importance of histopathology and lymph node involvement, whereas the prognostic significance of other factors, such as age and tumor size, changes as treatment efficacy improves.<sup>102,103 and 104</sup>

## NEUROBLASTOMA

### EPIDEMIOLOGY AND GENETICS

Neuroblastoma is the most common malignant intraabdominal tumor in children. Based on the most recent epidemiologic survey compiled in 1995, neuroblastoma (including ganglioneuroblastoma) occurs at an annual rate of 9.1 cases per 1 million U.S. children younger than 15 years of age.<sup>1</sup> Neuroblastoma occurs more frequently in boys than in girls. The median age at diagnosis was 2 years for both boys and girls.<sup>51</sup>

Neuroblastoma has been pathologically documented in additional members of immediate and extended families, including parents, siblings, twins, and cousins.<sup>51</sup> Mediastinal or cervical neuroblastoma is associated with heterochromia and Horner's syndrome.<sup>105</sup> Patients with neuroblastoma have been diagnosed with several other conditions, including neurofibromatosis, Beckwith-Wiedemann syndrome, and Hirschsprung's disease.<sup>51</sup>

Neuroblastoma *in situ* was identified in 0.37% to 2.58% of infants younger than 3 months of age who died of other causes and underwent autopsy examination.<sup>51</sup> This finding suggests that the frequency of neuroblastoma may be higher than indicated by figures derived from death certificate diagnoses or clinical (pathologic) diagnoses. Many *in situ* neuroblastomas may undergo involution or maturation or both.

### PATHOLOGY

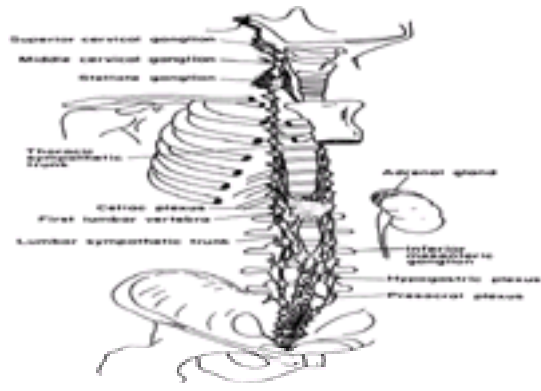

The microscopic features of a typical neuroblastoma include the presence of nests of tumor cells, separated by fibrovascular septa, with additional areas of hemorrhage, calcification, and necrosis. The tumor cells are uniform round cells with a round hyperchromatic or densely speckled nucleus. Mitoses are not frequent. Homer-Wright rosettes, with a central fibrillar core, may be present.<sup>106</sup> Lymphocytic infiltration may be observed. Neuroblastoma may contain mature elements, including ganglion cells.

Histochemical stains may aid in the differentiation of neuroblastoma from other common pediatric solid tumors. The periodic acid-Schiff stain result is generally negative, and neuron-specific enolase is generally positive.<sup>107</sup>

Shimada and colleagues developed a histologic classification of neuroblastomas based on the separation of tumors into two large groups: stroma-rich and stroma-poor tumors based on the presence or absence of schwannian spindle cell stroma. Stroma-poor tumors were further subdivided into those that were differentiated and those that were undifferentiated. Stroma-rich tumors were subdivided into those that were nodular, well-differentiated, or mixed. These histopathologic features were evaluated along with other characteristics, including patient age and the mitotic-karyorrhexis index for their importance in predicting prognosis. Patients with nodular, stroma-rich histology and undifferentiated, stroma-poor histology had a poor prognosis. This histologic classification was based on an examination of 295 pathologic specimens from a population of patients, of whom only 25% had stage IV (Evans') disease.<sup>108</sup> This stage distribution is not representative of unselected series of neuroblastoma patients. Several subsequent reports have evaluated the Shimada classification in case series that included patients with advanced disease.<sup>109,110</sup> There may be a high degree of overlap between classification as a ganglioneuroblastoma and stroma-rich tumors.<sup>111</sup> The International Neuroblastoma Pathology Committee has developed a modification of the Shimada system<sup>112</sup> that was validated in a case-cohort sample of 227 neuroblastic tumors.<sup>113</sup> The International Neuroblastoma Pathology Classification (the Shimada system) is proposed for international use in assessing neuroblastic tumors. Further statistical evaluation of this histopathologic classification and its correlation with other prognostic variables, such as age at diagnosis, stage, primary tumor site, and biologic variables (i.e., N-myc copy number and DNA ploidy), is necessary to establish the importance of histopathologic grading for the management of children with neuroblastoma.

## CLINICAL PRESENTATION AND NATURAL HISTORY

Neuroblastoma may originate from any sympathetic nervous system tissue in the body (Fig. 44.2-4). The most common site of origin of neuroblastoma is within the abdomen. The adrenal gland is the primary tumor site in 38% of cases. Other intraabdominal sites include the paravertebral sympathetic ganglia, celiac ganglion, superior mesenteric ganglion, and inferior mesenteric ganglion. The remaining patients with neuroblastoma have tumors that originate in the thorax or neck.<sup>51</sup>

**FIGURE 44.2-4.** Neuroblastoma may originate from the adrenal gland or any sympathetic nervous system plexus. (From House EL, Pansky B. General visceral efferent system. In: *A functional approach to neuroanatomy*, 2nd ed. New York: McGraw-Hill, 1967:281, with permission.)

Infants and children with neuroblastoma come to medical attention with a variety of signs and symptoms, most commonly the presence of abdominal swelling or an abdominal mass. Abdominal or thoracic paravertebral tumors frequently cause symptoms referable to the central nervous system. Children with hematogenous metastases may complain of pain in one or more bones or present with periorbital swelling or ecchymoses. Fever is present in 23% of patients at diagnosis. Uncommon clinical presentations include hydrops fetalis,<sup>51</sup> chronic diarrhea due to secretion of vasoactive intestinal polypeptide by the tumor,<sup>51,114</sup> and myoclonus-opsoclonus.<sup>51</sup> Jones and coworkers reported that 50% (8 of 16) of patients evaluated for acute cerebellar encephalopathy were found to have neuroblastoma.<sup>115</sup> Although the prognosis for complete recovery from the movement disorder is poor,<sup>116,117</sup> and <sup>118</sup> treatment with intravenous gamma globulin<sup>119</sup> has been effective in some patients, supporting an autoimmune etiology for this disorder.<sup>120</sup> Hypertension is an uncommon presenting sign in children with neuroblastoma.<sup>121</sup>

Infants and children with neuroblastoma frequently present with hematogenous metastases. These were identified in 62% of patients. The most frequently involved sites were bones, liver, bone marrow, lung, and skin.<sup>51</sup>

Normal sympathetic tissues secrete the catecholamines epinephrine and norepinephrine. Most patients with neuroblastoma have increased urinary excretion of vanillylmandelic acid, homovanillic acid, dihydroxyphenylalanine, dopamine, and norepinephrine at the time of diagnosis.<sup>51</sup>

Mass screening of infants at 4 months of age has been employed in Kyoto, Japan, since 1974, and throughout Japan since 1985. Data from both Kyoto and Sapporo suggest that mass screening has resulted in a decrease in the incidence of neuroblastoma among older children and a decrease in the percentage of patients who have metastatic disease at diagnosis.<sup>122,123</sup> However, the absence of adequate data have precluded the demonstration that screening in Japan has altered the mortality due to neuroblastoma. Population-based screening of 3-week-old infants has been conducted in Quebec province, Canada.<sup>124</sup> Because excellent population-based data on incidence, survival, and mortality are available,<sup>125</sup> these studies address the questions raised by the studies from Japan. Unfortunately, the Canadian experience has paralleled the outcome of the Japanese efforts. Mass screening in both countries has led to the preclinical identification of increased numbers of infants with favorable tumor biology. Most of these infants would have had an excellent prognosis with little, if any, therapy. Neither screening effort has had any effect on the number of children identified with clinically advanced disease and unfavorable tumor biology. To date, newborn screening has had a negligible effect on survival and may have led to overtreatment of children with good prognostic features.<sup>126,127</sup>

## STAGING

Local features of neuroblastoma that can be related to treatment success include the extent of the primary tumor and the presence or absence of lymph node metastases. Dissemination of tumor to the liver, subcutaneous tissue, bone marrow, and bones can also influence prognosis.

Evans and colleagues developed a staging system, first reported in 1971, that considered the extent of the primary tumor, the presence or absence of regional lymph node tumor metastases, and the presence or absence of hematogenous metastases in determining the tumor stage. This system recognized the existence of a unique group of infants with small primary tumors and liver, skin, and bone marrow metastases, but without positive findings in the skeletal survey (stage IVS). This system demonstrated the favorable prognosis of patients with localized primary tumors, but did not consider the possible independent effects of lymph node involvement or surgical excision on prognosis.<sup>128</sup>

A new staging system, the International Neuroblastoma Staging System, was proposed in 1988.<sup>129</sup> Because of ambiguity regarding the classification of tumors originating near the midline and having a favorable prognosis,<sup>130</sup> the staging system was revised in 1993.<sup>131</sup> This staging system, recommended for adoption by the Children's Cancer Group (CCG) and the Pediatric Oncology Group (POG), is shown in Table 44.2-4.

Stage	Description
I	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor cells; resectable (nodes attached to and removed with the primary tumor may be positive).
IIA	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
IIB	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Contralateral lymph nodes must be negative microscopically.
III	Unresectable unilateral tumor infiltrating across the midline (defined as the vertebral column), with or without regional lymph node involvement; or localized unilateral tumor with contralateral lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
IV	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs (except as defined for stage IVS).
IVS	Localized primary tumor (as defined for stage I, IIA, or IIB), with dissemination limited to skin, liver, or bone marrow (less than 10% of resected cells identified as malignant), limited to infants younger than 1 year of age.

**TABLE 44.2-4.** International Neuroblastoma Staging System

## CLINICAL EVALUATION

The evaluation of a child suspected to have neuroblastoma begins with a careful history. The maternal history should be examined for the use of tranquilizers, anticonvulsant medications, and the abuse of alcohol. The review of systems should include careful questioning regarding symptoms such as diarrhea and ataxia. The physical examination should include a careful examination of the skin. Subcutaneous metastases from neuroblastoma are reddish-purple, raised lesions that may be solitary. Periorbital ecchymoses are a frequent finding in children with disseminated tumor. The color of the irises and the location and consistency of the abdominal mass should be noted. A careful neurologic examination should be performed. Occasionally, the tumor mass in a child with paraplegia can be detected only on rectal examination.

The laboratory examination of a child suspected to have a neuroblastoma should include a complete blood cell count, urinalysis, liver and renal function tests, sedimentation rate, serum ferritin, and a urine sample for quantitation of the excretion of vanillylmandelic acid and total catecholamines.

The radiographic evaluation of a child with an abdominal mass suspected to be a neuroblastoma begins with a plain supine examination of the abdomen that may demonstrate the presence of a soft tissue mass frequently having calcification. Abdominal ultrasonography demonstrates the presence of a solid mass that may contain cystic areas.<sup>132</sup> CT provides information regarding the extent of intraabdominal disease that is not obtained with the plain radiography or abdominal ultrasound. However, there is a substantial difference between findings using CT and surgical findings.<sup>133,134</sup> Patients with thoracic neuroblastomas typically have a posterior mediastinal mass demonstrated on plain chest radiography. Calcification is present within this mass less frequently than within primary intraabdominal neuroblastomas. Detailed films of the ribs and vertebral bodies may demonstrate erosion of the adjacent ribs, transverse processes, and widening of the intervertebral foramina.

Patients with paraspinal primary tumors may have asymptomatic extension of the tumor through the spinal foramina. Armstrong and coworkers reported symptoms suggestive of spinal cord or nerve root compression by tumor were present in only 55% of patients with paraspinal neuroblastoma subsequently shown to have such compression at myelography.<sup>135</sup> Due to the increased risk of neurologic compromise with paraspinal tumors, patients with tumors in this location should undergo careful evaluation of the spinal canal using MRI with gadolinium.

All patients should have a conventional skeletal survey, including the long bones, spine, ribs, and skull, and a technetium 99m methylene diphosphonate bone scan. Although most bone metastases are identified using the radionuclide bone scan, occasional lesions, especially in the metaphyses of long bones, are identified only on the conventional skeletal survey.<sup>136</sup>

Bilateral trephine bone marrow biopsies and bone marrow aspirates should be performed. The biopsy is positive in 11% to 30% of children with negative bone marrow aspirate results.<sup>137,138</sup> Bone marrow replacement by tumor is occasionally so extensive that the microscopic picture resembles acute leukemia.<sup>51</sup>

## TREATMENT

### *Surgery*

Surgery plays a major role in the treatment of low-stage neuroblastoma. The surgical approach varies depending on the stage and site of the primary. It is increasingly recognized that the biologic characteristics of the tumor should also contribute to therapeutic decision making. Most thoracic, pelvic, and cervical primaries and limited abdominal lesions that do not extend across the midline to involve the great vessels are resectable at presentation. Surgery alone is curative in many children with low-stage disease. The need for postresection chemotherapy is now frequently determined by the biologic markers of the resected tumor. Reports suggest that even subtotal resection in infants and children with neuroblastoma with favorable biologic features results in a correspondingly favorable outcome and constitutes adequate therapy.<sup>139,140</sup>

Improved survival has been identified in children with more extensive primary tumors (stage III disease) whose tumors were completely resected at initial exploration or during subsequent surgeries following administration of chemotherapy.<sup>141</sup> This improvement in outcome may be more a reflection of favorable biology than a product of skillful surgery. Children previously treated on CCG protocols were reclassified using the International Neuroblastoma Staging System. This study demonstrated a strong correlation between survival and the extent of residual tumor after resection.<sup>142</sup> Histologically, viable neuroblastoma is found in most tumors resected following preliminary chemotherapy, supporting the important role of resection in achieving local control.<sup>143</sup> No difference in survival was found between those children undergoing resection at presentation versus those receiving preliminary chemotherapy.

Neuroblastoma arising in the posterior mediastinum appears to have a favorable prognosis when compared with other primary sites.<sup>144</sup> This has been correlated with a higher incidence of favorable biologic markers in mediastinal tumors.<sup>145</sup> Large tumors are also more readily resected in the chest than in the abdomen where they may surround the aorta, vena cava, renal vessels, celiac axis, and the superior mesenteric artery.<sup>146</sup>

Regrettably, the majority of infants and children present with metastatic disease. In these cases, the initial role of surgery is obtaining diagnostic tissue. Traditionally, surgical diagnosis has employed either a laparotomy or thoracotomy. Improved methods have been developed for percutaneous biopsy with radiographic imaging or biopsy via laparoscopic or thoracoscopic techniques. If these latter methods are used, it is critical that adequate tissue be obtained for evaluation of biologic markers.

Most children with widely disseminated disease have large primaries. Abdominal primaries arising from adrenal or paravertebral sites often encircle the celiac axis and the superior mesenteric vessels. Several studies have demonstrated that resection of these extensive lesions can be best accomplished after initial treatment with chemotherapy. In addition to reducing tumor volume, preoperative chemotherapy decreases the vascularity and friability of the tumor. This neoadjuvant approach has also contributed to decreased operative morbidity,<sup>143</sup> including a lower complication ratio with nephrectomy.<sup>147</sup>

Postoperative diarrhea may complicate resections of extensive tumors surrounding the superior mesenteric or celiac arteries.<sup>148</sup> This increased stool output is presumably produced by disruption of the autonomic nerve supply to the gut and not related to the timing of surgery. Several studies have demonstrated an apparent decrease in the frequency of local recurrences following resection of the primary in stage IV tumors.<sup>149,150 and 151</sup> Improved survival, however, has not been achieved since the majority of these advanced stage patients ultimately succumb to relapse at distant sites.<sup>152</sup> As systemic therapy improves, local control will become more critical. Use of radiolabeled metaiodobenzylguanidine<sup>153</sup> and a hand-held gamma detector to identify sites of neuroblastoma in extensive or recurrent cases has been described. Whether use of these techniques will result in better outcomes has yet to be established.

Attempts should be made to preserve the ipsilateral kidney during resection of the primary tumor in children with stage IV neuroblastoma.<sup>154</sup> Many of these children receive either a bone marrow transplant or nephrotoxic agents, making maximal preservation of maximum renal function an important goal. Children with adrenal or paravertebral primaries generally have metastatic tumor in lymph nodes that wraps around the renal vessels. These must be dissected free to preserve the kidney. The risk of nephrectomy is greatest in children undergoing resection before the administration of chemotherapy.<sup>143</sup>

Infants with stage IVS disease require exploration or a percutaneous biopsy for diagnosis. In most cases resection is not necessary unless the most readily obtained tissue for diagnosis is a small, easily resected primary.<sup>155</sup> There is no convincing evidence that resection of the primary will accelerate or ensure resolution of metastatic disease.<sup>156,157</sup> In fact, one review of 110 infants with stage IVS disease treated by members of the POG showed that there was no statistical difference in survival rate for patients with complete resection of their primary tumor compared with those who underwent partial resection or biopsy only.<sup>158</sup> Decreased survival was associated with age less than 2 months, diploid ploidy, amplification of the N-myc protooncogene, or tumors with unfavorable histology. If a mass remains at the primary site after resolution of the distant disease, resection is often performed and frequently demonstrates a ganglioneuroma or neuroblastoma with extensive maturation. Surgical techniques have been developed for abdominal expansion for infants presenting with extensive hepatomegaly that impairs respiratory function. The abdominal fascia is divided and prosthetic material is inserted to increase the volume of the abdominal cavity.<sup>159,160</sup>

Antenatal diagnosis of neuroblastoma appears to identify a particularly good risk population of infants. The biologic markers on these tumors are favorable. In keeping with their less aggressive biology, infants have done well following resection of the primary tumor.<sup>161</sup> It is not known whether spontaneous regression would occur if these infants were observed, but a report of four infants with antenatal diagnosis of adrenal masses (two solid and two cystic) demonstrated resolution of the abnormalities by 2.5 to 8.0 weeks of age.<sup>162</sup>

### *Radiation Therapy*

Radiation therapy has been used in the treatment of patients with neuroblastoma both to decrease the frequency of local tumor recurrence and to eradicate microscopic or macroscopic distant metastases.<sup>49</sup> Wyatt and Farber systematically treated patients with neuroblastoma with local irradiation. They suggested radiation therapy should be instituted in every case once the diagnosis is established.<sup>163</sup>

Rosen and colleagues reported local control in 100% (14 of 14) of patients with stage I to stage III (Evans') neuroblastoma treated with 10 to 20 Gy, and in 87.5% (21

of 24) of patients treated with 20 to 40 Gy. One patient had recurrence in the treatment volume, whereas two others were considered marginal misses, occurring outside of high-dose boost volumes.<sup>164</sup>

Reports have demonstrated patients with stage I (International Neuroblastoma Staging System) neuroblastoma have a 4-year relapse-free survival percentage of 89% when treated with surgery only.<sup>165</sup> Children with stage II (Evans') neuroblastoma with microscopic residual disease may benefit from local irradiation.<sup>166</sup> The POG randomized patients with stage C neuroblastoma to treatment with postoperative chemotherapy or postoperative chemotherapy and local irradiation (24 to 30 Gy). The 3-year event-free survival percentage was 32% for patients with stage III (Evans') randomized to treatment with combination chemotherapy, compared with 59% for those randomized to the same chemotherapy and local radiation therapy ( $P = .009$ ).<sup>167</sup> Thus, in patients with residual disease or positive lymph nodes, the addition of radiation therapy appears to improve the prognosis. Refinements of these recommendations may be necessary in the future as newer studies that use biologic markers for treatment stratification identify subsets that do or do not benefit from local radiation therapy.

### Chemotherapy

Although two published studies offer a glimmer of hope for metastatic patients treated with dose-intensive regimens incorporating stem cell support,<sup>169,173</sup> prospects for long-term survival in advanced stage disease remain poor despite increasingly toxic therapies. At the other end of the spectrum, trials conducted in patients without evidence of gross residual disease have not demonstrated a survival advantage for adjuvant chemotherapy. A retrospective analysis of patients with *locally* unresected disease, however, demonstrated a clear survival advantage for children treated with teniposide and cisplatin (93%) versus those whose treatment did not include these two drugs (42%;  $P = .02$ ).<sup>170</sup> The role of chemotherapy in these patients must be addressed in future randomized trials.

The poor response of patients with metastatic neuroblastoma to aggressive combination chemotherapy programs stimulated clinical trials that incorporated autologous bone marrow transplantation (ABMT) or peripheral blood stem cell rescue. Event-free survival 2 years after ABMT was reported to be 6% to 64%<sup>171,172</sup> and <sup>173</sup> among progression-free patients with advanced neuroblastoma who received a bone marrow transplant. The spectrum of results may reflect patient selection. A retrospective analysis by the POG showed no significant prognostic benefit of changing, in remission, from conventional therapy to bone marrow transplant.<sup>174</sup> The CCG reported the results of a randomized trial comparing the outcome following intensive chemotherapy without bone marrow transplant to that following ABMT. The 3-year event-free survival was 34%  $\pm$  4% for those randomized to ABMT, compared with 22%  $\pm$  4% for those randomized to continuation chemotherapy ( $P = .034$ ). However, 32% of patients randomized to ABMT did not receive the randomized therapy, whereas 21% of those randomized to continuation chemotherapy did not receive the randomized treatment. ABMT did not improve overall survival compared with continuation chemotherapy. A secondary randomization involving a 6-month course of 13-*cis* retinoic acid following completion of treatment produced a 3-year relapse-free survival rate of 46%  $\pm$  6% for those who received the drug. This outcome compared favorably with the 29%  $\pm$  5% relapse-free survival for patients who were not randomized to treatment with *cis*-retinoic acid ( $P = .027$ ).<sup>168</sup> Current treatment protocols employed by the POG and the CCG stratify patients by stage, age, N-myc status, Shimada histology, and DNA ploidy ( [Table 44.2-5](#)).

International Neuroblastoma Staging System Stage	Age (yr)	N-myc Status	Shimada Histology	DNA Ploidy	Risk Group/Study

**TABLE 44.2-5.** Risk Group and Protocol Assignment Schema: Pediatric Oncology Group and Children's Cancer Group

### Low-Risk Patients

Children with stage I neuroblastoma have an excellent prognosis following excision of the primary tumor without adjuvant therapy. Children with stage II disease with a single copy of N-myc, regardless of histology, have an excellent prognosis following tumor excision alone. Stage II patients with greater than ten copies of N-myc and favorable Shimada histology also have a good prognosis following tumor resection. Despite the amplification of N-myc in this subset of children with localized disease, the favorable Shimada histology has sufficient predictive power that radiation and chemotherapy are not recommended unless recurrence is documented. Perhaps the most unique cohort of low-risk patients consists of asymptomatic infants with disseminated stage IVS neuroblastoma and hyperdiploidy (DNA index greater than 1.0). Since many of these infants spontaneously improve, they should be observed without treatment.

### Intermediate-Risk Patients

Among children without N-myc amplification, those with stage III neuroblastoma who are younger than 12 months of age, stage III patients with favorable Shimada histology who are more than 12 months of age, and those with stage IV neuroblastoma who are less than 12 months of age all have a moderate risk of disease recurrence. Their treatment may include local radiation therapy and combination chemotherapy. As noted previously, infants with stage IVS neuroblastoma require supportive care only. Those younger than 6 weeks of age at diagnosis may have feeding intolerance or respiratory insufficiency due to massive hepatomegaly, mandating a brief course of chemotherapy.

### High-Risk Patients

All children with N-myc amplification, regardless of stage, and all children older than 1 year of age with stage IV neuroblastoma have a substantial risk of disease progression. These children should be treated using study regimens being evaluated by the national or international pediatric clinical trials groups. The role of ABMT is being evaluated in the subgroup of patients who have a favorable response to combination chemotherapy.

## PROGNOSTIC FACTORS

Breslow and McCann evaluated the interaction between age at diagnosis, stage (Evans'), and probability of survival. These investigators confirmed the adverse effect of both increasing age at diagnosis and advanced stage on the probability of survival.<sup>175</sup>

Other clinical investigators have reported lower survival percentages in stage IV (Evans') patients with a vanillylmandelic acid to homovanillic acid ratio of less than 1.5.<sup>176</sup> A poorer prognosis has also been ascribed to stage III and IV (Evans') patients with a neuron-specific enolase level greater than 100 ng,<sup>177</sup> and for stage IV patients (Evans') with serum lactate dehydrogenase greater than 1000 IU.<sup>178</sup>

Look and coworkers reported that patients with hyperdiploid tumor cells had a more favorable response to combination chemotherapy than did patients with diploid tumor cells.<sup>179</sup> Brodeur and colleagues demonstrated the relationship between advanced tumor stage and increased copy number of N-myc,<sup>180</sup> and Nakagawara and associates reported that increased expression of TRK-A was associated with a favorable prognosis.<sup>181</sup> Although several reports have documented the prognostic effect of several of these markers,<sup>181,182</sup> and <sup>183</sup> the retrospective design of the published analyses and the small number of patients with all markers evaluated has prevented an adequate multivariate analysis from being performed. A prospective study in which treatment was not a variable would facilitate this important analysis.

## RETINOBLASTOMA

## EPIDEMIOLOGY AND GENETICS

Retinoblastoma is the most frequent malignant ocular tumor in pediatric patients. The incidence rate per year is 3.8 cases per 1 million U.S. children younger than 15 years of age.<sup>1</sup> Approximately 70% to 75% of all cases are unilateral. Among children with unilateral disease, 10% to 15% have hereditary germline deletions of chromosome 13, band q14, which contains the RB1 tumor suppressor gene locus. Germline mutations of 13q14 uniformly affect the 25% to 30% of children with bilateral disease.<sup>19</sup> Retinoblastoma occurs slightly more frequently in boys than girls, especially among those who have bilateral retinoblastoma. The median age at diagnosis was 2 years for boys and 1 year for girls with unilateral retinoblastoma. In cases of bilateral disease, the median age at diagnosis is less than 12 months for both boys and girls.<sup>51</sup>

Retinoblastoma may occur in children with other anomalies, including congenital cardiovascular defects, cleft palate, Bloch-Sulzberger syndrome, infantile cortical hyperostosis, dentinogenesis imperfecta, incontinentia pigmenti, and familial congenital cataracts.<sup>51</sup>

Although most children with retinoblastoma have normal intellectual function, some patients have been reported who had mental retardation in addition to a constellation of features associated with the deletion of the more distal portion of 13q.<sup>184,185</sup> These features include a broad nasal bridge, hypertelorism, microphthalmos, micrognathia, and variable foot and toe anomalies.<sup>51</sup>

While the majority of new cases of retinoblastoma arise spontaneously from new somatic mutations, a significant, and possibly increasing, fraction of retinoblastoma cases are hereditary. The familial pattern may demonstrate direct transmission of retinoblastoma from parent to child, or the presence of two or more affected offspring from unaffected parents who have affected first-degree relatives. Retinoblastoma is transmitted in each of these situations as a highly penetrant, autosomal dominant trait.<sup>186</sup> An analysis of the offspring of patients with sporadic, bilateral retinoblastoma demonstrated that 49.2% of the offspring developed the disease. This suggests that essentially all patients with sporadic, bilateral retinoblastoma had a germinal mutation that was transmitted in an identical manner as in families with a positive history of retinoblastoma. Approximately 5.5% of the offspring of patients with sporadic, unilateral retinoblastoma developed the disease, suggesting that 9.9% to 12.3% of patients with sporadic, unilateral retinoblastoma actually have a germinal mutation that may be transmitted to their offspring.<sup>187</sup>

A more complex problem in genetic counseling arises when one is asked to estimate the risk of an unaffected member of a sibship with a positive family history for retinoblastoma who carries the retinoblastoma gene. It is also difficult to estimate the risk for recurrence of retinoblastoma in a sibship from unaffected parents with one affected sibling. Nussbaum and Puck have analyzed these situations and developed equations for estimating these various probabilities.<sup>188</sup>

The parents and siblings of all patients with retinoblastoma should have a thorough ophthalmoscopic examination. Retinoblastomas may undergo spontaneous regression, leaving characteristic retinal changes.<sup>189</sup> Margo and associates suggested such lesions were benign at their outset. These lesions indicated the presence of the same mutation found in patients with retinoblastoma, although they occurred in a more mature retinal cell.<sup>190</sup>

## PATHOLOGY

The gross appearance of retinoblastoma is that of a chalky white, friable tumor with dense foci of calcification. Those arising from cells in the internal nuclear layer, nerve fiber layer, ganglion cell layer, or external, nuclear layer grow toward the subretinal space, pushing the retina inward and frequently causing retinal detachment. Such tumors are called the *exophytum type*. Those tumors arising from the inner layers of the retina grow toward the vitreous and are called the *endophytum type*. Multiple foci of tumor are usually present.<sup>191</sup>

Retinoblastoma is composed of uniform small, round, or polygonal cells, which have scanty, poorly staining cytoplasm. The sparse cytoplasm is located at one side of the cell, suggesting the appearance of an embryonal retinal cell. The nucleus is large and deeply staining. Three types of cellular arrangements may be identified: the Homer-Wright rosette (a radial arrangement of cells surrounding a tangle of fibrils), the Flexner-Wintersteiner rosette (a radial arrangement of cuboidal to short columnar cells about a lumen, with the nuclei displaced basally, away from the lumen), and the fleurette (areas composed of pale-appearing cells, with abundant, pale eosinophilic cytoplasm and small, hyperchromatic nuclei; the cells are arranged in a fleur-de-lis pattern). Calcification and necrosis are often observed in retinoblastomas.<sup>192</sup>

## CLINICAL PRESENTATION

Patients with retinoblastoma come to medical attention most frequently because of the presence of leukokoria. Strabismus, conjunctival erythema, or decreased visual acuity are other common presenting complaints. The tumor may be diagnosed during a routine examination performed because of a family history of retinoblastoma or during an examination for an unrelated complaint in patients without a family history of retinoblastoma.<sup>51</sup>

The history obtained during the evaluation of a child with leukokoria should include questions regarding the administration of oxygen following birth, the eating of dirt, or the close association of the patient with a dog. Prolonged administration of oxygen is associated with the occurrence of retrolental fibroplasia. Domestic animals, particularly young puppies, may be infested with *Toxocara canis*, a parasite that may cause an ocular lesion resembling retinoblastoma in some of its clinical features. The family history should be examined for other cases of eye and bone tumors.

The physical examination reveals the presence of a white pupillary reflex. Tumors located near the macula may be readily apparent with direct ophthalmoscopy, whereas those located at the periphery of the retina may not be detected unless the patient looks in a particular direction. Esotropia or exotropia may be identified. The eye may be red and painful due to uveitis following spontaneous necrosis of a retinal tumor or due to glaucoma. Decreased visual acuity may be due to involvement of the macula by the tumor or the presence of cells and debris in the vitreous.<sup>191</sup>

## EVALUATION

The laboratory evaluation of a child suspected of having retinoblastoma should include a complete blood cell count with white blood cell differential, tests of renal and hepatic function, and a urinalysis. An enzyme-linked immunosorbent assay for the detection of *Toxocara* antibody is available. An antibody was detected in the serum of 65% of patients with ocular toxocariasis, indicating this determination may be helpful in differential diagnosis when an antibody is present.<sup>193</sup>

Radiographic evaluation of a child with suspected retinoblastoma may include CT of the orbit or orbital ultrasonography.<sup>194</sup> CT may be used both to define the extent of the intraocular tumor and to determine the presence and extent of extraocular disease. Calcification was identified in orbital CT scans of 48% of patients with retinoblastoma confined to the globe, compared with 13% of patients with tumor extension beyond the globe.<sup>195</sup> Head CT or MRI may identify intracranial extension in patients who have normal plain radiographs of the bones adjacent to the orbit. Retinoblastoma may metastasize to the central nervous system, bones, or bone marrow.<sup>196</sup> The risk of such dissemination is related to the extent of the ocular tumor. A diagnostic lumbar puncture with examination of the cerebrospinal fluid following cytocentrifugation should be performed on all patients with involvement of the choroid, ora serrata, ciliary body, or anterior chamber. It should also be performed on patients with involvement of other extraocular structures, including the orbit or optic nerve, or when symptoms, signs, or diagnostic imaging studies suggest involvement of bones, soft tissues, or the central nervous system.<sup>197</sup>

Radionuclide bone scans should be obtained only for patients with extensive ocular involvement, symptoms suggesting the presence of a bone metastasis, and bone marrow involvement by retinoblastoma.<sup>198</sup>

## STAGING

Martin and Reese proposed the first staging system for patients with retinoblastoma in 1942. The classification segregated patients into large treatment groups and established four categories: (1) unilateral tumors not extending outside of globe; (2) bilateral tumors; (3) residual tumors in the optic nerve or orbit at the time of enucleation or recurrent tumors following enucleation; and (4) widely disseminated retinoblastoma.<sup>199</sup> These investigators recognized the more favorable prognosis of patients with a small flat tumor and the ominous nature of tumors that extended toward the vitreous or into the choroid.<sup>200</sup> Subsequently, those patients with anteriorly located tumors were shown to have an unfavorable prognosis.<sup>201</sup> These factors were considered in developing a more detailed staging system ( [Table 44.2-6](#) ).

Group	Description
Group I	
A	Solitary tumor, less than 4 disc diameters in size, at or behind the equator
B	Multiple tumors, 4 to 10 disc diameters in size, all at or behind the equator
Group II	
A	Solitary tumor, 4 to 10 disc diameters in size, at or behind the equator
B	Multiple tumors, 4 to 10 disc diameters in size, behind the equator
Group III	
A	Any lesion anterior to the equator
B	Solitary tumors larger than 10 disc diameters behind the equator
Group IV	
A	Multiple tumors, some larger than 10 disc diameters
B	Any lesion extending anteriorly to the ora serrata
Group V	
A	Massive tumors involving over half the retina
B	Vitreous seeding

**TABLE 44.2-6.** Staging System for Retinoblastoma (Reese and Ellsworth)

A useful staging system for patients with retinoblastoma must incorporate those features known to influence prognosis, therapy, or both. Simplicity would allow easy adoption of the system by investigators at many treatment centers. The system adopted by the St. Jude Children's Research Hospital incorporates many of these features (Table 44.2-7).<sup>202,203</sup>

Stage	Description
Stage I	Tumor (unifocal or multifocal) confined to retina
A	Occupying one quadrant or less
B	Occupying two quadrants or less
C	Occupying more than 50% of retinal surface
Stage II	Tumor (unifocal or multifocal) confined to globe
A	With vitreous seeding
B	Extending to optic nerve head
C	Extending to choroid
D	Extending to choroid and optic nerve head
E	Extending to extraculus
Stage III	Extraculus extension of tumor (regional)
A	Extending beyond cut end of optic nerve (including subarachnoid extension)
B	Extending through sclera into orbital contents
C	Extending to choroid and beyond cut end of optic nerve (including subarachnoid extension)
D	Extending through sclera into orbital contents and beyond cut end of optic nerve (including subarachnoid extension)
Stage IV	Distant metastases
A	Extending through optic nerve to brain
B	Blood-borne metastases to soft tissues and bones
C	Bone marrow metastases

**TABLE 44.2-7.** Staging System for Retinoblastoma (St. Jude Children's Research Hospital)

## TREATMENT

The diagnosis of retinoblastoma is based on the clinical history of the patient (including the family history) and the results of an examination of both eyes under general anesthesia. Ellsworth suggested the pupils must be maximally dilated and the examination be performed with the binocular indirect ophthalmoscope.<sup>191</sup> Scleral indentation must be performed around the entire circumference of the ora serrata to ensure detection of all anteriorly located tumors. Using scleral indentation, retinoblastoma may be identified in the periphery of the fundus in approximately 65% of patients. These tumors either originated posterior to the equator of the globe (82%) or were of small to moderate size and located anterior to the equator, where they could only be seen with indentation of the sclera.<sup>204</sup> The examination of the retinal surface is not completed when the first tumor is identified. The entire retinal surface of both eyes must be evaluated and the locations of tumors noted on a diagram.

## SURGICAL CONSIDERATIONS

The indications for enucleation include (1) unilateral retinoblastoma that completely fills the globe or that has damaged and disrupted the retina so extensively that restoration of useful vision is not possible; (2) bilateral retinoblastoma in which the previously mentioned conditions exist in only one eye; (3) a tumor present in the anterior chamber; (4) painful glaucoma with loss of vision following rubeosis iridis; (5) extensive bilateral retinoblastoma in which there is no potential for restoration of useful vision; (6) retinoblastoma unresponsive to other forms of local therapy; and (7) cases with permanent visual loss in which intraocular tumor is suspected.<sup>205</sup>

## ADVANCED UNILATERAL DISEASE

Patients with suspected retinoblastoma should be referred to a pediatric ophthalmologist experienced with the treatment of retinoblastoma. The standard surgical technique is modified to allow excision of the longest possible segment of optic nerve in continuity with the globe. The surgeon must be careful not to perforate the globe when the extraocular muscles are divided. The globe and optic nerve are inspected for evidence of extraocular extension of the tumor. Orbital biopsies should be obtained when extraocular extension is suspected to be present. After the globe is enucleated, a plastic implant is placed in the muscle funnel. Although the presence of the ocular prosthesis may prevent early detection of an orbital recurrence of tumor, the cosmetic result and promotion of normal development of the bony orbit are considerably improved with the use of a prosthesis.<sup>204</sup>

The importance of including a sufficient (10 to 15 mm) length of optic nerve in the surgical specimen is emphasized by reports of inferior survival rates among patients with extension of retinoblastoma to the margin of the excised optic nerve.<sup>206,207</sup>

The survival rate reported for patients with retinoblastoma confined to one or both globes, treated only with enucleation, was 86% for those with unilateral disease and 97% for those with bilateral disease.<sup>51</sup>

## LIMITED UNILATERAL OR LIMITED BILATERAL DISEASE

Patients with limited unilateral or bilateral residual or recurrent disease after radiation therapy may benefit from photocoagulation or cryotherapy. Photocoagulation was reported to have successfully eradicated retinoblastomas in 80% of the patients treated. Hopping and Meyer-Schwickerath stated that suitable cases for this technique included solitary or multiple tumors, less than 4 to 5 disc diameters in size, situated at or posterior to the equator. Tumors located near the macula or papillary area and those with a mushroom shape should not be treated with photocoagulation.<sup>208</sup>

Cryotherapy was first employed for the treatment of a patient with retinoblastoma in 1963.<sup>209,210</sup> Subsequent reports that included some patients treated sequentially with local irradiation and cryotherapy suggested long-term control of retinoblastoma was possible using this technique.<sup>211</sup> Abramson and colleagues reported long-term control of retinoblastoma with one cryotherapy session in 80% of patients with previously untreated tumors, 59% of new postirradiation tumors, and 56% of recurrent tumors following irradiation. Tumors arising from the vitreous base were not responsive to cryotherapy. These investigators stated that previously untreated patients with tumors located anterior to the equator and those with recurrent or new tumors following irradiation were candidates for cryotherapy.<sup>212</sup> Cryotherapy is generally effective for tumors up to 2.5 mm in diameter and 1.0 mm thick that are confined to the sensory retina.<sup>213</sup>

## BILATERAL DISEASE

Historically, external-beam irradiation was used for the treatment of the less involved eye, following enucleation of the more involved eye of a patient with bilateral retinoblastoma. The decision to irradiate or enucleate the remaining eye was based on consideration of the location of the tumor, the presence of multiple foci of

tumor or vitreous seeding with tumor, and the size of the tumor.

The development of megavoltage radiation allowed the design of treatment plans that could irradiate the retinal surface to a uniform dose, while relatively sparing the posterior surface of the lens. All current techniques require meticulous attention to daily field placement. Treatment can be administered reproducibly with the use of general anesthesia.<sup>214</sup> Many radiation oncologists prefer to use a single, temporal field, moving the edge of the field anteriorly in patients who are at high risk of anterior recurrence of tumor.<sup>215</sup>

Many new techniques have been proposed for a more conformal dose distribution in retinoblastoma.<sup>216</sup> Proton beam therapy or stereotactic techniques offer significant advantages in sparing normal tissues. For example, even with the conventional small fields used, the posterior field edge frequently encompasses the hypothalamic and pituitary area. This may lead to the late occurrence of endocrine dysfunction. Proton beam techniques avoid such an exit dose to normal structures.<sup>217</sup>

Several patterns of tumor regression following irradiation have been described, including the following patterns. In type I ( *cottage cheese* calcium) the tumor shrinks in size and assumes an irregular, glistening white appearance similar to cottage cheese. In type II, the tumor shrinks in size to one-half to three-fourths of the initial volume and loses the pink color of capillary injection. The surface is gray and homogeneous, and some areas may be markedly translucent. An annulus of pigment disturbance may be exposed at the border of the tumor. In type III, a glistening white nidus of calcium, or DNA, is present in the center of an amorphous, translucent gray mass. The lesion loses its pink, solid appearance. It may be possible to see through the translucent tumor and identify normal choroidal markings. A pigment disturbance is frequently noted at the periphery of this lesion.<sup>191</sup>

Increased awareness of the risk of retinoblastoma among the siblings and offspring of retinoblastoma patients resulted in the diagnosis of tumors when they were small. Abramson and coworkers reported on the treatment of patients with early, bilateral retinoblastoma using bilateral irradiation. The radiation dose used for the treatment of the majority of the patients was 35 Gy. Residual tumors were present in 37% of the eyes when treatment was completed, and additional tumors developed in 16% of the eyes treated. All patients had group I, II, or III tumors. The risk of developing a second, nonocular malignancy in this group of irradiated patients is significant.<sup>218</sup>

Patients presenting with group IV and V bilateral retinoblastoma have been treated with radiation doses of 35 to 60 Gy. Enucleation was subsequently required for persistent or recurrent tumors in 67% of the treated eyes. The survival rate of the combined series of patients treated with bilateral irradiation was 82% compared with a survival rate of 71% among a group of patients treated only with bilateral enucleation.<sup>219</sup> Although the risk of a radiation-related second malignant tumor developing in a patient with bilateral retinoblastoma is considerable, the data available suggest the long-term survival of patients treated with bilateral irradiation is not worse than that of patients treated with bilateral enucleation only. The preservation of some useful vision in these patients is an obvious advantage of such a treatment approach, but prolonged follow-up of patients so treated will be necessary to thoroughly evaluate the effect of radiation-related second malignant tumors on long-term survival.<sup>220</sup>

Local irradiation, after enucleation, is recommended for all patients with extension of retinoblastoma into the orbit. Presentation with exophthalmos or a palpable mass through the eyelids suggests the presence of orbital extension of the tumor. The identification of an encapsulated or unencapsulated extraocular mass, enlargement of the cut end of the optic nerve at the time of enucleation, or rupture of the globe during removal are associated with orbital contamination with the tumor. These findings are confirmed histologically by the identification of an episcleral mass of tumor tissue or tumor at the margin of the cut end of the optic nerve.<sup>221</sup> The presence of tumor cells in the choroid and scleral emissaria, in the tissue between the choroid and optic nerve, or the presence of significant scleral necrosis, are highly suggestive of orbital contamination with the tumor. Patients with orbital retinoblastoma should receive irradiation to a volume, including the entire orbit and the optic nerve to the optic chiasm, as indicated. The recommended dose is 44 Gy in 4 weeks to 50 Gy in 4.5 to 5.0 weeks.<sup>222</sup>

## CHEMOTHERAPY

The role of adjuvant single-agent or combination chemotherapy in the management of patients with retinoblastoma is not well defined. Wolff and associates reported the results of a randomized study of adjuvant chemotherapy with cyclophosphamide (40 mg/kg) and vincristine (0.05 mg/kg) administered every 3 weeks for 57 weeks to patients with unilateral group V retinoblastoma following enucleation. The control patients received no adjuvant chemotherapy. The relapse rates of 7.4% among those randomized to receive adjuvant chemotherapy and 11.1% among those randomized to receive no adjuvant chemotherapy did not differ statistically.<sup>223</sup> Subsequently, Pratt and his colleagues<sup>224,225</sup> and others<sup>226,227</sup> reported successful treatment of some patients with advanced or recurrent retinoblastoma using various combinations of etoposide, cisplatin, doxorubicin, and cyclophosphamide.

The combination of etoposide and carboplatin was evaluated in patients with extraocular retinoblastoma, 85% of whom had partial or complete responses following treatment.<sup>228</sup> These two drugs, in combination with vincristine, doxorubicin, and cyclophosphamide, have been recommended for treatment of children with orbital involvement from retinoblastoma.<sup>229</sup>

The demonstration that combination chemotherapy can produce responses in children with advanced or recurrent tumors has led to pilot studies of combination chemotherapy for reduction of tumor bulk in previously untreated patients. The goal of these trials has been preservation of vision, primarily in children with bilateral disease. Tumor shrinkage may decrease the need for enucleation or external-beam radiation therapy for local control. Unfortunately, the use of different end points, particularly for the definition of treatment failure, has complicated interpretation of the outcomes of these studies. Responses to chemotherapy have been sufficiently provocative, however, that a multiinstitution, randomized trial of chemotherapy has been undertaken. This trial is intended to assess the therapeutic value of chemotherapy combined with cyclosporin for multidrug resistance reversal in managing advanced stage retinoblastoma.<sup>230,231,232,233,234,235 and 236</sup>

## RHABDOMYOSARCOMA

### EPIDEMIOLOGY AND GENETICS

RMS is the most common malignant tumor of the soft tissues in infants and children. The incidence rate per year is 4.6 cases per 1 million U.S. children younger than 15 years of age.<sup>1</sup> The annual incidence is lower for Asian children than for whites or African American children.<sup>27</sup> RMS occurs slightly more frequently in boys.<sup>51</sup> The median age at diagnosis of children with RMS is approximately 4 years, with girls presenting at slightly older ages than boys.<sup>51</sup>

RMS has been pathologically documented in siblings and cousins of patients<sup>51</sup> and is a frequent tumor in families affected by the Li-Fraumeni syndrome.<sup>17</sup> This syndrome is defined by familial clustering of cancers that include RMS and adrenocortical carcinoma in children and breast cancer in young adults. Affected relatives share germline mutations in the p53 tumor suppressor gene, which maps to chromosome 17p13.<sup>237</sup> In addition to p53 mutations, which have been associated with nearly 50% of RMS cases, mutations in the NF1 gene occurring in children with neurofibromatosis confer an increased risk for developing RMS.<sup>238,139 and 240</sup>

RMS may arise anywhere in the body, although the head and neck region is most frequently involved, accounting for 35% of all cases<sup>241</sup> (Fig. 44.2-5). The most common primary site for RMS is the orbit, accounting for 29% of the RMS in the head and neck, and 13% of all RMS in children.<sup>51</sup>

**FIGURE 44.2-5.** Overall distribution of patients in major Intergroup Rhabdomyosarcoma Study clinical trials according to clinical group and primary site. (From ref. 241, with permission.)

The remaining primary tumor sites in the head and neck are divided into parameningeal and nonparameningeal locations. The parameningeal sites, including the nasopharynx, paranasal sinuses, middle ear, mastoid, pterygopalatine fossa, and infratemporal fossa, account for 40% of the RMS that originate in the head and neck. Additional primary tumor sites in the head and neck include the scalp, oral cavity, oropharynx, larynx, parotid gland, and neck.<sup>51</sup>

The second most frequently involved regions include the abdomen and genitourinary tract, which account for the location of 29% of primary tumor sites in children with RMS. These tumors originate most frequently from the paratesticular tissues. Other primary tumor sites include the bladder, prostate, vagina, uterus, cervix, and bile ducts.<sup>51</sup> RMS arising in the genitourinary tract tends to affect young children, particularly the vaginal botryoid variant, which commonly presents in infancy.

The third group of tumor sites for RMS originates within the thorax or from the soft tissues of the trunk or extremities. The most common sites involve the lower extremities, with 22% originating in the thigh or groin.<sup>51</sup> In contrast to the predilection for genitourinary tumors to develop in young children, RMS arising in the extremities is more likely to be identified in the second decade of life. Almost one-half of these extremity primaries contain alveolar elements that are associated with a more aggressive tumor biology (see [Pathology](#), later in this chapter).

Overall, nearly 25% of all newly diagnosed cases of RMS are metastatic at initial presentation. The most common sites of dissemination include lung, bone marrow, bone, and lymph nodes, in approximate order of frequency.<sup>242</sup>

## **PATHOLOGY**

RMS has been traditionally classified into three histologies, consisting of embryonal (including botryoid), alveolar, and pleomorphic subtypes. As noted previously, tumor histology is strongly correlated with the primary tumor site. Alveolar histology is uncommon except in primary tumors of the trunk and extremity, whereas embryonal histology is most common in RMS of the head and neck and those of the genitourinary system.<sup>51</sup> Slightly over one-half of all cases are characterized by favorable embryonal histology, with an additional 6% demonstrating the uniquely favorable botryoid architecture. The prognostically unfavorable alveolar histology constitutes only 21% of all cases of RMS.<sup>242</sup>

Various histologic classification schemes have been proposed since Horn and Enterline first categorized RMS as either embryonal or alveolar in 1958.<sup>243,244,245</sup> and <sup>247</sup> A revised classification of childhood RMS was proposed in 1995, based on the results of an international collaborative study. This system recognizes six subtypes: botryoid RMS, spindle cell RMS, embryonal RMS, alveolar RMS, undifferentiated sarcoma, and RMS with rhabdoid features. Application of this system has been shown to have greater reproducibility than prior classification schemes, separating patients into prognostically significant groups.<sup>248</sup> Histologic classification of childhood RMS can be difficult, however, since individual tumors may have areas consistent with two or more histologic subtypes. Although immunohistochemical staining for desmin may be useful for the identification of RMS, some tumors lack distinguishing microscopic characteristics and cannot be further categorized.

In light of the limitations of immunohistochemical assessment, molecular diagnostics may prove to be important in identifying biologically less favorable subsets of patients for stratification to more intensive treatment regimens. Embryonal RMS is characterized by loss of heterozygosity at the chromosome 11p15 locus. Although chromosomal translocations are rarely associated with embryonal histology, alveolar tumors are characterized by rearrangement of the PAX3 gene on the long arm of chromosome 2 with the FKHR gene on the long arm of chromosome 13. Rearrangement of these genes produces the characteristic translocation t(2;13)(q35;q14).<sup>249</sup> The fusion transcript of this chimeric gene is thought to contribute to dysregulated transcriptional activation, culminating in transformation.<sup>241</sup> Employing reverse transcriptase polymerase chain reaction methodology, this signature translocation can now be identified with great sensitivity.

## **CLINICAL PRESENTATION AND EVALUATION**

Because RMS may originate from so many sites, the radiographic examination of the primary tumor must be individualized. Evaluation of children with RMS requires expert radiographic interpretation, competent pathologic examination of surgical specimens, and knowledge of distant sites to which RMS may spread.

The lungs should be evaluated with plain chest radiography and CT of the chest. Pulmonary nodules identified in children with RMS are frequently benign,<sup>250</sup> suggesting that solitary nodules identified on a chest radiograph of a child with RMS should be examined pathologically.

The skeleton may be evaluated using conventional radiography and radionuclide scanning.<sup>251,252</sup>

The bone marrow may be involved by RMS in the absence of bone or pulmonary metastases. Potential bone marrow involvement that may produce hypercalcemia<sup>253,254</sup> is assessed by bilateral bone marrow aspiration and biopsy. The bone marrow aspirate was positive at the time of diagnosis in approximately 10% of patients and may be the only definite site of identifiable disease.<sup>255</sup>

In addition to the aforementioned sites of hematogenous dissemination, lymph node involvement has been documented in 10% to 20% of cases of RMS.<sup>256</sup> These nodal sites may be evaluated radiographically or pathologically.

## **STAGING**

Staging and risk-group stratification of children with RMS is complicated by the many potential sites from which the tumor may originate and the correspondingly different prognoses for affected children depending on site, resectability, and histology. Recognizing these difficulties, an international panel of experts evaluated two staging systems and concluded that the TNM system ([Table 44.2-8](#)) best defined the pretreatment extent of the disease, facilitating patient management based on the extent of the disease and comparisons of treatment outcome between studies.<sup>257</sup> Treatment decisions for patients treated using the Intergroup Rhabdomyosarcoma Study Group protocols are based on both TNM stage and clinical group, as shown in [Table 44.2-9](#).

Stage	Site	T	N	M
1	Other Head and neck (excluding parameningeal) Conjunctiva; nasopharynx/larynx	T1 or T2	a or b	N0 or N1 or N2
2	Bladder/prostate Esophagus Cervical parameningeal Other	T1 or T2	a	N0 or N1
3	Bladder/prostate Rectum Cervical parameningeal Other	T1 or T2	a	N1
4	All	T1 or T2	a or b	N0 or N1

Notes:  
T1: confined to anatomic site of origin  
a: size less than 5 cm in diameter  
b: greater than 5 cm in diameter  
T2: extension, fixation, or both to surrounding tissue  
a: less than 5 cm in diameter  
b: greater than 5 cm in diameter  
N0: regional lymph nodes are clinically involved  
N1: regional lymph nodes clinically involved by tumor  
N2: clinical status of regional lymph nodes unknown  
M0: no distant metastases  
M1: metastases present

**TABLE 44.2-8.** Tumor (T), Node (N), Metastasis (M) Pretreatment Staging for Rhabdomyosarcoma

Group	Description
Group I	Embryonal rhabdomyosarcoma, completely resected. Microscopic complete remission. In the primary site, no evidence of disease. Classified as favorable or unfavorable histology.
Group II	Embryonal rhabdomyosarcoma, completely resected. Microscopic complete remission. In the primary site, no evidence of disease. Classified as favorable or unfavorable histology. Also includes rhabdomyosarcoma of the bladder, prostate, vagina, and uterus.
Group III	Embryonal rhabdomyosarcoma, completely resected. Microscopic complete remission. In the primary site, no evidence of disease. Classified as favorable or unfavorable histology. Also includes rhabdomyosarcoma of the bladder, prostate, vagina, and uterus.
Group IV	Embryonal rhabdomyosarcoma, completely resected. Microscopic complete remission. In the primary site, no evidence of disease. Classified as favorable or unfavorable histology. Also includes rhabdomyosarcoma of the bladder, prostate, vagina, and uterus.

TABLE 44.2-9. Intergroup Rhabdomyosarcoma Study Group Grouping System for Rhabdomyosarcoma

TREATMENT

Surgery

Surgical considerations for RMS are site specific. Although biopsy is required of tumors in all locations, progressive improvements in the response to chemotherapy and radiotherapy have obviated the need for immediate surgical resection, particularly of orbital primaries. Surgery is more frequently employed at other sites where resection does not produce major functional impairment (e.g., paratesticular and extremity lesions).

In most cases an initial incisional biopsy should be performed. The biopsy site and direction of the incision should always be planned with future excision in mind. Unsuccessful attempts at initial resection of an extremity lesion, leaving positive margins, can greatly complicate future resection.

Lymph node biopsy should be considered based on the primary site. Children presenting without distant metastases have an overall 10% incidence of lymphatic spread. Lymph node involvement is most frequent for tumors arising in the prostate (41%), paratesticular (26%), and genitourinary sites (24%). Extremity lesions had an intermediate frequency of 12%, whereas orbit (0%), nonorbital head and neck sites (7%), and truncal sites (3%) had the lowest frequency of lymphatic dissemination.<sup>256</sup> In the extremity and genitourinary sites, assessment of lymph node involvement is essential to ensure that radiation fields are appropriately designed and sufficiently inclusive.

Radiation Therapy

Cassady and colleagues demonstrated in 1968 that embryonal RMS of the orbit could be controlled locally with irradiation.<sup>258</sup> In fact, orbital irradiation was proven to be superior to exenteration for the treatment of orbital RMS.<sup>259</sup>

Local irradiation is necessary for patients with known microscopic or gross residual disease. The role of local irradiation in the treatment of patients with group I disease was examined in the first Intergroup Rhabdomyosarcoma Study (IRS).<sup>260</sup> All patients had gross and microscopic complete tumor excisions, and all received adjuvant chemotherapy with vincristine, dactinomycin, and cyclophosphamide (VAC). One-half of these patients were randomized to receive tumor bed irradiation. Relapse-free survival was 86% for those who did not receive local irradiation compared with 80% for stage I patients who were irradiated. The incidence of local failure was 6.3% (3 of 47) for those who did not receive local irradiation versus 7.6% (2 of 26) for those patients randomized to receive irradiation.<sup>261,262</sup> These findings indicated that radiation did not confer a survival advantage to clinical group I patients (i.e., patients who had undergone complete resections with negative margins). In light of these findings, radiation was not included in the treatment of group I patients enrolled on IRS-II.

IRS-III accrued 1062 patients from 1984 through 1991. All patients received postoperative radiation therapy except those with group I, favorable histology tumors and selected special pelvic sites, who had pathologic confirmation of complete remission after primary chemotherapy. The dose for microscopic residual disease was 41.4 Gy and 50.4 Gy for gross residual disease. The overall survival in IRS-III improved to 73%, a significant improvement from the results of IRS-I and -II.<sup>263</sup> (Fig. 44.2-6).

FIGURE 44.2-6. Survival (S) by primary site for all patients treated in Intergroup Rhabdomyosarcoma Study-III. BP, bladder/prostate; Ext, extremities; GU, genitourinary tract; HN, head and neck; PM, parameningeal sites. (From ref. 263, with permission.)

IRS-IV opened in 1991, completing accrual in 1997. This study used the TNM staging system to determine the chemotherapy regimen, and the IRS clinical group system to determine radiation therapy. Group III patients were randomized between hyperfractionated radiation therapy (110 cGy twice a day to a total dose of 59.4 Gy) and conventional radiation therapy (180 cGy once a day to a total dose of 50.4 Gy).<sup>264</sup>

Chemotherapy

The development of combination chemotherapy programs for children with RMS paralleled the identification of new chemotherapeutic agents with significant activity. The first combination reported to be active included VAC.<sup>51</sup>

IRS-I was initiated in 1972 to answer questions suggested by the results of the prior pilot studies in children with RMS.<sup>261,262</sup> Three additional studies have been completed (IRS-II, IRS-III, and IRS-IV). The results of these studies suggest the following points: (1) The addition of cyclophosphamide to the combination of vincristine and dactinomycin does not improve the relapse-free survival percentage of children with group I RMS (excluding alveolar RMS of the extremity).<sup>263,265</sup> (2) The addition of cyclophosphamide to the combination of vincristine and dactinomycin did not improve the relapse-free survival percentage of children with group II RMS (excluding alveolar RMS of the extremity).<sup>265</sup> The addition of doxorubicin to the combination of vincristine and dactinomycin improved the relapse-free survival of children with group II RMS (excluding alveolar histology and excluding primary tumors of the orbit, head, and paratesticular tissues) from 63% to 77%.<sup>263</sup> Analysis of histotypes among group II patients on IRS-II and IRS-III revealed a disproportionate number of patients with favorable histologies on IRS-III. Thus, the better outcome on IRS-III with the addition doxorubicin may have reflected a more favorable patient cohort, rather than more effective therapy. In light of the uncertainty around the therapeutic value of doxorubicin in this setting, the current recommendations for nonalveolar group II disease remains vincristine plus dactinomycin, without doxorubicin.<sup>241</sup> (3) The addition of doxorubicin to the combination of VAC did not improve the relapse-free survival percentage of children with group III RMS (excluding primary tumors of the bladder, prostate, vagina, and uterus).<sup>265</sup> The addition of cisplatin with or without etoposide to the combination of VAC did not improve the relapse-free survival of children with group III RMS (excluding primary tumors of the bladder, prostate, vagina, uterus, orbit, scalp, parotid gland, oral

cavity, larynx, oropharynx, and cheek).<sup>263</sup> (4) The addition of doxorubicin to the combination of VAC did not improve the relapse-free survival of children with group IV RMS.<sup>265</sup> The addition of doxorubicin and cisplatin, with or without etoposide, to the combination of VAC did not improve the relapse-free survival of children with group IV RMS.<sup>263</sup>

From 1991 to 1997, 894 patients were enrolled on IRS-IV. This study randomized patients between VAC, VAI (vincristine, actinomycin-D, ifosfamide), and VIE (vincristine, ifosfamide, etoposide). The 3-year failure-free survival for all three groups was approximately 75% for nonmetastatic disease. There were no statistically significant differences in outcome between the randomized treatment groups. In light of the therapeutic parity of the three regimens, VAC remains the gold standard due to the lesser risk of renal damage compared with the two regimens containing ifosfamide.<sup>266</sup>

The current IRS-V study, which was first started in 1995, focuses on improving survival in the intermediate- and high-risk subsets of patients. An attempt at dose-escalating cyclophosphamide (Cytoxan) in one of these pilots was proven to be prohibitively toxic. Since all three agents in the VAC regimen are currently delivered at maximal dose intensity, improvements in survival will require identification of new active agents. Based on encouraging pilot data from treatment of metastatic patients with VAC plus topotecan, a phase III study is now being conducted in intermediate-risk patients. Eligible patients are being randomized to VAC alone versus VAC alternating with vincristine, topotecan, and Cytoxan.

Survival for metastatic (stage IV) patients has only marginally improved from 20% to 32% since the inception of the IRS in 1972. In an effort to improve survival in this very high-risk subset of children, a series of phase II window studies have been undertaken. Patients with metastatic RMS are now being treated with an induction regimen that combines vincristine with irinotecan. Like topotecan, irinotecan is a camptothecin analogue that exerts its cytotoxic effect by inhibition of topoisomerase I. Irinotecan has demonstrated impressive antitumor activity in preclinical studies with murine xenografts. Subsequent pilot studies for metastatic patients may revisit the therapeutic potential of anthracyclines in the form of Doxil, a liposomally encapsulated analogue of doxorubicin, currently in phase I studies. It is hoped that the liposomal delivery system will minimize cardiotoxicity, permitting more dose-intensive application of anthracyclines to sarcoma therapy.

## SPECIFIC PRIMARY TUMOR SITES

### Head and Neck

**ORBIT.** Children with orbital RMS present with proptosis, due to a retrobulbar tumor, or swelling of the eyelid. The radiographic evaluation must demonstrate whether the tumor is confined to the orbit or has extended inferiorly into the maxillary sinus or posteriorly into the ethmoid sinus and cranial cavity. CT provides excellent definition of the soft tissue mass and can demonstrate the presence of bone destruction.<sup>267</sup>

*Surgery.* Biopsy is required before beginning treatment of orbital tumors. Due to the excellent response to radiation and chemotherapy, orbital exenteration is not indicated except for the unusual cases of recurrent disease in this site.

*Radiation Therapy.* The technique of local irradiation should include treatment of a volume that includes the entire soft tissue mass, demonstrated radiographically, with a margin of normal tissue. The dose given to the macroscopic tumor should be 45 to 55 Gy, administered over 5 to 6 weeks. Historically, a wedged lateral and anterior or three-field treatment plan was used. Three-dimensional treatment planning yields a superior dose distribution and can potentially avoid irradiation of the pituitary gland. Children with RMS of the orbit are at a small risk of developing disease recurrence in the meninges.<sup>258,268,269</sup>

*Chemotherapy.* Children with group II or III RMS of the orbit have a 5-year progression-free survival of approximately 90% when treated with local radiation therapy and chemotherapy that includes vincristine and dactinomycin.<sup>263,265</sup> These patients do not benefit from the addition of either doxorubicin or cyclophosphamide to the chemotherapy regimen.

**PARAMENINGEAL SITES.** The parameningeal sites include the middle ear, nasopharynx, and adjacent areas. Children with a primary tumor in the middle ear present with a peripheral facial nerve palsy or a mass in the external auditory canal and may have been misdiagnosed as having chronic otitis media or Bell's palsy.<sup>270</sup> Those with a RMS of the nasopharynx present with signs of upper airway obstruction, which is frequently associated with cranial nerve palsies. On examination, they are found to have a soft tissue mass that is depressing the palate and extending into the retropharyngeal space.

The radiographic evaluation of a patient with a parameningeal RMS must document the presence and extent of bone destruction and identify local or intracranial extension of the tumor. The temporal bone, petrous bone, mastoid, and infratemporal fossa can be adequately evaluated using CT. Coronal sections obtained either by rescanning the patient or reprocessing the data obtained from the axial scan of the head allow identification of tumor extension into the floor of the middle and posterior cranial fossae.<sup>51</sup>

*Surgery.* Surgical resection is infrequently required at this site because of the excellent response to chemotherapy and radiotherapy. In children who have persistent disease after completion of radiotherapy or who have tumor recurrence, surgery should be considered.<sup>271</sup> Modern methods of resection and reconstruction of these sites make surgery much less mutilating than in the past, with improved long-term functional outcomes. Before the initiation of therapy, a lumbar puncture should be performed. A cytocentrifuge preparation of the cerebrospinal fluid should be examined for tumor cells.

*Radiation Therapy.* Parameningeal RMS progresses locally by destruction of the adjacent bones and by growth along nerves.<sup>272,273</sup> To achieve local control of this tumor, a generous margin of these tissues must be included within the volume of irradiation.<sup>274,275</sup> The tumor mass must receive a radiation dose of at least 50 Gy. Meticulous treatment planning is necessary to deliver adequate therapy to the tumor without causing excessive or unnecessary damage to adjacent normal tissues including the brain and eye.<sup>275</sup>

RMS of the middle ear may recur as diffuse meningeal disease. This occurred in 17.5% of patients with a parameningeal primary tumor entered on IRS-I.<sup>276</sup> The high rate of primary meningeal relapse in this study may have been related to inadequate radiation technique. Although these investigators recommended the administration of craniospinal irradiation to prevent meningeal recurrence, others reported isolated meningeal relapse in 5.4% to 7.4%<sup>274,277,278</sup> of patients with parameningeal RMS.

This suggests that the rate of meningeal recurrence is related to the adequacy of the volume and dose of irradiation to the primary tumor. Current guidelines in IRS-V for parameningeal disease do not recommend craniospinal irradiation. Treatment is confined to the tumor volume plus a 2-cm margin for parameningeal tumors without intracranial extension. In cases of documented intracranial extension, the skull is included in the radiated target volume.

*Chemotherapy.* Approximately one-half of children with parameningeal primary tumors have group III tumors. These children require treatment with the combination of vincristine, dactinomycin, and doxorubicin. The 5-year progression-free survival percentage for all children with parameningeal primary tumors on IRS-III was 70%,<sup>263</sup> a result similar to that reported for IRS-II.<sup>265</sup> Patients who present with bone erosion of the cranial base, with or without a cranial nerve palsy, have a 3-year disease-free survival percentage of 43%, compared with 65% for those with intracranial extension and 81% for those without any evidence of meningeal involvement.<sup>279</sup> VAC remains the therapy of choice for parameningeal disease.

### Other Head And Neck Sites.

RMS may originate in several nonorbital and nonparameningeal sites, including the parotid region, larynx, soft and hard palate, tonsil, tongue, cheek, nose, scalp, and neck. Children with a parotid RMS present with unilateral swelling at the angle of the mandible and local pain. Those with RMS of the larynx present with hoarseness or signs of airway obstruction.

Although radical excision of tumor in these sites has been reported in a few cases, local infiltration of the tumor usually precludes gross total excision. Despite the prohibitions of surgical morbidity, local tumor control can be achieved with irradiation. The volume of irradiation should include a margin of normal tissue. Direct tumor extension along the extracranial portions of the adjacent cranial nerves may occur. These areas should be included within the treatment volume. The dose to gross residual disease should be 45 to 50 Gy. These patients should receive combination chemotherapy with VAC. The 5-year progression-free survival percentage for these children was 78% on IRS-III, similar to the result of IRS-II.<sup>263,265</sup>

## **TRUNK.**

RMS of the thorax may arise from the soft tissues of the chest wall or within the thoracic cavity. Primary tumors of the chest wall present as a localized swelling.

The radiographic evaluation of a patient with a primary tumor of the chest wall should include plain chest radiography and CT.

**SURGERY.** Lesions in the trunk, arising in the chest or abdominal wall and paraspinal or retroperitoneal sites, are best resected if possible because of their less favorable response to chemotherapy and radiotherapy. Complete surgical removal is limited by the frequently large size of these lesions at diagnosis as well as their involvement of vital structures within the abdomen or chest. Resections of the chest or abdominal wall often require prosthetic mesh reconstruction. Primary reexcision should be considered if pathologic examination of the initial specimen demonstrates microscopic residual disease.<sup>280</sup> In a review of IRS studies II and III, there were 84 patients with thoracic sarcomas.<sup>281</sup> Although 71% (60 patients) achieved an initial complete response, 39 suffered a local relapse, whereas an additional 22 patients developed distant relapse. Fifty-eight percent (49 patients) have died, with an average survival of 1.1 years. Survival was significantly associated with clinical group, size, and local or distant recurrence.

RMS arising in the abdominal wall is rare, accounting for only 1% of all cases of this disease. A review of patients with abdominal wall primaries treated on IRS I through IV demonstrated a substantial advantage to complete versus partial resection of localized tumors (100% vs. 62%).<sup>282</sup>

Biliary tract primaries appear to be more responsive to chemotherapy than other truncal sites. Affected children typically present with symptoms of biliary tract obstruction. Diagnostic biopsy followed by chemotherapy is appropriate, with resection reserved for those children with persistent disease.

Initial biopsy followed by chemotherapy and radiation has also been standard therapy for bulky tumors of the retroperitoneum and nongenitourinary pelvic sites. These tumors make up approximately 10% of all RMS. The treatment outcome for these tumors on IRS-III and -IV has been reviewed. All of the 138 eligible patients with tumors in these locations were either group III (gross residual) or group IV (metastatic). Nearly one-half of these patients were metastatic at diagnosis. Children with embryonal histology had a 4-year failure-free survival of 56% versus only 33% for children with alveolar or undifferentiated histology. Nearly all of the patients with alveolar tumors underwent biopsy only, followed by chemotherapy and radiation. In contrast, 40% of patients with embryonal tumors underwent extensive debulking at initial surgery. Among the embryonal patients, the failure-free survival at 4 years was 72% for those who underwent debulking versus only 48% for those embryonal patients who underwent biopsy followed by chemotherapy and radiation. The apparent advantage to debulking will be prospectively analyzed in IRS-V.<sup>284</sup>

**RADIATION THERAPY.** When complete tumor excision is not possible, local control is established with the use of radiation therapy. The volume must include the grossly apparent tumor with a margin of normal tissue. A radiation dose of 40 Gy is adequate for microscopic residual disease, while 50 Gy is required for gross residual disease. The pleural space is considered contaminated if there is a malignant pleural effusion, or if the tumor is cut across and the pleural space is opened at the time of surgery. The entire pleural surface must be irradiated when pleural contamination with tumor cells has occurred. Failure to do so may result in disease recurrence on the pleural surface not included within the volume of irradiation.

**CHEMOTHERAPY.** Embryonal RMS of the trunk should be treated using the chemotherapy regimens appropriate for the clinical group. Group I tumors are treated with the combination of vincristine and dactinomycin,<sup>263,265</sup> whereas groups II, III, and IV are managed with the combination of VAC.<sup>263,265</sup> Primary tumors of the trunk frequently consist of alveolar elements.<sup>285</sup> As in other sites, alveolar tumors in the trunk do not respond to chemotherapy as favorably as embryonal disease. Children with intermediate- or high-risk disease arising in these sites are currently being evaluated for response to VAC plus one of the camptothecin analogues.

## **Extremity**

Patients with RMS of an extremity usually present with localized swelling. Occasionally, a child with RMS of an extremity comes to medical attention due to symptoms caused by metastases, such as spinal cord compression secondary to vertebral body metastases, or pain due to other bone metastases. Nearly 25% of extremity primaries are metastatic at the time of diagnosis.

Radiographic evaluation of a patient with an RMS of the extremity should include plain radiographs of the primary tumor site and a bone scan. The presence of increased radionuclide uptake in the adjacent bone, although generally not associated with frank invasion of the bone by tumor, is correlated with the presence of inflammatory adhesions between the tumor and adjacent bone. Local recurrence of the tumor is likely if the tumor is not removed *en bloc* with the adjacent bone.<sup>286</sup> CT and MRI are useful for defining the extent of the soft tissue mass and the presence of bone destruction. Arteriography may be necessary to evaluate the relationship between the tumor, contiguous muscle compartments, and their vascular supply.

**SURGERY.** Complete resection of the tumor with negative microscopic margins is the goal in extremity sarcomas.<sup>287</sup> There is no advantage to amputation or muscle group excision compared with local excision with an adequate surrounding rim of normal tissue, provided the resection results in negative microscopic margins. The extent of the resection is often tempered by attempts to minimize functional impairment. In extremity tumors, consideration of the initial biopsy site and the direction of the incision are particularly important, because an inappropriate biopsy can greatly complicate later resection. Extremity lesions should rarely be resected without an initial biopsy because the surgical approach when resecting a malignant lesion will be quite different from the approach for a benign lesion.

Extensive local lesions with invasion of vital structures are often treated first with chemotherapy and subjected to delayed surgical resection. The goal of delayed resection is to render the child free of gross residual disease and accept microscopic residual disease that can be controlled with a lower dose of radiotherapy than the dose required for gross residual disease (40 vs. 55 Gy). This multidisciplinary approach results in good local control, while minimizing the potential morbidity of a more extensive initial resection or amputation.

Lymph node sampling is important in extremity RMS due to the significant risk of lymphatic involvement. Nearly 25% of all extremity tumors demonstrated regional nodal infiltration.<sup>242</sup> A representative sample of lymph nodes from the draining nodal group should be biopsied. A lymph node resection should not be performed because of the risks of producing lymphedema, which complicate radiotherapy and subsequent surgical resection of the primary lesion.

Analysis of data from IRS-III has shown that estimated 5-year survival was directly related to the clinical group, with a 95% survival in group I, versus 67% in group II, 58% in group III, and 33% in group IV. Survival was independent of histology or site. Multivariate analysis of pretreatment factors showed that lymph node metastasis, age over 10 years, and distant metastasis predicted worse survival. The difference between the survival percentage of 51 group II and III patients with lymph node–negative distal extremity lesions who could have been made group I with extensive resection and that of patients with group I distal extremity tumors approached statistical significance in univariate analysis ( $P < .06$ ).<sup>288</sup> All four group II patients who had reexcision of margins survived, whereas only 18 of 31 without reexcision survived. In IRS-IV, the failure-free survival rate was 55%, with an overall survival rate of 70%. Again, the 3-year failure-free survival was closely related to group (group I, 91%; II, 72%; III, 50%; IV, 23%). In this cohort, clinical group and stage were both highly predictive of outcome. None of the other variables were predictors of failure-free survival by multivariate analysis.<sup>289</sup>

**RADIATION THERAPY.** Postoperative irradiation must be to a volume that includes a generous margin around the tumor. The radiation dose should be 50 Gy to areas of gross residual disease. Patients with histologic confirmation of regional lymph node involvement should receive similar treatment to a volume that includes the involved lymph nodes.

**CHEMOTHERAPY.** Embryonal RMS of the extremity should be treated using the chemotherapy regimens described earlier for RMS of the trunk. Approximately one-half of extremity RMS have alveolar histology and require chemotherapy appropriate for this histologic subtype with a poorer prognosis.<sup>285</sup>

## **Genitourinary**

Patients with RMS of the paratesticular tissue present with painless enlargement of the testis. The age distribution is bimodal, with peaks at 5 and 16 years of age.<sup>51</sup> Children with RMS of the prostate present most frequently with acute urinary retention or with difficulty in voiding. Hematuria, dysuria, and abdominal swelling are also observed. Those with RMS of the bladder usually present because of hematuria, urinary frequency, or dysuria.<sup>51</sup> The physical examination of children with a prostate tumor is unremarkable except for the presence of a mass between the bladder and rectum that is palpable on rectal examination. Radiographic evaluation should include a voiding cystourethrogram or CT of the abdomen and pelvis. These studies demonstrate displacement of the bladder, in the case of a prostatic primary

tumor, or the presence of multiple polypoid masses within the bladder, with thickening of the bladder wall in the case of a bladder primary tumor. <sup>290</sup>

Children with sarcoma botryoids of the vagina frequently present with a polypoid mass protruding from the vaginal orifice or with vaginal bleeding. These children should have an  $\alpha$ -fetoprotein (AFP) level obtained before tumor biopsy or excision, since yolk sac tumor may also present as a vaginal mass.

**SURGERY.** Anterior pelvic exenteration is rarely required today. Bladder, prostate, and vaginal primaries are first biopsied, and lymph node extension is defined. Chemotherapy and radiotherapy are then used to eradicate residual disease. In the IRS-I and -II studies there were 28 vaginal and 10 uterine lesions. <sup>291</sup> Vaginal lesions generally arise from the anterior vaginal wall in the area of the embryonic vesicovaginal septum. The mean age of children with vaginal tumors was under 2 years. Over the course of the first four IRS studies spanning 25 years, the percentage of children undergoing resections of vaginal tumors has steadily decreased from 90% to 13%. Despite the limitation of surgical intervention to biopsy, survival in this group remains excellent, exceeding 90% with minimal surgical morbidity. <sup>292</sup>

In contrast to vaginal lesions, uterine primary tumors arise in older children demonstrate a greater propensity for local recurrence. As with vaginal lesions, initial surgical intervention is limited to biopsy in most cases. Hysterectomy is reserved for those patients who fail to achieve a complete response to chemotherapy and radiation. Survival in children with uterine disease approaches 90%. <sup>293</sup>

Preservation of the bladder and prostate was one of the primary goals of the IRS-II study in which surgical therapy was shifted from initial resection to primary biopsy with subsequent radiotherapy or surgery. <sup>294</sup> The 3-year survival rate of patients on IRS-II (70%) was similar to that of IRS-I (78%), but the 3-year disease-free survival rate was lower (52% vs. 70%). The percentages of 95 children with bladder and prostate tumors in IRS-II who retained their bladder and were alive at 2 and 3 years of age were 33% and 22%, respectively, compared with 26% and 23% in the 66 children with bladder or prostate tumors in IRS-I. Sequential treatment on this protocol failed to improve bladder salvage. The rate of retention of a functional bladder at 4 years from diagnosis was 60%. Excluding children who presented with disseminated disease, mortality was only 10% among children treated on IRS-III for bladder or prostate tumors. <sup>295</sup>

Successful treatment of paratesticular RMS first requires a transinguinal radical orchiectomy. Testicular masses should never be approached through the scrotum due to the risk of inducing spread into the pelvis via the inguinal lymphatics. In addition, the desired high inguinal ligation of the spermatic cord cannot be accomplished by the scrotal approach. A total of 121 boys with paratesticular RMS treated on IRS-III had retroperitoneal lymph node dissection to evaluate nodal status. <sup>296</sup> Lymph nodes were radiographically negative based on CT in 81% of the boys, 14% of whom had positive nodes when biopsy or retroperitoneal lymph node dissection was performed. Among the boys with abnormal nodes by radiographic criterion, 94% had pathologic confirmation of lymph node involvement. Retroperitoneal relapse occurred in only 2 of the 121 boys, one of whom had pathologically negative lymph nodes and did not receive radiotherapy. While CT was accurate if lymph node abnormalities were identified, it was not extremely sensitive in identifying nodal involvement.

**RADIATION THERAPY.** The IRS reported that there was no obvious benefit from prophylactic retroperitoneal lymph node irradiation among patients with paratesticular RMS, who had negative pathologic staging of retroperitoneal nodes. <sup>297</sup>

Tumors of the bladder and prostate were initially managed with radical resections including cystectomy. <sup>298</sup> Although excellent survival was achieved with this approach, the extensive surgical morbidity of this strategy prompted subsequent efforts at tissue-sparing treatment designs. Current IRS guidelines now recommend early introduction of radiation in combination with chemotherapy following a minimally invasive biopsy. <sup>299</sup> Employing this multimodal approach on IRS-III produced improved progression-free survival of approximately 75%, while maintaining partial or complete bladder function. <sup>263</sup>

**CHEMOTHERAPY.** Patients with group II paratesticular primary tumors of embryonal histology have an excellent prognosis when treated with the combination of vincristine and dactinomycin, with a 5-year progression-free survival percentage of 81%. <sup>263</sup> All patients with group III (biopsy only) genitourinary tumors are treated with VAC.

## PROGNOSTIC FACTORS

As noted previously, the favorable prognostic factors for children and adolescents with RMS include tumor status (T1, tumor localized in the organ or tissue of origin) and primary tumor site (orbit, genitourinary nonbladder, or prostate). <sup>300</sup> Although alveolar histology predicts a poorer outcome with standard therapy, the difference in survival between alveolar and embryonal cases resolves when more intensive therapy is applied to alveolar tumors. Despite improvements in therapy, however, children with metastatic disease still fare poorly, with a 5-year survival between 20% and 30%. Most of these metastatic patients have alveolar tumors. In a noteworthy departure from the dismal prognosis for children with disseminated RMS, there is a subset of younger children with embryonal histology with a 50% rate of failure-free survival. Identification of this relatively favorable subset of metastatic patients reinforces the importance of histology in predicting the behavior of this disease. Unfortunately, efforts at maximal dose intensification of chemotherapy with stem cell support have failed to improve the prognosis for children with metastatic disease. <sup>301</sup> Improved survival will require identification of new active cytotoxic agents in conjunction with efforts to target the unique genetic perturbations that are ubiquitous features of alveolar disease.

## EWING'S SARCOMA AND PERIPHERAL PRIMITIVE NEUROECTODERMAL TUMOR

### EPIDEMIOLOGY AND GENETICS

Ewing's sarcoma and primitive neuroectodermal tumor are closely related, if not identical, malignancies that may occur as osseous or soft tissue tumors. <sup>302,303</sup> Ewing's sarcoma is the second most common primary bone tumor in pediatric patients. The incidence rate per year is 3.4 cases per 1 million U.S. white children less than 15 years of age. The corresponding figure for African American children is only 0.6 per 1 million. <sup>1</sup> The rarity of Ewing's sarcoma in African American and Asian populations has been confirmed by several investigators. <sup>27</sup> Ewing's sarcoma occurs more frequently in boys than girls and has been reported in three pairs of female siblings. <sup>51</sup>

The femur is the most frequent primary site for Ewing's sarcoma, accounting for approximately 20% to 25% of all cases. Lower extremity tumors may also arise in the tibia, fibula, or the bones of the feet. Combining all potential sites of lower extremity disease, these tumors account for 45% of newly diagnosed Ewing's sarcomas. <sup>304</sup> The pelvis is the second most common primary site for Ewing's sarcoma, accounting for an additional 20% of new cases. Pelvic tumors may arise in the ilium, ischium, pubic bone, or sacrum. Upper extremity sites comprise another 12% to 16% of new diagnoses, with the humerus accounting for the majority of these cases. The remainder of Ewing's sarcomas originate from the vertebrae, ribs, clavicle, mandible, and skull. <sup>51</sup> These axial lesions account for nearly 13% of all newly diagnosed cases. <sup>304</sup>

### PATHOLOGY

Ewing's sarcoma and primary neuroectodermal tumors are counted among the small blue round cell tumors of childhood. Based on readily apparent features noted on light microscopy, this grouping includes neuroblastoma, RMS, and non-Hodgkin's lymphoma. Tumors of the Ewing's sarcoma family are characterized by the presence of highly cellular aggregates of tumor cells compartmentalized by widely separated strands of fibrous tissue. The tumor cells are regular in shape, with round to oval nuclei. The slightly granular cytoplasm is often framed by indistinct cellular outlines. The nuclei contain finely dispersed chromatin, giving the nucleus a ground glass appearance. Inconspicuous nucleoli may be present with occasional mitotic figures. <sup>305</sup>

Within the Ewing's family of tumors, primary neuroectodermal tumors are characterized by significant neuroectodermal differentiation. These tumors typically demonstrate Homer-Wright pseudorosettes on light microscopy and positive immunohistochemical staining for synaptophysin and neuron-specific enolase. In contrast to primary neuroectodermal tumors, Ewing's sarcomas are poorly differentiated tumors that do not form pseudorosettes and do not stain positively for neural markers. <sup>306,307</sup> Regardless of the extent of neural differentiation, nearly all tumors within the Ewing's sarcoma family express the MIC2 gene product (CD99) on their cell membranes. <sup>308</sup> Approximately 95% of all Ewing's family tumors contain translocations consisting of either t(11;22) or t(21;22). These gene rearrangements combine the N-terminal region of the EWS gene on chromosome 22 with the C-terminal region of one of two closely related genes on chromosome 11 (FLI1) or chromosome 21 (ERG). Both FLI1 and ERG are members of the Ets gene family of transcriptional activators. The majority of these translocations involve EWS and FLI1, t(11;22), producing a fusion transcript that is presumed to contribute to dysregulated cell growth and transformation. <sup>309</sup> Although the mechanism of tumorigenesis mediated by EWS-FLI1 remains uncertain, one study implicates the transforming growth factor-b (TGF-b) type II receptor as a target. TGF-b is a putative tumor suppressor gene. Levels of TGF-BR2 are reduced when EWS-FLI1 is introduced into embryonic stem cells. Antisense oligonucleotides to EWS-FLI1

restore TGF- $\beta$  sensitivity and block tumorigenicity in cell lines containing the fusion gene. <sup>310</sup>

Studies of EWS-FLI1 have demonstrated a variety of genomic breakpoints within the rearranged genes. Differences in the resulting fusion transcripts are thought to contribute to the clinical heterogeneity of Ewing's sarcoma. The most common rearrangement, designated *type 1*, consists of the first seven exons of EWS fused to exons 6 to 9 of FLI1. This fusion gene accounts for nearly two-thirds of all cases. The type 2 rearrangement, constituting an additional 25% of cases, fuses EWS to exon 5 of FLI1. Type 2 appears to be a more potent transactivator, which may account for the poorer prognosis associated with this fusion product. <sup>311,312 and 313</sup>

Rapid identification of EWS gene rearrangement using fluorescent *in situ* hybridization on frozen section specimens has been described. <sup>314</sup> Application of this diagnostic tool may facilitate prompt discrimination between the Ewing's family tumors and other morphologically similar small round cell tumors, expediting the initiation of appropriate therapy.

## CLINICAL PRESENTATION AND NATURAL HISTORY

Localized pain is typically the first symptom reported by pediatric patients with bone tumors. The pain progresses from intermittent to more constant, often awakening the patient from sleep. Depending on the location of the tumor, the patient may develop a limp, complain of pain that increases with respiration, or experience pain that is radicular in character. Local swelling is often noticed by the patient. This finding is more readily identified when the tumor is located in an extremity. Paraplegia secondary to vertebral disease is present at the time of diagnosis in approximately 3% of patients.

The clinical presentation of patients with Ewing's sarcoma is similar to that of patients with osteomyelitis. <sup>315</sup> Fever is present in 28% of patients with Ewing's sarcoma at the time of diagnosis. <sup>51</sup>

Metastases are present in approximately 26% of patients at initial diagnosis. The most frequent sites of metastases are the lungs and other bones. Patients may seek medical attention because of symptoms related to metastatic disease, rather than the primary tumor. Multiple pulmonary metastases may produce respiratory insufficiency, or paraplegia may develop secondary to a vertebral body metastasis.

Evaluation of a patient suspected of having Ewing's sarcoma includes radiographic examinations of the primary tumor site, documentation of the presence or absence of hematogenous metastases, and additional laboratory studies that correlate with prognosis or exclude the presence of other possible diagnoses.

Lesions that originate in the long bones characteristically involve the diaphysis, with extension toward the metaphases. A lytic or mixed lytic-sclerotic lesion is identified in the bone. Parallel, lamellated periosteal new bone formation (onion skin) or, less frequently, radiating bone spicules may be present. A soft tissue mass is frequently identified on CT or gadolinium-enhanced MRI.

Plain radiographs of tumors that originate in the pelvic bones frequently demonstrate a mixed lytic and blastic lesion. CT and MRI of the pelvis are required to adequately delineate the presence and extent of any associated soft tissue mass.

Radionuclide bone scans should be obtained, both to define more precisely the extent of disease at the primary site and to determine whether bone metastases are present.

The sedimentation rate and serum lactate dehydrogenase level are frequently elevated in patients with Ewing's sarcoma. <sup>316,317</sup>

## STAGING

Ewing's sarcoma can metastasize to the lungs, other bones, and bone marrow. As with other sarcomas, nodules identified on plain chest radiography or CT of the chest in patients with Ewing's sarcoma are not always malignant. Cohen and colleagues reported that 60% (three of five) of nodules identified in such radiographs were benign. <sup>250</sup> A solitary nodule identified only on the CT scan of one patient was shown pathologically to be secondary to histoplasmosis. <sup>318</sup>

Radionuclide bone scans demonstrated disease in additional bones in approximately 10% of patients with Ewing's sarcoma. <sup>319,320</sup>

Patients with Ewing's sarcoma may have disseminated bone marrow disease in the absence of radiographically detectable bone metastases. <sup>321</sup> Bilateral bone marrow sampling is required to complete the staging of all patients regardless of primary site or tumor size.

## TREATMENT

### Surgery

Local control must be achieved by either high-dose radiotherapy or resection. Larger tumor size (more than 8 cm) or volume (more than 100 cm<sup>3</sup>) has correlated with decreased success in achieving durable local control. <sup>322,323 and 324</sup> No randomized study has been performed to define whether local control is better accomplished with surgical resection or radiotherapy. In nonrandomized trials, the improved survival in the surgical resection group has been attributed to the allocation of larger tumors with correspondingly poorer prognosis to the radiation group. <sup>325,326 and 327</sup> Not all series have reported better survival among patients treated surgically than among those treated with radiation therapy. <sup>328</sup> In the German Cooperative Ewing's Sarcoma Study, survival with resection was better, although this relative advantage of surgery lost statistical significance when tumor size was considered. <sup>329</sup> The 3-year relapse-free survival was 78% for patients whose tumor volume was less than 100 mL, compared with 17% for patients with tumor volumes greater than 100 mL. Extrasosseous extension has also been associated with an increased risk of distant relapse. <sup>330</sup>

The long-term morbidity produced by radiotherapy versus surgery is often the deciding factor when selecting the most appropriate modality for local control. In addition to analyses of resectability and functional outcome, deliberations about local control must also consider the risk of late-onset second malignancies in tissues treated with intensive radiotherapy. Central pelvic or spinal lesions are frequently treated with radiation alone. Extremity lesions amenable to limb-sparing resections are treated predominantly with resection after an initial 12- to 15-week phase of induction chemotherapy. It is critical for the surgeon performing the diagnostic biopsy to place the incision appropriately to avoid complicating future resection.

Chest wall lesions make up 6.5% of primary Ewing's sarcomas, representing the most frequent chest wall tumor in children. They frequently present with large lesions extending into the thoracic cavity. Traditionally, these have been biopsied by open techniques that can be difficult because of the extremely vascular nature of this tumor and the limited surgical exposure. Percutaneous biopsy, which can provide adequate material for histologic and cytogenetic testing, may be a preferable approach in many cases. <sup>331</sup>

Preoperative chemotherapy can greatly reduce the size, vascularity, and friability of the tumor, facilitating resection and decreasing the risk of intraoperative tumor rupture. <sup>332</sup> Analysis of the 53 patients with nonmetastatic chest wall primaries treated on the first intergroup Ewing's Sarcoma Study (POG/CCG) demonstrated a decreased incidence of residual tumor in those patients resected after induction chemotherapy, in contrast to those who underwent resections before treatment with chemotherapy. <sup>333</sup> Current practice mandates the addition of radiotherapy for all patients with microscopic or gross residual disease after resection. Since surgical outcome was improved in patients receiving preoperative chemotherapy, they were less likely to require postoperative chest wall radiotherapy with its well-established risks of cardiac and pulmonary damage. As noted previously, the inclusion of 12 to 15 weeks of systemic chemotherapy before introduction of local control measures has become standard practice, regardless of tumor size, location, or stage.

### Radiation Therapy

Radiation responsiveness was one of the cardinal diagnostic features of the bone tumor first described by Ewing in 1921. <sup>304</sup> Unfortunately, the long-term survival rate of patients with Ewing's sarcoma following treatment with local radiation alone was only 9%. The vast majority of these patients ultimately succumbed to metastatic disease, suggesting the presence of occult metastatic tumor foci in most affected children. <sup>51</sup> These findings presaged the routine inclusion of systemic chemotherapy

in the treatment of this disease, leading to a marked improvement in survival over the past three decades.

Local control of Ewing's sarcoma with radiation is dependent on the delivery of a sufficient dose of irradiation to an adequate volume of tissue. Both the requisite minimum dose and the optimal treatment volume continue to be debated. Although dose-response information is limited for modern studies that employ adjuvant chemotherapy, local control rates have been fairly similar, ranging from 75% to 90% at radiation doses varying from 45 to 65 Gy. <sup>334</sup>

Local control rates have improved with the introduction of adjuvant chemotherapy. Chan and colleagues <sup>505</sup> reported local tumor recurrence in only 2.8% of patients treated with 60 Gy and adjuvant chemotherapy. Local disease recurrence was identified in 33.3% of patients who received identical local irradiation, but no adjuvant chemotherapy.

The Intergroup Ewing's Sarcoma Study (IESS) examined the relation of primary tumor site, radiation therapy dose, treatment volume, and adjuvant chemotherapy regimen to local tumor control. Local tumor recurrence occurred in 22.6% of patients with primary tumors in the humerus, 15.3% of those with tumors originating in the pelvis, 10.3% of patients with tibial primaries, and 6.7% of those whose tumor originated in the femur. A dose-response relationship was not apparent when local control was evaluated in patients who had received treatment to an adequate volume. <sup>335</sup>

Minor or major violations of radiation therapy technique, resulting in treatment of an insufficient volume, yielded inferior local control rates among patients who did not receive doxorubicin as part of the adjuvant chemotherapy program. <sup>335</sup> Local recurrence occurred in 21.4% of patients who had a margin of less than 5 cm of normal tissue included within the treatment volume. This compared with 7.9% of patients who had a margin of 5 or more centimeters of normal tissue within the treatment volume. <sup>336</sup> There was no improvement of the local control rate in patients with a pelvic primary tumor from the addition of doxorubicin when an adequate volume of tissue was irradiated. <sup>337</sup>

Local control percentages that are derived from series in which the majority of patients who died of disease did not have an autopsy may overestimate the frequency of local control. <sup>338</sup>

Studies from the National Cancer Institute confirmed the importance of autopsy examination for the identification of locally recurrent Ewing's sarcoma. Telles and colleagues identified recurrent or persistent tumor at the primary site in 13 of 20 patients at autopsy. <sup>339</sup> Tepper and coworkers reported that local tumor recurrence was clinically apparent in 5 of 20 autopsied patients, but was identified histologically in an additional 6 of 20 patients. <sup>340</sup> Since many of these patients had widespread metastatic disease, the possibility that the primary tumor site was reseeded with tumor cells derived from metastatic disease cannot be excluded. These results suggest that local failure rates in irradiated patients may be higher than suggested by the clinical determination of locally recurrent tumor.

Improved local control of tumor with irradiation followed the identification of a target volume encompassing the entire medullary cavity to moderately high-dose levels. <sup>341,342</sup> Suit summarized the experience of the 1950s and 1960s in recommending irradiation to the entire involved bone with a higher dose boost to the primary tumor site, noting few instances of marginal or distant intramedullary recurrence with such treatment. <sup>343</sup>

Assessment of the primary target volume requires detailed attention to both intraosseous and adjacent soft tissue tumor extent. Prior treatment recommendations included a 3- to 5-cm margin beyond the known soft tissue extension and inclusion of the entire intramedullary cavity. The radiation therapy results of IESS-I demonstrated an overall increase in local recurrence with fields that had not included the opposite epiphysis. <sup>337</sup> Although local failure increased from 7% to 20% with marginal or inadequate treatment fields, the differences were not statistically significant. Subsequent studies have reported comparable irradiation results using treatment techniques that have not included the opposite epiphysis. <sup>326,344</sup>

The results of the German Cooperative Ewing Sarcoma Study indicated an excessive rate of local recurrence attributed to poor quality control for radiation therapy. Protocol modifications, which included central planning for radiation therapy, diminished the frequency of local treatment failure. <sup>344,345</sup>

Local or tailored fields encompassing the primary tumor with a 3- to 5-cm margin, rather than treatment of the entire bone, have been evaluated. <sup>346,347</sup> Marcus et al. reported excellent local control using tailored fields, noting the ability to spare a component of the long bones in tumors less than 8 cm in diameter, while frequently requiring whole bone irradiation to achieve a 4-cm margin around larger tumors. <sup>347</sup>

The POG prospectively evaluated whole bone (conventional) irradiation compared with tailored treatment fields, ultimately collapsing a planned randomized study to a single arm trial using only tailored fields. A published analysis of this trial supports the efficacy of more limited treatment volume as defined by prechemotherapy tumor extent. <sup>291</sup> There was no difference in local control rates between patients receiving whole bone versus involved field radiation. This more tailored field has become the standard strategy used in the most recent CCG and POG Ewing's sarcoma trials.

The data available in the literature, and those accumulated by the IESS, have not demonstrated a strong relationship between the radiation dose and the local control rate when doses greater than 40 Gy were employed. Radiation doses greater than 60 Gy did not appear to significantly increase the local control rate and were associated with considerable long-term morbidity. Although the available data did not suggest that doses exceeding 40 Gy were essential for adequate local control rates in patients treated with adjuvant chemotherapy, comparisons between this dose and higher doses should be conducted in controlled trials. The current standard for the open POG and CCG trial is 55.8 Gy for gross and 45 Gy for microscopic residual disease.

The comparable outcome achieved with smaller, tailored fields is most provocative when considered in the context of the late sequelae of radiation therapy. The risk of secondary sarcomas arising in irradiated bone is variously reported as ranging from 5% to 10% at 20 years from diagnosis. Although no clear therapeutic advantage can be attributed to radiation doses in excess of 60 Gy, analysis of the long-term outcome in patients treated with doses greater than or equal to 60 Gy demonstrated an unacceptable excess risk of secondary bone sarcomas. In marked contrast to the late complications seen in patients receiving very high-dose radiation, the risk of developing a secondary bone tumor in the irradiated field was negligible at doses below 48 Gy. <sup>348</sup>

## **Chemotherapy**

The availability of chemotherapeutic agents active against macroscopic deposits of Ewing's sarcoma suggested that improved relapse-free survival rates might be achieved with the use of these agents in patients with microscopic residual disease.

In 1973, the IESS initiated a trial (IESS-I) to evaluate the potential additional benefit of adding doxorubicin and prophylactic whole lung irradiation to standard treatment of patients with nonmetastatic Ewing's sarcoma with vincristine, dactinomycin, and cyclophosphamide. The patients treated with the four-drug regimen that included doxorubicin had superior relapse-free survival. <sup>349,350</sup> In a subsequent study (IESS-II), the efficacy of administration of high-dose (1400 mg/mn) cyclophosphamide every 6 weeks was compared with administration of cyclophosphamide (500 mg/m<sup>2</sup>) weekly for 6 weeks. The regimen that included high-dose cyclophosphamide also included a higher dose of doxorubicin (75 mg/m<sup>2</sup>) than did the weekly cyclophosphamide schema. The 5-year relapse-free survival was 73% for the high-dose cyclophosphamide, high-dose doxorubicin regimen, compared with 56% for the weekly cyclophosphamide regimen ( $P = .03$ ), <sup>351</sup> a finding supported by the analysis by Smith and colleagues. <sup>352</sup>

The POG and CCG completed an intergroup study comparing the combination of vincristine, doxorubicin, cyclophosphamide, and dactinomycin to the combination of these four drugs plus ifosfamide and etoposide. The 5-year event-free survival was 68% for those who received the six-drug regimen, compared with 52% for those who received the four-drug regimen ( $P = .0005$ ). <sup>353</sup> Similar improvements in survival with the addition of ifosfamide have been reported in studies by the National Cancer Institute and multiple European cooperative groups. <sup>354,355 and 356</sup>

Standard chemotherapy for nonmetastatic disease currently consists of a five-drug regimen including the three-drug combination of vincristine, doxorubicin, and cyclophosphamide, alternating with the two-drug combination of ifosfamide and etoposide for a total of 48 weeks. The intergroup POG/CCG study for nonmetastatic Ewing's sarcoma compared this 48-week five-drug combination with a dose-intensified 30-week schedule employing the same agents at identical cumulative doses. The experimental arm in this study increased the dose intensity of alkylating agents by 25%. Preliminary statistical analysis of this study reveals no evidence of improved event-free survival with the dose-intensified regimen. <sup>357</sup> Although the Kaplan-Meier plots for event-free survival may yet diverge, current data from this

randomized study suggest that new treatment strategies will be required if further improvements in survival are to be achieved.

In contrast to the improvement in survival for nonmetastatic patients treated with the addition of ifosfamide and etoposide, no comparable benefit could be demonstrated for metastatic patients. Previous studies, however, had shown improved survival with the addition of radiation to metastatic sites of disease. Patients with hematogenous metastases entered on IESS-II were treated with irradiation to the primary tumor, in addition to whole lung radiation (18 Gy) for patients with pulmonary metastases and local bone irradiation for bone metastases. This strategy yielded a progression-free survival of 39%, demonstrating that some patients with hematogenous metastases can be successfully treated.<sup>358</sup>

Several groups have explored the feasibility and efficacy of maximally dose intensive chemotherapy regimens in combination with total body irradiation and peripheral blood stem cell rescue in an effort to improve the prognosis for high-risk patients.<sup>359,360,361,362,363 and 364</sup> Analysis of these studies is complicated by the nonstandardized inclusion of both metastatic and nonmetastatic patients in some of the high-risk cohorts. One study reported a 3-year relapse-free survival of 43% following megatherapy with chemotherapy, total body irradiation and stem cell rescue.<sup>365</sup> Unfortunately, longer follow-up of this cohort revealed a disappointing decline in event-free survival to 27%.<sup>366</sup> Another study reported a 6-year event-free survival of 34% with similar high-dose chemoradiotherapy.<sup>367</sup> None of these results is clearly superior to the outcome reported for similar patients treated on IESS-II without intensive chemotherapy or total body irradiation. While the early response data from several of these dose-intensive regimens appears promising, their small size and short follow-up mandate a guarded approach to their therapeutic potential. Further substantial improvements in survival for both metastatic and nonmetastatic patients will require identification of new non-cross-resistant cytotoxic agents and translation of our growing understanding of the unique molecular derangements of this disease into targeted biologic therapies.<sup>368</sup>

## PROGNOSTIC FACTORS

Historically, the prognosis for children and young adults with Ewing's family tumors has been assessed based on tumor size, location, and extent. Aside from the poor prognosis associated with metastatic disease, large tumor size (greater than 8 cm in diameter) and volume (greater than 100 mL) have correlated with adverse outcome. Children with nonmetastatic pelvic primary sites also have a poorer prognosis than children with extremity primaries, although this difference may be related to the larger size and more difficult resectability of pelvic tumors. High serum lactate dehydrogenase levels at diagnosis have been shown to predict a poorer prognosis in several studies.

Although not true prognostic factors assessable at the time of diagnosis, radiographic and histologic response to initial chemotherapy appear to be strong predictors of treatment outcome. Poor histologic response correlates with a poor prognosis, while complete or near complete tumor necrosis strongly correlates with good outcome, with a 5-year event-free survival of 84% to 95%.<sup>369,370</sup> Researchers in Vienna and New York have independently identified the type of EWS-FLI1 fusion transcript as a strong predictor of outcome in nonmetastatic patients. Both studies reported remarkably congruent results, with a predicted 5-year event-free survival of approximately 70% for type 1 transcripts versus 20% for all other types of fusion transcripts.<sup>311,312</sup> Nearly two-thirds of all patients in both studies were found to have type 1 fusion transcripts. Although the prognostic significance of this finding appears to be substantial, these findings must be prospectively validated before they are used to stratify patients for therapeutic purposes. All upcoming north American pediatric cooperative group studies conducted by the Children's Oncology Group (POG/CCG) will require submission of diagnostic tissue for molecular analyses that will include determination of EWS-FLI1 gene rearrangement status.

## PRIMARY HEPATIC TUMORS

### EPIDEMIOLOGY AND GENETICS

Approximately 60% to 70% of all primary liver tumors in children are malignant, with hepatoblastoma and hepatocellular carcinoma (HCC) representing the vast majority of malignancies arising in this location. Hemangiomas and hamartomas constitute the majority of nonmalignant liver tumors in the pediatric population.<sup>371</sup>

Hepatoblastoma accounts for slightly more than one-half of hepatic malignancies, occurring at an annual rate of 1.3 cases per 1 million children less than 15 years of age. In contrast, HCC occurs less frequently in children, accounting for one-third of all malignant hepatic tumors, with an annual incidence of 0.4 cases per 1 million.<sup>27</sup> In addition to the significant difference in incidence, hepatoblastoma and HCC are distinguished by age at diagnosis. Hepatoblastoma tends to affect young children, with a median age at diagnosis of 1 year. HCC is typically identified in older children, with a median age of 12 years. Both tumors demonstrate a male predominance.<sup>372</sup>

Children diagnosed with hepatoblastoma have had additional anomalies, including hemihypertrophy, Meckel's diverticulum, congenital absence of the kidney, congenital absence of the adrenal gland, and umbilical hernia.<sup>371</sup> Infants and children with incomplete or complete forms of the Beckwith-Wiedemann syndrome have an increased risk of developing hepatoblastoma, suggesting a linkage between loss of heterozygosity at chromosome 11p15.5 and the pathogenesis of both diseases.<sup>373</sup> Familial adenomatous polyposis has been identified in the mothers and maternal relatives of several patients with hepatoblastoma.<sup>374</sup> The risk of hepatoblastoma arising in children from kindreds with the adenomatous polyposis coli (APC) gene on the long arm of chromosome 5 is 1000 to 2000 times higher than the risk in sporadic cases with no family history of familial adenomatous polyposis.<sup>375</sup> Other karyotypic abnormalities associated with the pathogenesis of hepatoblastoma include trisomy 1 or 1q,<sup>376</sup> trisomy 2 or 2q, and trisomy of chromosome 20.<sup>377</sup> In addition to these chromosomal derangements, children with a history of prematurity and very low birth weight appear to be at increased risk for hepatoblastoma.<sup>378,379</sup> In a study based on the Japanese Children's Cancer Registry, hepatoblastoma accounted for 58% of the cancer diagnoses in children with a history of extremely low birth weight (less than 1000 g).<sup>378</sup> The authors suggest that this association points to a combination of aberrant genetic endowments and prenatal events or exposures that contribute to disruptions in normal organogenesis, culminating in transformation of hepatocytes.

HCC is strongly associated with infection with hepatitis B virus, both in the presence and absence of pathologic evidence of cirrhosis in nontumorous hepatic tissue. Hepatitis B virus can be acquired via vertical transmission from seropositive mothers or through exposure to contaminated blood products.<sup>380,381</sup> Several studies have documented a near 100% rate of seropositivity for HBsAg in children who develop HCC.<sup>382</sup> Efforts to reduce the incidence of hepatitis B infection with universal hepatitis B vaccination in Taiwan have produced a corresponding decrease in the risk of developing HCC.<sup>380,381 and 382</sup>

In addition to the association with hepatitis B, HCC has been diagnosed in pediatric patients with several other underlying diseases, including tyrosinemia, galactosemia, biliary atresia, progressive familial cholestatic cirrhosis, giant cell hepatitis of infancy, Fanconi's anemia, type I glycogen storage disease, hepatic glycogenosis with Fanconi's syndrome,  $\alpha_1$ -antitrypsin deficiency (MZ phenotype), Soto's syndrome, and neurofibromatosis.<sup>51,383</sup> Hemochromatosis has not been associated with HCC in pediatric patients, although it is frequently associated with this disease in adult populations. Determinations of iron reserves, as estimated by serum iron, unsaturated iron-binding capacity, and serum ferritin, might clarify the relationship between hemochromatosis and HCC in children.<sup>384,385</sup>

## PATHOLOGY

Hepatoblastoma may be divided into two broad histologic subsets of uncertain prognostic significance. The pure epithelial type consists of either fetal or embryonal elements or a combination of both cell types. Alternatively, the tumor may consist of a mixture of epithelial cells with mesenchymal elements.<sup>386</sup> Pure fetal histology is prognostically favorable in patients with completely resected hepatoblastoma.<sup>387</sup> Hepatoblastoma tends to occupy a single site within the liver, most commonly arising in the right lobe.

Two types of HCC are frequently recognized in pediatric patients: microtrabecular and fibrolamellar.<sup>388,389</sup> The fibrolamellar histology is most commonly seen in older children and young adults. In contrast to hepatoblastoma, HCC is often multicentric at diagnosis, substantially limiting the feasibility of complete resection.<sup>372</sup>

## CLINICAL PRESENTATION

Infants and children with hepatoblastoma are most frequently identified by the discovery of an abdominal mass or abdominal distention. Symptoms such as weight loss, anorexia, or fever may also be present, although jaundice is infrequent. A rare but interesting presentation of patients with hepatoblastoma occurs in young boys with isosexual precocious puberty due to production of human chorionic gonadotropin (HCG) by the tumor cells.<sup>390</sup>

The presenting physical findings in children with HCC are quite similar to the characteristic features of hepatoblastoma. Children with HCC typically present with an

abdominal mass or abdominal distention. Abdominal pain, anorexia, and weight loss are less frequent complaints. Jaundice is infrequently present at the time of diagnosis, although it is a more common finding in HCC than hepatoblastoma. Occasionally, a patient with HCC presents with acute abdominal pain due to tumor rupture, with intraabdominal hemorrhage.<sup>51</sup>

## EVALUATION AND STAGING

The history of pediatric patients suspected of having a malignant hepatic tumor should be reviewed for any history of jaundice or hepatitis. Laboratory data obtained in the perinatal period for the evaluation of hyperbilirubinemia should be reviewed. The maternal prenatal history should be evaluated for the use of steroidal hormones. Previous exposures to hepatotoxic agents should be recorded. The family history should be reviewed for prior cases of hepatic or biliary disease in siblings or parents.

The physical examination may reveal a solitary or multiple hepatic nodules. The presence of dilated collateral vessels on the anterior thorax and abdomen should be noted. Hemihypertrophy or stigmata of the Beckwith-Wiedemann syndrome, such as macroglossia or omphalocele, may be present.

Laboratory evaluation should include a complete blood count, white blood cell differential, tests of renal and hepatic function, and a urinalysis. The serum levels of total bilirubin, alkaline phosphatase, and glutamic-oxaloacetic acid transaminase are not generally useful for the differential diagnosis of malignant hepatic tumors in children.

The serum level of AFP is increased in approximately 90% of patients with hepatoblastoma<sup>391,392</sup> and 78% of adult patients with HCC. The increase of AFP in 51% of white and 81% of African American patients with HCC suggests the presence of ethnic variability in the production of this protein by malignant hepatocytes.<sup>393</sup> Once the diagnosis of hepatocellular carcinoma is established, additional studies should include hepatitis B surface antigen, hepatitis B antibody, serum iron, total iron-binding capacity, serum ferritin, and a  $\alpha_1$ -antitrypsin phenotyping. The serum level of HCG should be determined if the clinical presentation included precocious puberty. Several authors reported the excretion of increased amounts of cystathionine in the urine of patients with hepatoblastoma.<sup>394</sup> This finding has also been reported in patients with neuroblastoma, decreasing the utility of this determination for the differential diagnosis of hepatomegaly.

Abdominal radiographic examination may demonstrate the presence of a homogeneous density in the upper abdomen. Malignant hepatic tumors are rarely calcified.<sup>395</sup>

Abdominal ultrasonography demonstrates the presence and extent of a solid mass. Sonography assesses both kidneys and the inferior vena cava, providing information useful for differential diagnosis and surgical management. The proximal extent of tumor thrombus within the inferior vena cava may be determined by echocardiography or cardiac angiography.

A radionuclide liver and spleen scan may demonstrate solitary or multiple defects in the liver. Transient, early perfusion of the defect is frequently observed in hepatic adenomas, hepatoblastomas, and HCCs. Persistent perfusion is found in hepatic hemangiomas and hepatic adenomas.<sup>396</sup>

Pulmonary metastases are identified on plain chest radiography in approximately 10% of patients with hepatoblastoma<sup>391</sup> and HCC.<sup>389</sup> The additional yield of CT in pediatric patients with hepatoblastoma or HCC has not been evaluated.

The grouping system employed in the therapeutic studies of children with malignant hepatic tumors conducted by the CCG and POG segregates patients according to the resectability of the primary tumor, a criterion that may vary among treatment centers. This staging system also accounts for the presence of lymph node or hematogenous metastases (Table 44.2-10).<sup>397</sup>

Stage	Description
Stage I	Patient had complete resection of tumor by wedge resection, lobectomy, or extended lobectomy, as the initial procedure.
Stage II	Patient has microscopic residual disease after surgical resection. There is no evidence of regional lymph node involvement by tumor. There was no spillage of tumor.
Stage III	Gross residual disease or regional lymph node involvement by tumor or tumor spilled.
A	Regional lymph node involvement by tumor or tumor spill, but primary tumor completely resected.
B	Gross tumor not completely resected.
Stage IV	Distant metastases are present.
A	Primary tumor completely resected.
B	Primary tumor not completely resected.

TABLE 44.2-10. Clinical Staging System for Childhood Hepatic Tumors

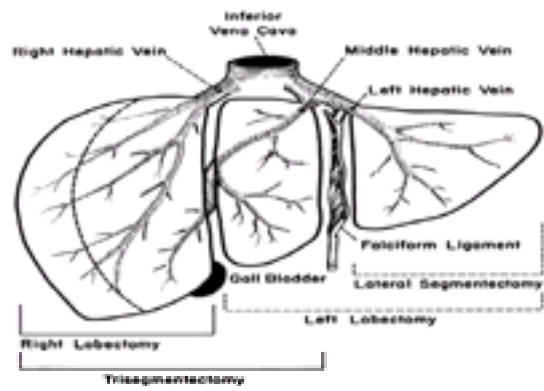

## TREATMENT

### Surgery

Resection is the cornerstone of treatment for hepatoblastoma and HCC. Long-term survival is rare for patients who have not undergone a successful resection.<sup>397</sup> Hepatoblastoma is generally unifocal, arising at one site within the liver parenchyma, whereas HCC is frequently multifocal. HCC has an invasive pattern of spread across anatomic planes and is generally unresponsive to current forms of chemotherapy.<sup>398</sup> Complete resection of HCC is frequently difficult due to its multifocality and invasiveness. Approximately one-half of all hepatoblastomas are resectable at initial presentation, whereas only 30% of HCCs can be fully resected at diagnosis.<sup>371</sup>

The resectability of a primary liver tumor is determined by its anatomic location within the liver and by its size. Surgical considerations are complex and best addressed by surgeons intimately familiar with hepatic anatomy and resection. For successful resection, perfusion and drainage for an anatomic segment of the liver must be preserved. The liver lobes are perfused by the two divisions of the hepatic artery and the portal vein, with one branch to each lobe. The left and right lobes are divided along a plane between the bed of the gallbladder and the anterior aspect of the vena cava. The liver is drained by three veins into the vena cava at the most superior aspect of the liver. The right hepatic vein drains the major portion of the right lobe (the posterior segment and a portion of the anterior segment of the lobe).<sup>399</sup> The middle hepatic vein, which courses along the plane anterior to the vena cava between the right and left lobes, drains one-third of the liver (a large portion of the anterior segment of the right lobe and all of the medial segment of the left lobe). The left hepatic vein, arising from a short common trunk with the middle vein in 50% of cases, travels along the umbilical fissure of the liver and primarily drains the lateral segment of the left lobe. In a right or left lobectomy, the left or right branches of the hepatic artery and portal vein are preserved, along with the left and middle or right and middle hepatic veins. In an extended right or left hepatectomy (also referred to as a *trisegmentectomy*), the same inflow vessels are removed, along with the middle and left or right hepatic veins. A much greater portion of the hepatic parenchyma is removed in this type of resection (Fig. 44.2-7).

**FIGURE 44.2-7.** Relation between hepatic anatomy and nomenclature for various types of hepatic resection. (From Iwatsuki S, Starzl TE. Hepatectomy in children. *Int Adv Surg Oncol* 1982;5:163, with permission.)

Radiographic imaging before surgical exploration is critical to the surgeon. It defines the critical relationship between the tumor and associated vasculature. Historically, most children underwent angiography to facilitate surgical planning before hepatic resection. In view of the remarkable anatomic detail afforded by current radiographic techniques including MRI and spiral CT, angiography is less frequently required.<sup>400</sup> Ultimately, the feasibility of resection can only be determined by direct surgical exploration. When angiography is not performed, the surgeon must be aware of the frequent anomalies of the hepatic artery. The right hepatic artery may arise from the superior mesenteric artery, while the left hepatic artery may arise from the celiac axis. These variations, if present, must be identified before division of any vessels in the hepatic porta. Factors that render a liver tumor unresectable include involvement of both lobes of the liver and lymph node involvement in the porta hepatis or mediastinum. Additional features that preclude resection include direct extension into the inferior vena cava, a central lesion that involves both the left and right hepatic arteries or the portal vein, or lesions that involve all branches of the hepatic vein.

A large hepatoblastoma grossly distorts the normal anatomy and relationships of the vessels. Hepatoblastoma, in contrast with HCC, does not invade surrounding liver segments as much as it distorts them. It is as if a balloon is placed within the liver parenchyma and is progressively inflated. The vessels to the uninvolved segments may be tightly drawn over a massively enlarged segment, making safe dissection and preservation difficult. As the tumor responds to chemotherapy, it does not regress from areas of involvement, although its decreased volume permits identification of the normal uninvolved segments. Treatment with chemotherapy before definitive surgery has permitted complete resections in children whose hepatoblastomas were initially deemed unresectable.<sup>401,402</sup> Regrettably, HCC has been much less responsive to chemotherapy, limiting the effectiveness of preoperative pharmacologic intervention. When feasible, aggressive attempts at initial resection of HCC should be pursued.

Although complications from hepatectomy persist, perioperative mortality has significantly decreased. Bile leaks, strictures, subphrenic or subhepatic abscesses, and intraoperative hemorrhage are the most frequent complications. Major postoperative complications have occurred more frequently in children undergoing resection after chemotherapy (25%) than in children resected at presentation (8%).<sup>403</sup> In a series published by King et al. in 1991, the increased frequency of complications in the group resected following chemotherapy did not appear to be explained by disproportionate numbers of more extensive resections being performed in that subset. The distribution between lobectomies and trisegmentectomies was similar for children undergoing primary resections and resections following several courses of induction chemotherapy.<sup>403</sup>

Hepatic transplantation has been used by several centers for children with unresectable liver tumors, with a survival rate of 50.0% to 87.5% reported for children with hepatoblastoma.<sup>404,405</sup> Success with this treatment approach for patients with hepatocellular carcinoma has been extremely limited and is difficult to justify. Disease must be limited to the liver for efforts to be successful. Lymph node involvement is a contraindication for efforts at resection and transplantation.

Cryoablation or radiofrequency ablation of hepatic malignancies has been increasingly used in adults, particularly for metastatic lesions in the liver.<sup>406</sup> While these techniques have been employed in treatment of recurrent disease, their overall role in treatment of pediatric neoplasms remains to be defined.

Long-term evaluation of infants and children following hepatic resection has demonstrated normal synthetic and degradative function of the liver. Liver volumes assessed by MRI are near normal, despite prior anatomic lobectomies or trisegmentectomies. Sequential studies have shown that hepatic volumes continue to increase as the children grow following completion of their treatment.<sup>407</sup>

### **Radiation Therapy**

Radiation therapy has a limited role in the treatment of hepatoblastoma or HCC. Generally, combination chemotherapy is given preoperatively to patients with large, unresectable tumors. Postoperative radiation therapy may be valuable in the treatment of children with residual disease following resection.<sup>408</sup> Generally, doses of 25 to 40 Gy are recommended for treatment of limited volumes.

### **Chemotherapy**

Following initial biopsy, combination chemotherapy has been administered to children with malignant hepatic tumors to facilitate subsequent surgical excision. In addition to its role in reducing the size of tumors before attempted resections, chemotherapy has been employed as a postoperative adjuvant following complete excision of the primary tumor. Initially reported by single institutions,<sup>409,410,411,412</sup> and <sup>413</sup> these results led to the design of much larger cooperative group trials of combination chemotherapy in children with hepatoblastoma and HCC.

Evans and coworkers reported the results of sequential studies conducted by two pediatric cooperative groups in patients with malignant hepatic tumors. Patients with hepatoblastoma and HCC were evaluated together. Those patients with completely resected disease (group 1) entered on the first study received no therapy following surgery. Those entered on the second study received adjuvant chemotherapy consisting of doxorubicin, cyclophosphamide, vincristine, and 5-fluorouracil. Comparison of these sequential studies demonstrated a significant survival advantage for those patients who received adjuvant chemotherapy compared with patients treated only with surgery.<sup>397</sup>

Based on pilot data that demonstrated the activity of the combination of doxorubicin and cisplatin<sup>408</sup> and of the combination of cisplatin, vincristine, and 5-fluorouracil<sup>414</sup> in patients with malignant liver tumors, the CCG and POG conducted a randomized comparison of these two combinations. The results of this trial demonstrated that the two combinations produced similar relapse-free and overall survival percentages within stages. The combination of cisplatin, vincristine, and 5-fluorouracil produced substantially less severe myelosuppression, less need for prolonged hyperalimentation, and fewer toxic deaths. Event-free survival rates for patients treated with the three-drug regimen were 85% for stage I, 100% for stage II, 62% for stage III, and 23% for stage IV.<sup>415</sup> Similar results have been reported by investigators in Toronto,<sup>416</sup> Japan,<sup>417</sup> and Germany.<sup>418</sup> These studies have consistently demonstrated that a substantial number of initially unresectable tumors can be surgically removed at second exploration following treatment with variations on either of the two drug combinations.<sup>403,419</sup> Despite the remarkable similarity in outcomes between these various studies, there was a significant difference in survival for children who underwent initial complete resection, corresponding to postoperative management. The Toronto group reported a 100% event-free survival for children with complete resections treated with postoperative chemotherapy, versus 72% survival for a similar group of children on the POG/CCG study who received no chemotherapy following definitive surgery.<sup>416</sup> Although the numbers in the comparison groups are small, the more favorable outcome with inclusion of chemotherapy suggests that this approach should be prospectively examined.

Japanese investigators have reported successful application of transarterial chemoembolization using cisplatin and doxorubicin in combination with iodized oil in treatment of a small number of children with inoperable hepatoblastoma.<sup>420</sup> Although the results of this limited series are provocative, the role of this more invasive technique is uncertain given the efficacy of systemic, intravenous administration of the same chemotherapeutic agents.

### **PROGNOSIS**

For both hepatoblastoma and HCC, resectability of the primary tumor and disease extent at diagnosis remain the strongest predictors of survival. Prospects for long-term survival are extremely poor for both histologies in cases of widely metastatic disease. Despite aggressive efforts at surgical management of HCC, long-term survival remains dismal even for patients with fully resected tumors. A North American Pediatric Cooperative Group study demonstrated only 13% survival for children with totally resected HCC.<sup>421</sup> This outcome sharply contrasts with the good survival documented for children with localized, completely resected hepatoblastoma, as described previously (see [Surgery](#), earlier in this chapter).

Although correlation of survival with histology in hepatoblastoma and HCC remains controversial, there appear to be favorable histologic subsets within both types of hepatic malignancy. Multiple studies have demonstrated that pure fetal histology is prognostically favorable in patients with completely resected hepatoblastoma.<sup>387,422,423</sup> Several studies have shown a better outcome for children with the fibrolamellar variant of HCC,<sup>424</sup> although this advantage was not apparent in the cooperative studies conducted by the POG and CCG.<sup>423</sup> Multivariate analysis of prognostic factors in children with hepatoblastoma by the German Pediatric Liver Tumor Study group has identified AFP level at diagnosis and vascular invasion as important prognostic factors. Children with either very low AFP (less than 100 ng/mL) or very high AFP (greater than 1 million ng/mL) had a poorer prognosis than children with intermediate levels (100 to 1 million ng/mL). Children with venous tumor invasion also fared poorly.<sup>422</sup>

## GERM CELL TUMORS

Germ cell tumors arising in gonadal or extragonadal sites constitute a remarkably heterogeneous group of tumors that account for approximately 3% of all pediatric malignancies. Although extragonadal germ cell tumors are relatively infrequent in adults, accounting for only 5% to 10% of all cases, extragonadal tumors make up nearly two-thirds of all germ cell tumors in children.<sup>425</sup> The sacrococcygeal region represents the most common site for germ cell tumors in children, constituting 40% of all childhood germ cell tumors,<sup>426</sup> and 78% of all extragonadal disease.<sup>427</sup> Less commonly, extragonadal disease arises in the mediastinum, retroperitoneum, vagina, and pineal region. Biologic behavior among this diverse grouping of tumors varies from the benign mature teratoma to the highly malignant embryonal carcinoma and choriocarcinoma. Fortunately, the introduction of platinum-based chemotherapy by Einhorn and Donahue in the 1970s has greatly improved survival for most children affected by these highly chemosensitive tumors<sup>428</sup> ([Table 44.2-11](#)).

Site	Relative Incidence (%)	Age	Pathology
Sacrocoxa	30	Neonate	Teratoma mature 65%, immature 35%, yolk sac 10-35%
Ovary	25	Early years	Teratoma mature 65%, immature 35%, yolk sac 35%, mixed 35%
Testis	20	Infancy/adulthood	Teratoma mature 25%, yolk sac 45% or 55%, germinoma 15%, embryonal carcinoma 1-15%
Ovary	1	Child	Germinoma 20-35%, embryonal carcinoma 20-35%, mature teratoma 20-35%
Mediastinum	1	Adolescent	Teratoma mature 65%, mixed 35%, embryonal carcinoma 35%
Retroperitoneum	1	Infant	Teratoma mature w/ immature, yolk sac/germ
Head and neck	1	Infancy/adulthood	Embryonal carcinoma, immature yolk sac/germ
Vagina	1	Infant	Embryonal carcinoma

(From ref. 428 with permission.)

**TABLE 44.2-11.** Relative Incidence According to Age and Pathology

## EMBRYOLOGY

Primordial germ cells arise in the embryonic yolk sac endoderm. These cells migrate through the wall of the midgut to the genital ridge at 4 to 5 weeks' gestation. Migration along this paravertebral gonadal ridge proceeds in a caudal to cranial direction. Arrested migration of these germ cells along this pathway has been proposed as an explanation for the near midline location of most extragonadal germ cell tumors, including the sacrococcygeal region, retroperitoneum, mediastinum, and intracranial sites, which primarily consist of the pineal and suprasellar regions.<sup>425,427,429</sup>

## PATHOLOGY

Pediatric germ cell tumors include an enormously diverse array of histologies. The majority of extragonadal tumors arising in infancy are benign teratomas. Similarly, most ovarian germ cell tumors are benign lesions. In contrast, the vast majority of germ cell tumors developing in the testis contain malignant yolk sac elements. While many of these tumors contain a mixture of benign and malignant elements, their clinical behavior and therapeutic management are determined by the most malignant component identified on extensive sectioning.<sup>427</sup> This section reviews the various histopathologic subtypes of germ cell tumors most frequently seen in children.

## TERATOMA

Teratomas contain elements derived from more than one of the three primary germ layers (ectoderm, mesoderm, endoderm), frequently arranged in a haphazard manner. The tissues are immature to well differentiated and foreign to the anatomic site. Mature teratomas are either cystic or solid, although the cystic presentation predominates in gonadal sites. Immature teratomas are graded according to the amount of immature tissue present on light microscopic assessment of sampled tissue. Grade 1 immature teratomas have neuroepithelium or other immature elements limited to only one low-power field per slide. Grade 3 immature teratomas contain abundant immature tissue that is identifiable on greater than or equal to four low-power fields per slide.<sup>430</sup> Nearly all mature teratomas are diploid with normal karyotypes. In contrast, chromosomal derangements are frequently identified in immature teratomas. Ploidy may correlate with clinical behavior in immature ovarian teratomas. Grade 1 and 2 immature teratomas are typically diploid, whereas grade 3 tumors are often aneuploid.<sup>431</sup>

## YOLK SAC TUMOR (ENDODERMAL SINUS TUMOR)

Intracellular and intercellular hyaline droplets are present in typical yolk sac tumors. This material is periodic acid–Schiff-positive and resists digestion with diastase. Several groups of investigators have shown that these droplets contain AFP as well as other proteins.<sup>51,432</sup> Teilum and colleagues suggested that the presence of AFP in these tumors supported the theory that such tumors contained or originated from the yolk sac endoderm.<sup>433</sup>

The polyvesicular vitelline tumor is a variant of the yolk sac tumor that is composed predominantly of cystic structures.<sup>434,435</sup> Such evidence of differentiation has been associated with a more favorable prognosis for patients with this histologic subtype of yolk sac tumor.

A cytogenetic study of childhood endodermal sinus tumors employing fluorescent *in situ* hybridization demonstrated deletions of the distal portion of the short arm of chromosome 1 (1p36) in eight of ten cases. This deletion maps to the same locus identified in neuroblastoma, another embryonal malignancy that typically affects young children.<sup>436</sup> The prognostic importance of this finding remains uncertain. Several putative tumor suppressor genes have been mapped within or adjacent to this locus, however, suggesting a role of this deletion in the pathogenesis of these tumors.

## EMBRYONAL CARCINOMA

Embryonal carcinoma is composed of cells that resemble epithelial cells. There is considerable variation in their size, shape, and arrangement. They may be large and pleomorphic without distinct cell borders. The cytoplasm may be homogeneously amphophilic or vacuolated. The nuclei are irregular, oval, or round, with an irregular and coarse nuclear membrane, and one or more large nucleoli. The cells may occur as solid sheets. Frequently, small or large acinar, tubular, and papillary structures are formed. Hemorrhage and necrosis are frequent.<sup>437</sup>

## SEMINOMA

Seminomas arising outside the testis are referred to as *germinomas* or *dysgerminomas (ovarian)*. Typical seminoma is composed of uniform cells supported by a delicate connective tissue stroma. Characteristically, the seminoma cell is large, polyhedral, or round, with a distinct cell border. It has clear or granular cytoplasm and a large, centrally located, spherical hyperchromatic nucleus, an irregular nuclear membrane, distinct and granular chromatin distribution, and one or two basophilic nucleoli. Tumor giant cells may be seen. Lymphocytic infiltration is present in most seminomas, with a granulomatous reaction identifiable in approximately one-half of cases.<sup>437</sup> As is commonly found in adult testicular tumors, isochromosome 12p (two copies of the short arm of chromosome 12) is frequently identified in adolescent testicular germinomas.<sup>438,439</sup> This chromosomal abnormality is rarely seen in malignant testicular tumors of infancy in which yolk sac tumor is the predominant histology.

## CHORIOCARCINOMA

Choriocarcinoma consists of two distinct cell types: syncytiotrophoblast and cytotrophoblast. The syncytiotrophoblast is a large, multinucleated cell with many hyperchromatic, irregular nuclei and cytoplasm usually eosinophilic or amphophilic. Cytotrophoblast cells are medium sized and closely packed with clear cytoplasm, distinct cell borders, and a single, uniform, moderate-sized vesicular nucleus.<sup>437</sup>

## TERATOCARCINOMA

Teratocarcinomas contain derivatives of more than one of the three primary germ cell layers (entoderm, mesoderm, ectoderm) consistent with the diagnosis of teratoma, and areas of embryonal carcinoma. In addition, areas of seminoma, endodermal sinus tumor, and choriocarcinoma may be identified within the tumor.<sup>437</sup>

## LABORATORY MARKERS

AFP and the b subunit of HCG (b-HCG) are oncofetoproteins that are found at elevated serum levels in association with a variety of germ cell tumors. These proteins are clinically useful both as diagnostic tools and in surveillance of children on or off treatment for tumors that secrete these markers. AFP is a glycoprotein that is produced in the liver, gastrointestinal tract, and yolk sac of the human fetus. The serum concentration of AFP reaches a maximum at 13 weeks of gestation.<sup>440</sup> It is readily detectable at birth, when high physiologic levels confound its diagnostic utility in infants with suspected germ cell tumors. Due to its long serum half-life of 7 days, the level of AFP may remain elevated in normal infants as old as 6 months of age.<sup>441,442</sup> Abelev and colleagues reported in 1967 that patients with testicular tumors that contained elements of embryonal carcinoma had elevated levels of AFP in their serum.<sup>443</sup> Other investigators have reported that children with embryonal carcinomas and malignant teratomas have elevated serum levels of AFP. Most commonly, high serum levels of AFP are identified in pediatric patients with testicular, ovarian, presacral, and vaginal primary yolk sac tumors.<sup>51,444</sup>

HCG is a glycoprotein that is secreted by the placenta. Patients with a pure yolk sac tumor do not have detectable serum levels of HCG. Patients with malignant germ cell tumors of the ovary or embryonal carcinoma of the ovary or testis may have elevated serum HCG levels.<sup>445</sup> HCG has a much shorter serum half-life than AFP, lasting only 24 to 36 hours. Thus, a decline in the serum level of this marker occurs much more rapidly with successful therapeutic intervention than is seen in management of tumors that secrete AFP.

## CLINICAL PRESENTATION AND TREATMENT BY ANATOMIC SITE

### SACROCOCCYGEAL TUMORS

Presacral and sacrococcygeal teratomas are usually diagnosed at birth or during the first month of life. Four types have been defined on the basis of the extent of pelvic and abdominal extension of the teratoma, and the presence or absence of external extension of the teratoma ( Fig. 44.2-8).<sup>446</sup>

**FIGURE 44.2-8.** The types of presacral teratomas. Malignancy rates are as follows: type 1, 8%; type II, 21%; type III, 34%; type IV, 38%. (From ref. 446, with permission.)

Only 2% of presacral and sacrococcygeal teratomas diagnosed before 6 months of age were malignant, compared with 65% of those diagnosed after 6 months of age. Both benign and malignant teratomas are more frequent in girls.<sup>426</sup> Children with presacral or sacrococcygeal teratomas frequently have congenital anomalies of the vertebrae, genitourinary system, or anorectum.<sup>446,447</sup>

Malignant presacral or sacrococcygeal teratomas may arise *de novo* or at the site of a previously excised benign teratoma.<sup>448,449</sup> The frequency of malignancy depends on the type of teratoma, varying from 8% for patients with type I, to 21% for those with type II, 34% for those with type III, and 38% for those with type IV lesions.<sup>446</sup> The much higher rate of malignancy in type IV tumors may reflect inadequate or delayed treatment of infants with foci of endodermal sinus tumor within a mature or immature sacrococcygeal teratoma.<sup>450</sup>

### Clinical Presentation and Evaluation of Sacrococcygeal Teratomas

Children with malignant pelvic teratomas present with an abdominal or buttock mass or signs of urinary and fecal obstruction. Rectal examination reveals the presence of a mass between the rectum and the sacrum. The mass may extend through the sciatic notch deep into the gluteal muscles.

Staging of the patient with a sacrococcygeal teratoma requires a radionuclide bone scan, plain radiographs of any positive area on the scan and any symptomatic bone, plain chest radiography and CT of the chest, abdomen, and pelvis ( Table 44.2-12).

Stage	Description
I	Complete resection at any site; coccygectomy for sacrococcygeal site; negative tumor margins; tumor markers positive or negative
II	Microscopic residual; lymph nodes negative; tumor markers positive or negative
III	Gross residual or biopsy only; retroperitoneal nodes negative or positive; tumor markers positive or negative
IV	Distant metastases, including liver

(From ref. 425, with permission.)

**TABLE 44.2-12.** Pediatric Oncology Group/Children's Cancer Group Staging for Malignant Extragonadal Germ Cell Tumors

Yolk sac tumor accounts for the vast majority of malignant presacral and sacrococcygeal teratomas.<sup>451</sup> In marked contrast to the predominance of benign teratomas in neonates with type I tumors, nearly 90% of children with type IV anatomy have tumors consisting of malignant elements.<sup>451</sup> Before the inclusion of cisplatin in chemotherapy regimens for pelvic yolk sac tumors, survival was poor, barely exceeding 10%.<sup>452</sup> Since the advent of modern, platinum-based chemotherapy in the late 1970s, however, more than 80% of patients with malignant sacrococcygeal teratomas are survivors.<sup>425</sup>

### **Surgery**

Before surgical resection, the upper limit of the tumor should be assessed by both rectal examination and either ultrasonography or MRI. In the vast majority of cases, the tumor can be resected by a perineal approach in which an incision is placed around the periphery of the protruding teratoma, preserving the maximum amount of skin. In approximately 10% of infants, a combined perineal and abdominal approach is required.<sup>446</sup> The plane between a benign teratoma and the normal anatomic structures can be readily defined. All normal structures should be preserved, accepting a narrow margin of resection. In light of a much higher recurrence rate when the adjacent coccyx is spared, the coccyx should routinely be removed with the tumor. The sacrum, however, can be preserved. Caution must be taken when resecting the anterior aspect of the teratoma to preserve the anal musculature, which may be directly adherent, and to avoid injury to the rectum that is draped over the anterior aspect of the tumor. If the tumor is identified in an older child or there is suspicion of malignancy, a preliminary biopsy should be performed. Preoperative chemotherapy should be administered if malignancy is confirmed. A complete resection of malignant teratomas can rarely be achieved without prior treatment with combination chemotherapy. This approach allows maximum preservation of normal structures including the rectum, anus, and the sacral plexus, which is critical for bladder and bowel function. If significant abdominal extension of the tumor is present, initial abdominal exploration allows control of the vascular supply to the tumor before the perineal dissection.<sup>453</sup>

### **Radiation Therapy**

Radiation therapy is not necessary for those children who undergo a complete excision or who have a complete response to combination chemotherapy.<sup>454</sup> In patients who have residual disease after treatment with chemotherapy and second-look surgery, local control with irradiation is poor.<sup>455</sup> If irradiation is indicated, the dose required for extragonadal germ cell tumors is 45 to 50 Gy.

### **Chemotherapy**

As noted previously, malignant pelvic yolk sac tumors are highly responsive to chemotherapy regimens that include cisplatin.<sup>456,457</sup> and <sup>458</sup> Children with pelvic yolk sac tumors should be treated aggressively, with the expectation that such an approach will result in long-term tumor control. [Table 44.2-13](#) contains an algorithm for the inclusion of chemotherapy in the treatment of germ cell tumors based on the risk-group stratification currently employed by North American pediatric cooperative groups (POG/CCG).<sup>425</sup>

Group	Treatment
Low risk Stage I gonadal Stage I extragonadal All immature teratomas	Surgery and observation
Intermediate risk Stage II-IV gonadal Stage II extragonadal	Surgery and PEB × 3 cycles*
High risk Stage III-IV extragonadal	Surgery and PEB-C × 4 cycles*

B, bleomycin; C, cyclophosphamide; E, etoposide; P, cisplatin.  
\*Patients with initial biopsy or incomplete resection have surgical resection of residual disease after completion of initial therapy. Patients who are complete responders (no viable tumor) receive no further therapy, and those with partial response receive additional chemotherapy. Patients with progressive disease receive alternative chemotherapy.  
(From ref. 425, with permission.)

**TABLE 44.2-13.** Management Schema for Pediatric Germ Cell Tumors

## **TESTICULAR TUMORS**

Testicular tumors make up approximately 10% of all pediatric germ cell tumors. The vast majority of these tumors are malignant (80%), characteristically containing yolk sac elements. In contrast to adult testicular tumors, which are frequently metastatic at initial diagnosis, 90% of pediatric testicular germ cell tumors are localized.<sup>427</sup> Malignant germ cell tumors of the testis occur at an annual incidence of 1.1 cases per 1 million U.S. white children younger than 15 years of age. The corresponding figure for African American children is only slightly lower at 0.9 cases per 1 million.<sup>459</sup> Testicular germ cell tumors follow a bimodal age distribution, occurring in very young children and adolescent boys. Yolk sac tumor, or endodermal sinus tumor, is the most common malignant germ cell tumor of the testis in prepubertal boys, with a median age at diagnosis of 24 months. Testicular tumors in adolescent boys have histologic features similar to those of adults.<sup>429</sup>

Children with yolk sac tumors of the testis have been diagnosed with additional anomalies including inguinal hernia, double ureter, ectopic kidney, hypospadias, and renal agenesis.<sup>460</sup>

### **Clinical Presentation and Evaluation**

Most children with primary testicular tumors present with painless testicular enlargement. In the relatively infrequent cases of metastatic disease, patients present with abdominal swelling due to malignant ascites, inguinal lymphadenopathy, or acute abdominal pain.

Physical examination reveals testicular enlargement. Transillumination is usually negative, but the presence of a hydrocele should not decrease the index of suspicion that a testicular tumor is present. Yolk sac tumor occurs with equal frequency in the right and left testis. Less than 1% of cases had bilateral testicular involvement at the time of initial presentation.<sup>51</sup>

The preoperative evaluation of a child suspected to have a malignant tumor of the testis should include a plain chest radiograph and serum AFP and HCG levels. Additional studies, including CT of the abdomen, pelvis, and chest, are not necessary before orchiectomy, although they are ultimately required for complete staging of testicular tumors containing malignant elements.

### **Management of the Undescended Testis**

Patients with an undescended testis have an increased risk of developing testicular cancer, although most associated tumors are diagnosed well beyond 15 years of age, often arising in the fourth decade.<sup>461,462</sup> and <sup>463</sup> The undescended testis occupies an intraabdominal location in 14.2% of patients. Cryptorchid testes in intraabdominal sites account for 51.5% of the cases of cancer diagnosed in patients with undescended testes, suggesting these patients are at the greatest risk of malignancy.<sup>462,464</sup>

Orchiopexy has been recommended both to preserve testicular function and to facilitate the identification of malignancy in the abnormally located testis. Several authors have reported the occurrence of testicular cancer in maldescended testes following orchiopexy.<sup>465</sup> Most patients were more than 6 years of age when

orchiopey was performed.<sup>466</sup> While orchiopey permits identification of tumors, it does not uniformly prevent their occurrence. Normal testicular function is unlikely in boys who undergo orchiopey after 2 years of age.<sup>467,468</sup> Children with an undescended testis and a normal contralateral testis should undergo orchiopey if the undescended testis is not recognized until puberty. Orchiopey is the treatment of choice for younger patients with cryptorchidism. Preservation of normal testicular function is most likely if surgical repair is performed before 2 years of age.<sup>469</sup>

### Staging

Once the histologic diagnosis is established, the patient must be staged. Although the majority of pediatric testicular germ cell tumors are nonmetastatic, the tumors may spread to retroperitoneal lymph nodes, liver, lungs, and rarely to bones or brain.

As noted previously, staging must include CT of the chest, abdomen, and pelvis, in addition to a radionuclide bone scan.

The retroperitoneal lymph nodes may be evaluated by CT or MRI. Absence of significant retroperitoneal fat in these young children and the inability of CT to identify normal sized lymph nodes that contain tumor may limit the sensitivity of CT for staging these patients. Since 90% of malignant testicular germ cell tumors in young children elaborate AFP, adjuvant chemotherapy is reserved for advanced stage disease and the small percentage of children with occult metastatic disease whose AFP fails to decline following orchiopey ([Table 44.2-14](#)).

Stage	Description
I	Limited to testis; tumor markers normal after appropriate half-life decline (αfetoprotein, 5 days; human chorionic gonadotropin, 16 hours)
II	Transscrotal orchiopey; microscopic disease in scrotum or high in spermatic cord (<5 cm from proximal end); retroperitoneal lymph node involvement (>2 cm); increased tumor markers after appropriate half-life decline, or both
III	Retroperitoneal lymph node involvement (>2 cm) but no visceral or extraabdominal involvement
IV	Distant metastases, including liver

(From ref. 425, with permission.)

**TABLE 44.2-14.** Pediatric Oncology Group/Children's Cancer Group Staging System for Testicular Germ Cell Tumors

### Treatment Planning

**SURGERY.** Preoperative diagnostic studies of a scrotal mass may include ultrasonography that can define the solid or cystic nature of the mass and its relationship to the testicle. All scrotal masses should be explored through an inguinal incision. A transscrotal biopsy contaminates the scrotum and its lymphatic drainage to the inguinal lymph nodes and prevents high ligation of the spermatic cord. If the tumor is clearly malignant, high ligation of the spermatic cord should be performed at the internal ring.

Increasingly, effective cisplatin-based chemotherapy for nonseminomatous germ cell tumors has decreased the role of surgical resection of the retroperitoneal lymph nodes as a therapeutic modality. Infants have a predominance of early-stage lesions that are primarily endodermal sinus tumors (yolk sac tumors), in contrast with teenage boys in whom the embryonal carcinoma or mixed germ cell tumors predominate. Teenagers frequently delay seeking medical attention, resulting in a higher proportion of advanced stage disease at initial presentation.<sup>470</sup> In most series, infants with clinical stage I ([Table 44.2-15](#)) endodermal sinus tumors are treated by radical orchiopey and then close follow-up. In the United Kingdom Children's Cancer Group Study of malignant germ cell tumors, 87% of the boys presented with stage I testicular tumors that were treated by orchiopey alone.<sup>471</sup> The pathology of these lesions was predominantly yolk sac tumors (57 of 61). In seven boys, a rising serum AFP was the only evidence for incomplete resection. All responded well to chemotherapy. Survival using this protocol was 100%. A smaller series from the Institute Gustave-Roussy reported recurrence in 2 of 12 boys followed without adjuvant chemotherapy or retroperitoneal lymph node dissection. Both were cured by surgery and chemotherapy.<sup>472</sup>

Stage	Description
Stage I	Tumor limited to one (or both) testes, which are removed by high inguinal orchiopey; no clinical, radiographic, or histologic evidence of residual disease beyond the testis; serum αfetoprotein negative postoperatively
Stage II	Transscrotal tumor aspiration, biopsy of tumor within the scrotal sac or scrotal orchiopey; microscopic residual disease within the scrotum or high in the spermatic cord (less than 5 cm from the proximal end); microscopic retroperitoneal lymph node involvement (lymph nodes less than 2 cm in diameter, less histologically positive for tumor) or serum αfetoprotein positive more than 4 weeks after orchiopey
Stage III	Great retroperitoneal lymph node involvement (lymph nodes more than 2 cm in diameter and histologically positive for tumor)
Stage IV	Extraabdominal lymph node metastases
A	Extraabdominal metastases are present (e.g., liver, peritoneum, bones, bone marrow, or brain)
B	Extraabdominal metastases are present (e.g., liver, peritoneum, bones, bone marrow, or brain)

**TABLE 44.2-15.** Staging System for Yolk Sac Tumor of the Testis

The clinical behavior of testicular embryonal carcinomas is similar in teenagers and adults. Studies have demonstrated that adults with clinical stage I embryonal carcinoma of the testes have positive retroperitoneal lymph nodes in approximately 30% of cases.<sup>473</sup> This earlier finding is supported by reports of a 28% relapse rate in adults with stage I disease who were initially observed after radical orchiopey.<sup>474</sup> A similar approach to localized disease in children was employed at the St. Jude Children's Research Hospital where relapse with a pulmonary metastasis was seen in one of eight boys.<sup>475</sup> In many current protocols, children with clinical stage I disease (i.e., no radiographically identifiable retroperitoneal tumor and falling serum markers) are followed after radical orchiopey. Children with identifiable retroperitoneal tumor frequently receive initial chemotherapy, with surgery reserved for residual masses or persistently elevated markers. Resection of postchemotherapy residual masses in adults demonstrated that 45.0% had necrosis, 42.5% had teratoma, and 12.5% had viable germ cell tumor.<sup>476</sup> Both the North American and European pediatric cooperative groups currently employ this strategy of surgery alone followed by close surveillance in children with stage I germ cell tumors, regardless of site or histology.

Children with yolk sac tumors of the testis rarely require bilateral retroperitoneal lymph node dissection for adequate staging. The procedure results are usually negative, but the procedure carries a substantial risk of producing impotence and retrograde ejaculation. In one series, only 2 of 49 bilateral retroperitoneal lymph node dissections and 4 of 29 unilateral retroperitoneal lymph node dissections performed in children with yolk sac tumor of the testis were positive.<sup>51</sup> The percentage of positive retroperitoneal lymph node dissections was not influenced by the age of the patient. Since this diagnostic procedure carries substantial potential morbidity and infrequently provides information that will change the stage or influence therapy, retroperitoneal lymphadenectomy should be avoided.

**CHEMOTHERAPY.** Current therapeutic practice reserves chemotherapy for children with either advanced stage disease, recurrent localized tumors, or children with stage I disease whose tumor markers fail to decline following orchiopey. Inclusion of chemotherapy in the treatment of children with stage I disease has not provided a statistically significant advantage in relapse-free survival.

The application of combination chemotherapy to the treatment of children with advanced stage or recurrent yolk sac tumor has proceeded from the use of similar programs for the management of adults with nonseminomatous germ cell tumors of the testis. The first effective combinations included dactinomycin, chlorambucil,

and methotrexate or dactinomycin, vincristine, and cyclophosphamide.<sup>51</sup> Unfortunately, neither of these regimens significantly increased the number of patients with advanced abdominal or pulmonary metastatic disease who achieved long-term, disease-free survival.

Subsequent identification of bleomycin and cisplatin as active agents against testicular germ cell tumors, however, has substantially improved survival for patients with disseminated disease. The Einhorn regimen, consisting of cisplatin, vinblastine, and bleomycin (PVB), was developed at the Indiana University Medical Center in 1974. It has been active against embryonal carcinoma, teratocarcinoma, choriocarcinoma, and yolk sac tumor of the testis.<sup>428</sup> The addition of doxorubicin did not increase the complete response rate. The activity of this three-drug combination has been confirmed by several groups of investigators. Increasing the dose intensity of cisplatin does not improve the response rate or survival rate, but does increase the toxicity of the PVB regimen.<sup>477</sup> Substitution of etoposide for vinblastine in the PVB regimen did not change the response rate and substantially decreased the toxicity of the chemotherapy regimen.<sup>478,479</sup> In light of the pulmonary toxicity of bleomycin, multiple studies have been conducted to assess the value of continued inclusion of this agent in platinum-based regimens. Although several randomized adult studies suggest that bleomycin may be deleted from the cisplatin, etoposide, and bleomycin combination based on comparable response rates with and without this agent, there were sufficient differences in overall and relapse-free survival to recommend its continued use.<sup>480,481</sup> and <sup>482</sup> In view of impressive responses to alternative regimens using ifosfamide and etoposide and a United Kingdom study that effectively substituted carboplatin for cisplatin, there are now several potentially less toxic chemotherapy options that need to be prospectively tested.<sup>483,484,485</sup> and <sup>486</sup>

The same guidelines for management of young children with yolk sac tumors of the testis should be applied to adolescents with malignant germ cell tumors. Teenagers with stage I nonseminomatous germ cell tumors may be managed with close surveillance.<sup>487</sup> Those with more advanced stage disease should receive platinum-based combination chemotherapy.

## OVARY

Ovarian tumors account for approximately 25% of all pediatric germ cell tumors. The majority of these tumors arise later in childhood, with a peak incidence at 10 years of age. Most of these tumors are benign mature cystic teratomas, although nearly one-third contain malignant elements. In contrast to adult ovarian tumors, malignancies of epithelial or stromal cell origin are uncommon in children. The most common pediatric ovarian neoplasias are dysgerminomas and yolk sac tumors. Immature teratomas account for approximately 10% of ovarian masses.<sup>426,429,488,489</sup>

### Clinical Presentation

Patients with ovarian tumors present with abdominal pain or an abdominal mass. The pain may be severe due to torsion of the ovarian pedicle by the ovary and tumor.<sup>490</sup> Fever is present in 24% of patients at the time of diagnosis.

Preoperative radiographic evaluation should include studies that localize the mass to the ovary. A plain abdominal radiograph should be obtained and examined for the presence of calcification. Abdominal ultrasonography demonstrates whether the mass is cystic in nature. CT provides more detailed information about the site of origin of the tumor. In patients with suspected ovarian germ cell tumors, serum levels of AFP and HCG should be assayed before diagnostic or therapeutic surgical intervention. Once the tissue diagnosis is established, the potential sites of metastatic disease should be examined. Possible sites of dissemination include peritoneal implants, retroperitoneal lymph nodes, lung, liver, and bone. There has been considerable controversy regarding the proper risk group stratification and treatment of patients with immature teratomas and gliomatosis peritonei (peritoneal seeding with mature glial tissue). In general, immature teratomas are treated with surgery alone. The controversy resides in questions about the appropriateness of surgery alone for immature teratomas that have extensively seeded the omentum and peritoneal surfaces. In a report by POG/CCG documenting 135 cases of childhood immature teratomas, 22 of 86 cases of ovarian immature teratoma were characterized by gliomatosis peritonei. Investigators on this study found that this feature had no adverse effect on outcome in patients treated with surgery alone.<sup>491</sup> Only the finding of microscopic foci of malignant yolk sac tumor in immature teratomas correlated with poor prognosis, mandating inclusion of adjuvant chemotherapy for this small subset of children. These same authors note that while modest elevations of AFP (less than 60) may be recorded in children with immature teratomas without malignant elements, nearly all patients with AFP greater than 100 have occult foci of malignant yolk sac tumor.<sup>491</sup>

### Staging

Staging evaluation should include CT of the chest, abdomen, and pelvis, in addition to bone scintigraphy with technetium 99m pertechnetate. Ovarian tumors are staged using the POG/CCG staging system, which represents a simplified derivation of the International Federation of Gynecology and Obstetrics staging system.<sup>425,492</sup> (Table 44.2-16).

Stage	Description
I	Limited to ovary (ovaries) peritoneal washings negative; tumor markers normal after appropriate half-life decline ( $\alpha$ -fetoprotein, 5 days; human chorionic gonadotropin, 16 hours)
II	Microscopic residual or positive lymph nodes ( $<2$ cm); peritoneal washings negative for malignant cells, tumor markers positive or negative
III	Lymph node involvement ( $>2$ cm); gross residual or biopsy only; contiguous visceral involvement (omentum, intestine, bladder); peritoneal washings positive for malignant cell; tumor markers positive or negative
IV	Distant metastases, including liver

**TABLE 44.2-16.** Pediatric Oncology Group/Children's Cancer Group Staging System for Pediatric Ovarian Germ Cell Tumors

### Treatment Planning

**SURGERY.** Surgical exploration of an ovarian mass must accomplish two goals: resection of the primary tumor and adequate staging. Peritoneal fluid should be aspirated for cytology. If no fluid is present, peritoneal washings should be obtained. Any peritoneal seeding should be biopsied and a partial or complete omentectomy performed. Ipsilateral lymph nodes should be examined and biopsies taken from the iliac, low periaortic, or pericaval nodes and the periaortic or pericaval nodes at the level of the renal vessels. The contralateral ovary should be examined closely, and if nodules are present, particularly in dysgerminomas or teratomas, a biopsy should be obtained. With current techniques available for *in utero* fertilization, increasing efforts are taken to preserve the fallopian tube and uterus in cases in which both ovaries must be resected.<sup>493</sup>

**CHEMOTHERAPY.** Combination chemotherapy with VAC was employed in the 1970s in two small series of pediatric patients with ovarian yolk sac tumor. These early studies demonstrated that improved survival could be achieved with inclusion of chemotherapy in treatment of patients with stage I and II disease.<sup>494,495</sup> Results of these pediatric trials were consistent with the outcomes of studies in adults with ovarian yolk sac tumor that documented similar improvements in survival with adjuvant VAC chemotherapy.<sup>496,497</sup> Neither study reported the response rate of women with advanced ovarian yolk sac tumor to VAC.

Closely paralleling the chronology and evolution of chemotherapy for testicular germ cell tumors, subsequent clinical trials for ovarian germ cell tumors employed the combination of PVB in the treatment of women with advanced ovarian germ cell tumors. In one series, the response rate was 91%, with six women achieving a complete response.<sup>498</sup> Several other investigators have reported activity of the PVB combination against a variety of ovarian germ cell tumor histologies.<sup>499,500</sup> Current pediatric practice uses the cisplatin, etoposide, and bleomycin regimen for treatment of primary nonlocalized or recurrent ovarian germ cell tumors. This regimen has produced survival rates exceeding 90% for localized and advanced stage ovarian germ cell tumors in children.<sup>425</sup>

**RADIATION THERAPY.** With the advent of such effective chemotherapy for ovarian germ cell tumors, the current role of radiation therapy is uncertain. No radiation therapy is given for histologies other than dysgerminoma if surgery and chemotherapy render the child free of disease.<sup>434</sup> In the unusual situation in which there is

persistent disease after initial surgery, chemotherapy, and a second-look operation, 40 Gy is recommended.

Treatment options for ovarian dysgerminoma are more complex. Dysgerminomas are curable with irradiation, with one small pediatric study documenting a 5-year overall survival of 94%. Unfortunately, this same study described extensive late sequelae to radiation therapy, including infertility, dysmenorrhea, hypogonadism, and pelvic fibrosis.<sup>501</sup> Given the morbidity of pelvic irradiation and the exquisite chemosensitivity of this tumor, radiation should be reserved for second-line therapy in patients who have relapsed following surgery and chemotherapy. In those rare cases in which radiation therapy is indicated, doses required for dysgerminoma are 20 to 25 Gy, with a boost to gross residual disease to a total dose of 35 to 40 Gy.<sup>493</sup>

## MEDIASTINUM

Germ cell tumors of the thoracic cavity typically arise in the anterior mediastinum of adolescent boys. While the majority of these tumors are benign teratomas, malignant yolk sac tumor and choriocarcinoma have been identified in this location.<sup>502,503</sup> Several patients with Klinefelter's syndrome have developed yolk sac tumors.<sup>504</sup> The clinical presentation is characterized by a brief history of cough, dyspnea, and chest pain due to tracheobronchial compression.

Routine chest radiographs may demonstrate an incidental anterior mediastinal mass. The diagnosis is established by biopsy of the primary tumor at thoracotomy or mediastinoscopy, or by biopsy of an involved supraclavicular lymph node. Staging studies, including a bone scan, skeletal survey, bone marrow aspirate, and biopsy, should be performed immediately after tissue diagnosis is established.

The results of therapy have improved with the use of cisplatin-containing chemotherapy regimens, with approximately 40% of patients being relapse-free survivors.<sup>454,498,502</sup>

There are insufficient data available to evaluate the relative importance of surgical excision, local irradiation, and combination chemotherapy in the management of patients with yolk sac tumor of the mediastinum. Frequently, therapeutic failure is due to local progression of the tumor. Since achieving complete surgical excision in this site may be difficult, therapeutic morbidity may be minimized by treating malignant tumors with neoadjuvant chemotherapy followed by delayed resection. Treatment outcomes have improved with the application of cisplatin-based chemotherapy regimens.<sup>454,499,503</sup>

## INTRODUCTION

The term *lymphoma* identifies two distinct groups of neoplasms: non-Hodgkin's lymphoma (NHL) and Hodgkin's lymphoma (HL).<sup>1,2</sup> Since the late 1970s, significant progress has been made in the elucidation of the pathogenesis of NHL as a clonal malignant expansion of B or T cells. The molecular characterization of the most frequent cytogenetic abnormalities associated with NHL has led to the identification of a number of genes that are altered in B-cell or T-cell NHL. The pathogenicity of most of these alterations has been confirmed by their ability to cause tumors in transgenic animal models. In addition, it has been established that most of these genetic lesions selectively associate with specific NHL types, thus representing specific markers of possible diagnostic significance for various NHL subtypes.<sup>1,2</sup> In contrast to NHL, the molecular pathogenesis of HL is less well understood, and until the advent of single-cell molecular analysis, genetic studies of HL had been hampered by the paucity of the neoplastic population within HL biopsies.

This chapter outlines the main types of genetic lesions in lymphomas and their distribution among the various clinicopathologic subtypes of these disorders, with major emphasis on NHL. The last section of the chapter briefly discusses the present and future applications of molecular genetic analysis in the clinical management of lymphomas.

## HISTOGENETIC PATHWAYS OF LYMPHOMA

The histogenesis of lymphoma can be assessed by identifying the precise cellular subset from which a given lymphoma category derives ( [Fig. 45.1-1](#)). This is achieved by defining the lineage and the precise differentiation stage of the various types of lymphoma and by comparing them with the features proper of the different maturation stages of normal lymphocytes. To date, the histogenesis of lymphoma has been clarified to a sizable extent in the case of lymphomas derived from B cells, whereas it is still poorly understood in the case of lymphomas originating from T cells.

**FIGURE 45.1-1.** Model of B-cell non-Hodgkin's lymphoma (NHL) histogenesis and pathogenesis. A lymphoid follicle, constituted by the germinal center (GC) and the mantle zone (MZ), is represented together with the surrounding marginal zone (MargZ). On entering the GC, B cells activate into centroblasts, proliferate, and mature into centrocytes. These events are coupled to somatic hypermutation of immunoglobulin (Ig) genes and isotype switch of the Ig produced. Only GC B cells that are positively selected by antigen survive and exit the GC successfully. Cells that have exited the GC (post-GC B cells) have two fates: differentiation into plasma cells or memory B cells. Based on the absence or presence of somatic Ig hypermutation, B-cell NHL may be distinguished into two broad histogenetic categories: (1) B-cell NHL derived from pre-GC B cells and devoid of Ig mutations, represented in the figure by mantle cell lymphoma (MCL) and a fraction of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL); and (2) B-cell NHL derived from B cells that have transited through the GC and harbor Ig mutations, represented in the figure by follicular lymphoma (FL), lymphoplasmacytoid lymphoma (LPL), mucosa-associated lymphoid tissue lymphoma (MALT), diffuse large cell lymphoma (DLCL), and Burkitt's lymphoma (BL). For each lymphoma category, the arrow indicating the histogenetic origin is flanked by the genetic lesion associated with the lymphoma. In the case of CLL/SLL, as well as in a subset of DLCL, the relevant cancer related gene has not been identified.

B lymphocytes are generated in the bone marrow as a result of a multistep differentiation process.<sup>3,4 and 5</sup> Precursor B cells usually begin immunoglobulin (Ig) gene rearrangements of the heavy-chain locus followed by rearrangements of the light-chain locus.<sup>3,4 and 5</sup> If precursor B cells express a functional surface antibody acting as antigen receptor, they are positively selected into the peripheral B-cell pool comprising naive B cells.<sup>3,4 and 5</sup> Cells failing to express a functional antigen receptor are eliminated within the bone marrow.<sup>3,4 and 5</sup> For many B cells, the subsequent maturation steps are linked to the histologic structure of the germinal center.<sup>3,4 and 5</sup> The germinal center is constituted by a dark zone, characterized by a dominant growth of rapidly proliferating B cells, and by a light zone, in which nonproliferating B cells are selected and induced to differentiate through interactions with follicular dendritic cells and T helper cells. Within the germinal center, antigen-activated B cells accumulate somatic point mutations within their rearranged heavy- and light-chain genes (a phenomenon known as *somatic hypermutation*), which modify the affinity of their surface antibody to the antigen.<sup>3,4,5,6,7 and 8</sup> Only B cells that have acquired mutations leading to high-affinity binding are positively selected and differentiate into memory B cells or plasmablasts, whereas the majority of B cells are eliminated by apoptosis within the germinal center.<sup>3,4,5,6,7 and 8</sup>

The use of somatic hypermutation as a specific marker of B-cell transition through the germinal center allows for the definition of two broad histogenetic categories of B-cell lymphoma<sup>9,10</sup>:

1. Lymphomas devoid of somatic Ig hypermutation, which may derive from either pre-germinal center B cells or from B cells that have achieved maturation without transiting through the germinal center. Lymphomas generally devoid of somatic Ig hypermutation include mantle cell lymphoma and a substantial percentage of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma.<sup>9,10</sup>
2. Lymphomas associated with somatic Ig hypermutation and thus putatively derived from germinal center or post-germinal center B cells. Among the NHLs, lymphomas generally associated with somatic Ig hypermutation include follicular lymphoma, lymphoplasmacytoid lymphoma, mucosa-associated lymphoid tissue (MALT) lymphoma, diffuse large cell lymphoma (DLCL), Burkitt's lymphoma, and primary effusion lymphoma.<sup>9,10,11,12,13,14,15 and 16</sup> In addition, a fraction of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, approximating 50% of cases, is thought to originate from germinal center-related B cells.<sup>17,18</sup> Most, if not all, HL cases also are thought to derive from germinal center or post-germinal center B cells.<sup>19,20,21,22 and 23</sup> Extranodal lymphomas associated with somatic Ig hypermutation are postulated to originate from B cells that have transited through the germinal center and subsequently migrated to the involved extranodal site.

## GENERAL MECHANISMS OF GENETIC LESIONS IN LYMPHOMA

Analogous to most cancer types, the pathogenesis of lymphoma represents a multistep process involving the progressive and clonal accumulation of multiple genetic lesions affecting protooncogenes and tumor suppressor genes. However, several important features distinguish the mechanism and type of genetic alterations associated with lymphoma from those associated with solid tumors. Extensive cytogenetic studies have shown that, during most stages of the disease, the genome of lymphoma cells is relatively stable and is not affected by the generalized random instability typical of many solid tumors, particularly those of epithelial origin.<sup>24</sup> Lymphoma also appears devoid of microsatellite instability, the hallmark of molecular defects in DNA mismatch repair genes observed in some hereditary cancer predisposition syndromes as well as in most sporadic tumor types.<sup>25,26 and 27</sup> Conversely, the genome of lymphoma cells is characterized by few, sometimes single, nonrandom chromosomal abnormalities, commonly represented by chromosomal translocations.<sup>28</sup>

At the molecular level, the genetic lesions identified so far in lymphomas include activation of oncogenes by chromosomal translocations, as well as inactivation of tumor suppressor loci by chromosomal deletion and mutation. In addition, the genome of certain lymphoma subtypes can be altered by the introduction of exogenous genes by various oncogenic viruses.

## CHROMOSOMAL TRANSLOCATIONS

Chromosomal translocations represent the genetic hallmark of lymphoid malignancies, including NHL. As in other types of malignancies, NHL-associated translocations represent reciprocal and balanced recombinations between two specific chromosomes that are recurrently associated with a given tumor type and clonally represented in each tumor case.

The precise mechanisms leading to chromosomal translocations in hematopoietic neoplasms are not clearly understood. However, data suggest that the translocation process most likely occurs during Ig gene and T-cell receptor gene rearrangements in B and T cells, respectively, as a consequence of errors of the VDJ recombination machinery or the class switch machinery. This evidence is supported by the following observations:

1. A significant number of translocations involve chromosomal breakpoints within the Ig or T-cell receptor loci.<sup>24</sup>
2. In B-cell NHL, breakpoints within the Ig loci are often located precisely within sequences that normally mediate Ig gene rearrangement in B cells, such as the J and switch sequences.<sup>29</sup> Moreover, N-nucleotides, which are template-independent nucleotide additions generated at the site of VDJ recombination by terminal deoxynucleotidyl transferase, can be detected at certain breakpoint junctions, suggesting the action of the recombinase.<sup>30</sup>
3. Similarity has been shown between the sequences surrounding the breakpoints and recombination targeting motifs, such as the heptamer/nonamers and the bp45 nuclease binding sequence.<sup>31</sup>

Not all the chromosomal translocations are due to errors of the recombination machinery of the immune system. A defect in the DNA damage repair mechanism may be responsible in at least some translocations.<sup>32</sup> For example, based on sequence analysis of reciprocal chromosomal breakpoints, the chromosomal translocation t(4;11) seen in acute leukemias of B lineage appears to be initiated by several DNA strand breaks on both participating chromosomes and by subsequent DNA repair by an "error-prone" DNA repair mechanism. Similarly, analysis of the breakpoint junction sequence at *TEL* in t(12;21)(p13;q22) supports the occurrence of staggered DNA double-strand breaks followed by DNA repair.<sup>33</sup> Therefore, the generation of DNA double-strand breaks by exogenous and endogenous sources (e.g., chemicals and oxygen-free radicals) and faulty DNA repair can lead to chromosomal rearrangements.<sup>34,35</sup> These models have been validated by mouse models but have yet to be proven in humans.<sup>36</sup>

The suggestion also has been made that some translocations, namely those occurring in lymphoid malignancies derived from germinal center B cells, such as Burkitt's lymphoma and DLCL, may be a result of somatic hypermutation that takes place in the germinal center B cells.<sup>37</sup> It has been shown that deletions and duplications can be introduced into the rearranged variable ( $V_H$ ) genes in a substantial portion of germinal center cells during somatic hypermutation. Because the formation of these deletions and duplications is intrinsically associated with DNA double-strand breaks, they may provide a potential source for chromosomal translocations in germinal center B cells. Somatic hypermutation may be the underlying mechanism of the chromosomal translocations between the  $Ig_H$  locus and *c-MYC* in the endemic form of Burkitt's lymphoma, and these translocations are generally believed to be a result of errors of the VDJ recombination machinery. This theory is supported by the observation that the breakpoints at the  $Ig_H$  loci in endemic Burkitt's lymphoma are not usually directly adjacent to the recombination signal sequence that mediates VDJ recombination, but are located in the J intron or within rearranged VJ genes (i.e., the target region for hypermutation).<sup>38</sup> It remains to be seen if somatic hypermutation also plays a role in the generation of chromosomal translocations at the *BCL-6* locus, which also is a target for somatic hypermutation, in B-cell DLCL (see [Diffuse Large Cell Lymphoma](#), later in this chapter).

The common feature of all chromosomal translocations associated with NHL is the presence of protooncogenes in proximity to the chromosomal recombination sites. In most cases, the structure of the protooncogene and, in particular, its coding domain is not affected by the translocation, but the pattern of expression of the gene is altered as a consequence of the juxtaposition of heterologous regulatory sequences derived from the partner chromosome (protooncogene deregulation) ( [Fig. 45.1-2](#)). Two distinct types of protooncogene deregulation may occur, including homotopic and heterotopic deregulation. Homotopic deregulation occurs when the protooncogene is expressed constitutively in the lymphoma, whereas its expression is tightly regulated in normal lymphoid cells. Conversely, heterotopic deregulation occurs when the protooncogene, which is normally not expressed in lymphoid cells, undergoes ectopic expression in the lymphoma. In most types of NHL-associated translocations, the heterologous regulatory regions responsible for protooncogene deregulation are derived from antigen receptor loci, which are expressed at high levels in the target tissue.

**FIGURE 45.1-2.** Models of chromosomal translocations in non-Hodgkin's lymphoma (NHL). The two genes involved in the translocation event are represented by their coding sequences (CS), which are represented by the rectangles, and by their regulatory sequences (RS), which are represented by the circles. The two genes are identified by different colors (black or white). **Top:** Germline configuration of the two genes involved in the translocation. The coding sequence of each of the two

genes is proximal to its physiologic regulatory sequences, which coordinate the normal expression of the gene. **Bottom:** Chromosomal translocations may lead to two different consequences. In the case of transcriptional deregulation, the normal regulatory sequences of the protooncogene are removed and substituted with regulatory sequences derived from the partner chromosome. The protooncogene coding sequence (*black rectangle*) is thus juxtaposed to heterologous regulatory sequences (*white circle*). In NHL, most commonly the novel regulatory regions are derived from the immunoglobulin gene loci, which are consistently expressed at high levels in mature B cells. In the case of fusion transcript formation, part of the coding sequence of the two genes involved is fused together, generating a novel fusion protein with biochemical properties distinct from the native proteins.

An alternative mechanism of oncogene activation by chromosomal translocation is the juxtaposition of two genes to form a chimeric gene coding for a novel chimeric protein. This mechanism, which is common in chromosomal translocations associated with acute leukemias, is rarely associated with NHL. Examples are the t(11;18) of MALT lymphoma and the t(2;5) of T-cell anaplastic lymphoma.

The molecular cloning of the genetic loci involved in the translocations most frequently associated with NHL has led to the identification of a number of protooncogenes involved in lymphomagenesis (Table 45.1-1). The majority of these protooncogenes code for nuclear molecules belonging to major families of transcription factors, although regulators of programmed cell death and signal transducers may also be involved. The structural and functional consequences of each chromosomal translocation associated with NHL are described in each section of this chapter dedicated to the molecular pathogenesis of the various NHL subtypes.

Site/Region/Line Name/Phenotype	Translocation	Protooncogene Involved	Mechanism of Protooncogene Activation	Protooncogene Function
Lymphoblastoid lymphoma	t(14;18)(q32;q21)	BCL2	Transcriptional deregulation	Transcription factor regulating cell proliferation and differentiation
Follicular lymphoma	t(14;18)(q32;q21)	BCL2	Transcriptional deregulation	Negative regulator of apoptosis
Mantle cell lymphoma	t(11;14)(q13;q32)	MYC	Fusion protein	Negative regulator of apoptosis
Mantle cell lymphoma	t(11;14)(q13;q32)	BCL6	Transcriptional deregulation and translocation of target nucleosome domain	Regulator of apoptosis
Mantle cell lymphoma	t(11;14)(q13;q32)	BCL11 and BCL2	Transcriptional deregulation	Regulator of the early phase of the cell cycle
Diffuse large cell lymphoma	t(2;5)(p21;q35)	BCL6	Transcriptional deregulation	Transcriptional repressor; suppresses transcription and function of germinal centers
Burkitt's lymphoma	t(8;14)(p21;q32)	c-MYC	Transcriptional deregulation	Transcription factor regulating cell proliferation, differentiation, and apoptosis
T-cell anaplastic large cell lymphoma	t(2;5)(p21;q35)	MYC	Fusion protein	Anti-apoptotic kinase

TABLE 45.1-1. Chromosomal Translocations of Non-Hodgkin's Lymphomas

## OTHER MECHANISMS OF PROTOONCOGENE ALTERATION

In addition to chromosomal translocations, other mechanisms of protooncogene activation can also occur in NHL. Protooncogene amplification is substantially less common than in epithelial cancers, yet it occurs in some cases of high-grade NHL, as exemplified by the instance of *REL* amplifications in DLCL.<sup>39</sup> Amplification may involve many other unknown chromosomal sites, which are likely to be revealed by the extensive use of advanced cytogenetic techniques, such as comparative genomic hybridization. Point mutations can alter the coding sequence of the protooncogene, as in the case of *c-MYC* and *BCL-2*, and thus alter the biologic properties of the protooncogene product.<sup>40,41</sup> Alternatively, mutations may affect the protooncogene regulatory sequences, as in the case of *c-MYC* and *BCL-6*, thus altering their sensitivity to factors normally regulating the expression of the protooncogene through binding to its regulatory sequences.<sup>42,43,44</sup> and <sup>45</sup> Mutations of the *RAS* genes, which represent a frequent protooncogene alteration in human neoplasia, are virtually always absent in NHL.<sup>46</sup> Mutations activating unknown oncogenes may be a frequent event in NHL, and the search for these oncogenes is the focus of current investigations.

## INACTIVATION OF TUMOR SUPPRESSOR GENES

Deletions and mutations of the *p53* tumor suppressor gene, which are thought to represent the most common genetic alteration in human cancer,<sup>47</sup> are restricted to specific subsets of NHL, including late stages of follicular lymphoma and Burkitt's lymphoma.<sup>48,49</sup> and <sup>50</sup> The mechanisms of *p53* inactivation in NHL is similar to that detected in human neoplasia in general and occurs through point mutation of one allele, chromosomal deletion of the second allele, or both.<sup>47</sup>

In addition, NHLs are associated with specific chromosomal deletions, suggesting the loss of presently unknown tumor suppressor genes. The most frequent of these deletions involves the long arm of chromosome 6 (6q).<sup>24,51</sup> The observations that 6q deletions may occur as the sole cytogenetic abnormality in some NHL cases<sup>24</sup> and are associated with poor prognosis<sup>28</sup> strongly support a pathogenetic role for these alterations. Deletions of chromosome 13q14 represent the most frequent lesion in B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, occurring in more than 50% of cases.<sup>24</sup> Mapping studies have ruled out the involvement of the *RB1* tumor suppressor gene, which is also located on chromosome 13q14, and have suggested the presence of a distinct tumor suppressor gene in the same region.<sup>52,53,54,55,56,57</sup> and <sup>58</sup>

## ONCOGENIC VIRUSES

The infection of tumor cells by oncogenic viruses must be considered as a mechanism of genetic lesion because viruses introduce foreign genes into their target cells. Three distinct viruses are associated with the pathogenesis of specific NHL subtypes: Epstein-Barr virus (EBV), human herpesvirus-8 (HHV-8), and human T-cell leukemia virus type I (HTLV-I).

EBV was initially identified in cases of endemic Burkitt's lymphoma from Africa; subsequently, EBV also was detected in a fraction of sporadic forms of Burkitt's lymphomas, acquired immunodeficiency syndrome (AIDS)-associated lymphomas, and primary effusion lymphomas.<sup>49,59,60,61,62,63,64,65,66,67</sup> and <sup>68</sup> With infection of a B lymphocyte, the EBV genome is transported into the nucleus, where it exists predominantly as an extrachromosomal circular molecule (episome).<sup>59</sup> The formation of circular episomes is mediated by the cohesive terminal repeats, which are represented by a variable number of tandem repeats sequence.<sup>59,69</sup> Because of this terminal heterogeneity, the number of variable number of tandem repeats sequences enclosed in newly formed episomes may differ considerably, thus representing a constant clonal marker of the episome and, consequently, of a single infected cell.<sup>69</sup> Evidence for a pathogenetic role of the virus in NHL infected by EBV is at least twofold. On one side, it is well recognized that EBV is able to significantly alter the growth of B cells.<sup>59</sup> On the other side, EBV-infected lymphomas usually display a single form of fused EBV termini, suggesting that the lymphoma cell population represents the clonally expanded progeny of a single infected cell.<sup>49,61</sup>

HHV-8 is a gamma herpesvirus initially identified in tissues of patients with AIDS-related Kaposi's sarcoma, and it subsequently was found to infect a peculiar type of lymphoma known as *primary effusion lymphoma*<sup>70,71,72,73,74</sup> and <sup>75</sup> as well as a substantial fraction of multicentric Castleman's disease.<sup>76</sup> Phylogenetic analysis has shown that the closest relative of HHV-8 is herpesvirus saimiri, a gamma-2 herpesvirus of primates associated with T-cell lymphoproliferative disorders.<sup>77,78</sup> Like the other gamma herpesviruses, HHV-8 is lymphotropic, because it can be found in lymphocytes both *in vitro* and *in vivo*.<sup>67,70,71,72,73,74,75</sup> and <sup>76,79,80</sup> Lymphoma cells naturally infected by HHV-8 harbor the viral genome in its episomal configuration and display a marked restriction of viral gene expression, suggesting a pattern of latent infection.<sup>78</sup> HHV-8 carries several genes that may behave as oncogenes, including a gene homologous to the cellular D-type cyclins, a G protein-coupled receptor displaying constitutive activation, and several genes encoding for molecules displaying high homology with cellular cytokines [viral interleukin (IL)-6] and chemokines [viral macrophage inflammatory protein (MIP)-1a, MIP-2].<sup>81,82</sup> and <sup>83</sup> However, because primary effusion lymphoma cells carry latent HHV-8 infection, only a restricted subset of viral genes are expressed *in vivo*, including viral cyclin D and viral IL-6.<sup>81,84</sup>

HTLV-I is a member of the lentivirus group, which can immortalize normal T cells *in vitro* and can cause adult T-cell leukemia/lymphoma.<sup>85,86</sup> and <sup>87</sup> Unlike acutely transforming retroviruses, the HTLV-I genome does not encode a viral oncogene.<sup>85,86</sup> and <sup>87</sup> Furthermore, this retrovirus does not transform T cells by *cis*-activation of an adjacent cellular protooncogene, because the provirus appears to integrate randomly within the host genome.<sup>85,86</sup> and <sup>87</sup> Rather, the pathogenetic effect of HTLV-I

seems to be due to viral production of a transregulatory protein (HTLV-I tax) that markedly increases expression of all viral gene products and transcriptionally activates the expression of certain host genes, including IL-2, the  $\alpha$  chain of the IL-2 receptor (CD25), c-sis, c-fos, and granulocyte-macrophage colony-stimulating factor.<sup>88,89,90,91 and 92</sup> The central role of these genes in normal T-cell activation and growth, coupled to direct experimental evidence, support the notion that tax-mediated activation of these host genes represents an important mechanism by which HTLV-I initiates T-cell transformation.<sup>93</sup> In addition, it has been suggested that tax may mediate DNA damage as a consequence of either inactivation of the *p53* checkpoint or a repression of DNA repair functions.<sup>94,95</sup> It has been shown that tax may abrogate a mitotic checkpoint by targeting the TXBP181 cellular gene, a homologue of the yeast mitotic checkpoint MAD1 protein.<sup>96</sup> These features of tax are consistent with the fact that adult T-cell leukemia/lymphoma cells are karyotypically abnormal and frequently present as pleomorphic multinucleated giant cells.<sup>97,98</sup>

## MOLECULAR PATHOGENESIS OF B-CELL NON-HODGKIN'S LYMPHOMA

The following section describes the detailed genetic lesions and the molecular pathways presently identified in association with distinct B-cell NHL categories classified according to the World Health Organization (WHO) system of lymphoid neoplasia.<sup>2</sup> B-cell NHL categories known to associate with specific genetic lesions include B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, lymphoplasmacytoid lymphoma, mantle cell lymphoma, follicular lymphoma, MALT lymphoma, DLCL, and Burkitt's lymphoma among B-cell NHL. The molecular pathogenesis of AIDS-related NHL also is addressed. The precise molecular pathogenesis of all other B-cell NHL types has not yet been elucidated.

### B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTIC LYMPHOMA

The molecular pathogenesis of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma is still largely unknown (see Fig. 45.1-1). Mutations of the *p53* gene and loss of heterozygosity at 17p, the *p53* site, are found in a small number (10% to 15%) of cases.<sup>48,99</sup> A higher frequency of *p53* alterations is observed after transformation of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma to Richter's syndrome, a highly aggressive lymphoma with a poor clinical outcome,<sup>48</sup> suggesting that *p53* may be involved in the genetic mechanisms underlying B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma progression. Despite initial suggestions, it is now well established that "true" cases of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma (i.e., CD5+, CD23+, according to the WHO and the Revised European-American Lymphoma classification<sup>1,2</sup>) are consistently devoid of *BCL-1* and *BCL-2* rearrangements<sup>99</sup> (Table 45.1-2). Because high levels of *bcl-2* expression are consistently seen in B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma,<sup>100</sup> it is conceivable that they result from mechanisms other than chromosomal translocation. A small fraction of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma harbor mutations of the ataxia-telangiectasia mutated (*ATM*) gene.<sup>101,102 and 103</sup> Because these mutations may occur in the patient germline, *ATM* mutations may account, at least in part, for the familial cases of the disease.

Despite the paucity of information regarding the molecular lesions associated with B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, cytogenetic studies have revealed several recurrent chromosomal abnormalities.<sup>24,104</sup> Trisomy 12 is found in approximately 35% of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma cases evaluated by interphase fluorescence *in situ* hybridization and correlates with a poor survival.<sup>105,106 and 107</sup> Based on karyotypic and deletion mapping studies, it is likely that the 13q14 chromosomal region harbors a novel tumor suppressor gene that is involved at high frequency in B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma.<sup>52,53,54,55,56,57 and 58</sup> In fact, deletions of 13q14 occur in approximately 60% of cases when analyzed by sensitive molecular tools, but the relevant gene has not been identified.<sup>52,53,54,55,56,57 and 58</sup> Deletions of 6q define a subset of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma cases displaying polyclonal features.<sup>108</sup>

Studies of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma have revealed novel insights into the disease histogenesis. It is now apparent that the clinical heterogeneity of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma might be related to heterogeneity in the disease histogenesis. Although B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma has been traditionally viewed as a tumor of naive, pre-germinal center B cells, more recent data have suggested that a fraction of cases derives from germinal center-related B cells. In fact, the malignant cells of approximately 50% of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma harbor mutations of Ig genes, with or without *BCL-6* mutations,<sup>17,18,45,109</sup> which are well-established markers of germinal center transit. The molecular spectrum of Ig and *BCL-6* mutations in B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma is superimposable to that of germinal center-derived lymphomas.<sup>17,18,45,109</sup> Intriguingly, the histogenetic heterogeneity of B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma appears to carry prognostic relevance, because cases with mutations of Ig genes are associated with a significantly longer survival.<sup>110,111</sup>

### LYMPHOPLASMACYTOID LYMPHOMA

Lymphoplasmacytoid lymphoma is typically CD5-negative and associates in a large fraction of cases with a monoclonal serum IgM-type paraprotein, causing the clinical syndrome known as *Waldenström's macroglobulinemia*.<sup>12</sup> Approximately 50% of these lymphomas associate with the t(9;14)(p13;q32) translocation, a recurrent chromosomal abnormality in B-cell NHL<sup>112</sup> (see Table 45.1-1 and Fig. 45.1-1). The chromosomal breakpoints of t(9;14)(p13;q32) involve the Ig<sub>H</sub> locus on chromosome 14q32 and, on chromosome 9p13, a genomic region containing the paired homeobox-5 (*PAX-5*) gene.<sup>113</sup> *PAX-5* encodes a B-cell-specific transcription factor involved in the control of B-cell proliferation and differentiation.<sup>114</sup> Presumably, the juxtaposition of *PAX-5* to the Ig<sub>H</sub> locus in NHL carrying t(9;14)(p13;q32) causes the deregulated expression of the gene, thus contributing to tumor development.<sup>113</sup> Apart from t(9;14)(p13;q32), no other genetic lesion has been detected at significant frequencies in lymphoplasmacytoid lymphoma (see Table 45.1-2).

### MANTLE CELL LYMPHOMA

Mantle cell lymphoma constitutes 25% of nonfollicular small B-cell lymphomas and is typically associated with t(11;14)(q13;q32)<sup>1,2,115,116 and 117</sup> (see Fig. 45.1-1). The t(11;14)(q13;q32) translocation juxtaposes the *BCL-1* locus at 11q13 with Ig<sub>H</sub><sup>118,119 and 120</sup> (see Table 45.1-1). Although early characterization of the *BCL-1* locus did not identify a putative oncogene implicated in the translocation, it is now evident that t(11;14) consistently leads to homotopic deregulation of *BCL-1* (also known as *CCND1* or *PRAD1*), a gene located in proximity to the breakpoint region and encoding for cyclin D1, a member of the D-type G<sub>1</sub> cyclins that regulate the early phases of the cell cycle.<sup>121,122,123,124 and 125</sup> The consistent and selective clustering of *BCL-1* overexpression with NHLs carrying t(11;14) strongly suggests that this gene is indeed the critical component of t(11;14)(q13;q32).<sup>121,122,123,124 and 125</sup>

The precise contribution of cyclin D1 to cell-cycle regulation is still under investigation. As for other D-type cyclins, cyclin D1 is thought to act primarily as a growth factor sensor, integrating extracellular signals with the cell-cycle clock.<sup>126</sup> The pathogenetic role of *BCL-1* activation in human neoplasia is suggested by the ability of cyclin D1 overexpression to transform cells *in vitro* and contribute to B-cell lymphomagenesis in transgenic mice.<sup>127,128 and 129</sup>

The application of strict phenotypic criteria to the classification of B-cell lymphoproliferations has defined that the distribution of *BCL-1* rearrangements and activation are restricted to mantle cell lymphoma (see Table 45.1-2).<sup>130,131 and 132</sup> The frequency and specificity of this genetic lesion provide an excellent marker for diagnosis of mantle cell lymphoma.<sup>117</sup> The precise identification of mantle cell lymphoma among nonfollicular small B-cell lymphomas is clinically relevant because mantle cell lymphoma is a far more aggressive disease and displays a significantly shorter survival than other histologically related forms.<sup>115,116</sup>

Other genetic alterations may be also involved in mantle cell lymphoma. Inactivation of *p53* occurs in approximately 20% of cases and is a marker of poor prognosis.<sup>133</sup> Inactivation of *p16* by deletion, mutation, or hypermethylation is detectable in approximately one-half of cases belonging to the aggressive mantle cell lymphoma variant characterized by a blastoid cell morphology.<sup>134</sup>

### FOLLICULAR LYMPHOMA

The genetic hallmark of follicular lymphoma is represented by chromosomal breaks at 18q21 and rearrangements of *BCL-2*, which are detected in 80% to 90% of the cases independent of cytologic subtype<sup>135,136,137,138 and 139</sup> (see Table 45.1-2 and Fig. 45.1-1). Other genetic lesions may also occur, especially in follicular lymphoma cases that have undergone histologic progression to a high-grade NHL.<sup>50,134,140</sup>

than the stomach is also dependent on antigen stimulation and selection remains an open question. In this respect, it is remarkable that thyroid MALT lymphoma is generally a sequela of Hashimoto thyroiditis, an autoimmune process causing the exposure of B cells to thyroid-derived autoantigens.

Cytogenetic studies have pointed to several abnormalities selectively and recurrently involved in these tumors. The most common of these abnormalities is t(11;18)(q21;q21).<sup>24</sup> The t(11;18)(2;33) translocation occurs in approximately 50% of cytogenetically abnormal MALT lymphomas, independent of the site of origin.<sup>163,164</sup> The genes involved by t(11;18) are *API2* on 11q21 and *MLT* (for *MALT lymphoma translocation*) on 18q21. *API2* belongs to the family of inhibitor of apoptosis proteins that plays an evolutionary conserved role in regulating programmed cell death in diverse species. Although the function of *MLT* is currently unknown, it has been hypothesized that the *API2/MLT* fusion protein resulting from t(11;18)(q21;q21) may lead to increased inhibition of apoptosis and, therefore, confer a survival advantage to MALT lymphomas.<sup>163,164</sup>

Other recurrent chromosomal abnormalities of MALT lymphomas are trisomy 3 and t(1;14). The genes involved by trisomy 3 are not presently known.<sup>165</sup> Recurrent abnormalities of chromosomal band 1p22, generally represented by t(1;14)(p22;q32), occur in a small percentage of MALT lymphomas and cause alterations of the *BCL-10* gene.<sup>166,167</sup> *BCL-10* is a cellular homologue of the equine herpesvirus-2 E10 gene and encodes an amino-terminal caspase recruitment domain homologous to that found in several apoptotic molecules.<sup>166,167</sup> The wild-type *BCL-10* gene activates the NF-κB signaling cascade and is able to induce apoptosis in different cell types. Two distinct types of *BCL-10* aberrations are observed in MALT lymphomas carrying t(1;14)(p22;q32).<sup>166,167</sup> First, *BCL-10* is overexpressed. Second, *BCL-10* genes from t(1;14)-positive MALT lymphomas harbor truncations either in, or carboxy-terminal to, the caspase recruitment domain. *BCL-10* mutants lose the proapoptotic ability of wild-type *BCL-10* and, in some cases, also fail to activate NF-κB.<sup>166,167</sup> Therefore, it is conceivable that overexpression of *BCL-10*–translocated alleles might have a twofold effect on lymphomagenesis: Loss of *BCL-10* proapoptosis may confer a survival advantage to MALT B cells, and constitutive NF-κB activation may provide both antiapoptotic and proliferative signals mediated via its transcriptional targets.

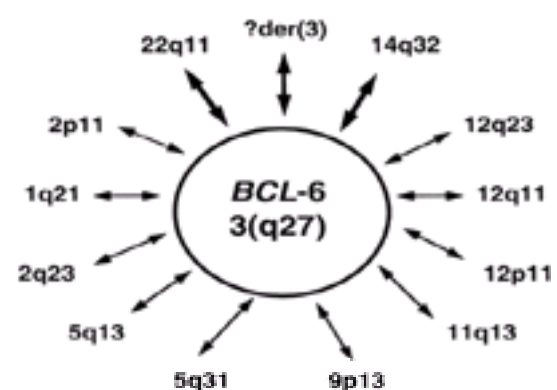

Other genetic alterations commonly involved in other lymphoma types also have been observed in MALT lymphomas, including *BCL-6* alterations and *p53* mutations.<sup>45,168,169</sup> and <sup>170</sup>

## DIFFUSE LARGE CELL LYMPHOMA

B-lineage DLCL is a potentially curable disease that accounts for approximately 40% of NHLs of adulthood.<sup>1,2</sup> The molecular pathogenesis of DLCL is complex and includes both genetic lesions specific for this disease (i.e., rearrangements of *BCL-6*) and molecular alterations common to other NHL categories (see Fig. 45.1-1).

### Chromosomal Translocations Involving the *BCL-6* Gene

Cytogenetic studies of NHL have demonstrated that chromosomal alterations affecting band 3q27 are a frequent recurrent abnormality in B-lineage DLCL.<sup>171,172</sup> These alterations are predominantly represented by reciprocal translocations between the 3q27 region and several alternative partner chromosomes, including, though not restricted to, the sites of the Ig genes at 14q32 (Ig<sub>H</sub>), 2p11 (Ig<sub>K</sub>), and 22q11 (Ig<sub>L</sub>).<sup>171,172</sup> (Fig. 45.1-4). The variability of the partner chromosomes juxtaposed to 3q27 in B-lineage DLCL translocations suggests that these abnormalities belong to the group of “promiscuous” translocations, which involve a fixed chromosomal breakpoint on one side and, on the other side, have different chromosomal partners in different cases.

**FIGURE 45.1-4.** Chromosomal sites implicated in der(3)(q27) and leading to rearrangement of *BCL-6*. The variability of the partner chromosome juxtaposed to 3q27 in B-lineage diffuse large cell lymphoma suggests that these chromosomal abnormalities belong to the group of “promiscuous” translocations. The thick arrows point to some sites that are involved more frequently than others. In many cases, indicated by ?*der*(3) in the figure, the partner chromosomal site cannot be identified with precision by conventional cytogenetics.

The cloning of the 3q27 chromosomal breakpoints revealed the *BCL-6* gene, which is involved in the overwhelming majority of B-lineage DLCL cases harboring 3q27 breaks, irrespective of the partner chromosome participating in the translocation<sup>173,174,175,176</sup> and <sup>177</sup> (see Table 45.1-1). The *BCL-6* gene is a transcriptional repressor belonging to the family of transcription factors containing zinc fingers, a protein sequence motif able to mediate the protein binding to specific DNA sites.<sup>173,174,175,176,177,178</sup> and <sup>179</sup> The amino-terminal region of the *BCL-6* protein contains a domain, termed *POZ*, which is homologous to domains found in several other zinc-finger transcription factors.<sup>180</sup> Apparently, the *POZ* domain acts as a protein-protein interface implicated in homo- and heterodimerization processes.<sup>180</sup> These structural features of the *BCL-6* protein are consistent with functional studies indicating that *BCL-6* can indeed function as a transcriptional repressor that inhibits the expression of genes carrying its specific DNA-binding motif.<sup>181</sup>

The pattern of *BCL-6* protein expression in human tissues is highly specific, and high levels are specifically found in B cells.<sup>182</sup> In particular, *BCL-6* expression is topographically restricted to the germinal center, where *BCL-6* is expressed by both centroblasts and centrocytes, whereas expression of *BCL-6* is absent in pre-germinal center B cells (virgin B cells) and post-germinal center B cells (memory B cells and plasma cells).<sup>182</sup> The observation that *BCL-6* is expressed within the germinal center, but not before entrance into or after exit from the germinal center, led to the postulation that *BCL-6* may be needed for germinal center development and sustainment, whereas its down-regulation may be necessary for further differentiation of B cells.<sup>182,183,184</sup> and <sup>185</sup>

The precise role of *BCL-6* in physiologic immune processes has been further clarified by knockout animal models carrying biallelically disrupted *BCL-6* genes.<sup>186,187</sup> Mice carrying the *BCL-6*<sup>-/-</sup> phenotype consistently fail to form germinal centers. Consistent with lack of germinal center formation, *BCL-6*<sup>-/-</sup> mice also display impairments in the T-cell-dependent antigen-specific IgG response. Overall, these animal models unequivocally demonstrate that *BCL-6* is a key regulator of germinal center formation and B-cell immune response.

Chromosomal translocations involving band 3q27 truncate the *BCL-6* gene within its 5' flanking region or within the first exon or intron ( Fig. 45.1-5), making these alterations readily detectable as rearrangements by Southern blot hybridization analysis of tumor DNA.<sup>173,174,175,176</sup> and <sup>177</sup> By conventional molecular assays, *BCL-6* rearrangements are detectable in 35% of B-lineage DLCL cases and in a small fraction of follicular lymphomas.<sup>188,189</sup> Conversely, *BCL-6* rearrangements are virtually absent in all other types of lymphoid neoplasms.<sup>188,189</sup> The coding domain of the *BCL-6* gene is left intact in all cases displaying *BCL-6* rearrangements, whereas the 5' regulatory sequences, which contain the *BCL-6* promoter, are either truncated or, alternatively, completely removed.<sup>173,174,175,176</sup> and <sup>177</sup> In all *BCL-6* rearrangements, the entire coding sequence of *BCL-6* is juxtaposed downstream to heterologous sequences that, based on cytogenetic data, may originate from different chromosomal sites in different patients (see Fig. 45.1-4 and Fig. 45.1-5). The common functional consequence of *BCL-6* translocations is the juxtaposition of heterologous promoters to the *BCL-6* coding domain, a mechanism called *promoter substitution*<sup>190,191</sup> (see Fig. 45.1-5). The substitution of the *BCL-6* promoter by heterologous regulatory sequences causes deregulated *BCL-6* expression in B-lineage DLCL carrying *BCL-6* rearrangements. One feature shared by the heterologous promoters linked to rearranged *BCL-6* alleles is that they are physiologically active in normal B cells and are not down-regulated during the late stages of B-cell differentiation.<sup>190,191</sup> Thus, *BCL-6* rearrangements may prevent down-regulation of *BCL-6* and, in turn, block the differentiation of germinal center B cells toward the

stage of plasma cells. According to this model, B-lineage DLCL cells carrying *BCL-6* rearrangements would thus be “frozen” at the stage of germinal center cells.

**FIGURE 45.1-5.** Schematic representation of *BCL-6* translocations. The germline configuration of the *BCL-6* gene, mapping to 3q27, is shown in the upper right panel of the figure. In its germline configuration, *BCL-6* is composed of ten exons. The coding region of the *BCL-6* gene is indicated by black boxes, whereas the noncoding exons (or portions of exons) are indicated by white boxes. The physiologic *BCL-6* promoter within exon 1 is shown by an arrow. The frequency of *BCL-6* breakpoint locations is also shown. The germline configuration of several *BCL-6* translocation partners (TTF, BOB1, Ig<sub>H</sub>, and other hypothetical genes designated as X) is shown in the upper left panel of the figure. The bottom panel of the figure depicts the molecular configuration of representative translocated *BCL-6* alleles. Independent of the partner chromosome involved, all translocated *BCL-6* alleles are deprived of their exon 1 and, consequently, of their physiologic promoter. The novel sequences derived from the partner chromosomes are thus juxtaposed 5' to the intron 1 of *BCL-6*. These novel sequences provide a heterologous promoter to *BCL-6*, such as the Ig<sub>H</sub> germline transcript promoter Ig (or, alternatively, Im) in the case of t(3;14); the TTF promoter in the case of t(3;4); and the BOB1 promoter in the case of t(3;11). The genomic configuration of the *BCL-6* gene downstream to the breakpoint site is preserved, thus leaving intact the *BCL-6* coding sequence. The transcripts resulting from representative *BCL-6* translocations are also shown in the lower part of the bottom panel of the figure. In all cases, the translocation gives rise to a fusion transcript, exemplified by TTF/*BCL-6*, BOB1/*BCL-6*, Ig/*BCL-6*, and X/*BCL-6*. These transcripts initiate from the heterologous promoter provided by the chromosomal site juxtaposed to *BCL-6*, and they retain the entire normal *BCL-6* coding domain, which translates into a normal-size *BCL-6* protein.

Beside promoter substitution, the *BCL-6* gene can also be altered by somatic hypermutation at its 5' noncoding region. Hypermutation of *BCL-6* can be found in normal germinal center cells.<sup>44,192</sup> It is also found in B-cell NHLs that are also characterized by somatic IgV hypermutation,<sup>43,44</sup> and <sup>45,193,194</sup> suggesting a common mechanism of mutation. Functional analysis of *BCL-6* mutated alleles indicates that some mutations derived from DLCL but not from normal germinal center cells may deregulate the basal level of *BCL-6* transcription (unpublished results). This finding indicates that *BCL-6* can also be deregulated by somatic hypermutation of its promoter, which further supports the role of *BCL-6* deregulation in the pathogenesis of DLCL.

### Molecular Heterogeneity of Diffuse Large Cell Lymphoma

The WHO classification has established that, with current knowledge and methods, it is impractical to histologically subclassify DLCL into its morphologic variants (i.e., diffuse centroblastic lymphoma and diffuse immunoblastic lymphoma).<sup>1,2</sup> However, both clinicians and pathologists reach consensus in suggesting that DLCL is in fact a heterogeneous disease.<sup>1</sup> Most likely, diversity does not depend on cytologic features, but rather on the tumor genotype. The biologic diversity of DLCL has been validated by the identification of at least three distinct genetic types of the disease<sup>50,141,195,196</sup> (Fig. 45.1-6). The first type, accounting for approximately 40% of cases, associates with rearrangements of *BCL-6* in the absence of other known genetic lesions. DLCLs harboring *BCL-6* rearrangements are *de novo* lymphomas, presenting without a previous history of follicular lymphoma. The second genetic type of DLCL involves activation of *BCL-2* in combination with *p53* mutations. DLCLs harboring *BCL-2* rearrangements and *p53* mutations derive from the histologic transformation of a previous follicular lymphoma. Finally, the third genetic group of DLCL displays germline *BCL-2* and *BCL-6* genes. The genotypic configuration of DLCL is thought to be of prognostic relevance. For example, some studies suggested that DLCLs associated with *BCL-6* rearrangements display the most favorable prognosis, whereas cases carrying *BCL-2* translocations have the poorest outcome.<sup>195,197,198</sup> The exact prognostic relevance of *BCL-6* rearrangements, however, still remains a controversial issue.<sup>188,199,200</sup>

**FIGURE 45.1-6.** Model of molecular pathways in B-lineage diffuse large cell lymphoma (B-DLCL) development. Three main pathogenetic pathways may be recognized in B-DLCL. The first two molecular pathways are designated *de novo* pathways, because in these instances B-DLCL develops without a preexistent follicular lymphoma. One *de novo* pathway implicates the *BCL-6* gene and occurs in approximately 35% of B-DLCL. The second *de novo* pathway involves presently unknown genetic lesions (indicated by the question mark), although some cases may harbor alterations of REL. The third pathway, designated as the *transformation pathway*, implicates the transformation of a preexisting follicular lymphoma to a B-DLCL histology. Cases of B-DLCL belonging to this pathway harbor rearrangements of *BCL-2* and mutations of *p53*. Whereas the *BCL-2* rearrangement is already present in the follicular lymphoma phase, *p53* mutations are gained during histologic transformation. Other genetic lesions, including *p16* inactivation, also associate with transformed B-DLCL.

The application of novel DNA technologies to DLCL is likely to refine the biologic heterogeneity of this disease. One study using DNA microarrays demonstrated diversity in gene expression among DLCL cases, allowing for the distinction between a germinal center–like variant of the disease and a variant resembling peripheral blood B cells activated *in vitro*.<sup>201</sup> This distinction has been proposed to be of prognostic value, because patients with the germinal center–like variant of the disease display a better overall survival.<sup>201</sup>

### BURKITT'S LYMPHOMA

Burkitt's lymphoma includes two clinical variants: sporadic Burkitt's lymphoma and endemic Burkitt's lymphoma.<sup>1,2</sup> Some cases may present as acute leukemias with Burkitt's tumor cells and are termed L3 acute lymphoblastic leukemia.<sup>1,2</sup> All Burkitt's lymphoma cases, including the leukemic variants, share one common genetic lesion (chromosomal translocations involving region 8q24 and one of the Ig loci) and, at variable frequency, other genetic lesions, including inactivation of *p53* and *p16*, deletions of 6q, and infection by EBV.<sup>48,51,59,60,61,62</sup> and <sup>63,134,202</sup> (see Fig. 45.1-1).

### Chromosomal Translocations Involving the c-MYC Gene

Translocations of region 8q24 involve the c-*MYC* locus and have provided the first example of the involvement of protooncogenes in tumor-associated chromosomal abnormalities.<sup>202</sup> The c-*MYC* locus can be involved in three distinct translocations with one of the Ig loci, including Ig<sub>H</sub>, Ig<sub>K</sub>, or Ig<sub>L</sub>.<sup>202,203,204,205,206</sup> and <sup>207</sup> (see Table 45.1-1). Ig<sub>H</sub> is involved in 80% of the cases leading to t(8;14)(q24;q32). The remaining 20% is composed of t(2;8)(p11;q24), which involves Ig<sub>K</sub> (15%), and

t(8;22)(q24;q11), which involves Ig<sub>H</sub> (5%).

Although fairly homogeneous at the microscopic level, these translocations display a high degree of molecular heterogeneity. The t(8;14) breakpoints are located 5' and centromeric to c-MYC, whereas they map 3' to c-MYC in t(2;8) and t(8;22).<sup>202,203,204,205,206 and 207</sup> Further molecular heterogeneity derives from the exact breakpoint sites of chromosomes 8 and 14 of t(8;14) (Fig. 45.1-7). Translocations of endemic Burkitt's lymphoma tend to involve sequences on chromosome 8 at an undefined distance (more than 1000 kilobases) 5' to c-MYC, and sequences on chromosome 14 within or in proximity to the Ig J<sub>H</sub> region.<sup>38,208</sup> In sporadic Burkitt's lymphoma, t(8;14) preferentially involves sequences within or immediately 5' (fewer than 3 kilobases) to c-MYC on chromosome 8, and sequences on chromosome 14 within the Ig switch regions.<sup>38,208</sup>

The common effect of t(8;14), t(2;8), and t(8;22) is that c-MYC-translocated alleles are expressed constitutively in tumor cells, as opposed to the tight regulation of c-MYC levels in normal B cells.<sup>209,210 and 211</sup> At least two distinct mechanisms may be responsible for c-MYC deregulation. These include (1) juxtaposition of c-MYC to heterologous enhancers derived from Ig loci; and (2) structural alterations in the 5' regulatory regions of c-MYC, putatively altering their responsiveness to cellular factors regulating c-MYC expression. In fact, the c-MYC exon 1–intron 1 border, where c-MYC regulatory sequences are located, is either decapitated by the translocation or undergoes selective and consistent mutations in translocated alleles.<sup>42,203,204,205,206 and 207</sup> (see Fig. 45.1-7). In addition to homotopic deregulation, oncogenic conversion of c-MYC is also thought to be due to amino acid substitutions in c-MYC exon 2 corresponding to the transactivation domain of the c-MYC protein.<sup>41,212</sup> These mutations would abolish the physiologic ability of p107, a nuclear protein related to RB1, to suppress the transactivation domain of c-MYC.<sup>213</sup>

**FIGURE 45.1-7.** Schematic representation of c-MYC translocations. The germline configuration of the c-MYC gene, mapping to 8q24, is shown in the upper panel of the figure. In its germline configuration, c-MYC is composed of three exons. The coding region of the c-MYC gene is indicated by black boxes, whereas noncoding exons (or portions of exons) are indicated by white boxes. The c-MYC promoters within exon 1 are indicated by arrows. The 8q24 breakpoint regions of sporadic Burkitt's lymphoma (sBL) and endemic Burkitt's lymphoma (eBL) also are indicated. The germline configuration of Ig<sub>H</sub> on chromosome 14q32 also is shown in the upper panel of the figure. Boxes indicate the joining (J), switch (S), and constant (C) regions of Ig<sub>H</sub>. The 14q32 breakpoint regions of sBL and eBL also are indicated. The bottom panels of the figure depict the molecular consequences of t(8;14)(q24;q32), which causes the juxtaposition of c-MYC to the Ig<sub>H</sub> locus. Two molecularly distinct types of translocations are recognized, which preferentially associate with either sBL or eBL. In the case of t(8;14) of sBL, the c-MYC breakpoint involves sequences within c-MYC, which is thus decapitated of its exon 1. Because the physiologically active promoters of c-MYC are removed by t(8;14) of sBL, a novel transcriptional initiation site (P3), located within c-MYC intron 1 and otherwise silent in physiologic conditions, is activated in c-MYC alleles involved by t(8;14) of sBL. Within the Ig<sub>H</sub> locus, the breakpoint falls in the proximity of the switch  $\mu$  ( $S\mu$ ) region. Notably, the gross configuration of the coding sequence of the translocated c-MYC allele is left intact. At the nucleotide level, however, translocated c-MYC alleles frequently harbor point mutations within the exon 2 coding sequence, leading to alteration in the amino acid sequence of the c-MYC protein. The complementary DNA (cDNA) resulting from t(8;14) of sBL includes c-MYC exons 2 and 3, which, on their 5' side, are preceded by an abnormally transcribed sequence of intron 1, starting from the novel transcriptional initiation site within c-MYC intron 1. Because the c-MYC coding region is intact, a normal-size c-MYC protein is translated by t(8;14) of sBL. The reader is referred to the text for a description of the functional consequences of t(8;14) of sBL in terms of deregulation of translocated c-MYC. In the case of t(8;14) of eBL, the c-MYC breakpoint involves sequences on chromosome 8 at an undefined distance (more than 100 kilobases) 5' to c-MYC and sequences on chromosome 14 within or in proximity to the immunoglobulin J<sub>H</sub> region. The internal genomic configuration of the translocated c-MYC allele is thus apparently preserved. However, c-MYC alleles involved by t(8;14) of eBL consistently harbor small mutations clustered around the exon 1–intron 1 border, where c-MYC regulatory regions are located. In addition, and in common with t(8;14) of sBL, point mutations within the exon 2 coding sequence, leading to alteration in the amino acid sequence of the c-MYC protein, also are frequently detected in c-MYC alleles affected by t(8;14) of eBL. The cDNA transcribed by t(8;14) of eBL includes c-MYC exons 1 through 3 and gives rise to a normal-size c-MYC protein. The reader is referred to the text for a description of the functional consequences of t(8;14) of eBL on the transcriptional regulation of c-MYC.

The product of c-MYC is a ubiquitously expressed nuclear phosphoprotein that functions as a transcriptional regulator controlling cell proliferation, differentiation, and apoptosis.<sup>202</sup> *In vivo*, c-MYC is found mainly in heterodimeric complexes with the related protein MAX, and such interaction is required for c-MYC-induced stimulation of transcription and cell proliferation.<sup>214,215,216,217,218 and 219</sup> Conversely, MAX can form heterodimers with MAD and MXI1, two novel basic helix-loop-helix/leucine zipper proteins that act as negative regulators of transcription.<sup>220,221</sup> In NHL carrying c-MYC translocations, it is conceivable that constitutive expression of c-MYC leads to the prevalence of MYC/MAX complexes over MAD/MAX and MXI1/MAX heterodimers, thus inducing positive growth regulation. In fact, expression of c-MYC regulates transcription of a subset of target genes that have diverse roles in regulating cell growth by affecting DNA metabolism and dynamics, energy metabolism, and protein synthesis.<sup>222</sup> One of these genes is represented by TERT (for telomerase reverse transcriptase), a specialized type of transcriptase modulating the activity of telomerase.<sup>223</sup> The fact that TERT is directly induced by c-MYC explains the association between c-MYC overexpression and telomerase activity observed in human cells.<sup>223</sup> Because telomerase preserves chromosome integrity by maintaining telomere length, and because telomere length is a limiting factor in determining the replicative lifespan of a cell, the maintenance of chromosomal integrity via stimulation of telomerase activity may be an important component of the role of c-MYC in facilitating cell proliferation.<sup>223,224</sup>

Substantial experimental evidence documents that the constitutive expression of c-MYC can influence the growth of B cells *in vitro* and *in vivo*, consistent with a role in B-cell lymphomagenesis. *In vitro*, the expression of c-MYC oncogenes transfected into EBV immortalized human B cells, a potential natural target for c-MYC activation in EBV-positive Burkitt's lymphoma, leads to their malignant transformation.<sup>225</sup> In addition, antisense oligonucleotides directed against translocated c-MYC alleles are able to revert tumorigenicity of Burkitt's lymphoma cell lines.<sup>226</sup> *In vivo*, the targeted expression of c-MYC oncogenes in the B-cell lineage of transgenic mice leads to the development of B-cell malignancy at relatively high frequency.<sup>227</sup>

#### Other Genetic Lesions

In addition to c-MYC activation in 100% of Burkitt's lymphoma cases, disruption of p53 occurs in 30% of sporadic and endemic Burkitt's lymphoma<sup>48</sup> (see Table 45.1-2). Deletions of 6q are detected in approximately 30% of the Burkitt's lymphoma cases independent of the clinical variant.<sup>51</sup> Inactivation of p16 also has been reported in a fraction of cases.<sup>228</sup> Another lesion that contributes to the development of this malignancy is monoclonal EBV infection, present in virtually all cases of endemic Burkitt's lymphoma and in approximately 30% of sporadic Burkitt's lymphoma<sup>50,61,62,63 and 64</sup> (see Table 45.1-2). Because EBV infection in Burkitt's lymphoma displays a peculiar latent infection phenotype characterized by negativity of both EBV-transforming antigens, LMP-1 and EBNA-2, the precise pathogenetic role of the virus has remained elusive. However, it has been proposed that a class of small RNA molecules, termed EBEB and consistently expressed by all Burkitt's lymphomas, may mediate the transforming potential of EBV in Burkitt's lymphoma.<sup>229</sup>

#### ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED NON-HODGKIN'S LYMPHOMA

The association between an immunodeficiency state and the development of lymphoma has been long since recognized in several clinical conditions, including congenital (e.g., Wiskott-Aldrich syndrome), iatrogenic (e.g., treatment with immunosuppressor agents), and viral-induced (e.g., AIDS) immunodeficiencies. The increasing frequency of human immunodeficiency virus infection has emerged as a major risk factor for lymphomagenesis and has prompted detailed investigations of

the molecular pathophysiology of AIDS-related NHL. [230,231,232,233](#) and [234](#)

AIDS-related NHLs invariably derive from B cells and are primarily classified into three main clinicopathologic categories: AIDS-related Burkitt's lymphoma, AIDS-related DLCL, and AIDS-related primary effusion lymphoma. [2,74,75,230,231,232,233](#) and [234](#) Based on the presence or absence of immunoblastic features, AIDS-related DLCL may be further distinguished into large noncleaved cell lymphoma and immunoblastic lymphoma plasmacytoid. [64,230,231,232,233](#) and [234](#) Based on the site of origin, AIDS-related NHLs are generally grouped into systemic AIDS-related NHL and AIDS-related primary central nervous system lymphoma. [230,231,232,233](#) and [234](#) Systemic AIDS-related NHLs may be either AIDS-related DLCL or AIDS-related Burkitt's lymphoma. Conversely, AIDS-related primary central nervous system lymphomas display a uniform morphology consistent with a diffuse architecture of large cells.

The different categories of AIDS-related NHL associate with distinctive molecular pathways. [230,231,232,233](#) and [234](#) Cases of AIDS-related Burkitt's lymphoma consistently display activation of *c-MYC* by chromosomal translocations that show structural similarities to those found in sporadic Burkitt's lymphoma. [49,62,230,231,232,233,234](#) and [235](#) Rearrangements of *BCL-6* are consistently absent in this type of AIDS-related NHL. [235,236](#) AIDS-related Burkitt's lymphoma also frequently harbors mutations of *p53* (60%), mutations of *BCL-6* 5' noncoding regions (60%) and, in 30% of cases, infection of the tumor clone by EBV. [49,64,68,193,235,236](#) The EBV-encoded antigens LMP-1 and EBNA-2 are not expressed by AIDS-related Burkitt's lymphoma. [64,238,239](#) In addition to genetic lesions and EBV infection, stimulation and selection by antigens, frequently represented by autoantigens, appear to be a prominent feature of AIDS-related Burkitt's lymphoma. [240,241](#)

AIDS-related DLCL displays several genotypic differences when compared with AIDS-related Burkitt's lymphoma. [230,231,232,233](#) and [234](#) First, the most frequent genetic alteration detected in AIDS-related DLCL is infection by EBV, which occurs in approximately 60% to 70% of cases and associates frequently, although not always, with expression of LMP-1. [49,64,68](#) Second, AIDS-related DLCL displays rearrangements of *BCL-6* in 20% of cases. [236](#) Mutations of *BCL-6* 5' noncoding regions occur in 70% of AIDS-related DLCL cases. [193](#) AIDS-related DLCL can be segregated into two distinct histogenetic categories based on the expression pattern of the *BCL-6* protein: the EBV-encoded LMP-1; and the CD138/syndecan-1 antigen, a proteoglycan associated with the terminal phases of B-cell differentiation. [64,239](#) AIDS-related DLCL associated with the *BCL-6*<sup>+</sup>/*syndecan-1*<sup>-</sup>/*LMP-1*<sup>-</sup> phenotype tend to display a large noncleaved cell morphology and closely reflect the phenotype of germinal center B cells. [64,239](#) Conversely, *BCL-6*<sup>-</sup>/*syndecan-1*<sup>+</sup>/*LMP-1*<sup>+</sup> AIDS-related DLCLs are morphologically consistent with immunoblastic lymphoma plasmacytoid and reflect a post-germinal center stage of B-cell differentiation. [64,239](#)

All AIDS-related primary central nervous system lymphomas harbor EBV infection. [66,242](#) However, only a fraction of AIDS-related primary central nervous system lymphomas, namely those with immunoblastic plasmacytoid morphology, express the LMP-1-transforming protein of EBV. [66](#) As for systemic AIDS-related DLCL, AIDS-related primary central nervous system lymphomas may be distinguished into two phenotypic categories based on the expression pattern of *BCL-6*: CD138/syndecan-1 and LMP-1. [66](#) AIDS-related primary central nervous system lymphomas also carry mutations of *BCL-6* in 60% of cases. [66](#) The association of AIDS-related primary central nervous system lymphoma with mutations of *BCL-6* as well as Ig genes indicates their origin from germinal center-related B cells. [66,243](#) Although some reports have suggested that HHV-8 may be related to primary central nervous system lymphoma pathogenesis in immunocompromised patients, extensive analysis of AIDS-related primary central nervous system lymphoma has unequivocally ruled out this hypothesis. [244,245](#)

The last type of AIDS-related NHL that has been characterized at the molecular level is represented by primary effusion lymphoma, also known as *body cavity-based lymphoma*. [71,74,75](#) This entity is a novel lymphoma characterized by HHV-8 infection and clinically presenting as effusions in the serosal cavities of the body (pleura, pericardium, peritoneum) in the absence of solid tumor masses. [71,74,75](#) Primary effusion lymphoma consistently derives from B cells that reflect a preterminal stage of B-cell differentiation. [71,74,75,237,246](#) Infection of the tumor clone by HHV-8 occurs in 100% of cases and is a sine qua non for the diagnosis of the disease. [71,74,75](#) In addition to HHV-8, cases of primary effusion lymphoma frequently carry coinfection of the tumor clone by EBV. [65,67,71,74,75](#)

## MOLECULAR PATHOGENESIS OF T-CELL NON-HODGKIN'S LYMPHOMA

Malignancies of mature T cells are a highly heterogeneous group of diseases. [1,2](#) These malignancies greatly differ in clinical behavior, immunophenotypic features, and genetic lesions involved in their pathogenesis. [1,2](#) In Western countries, mature T-cell malignancies overall represent only 15% to 20% of tumors derived from mature lymphocytes and are relatively uncommon when compared to mature B-cell malignancies. [247](#) A higher frequency of mature T-cell malignancies is reported in other parts of the world, namely Japan and the Caribbean. [247](#)

Only a few categories of mature T-cell malignancies have been investigated in detail at the molecular level. These include Ki-1<sup>+</sup> (CD30<sup>+</sup>) anaplastic large cell lymphoma, adult T-cell leukemia/lymphoma, T-cell prolymphocytic leukemia and, to a lesser extent, cutaneous T-cell lymphoma. CD30<sup>+</sup> anaplastic large cell lymphoma tends to occur in childhood and young adults. [1,2](#) The term *adult T-cell leukemia/lymphoma* encompasses a spectrum of lymphoproliferative diseases associated with the human retrovirus HTLV-1 and characteristically expressing large amounts of IL-2 receptors (CD25). The geographic distribution of adult T-cell leukemia/lymphoma is mainly restricted to Southwestern Japan and the Caribbean basin, although cases also have been reported in the United States and Europe in long-term immigrants from the affected geographic areas. [1,2](#) T-cell prolymphocytic leukemia represents a rare T-cell malignancy that presents predominantly as a leukemic disease. [1,2](#) An intrinsic tropism for the skin is displayed by cutaneous T-cell lymphoma, which includes mycosis fungoides and its leukemic manifestation, known as Sézary syndrome. [1,2](#)

### T-CELL ANAPLASTIC LARGE CELL LYMPHOMA

Anaplastic large cell lymphoma is a specific category of T-cell NHL composed of large pleomorphic cells that usually express the CD30 antigen. [1,2](#) Anaplastic large cell lymphoma is characterized by frequent cutaneous and extranodal involvement. [1,2](#) Conventional karyotyping analysis of anaplastic large cell lymphoma cases has shown a unique translocation involving bands 2p23 and 5q35 in a substantial fraction of cases. [24](#) The cloning of the t(2;5)(p23;q35) translocation has demonstrated that it involves the fusion of the nucleophosmin/B23 (*NPM*) gene on 5q35 to a novel anaplastic lymphoma kinase (*ALK*) on 2p23 (see [Table 45.1-1](#)). [248](#) As a consequence of this translocation, the *NPM* and *ALK* genes are fused to form a chimeric transcript that encodes a hybrid protein (p80) in which the amino-terminus of *NPM* is linked to the catalytic domain of *ALK*. [248](#) Two distinct oncogenic effects are thought to be caused by the t(2;5) translocation. First, the *ALK* gene, which is not physiologically expressed in normal T lymphocytes, undergoes heterologous expression in lymphoma cells, conceivably because of its juxtaposition to the promoter sequences of *NPM*, which are physiologically expressed in T cells. Second, based on the activation model of other tyrosine kinase oncogenes, one would predict that the truncated *ALK* constitutively phosphorylates intracellular targets to trigger malignant transformation.

The pathogenetic role of *NPM/ALK* rearrangements is supported by studies *in vitro* and *in vivo*. First, overexpression of the p80 hybrid protein induces neoplastic transformation of target cells in *in vitro* models, substantiating the notion that the p80 kinase is in fact aberrantly activated. [249](#) Second, retroviral-mediated gene transfer of *NPM/ALK* *in vivo* causes T-cell lymphoid malignancies in mice. [250](#) In such animal models, *NPM/ALK* selectively transforms lymphoid cells of T-cell lineage, whereas the growth properties of other hematopoietic cells remain unaffected. [250](#)

The distribution of *NPM/ALK* rearrangements throughout the spectrum of NHL is highly selective, being virtually restricted to T-cell lineage anaplastic large cell lymphoma. [251,252](#) and [253](#) Within this category, *NPM/ALK* rearrangements seem to preferentially associate with cases of childhood (more than 85% positivity), although they are also detected in a large fraction of cases of adulthood (60%). [251,252](#) and [253](#)

### ADULT T-CELL LEUKEMIA/LYMPHOMA

The molecular pathogenesis of adult T-cell leukemia/lymphoma has been elucidated to a wider extent in comparison with other mature T-cell tumors. Adult T-cell leukemia/lymphoma is associated with HTLV-I infection of the tumor cells in 100% of cases, although the rate of adult T-cell leukemia/lymphoma development among seropositive individuals is relatively low (less than 5% lifetime risk). [85,86](#) and [87,254,255,256,257,258,259](#) and [260](#) The period between infection and onset of clinical disease is typically quite long, varying between 10 and 30 years. [260](#) Unlike acutely transforming animal retroviruses, the HTLV-I genome does not encode a known oncogene. [85,86](#) and [87,254,255,256,257,258,259](#) and [260](#) Furthermore, this retrovirus does not transform T cells by *cis*-activation of an adjacent protooncogene, because this provirus appears to integrate randomly within the host genome. [85,86](#) and [87,254,255,256,257,258,259](#) and [260](#) Rather, the pathogenetic effect of HTLV-I in adult T-cell leukemia/lymphoma seems to be due to the viral production of a transregulatory protein (HTLV-I tax) that markedly increases expression of all viral gene products and transcriptionally activates the

expression of certain host genes, including IL-2, the  $\alpha$  chain of the IL-2 receptor (CD25), c-sis, c-fos, and granulocyte-macrophage colony-stimulating factor.<sup>88,89,90,91</sup> and<sup>92</sup> Indeed, a property of adult T-cell leukemia/lymphoma cells is the constitutive high level expression of IL-2 receptors. The central role of these genes in normal T-cell activation and growth, together with the results of *in vitro* studies, support the notion that tax-mediated activation of these host genes represents an important mechanism by which HTLV-I initiates T-cell transformation.<sup>89</sup> In addition, tax interferes at multiple sites with DNA damage repair functions and with mitotic checkpoints, consistent with the fact that adult T-cell leukemia/lymphoma cells harbor a high frequency of karyotypic abnormalities.<sup>94,95</sup> and<sup>96</sup>

The long period of clinical latency that precedes the development of adult T-cell leukemia/lymphoma, the small percentage of infected patients that develop this malignancy, and the observation that leukemic cells from adult T-cell leukemia/lymphoma are monoclonal suggest that HTLV-I is not sufficient to cause the full malignant phenotype.<sup>85,86</sup> and<sup>87</sup> An attractive model for adult T-cell leukemia/lymphoma would therefore include an early period of tax-induced polyclonal T-cell proliferation that, in turn, would facilitate the occurrence of additional genetic events leading to the monoclonal outgrowth of a fully transformed cell. In this respect, a recurrent genetic lesion in adult T-cell leukemia/lymphoma is represented by mutations of the *p53* tumor suppressor gene, which is inactivated in 40% of cases.<sup>261,262</sup>

## T-CELL PROLYMPHOCYTIC LEUKEMIA

T-cell prolymphocytic leukemia frequently carries cytogenetic abnormalities of chromosome 11, the most common abnormalities being monosomy 11, partial or terminal deletions of 11q, and unbalanced translocations involving the 11q arm.<sup>24</sup> The gene relevant to these abnormalities has been identified and has been shown to correspond to *ATM*, a gene that is also responsible for the hereditary disorder ataxia-telangiectasia.<sup>263,264</sup> Whereas *ATM* is mutated in the germline of ataxia-telangiectasia patients, it is altered somatically in cases of T-cell prolymphocytic leukemia.<sup>263,264</sup> Mutations of *ATM* in T-cell prolymphocytic leukemia associate with the deletion of the other allele and lead to the absence, premature truncation, or alteration of the *ATM* gene product, consistent with the inactivation model of tumor suppressor genes.<sup>263,264</sup> Circumstantial evidence suggests that *ATM* might be involved in cell-cycle regulation and DNA repair, which in fact have been shown to be defective in cells with biallelic *ATM* inactivation.<sup>265</sup>

## CUTANEOUS T-CELL LYMPHOMA

Rearrangements of the *lyt-10/NFKB-2* gene at 10q24 have been demonstrated in a sizable fraction of cutaneous T-cell lymphoma tumors. The *lyt-10* gene (also called *NFKB-2*) is a novel member of the NF- $\kappa$ B rel family of transcription factors.<sup>266,267</sup> The normal products of these genes have structural homologies within the DNA-binding rel domain and share the ability to bind to specific (kB) target sequences found in various inducible enhancer and promoter elements. In addition to the DNA-binding domain, the *lyt-10/NFKB-2* gene harbors an ankyrin motif, which is thought to regulate the physiologic nuclear/cytoplasm distribution of the *lyt-10/NFKB-2* protein.<sup>266,267</sup> The translocation breaks observed in NHL consistently disrupt the ankyrin domain, separating it from the DNA-binding domain. It is therefore conceivable that an intact DNA-binding domain, once separated from the regulatory ankyrin portion of the gene, might be constitutively activated and act as an oncogene to T cells.

## MOLECULAR PATHOGENESIS OF HODGKIN'S LYMPHOMA

HL, also known as *Hodgkin's disease*, is characterized by scattered large atypical cells residing in a complex admixture of inflammatory cells.<sup>1,2</sup> Two different biologic entities have been recognized within HL: nodular lymphocyte predominance HL (NLPHL) and classic HL comprising the nodular sclerosis, mixed cellularity, and lymphocyte depletion variants. Historically, biologic studies of HL have been hampered by the paucity of HL diagnostic cells [i.e., Reed-Sternberg (RS) or Hodgkin's cells] in HL biopsies. More recently, however, the availability of sophisticated laboratory techniques that enable the isolation and enrichment of HL neoplastic cells has been instrumental in the understanding of HL histogenesis.

The neoplastic cells of both classic HL and NLPHL typically represent clonal populations of B-lineage cells, as documented by the presence of clonal rearrangements of Ig genes.<sup>268,269,270,271,272,273</sup> and<sup>274</sup> The consistent occurrence of somatic mutations and their pattern within (V) region genes amplified from neoplastic cells of both classic HL and NLPHL indicate that both types of HL are derived from B cells that reside in, or have transited through, the germinal center.<sup>268,269,270,271,272,273</sup> and<sup>274</sup> Neoplastic cells of NLPHL display ongoing mutation of IgV genes, suggesting derivation from centroblasts residing in the germinal center. Also, neoplastic cells of NLPHL show the typical clues of antigen selection, indicating a putative pathogenetic role of stimulation by antigen molecules. Conversely, no ongoing mutation of IgV genes is observed in RS cells of classic HL, consistent with derivation from centrocytes or post-germinal center B cells. In some cases, RS cells of classic HL harbor stop codons in in-frame V<sub>H</sub> gene rearrangements (crippling mutations). Because IgV crippling mutations prevent antigen selection, it is likely that RS cells of classic HL have escaped apoptosis through a mechanism not linked to antigen stimulation, possibly represented by a transforming event, such as that mediated by the EBV LMP-1. The differences in the histogenesis of NLPHL and classic HL revealed by molecular studies also have been confirmed at the phenotypic level. In fact, the neoplastic cells of NLPHL consistently display the BCL-6<sup>+</sup>/syndecan-1<sup>-</sup> profile typical of germinal center B cells, whereas RS cells of classic HL frequently, although not always, display the BCL-6<sup>-</sup>/syndecan-1<sup>+</sup> phenotype of post-germinal center B cells. Although the overwhelming majority of HL cases derive from the B lineage, occasional cases have been formally proved to be of T-cell origin.<sup>278</sup>

The truly neoplastic nature of RS cells has been debated since the description of HL. The detection of heterogeneous clonal karyotypic changes in HL lymph nodes and in cells identifiable as RS cells suggested that HL may indeed represent a clonal malignancy.<sup>279,280,281</sup> and<sup>282</sup> Many chromosomal breaks detected in HL are also shared by other lymphoid malignancies, whereas a cytogenetic abnormality specifically associated with HL has yet to be found.

The *p53* pathway is thought to be altered in HL. RS cells express abnormal levels of the MDM2 protein,<sup>283</sup> which, in turn, conceals functional domains of the wild-type *p53*, thus blocking the physiologic activity of the tumor suppressor gene.<sup>284</sup> Despite initial observations,<sup>285,286</sup> it appears that the *p53* gene itself is not affected by mutations in HL.<sup>287</sup>

A number of epidemiologic features of HL suggest that the disease might result also from infectious cofactors. HL lesions express EBV antigens, carry EBV DNA demonstrable by conventional Southern blot or *in situ* hybridization techniques, and contain EBV-encoded RNA.<sup>288,289,290,291,292,293,294,295,296,297,298,299,300,301</sup> and<sup>302</sup> EBV infection of RS cells is virtually always absent in NLPHL, whereas it occurs in approximately 50% of classic HL and in 100% of AIDS-related HL.<sup>1,277,288,289,290,291,292,293,294,295,296,297,298,299,300,301</sup> and<sup>302</sup> Notably, the EBV infection of RS cells is monoclonal, suggesting that infection precedes clonal expansion and further confirming the monoclonal nature of RS cells. Of the two B-cell transforming antigens encoded by the EBV genome, infected RS cells most commonly express LMP-1 but not EBNA-2.<sup>288,289,290,291,292,293,294,295,296,297,298,299,300,301</sup> and<sup>302</sup> The latent infection protein phenotype of RS cells (LMP-1-positive, EBNA-2-negative) is distinct from that of Burkitt's lymphoma (LMP-1-negative, EBNA-2-negative) or B-lymphoblastoid cell lines (LMP-1-positive, EBNA-2-positive) and is similar to the EBV expression pattern detected in nasopharyngeal carcinoma and a fraction of AIDS-related DLCL. The reason for these alternative EBV expression patterns is not known with precision, but it is likely influenced by the developmental stage of the infected cells as well as by the host's immune function.

## GENETIC LESIONS AS CLINICAL TOOLS IN THE MANAGEMENT OF LYMPHOMA

From a clinical standpoint, NHL genetic lesions represent molecular markers of disease serving four purposes: (1) They assist morphologic diagnosis, (2) they provide a prognostic indicator in some cases, (3) they allow evaluation of minimal residual disease by highly specific and highly sensitive technologies, and (4) they provide targets for molecular therapy.

With respect to diagnosis, the use of genetic lesions as markers for NHL diagnosis is justified by the selective association between a given genetic alteration and a specific NHL category<sup>1,2</sup> (see [Fig. 45.1-1](#) and [Table 45.1-1](#)). For example, the detection of *BCL-1* activation in nonfollicular small cell NHL is considered the most specific clue to the diagnosis of mantle cell lymphoma.<sup>1,2</sup> The growing knowledge of the molecular pathogenesis of lymphoma will progressively refine the way we classify these disorders. Ideally, genetically distinct groups of lymphomas should be considered as distinct diseases requiring distinct therapeutic options.

The prognostic relevance of genetic lesions of lymphoma is a growing field of investigation that may provide significant improvement in the therapeutic stratification of lymphoma. Although several genetic alterations have been proposed to influence the prognosis of specific lymphoma categories, the application of novel DNA technologies, namely DNA microarrays, is likely to rapidly expand the molecular markers available for prognostic studies. On these grounds, the application of DNA microarrays to DLCL has allowed the recognition of distinct disease variants with different response to therapy and survival.<sup>201</sup>

Genetic lesions of lymphoma also represent the most specific and the most sensitive marker for evaluation of minimal residual disease by polymerase chain reaction (PCR). Examples are the PCR assay for *BCL-2* in follicular lymphoma and for *BCL-1* in mantle cell lymphoma. Overall, the sensitivity of PCR analysis is several-fold higher than that of standard diagnostic techniques and allows the detection of one tumor cell among  $10^6$  normal cells. To date, most studies of minimal residual disease in lymphoma have centered on follicular lymphoma and have demonstrated a survival advantage in cases achieving PCR negativity compared to cases that remained positive for minimal residual disease. [303](#)

Finally, the study of the molecular pathogenesis of lymphoma may provide molecular targets for therapeutic strategies aimed at reversing the very genetic lesions that are responsible for tumor development. Such therapy should, by definition, be largely specific for the lymphoma cells and, hence, devoid of the major side effects presently encountered with antineoplastic therapy.

#### LEUKEMIAS

The development of successful therapy for most children with acute lymphoblastic leukemia (ALL) can be attributed to a series of prospective clinical studies that clarified the pathophysiology of ALL and showed the importance of combination chemotherapy, sanctuary-specific treatment, and supportive care measures.<sup>1</sup> On the other hand, the relative resistance of acute myelogenous leukemia (AML) to chemotherapy led to the development of treatment strategies that include dose-intensified chemotherapy and bone marrow transplantation (BMT).<sup>2</sup> During the 1990s, we have also greatly advanced our knowledge of leukemia cell biology, most notably in the area of molecular pathogenesis. Molecular biologists have developed powerful diagnostic tools, sensitive methods for detecting minimal residual leukemia, and potential new therapeutic targets.<sup>3</sup> The improvement in long-term survival for children with acute leukemia has been gratifying but also has been associated with significant late effects that underscore the need for vigilant follow-up and for designing risk-adapted therapies.

#### EPIDEMIOLOGY

Leukemia is the most common form of cancer in children. Approximately 2500 new cases of childhood leukemia are diagnosed each year in the United States.<sup>4</sup> ALL and AML are diagnosed in 75% and 20% of the cases, respectively, and chronic myeloid leukemia in fewer than 5%. The well-established peak incidence of childhood leukemia at age 4 years is due to ALL. ALL affects males and whites more often than females and African Americans. Nearly a threefold higher incidence of ALL at 2 to 3 years of age occurs for white children compared to black children. The incidence of AML is constant during childhood, except for a slight peak in infancy and late adolescence.<sup>4</sup>

It is likely that the majority of acute leukemias in children are initiated by acquired mutations within the hematopoietic tissues.<sup>5</sup> Intriguing results of molecular genetic studies using stored neonatal blood spots from children who eventually developed ALL suggest a prenatal origin in some patients.<sup>6</sup> In studies of monozygotic twins who both developed acute leukemia (approximately 5% concordance rate), it appears that the initial chromosome translocation occurred *in utero* with subsequent transfer of the leukemia clone from one twin to the other via the shared blood supply. Because the concordance rate for leukemia is low in identical twins, it follows that an additional event or environmental exposure is required postnatally.

A small number of children are at increased risk to develop leukemia because of an inherited predisposition.<sup>5</sup> For example, children with Down syndrome have a 10- to 20-fold increased risk of leukemia during the first 10 years of life.<sup>7</sup> The types of leukemia in children with Down syndrome follow the usual distribution of childhood leukemia, except at younger than 3 years of age when AML (mostly FAB M7) is more likely to occur than ALL. Neonates with Down syndrome or trisomy 21 mosaicism may also develop a "transient myeloproliferative disorder" (TMD) that is indistinguishable from congenital AML. This disorder is usually diagnosed within the first 2 weeks of life, and the incidence is unknown. Peripheral blood or bone marrow blasts from infants with TMD have features of the megakaryocytic and erythroid lineages and, in some cases, have been shown to be clonal in origin. In more than 90% of these infants, however, the blasts spontaneously disappear and normal blood counts recover within the first several weeks to months after diagnosis of TMD. One retrospective study reported that up to 30% of infants with TMD eventually developed either a myelodysplastic syndrome or AML before the age of 3 years.<sup>8</sup> Because the majority of these infants appear never to develop leukemia, neonates with Down syndrome and a hematologic picture consistent with AML should be observed for 4 to 10 weeks before cytotoxic therapy is initiated. If therapy is eventually needed, the outcome for these children has been surprisingly favorable.<sup>9</sup>

Children with neurofibromatosis are predisposed to develop myeloid malignancies, especially myelodysplastic and myeloproliferative syndromes.<sup>10</sup> In patients with neurofibromatosis who develop leukemia, evidence indicates loss of both neurofibromatosis (NF-1) alleles in bone marrow cells. These data provide evidence that NF-1 may function as a tumor-suppressor gene in children with NF-1.

Some epidemiologic studies suggest that maternal reproductive history of previous fetal loss and maternal alcohol consumption during pregnancy is associated with an increased risk of AML in infants.<sup>11</sup> In general, most studies have not found a consistent association between common infectious or environmental exposures and an increased risk of childhood leukemia.<sup>5,12</sup> On the other hand, AML has been observed as a secondary leukemia in both children and adults who were treated with alkylating agents or topoisomerase II inhibitors (e.g., epipodophyllotoxins).<sup>13,14</sup>

#### CLONALITY AND CELL OF ORIGIN

Normal blood cell production is polyclonal, whereas leukemia is a clonal disorder. The return of polyclonal hematopoiesis in remission and the reappearance of the original clone at relapse suggests that the leukemic clone was suppressed but not eradicated by chemotherapy. This also implies that normal bone marrow stem cells repopulate the marrow during remission. In rare situations, patients with AML in remission have had persistent clonal hematopoiesis.<sup>15</sup> The significance of this observation remains unknown.

Within the hierarchy of hematopoietic development, there are many potential targets for leukemic transformation. Characterization of the leukemic blast population by morphology, genetics, and immunologic methods has helped to establish a revised classification system that may or may not reflect the nature of the leukemic "stem cell." The detection of lymphoid lineage-associated determinants on the surface of lymphoblasts plus an analysis of immunoglobulin (Ig) and T-cell receptor gene rearrangements suggest that ALL derives from either a precursor T or precursor B cell.<sup>16</sup> The cell of origin for AML has been postulated to be either a multipotent or committed myeloid progenitor (e.g., CFU-GEMM or granulocyte-macrophage colony-forming unit), but more recent data indicate that the AML stem cell may be more

primitive than previously postulated.<sup>17,18</sup>

## CLASSIFICATION

### Morphology

In the 1970s, a morphologic classification system was developed for the acute leukemias by a French-American-British (FAB) Cooperative Working Group and has since gained wide acceptance.<sup>19</sup> The FAB system divides ALL into three morphologic subtypes (L1, L2, and L3). L1 lymphoblasts, the most common FAB type in children, have scanty cytoplasm and inconspicuous nucleoli. Blasts in the L2 category account for 10% of cases; they are larger and more pleomorphic in size, with abundant cytoplasm and prominent nucleoli, and they may be difficult to distinguish by morphology alone from FAB subtype M0 AML.

L3 is the rarest subtype (1% to 2%) of ALL, and these blasts have very basophilic vacuolated cytoplasm. These L3 blasts have the same immunophenotype as well as karyotype and molecular genetic abnormalities as the tumor cells in small noncleaved or Burkitt lymphomas<sup>3</sup> (see [Non-Hodgkin's Lymphoma](#), later in this chapter).

The FAB classification recognizes eight subtypes of AML (M0 to M7). [Table 45.2-1](#) presents a distribution of FAB subtypes for 180 cases of AML in children younger than 18 years of age studied at St. Jude Children's Research Hospital from 1984 to 1992. Most children younger than 2 years of age with AML have either the M4 or M5 subtypes.<sup>2</sup> Although the M7 subtype may have several characteristic morphologic features, the diagnosis of M7 AML requires confirmation either by ultrastructural histochemistry (platelet peroxidase granules on electron microscopy) or monoclonal antibody positivity for specific megakaryocyte or platelet glycoproteins (e.g., IIB\IIIA or IB).<sup>20</sup> The FAB M7 subtype most often is seen in children younger than 3 years of age with Down syndrome.<sup>7</sup>

Subtype	Frequency (%)	Associations
M1: Myeloblasts with agranular toxic granules	1	Down syndrome (DS) and t(8;21)
M2: Myeloblasts with differentiation at hyperleukemic	10	
M3: Myeloblasts with differentiation at hyperleukemic	3	Down syndrome (DS) and t(8;21)
M4: Myeloblasts with monocytic differentiation >20% non-specific esterase activity	4	Down syndrome (DS) and t(8;21)
M5: Myeloblasts with monocytic differentiation >20% non-specific esterase activity	3	Down syndrome (DS) and t(8;21)
M6: Myeloblasts with monocytic differentiation >20% non-specific esterase activity	1	Down syndrome (DS) and t(8;21)
M7: Myeloblasts with megakaryocytic differentiation	1	Down syndrome (DS)

DS, Down syndrome; t(8;21), translocation (8;21)(q22;q22).  
Based on 180 cases of AML in children under 18 years of age studied at St. Jude Children's Research Hospital from 1984 to 1992.

**TABLE 45.2-1.** French-American-British Classification of Acute Myelogenous Leukemia in Children

### Immunophenotype

By using a panel of lineage-associated monoclonal antibodies, most cases of ALL can be broadly divided into precursor B- and precursor T-cell subgroups.<sup>16</sup> Precursor B-cell ALL is further subdivided into early pre-B and pre-B, and the T-cell cases are subtyped according to level of thymocyte differentiation (e.g. early, mid-, or late thymocyte).<sup>21</sup> The expression of several antigens, such as CD10 (CALLA) and CD34, are not lineage-specific and, in some studies, were of prognostic importance. The CALLA antigen is expressed in most cases of precursor B ALL, hence the derivation of the term *common ALL* previously used to define this large subgroup of childhood ALL. Most infants with ALL have a CALLA-negative, early pre-B immunophenotype.<sup>22</sup> The proportion of children with specific immunophenotypes of ALL is shown in [Table 45.2-2](#) according to age group.

Immunophenotype	Infants (<1.5 y)	Children (1.5 to 10.0 y)	Adolescents (>10 y)
Early pre-B	64	68	58
CD10 (CALLA)	49	94	87
Pre-B (cIgM)	26	18	18
T	6	13	23
B	4	1	1

cIgM, cytoplasmic immunoglobulin M.  
Numbers shown are weighted means from eight different studies.  
(Modified from Rivera G, Crist W. Blood: principles and practice of hematology. In: Handin R, Stossel T, Lux S, eds. *Acute lymphoblastic leukemia*. Philadelphia: JB Lippincott, 1995:747.)

**TABLE 45.2-2.** Percentage Distribution of Immunophenotypes of Acute Lymphoblastic Leukemia by Age Group

Compared to early pre-B-cell ALL, the pre-B (cytoplasmic Ig) immunophenotype develops more often in African Americans, is associated with a higher initial leukocyte count and hemoglobin level, and is more likely to have a DNA index lower than 1.16 and a pseudodiploid karyotype.<sup>23</sup> The previously known adverse outcome associated with pre-B ALL was due to the subgroup with the t(1;19)(q23;p13). The clinical features of T-cell ALL have long been recognized and include an adolescent male with a high leukocyte count, bulky lymphadenopathy (especially mediastinal), and extramedullary leukemia [central nervous system (CNS), skin, testes].<sup>24,25</sup> In the past, these children had a poor prognosis. However the prognostic distinctions among ALL immunophenotypes have been lost by improvements in therapy with risk-directed protocols.<sup>1</sup>

B-cell (surface Ig) ALL is associated with L3 morphology, male predominance, and bulky extramedullary disease (e.g., intraabdominal masses).<sup>1</sup> Many children with B-cell ALL come to medical attention because of a "primary tumor mass," which on biopsy is a small noncleaved or Burkitt lymphoma and on further staging is found to have extensive replacement of the bone marrow with L3 blasts. If more than 25% marrow blasts are present, these children are considered to have mature B-cell ALL rather than advanced-stage Burkitt's lymphoma, but they are treated on identical protocols and now enjoy a favorable prognosis.<sup>26</sup>

There has been limited clinical use for a classification of AML based on immunophenotype.<sup>27</sup> The primary value of cell surface antigen analysis in most cases of AML is distinguishing between AML and ALL (L2 versus M0) and diagnosing FAB M7 AML.

### Hybrid or Acute Mixed-Lineage Leukemias

Blasts from approximately 5% to 20% of children with acute leukemia have either morphologic, cytochemical, immunophenotypic, or genetic markers suggesting derivation from both myeloid and lymphoid lineages.<sup>28</sup> In these biphenotypic, hybrid, or acute mixed lineage leukemias, individual blasts usually co-express markers of more than one lineage, but in rare instances, two distinct populations of blasts are present. Whether these cases represent aberrant gene expression or transformation of a multipotent stem cell is unknown. Hybrid leukemias appear to be more common in patients with prior myelodysplastic syndromes, secondary leukemias, leukemias associated with 11q23 [especially t(4;11)] translocations and the Philadelphia (Ph) chromosome.

Myeloid-antigen expression (blasts reactive with two or more myeloid-specific monoclonal antibodies) is detected in fewer than 10% of cases of childhood ALL, and lymphoid-antigen expression is noted in approximately 15% of AML.<sup>28</sup> Mixed-lineage expression in AML lacks prognostic significance, and patients should be treated on AML protocols.<sup>27,29</sup> Myeloid-antigen-positive ALL is not associated with a poor prognosis if patients are treated on intensive, risk-adapted ALL protocols.<sup>30,31</sup>

Leukemias with two distinct leukemic clones (one lymphoid and the other myeloid) are rare. No specific treatment recommendations have been established for these patients, but most oncologists favor a hybrid ALL/AML protocol in this situation.

## CYTOGENETICS AND MOLECULAR GENETICS

The combination of cytogenetics, fluorescence *in situ* hybridization, and molecular methods identify chromosomal abnormalities in approximately 80% of cases of childhood acute leukemia.<sup>3,32</sup> Identification of numerous chromosomal abnormalities in leukemia blasts, including translocations, deletions, and inversions, have enabled molecular geneticists to clone the genes that ultimately have been shown to be important in the malignant transformation of hematopoietic cells. The genetic abnormalities also have been proved valuable as diagnostic and prognostic tools. For example, TEL-AML1, or ETV6-CBFA2, is a newly identified fusion gene that is detected in approximately 25% of children with precursor B ALL. The fusion gene results from a cryptic t(12;21) translocation and identifies a group of patients with a favorable prognosis.<sup>33,34</sup> (Fig. 45.2-1).

**FIGURE 45.2-1.** Kaplan-Meier analysis of event-free survival according to genetic features of blast cells in 369 children with acute lymphoblastic leukemia treated at St. Jude Children's Research Hospital from 1984 to 1997. The relatively good survival of patients with *BCR-ABL* fusion reflects successful treatment of a subgroup with low leukocyte counts at diagnosis. The *E2A-PBX1* abnormality, once associated with poor survival, now is associated with the same favorable prognosis as the *ETV6-CBFA2* (*TEL-AML1*) abnormality. (From ref. 1, with permission.)

Many of the chromosomal translocations in ALL involve Ig or T-cell receptor genes and transcription factors. The prototype translocation is the t(8;14) in L3 ALL and Burkitt's lymphoma [see [Small Noncleaved Cell \(Burkitt's\) Lymphoma](#), later in this chapter].<sup>1,3</sup> The t(1;19) is seen in approximately one-fourth of patients with pre-B-cell ALL and fuses the *E2A* gene on chromosome 19 with the *PBX1* gene on chromosome 1.<sup>35</sup> Approximately 2% to 5% of children with ALL have the t(9;22)(q34;q11) or Ph chromosome.<sup>1,3</sup> In Ph-positive chronic myelogenous leukemia, the translocation results in a *bcr-abl* fusion gene product of 210-kD, whereas in most cases of Ph-positive ALL, the breakpoint within the *bcr* region is more centromeric, yielding a smaller fusion protein (185 kD). The presence of the Ph chromosome in ALL usually indicates high-risk leukemia warranting a stem cell transplantation in first remission, except for those children presenting with a low leukocyte count or good early response to prednisone.<sup>36,37</sup> The genetic abnormalities associated with T-cell ALL are discussed in the section [Lymphoblastic Lymphoma](#), later in this chapter.<sup>25</sup> Genes involved in cell-cycle control (e.g., p53, p16) also have been implicated in the pathogenesis of ALL.<sup>38,39 and 40</sup>

Childhood ALL can also be classified by the number of chromosomes (or DNA content) per leukemic cell.<sup>41</sup> Hyperdiploidy with a DNA index greater than 1.16 (greater than 50 chromosomes) is associated with the precursor B-cell phenotype and a highly favorable prognosis, especially if there are trisomies of chromosomes 4 and 10.<sup>42</sup> It is not known why patients with a DNA index greater than 1.16 respond well to chemotherapy, but it may be related either to a favorable intracellular metabolism of methotrexate or the marked propensity for hyperdiploid blasts to undergo apoptosis.<sup>43,44</sup> On the other hand, hypodiploidy (less than 45 chromosomes) is associated with a poor prognosis.<sup>45</sup>

Many of the chromosomal abnormalities in AML are associated with specific FAB subtypes.<sup>46,47</sup> These include t(8:21)(q22;q22) and FAB M2; t(15;17)(q22;q11-21) and acute promyelocytic leukemia (FAB M3); translocations involving chromosome band 11q23 and various partner chromosomes [e.g., t(9;11) and FAB M4 and M5]; and inv(16)(p13;q22) and FAB M4eo. The t(8;21) and t(15;17) translocations are extremely rare in patients younger than 2 years of age, whereas translocations involving 11q23 are quite common in this age group.<sup>48</sup> Translocations of 11q23 almost always involve the *MLL* gene and are also the most frequent karyotypic change in infants with ALL. Infants with t(4;11)(q21;q23) or molecular rearrangements of *MLL* have an almost fivefold higher risk of relapse compared with other infants.<sup>49</sup> The *MLL* gene is also rearranged in most cases of secondary AML induced by topoisomerase II inhibitors.<sup>14</sup> The t(1;22)(p13,q13), a unique but rare chromosomal translocation, has been detected in infants with FAB M7 AML.<sup>50</sup> Monosomies or partial deletions of chromosomes 5 or 7 are commonly observed in adults with AML and patients with secondary AML (postalkylating agent therapy or myelodysplastic syndromes) but are unusual in *de novo* childhood AML.<sup>46</sup> The critical genes involved in leukemic transformation on chromosomes 5 and 7 have not yet been identified.

## CLINICAL AND LABORATORY MANIFESTATIONS AND DIAGNOSIS

The most common presenting signs and symptoms in children with acute leukemia are fever or infection, fatigue, pallor, and bleeding. These symptoms result from decreased normal hematopoiesis secondary to bone marrow infiltration by leukemic blasts, leading to neutropenia, anemia, and thrombocytopenia. Bone or joint pain (or both) are initial complaints in approximately 25% of children with acute leukemia and are more commonly observed in ALL than AML.<sup>51</sup> Bone pain is usually due to periosteal elevation but may be secondary to microfractures or bone necrosis. The classic radiologic findings in acute leukemia include metaphyseal lucent bands (growth arrest lines), periosteal elevation, and lytic lesions. These changes are best seen in the long bones near the knees, ankles, or wrists.

Moderate to massive lymphadenopathy and hepatosplenomegaly are associated with T-cell ALL and infant acute leukemias.<sup>21,52</sup> Nonspecific abdominal pain is relatively common and may be secondary to organomegaly, gastrointestinal bleeding or, rarely, leukemic infiltration of the bowel wall. Most of the gastrointestinal lesions encountered in patients with leukemia are secondary to complications of treatment and include oral mucositis, esophagitis, gastritis, typhlitis or neutropenic enterocolitis, lactose malabsorption, and hepatitis or cholestasis.

### Extramedullary Leukemia

Extramedullary spread of leukemia at either the time of diagnosis or relapse is important because it can cause local problems, represent a sanctuary site of disease, or herald bone marrow relapse. At diagnosis, clinically detectable extramedullary leukemia of the central nervous system (CNS), skin, and testes is rare, except in infants. Therefore, the major treatment strategies are aimed at eradication of subclinical disease.<sup>1</sup> In the past, the most common sites of extramedullary relapse included the CNS and testes.<sup>53</sup>

Symptomatic CNS leukemia (e.g., increased intracranial pressure or cranial nerve palsies) is extremely rare, but between 4% and 10% of children with acute leukemia have blasts present in the cerebrospinal fluid (CSF) at diagnosis.<sup>54,55</sup> The diagnosis of CNS leukemia is made by examining a cytocentrifuged preparation of CSF. Traditionally, CNS leukemia was defined by the presence of at least five leukocytes per microliter of CSF with blasts. However, more recent data indicates that the presence of blasts in CSF samples with fewer than five leukocytes per microliter may be of prognostic significance. The most common signs of CNS leukemia include headache, nausea and vomiting, lethargy, or cranial nerve palsies (sixth and seventh being most common). Neurologic symptoms in children with acute leukemia may also be due to epidural masses causing cord compression or myeloblastomas of the cerebral cortex or cerebellum, hemorrhage, or leukostasis (plugging of vessels by aggregates of leukemic blasts). Patients with AML and initial leukocyte counts greater than 200,000 cells per microliter are at highest risk for leukostasis.<sup>56</sup>

Leukemia cutis is a rare finding seen most often in AML (FAB M4 and M5) and T-cell ALL. Infants with AML are at particularly high risk for leukemia cutis.<sup>57</sup> The lesions of leukemia cutis are typically subcutaneous nodules that are blue-gray or salmon in color. The skin nodules in babies with AML have been observed to spontaneously regress for short periods before progressive leukemia ensues.

Overt testicular leukemia is extremely unusual at diagnosis, and with current effective chemotherapy regimens, it is rarely encountered as a site of relapse.<sup>1</sup> Clinically it presents as a firm, painless, unilateral or bilateral testicular swelling. The diagnosis should be confirmed by testicular biopsy. Enlarged kidneys from infiltration of leukemia is not uncommon but is usually asymptomatic. The rare cases of renal failure in newly diagnosed children with acute leukemia are either secondary to uric acid nephropathy or ureteral obstruction from retroperitoneal lymphadenopathy.

Leukemic infiltration of the pericardium/myocardium or lungs is also extremely rare at diagnosis or during treatment. Congestive heart failure during therapy is much more likely due to sepsis or anthracycline cardiac toxicity rather than leukemic infiltration. Diffuse pulmonary infiltrates are most often secondary to an infection, but leukemic infiltration, diffuse alveolar hemorrhage, and pulmonary leukostasis should be considered in the differential diagnosis.

The most common ocular findings in patients with acute leukemia include retinal hemorrhages secondary to either thrombocytopenia or vessel infiltration, or papilledema from CNS leukemia. Leukemic involvement of the anterior chamber (hypopyon) or retinal infiltration are both infrequent.

Myeloblastomas are also referred to as *chloromas* or *granulocytic sarcomas* and occur in fewer than 5% of children with AML.<sup>2,57,58</sup> These solid tumors of myeloid leukemia cells can appear simultaneously with bone marrow infiltration or may be the initial clinical manifestation of leukemia, occurring weeks to months before an increase in bone marrow blasts occurs. Myeloblastomas have a predilection for the CNS (brain or epidural) and the bones and soft tissues of the head and neck (especially the orbits).

### Laboratory Features and Differential Diagnosis

The peripheral blood findings in patients with acute leukemia often include a normocytic anemia with teardrop or nucleated red blood cells, thrombocytopenia with platelet counts averaging between 20,000 and 50,000 cells per microliter, and leukocyte counts between 5000 and 50,000 cells per microliter ( Table 45.2-3).<sup>51</sup> Approximately 20% of patients, however, have leukocyte counts greater than 100,000 cells per microliter. The white blood cell (WBC) differential usually reveals neutropenia (absolute neutrophil count <1000 cells per microliter) and circulating blasts, especially if the leukocyte count is greater than 5000 cells per microliter.

	Precursor B (%)	T Cell (%)
Leukocyte count/mm <sup>3</sup>		
<10,000	50	20
10,000-50,000	35	30
>50,000	15*	50
Platelet count/mm <sup>3</sup>		
<20,000	25	15
Hemoglobin (g/dL)		
<7.5	50	25
Hepatomegaly	8	13
Splenomegaly	10	20
Mediastinal mass	1-2	50
Lymphadenopathy (moderate/ marked)	25	50

\*Twenty-five percent of patients with pre-B subtype of precursor B acute lymphoblastic leukemia have leukocytes greater than 50,000.  
(Data from Coze W, Rivera G, Pullen J, Weinstein H. The leukemias of childhood. In: Rosenbald DS, Fennstein EH, Goodright S, McArthur JR, eds. Hematology. 1983. Washington, DC: American Society of Hematology, 1983.)

**TABLE 45.2-3.** Initial Clinical and Laboratory Features in Children with Acute Lymphoblastic Leukemia According to Major Immunophenotypes

The bone marrow biopsy in most cases of acute leukemia is hypercellular, with blasts accounting for the majority of nucleated cells. The numbers of normal granulocyte/monocyte, erythroid, and megakaryocytic precursors are markedly decreased. To establish the diagnosis of acute leukemia, the bone marrow aspirate or biopsy must have more than 25% and 30% blasts, respectively, in ALL and AML. Most cases of childhood acute leukemia can be readily diagnosed and classified by routine bone marrow morphology and histochemistry. Additional laboratory tests, such as genetics and immunophenotyping, are important for risk assignment and are sometimes necessary for distinguishing ALL from AML.

Other significant laboratory findings at diagnosis may include metabolic derangements [see [Small Noncleaved Cell \(Burkitt's\) Lymphoma](#), later in this chapter] and disseminated intravascular coagulation or fibrinolysis. Disseminated intravascular coagulation usually is associated with acute promyelocytic leukemia (FAB M3) or FAB M5 AML, but it may be seen in other children with newly diagnosed acute leukemia.<sup>59,60</sup>

The differential diagnosis in a child suspected of having acute leukemia includes juvenile myelomonocytic leukemia, myelodysplastic syndromes, metastatic tumors with marrow involvement (neuroblastoma and rhabdomyosarcoma), idiopathic thrombocytopenic purpura, juvenile rheumatoid arthritis, aplastic anemia, sepsis and other conditions that might result in neutropenia, infectious diseases associated with lymphocytosis, and the TMD in neonates with Down syndrome.<sup>7</sup>

## TREATMENT

### Acute Lymphoblastic Leukemia

Most children with acute leukemia are referred to tertiary care hospitals, where they are treated by pediatric oncologists according to institutional or cooperative group protocols [e.g., Pediatric Oncology Group (POG), Children Cancer Group (CCG), Berlin-Frankfort-Munster (BFM), Medical Research Council].<sup>61</sup> Therapy for childhood ALL has been based on risk classification systems because it has become clear that outcome of treatment varies substantially among different subsets of children with the disease. The philosophy behind this approach has been to use less toxic therapy for children with a lower risk of relapse and to treat high-risk patients with experimental and potentially more aggressive regimens. Because no single best protocol has been established for either low- or high-risk patients with ALL, enrollment in clinical trials is still encouraged.

**PROGNOSTIC FACTORS.** Numerous prognostic factors (Table 45.2-4) have been identified for children with ALL, and some of these have been incorporated into risk classification systems used to assign treatment. These prognostic factors include combinations of presenting clinical and laboratory parameters, biologic features of the leukemia blast, and early response to chemotherapy. Because prognostic factors are treatment-dependent, improvements in therapy may abrogate a previously accepted prognostic variable. In an effort to compare the results of various clinical trials worldwide, a uniform risk classification for treatment assignment was accepted at a National Cancer Institute workshop.<sup>62</sup> The agreed on standard risk category includes patients 1 to 9 years of age with precursor B ALL and a WBC count at diagnosis of less than 50,000 cells per microliter. The remaining patients are classified as high risk. The event-free survival rate for children in the standard-risk category is approximately 80% at 4 years and approximately 65% for the high-risk patients.

Acute lymphoblastic leukemia
Age younger than 1 or older than 10 y
White blood cell count >50,000/ $\mu$ L
DNA index <1.16
Chromosomal translocation t(9;22); t(4;11) in infants
Central nervous system leukemia at diagnosis
Slow response to induction chemotherapy
Acute myelogenous leukemia
White blood cell count >100,000/ $\mu$ L
Monosomy 7
Translocations involving 11q23 (controversial)
Secondary acute myelogenous leukemia or prior myelodysplastic syndromes
More than one course to complete response

**TABLE 45.2-4.** Acute Leukemia: Adverse Prognostic Factors

Some investigators continue to classify T-cell ALL as an independent high-risk feature, and others assign risk to these children based on age and WBC criteria. <sup>1,21,25</sup> The prognosis for patients with T-cell ALL has significantly improved during the 1990s with the advent of multiagent dose-intensified ALL protocols. <sup>25,63</sup> Children with mixed lineage or myeloid antigen-positive ALL are no longer considered high risk based on immunophenotype alone. <sup>30,31</sup>

In addition to age and WBC count, other important prognostic variables established in the workshop include hyperdiploidy, cytogenetics, early response to treatment, and CNS status. The prognosis for patients with blasts with additional copies of whole chromosomes (hyperdiploidy) has been very favorable, as reported by several groups. <sup>41,42,44</sup> Hyperdiploidy can be measured by DNA content (DNA index) of leukemic cells and by karyotyping. A DNA index of more than 1.16, especially if blasts contain extra copies of chromosomes 4 and 10, is associated with an extremely favorable prognosis. The majority of children with hyperdiploid blasts have standard-risk age and WBC features. In some studies, DNA index and trisomies of chromosomes 4 and 10 are used to change risk assignment independent of age and WBC criteria. <sup>42</sup>

Early response to chemotherapy as measured by bone marrow findings within 7 to 14 days of induction or peripheral blood blast response to corticosteroids on day 8 of treatment is associated with outcome. A more rapid clearing of blasts from either the blood or bone marrow confers a more favorable prognosis. <sup>64,65</sup> In one study, an augmented postinduction therapy for children with high-risk ALL and a slow response to induction has improved their long-term outcome. <sup>66</sup>

Patients with the Ph chromosome [t(9;22)] and a high initial WBC count or slow early response to prednisone, and infants with t(4;11), continue to be at high risk for treatment failure. <sup>37,67</sup> Experimental therapies, such as allogeneic stem cell transplantation in first remission, are recommended for these very high-risk patients. Studies have shown that the poorer response associated with t(1;19) can be overcome by more intensive therapy. <sup>35</sup>

New genetic abnormalities are continuing to be identified in patients with ALL. For example, the TEL/AML1 fusion gene occurs in approximately 25% to 30% of cases of pediatric precursor B ALL and defines a subgroup with a favorable prognosis. <sup>33,34</sup> Molecular studies also are identifying genetic changes (e.g., MLL, TAL, TEL/AML1) in leukemic blasts that are undetectable at the routine cytogenetic level. <sup>1,68</sup>

Other factors that have been shown to independently affect prognosis include race, gender, blast cell morphology, lymphomatous presentations, and serum lactic dehydrogenase. <sup>69,70</sup> and <sup>71</sup> African Americans have a poorer prognosis than whites for reasons that cannot be totally explained based on known prognostic factors. <sup>71</sup> In several studies, males had a higher risk of bone marrow relapse compared to females. <sup>70,72</sup> Long-term follow-up data also indicate that females have an increased risk for some late effects, especially CNS and cardiac effects. <sup>73,74</sup>

**REMISSION INDUCTION.** The achievement of a complete remission is a prerequisite for the long-term survival of patients with acute leukemia. In 1948, Sidney Farber demonstrated the first remissions in ALL using aminopterin, an analogue of methotrexate. <sup>75</sup> Vincristine and prednisone are effective in inducing remissions in 85% to 90% of children with ALL, without unduly suppressing normal bone marrow function. Daunorubicin and L-asparaginase were subsequently identified as active drugs in the treatment of ALL. The addition of either one of these drugs to vincristine and prednisone increased the complete remission rate in childhood ALL to more than 95%. The combination of vincristine, prednisone, and L-asparaginase is one of the standard remission induction regimens in childhood ALL. <sup>1,76</sup> The use of additional drugs, such as the anthracyclines (daunorubicin or doxorubicin) or cyclophosphamide, are often reserved for children with high-risk ALL. <sup>66,76</sup>

Data from both experimental models and human clinical trials indicate that maximum leukemia cell kill during induction decreases the likelihood for the emergence of drug-resistant clones and results in higher cure rates. Therefore, maximum tolerated doses of all active agents are delivered as early as possible during treatment. As previously discussed, a more rapid response to induction chemotherapy as measured by day 8 peripheral blast count or day 14 marrow aspirate is a favorable prognostic sign. <sup>64</sup> New technologies, including polymerase chain reaction and multiparameter flow cytometry, are able to quantitate “minimal residual leukemia” at the end of induction. <sup>77,78</sup> The results of this type of analysis may be predictive for risk of subsequent relapse, although the best assay and optimal timing for testing are not known.

**CONTINUATION THERAPY.** It has been estimated that approximately two to three logs of leukemic blasts are killed during the induction phase of therapy, leaving a residual leukemic burden of approximately 100 million cells. Therefore, additional treatment is necessary to prevent relapse. In the past, children with ALL relapsed within a median of 4 to 6 months when treatment was not continued beyond the remission induction phase. In the late 1960s, investigators at St. Jude Children's Research Hospital developed a “total therapy” approach for the treatment of children with ALL. <sup>1</sup> The model included remission induction, continuation chemotherapy with or without intensification, and preventive CNS therapy. The choice of continuation therapy was empiric. The early St. Jude studies evaluated 6-mercaptopurine, methotrexate, cyclophosphamide, and cytarabine in various doses and combinations. The best outcome was achieved in patients who received 2 to 3 years of daily oral 6-mercaptopurine and weekly methotrexate. Long-term follow-up of patients treated with this latter combination show a 42% disease-free survival rate for children with initial WBC counts of fewer than <25,000 cells per microliter, whereas it was only 16% for all other patients. <sup>79</sup>

Before the observation that the intensity of treatment required for a successful outcome varied substantially among subsets of patients, investigators in the BFM group, at Memorial Sloan-Kettering Cancer Center and the Dana Farber Cancer Institute treated all children with ALL with up-front intensive multiagent chemotherapy. The Memorial Sloan-Kettering Cancer Center protocols used a cell kinetic rationale that combined eight cell-cycle specific and nonspecific agents. <sup>80</sup> The Dana Farber Cancer Institute protocols emphasized the intensive use of L-asparaginase and doxorubicin, and the BFM group used 4 months of intensive multidrug therapy (induction, consolidation, and intensification). <sup>63,76</sup> CNS prophylaxis varied between the groups (see [Central Nervous System Prophylaxis](#), later in this chapter). Children with high-risk ALL benefited most from these protocols. The advantage of these regimens compared to antimetabolite-based protocols for children with lower risk ALL was less obvious. However, more recent BFM and POG randomized trials have shown the importance of intensive reinduction therapy or dose intensified antimetabolite therapy, even for patients with favorable risk features. <sup>72,76</sup>

Other successful approaches for patients with high-risk ALL have included the use of alternating non-cross-resistant pairs of active agents. For example, investigators at St. Jude Children's Research Hospital reported encouraging results with the combination of VM-26 and cytarabine in refractory ALL and subsequently introduced those drugs into front-line protocols. <sup>1,79</sup> Most protocols for high-risk patients include the use of four or more drugs during remission induction, followed by intensification therapy for a brief period, CNS prophylaxis, and continuation therapy. With this approach, the cure rates for these very high-risk patients have reached levels of 65% to 75%. The use of bone marrow transplant (BMT) from a related or unrelated histocompatible donor for select groups of very high-risk patients in first remission is being investigated. <sup>81</sup>

Several groups treat infants with ALL and those with T-cell ALL on separately designed protocols. <sup>21,80,82</sup> The results of these studies have been comparable to therapies used to treat a more inclusive group of patients with high-risk ALL. On the other hand, because children with B-cell ALL (Burkitt's or L3 type) had such a dismal prognosis after treatment with classic ALL protocols, an entirely different treatment approach was developed. These children were treated according to regimens that were designed for patients with advanced-stage Burkitt's lymphoma. The protocols for B-cell ALL and advanced-stage Burkitt's lymphoma included short but dose-intensive chemotherapy cycles that include cyclophosphamide, methotrexate, and cytarabine plus intensive intrathecal (IT) chemotherapy. The long-term disease-free survival rates increased from less than 10% to more than 60% with this approach. <sup>26,83</sup> As more is learned about the biologic, pharmacologic, and other factors that distinguish the various “genotypic species” or subtypes of ALL, we will hopefully be able to select our therapies accordingly.

The duration of continuation therapy for children with ALL has been empiric. Chemotherapy has not been given for indefinite periods because of its short- and long-term toxicities. Because of our new techniques for quantifying minimal residual leukemia, we may soon be able to adjust the length of treatment based on more objective measures. <sup>77,78</sup> The duration of continuation chemotherapy has gradually been shortened from 5 to approximately 2 years without undue risk of relapse. <sup>1,79</sup> The risk of relapse after cessation of therapy is highest in the first year and tapers off to 2% to 3% in the second and third years. <sup>79</sup> Very late relapse, after 5 or more years in remission, is rare but reported. There appears to be an increased risk of relapse off therapy for males compared to females.

**PREVENTIVE OR PROPHYLACTIC CENTRAL NERVOUS SYSTEM THERAPY.** CNS relapse in children with ALL became clinically apparent as bone marrow remissions became more durable. Before the use of preventive CNS therapy, CNS relapse heralded bone marrow relapse in almost 60% of patients. It was postulated by investigators at St. Jude Children's Research Hospital that leukemia blasts were already present in the CNS by the time ALL was diagnosed and that the drugs used to treat leukemia did not penetrate the meninges in therapeutic concentrations. The CNS was considered a “sanctuary site,” requiring site-specific therapy for subclinical disease. This concept proved to be correct and led to major increments in cure rates for childhood ALL. Clinical trials at St. Jude Children's Research

Hospital established that the risk for CNS relapse could be reduced to less than 5% by the early use of 24 Gy of craniospinal irradiation (CSI) or 24 Gy of cranial irradiation plus IT methotrexate.<sup>84</sup> Cranial irradiation plus IT methotrexate replaced craniospinal irradiation because of the toxicities of CSI. CSI was myelosuppressive and also caused impaired growth of vertebral bodies.

The target volume for cranial irradiation includes the entire intracranial subarachnoid space. By convention, the caudal margin of the field extends to the bottom of the second cervical vertebra. Standard guidelines for preventive cranial irradiation also include the posterior retina and orbital apex, encompassing the extension of the subarachnoid space along the optic nerves. A subacute somnolence syndrome that follows cranial irradiation has been well described.<sup>85</sup> Approximately 50% of children develop some degree of lethargy, irritability, or low-grade fever at a median onset of 4 to 8 weeks after cranial irradiation.

The neurologic and cognitive sequelae of 24-Gy cranial irradiation led to treatment modifications.<sup>86,87</sup> and<sup>88</sup> The CCG safely reduced the dose of cranial irradiation to 18 Gy.<sup>88</sup> In an effort to further reduce toxicity, the Dana Farber ALL consortium compared 18 Gy given in a single daily fraction with a hyperfractionated schedule (twice daily), and the BFM reduced the dose to 12 Gy.<sup>90,91</sup>

An alternative strategy for preventing CNS relapse has been the use of IT chemotherapy alone, starting during induction and continuing for an extended period throughout therapy.<sup>92,93</sup> Protocols using repetitive doses of IT chemotherapy also include multiple cycles of intravenous moderate- to high-dose methotrexate. This approach has been successful in preventing CNS relapse in children with standard-risk ALL, as well as intermediate- and high-risk patients in some studies, but it is also associated with neurotoxicity.<sup>94</sup>

IT methotrexate has the same efficacy as triple IT therapy (methotrexate, hydrocortisone, and cytarabine) and may be less neurotoxic. The risk of a CNS event was gender-dependent in the CCG trials. Boys were at greater risk for relapse, whereas girls were more vulnerable than boys to cognitive and growth dysfunction after cranial irradiation and IT chemotherapy.<sup>95</sup> Similar findings have been observed by the Nordic and Dana Farber groups.<sup>90</sup>

In some protocols, select subgroups of children with ALL at high risk of CNS relapse (e.g., WBC count higher than 50,000 cells per microliter, T-cell ALL, Ph-positive ALL, and infants) continue to be treated with cranial irradiation (12 to 18 Gy) plus IT chemotherapy.<sup>90,91</sup> The percentage of children with ALL who currently receive cranial irradiation as part of CNS prophylaxis ranges from 15% to 60% depending on the protocol.

**OVERT CENTRAL NERVOUS SYSTEM LEUKEMIA AT DIAGNOSIS.** Fewer than 5% of children with ALL have leukemic blasts detected in the CSF at diagnosis. The definition of CNS leukemia has been revised.<sup>54</sup> Three categories have been defined according to CSF findings: CNS-1 (no blasts), CNS-2 (fewer than 5 WBCs per microliter with blasts), and CNS-3 (more than 5 WBCs per microliter with blasts or cranial nerve palsy). Patients with CNS-3 status have a higher frequency of isolated CNS relapse and a lower long-term survival rate than patients with CNS-1 status, but the significance of CNS-2 status is not clear. Some investigators treat patients with CNS-2 status with additional doses of IT chemotherapy but give a risk assignment based on age and WBC criteria.

The management of patients with overt CNS leukemia (CNS-3) is less controversial than is the choice of preventive or prophylactic CNS therapy. After inducing a complete hematologic and CNS remission with IT and systemic chemotherapy, most investigators give CNS irradiation toward the latter part of the first year of treatment. Doses of 24 to 30 Gy of radiation have been given to these children.

**THERAPY AFTER RELAPSE.** The two most important factors relating to prognosis after relapse are the length of the initial remission and the site of relapse.<sup>96,97</sup> Children with late relapse have a better prognosis than those with early relapse, but the definition of early and late relapse is variable. An initial remission duration of less than 3 years is considered to represent an early relapse. Relapse in extramedullary sites compared to bone marrow is also more favorable in terms of survival.<sup>97</sup>

The second complete remission rate is more than 80%. The question of whether to perform a BMT or to continue chemotherapy has been one of the most controversial issues in second remission.<sup>98,99</sup> The likelihood of long-term survival after chemotherapy alone is less than 10% to 15% for patients with early relapse. This finding is in contrast to a 40% to 50% leukemia-free survival rate for children whose first remission was longer than 3 years.<sup>96</sup> These children also require a second course of CNS-directed therapy. BMTs from HLA-identical sibling donors compared with chemotherapy result in fewer relapses and better leukemia-free survival rates for the early-relapse group and, in some studies, for all risk groups<sup>98,99</sup> (Fig. 45.2-2).

**FIGURE 45.2-2.** Actuarial probability of leukemia-free survival in matched cohorts of children receiving chemotherapy or undergoing transplantation, according to the duration of the first remission. The numbers below the figure indicate the numbers of children at risk. (From ref. 98, with permission.)

Some investigators recommend autologous BMT for children with ALL in second remission who lack histocompatible family donors.<sup>100,101</sup> Various methodologies have been developed to purge or remove contaminating leukemia cells present in the patient's harvested marrow, but the merits of this approach are unknown. The relapse rates are higher after autologous BMT compared to allogeneic BMT because of the lack of a graft-versus-leukemia effect. It remains controversial as to whether autologous BMT is superior to chemotherapy for children with ALL in second remission. The value of matched unrelated stem cell transplantation in the therapy of children with recurrent ALL is under investigation.<sup>102</sup>

Isolated CNS relapse occurs in 5% to 10% of children treated for ALL on current protocols despite CNS-directed therapy. In the past, CNS relapse was associated with a very poor long-term prognosis, and the few survivors had serious long-term neurotoxicity. Salvage therapies included cranial or craniospinal irradiation plus IT or intraventricular chemotherapy. In the early trials, hematologic relapse rather than a subsequent CNS event was the main obstacle to a long-term second remission. Current approaches for these children include intensified reinduction and consolidation chemotherapy, IT chemotherapy, and delayed craniospinal irradiation to 6 months in remission.<sup>103</sup> The delay in craniospinal irradiation allows for intensive chemotherapy to be administered during the early phases of therapy. The 5-year-disease-free survival estimates are approximately 70% with this strategy. However, a very high rate of relapse still occurs in children whose initial duration of remission was less than 18 months. The neurologic toxicity with this type of therapy has been acceptable. BMT should be considered for the very high-risk patients with an isolated CNS relapse.

Reports of ALL treatment in the 1970s indicated that 5% to 16% of boys had a testicular relapse during hematologic remission.<sup>79,104</sup> Males with T-cell ALL were at highest risk for testicular leukemia. The time of testicular relapse was early for patients with T-cell ALL and usually was after cessation of therapy for most others. These data led to trials of prophylactic testicular irradiation in T-cell ALL and testicular biopsies at completion of chemotherapy for patients with precursor B ALL. Prophylactic testicular irradiation significantly reduced the incidence of testicular relapse but did not influence overall survival. As therapy for children with ALL has improved, testicular relapse has become a rare event. As with other sites of relapse, patients who develop early testicular relapse have a worse prognosis than those with a late relapse. Treatment includes both local radiation (24 Gy to both testes) and systemic chemotherapy. The target volume for radiation therapy includes the entire scrotal region, encompassing both the testes and epididymis bilaterally. Patients with late isolated testicular relapse have a 75% long-term disease-free survival rate.<sup>104</sup> However, hormonal dysfunction usually is seen after these doses of gonadal irradiation.

**COMPLICATIONS.** The most concerning late complications of leukemia therapy include second cancers, adverse effects on growth and development, cardiotoxicity,

and neuropsychological dysfunction.<sup>105,106</sup> and <sup>107</sup> In a retrospective review of children treated for ALL, a sevenfold excess of all cancers and a 22-fold excess of CNS tumors were found compared with the prevalence rate in the general population.<sup>107</sup> Children who received cranial irradiation before the age of 5 years had the highest incidence of brain tumors. Patients treated intensively for ALL with the epipodophyllotoxins are at high risk for developing secondary AML.<sup>108</sup>

Short stature and obesity are common in children who received cranial irradiation, especially girls who were treated at a very young age.<sup>105</sup> Many of these patients, however, have had satisfactory growth after growth hormone replacement therapy. The chemotherapeutic agents used in the treatment of the acute leukemias have been associated with many acute and chronic toxicities. The prolonged use of corticosteroids may induce osteoporosis and pathologic fractures. Avascular necrosis of long bones and foot bones also has been observed in patients with ALL who have received steroid treatment. The antimetabolites (e.g., methotrexate, 6-mercaptopurine, and cytarabine) induce cholestatic and hepatotoxic changes in the liver but are associated with few documented long-term toxicities in this population of patients. L-Asparaginase is associated with significant acute toxicity, including allergy, pancreatitis, and deep venous thrombosis, but has not been associated with long-term complications. The anthracycline antibiotics, doxorubicin and daunorubicin, have been associated with cardiomyopathy, especially when the cumulative doses administered are more than 300 mg per square meter of body surface area. Studies indicate that a very high percentage of long-term survivors of childhood cancer who received doxorubicin have subclinical echocardiographic abnormalities, including impaired contractility and increased afterload. Risk factors for doxorubicin cardiac toxicity include female gender, young age at treatment, cumulative dose, and dose intensity.<sup>73</sup> The clinical significance of these findings remains to be determined, but late congestive heart failure and death have been reported. ALL regimens that do not include alkylating agents appear not to impair reproductive function.

The neurologic and cognitive sequelae of CNS-directed therapy for children with acute leukemia have been a major concern and a highly controversial subject.<sup>74,88,94</sup> It was once thought that cranial irradiation produced a greater impairment in cognitive function (e.g., impairment of verbal memory and coding and IQ declines) than did chemotherapy. Because of those concerns, many investigators eliminated cranial radiation from therapeutic protocols. However, studies indicate that prednisone and high doses of intravenous or IT methotrexate are associated with neurotoxicity and that 18 Gy of cranial irradiation may not be an independent toxic agent for cognitive outcome.<sup>90,94</sup> High-dose intravenous methotrexate is particularly toxic if it follows cranial irradiation.<sup>74</sup>

### **Acute Myelogenous Leukemia**

In contrast to ALL, only a modest improvement has been made in the long-term survival of children with AML since the late 1970s.<sup>2,109</sup> The complete remission rate has increased from less than 50% to approximately 85%, but only 30% to 50% of patients are long-term survivors.<sup>110,111,112,113</sup> and <sup>114</sup> The survival rate is somewhat better for those children with HLA-matched family donors who receive an allogeneic BMT early in first remission.<sup>111,112,114</sup>

**INDUCTION.** The most commonly used remission induction regimen for children with AML, excluding those with Down syndrome and FAB M3, includes a 5- to 7-day course of cytosine arabinoside, plus 2 to 3 days of daunorubicin, with or without thioguanine or etoposide.<sup>2,109</sup> The high complete remission rate with all-*trans*-retinoic acid (ATRA) in patients with acute promyelocytic leukemia (FAB M3) led to prospective randomized trials testing the value of ATRA in the overall treatment plan.<sup>115,116</sup> Results of these studies clearly show that the combined use of ATRA and chemotherapy is superior to chemotherapy alone for patients with acute promyelocytic leukemia.<sup>115,116</sup> Therefore, induction therapy for all patients with acute promyelocytic leukemia should include ATRA combined with an anthracycline (daunorubicin or idarubicin) and cytarabine. Chemotherapy for children with Down syndrome and AML needs to be less intensive than standard AML therapy because of the increased risk of toxicity in these patients. Despite dose modifications, the outcome of children with Down syndrome and AML is excellent.<sup>9</sup>

**CENTRAL NERVOUS SYSTEM PROPHYLAXIS.** Isolated CNS relapse occurs in approximately 20% of children with AML.<sup>2,109</sup> IT chemotherapy in combination with high-dose systemic cytosine arabinoside is effective in lowering the CNS relapse rate. Data from the BFM studies using historical comparisons suggests that cranial irradiation plus IT chemotherapy in children with standard-risk AML improves outcome.<sup>117</sup>

**POSTREMISSION THERAPY.** The intensity and duration of postremission chemotherapy and the role of allogeneic and autologous BMT in first remission have been under active investigation. The improvement in overall survival rates to approximately 40% to 50% at 5 years is a result of more effective remission induction and postremission chemotherapy.<sup>2,113,118,119</sup> There is no proven role for maintenance chemotherapy if it follows several courses of high-dose cytarabine-based consolidation chemotherapy.<sup>119</sup> Most pediatric AML protocols include one to three cycles of high-dose cytarabine after remission is achieved.

**BONE MARROW TRANSPLANTATION IN FIRST REMISSION.** Allogeneic BMT was first applied to children and young adults with AML in first remission as an alternative to continued chemotherapy in the mid-1970s.<sup>112,120,121</sup> The early results were favorable compared with chemotherapy, but the transplantations were done in a selected group of patients. The CCG initiated the first cooperative group study comparing allogeneic BMT to chemotherapy in children with AML in first remission.<sup>112</sup> Long-term follow-up of that study, plus data from POG and Associazione Italiana Ematologia ed Oncologia Pediatrica, all show a survival advantage for allogeneic BMT compared to chemotherapy.<sup>111,112,114</sup> However, fewer than one-fourth of children have a fully histocompatible family donor. Because of improving results of chemotherapy and the morbidity and mortality associated with BMT, the German BFM and Medical Research Council cooperative groups are not recommending allogeneic BMT in first remission for patients with favorable prognostic factors.<sup>110,113</sup> BMTs are reserved for second remission in this group of patients.

For patients who lack histocompatible family donors, autologous BMT became an attractive option in first remission after it was reported to be efficacious (30% to 40% survival) in second remission of AML.<sup>122</sup> The results of the early studies were controversial because they were not prospectively controlled. Beginning in the mid-1980s, both the adult and pediatric AML cooperative groups initiated prospective randomized studies to compare autologous BMT and intensive postremission chemotherapy.<sup>111,114,118</sup> In the pediatric trials, no event-free or survival advantage was found for autologous BMT compared with chemotherapy. The majority of failures after autologous BMT are due to recurrent leukemia.

**PROGNOSTIC FACTORS.** In contrast to childhood ALL, very few clinical or laboratory factors are consistently related to prognosis<sup>2,46,47,110</sup> (see [Table 45.2-4](#)). A leukocyte count of more than 100,000 cells per microliter, karyotype with monosomy 7, and secondary AML are associated with lower remission rates. The lower remission rates associated with hyperleukocytosis are only partially accounted for by early deaths secondary to leukostasis. In the German BFM AML studies, two risk groups were identified.<sup>110</sup> Standard-risk patients included FAB subtypes M1 or M2 with Auer rods, M3 or M4eo, rapid response to initial induction chemotherapy, and Down syndrome. The standard-risk group includes patients with "favorable chromosomal abnormalities" [t(8;21), t(15;17), and inv 16].<sup>47</sup> All other patients are high risk and include approximately 70% of the entire group. Event-free survival rates for standard-risk versus high-risk patients was 65% and 34%, respectively.

**MANAGEMENT OF THE RELAPSED PATIENT.** The prognosis for children with AML who do not enter complete remission or who relapse is poor.<sup>2,123</sup> BMT offers these patients a chance for long-term survival.<sup>102,123,124</sup> A variety of chemotherapy regimens have been evaluated in children with refractory or relapsed AML.<sup>2,109,123,125</sup> The second remission rates range from approximately 30% to 50% and are highest for children whose first remission duration was longer than 1 year. However, the length of chemotherapy-maintained second remissions are very brief. On the other hand, 5-year event-free survival ranges from 30% to 50% for those patients who receive an allogeneic (related or unrelated marrow donor) marrow transplantation.<sup>124</sup> Autologous BMT in second remission for patients who lack suitable marrow donors offers some hope for long-term survival, but it has become a less attractive option because of the expanding unrelated marrow and cord blood banks and the opportunity to find a matched unrelated donor for an allogeneic transplantation.<sup>102,126</sup>

### **FUTURE DIRECTIONS**

The major challenge for the future is to develop effective therapy for patients who have a poor prognosis and to minimize toxicity for those children who are successfully treated. Strategies are being developed to target drug doses to achieve predetermined serum or intracellular concentrations to improve the therapeutic index.<sup>1</sup> The use of recombinant human hematopoietic growth factors may reduce the myelosuppressive complications from chemotherapy and allow dose intensification to proceed safely.

Mechanisms of drug resistance are beginning to be elucidated.<sup>127</sup> For example, increased expression of the multidrug resistance gene (*mdr1*) or its protein product (P glycoprotein) has been demonstrated in blasts from 20% to 40% of newly diagnosed patients with AML, and it increases approximately twofold at the time of relapse. High *in vitro* expression of *mdr1* correlates with resistance to multiple drugs (e.g., etoposide, anthracyclines, vincristine) by promoting their cellular efflux. A number of biologically active agents, including verapamil and cyclosporine, are capable of reversing the *mdr1* phenotype *in vitro*. To date, only limited evidence indicates that this strategy works *in vivo*, but controlled clinical trials are under way.

The wider availability of stem cell transplantations from unrelated marrow or cord blood donors has enabled many more patients to successfully undergo marrow transplantation.<sup>102,126</sup> Studies are testing nonmyeloablative marrow transplantations in an effort to achieve mixed chimerism that will hopefully achieve a more favorable balance of the graft-versus-host and graft-versus-leukemia reactions.<sup>128</sup> Biologic response modifiers, such as interleukin-2 and -12, are under study for their potential to enhance the host response to tumor. It is now possible to target the genetic lesions of leukemia cells, as exemplified by the successful use of ATRA in acute promyelocytic leukemia and a specific bcr-abl tyrosine kinase inhibitor in Ph-positive leukemias.<sup>115,129</sup>

## NON-HODGKIN'S LYMPHOMA

The lymphomas are the third most common childhood malignancy and account for approximately 10% of cancers in children.<sup>4,26</sup> Approximately two-thirds of the lymphomas diagnosed in children are non-Hodgkin's lymphoma (NHL) and the remainder are Hodgkin's disease. The spectrum of NHL seen in pediatric patients differs significantly from that seen in adults. The three major histologic categories of NHL in children are lymphoblastic, small noncleaved cell (Burkitt's), and large cell lymphoma (Table 45.2-5).<sup>26</sup> In adults, Burkitt's and lymphoblastic lymphoma are rare, but follicular center cell lymphoma, a histologic type exceedingly rare in children, predominates.<sup>130</sup> No sharp age peak (median age, 11 years) occurs in children with NHL, and the male to female ratio approaches 3:1.

Histology	Frequency	Major Presenting Sites by Age	Immunophenotype
Lymphoblastic	30%	Stage I-IV: testis, bladder/ovary, celiac axis, retroperitoneum Stage I-IV: anterior mediastinum, pleural effusion, bone marrow, bone, peripheral lymphadenopathy, meninges	Precursor B Precursor T
Small noncleaved cell (Burkitt's)	40-50%	Stage I-IV: Waldeyer's ring, testis, ovary, celiac axis, retroperitoneum Stage I-IV: (resectable) abdominal masses, ovary, testis, bone marrow, central nervous system, and bone	B cell
Diffuse large cell	25%	Stage I-IV: Waldeyer's ring, cervical nodes, retroperitoneum, bone Stage I-IV: anterior mediastinum, paravertebral area, bone, peripheral lymphadenopathy, retroperitoneum, and brain	B cell and T cell

TABLE 45.2-5. Pediatric Non-Hodgkin's Lymphoma: Correlation of Histology, Presenting Sites, and Immunophenotype

Therapy is best delivered by a team of pediatric oncologists, surgeons, and radiation oncologists at a major medical center with expertise in treating children. Before the use of multiagent leukemia regimens for children with all stages and histologic subtypes of NHL, fewer than 20% of children were cured.<sup>131</sup> The survival of children with NHL, especially those with advanced-stage disease, has markedly improved during the 1990s. The 5-year survival rate is approximately 90% for children with early-stage NHL and 70% for those with advanced-stage disease.<sup>26,132,133</sup>

## RISK FACTORS

Numerous factors have been linked to an increased risk of NHL. Children with severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome, common variable immunodeficiency, ataxia-telangiectasia, and the X-linked lymphoproliferative syndrome are at increased risk for developing a lymphoma.<sup>26,134,135</sup> Acquired immunodeficiency secondary to human immunodeficiency virus infection or immunosuppressive therapy, especially after solid organ transplantation or BMT, also places individuals at greater risk for developing a lymphoproliferative disorder or malignant lymphoma.<sup>136,137</sup> Most of the lymphomas that occur in these high-risk groups are B-lineage large cell or small noncleaved (Burkitt's). Monoclonal Epstein-Barr virus (EBV) DNA has been identified in tumor tissue from many of these patients, indicating an important and early role for the virus in tumor development.<sup>138</sup> It has been postulated that the immunodeficient host does not generate an adequate T-lymphocyte response (EBV-specific cytotoxic T cells) against B cells that are latently infected with EBV.

EBV has long been associated with endemic Burkitt's lymphoma, and more recently with hairy leukoplakia, nasopharyngeal carcinoma, and leiomyosarcomas in children with human immunodeficiency virus.<sup>139</sup> The role of EBV in the pathogenesis of Burkitt's lymphoma and other malignancies is unknown [see [Small Noncleaved Cell \(Burkitt's\) Lymphoma](#), later in this chapter].

## CLASSIFICATION

In the Working Formulation, the major categories of childhood NHL are lymphoblastic, small noncleaved cell (Burkitt's and non-Burkitt's), diffuse large cell, and large cell immunoblastic.<sup>140</sup> The pediatric NHLs in the Revised European-American Lymphoma classification include precursor B and precursor T lymphoblastic lymphoma/leukemia, Burkitt's lymphoma, diffuse large B-cell lymphoma, and anaplastic large cell lymphoma (ALCL) (T- and null cell types).<sup>141</sup>

## STAGING

The Ann Arbor staging classification is not well suited for childhood NHL for several reasons. It does not adequately reflect prognosis, because there is early widespread, noncontiguous dissemination of disease despite the limited initial sites of involvement (e.g., mediastinal lymphoblastic lymphoma). In addition, extranodal involvement is common, whereas stage III nodal disease is rare. In view of these deficiencies, an alternative staging system (see Table 45.2-6) was developed at St. Jude Children's Research Hospital.<sup>131</sup> The St. Jude system considers both primary site and extent of tumor in assigning a clinical stage, and it has been widely accepted. Pathologic staging is not helpful in the overall management of children with NHL because the mainstay of treatment is systemic chemotherapy with a very limited role for irradiation of involved sites of disease.<sup>25,133</sup>

Stage	Description
I	A single tumor (extranodal) or single anatomic area (nodal), with the absence of dissemination or dissemination
II	A single tumor (extranodal) with regional node involvement Two or more nodal areas on the same side of the diaphragm Two stage I extranodal tumors with or without regional node involvement on the same side of the diaphragm A primary gastrointestinal tract tumor, usually in the ileocecal area, with no nodal involvement or associated extranodal tumor only
III	Two stage I tumors (extranodal) on opposite sides of the diaphragm Two or more nodal areas above and below the diaphragm All the primary intrathoracic tumors (extranodal, pleural, etc.) All extranodal primary intrathoracic tumors
IV	All paraneoplastic or systemic tumors, regardless of other tumor sites Any of the above with initial central nervous system or bone marrow involvement

\*Stage II abdominal disease is defined as limited to a segment (usually distal ileum) of the small intestine or ileocecal junction, associated nodal involvement, and the primary tumor can be completely removed grossly by surgical resection. Stage III abdominal disease requires additional spread to paraneoplastic and extrathoracic areas by lymphatics and pleura or metastasis to paraneoplastic or the other abdominal or extrathoracic sites on the primary tumor. Anatomic sites for paraneoplastic and extrathoracic metastases of all given tumors are not given.  
†If there are more extranodal sites in a segment, the primary tumor or abdominal sites must be 20% or less in the abdominal or stage II extrathoracic lymphoma. If there are more than 20% in any, the patient is classified as having stage III abdominal or extrathoracic disease. If there are more than 20% in any extrathoracic lymphoma or I, II or III extrathoracic lymphoma.

TABLE 45.2-6. St. Jude Children's Research Hospital Staging System for Pediatric Non-Hodgkin's Lymphoma

## LYMPHOBLASTIC LYMPHOMA

Lymphoblastic lymphomas account for 30% of childhood NHL and share many clinical and biologic features with ALL.<sup>21,25,142</sup> The distinction between lymphoblastic lymphoma and ALL is arbitrary (see Table 45.2-2) and has not been based on clinical presentation. If the bone marrow has more than 25% lymphoblasts, the patient is considered to have ALL rather than stage 4 lymphoblastic lymphoma.

The tumor cells of lymphoblastic lymphoma are morphologically indistinguishable from the lymphoblasts of precursor B and precursor T ALL. <sup>141</sup> They have round or convoluted nuclei, finely dispersed chromatin, inconspicuous nucleoli, and scant cytoplasm. <sup>142</sup> Lymphoblastic lymphomas in the anterior mediastinum have a precursor T cell immunophenotype that most often correlates with the middle or late stage of thymocyte maturation. <sup>21</sup> The cells express various combinations of the CD1, CD2, CD5, and CD7 antigens and, in many cases, express both CD4 and CD8. The CD3 antigen and associated T-cell receptor molecule are not commonly expressed. The CD10 or CALLA antigen is variably present. Significant overlap of the immunophenotype is found in many cases of lymphoblastic lymphoma and T-cell ALL, suggesting a common cell of origin. <sup>142</sup> The early-stage lymphoblastic lymphomas have the phenotype of an early B-cell precursor, identical to that seen in most children with ALL. <sup>1,143</sup>

In more than one-half of the cases of T-cell lymphoblastic lymphoma/leukemia, recurrent nonrandom chromosomal translocations involving the a, b, and g chains of the T-cell receptor have been identified. Many of these translocations arise in error during the normal process of rearrangement of the T-cell receptor genes, a situation that is analogous to the Ig rearrangements noted in Burkitt's lymphoma. <sup>25,144</sup> Several of the partner genes involved in these translocations include the transcription factors TAL1 and HOX11, and the cysteine-rich (LIM) proteins RHOMB1 and RHOMB2. In the t(1;14)(p32;q11), detected in 3% of patients with T ALL, the TAL1 gene is rearranged in its 5' regular sequence by its translocation into the T-cell receptor a/d chain locus. A submicroscopic deletion in the same region of TAL1 is detected in up to 25% of patients with T-cell ALL/lymphoblastic lymphoma, making it the most common genetic change in this disease. <sup>25,145</sup>

### Clinical Presentation and Staging

Most children with lymphoblastic lymphoma present with rapidly enlarging neck and mediastinal lymphadenopathy, although subdiaphragmatic nodal presentations are occasionally seen. <sup>26</sup> The classic presentation is that of an adolescent male with respiratory distress due to a large anterior mediastinal mass with or without pleural effusions. Cough, wheezing, or shortness of breath and facial swelling (evidence of superior vena cava syndrome) are frequent complaints in these patients. Other common presenting sites of disease include cervical nodes, Waldeyer's ring, cutaneous lesions, bone marrow, and single- or multiple-site bone disease. The majority of children have advanced-stage disease (see [Table 45.2-5](#)).

Because the pace of the disease is usually rapid, diagnostic studies and institution of therapy should proceed quickly. The least invasive procedure should be used to establish the diagnosis. Because bone marrow is frequently involved and patients with T-cell ALL often present with an anterior mediastinal mass, a close examination of the peripheral blood and bone marrow should be undertaken before proceeding to a more invasive procedure. Pleural effusions should be tapped because they are often positive for malignant cells. If the bone marrow and pleural fluid are nondiagnostic, a lymph node outside of the mediastinum should be biopsied, if possible. Sufficient tissue should be obtained for histopathology, genetic studies, and immunophenotyping. Biopsy under general anesthesia should be avoided if at all possible, especially if there is significant airway narrowing or symptoms of respiratory distress. <sup>146,147</sup> The prebiopsy use of mediastinal irradiation or steroids for respiratory distress results in rapid disappearance of the mass and jeopardizes the likelihood of establishing a tissue diagnosis. The remainder of the workup should include a lumbar puncture with a cytocentrifuged examination of cerebral spinal fluid, and a computed tomographic (CT) scan or magnetic resonance imaging of the primary site. Bone and liver-spleen scans are not necessary. Routine blood chemistries and liver function tests should be obtained before starting therapy.

### TREATMENT

Historically, children with lymphoblastic lymphoma had less than a 10% survival rate after careful pathologic staging followed by extended-field radiotherapy. <sup>148,149</sup> Within several months from the start of radiation therapy, disease progression to a leukemic phase that was indistinguishable from ALL was noted in most patients. This finding suggested that widespread dissemination of lymphoma already existed at the time of diagnosis, especially to the bone marrow and meninges. Based on these observations, investigators at St. Jude Children's Research Hospital added chemotherapy that was effective against childhood ALL to local irradiation. <sup>149</sup> This systemic treatment approach dramatically improved the outcome for children with lymphoblastic lymphoma. Similar treatment strategies were adopted for the other histologic types of childhood NHL.

The combined use of ALL therapy with local irradiation was very effective for children with early-stage lymphoblastic lymphoma (80% survival). <sup>150,151</sup> Despite the favorable outcome, the toxicity of combined modality therapy led to attempts to reduce the intensity and duration of treatment without compromising survival. Several single-institution and cooperative group protocols were successful in maintaining excellent survival rates (85% to 90%) while reducing the morbidity and mortality of therapy. The CCG protocols demonstrated the equal efficacy of 6 and 18 months of the cyclophosphamide, Oncovin, methotrexate, and prednisone (COMP) combination. <sup>151</sup> However, all children also received radiotherapy to involved fields. A POG study demonstrated that the omission of radiotherapy from the treatment of localized NHL in children did not jeopardize survival. <sup>133</sup> The POG chemotherapy regimen included three cycles of cyclophosphamide, doxorubicin, Oncovin, and prednisone (CHOP) followed by 24 weeks of 6-mercaptopurine and methotrexate. The CCG and POG protocols included IT methotrexate for patients with primary tumors in the head and neck region. Treatment with either CHOP or COMP results in 65% event-free survival for children with localized lymphoblastic lymphoma, but survival is 90% because of the successful treatment of relapse with salvage chemotherapy.

Fewer than 40% of patients with advanced-stage (stages 3 and 4) lymphoblastic lymphoma were cured with standard-risk ALL regimens (e.g., vincristine, steroid, L-asparaginase, methotrexate, and 6-mercaptopurine) or COMP therapy. <sup>131,150</sup> The addition of drugs such as the anthracyclines, cyclophosphamide, cytosine arabinoside, or the epipodophyllotoxins to ALL regimens substantially improved the prognosis for these children.

The vincristine, doxorubicin (Adriamycin), and prednisone (APO) and LSA2L2 regimens were two of the early successful protocols for children with high-risk ALL or advanced-stage lymphoblastic lymphoma. LSA2L2 included ten drugs, and the APO protocol featured intensification with doxorubicin and L-asparaginase ([Table 45.2-7](#)). <sup>150,152,153</sup> Both protocols included preventive CNS therapy. Radiation therapy to the mediastinum was generally limited to emergency situations. These regimens resulted in approximately 65% survival for children with advanced-stage lymphoblastic lymphoma. The use of more intensive ALL chemotherapy regimens appears to further improve the outcome for these children. <sup>25,132</sup> Although radiotherapy has been omitted from most of the protocols, a small percentage of patients have local tumor failure. <sup>154</sup>

Histology	Protocol	OS (%)	Relapse-free (%)
Lymphoblastic	Stage 1 (n=10)	100	100
	Stage 2 (n=10)	100	100
	Stage 3 (n=10)	100	100
Mixed non-Hodgkin's	Stage 1 (n=10)	100	100
	Stage 2 (n=10)	100	100
	Stage 3 (n=10)	100	100
Large cell	Stage 1 (n=10)	100	100
	Stage 2 (n=10)	100	100
	Stage 3 (n=10)	100	100

**TABLE 45.2-7.** Recommended Protocols by Histology and Stage for Pediatric Non-Hodgkin's Lymphoma

Early preventive CNS therapy is critical in the treatment for children with advanced-stage lymphoblastic lymphoma. IT chemotherapy alone or combined with cranial irradiation has been the mainstay of CNS preventive therapy. <sup>154</sup>

Relapse at any site is a significant obstacle to cure in children with advanced-stage lymphoblastic lymphoma. Most of the relapses occur within 2 years from diagnosis, but occasional late relapse is observed. In contrast to relapse for early-stage disease, the outcome after a second course of chemotherapy is poor. However, these patients have a 30% to 50% survival rate after allogeneic BMT from a histocompatible sibling donor. <sup>155</sup>

## SMALL NONCLEAVED CELL (BURKITT'S) LYMPHOMA

The small noncleaved cell lymphomas (Burkitt's type) were initially described by Dennis Burkitt in equatorial Africa where the tumor is endemic.<sup>156</sup> These lymphomas were subsequently recognized worldwide and account for approximately 40% of childhood NHL. The endemic form is common (100 per 1 million children) and is nearly always associated with EBV (95%), whereas the sporadic form is rare (1 to 2 per 1 million children) and uncommonly associated with EBV (15%). In endemic areas, involvement of the jaw and other facial bones is frequent, whereas extensive intraabdominal disease and bone marrow involvement are commonly seen in sporadic cases.<sup>157</sup>

Histologically, the small noncleaved cell lymphomas include the Burkitt's and non-Burkitt's types. The Burkitt's type was defined by the World Health Organization in 1969. It is characterized by homogeneous cells with round to oval nuclei with multiple nucleoli and intensely basophilic vacuolated cytoplasm that contains neutral fat. The non-Burkitt's type has a greater degree of nuclear pleomorphism compared to the Burkitt's type. The non-Burkitt's type may be difficult to distinguish on a morphologic basis from some large B-cell lymphomas. In children, no obvious differences are found between the Burkitt's and non-Burkitt's lymphomas, and therefore they are considered the same for treatment purposes.<sup>158</sup>

Burkitt's lymphoma is a B-cell tumor based on expression of cell surface Ig heavy chains (usually IgM) and either k or l light chains.<sup>11</sup> Approximately 50% of cases are also CD10 (CALLA)-positive. L3 lymphoblasts have a similar immunophenotype and are cytologically indistinguishable from Burkitt's cells. Because many patients with L3 ALL also have primary tumor masses, it is likely that the essential difference in these diseases lies in their extent at presentation. Cure rates of 75% to 85% have been achieved for children with B-cell ALL (FAB L3) using treatment programs developed for advanced-stage Burkitt's lymphoma.<sup>83,159,160</sup>

Chromosomal translocations involving the c-myc locus on chromosome 8q24 and Ig receptor genes are characteristic of Burkitt's lymphoma.<sup>3,26,161</sup> These translocations appear to result from errors in the normal process of recombination that drives Ig gene rearrangement during B-cell development. The majority of cases have a t(8;14)(q24;q32) translocation in which c-myc is translocated into the Ig heavy-chain gene on chromosome 14q32. Two variant translocations, t(2;8)(p12;q24) and t(8;22)(q24;q11), occur with less frequency. In these translocations, c-myc is fused with the k or l light-chain genes located on chromosome 2 and 22, respectively. These translocations juxtapose Ig transcriptional regulatory sequences adjacent to the c-myc gene, leading to its dysregulated activity. In endemic and sporadic cases, the breakpoints on chromosome 14 involve the Ig heavy-chain joining region and switch region, respectively, suggesting that the translocation in the sporadic cases occurs at a later stage of B-cell development.<sup>162</sup> Up-regulation of c-myc influences the ratio between myc/max complexes in favor of transcriptional activation and B-cell proliferation.<sup>163</sup> In transgenic mice, the translocation-induced dysregulation of c-myc has been shown to directly induce B-cell lymphomas.<sup>164</sup>

The role of EBV in the pathogenesis of endemic Burkitt's lymphoma is unknown.<sup>165</sup> Studies of EBV gene expression in lymphoblastoid cell lines and in human tumor biopsy specimens have identified three distinct forms of virus latency. EBV gene expression is more restricted in Burkitt's lymphoma (EBNA1 and EBERs) compared with lymphoblastoid cell lines, posttransplantation lymphoproliferative processes, and some cases of EBV-positive Hodgkin's disease and nasopharyngeal cancer.<sup>166</sup> Tumor cells of endemic Burkitt's lymphoma are not susceptible to killing by EBV-specific cytotoxic T cells, which may be due to the lack of the EBNA3 family of proteins. Furthermore, Burkitt's cells display down-regulated expression of adhesion molecules and HLA class I alleles, further impairing the action of cytotoxic T cells. The role of malarial infection remains unknown but may also result in a relative T-cell immunodeficiency.

### Clinical Presentation

The abdomen is the most common presenting site in sporadic cases of Burkitt's lymphoma (see [Table 45.2-5](#)).<sup>26</sup> Approximately one-third of children with an abdominal primary tumor present with a right lower quadrant mass or with signs and symptoms of either acute appendicitis or intestinal obstruction secondary to an ileocecal intussusception.<sup>157,167</sup> This presentation is typically seen in boys between 5 and 10 years of age. An exploratory laparotomy is indicated for diagnostic purposes. If a tumor is discovered, it is invariably a small noncleaved Burkitt's lymphoma that is limited in extent to the distal ileum or cecum. Complete surgical resection of the involved segment of gut with its associated mesentery, followed by an end-to-end anastomosis, is the proper treatment. Children with completely resected Burkitt's lymphoma (stage 2) of the intestinal tract have an excellent prognosis after treatment with a limited course of chemotherapy (discussed later, in the section [Treatment](#)). The majority of patients with Burkitt's lymphoma of the abdomen, however, have unresectable disease that may involve the mesentery, retroperitoneum, kidneys, ovaries, and peritoneal surfaces (often associated with malignant ascites). Surgical debulking is not feasible or appropriate for this latter group of patients.<sup>167</sup>

The head and neck region is the second most common site of disease presentation. Patients in nonendemic areas present with tonsillar enlargement, cervical lymphadenopathy and, occasionally, a soft tissue facial mass associated with involvement of the jaw or other facial bones.<sup>133,157</sup> Less common presenting sites include an epidural mass, skin nodules, bone, and bone marrow.

The least invasive procedure should be used to establish the diagnosis, and the staging evaluation should be expedited because these patients usually have rapidly growing tumors with significant electrolyte imbalance as well as impaired renal function. This is especially true for children with massive abdominal disease. Effusions are usually malignant in these children and contain sufficient numbers of tumor cells for cytology and biology studies. Imaging should include a CT scan or magnetic resonance imaging of the primary site and a bone scan. Patients with head and neck primary tumors may have clinically nondetectable disease in the abdomen (especially of the kidneys) and therefore should also have abdominal imaging studies.

Particular attention to kidney function, and the serum levels of uric acid, potassium, calcium, and phosphorus, is critical in children with advanced-stage Burkitt's lymphoma. These patients are at high risk for the "tumor lysis syndrome" and uric acid nephropathy.<sup>168</sup> Measures should be taken to reduce the likelihood of uric acid nephropathy, including vigorous intravenous hydration, alkalization of urine with either sodium bicarbonate or Diamox, administration of allopurinol, and careful monitoring of serum electrolytes. Hemodialysis is required in a small percentage of cases.<sup>160</sup>

### Treatment

Complete remissions were induced in 80% of African children with Burkitt's lymphoma with cyclophosphamide administered as a single agent.<sup>169</sup> Patients with facial tumors (early stage) had sustained remissions with single- or multiple-dose cyclophosphamide, whereas the majority of children with abdominal tumors relapsed with systemic and CNS disease. Successor protocols used combination chemotherapy and IT methotrexate. The use of cyclophosphamide and vincristine with methotrexate or cytarabine was associated with higher remission rates and more durable remissions compared to single-agent cyclophosphamide.<sup>170</sup> The most important prognostic factor was the extent of tumor at diagnosis.

Clinical trials in the United States demonstrated that the complete response rate, relapse frequency, and survival in American patients were similar to results in Africa.<sup>171</sup> Approximately 85% of patients with early-stage Burkitt's lymphoma were cured using as little as 9 weeks of CHOP chemotherapy.<sup>133</sup> Similar results were achieved after 6 months of COMP therapy.<sup>151</sup> A POG study demonstrated that the addition of involved-field radiation therapy did not influence outcome.<sup>133</sup> Treatment for patients with head and neck primary sites of disease also included IT methotrexate.

COMP therapy, however, resulted in only a 40% survival rate for patients with advanced-stage disease,<sup>150</sup> which was similar to the African experience.<sup>170</sup> Relapses occurred in systemic and CNS sites at a median of 3 months from the beginning of therapy. Protocols that were highly effective for children with ALL and lymphoblastic lymphoma (e.g., LSA2L2 and APO) were less effective than COMP for advanced-stage Burkitt's lymphoma or L3 ALL.<sup>150</sup> These poor results were most likely due to the omission or limited use of cyclophosphamide.

Several groups of investigators began to evaluate dose-intensified systemic and IT chemotherapy for these high-risk patients.<sup>83,159,160</sup> Cyclophosphamide, methotrexate, and cytarabine were administered in high doses with or without anthracyclines and the epipodophyllotoxins. Treatment courses were repeated at early signs of bone marrow recovery in an attempt to prevent regrowth of tumor between cycles of chemotherapy. Hematopoietic growth factors were used in some protocols to enhance bone marrow recovery. CNS prophylaxis included systemic chemotherapy that penetrated the CNS (high-dose methotrexate and cytarabine) and intensive IT chemotherapy. Radiation therapy was usually reserved for patients who presented with initial CNS involvement. The duration of treatment ranged from 2 months to 1 year. The results of these studies were impressive. Event-free survival increased from 50% to 80% for stage 3 and from less than 20% to more than 80% for patients with stage 4 Burkitt's lymphoma and L3 ALL (see [Table 45.2-7](#)).

The management of patients with recurrent Burkitt's lymphoma is problematic. Relapse tends to occur early, while the patient is still on therapy. BMT offers the only

realistic hope of long-term survival for these children.<sup>26,172</sup> The outcome is more favorable for patients who achieve a second remission before proceeding to BMT. However, second remissions are difficult to induce in these patients, especially for those with advanced-stage disease.

## LARGE CELL LYMPHOMA

The large cell lymphomas constitute approximately 30% of childhood NHL.<sup>26</sup> Approximately 30% of pediatric large cell lymphomas are classified as ALCL in the Revised European-American Lymphoma classification.<sup>141</sup> The remainder are diffuse large B-cell lymphoma, primary mediastinal large B-cell lymphoma, and the rare peripheral T-cell lymphoma. ALCL in children tends to involve lymph nodes and extranodal sites, including the skin, soft tissues, lung, and bone.<sup>173</sup> Lymphomatoid papulosis and the primary cutaneous form of ALCL are rare in childhood. The majority of the cases of ALCL studied in children have had a T-cell phenotype. The t(2;5)(p23;q35) translocation has been associated with Ki-1+ or CD30+ lymphomas in both children and adults.<sup>174</sup> The chromosomal breakpoints involved in the t(2;5) have been cloned and involve the gene that encodes nucleophosmin (NPM), a nonribosomal nuclear phosphoprotein on chromosome 5, and a gene that encodes a novel transmembrane tyrosine-specific protein kinase (ALK) located on chromosome 2.<sup>175</sup> The translocation results in the fusion of these genes, producing a chimeric NPM-ALK gene and message. Reverse transcriptase–polymerase chain reaction assays for this translocation have been positive in all cases with cytogenetic evidence of the t(2;5) and in several cases of ALCL with a normal karyotype.

### Clinical Presentation

The clinical presenting features of large cell lymphoma in children are more varied than those for lymphoblastic or Burkitt's lymphoma. Also, a relatively equal distribution is seen between early- and advanced-stage disease. The most common primary sites of disease include the nasopharynx, cervical nodes, skin, soft tissues, mediastinum, bone, and abdomen. The bone marrow and CNS are rarely infiltrated (see [Table 45.2-5](#)).

### Evaluation and Treatment

The workup and staging of the child with large cell lymphoma are similar to that recommended for children with the other histologic subtypes of NHL. The treatment of large cell lymphoma in children has evolved from local radiotherapy to primarily combination chemotherapy.<sup>26,176</sup> Because of the relative rarity of large cell lymphoma in children, many of the treatment strategies and protocols derive from adult studies.<sup>177</sup>

Children with localized large cell lymphoma have a very favorable prognosis. The COMP and CHOP regimens that are effective in early-stage lymphoblastic and Burkitt's lymphoma also result in 85% survival for these children (see [Table 45.2-7](#)).<sup>133,150</sup> The results of CHOP with or without involved-field irradiation were similar.

CHOP has not been systematically evaluated in children with advanced-stage large cell lymphoma. The results of COMP therapy for these children were disappointing (approximately 50% event-free survival).<sup>150</sup> However, the use of the APO and Adriamycin, Cytosan, Oncovin, and prednisone (ACOP+) regimens resulted in approximately 70% event-free survival for children with stage 3 or 4 large cell lymphoma.<sup>176,178</sup> These latter protocols include up-front vincristine, prednisone, doxorubicin, and cyclophosphamide (ACOP+ only). Because of the similar outcomes after APO and ACOP+ therapy and the concerns of secondary malignancy and gonadal failure after cyclophosphamide, POG investigators prospectively compared APO to ACOP+ in children with advanced-stage large cell lymphoma.<sup>179</sup> The event-free survival rate is approximately 70% in both arms at 5 years, thereby questioning the value of the addition of an alkylating agent to an Adriamycin-containing regimen. Conclusions about the safety of omitting cyclophosphamide await confirmatory studies and a detailed analysis of various subsets of patients.

The most important prognostic factor in children with large cell lymphoma is stage. Children with ALCL do not have an adverse prognosis compared with other subgroups of patients with large cell lymphoma. In a retrospective POG study, B-cell phenotype was associated with superior survival.<sup>180</sup>

Most protocols for children with advanced-stage large cell lymphoma do not include involved-field radiotherapy, but no controlled trials have addressed this issue.<sup>181</sup> The risk of an isolated CNS relapse is rare, but nevertheless, pediatric protocols include IT chemotherapy for these patients.

## HODGKIN'S DISEASE

Approximately 10% to 15% of all cases of Hodgkin's disease occur in patients younger than 16 years.<sup>182,183</sup> The natural history of Hodgkin's disease and outcome of treatment is similar in children and young adults 20 to 45 years of age.<sup>184,185,186</sup> and <sup>187</sup> Fully grown adolescents generally are evaluated and managed in the same way as adults. Treatment decisions are more complex in young children because of the adverse effects of irradiation on growth of bone and soft tissues and the risk of secondary malignancies.<sup>189,190</sup> The preceding concerns led to the development in the 1970s of combined modality therapy with reduced doses and volumes of irradiation for children with both early and advanced stages of Hodgkin's disease.<sup>191,192</sup> The following section focuses on the unique aspects of the treatment of Hodgkin's disease in children.

### EPIDEMIOLOGY

In industrialized countries, the age of Hodgkin's incidence is bimodal, with a first peak in adults 20 to 30 years of age and a second peak in late adulthood. Hodgkin's is uncommon before age 5 years, and the majority of pediatric cases are in children older than 11 years.<sup>4,182</sup> Before age 10, the male to female ratio is approximately 3:1; this ratio approaches 1:1 by adolescence.

The etiology of Hodgkin's disease remains unknown. An increased risk of Hodgkin's disease is noted in children with inherited immunodeficiency syndromes. Genetic susceptibility and environmental factors probably both play a role in the pathogenesis of Hodgkin's disease (discussed in detail in [Chapter 45.1](#) and [Chapter 45.6](#)). Although rare, Hodgkin's can be familial. Evidence is increasing for the role of EBV in some subgroups of patients with Hodgkin's disease, especially children with mixed-cellularity histology.<sup>193</sup>

### CLINICAL PRESENTATION, STAGING, AND WORKUP

Hodgkin's disease usually presents in supradiaphragmatic lymph nodes, with cervical, anterior mediastinal, and axillary nodes occurring in decreasing frequency. Mediastinal adenopathy may produce symptoms such as dyspnea, cough, or superior vena cava syndrome. Approximately 90% of children present with painless neck adenopathy, and 60% have involvement of anterior mediastinal, paratracheal, or hilar lymph nodes. Isolated infradiaphragmatic Hodgkin's disease is rare. Approximately one-third of children have B symptoms [unexplained fever (exceeding 100.4°F), drenching night sweats, more than 10% weight loss]. The Ann Arbor staging system is used for all age groups of patients with Hodgkin's disease and is described in detail in [Chapter 45.6](#).

Although not included in the staging system, a precise measurement of the size of the anterior mediastinal mass is important. If the ratio of the width of the mediastinal mass over the maximum transthoracic diameter is greater than one-third, this is considered large mediastinal adenopathy and is an adverse prognostic variable.<sup>194</sup> The diagnosis of Hodgkin's disease must be established by lymph node or tissue biopsy. The lymphocyte-predominant subtype is closely associated with stage I and II Hodgkin's disease, and lymphocyte depletion is extremely rare in children.<sup>183</sup> Despite the unique biology and natural history of lymphocyte-predominant Hodgkin's disease, most pediatric oncologists recommend the same stage-appropriate treatment as given to other children with Hodgkin's disease.<sup>195</sup> The pathology and immunobiology of Hodgkin's disease is reviewed in detail in [Chapter 45.6](#).

Once the diagnosis is established, the pretherapy evaluation begins with "clinical" staging.<sup>196,197</sup> Clinical staging should include a history and physical examination with particular emphasis on defining lymphadenopathy by palpating the major lymph node chains. The size of the nodes should be measured and recorded for staging and follow-up. Laboratory studies include complete blood cell count with platelets, erythrocyte sedimentation rate, and kidney and liver function studies. Patients with B symptoms or stage III or IV disease should have bone marrow biopsies from two separate sites.

Imaging studies should include a chest radiograph with a posteroanterior and lateral view, and thoracic and abdominal CT scans. Lower extremity lymphangiography is no longer routinely performed in most centers because it does not visualize the upper abdominal nodes and spleen and sometimes require general anesthesia in children. High-dose gallium scanning in children with Hodgkin's disease, similar to the situation in adults, is most helpful for following response to therapy if the tumor

MOPP and three cycles of ABVD plus extended-field low-dose radiotherapy. Patients with a poor response to chemotherapy received full doses of irradiation. The disease-free survival rate is 88%, and the actuarial survival for the entire group is 95% (see [Table 45.2-8](#)).

The German-Austrian multicenter studies also have developed successful combined modality treatment programs for children with all stages of Hodgkin's disease.<sup>205,207</sup> The frequency of exploratory laparotomy and splenectomy has been greatly reduced. In DAL-HD-90 (German-Austrian Hodgkin's trials), chemotherapy was limited to two cycles for stages I and IIA. Boys received vincristine, etoposide, prednisone, and Adriamycin (OEPA), and girls were given two cycles of vincristine, procarbazine, prednisone, and Adriamycin (OPPA). Radiation was applied to involved sites (25 Gy). The 5-year event-free survival rate is 95%. Patients with more advanced-stage disease received two cycles of OPPA or OEPA and an additional two cycles (stages IIB and IIIA) or four cycles (stages IIIB and IV) of cyclophosphamide, Oncovin, procarbazine, and prednisone (COPP) plus involved-field irradiation. Five-year event-free survival rates were 90% to 95% for intermediate stages and 84% to 89% for stages IIIB and IV. Testicular function was normal in the regimens without procarbazine.<sup>207</sup>

In the past, there had been only limited experience using chemotherapy as the only treatment modality in children with Hodgkin's disease. The early experience was reported by the investigators from the Royal Children's Hospital in Melbourne, Australia.<sup>208</sup> After clinical staging, they treated children with stage I to IV Hodgkin's disease with either MOPP or chlorambucil, vinblastine, procarbazine, and prednisone (ChIVPP) therapy. The event-free survival rate was 92% at a median follow-up of 45 months. Twenty-eight of 32 patients with stage I or II disease and 14 of 15 patients with stage III or IV were disease-free. Although the outcome was excellent, these children were exposed to multiple cycles of alkylating agents with the high risk of secondary leukemia and infertility in males.

The POG investigators have completed two large randomized trials in early-stage and advanced-stage Hodgkin's disease. The first POG study compared six cycles of MOPP alternating with ABVD to four cycles of the same chemotherapy followed by involved-field irradiation (25 Gy) in surgically staged children with stage I to IIIA Hodgkin's disease.<sup>209</sup> The event-free survival rate was 90% at 6 years, with no difference noted in the two arms of the study (see [Table 45.2-8](#)). These children were exposed to less alkylating agent than in the Australian study because of the alternating use of MOPP and ABVD.

In the second randomized study, POG showed that no benefit existed for low-dose total nodal or subtotal nodal radiation after eight cycles of MOPP alternating with ABVD in children with advanced-stage Hodgkin's disease.<sup>210</sup> Results of CCG study 5942 indicate inferior results in patients with advanced-stage disease or B symptoms who were randomized to receive chemotherapy only (J. Nachman, personal communication). Further investigations are needed before radiation therapy is omitted in the treatment of children with Hodgkin's disease, especially for unfavorable subgroups.

The combined modality approach using limited doses of both radiation (15 to 30 Gy) and alkylating agents for children with all stages of Hodgkin's disease produces an excellent outcome with significant reduction in the risk of serious late effects. As the doses of irradiation are safely lowered in combined modality treatments, future studies will undoubtedly test whether chemotherapy alone can achieve these excellent results. In addition, less toxic and equally effective chemotherapy regimens are being tested.

## COMPLICATIONS

The risk of infertility, secondary cancers, and late cardiopulmonary complications of newer generation combined modality therapies in young children with Hodgkin's disease remains to be determined.<sup>207</sup> Several reports provide evidence that the risk of a second neoplasm is increased approximately 18 times in long-term survivors of childhood Hodgkin's disease.<sup>190,204</sup> Breast cancer and thyroid cancer were the most common solid tumors. The actuarial risk of a solid tumor at 20 years after the diagnosis of Hodgkin's disease was significantly higher among women (12.6%) than men (3.9%). The actuarial risk of breast cancer among women approached 35% at 40 years of age. An age of more than 10 years at the diagnosis of Hodgkin's disease and a higher dose of mantle radiation were independently associated with increased risk. The relative risk for a dose between 20 Gy and 40 Gy was 5.9 and 23.7 for a dose exceeding 40 Gy.

The cumulative risk of leukemia was highest in patients receiving chemotherapy alone (7.9%) and rose with an increase in the alkylating agent score. Based on these data, efforts to lower the doses and volumes of radiation and limit exposure to alkylating agents and anthracyclines are steps in the right direction.

## INTRODUCTION

Neoplasms of lymphoid cells can present clinically as leukemia, lymphoma, and myeloma. Leukemia and myeloma are dealt with in separate chapters in this text (see individual [Chapter 46.1](#), [Chapter 46.2](#), [Chapter 46.3.1](#), [Chapter 46.3.2](#), [Chapter 46.4](#), and [Chapter 46.5](#)). Lymphomas (i.e., the solid tumors of lymphoid cells) are typically subdivided into Hodgkin's disease (see [Chapter 45.6](#)) and non-Hodgkin's lymphomas (NHL), the topic of this chapter.

Our knowledge of the biology of NHLs has increased dramatically over the last decade. This is reflected in an improved system of classification that categorizes patients in a more clinically relevant way. New insights into the immunology and genetics of lymphomas have offered new therapeutic opportunities. Some of these, such as monoclonal antibodies directed against specific proteins on the surface of malignant lymphoma cells, have already become widely applied.

It has been known for more than 30 years that some patients with NHL can be cured using chemotherapy. Those clinical factors that predict curability are now well known. The prognostic effect of clinical variables such as age, stage, performance status, serum lactic dehydrogenase level, and specific sites of involvement must be mediated through expression of certain genes. The next improvement in lymphoma classification, improved prognostic categories, and new opportunities for therapy will come as the patterns of gene expression that underlie clinical variables become increasingly apparent.

## EPIDEMIOLOGY

In 2000 it is estimated that there will be 54,900 new cases of NHL diagnosed in the United States, and that 26,100 people will die with this diagnosis. <sup>1</sup> NHL accounts for 5% of new cancers in men and 4% of new cancers in women each year in the United States and is responsible for 5% of deaths. In 1997, NHL was reported to be the leading cause of death from cancer in men between the ages of 20 and 39.

According to the Surveillance, Epidemiology, and End Results program of the National Cancer Institute, the U.S. age-adjusted incidence rate for NHL was 15.5 per 100,000 in 1996. <sup>2</sup> International NHL incidence rates vary as much as fivefold. The highest reported incidence rates are in the United States, and also Europe and Australia, while the lowest rates have generally been reported in Asia. <sup>3,4</sup> and <sup>5</sup>

NHL is more common in male subjects, with a reported incidence of 19.2 per 100,000 as compared with 12.2 per 100,000 for women. <sup>2</sup> In some sites, such as the thyroid, NHL incidence may be higher in women, however. <sup>6</sup> The incidence rate for whites is 15.9 per 100,000 as compared with 12.0 per 100,000 for African Americans. The NHL incidence rate for white male subjects is approximately 54% higher than Japanese Americans and 27% higher than Chinese Americans. <sup>3</sup> Incidence rates are also lower among Native Americans and Hispanics. <sup>2</sup>

The median age of NHL diagnosis was 65 years in the American College of Surgeons' National Cancer Data Base. <sup>7</sup> NHL incidence increases with age and peaks in the 80 to 84 age group ([Fig. 45.3-1](#)). In the period between 1992 and 1996, the incidence rate for white men in this age group was 131.5 per 100,000. <sup>2</sup> Incidence rates have tripled for patients older than 65 years of age. <sup>8</sup>

**FIGURE 45.3-1.** The Surveillance, Epidemiology, and End Results incidence for non-Hodgkin's lymphoma by age from 1973 to 1975 versus 1994 to 1996 for all races and male sex. (From ref. 2, with permission.)

There has been a striking increase in NHL incidence rates over the last four decades that has been referred to as an epidemic of NHL. The lifetime risk of being diagnosed with NHL is 2.08%.<sup>2</sup> The incidence rate for white men and women increased 150% between the late 1940s to the late 1980s.<sup>3</sup> The incidence rate is increasing approximately 3% per year and has increased more than 80% since 1973 (Fig. 45.3-2). An increase in incidence has been observed in all geographic areas of the United States, although the largest increase has been from the San Francisco area.<sup>2,9</sup> A registry analysis from seven European countries showed that the incidence rate for NHL increased 4.8% each year between 1985 and 1992.<sup>10</sup> Similar increases in NHL incidence have been noted in international cancer registries in addition to well-defined population-based registries.<sup>5,8,11</sup>

**FIGURE 45.3-2.** Surveillance, Epidemiology, and End Results incidence and U.S. mortality for non-Hodgkin's lymphoma for male sex and by race. **A:** White. **B:** Black. (From ref. 2, with permission.)

There has been an increase in all histologic types of NHL except for diffuse small cleaved histology.<sup>2,6</sup> The decreasing incidence of this histology probably reflects the reclassification of most of these biopsies to a diagnosis of mantle cell histology. The largest increases have occurred in patients with high-grade lymphomas.<sup>2,3</sup> The incidence of extranodal lymphomas has increased more rapidly than nodal disease in some reports,<sup>3,6,8</sup> whereas others have noted similar increases in the incidence of nodal and extranodal disease.<sup>4</sup> The incidence of primary CNS lymphoma in the United States increased more than tenfold between 1973 and 1991 to 1992.<sup>12</sup> This increase is undoubtedly related to the occurrence of primary CNS lymphomas in patients with acquired immunodeficiency syndrome (AIDS),<sup>13</sup> although the increase in incidence began before the AIDS epidemic, and incidence rates have increased in non-AIDS populations.<sup>8,12</sup> Furthermore, some studies have failed to show evidence of an increasing incidence of primary CNS lymphoma in non-AIDS populations.<sup>14,15</sup>

Geographic differences in histologic subtypes of NHL have been noted. Examples include the endemic form of Burkitt's lymphoma, which is seen most commonly in children in equatorial Africa.<sup>16</sup> Higher rates of gastric lymphoma have been reported to occur in Northern Italy.<sup>17</sup> Other examples include nasal T-cell lymphomas, which are most common in China, certain small intestinal lymphomas, which are most common in the Middle East, and adult T-cell leukemia/lymphoma (ATL), which is most common in southern Japan and the Caribbean. Several reports have shown a lower incidence of follicular lymphomas in Asia and in developing countries.<sup>18,19</sup> and <sup>20</sup> The incidence of follicular lymphomas is lower in Asian immigrants to the United States as compared with later generations, suggesting an environmental influence.<sup>21</sup> Geographic differences in the distribution of mantle cell lymphoma, certain T-cell lymphomas, and in the incidence of primary extranodal lymphomas have also been described.<sup>4,20</sup>

The mortality for NHL has also increased steadily over the last four decades, although mortality increased more slowly than incidence (see Fig. 45.3-2). Increasing mortality suggests that increased incidence rates cannot be entirely due to artifacts of improved detection.<sup>8,22</sup> Between 1973 and 1996 the U.S. mortality increased from 4.7 per 100,000 to 6.9 per 100,000.<sup>2</sup> Mortality for NHL is approximately 20% higher in urban areas when compared with rural areas, and rates are higher in counties with higher median education levels among residents.<sup>3</sup>

Several hypotheses have been used to explain the increasing incidence of NHL. Some of the increase may be artifactual. For example, new NHL classification systems and techniques such as gene rearrangement studies have led to a diagnosis of NHL in some patients who would have previously had other diagnoses such as pseudolymphoma or atypical lymphoid hyperplasia.<sup>3</sup> This is especially true for entities such as lymphomas of mucosa-associated lymphoid tissue (MALT) as well as certain T-cell lymphomas that might have previously been given diagnoses such as angioimmunoblastic lymphadenopathy. However, these changes in diagnosis can only account for a small fraction of the increase in incidence.<sup>8,23</sup> In addition, improved imaging techniques have undoubtedly led to more NHL diagnoses, particularly for primary CNS lymphoma, and less invasive biopsy techniques have led to more vigorous attempts at establishing a diagnosis than before.<sup>3</sup> Finally, some increase in NHL incidence can be attributed to reclassification of cases that would have previously been called Hodgkin's disease.<sup>3,5,8,23</sup> It has been estimated that this may account for 10% to 15% of cases,<sup>23</sup> although in some series more than 25% of Hodgkin's disease patients were reclassified as NHL.<sup>5</sup> However, such large discrepancies apply mostly to cases diagnosed before the 1970s and are unlikely to be responsible for much of the later increase in incidence.<sup>23,24</sup> While these artifacts have undoubtedly led to some increase in the reported incidence of NHL, they can only account for a small fraction of the increase.<sup>25</sup>

The aging U.S. population can account for only a small increase in NHL incidence, although other factors, such as the AIDS epidemic, may be responsible to a greater extent. In 1996 the incidence rate for NHL in men was 44.4 per 100,000 in the San Francisco city and county region as compared with 18.1 per 100,000 for areas exclusive of the San Francisco metropolitan area.<sup>2</sup> The incidence rate was 62.4 per 100,000 men aged 20 to 54 in the San Francisco city and county area. While AIDS can account for some of the increased NHL incidence, the rise in NHL incidence began before the AIDS epidemic, and it has been estimated that only 8% to 27% of NHL cases can be attributable to AIDS,<sup>26</sup> although studies have demonstrated that in some areas such as San Francisco, as many as 66% of the increased NHL incidence can be attributed to AIDS.<sup>13</sup>

In summary, even when factors such as accuracy and completeness of diagnosis, the effect of human immunodeficiency virus, and occupational exposures are considered, the reason for most of the increase in NHL incidence is unexplained.<sup>24</sup> Many investigators have postulated that a ubiquitous environmental or toxic exposure is responsible.<sup>22,25</sup>

## ETIOLOGY

The cause of most cases of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents have been associated with the development of lymphoma. Although the existence of a familial NHL risk is debated, familial aggregations of NHL have been described, and some studies have shown a higher risk of NHL in siblings or first-degree relatives of people with lymphoma or other hematologic malignancies.<sup>27,28</sup> and <sup>29</sup> Three categories of familial aggregates have been described.<sup>29</sup> The first consists of male preadolescents and adolescent siblings who often have extranodal lymphoma. The second category consists of adult siblings with NHL, and the third is represented by adults with NHL from two or more generations. Familial clustering may reflect a true genetic susceptibility or a shared environmental exposure.<sup>29,30</sup> In some cases, affected individuals in familial clusters have had well-defined or subtle immune deficiencies.<sup>28,29</sup> In one study, no evidence of germline p53 mutations was noted in unaffected members of lymphoma-prone kindreds.<sup>31</sup>

## IMMUNODEFICIENCY

Several rare inherited disorders are associated with as much as a 25% risk of developing lymphoma.<sup>32,33</sup> These disorders include severe combined immunodeficiency, hypogammaglobulinemia, common variable immunodeficiency, Wiskott-Aldrich syndrome, and ataxia-telangiectasia. Lymphomas associated with these disorders are often associated with Epstein-Barr virus (EBV) and vary in appearance from polyclonal B-cell hyperplasia at one end of the spectrum to monoclonal lymphomas at the other end.<sup>32,34</sup>

Ataxia-telangiectasia is an autosomal recessive multisystem disorder associated with a risk of lymphoma that is increased more than 250-fold in affected individuals.<sup>35</sup> Both B-cell and T-cell NHL has been described.<sup>36</sup> A mutated ataxia-telangiectasia gene (ATM) has been cloned and localized to chromosome 11. Mutations are thought to inactivate or eliminate a protein involved with control of cell-cycle checkpoints responding to DNA damage.<sup>37</sup> Mutations and deletions of ATM have also been identified in chronic lymphocytic leukemia and mantle cell lymphoma.<sup>38,39</sup>

The Wiskott-Aldrich syndrome is an X-linked recessive disorder. The relative risk of developing malignancy is more than 100 times that expected in the general population.<sup>33,40</sup> NHL accounts for most of the increased cancer risk, and the incidence of NHL increases with age. Patients frequently have extranodal and CNS lymphomas. A 30-fold excess of lymphoma has been noted in individuals with common variable immunodeficiency,<sup>41</sup> and a similar increase in risk has been noted in patients with severe combined immunodeficiency syndrome.<sup>33</sup>

The X-linked lymphoproliferative syndrome is characterized by a defective immune response to EBV.<sup>42</sup> After primary EBV infection, male subjects can develop fatal infectious mononucleosis, aplastic anemia, dysgammaglobulinemia, or NHL.<sup>43,44</sup> Lymphomas are frequently of small noncleaved histology and often occur in the ileocecal region.<sup>33</sup> The SH2D1A gene has been identified as the gene responsible for X-linked lymphoproliferative syndrome, and mutations and deletions have been identified in affected individuals.<sup>44,45</sup>

In addition to these inherited immunodeficiency states, a number of acquired conditions are associated with an increased risk of NHL. The occurrence of NHL in patients with AIDS and following solid organ transplantation are discussed later (see [Human Immunodeficiency Virus–Associated Non-Hodgkin's Lymphoma](#) and [Posttransplant Lymphoproliferative Disorders](#), later in this chapter). Patients with a variety of autoimmune disorders also have an increased risk of developing NHL.

Several registry-based studies and case-control studies have shown that the risk of developing NHL is increased approximately twofold in patients with rheumatoid arthritis.<sup>46,47</sup> and <sup>48</sup> Other series have failed to find an increased risk, however.<sup>49</sup> EBV-related lymphoproliferative disorders have also been seen in patients receiving methotrexate and other immunosuppressive drugs for rheumatoid arthritis and similar disorders.<sup>50</sup> These lymphomas may undergo regression on withdrawal of immunosuppression.

The risk of developing NHL in association with Sjögren's syndrome is increased approximately 30- to 40-fold.<sup>46,51,52</sup> These lymphomas are usually marginal zone lymphomas that most commonly occur in salivary glands and other extranodal sites such as the stomach and lung.<sup>51,53</sup> Another condition associated with NHL is Hashimoto's thyroiditis. Most cases of thyroid lymphoma occur in association with thyroiditis.<sup>54</sup> NHL may also be more common in patients with systemic lupus erythematosus.<sup>55</sup> Celiac sprue is associated with poor-prognosis lymphomas that are now classified as enteropathy-type intestinal T-cell lymphomas.<sup>56,57</sup>

## INFECTIOUS AGENTS

EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt's lymphoma. EBV DNA is associated with 95% of endemic Burkitt's lymphomas, and less commonly with sporadic Burkitt's lymphoma.<sup>58,59</sup> Both type A and type B EBV strains are observed.<sup>60</sup> Since EBV is not seen in all cases of Burkitt's lymphoma, the actual relationship and the mechanism by which EBV might contribute to the development of Burkitt's lymphoma is unknown.<sup>58,61</sup> Burkitt's lymphoma is associated with c-myc deregulation, although different chromosome 8 breakpoints are observed in the endemic and sporadic forms, and the presence or absence of EBV DNA is related to the breakpoint location.<sup>62</sup> It is hypothesized that early EBV infection and environmental factors may increase the numbers of EBV-infected precursors and the risk of genetic error.<sup>58</sup>

EBV is also linked to posttransplant lymphoproliferative disorders (PTLDs), some AIDS-associated lymphomas, and some lymphomas associated with congenital immunodeficiency. Virtually all AIDS-associated primary CNS lymphomas have EBV in the tumor clone, although EBV is associated with other AIDS-associated lymphomas less frequently.<sup>63</sup> Following EBV infection, normal host immune responses mediated by T lymphocytes suppress EBV-induced proliferation.<sup>64</sup> In patients with depressed T-cell immunity, clones of EBV-transformed B cells can proliferate, leading to the development of lymphoma. The pattern of EBV-associated nuclear proteins in AIDS-associated Burkitt's lymphomas differs from large cell lymphomas.<sup>63</sup> C-myc activation in the absence of EBV infection can occur in AIDS-associated lymphomas.<sup>65</sup> The EBV latent membrane protein 1 is a viral analogue of the tumor necrosis factor receptor. The activity of this protein is similar to activated CD40 and is essential for *in vitro* transformation of B cells by EBV.<sup>64,66</sup> In EBV-positive AIDS-associated NHL and PTLD, it appears that latent membrane protein 1 binds to members of the tumor necrosis factor receptor–associated factor family and activates the NF-κB transcription factor, leading to cellular proliferation.<sup>66</sup> EBV is also seen in association with humanherpesvirus-8 (HHV-8) in primary effusion lymphomas.

The human T-cell lymphotropic virus type I (HTLV-I) was the first human retrovirus associated with a malignancy. HTLV-I is a type C RNA virus that is responsible for ATL in addition to HTLV-I–associated myelopathy/tropical spastic paraparesis and other disorders.<sup>67</sup> HTLV-I is primarily transmitted by means of breast feeding, sexual contact, and blood transfusion. The latent period between infection and development of ATL is several decades.<sup>59,68</sup> HTLV-I seropositivity and ATL are most prevalent in southern Japan, South America, Africa, and the Caribbean,<sup>69</sup> although ATL is sometimes seen in the United States.<sup>70</sup> In endemic areas more than 50% of all NHL cases are ATL, although the risk of developing disease is only approximately 5% in infected patients.<sup>69</sup> The HTLV-I genome contains the regulatory *tax* gene, whose product is a potent transcriptional activator of several genes and is thought to be responsible for the transforming features of HTLV-I.<sup>67,68,71</sup> The risk of ATL may be higher in patients with higher anti-HTLV-I titers and lower reactivity to *tax*.<sup>72</sup>

A third virus associated with NHL is HHV-8. This virus was originally discovered in Kaposi's sarcoma lesions from AIDS patients and was called *Kaposi's sarcoma–associated herpesvirus*.<sup>73</sup> The virus is also associated with multicentric Castleman's disease.<sup>74</sup> An analysis of 193 lymphoma specimens from patients with and without AIDS identified the presence of virus in only eight specimens, all of which were from patients with primary effusion lymphomas.<sup>75</sup> The virus was subsequently shown to be a member of the gamma herpesvirus subfamily and was named *HHV-8*.<sup>76</sup> Subsequent studies have shown that primary effusion lymphomas are EBV-associated, lack c-myc gene rearrangements, and have distinct clinical and phenotypic features.<sup>77</sup> The mechanism of HHV-8 growth stimulation is unknown, although several potential mechanisms have been proposed.<sup>64</sup> It has been suggested that HHV-8 may be necessary for EBV-induced transformation in these patients.<sup>64,77</sup>

Evidence also links hepatitis C virus (HCV) infection with NHL. Infection with HCV is strongly associated with essential mixed cryoglobulinemia, which is itself associated with low-grade NHL. Several analyses have demonstrated significantly higher rates of HCV infection when B-cell NHL patients were compared with controls.<sup>78,79</sup> The association appears strongest for patients with monocytoid B-cell lymphoma and lymphoplasmacytoid lymphomas. HCV has been identified in NHL cells from a patient with type II mixed cryoglobulinemia.<sup>80,81</sup> Although HCV is not thought to be oncogenic, chronic antigenic stimulation from circulating HCV RNA may produce clonal expansion leading to development of NHL.<sup>82</sup> Some studies have failed to find an association between HCV infection and NHL.<sup>83</sup>

Several lines of evidence link the bacteria *Helicobacter pylori* to gastric MALT lymphomas.<sup>84</sup> *H pylori* can be found in the gastric mucosa of patients with gastric MALT lymphoma,<sup>85</sup> and patients with gastric lymphoma are more likely than controls to have serologic evidence of past *H pylori* infection.<sup>86</sup> It is hypothesized that development of gastric MALT lymphomas is a multistep process beginning with *H pylori* colonization. This leads to chronic antigenic stimulation and gastritis and the subsequent development of malignant B-cell clones.<sup>87,88</sup> Stimulation by *H pylori*–associated antigens appears to be strain specific and T-cell mediated.<sup>89</sup>

## ENVIRONMENTAL AND OCCUPATIONAL EXPOSURES

Studies of occupational and environmental NHL risk are frequently inconsistent and contradictory. Difficulties in estimating risk are often related to sample size and other methodologic difficulties in addition to difficulties in quantifying exposure. The risk of NHL has been reported to be increased in several occupations.<sup>90,91,92</sup> and <sup>93</sup> Occupations frequently associated with a higher risk include farmers, forestry workers, and agricultural workers. Metaanalysis has shown a slightly increased risk of

NHL in farmers.<sup>94,95</sup> Increased risk of NHL in farmers may be related to an infectious agent or chemical exposure.

Several studies have shown an increased risk of NHL in relation to herbicide exposure, especially phenoxy herbicides such as 2,4-dichlorophenoxyacetic acid.<sup>93,96,97</sup> Other analyses have found less evidence for an association between 2,4-dichlorophenoxyacetic acid exposure and NHL.<sup>98,99</sup> and <sup>100</sup> The development of NHL has also been linked to hair dyes, especially darker and permanent colors,<sup>101,102</sup> and <sup>103</sup> although some studies have failed to find an association.<sup>104,105</sup> NHL has also been associated with organic solvents.<sup>90,91,106,107</sup> High levels of nitrates in drinking water have been associated with NHL in some studies,<sup>108</sup> but not others.<sup>109</sup>

## DIET AND OTHER EXPOSURES

Cohort and case-control studies suggest that the risk of NHL is increased approximately twofold in association with higher intake of meats and dietary fat.<sup>110,111</sup> and <sup>112</sup> Recreational drug use has been associated with increased NHL risk,<sup>113</sup> and tobacco use has been associated with a higher risk in some studies, but not others.<sup>114,115</sup> and <sup>116</sup> The risk of NHL may be increased more than 20-fold after treatment for Hodgkin's disease.<sup>117,118</sup> and <sup>119</sup> Studies examining the relative risk of combined modality treatment have been inconsistent, although the risk of NHL in association with ionizing radiation is minimal.<sup>120</sup> Solar ultraviolet exposure has been associated with NHL in some studies.<sup>121,122</sup> Although some analyses have shown that the risk of NHL is increased after blood transfusion, other studies have failed to identify a significantly increased risk.<sup>123</sup>

## BIOLOGIC BACKGROUND FOR CLASSIFICATION OF LYMPHOID NEOPLASMS

Although the normal counterpart of the neoplastic cell is not known for all types of lymphoid neoplasms, it can be postulated for many of them. Understanding the normal counterpart of neoplastic cells can provide a useful framework for understanding the morphology, immunophenotype, and to some extent, the clinical behavior of the neoplasms (Fig. 45.3-3A, Fig. 45.3-3B and Fig. 45.3-3C).

**FIGURE 45.3-3. A:** Hypothetical scheme of lymphocyte differentiation, showing anatomic locations of different stages of T- and B-cell differentiation. T cells are shown at top; B cells are at bottom. **B:** Differentiation scheme, showing nomenclature for various types of T cells (top) and B cells (bottom). **C:** Differentiation scheme, showing postulated normal counterpart of many of the T- and B-cell neoplasms that can currently be recognized. B-ALL, B-cell acute lymphoblastic leukemia; B-CLL, B-cell chronic lymphocytic leukemia; Ig, immunoglobulin; LBL, lymphoblastic lymphoma; MALT, mucosa-associated lymphoid tissue; SLL, small lymphocytic lymphoma; T-LGL, T-cell large granular lymphocyte; T-PLL, T-cell prolymphocytic leukemia.

## Anatomy and Morphology of Normal Lymphoid Tissues

Lymphoid tissues can be divided into two major categories: (1) the *central* or *primary* lymphoid tissues, which harbor lymphoid precursor cells and provide for their maturation to a stage at which they are capable of performing their function in response to antigen; and (2) the *peripheral* or *secondary* lymphoid tissue, in which antigen-specific reactions occur.

### Primary (Central) Lymphoid Tissues

**BONE MARROW (BURSA EQUIVALENT).** Many of the early experiments that elucidated the basic biology of the lymphoid system used chickens and other avian species as experimental animals; in avians, an organ known as the bursa of Fabricius, located in the region of the cloaca, was proven to be the source of cells capable of producing antibody. Thus, these cells were termed *B cells*, for bursa-derived cells. In mammals, the bursa does not exist, and experiments have shown that the precursors of antibody-producing cells come from the bone marrow. The bone marrow is also the source of other hematopoietic cells, including T cells (so named because their crucial maturation steps cannot occur in the absence of the thymus).

**THYMUS.** The thymus, located in the anterior mediastinum, is the site at which immature T-cell precursors (prethymocytes) that migrate from the bone marrow undergo maturation and selection to become mature, naive T cells, which are capable of responding to antigen. The thymus is divided into a cortex and a medulla, each of which is characterized by specialized epithelium and accessory cells, which provide the milieu for T-cell maturation.

### Secondary (Peripheral) Lymphoid Tissues

**LYMPH NODES.** Lymph nodes are located at sites throughout the body, strategically placed to process antigens present in lymph drained from most organs via the afferent lymphatics. Lymph nodes have a capsule, a cortex, a medulla, and sinuses (subcapsular, cortical, and medullary). The sinuses contain macrophages, which take up and process antigen, which may then be presented to lymphocytes. The cortex is divided into follicular and diffuse (paracortical) regions, and the medulla into medullary cords and sinuses. The paracortex contains high endothelial venules, through which both T and B lymphocytes enter the node, and specialized antigen-presenting cells (APC), the interdigitating dendritic cells, which may be related to the cutaneous Langerhans' cell, and which present antigen to T cells. Both T-cell and early B-cell reactions to antigen occur in the paracortex, while the germinal center reaction occurs in the follicular cortex. The follicular cortex also contains a specific type of accessory cell, the follicular dendritic cell (FDC); adhesion to the FDC-antigen complex is important in the differentiation of B cells in response to antigen. Plasma cells and effector T cells generated by immune reactions accumulate in the medullary cords and exit via the medullary sinuses.

**SPLEEN.** The spleen, located in the left upper abdomen, has two major compartments: the red pulp, which functions as a filter for particulate antigens and for the formed elements of the blood, and the white pulp, which is virtually identical in its compartments to the lymphoid tissue of the lymph node. Follicles and germinal centers are found in the Malpighian corpuscles, whereas T cells and interdigitating dendritic cells are found in the adjacent periarteriolar lymphoid sheath. Plasma cells accumulate in the red pulp.

**MUCOSA-ASSOCIATED LYMPHOID TISSUE.** Specialized lymphoid tissue is found in association with certain epithelia, in particular the nasopharynx and oropharynx (Waldeyer's ring: adenoids, tonsils), the gastrointestinal tract (gut-associated lymphoid tissue: Peyer's patches of the distal ileum, mucosal lymphoid aggregates in the colon and rectum), and lung (bronchus-associated lymphoid tissue). Collectively, this is known as mucosa-associated lymphoid tissue (MALT). These tissues tend to have prominent B-cell follicles, but also may have discrete T-cell zones, similar to the paracortex of lymph nodes. MALT is thought to function in response to intraluminal antigens and the generation of mucosal immunity. Lymphoid cells that respond to antigen in the MALT acquire homing properties that enable them to return to these tissues.<sup>3</sup>

### B- and T-Cell Differentiation

In both the T- and B-cell systems, there are two major phases of differentiation: antigen-independent and antigen-dependent (see Fig. 45.3-3A and Fig. 45.3-3B). Antigen-independent differentiation occurs in the primary lymphoid organs [bursa equivalent (bone marrow possibly) and thymus] without exposure to antigen and produces a pool of lymphocytes that are capable of responding to antigen (naive or virgin T and B cells). The early stages are stem cells and lymphoid blasts, which

are self-renewing, while the later stages are resting cells with a finite life span ranging from weeks to years. On exposure to antigen, the naive lymphocyte undergoes *blast transformation* and becomes a large, proliferating cell, which gives rise to progeny that are capable of direct activity against the inciting antigen (antigen-specific effector cells). The earlier stages of antigen-dependent differentiation are proliferating cells, while the fully differentiated effector cells are less mitotically active. Thus, neoplasms that correspond to proliferating stages of either antigen-independent or antigen-dependent differentiation are likely to be aggressive, whereas those that correspond to naive or mature effector stages are likely to be indolent.

## **B-Cell Differentiation**

### **ANTIGEN-INDEPENDENT B-CELL DIFFERENTIATION.**

*Precursor B Cells.* The earliest B cells have rearranged immunoglobulin (Ig) heavy-chain genes, but lack surface immunoglobulin (SIg); the B cells at this stage are called *precursor B cells* or *pre-pre-B cells*. At the next stage, pre-B cells make cytoplasmic  $\mu$  heavy-chain, but no light-chain, and do not express SIg. Both types of cells are lymphoblasts, with dispersed chromatin and small nucleoli. They contain the intranuclear enzyme, terminal deoxynucleotidyl transferase (TdT), and express CD34, a glycoprotein present on immature cells of both lymphoid and myeloid lineage, HLA-DR [class II major histocompatibility complex (MHC) antigens], and the common acute lymphoblastic leukemia (ALL) antigen (CD10). Expression of class II MHC antigens persists throughout the life of the B cell and is important in interactions with T cells. Pan-B-cell antigens are sequentially expressed on precursor B cells: CD19 and cytoplasmic CD22, followed by surface CD20. The leukocyte common antigen (CD45) does not appear until surface CD20; thus, staining for CD45 may not be useful in identifying early B-cell neoplasms. Precursor B cells also express CD79a, a molecule that is associated with SIg and is involved in transduction of signal after engagement of the SIg with antigen, analogous to CD3 and the T-cell receptor (TCR) molecule.

Fetal early B-cell development occurs in the liver, bone marrow, and spleen, whereas in adults it is restricted to the bone marrow. Cells with the morphologic and immunologic features of precursor B cells can be found in normal and regenerating bone marrow, where they correspond to the lymphocyte-like cells known as *hematogones*. Neoplasms of precursor B cells usually involve bone marrow and peripheral blood and are known as common or precursor B ALL; rarely, they present as solid tumors (precursor B lymphoblastic lymphoma).

*Naive B Cells.* The end stage of antigen-independent B-cell differentiation is the mature, naive (virgin) B cell, which expresses both complete surface IgM and IgD, lacks TdT and common ALL antigen, and is capable of responding to antigen. Naive B cells have rearranged but unmutated Ig genes. Each individual B cell is committed to a single light-chain, either k or l, and all of its progeny express the same light-chain. In contrast to precursor B cells, naive B cells lack CD10 and CD34. In addition to SIg, naive B cells express pan-B-cell antigens (CD19, CD20, CD22, CD40, and CD79a), HLA class II molecules, complement receptors (CD21 and CD35), CD44, Leu-8 (L-selectin), CD23, and the pan-T-cell antigen, CD5. Many of the surface antigens expressed by mature B cells are involved in *homing* or adhesion to vascular endothelium, interaction with APCs, and signal transduction. SIg, CD79a, CD19, and CD20, appear to be involved in signal transduction, CD22 is involved in signaling, and CD40 is involved in interaction with T cells and in further differentiation of B cells. Resting B cells also produce the bcl-2 protein, which promotes survival in the resting state. CD5-positive B cells produce Ig that often has broad specificity (cross-reactive idiotypes) and reactivity with self-antigens (autoantibodies).

Naive B cells are small resting lymphocytes. In fetal tissues, they are the predominant lymphoid cell in the spleen; in adults, they circulate in the blood and also make up a minor fraction of the B cells in primary lymphoid follicles and follicle mantle zones (so-called recirculating B cells). Studies of single cells picked from the mantle zones of reactive follicles show that they are clonally diverse and contain unmutated Ig genes, consistent with naive B cells. Tumors of these cells are usually clinically indolent and histologically low grade. In addition, they are often widespread and leukemic, consistent with the recirculating behavior of the normal naive B cell. Two neoplasms appear to correspond to CD5-positive B cells: B-cell chronic lymphocytic leukemia (B-CLL) and mantle cell (centrocytic/intermediate) lymphoma.

### **ANTIGEN-DEPENDENT B-CELL DIFFERENTIATION.**

*Immunoblastic and Plasma Cell Reaction.* On encountering antigen, the naive B cell transforms into a proliferating cell, which ultimately matures into an antibody-secreting plasma cell. In T-cell-independent reactions, and in the early primary immune response, naive B cells transform into IgM-positive blast cells (B blasts or immunoblasts) in the T-cell zones, proliferate, and differentiate into IgM-secreting plasma cells, producing the IgM antibody of the primary immune response. These plasma cells have largely unmutated Ig genes. Surface IgD is lost during blast transformation, as are some other antigens, such as CD21 and CD22. Other antigens associated with activation are up-regulated. With maturation to plasma cells, most surface antigens are lost, including pan-B-cell antigens HLA-DR and the leukocyte common antigen CD45, and secretory cytoplasmic IgM accumulates. The corresponding neoplasm to the IgM-producing plasma cell may be lymphoplasmacytic lymphoma (immunocytoma) or Waldenström's macroglobulinemia.

*Germinal Center Reaction.* Later in the primary response (within 3 to 7 days of antigen challenge in experimental animals) and in secondary responses, the T-cell-dependent germinal center reaction occurs. Each germinal center is formed from between three and ten naive B cells and ultimately contains approximately 10,000 to 15,000 B cells; thus, more than ten generations are required to form a germinal center. Proliferating IgM-positive B blasts formed from naive B cells that have encountered antigen in the T-cell zone (paracortex) migrate into the center of the primary follicle and fill the FDC mesh work by approximately 3 days after antigen stimulation, forming a germinal center. These B blasts differentiate into Ig-negative *centroblasts* (large noncleaved follicular center cells), which appear at approximately 4 days, and accumulate at one pole of the germinal center, forming the *dark zone*. Centroblasts are large proliferating cells with vesicular nuclei, one to three prominent, peripheral nucleoli, and a narrow rim of basophilic cytoplasm. They lack SIg and also switch off the gene that encodes the bcl-2 protein; thus, they and their progeny are susceptible to death through apoptosis. Germinal center cells express antigens associated with activation, most of which are involved with interaction with T cells, including CD23, CD71, CD40, and CD86, as well as antigens associated with adhesion to FDCs, including CD11a/18 and CD29/49d, and antigens that may promote apoptosis, such as CD95. An important event in germinal center development is expression of bcl-6 protein, a nuclear zinc finger transcription factor that is expressed by both centroblasts and centrocytes, but not by naive or memory B cells, mantle cells, or plasma cells. Interestingly, normal resting B cells express high levels of bcl-6 messenger RNA, while lacking the protein.

In centroblasts, a process of somatic mutation of the Ig gene variable (V) region begins, which alters the affinity for antigen of the antibody that will be produced by the cell. In addition, the cell may also switch from IgM to IgG or IgA production; through these mechanisms, the germinal center reaction gives rise to the better fitting IgG or IgA antibody of the late primary or secondary immune response. Studies on single centroblasts picked from the dark zone of germinal centers suggest that in the early stages, a germinal center may contain approximately five to ten clones of centroblasts, which show only a moderate amount of Ig gene V region mutation; later, the number of clones diminishes to as few as three, and the degree of somatic mutation increases.

Centroblasts mature to nonproliferating medium-sized cells with irregular nuclei, inconspicuous nucleoli, and scant cytoplasm, called *centrocytes* (small or large cleaved follicular center cells), which accumulate in the opposite pole of the germinal center, known as the *light zone*, which also contains a high concentration of FDCs. Centrocytes reexpress SIg, which has the same VDJ rearrangement as the parent naive B cell and the centroblast of the dark zone, but which may have undergone heavy-chain class switch and which has an altered antibody-combining site, because of the somatic mutations in the Ig V region. This process of somatic mutation thus results in marked intraclonal diversity of antibody-combining sites in a population of cells derived from only a few precursors. Also in the germinal center, the bcl-6 gene undergoes somatic mutation of the 5' noncoding promoter region, at a lower frequency than is seen in the Ig genes. Thus, both Ig gene mutation and bcl-6 mutation serve as markers of cells that have experienced the germinal center.

Centrocytes whose Ig gene mutations have resulted in *decreased* affinity for antigen rapidly die by apoptosis (programmed cell death); the prominent *starry sky* pattern of phagocytic macrophages seen in germinal centers at this stage is a result of the apoptosis of centrocytes. In contrast, centrocytes whose Ig gene mutations have resulted in *increased* affinity are able to bind to native, unprocessed antigen trapped in antigen-antibody complexes by the complement receptors on the processes of FDCs. The centrocytes are able to process the antigen and present it to T cells in the light zone of the germinal center. It is thought that this activation of T cells may induce them to express CD40 ligand (CD40L), which can engage CD40 on the B cell. Both ligation of the antigen receptor by antigen and ligation of CD40 on the surfaces of germinal center B cells can *rescue* them from apoptosis. Interaction with surface molecules expressed by FDCs, such as CD23, appears to be important in directing differentiation of the centrocytes into plasma cells, while interaction with the numerous T cells present in the light zone, through the CD40 molecule and its ligand on T cells, appears to be important in the generation of memory B cells. In addition, both antigen receptor ligation and CD40 ligation switch off bcl-6 messenger RNA production and bcl-6 protein expression.

Follicular lymphomas are tumors of germinal center B cells, in which centrocytes fail to undergo apoptosis because they have a chromosomal rearrangement, t(14;18), that prevents the normal switching off of the antiapoptosis gene, bcl-2. Most large B-cell lymphomas are composed of cells that at least in part resemble centroblasts and have mutated Ig V region genes and are therefore thought to derive from the germinal center stage of differentiation. Finally, it is possible that

Burkitt's lymphoma corresponds to the early SIgM-positive B blast found in the early germinal center reaction in experimental animals.

**Marginal Zone and Monocytoid (Parafollicular) B Cells.** When the germinal center polarizes into a dark and a light zone, the mantle zone becomes better defined and eccentric, with the broader portion surrounding the light zone of the germinal center. Antigen-specific B cells generated in the germinal center reaction leave the follicle and reappear in the outer mantle zone, to form a *marginal zone*; these are particularly prominent in mesenteric lymph nodes, Peyer's patches, and the spleen. Marginal zone B cells have slightly irregular nuclei, resembling those of centrocytes, but with more abundant, pale cytoplasm. The term *centrocyte-like* has been applied to similar neoplastic cells. On rechallenge with antigen, splenic marginal zone B cells migrate first into the germinal center and then quickly appear in the T-cell zone as Ig-positive blast cells, which give rise to antigen-specific plasma cells; thus, they are thought to be memory B cells. Memory B cells are also detectable in the peripheral blood, where they may be IgM-positive and even CD5-positive. Studies on single marginal zone B cells from spleen and Peyer's patches show that they have mutated V region genes, may be oligoclonal, and are not clonally related to the adjacent germinal center. Cells that resemble marginal zone B cells, but with even more nuclear indentation and abundant cytoplasm, known as monocytoid B lymphocytes, are seen in clusters adjacent to subcapsular and cortical sinuses of some reactive lymph nodes, peripheral to and often continuous with the follicle marginal zone. In contrast to marginal zone B cells, the monocytoid B cells found in reactive lymph nodes appear to have either unmutated Ig V region genes or to show only a small number of randomly distributed mutations that do not suggest selection by antigen. Nodal and splenic tumors resembling normal marginal zone and monocytoid B cells have been described. Analysis of Ig V region genes suggests that most of these have mutations consistent with germinal center exposure and antigen selection.

**Bone Marrow Plasma Cells.** IgG-producing plasma cells accumulate in the lymph node medulla, but it appears that the immediate precursor of the bone marrow plasma cell leaves the node and migrates to the bone marrow. Plasma cells lose SIg, pan-B-cell antigens, HLA-DR, CD40, and CD45, and cytoplasmic IgG or IgA accumulates. Plasma cells also express CD38. They have rearranged and mutated Ig genes, but do not have the ongoing mutations seen in follicle center cells. Tumors of these marrow-homing plasma cells correspond to plasmacytoma and multiple myeloma.

**Mucosa-Associated Lymphoid Tissue.** A subset of B cells, including all the differentiation stages listed previously, are programmed for gut-associated rather than nodal lymphoid tissue. In these tissues (Waldeyer's ring, Peyer's patches, and mesenteric nodes), similar responses occur to antigen, but both the intermediate and end-stage B cells that originate in the gut or mesenteric lymph nodes preferentially return there, rather than to peripheral lymph nodes or bone marrow. Thus, the plasma cells generated in gut-associated lymphoid tissue home preferentially to the lamina propria, rather than to the bone marrow.<sup>3</sup> Many extranodal low-grade B-cell lymphomas are thought to arise from this MALT. Since most MALT lymphomas contain prominent marginal zone type B cells, in addition to small B lymphocytes and plasma cells, and since similar lymphomas occur in non-MALT sites, the term *extranodal marginal zone lymphoma of MALT type* has been proposed for these tumors.<sup>124</sup> MALT-type lymphomas have somatically mutated V region genes, consistent with an antigen-selected post-germinal center B-cell stage.

## **T-Cell Differentiation**

### **ANTIGEN-INDEPENDENT T-CELL DIFFERENTIATION.**

**Cortical Thymocytes.** As in the B-cell system, the earliest stages of T-cell differentiation involve characteristic rearrangement of the DNA encoding the antigen receptor molecule. The earliest antigen-independent stages of T-cell differentiation occur in the bone marrow; later stages occur in the thymic cortex. The exact site at which precursor cells become committed to the T lineage is not known, since the thymus contains cells that can differentiate into either T cells or natural killer (NK) cells, but not B cells. Cortical thymocytes are lymphoblasts, which contain the intranuclear enzyme TdT. The earliest committed T-cell precursors are CD34+ and CD45RA+, express the CD13 and CD33 antigens usually associated with myeloid cells, and lack CD3, CD4, and CD8 (*triple negative* cells); within the thymus they sequentially acquire CD1, CD2, CD5, and cytoplasmic CD3, and first the CD4 helper and then the CD8 suppressor antigen (*double positive*). In the thymus, rearrangement of the TCR genes is initiated, beginning with the g and d chains, followed by the b and then the a chain genes; these proteins are then expressed on the cell surface. Surface CD3 expression appears at the same time as expression of the T-cell antigen receptor b chain, with which it is closely associated and participates in signal transduction. Cortical thymocytes express the CD45RO epitope of the leukocyte common antigen, instead of CD45RA, and lack the antiapoptosis protein bcl-2.

In addition to providing a pool of mature T cells through proliferation of precursor cells, the thymus plays a major role in the selection of T cells, so that the resulting pool of mature T cells do not react to self-antigens. Both positive and negative selection occur in the thymus at the double positive (CD4+, CD8+) stage. Thymocytes that have anti-self-specificity bind strongly via their TCR ab complex to self-antigens presented by the MHC on thymic dendritic cells and die by apoptosis. Those that lack anti-self-reactivity undergo positive selection on thymic epithelial cells; they then express increased levels of surface CD3, acquire CD27 and CD69, switch their CD45 isotype from RO back to RA, lose CD1, express bcl-2, and lose either CD4 or CD8 to become mature, naive T cells. The tumor that corresponds to the stages of T-cell differentiation in the thymic cortex is precursor T-lymphoblastic lymphoma and leukemia; the variety of immunophenotypes and antigen receptor gene rearrangements found in precursor T-cell neoplasia corresponds to the variety of stages of intrathymic T-cell differentiation.

**Naive T Cells.** Mature, naive (virgin) T cells have the morphologic appearance of small lymphocytes, have a low proliferation fraction, lack TdT and CD1, and express either (but not both) CD4 or CD8, as well as surface CD3 and CD5, CD45RA, and bcl-2. These cells leave the thymus and can be found in the circulation, in the paracortex of lymph nodes, and in the thymic medulla. Some cases of T-cell prolymphocytic leukemia and peripheral T-cell lymphoma may correspond to naive T cells.

**ANTIGEN-DEPENDENT T-CELL DIFFERENTIATION.** A complex interaction of T-cell surface molecules with molecules on the surface of APCs is required for T-cell activation in response to antigen. On the T cell, the CD4 or CD8 molecules bind to MHC class II or class I molecules, respectively, on the APC. A complex of CD3 and the T-cell antigen receptor (which may be of either gd or ab type and has a combining site that fits the specific peptide antigen) binds to the antigen-MHC complex on the APC. The adhesion molecule lymphocyte function-associated-1 on the T cell binds to intercellular adhesion molecule-1 on the APC; the activation-associated molecule CD40L on the T cell binds to CD40; and CD28 and CTLA4 on the T cell bind to B7-1 and B7-2 (CD86) on the APC. The binding of CD40-CD40L provides an activation stimulus for both the T cell and the APC, and binding of CD28 or CTLA4 to B7 provides a crucial second stimulus for the T cell, without which anergy develops. In addition, both the T cell and the APC release stimulatory molecules, such as interferon-g and interleukins, which provide further mutual activation stimuli.

**T Immunoblasts.** On encountering antigen, mature T cells transform into immunoblasts, which are large cells with prominent nucleoli and basophilic cytoplasm, that may be indistinguishable from B immunoblasts. T immunoblasts, in contrast to T lymphoblasts (thymocytes), are TdT and CD1 negative, strongly express pan-T-cell antigens, and continue to express either CD4 or CD8, not both. Activated or proliferating T cells express HLA-DR, as well as CD25 (interleukin-2 receptor), and both CD71 and CD38. Antigen-dependent T-cell reactions occur in the paracortex of lymph nodes and the periarteriolar lymphoid sheath of the spleen, as well as at extranodal sites of immunologic reactions.

**Effector T Cells.** From the T-immunoblastic reaction come antigen-specific effector T cells of either CD4 or CD8 type, as well as memory T cells. Antigen-stimulated T cells switch their CD45 isotype from CD45RA to CD45RO. Effector T cells of the CD4 type typically act as helper cells, and those of the CD8 type as suppressor cells *in vitro*; however, both types can be cytotoxic. CD4 cells are cytotoxic to cells that display antigen complexed with MHC class II antigen, whereas CD8 cells are cytotoxic to cells that display it complexed with MHC class I antigen. In addition to cytotoxicity, effector T cells produce a variety of cytokines that affect the function of B cells and APCs, which modulate the immune response. Fully differentiated T-effector cells are small lymphocytes, morphologically similar to other nonproliferating lymphocytes of either T or B type. In addition to differences in subset antigen (CD4 vs. CD8 or double negative) expression, peripheral T cells may differ in their TCR expression (gd vs. ab). The majority of T cells in the circulation and in most lymphoid tissues are gd+; ab T cells are more numerous in mucosae and in the spleen.

Most cases of peripheral T-cell lymphoma are thought to correspond to stages of antigen-dependent T-cell differentiation (e.g., mycosis fungoides corresponds to a mature effector CD4+ cell; hepatosplenic gd T-cell lymphoma to a gd T cell; T-cell large granular lymphocyte leukemia to a mature effector CD8+ cell); however, the relationship between neoplastic and normal T cells is not nearly as well understood as in the B-cell system. The systemic symptoms such as fever, skin rashes, and hemophagocytic syndromes associated with some peripheral T-cell lymphomas may be a consequence of cytokine production by the neoplastic T cells.

**Natural Killer Cells.** A third line of lymphoid cells, called *NK cells* since they can kill certain targets without sensitization and without MHC restriction, appears to derive from a common progenitor with T cells. NK cells recognize self class I MHC molecules on the surfaces of cells and kill cells that lack these antigens. Immature NK cells have cytoplasmic CD3, but these cells do not rearrange their T-cell receptor genes or express T-cell receptors or surface CD3. They are characterized by certain NK cell-associated antigens (CD16, CD56, and CD57), which can also be expressed on some T cells and also express some T-cell-associated antigens (CD2, CD28, and CD8). NK cells appear in the peripheral blood as a small proportion of circulating lymphocytes; they are usually slightly larger than most normal T and B cells, with abundant pale cytoplasm containing azurophilic granules (so-called large granular lymphocytes). Angiocentric and nasal T/NK cell lymphoma and some

types of large granular lymphocytes leukemia appear to correspond to immature and mature NK cells, respectively.

## IMMUNOPHENOTYPING OF LYMPHOID CELLS

Individual B- and T-lymphoid cells as well as accessory cells of the mononuclear phagocyte system can be recognized in cell suspensions or tissue sections by the presence of surface or cytoplasmic molecules (antigens) that can be detected using antibodies labeled with either fluorescence or enzymatic (immunohistochemical) methods. Immunophenotyping with monoclonal antibodies can be done using viable cell suspensions, frozen tissue sections, or paraffin-embedded tissue sections. Using monoclonal antibodies and acetone-fixed cryostat sections, it has been possible to characterize many types of normal and neoplastic lymphoid cells. A series of international workshops has developed a standardized nomenclature for many of the antigens detected by more than one monoclonal antibody. For cells in body fluids, particularly the peripheral blood, flow cytometry with fluorescent-labeled antibodies is the method of choice; this method can also be applied to fine-needle aspiration biopsy specimens and to cell suspensions prepared from fresh tissue specimens, but sampling problems can occur due to selective loss of fragile neoplastic cells. Acetone-fixed frozen sections are the most reliable method for the pathologist to assess the phenotype of lymphoid cells in tissue sections. However, the technology for detecting lymphocyte-associated antigens in paraffin-embedded tissue has greatly improved, so that most clinically necessary immunophenotyping can be accomplished using only routinely processed tissue. Nonetheless, it is still advisable to prepare fresh frozen tissue in all cases of suspected lymphoma, in case a diagnosis cannot be made with certainty on paraffin tissue section analysis and also for possible molecular genetic analysis.

## MOLECULAR GENETIC ANALYSIS OF LYMPHOID CELLS

Lymphocyte differentiation involves rearrangement of the genes involved in antigen recognition. This process is required for development of a functional antigen receptor gene and serves to increase the diversity of these receptors beyond what can be *hard-coded* into the genome, so that lymphoid cells can develop a repertoire large enough to respond to the majority of antigens they may encounter. Analysis of these rearrangements has provided insights into normal T- and B-cell differentiation and can also be useful in the diagnosis and classification of lymphoid neoplasms. In addition to these normal rearrangements, chromosome translocations frequently occur in lymphoid neoplasms, as they do in other tumors. In lymphomas, these translocations often involve *hot spots* in the antigen receptor genes; these translocations can also be useful in the diagnosis and classification of lymphoid neoplasms.

### Antigen Receptor Gene Rearrangement

**IMMUNOGLOBULIN GENE REARRANGEMENT.** B-cell differentiation involves rearrangements of the genes involved in Ig production. The genes that encode the constant and variable regions of the Ig heavy and light-chain molecules are located far apart on the chromosomes in germline cells. To produce RNA for an Ig protein, many thousands of base pairs of DNA must be deleted from the genome to bring the different portions of the Ig gene together. These rearrangements change the position on the DNA of restriction sites (points at which restriction endonucleases cleave the DNA). Thus, fragments produced by digesting B-cell DNA with these enzymes are of a different size than those produced by digesting non-B-cell (germline) DNA and migrate differently in an electrophoresis gel. When radiolabeled DNA probes (cloned segments of DNA produced by bacteria) that are complementary to specific portions of the Ig gene are applied to such a gel, they specifically mark the position of the Ig gene, which can be demonstrated on an autoradiograph. The exact size, and therefore position on the gel (Southern blot), of each Ig gene fragment is unique to an individual B cell; thus, this technique provides not only a specific marker for B cells, but also a true marker for monoclonality.

**T-CELL RECEPTOR GENE REARRANGEMENT.** A process of gene rearrangement analogous to that seen in B cells also occurs during T-cell differentiation. This process involves the DNA encoding a T-cell-specific surface molecule that serves as the T-cell receptor for antigen, analogous to surface Ig on B cells. As in the B-cell system, the size of restriction fragments of the DNA encoding the T-cell receptor gene is specific for a single clone of T cells. Thus, T-cell receptor gene rearrangement is a specific marker for T cells and also a true marker for monoclonality in T cells.

### Oncogene Rearrangements

In addition to rearrangements of antigen receptor genes, hematologic malignancies frequently have specific chromosomal translocations. Cellular oncogenes (genes that can cause malignant transformation when transfected in activated or altered form into cultured normal cells) have been identified in association with some of the more common chromosome translocations that characterize lymphoid malignancies. These translocations can be detected using DNA probes that hybridize to the breakpoint regions on the chromosome carrying the oncogene. Using a technique for amplifying unique DNA segments [polymerase chain reaction (PCR)], rare cells carrying a given translocation can be detected, using probes that span the breakpoint, or using a reverse transcriptase technique to detect RNA produced by the altered or fused gene (reverse transcriptase-PCR). Numeric abnormalities of chromosomes are also common in lymphoid malignancies; these can be detected by fluorescence *in situ* hybridization, using probes to specific chromosomes.

To the extent to which specific histologic subtypes, prognostic groups, or both of lymphomas are associated with specific gene rearrangements, detection of these rearrangements may prove useful in the characterization of lymphomas. In addition, this technique can potentially be used to detect disseminated or recurrent lymphoma on small biopsy specimens or in the blood. Finally, study of the function of the translocated oncogene is providing clues to the mechanisms of oncogenesis.

## USE OF IMMUNOPHENOTYPING AND GENETIC STUDIES IN THE DIAGNOSIS OF LYMPHOID NEOPLASMS

Each of the lymphoid neoplasms has a characteristic morphology, which may be sufficient in a given case to permit diagnosis and classification on morphologic grounds alone, if well-prepared sections are available; thus, most cases of lymphoma can be diagnosed and classified with reasonable certainty on the basis of routine histologic sections alone. However, there are many pitfalls in the histologic diagnosis of malignant lymphoma, and immunophenotyping or, less often, genetic studies can be useful in resolving major differential diagnostic problems ( [Table 45.3-1](#)). Problems that can be resolved by these techniques include (1) reactive versus neoplastic lymphoid infiltrates; (2) lymphoid versus nonlymphoid malignancies; and (3) subclassification of lymphoma. In a clinical study of the Revised European-American Classification of Lymphoid Neoplasms (REAL), the interobserver reproducibility of experts using the classification was tested, and the contribution of immunophenotype to reproducibility was assessed ( [Table 45.3-2](#)). For most of the common entities (follicular lymphoma, MALT lymphoma, B-CLL), immunophenotyping was not necessary; however, in some diseases (mantle cell lymphoma, diffuse large B-cell lymphoma) it was helpful, and in all types of T-cell lymphoma it was essential. In a given case, if the morphology is typical of a given entity but the immunophenotypic or genetic features are unusual, the histologic sections should be reexamined; however, the case may still be accepted as an example of the entity suggested by morphologic features. If the morphology is atypical but the immunophenotype and genetic features are classic for a given entity, these features may override morphology in classification. If both the morphology and the immunophenotype are atypical, then the case is best regarded as unclassifiable or borderline.

**TABLE 45.3-1.** Cluster Designation (CD) of Leukocyte-Associated Molecules

Lymphoma	IHC						Cytogenetic Abnormality		Immunophenotype
	CD19	CD20	CD22	CD23	CD25	CD27	Gene	Abnormality	
Diffuse large B-cell lymphoma	+	+	+	+	+	+	t(14;18)	CD19+, CD20+, CD22+, CD23+, CD25-, CD27+

TABLE 45.3-2. Immunohistologic and Genetic Features of Common B-Cell Neoplasms

PRINCIPLES OF CLASSIFICATION OF LYMPHOID NEOPLASM

Revised European-American Classification of Lymphoid Neoplasms from the International Lymphoma Study Group

The International Lymphoma Study Group (ILSG), an informal group of 19 hematopathologists from the United States, Europe, and Asia, adopted a new approach to lymphoma classification in 1993. In this approach, all available information (i.e., morphology, immunophenotype, genetic features, and clinical features) is used to define a disease entity. The relative importance of each of these features varies among diseases, and there is no one gold standard. Morphology is always important, and some diseases are primarily defined by morphology (e.g., follicular lymphoma, angioimmunoblastic T-cell lymphoma, nodular sclerosis Hodgkin's disease), with immunophenotype as backup in difficult cases. Some diseases have a virtually specific immunophenotype [e.g., mantle cell lymphoma, small lymphocytic lymphoma (SLL), anaplastic large cell lymphoma] such that one would hesitate to make the diagnosis in the absence of the immunophenotype. In some lymphomas a specific genetic abnormality is an important defining criterion [e.g., t(11;14) in mantle cell lymphoma, t(8;14) in Burkitt's lymphoma; t(14;18) in follicular lymphoma], whereas others lack specific genetic abnormalities (e.g., MALT lymphoma and diffuse large B-cell lymphoma). Still others require a knowledge of clinical features as well (e.g., nodal vs. extranodal presentation in marginal zone lymphoma and peripheral T-cell lymphomas, and mediastinal location in mediastinal large B-cell lymphoma). The inclusion of clinical criteria was one of the most novel aspects of the ILSG approach. The emphasis on defining real disease entities, rather than focusing on subtleties of morphology or immunophenotype or primarily on patient survival, represented a new paradigm in lymphoma classification.

The ILSG developed a consensus on a list of diseases that its members recognized in daily practice, using a combination of available morphologic, immunologic, and genetic information, and that appeared to be distinct clinical entities. This consensus approach represented the second major departure from previous classifications, most of which represented the work of one or a few individuals. The ILSG recognized that the complexity of the field in the 1990s made it impossible for a single person or small group to be completely authoritative, and also that broad agreement is necessary if the result is to be used by multiple pathologists, even if it requires compromise. The ILSG consensus list of well-defined, real diseases was published in 1994 (Table 45.3-3).<sup>124</sup> Since it represented a revision of current or prior European and American lymphoma classifications (Table 45.3-4), it was called the Revised European-American Classification of Lymphoid Neoplasms. Although its initial publication incited considerable controversy, experience over the intervening years has shown that it can be used by most pathologists, and that the entities it describes have distinctive clinical features, making it a useful and practical classification, despite its apparent complexity.<sup>125,126 and 127</sup>

TABLE 45.3-3. Revised European-American Classification of Lymphoid Neoplasms (1994)

TABLE 45.3-4. Comparison of the Original Revised European-American Classification of Lymphoid Neoplasms with the Kiel Classification and the Working Formulation

World Health Organization Classification of Hematologic Malignancies

Since 1995, members of the European and American Hematopathology societies have been collaborating on a new World Health Organization (WHO) classification of hematologic malignancies. It will use an updated version of the REAL classification for lymphomas (Table 45.3-5) and will expand the principles of the REAL classification to the classification of myeloid and histiocytic neoplasms.<sup>128,129</sup> The WHO project includes over 50 pathologists from around the world, as well as a Clinical Advisory Committee of more than 30 international expert hematologists and oncologists.<sup>130</sup> Proponents of current classifications (e.g., Working Formulation, Kiel, REAL and French-American-British) are in agreement that the final WHO consensus will replace existing classifications. Thus, it will represent the first true international consensus on the classification of hematologic malignancies.

Category	Subcategory	Code
EARLY LESIONS	Reactive plasmacytic hyperplasia	
	Infectious mononucleosis-like	
POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS, POLYCLONAL	Polyclonal (rare)	
	Monoclonal	
POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS, MONOCLONAL (CLASSIFY ACCORDING TO LYMPHOMA CLASSIFICATION)	B-cell lymphomas	
	T-cell lymphomas	
OTHER TYPES (RARE)	Hodgkin's disease-like lesions (associated with methotrexate therapy)	
	Plasmacytomatous lesions	

**TABLE 45.3-5.** Proposed Updated Revised European-American Classification of Lymphoid Neoplasms/World Health Organization Classification of Lymphoid Neoplasms<sup>a</sup>

**Principles of the Revised European-American Classification of Lymphoid Neoplasms/World Health Organization Classification of Lymphoid Neoplasms**

The REAL/WHO classification is a list of distinct disease entities, which are defined by a combination of morphology, immunophenotype, and genetic features, and which have distinct clinical features. It recognizes that all of these criteria are at best approximations, and that continued research and experience will be needed to continue to improve the definition of these diseases. Morphology remains the first and most basic approach and is sufficient for both diagnosis and classification in many typical cases of lymphoma. Immunophenotyping and, particularly, molecular genetic studies are not needed in all cases; however, they are useful in difficult cases and improve interobserver reproducibility. It is the availability of these more objective methods that make a consensus on lymphoma classification possible now, while it was impossible in the 1970s, when classification was based purely on subjective morphologic features.

The classification includes all lymphoid neoplasms (i.e., Hodgkin's disease, NHLs, lymphoid leukemias, and plasma cell neoplasms). Both lymphomas and lymphoid leukemias are included, since both solid and circulating phases are present in many lymphoid neoplasms, and distinction between them is artificial. Thus, B-CLL and B-SLL are simply different manifestations of the same neoplasm, as are lymphoblastic lymphomas and ALLs. In addition, Hodgkin's disease and plasma cell myeloma are now recognized as lymphoid neoplasms of B lineage and therefore belong in a compilation of lymphoid neoplasms. Immunodeficiency-associated lymphomas are classified according to the basic lymphoma classification; a separate classification of the posttransplant lymphoid proliferations that do not fulfill criteria for lymphoma is also given (Table 45.3-6). Many of the neoplasms recognized in the classification have morphologic variants, clinical subtypes, or both.

Category	Subcategory
EARLY LESIONS	Reactive plasmacytic hyperplasia
	Infectious mononucleosis-like
POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS, POLYCLONAL	Polyclonal (rare)
	Monoclonal
POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS, MONOCLONAL (CLASSIFY ACCORDING TO LYMPHOMA CLASSIFICATION)	B-cell lymphomas
	T-cell lymphomas
OTHER TYPES (RARE)	Hodgkin's disease-like lesions (associated with methotrexate therapy)
	Plasmacytomatous lesions

**TABLE 45.3-6.** Categories of Posttransplant Lymphoproliferative Disorders

**Clinical Test of the Revised European-American Classification of Lymphoid Neoplasms**

An initial criticism of the REAL was that it had not been tested in a clinical study,<sup>131</sup> although it only included diseases that had been previously published and for which the clinical features were known.<sup>132</sup> To address this issue, an international group of oncologists and pathologists devised a clinical study of the classification, in which five expert pathologists reviewed over 1300 cases of NHL at centers around the world.<sup>126,127</sup> The aims of the study were to (1) see whether the classification could be used in practice; (2) test its interobserver reproducibility; (3) determine the need for immunophenotyping in diagnosis; (4) determine whether the categories of disease identified in the classification were clinically distinctive either at presentation or in outcome; and (5) determine the relative frequency of these diseases in the populations studied.

This study convincingly demonstrated that the classification could be used by expert hematopathologists: Over 95% of the cases with adequate material could be classified into one or another of the categories. The interobserver reproducibility was substantially better than that for other classifications and was better than 85% for most diseases (Table 45.3-7). Immunophenotyping was helpful in some diseases, such as mantle cell lymphoma and diffuse large B-cell lymphoma, in which it improved accuracy by 10% to 15% and was essential for all types of T-cell lymphoma, improving reproducibility from approximately 50% to over 90%. It was not required for many diseases, such as follicular lymphoma, B-SLL, and MALT lymphoma.<sup>126</sup>

Category	Contribution of Immunophenotype (%)
<b>REPRODUCIBILITY &gt;85% (86% TO 96%)</b>	
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	5
Mantle cell lymphoma	10
Follicular lymphoma	0
Marginal zone/mucosa-associated lymphoid tissue	2
Diffuse large B-cell lymphoma	15
Thymoblastic lymphoma	40
Anaplastic large-cell lymphoma	39
Peripheral T-cell lymphoma, unspecified	41
Mycosis fungoides	
<b>REPRODUCIBILITY 86%</b>	
Angioimmunoblastic T-cell lymphoma	
Extranodal natural killer/T-cell lymphoma	
<b>REPRODUCIBILITY &lt;86%</b>	
Burkitt-like lymphoma	6
Lymphoplasmacytic lymphoma	

**TABLE 45.3-7.** Reproducibility of Lymphoma Diagnosis

The relative frequency of the different B-cell and T/NK-cell lymphomas in the study population was similar to previous patterns reported in the literature (Table 45.3-8). The most common lymphoma was diffuse large B-cell lymphoma, followed by follicular lymphoma; together, these accounted for 50% of the lymphomas in the study. New entities not specifically recognized in the Working Formulation accounted for 27% of the cases: MALT lymphoma, 8%; mantle cell, 7%; peripheral T-cell, 6%; nodal marginal zone, 2%; mediastinal large B-cell, 2%; and anaplastic large T/null-cell, 2%. These results are reassuring, confirming that the majority of the cases that will be encountered by oncologists and pathologists will be only a few subtypes, with which they are already familiar. However, they also underscore the need for recognizing the more recently described entities, which although less common, have important clinical differences. The study also found differences in geographic distribution of the lymphoma types, with follicular lymphoma being more common in North America and western Europe, T-cell lymphomas more common in Hong

Lymphoma	Patients (%)	Age					Sex	Site	Stage	Survival (months)	5-year survival (%)
		<40	40-59	60-79	80-99	>100					
Large B-cell	18	14	33	25	13	25	71	16	31	35	
Mediastinal	2	0	14	14	14	14	14	14	14	14	
Follicular	22	14	42	33	11	28	44	42	4	68	
Small lymphocytic	8	40	38	14	8	25	80	72	7	25	
Non-Hodgkin's	8	40	38	14	8	25	80	72	7	25	
Mantle cell	4	40	75	13	7	28	41	31	9	25	
Peripheral T-cell	7	42	29	11	18	30	42	36	11	27	
Anaplastic large cell	2	50	50	50	50	50	50	50	50	50	

**TABLE 45.3-8.** Presenting Features of Common B- and T-Cell Neoplasms

The different entities recognized by the classification had significantly different clinical presentations and survivals. For example, diffuse aggressive lymphomas, which would be lumped as intermediate or high grade in the Working Formulation, include diffuse large B-cell lymphoma, mediastinal large B-cell lymphoma, peripheral T-cell lymphoma, and anaplastic large T/null-cell lymphoma. The clinical features at presentation were strikingly different, with a younger age group for mediastinal large T-cell lymphoma and anaplastic large T/null-cell lymphoma, and striking differences in male to female ratios, suggesting that these are distinctive biologic entities (see [Table 45.3-8](#)). When overall survivals were analyzed, entities that would have been lumped together as *low grade* or *intermediate/high grade* in the Working Formulation showed marked differences in survival, again confirming that they need to be recognized and treated as distinct entities.

A critical finding in this study was that classification is not the only predictor of clinical outcome. Patients with any of these diseases could be stratified into better and worse prognostic groups according to the International Prognostic Index. <sup>133</sup> For example, although patients with follicular lymphoma typically have International Prognostic Index scores of 1 to 3, those patients with scores of 4 or 5 had a predicted median overall survival of only 18 months. Thus, to plan treatment for an individual patient, the oncologist must know not only the diagnosis, but the clinical prognostic factors that influence that patient's course.

#### DIFFERENTIAL DIAGNOSIS OF INDOLENT DISSEMINATED LYMPHOMA

For most of the indolent lymphoid neoplasms, both the clinical and pathologic differential diagnosis includes, first, a benign lymphoid proliferation, and second, another type of indolent lymphoma or leukemia. In distinguishing B-CLL/SLL, immunocytoma, or splenic marginal zone lymphoma (SMZL) with villous lymphocytes from reactive lymphocytosis, cytologic criteria can be difficult, since cytologic atypia may be minimal; the only reliable technique is SIg analysis for clonality, usually by flow cytometry. In lymph nodes or other tissues, the most important distinguishing features include effacement of the architecture and the presence or absence of pseudofollicles. On frozen sections or flow cytometry, demonstration of monotypic SIg and CD5 expression are also useful. On paraffin sections, demonstration of a predominance of interfollicular B cells, often with coexpression of CD43, can provide suggestive evidence of B-cell lymphoma.

B-SLL/CLL, immunocytoma, and SMZL must be distinguished from one another and from MALT type lymphoma (in extranodal sites) and mantle cell lymphoma (which can involve blood, bone marrow, and spleen). The presence of pseudofollicles is diagnostic of CLL/SLL; expression of CD23 (frozen sections) and lack of cyclin D1 (paraffin sections) can exclude mantle cell lymphoma, whereas expression of CD5 argues against a diagnosis of MALT type lymphoma, lymphoplasmacytoid lymphoma, or SMZL. By flow cytometry, SIg in CLL is usually weak, whereas it tends to be stronger in the other lymphomas; CD25 or CD103 are also uncommon in B-CLL and more common in some of the other lymphoid leukemias.

Clinically and pathologically, the differential diagnosis of SMZL also includes hairy cell leukemia. Although the cells in the peripheral blood may resemble hairy cells, the nuclei are usually smaller, with more condensed chromatin, and the villi are polar and less conspicuous than those of hairy cell leukemia. The marrow infiltrate is usually sparse and nodular, in contrast to hairy cell leukemia. The cells may, however, express CD25, CD103, and even TRAP. In the past, many cases were probably diagnosed as atypical hairy cell leukemia or B-CLL. Distinction from lymphoplasmacytoid lymphoma is more problematic; both are CD5- and both may have an M component and evidence of plasmacytoid differentiation. The relationship between SMZL/splenic lymphoma with villous lymphocytes and lymphoplasmacytoid lymphoma needs further study.

#### DIFFERENTIAL DIAGNOSIS OF INDOLENT EXTRANODAL AND NODAL LYMPHOMAS

The most important clinical and pathologic differential diagnosis in indolent lymphomas in either lymph nodes or extranodal sites is with benign lymphoid hyperplasias. In this situation, if morphologic criteria are insufficient, staining for Ig light-chains is the most useful test to determine clonality.

In the differential diagnosis of gastric MALT type lymphomas, clinical features favoring lymphoma include evidence of a mass, enlargement of gastric folds, or a multinodular appearance to the mucosa. Histologically, the presence of a dense, diffuse infiltrate of marginal zone B cells, with destruction of glands and prominent lymphoepithelial lesions is required for a confident diagnosis. In borderline cases, paraffin section immunoperoxidase stains for cIg may be helpful in approximately 50% of the cases; frozen section immunophenotyping for detection of monotypic SIg is definitive in the rest. If gastric MALT lymphoma is suspected in a patient with *Helicobacter* infection, it is important *not* to treat with antibiotics until the diagnosis is ruled in or out by special studies, including rebiopsy if necessary. Antibiotic therapy often causes the lymphoma to regress, but the long-term outcome of these patients is not known, and therefore it is important to know *before* treatment, whether the patient has lymphoma or just gastritis.

The major differential diagnosis, both clinically and pathologically, for follicular lymphoma is with reactive follicular hyperplasia. The presence of persistent, nontender lymph nodes in an older adult should raise the suspicion of follicular lymphoma, particularly if more than one site is involved. Histologic criteria for this differential diagnosis are well established; in the minority of cases in which a confident diagnosis is not possible on routine sections, demonstration of monotypic SIg on flow cytometry or frozen section, or of bcl-2 expression within the follicles, can confirm the diagnosis. Molecular genetic studies to confirm Ig gene or bcl-2 rearrangement are rarely necessary but can be helpful.

Follicular lymphoma, mantle cell lymphoma, nodal monocytoid B-cell lymphoma, and extranodal MALT lymphoma must all be distinguished from one another. Clinically, the first three usually involve generalized lymph nodes; however, when mantle cell lymphoma presents with extranodal involvement in the form of lymphomatous polyposis of the gastrointestinal tract, it may be confused with MALT type lymphoma. The presence of widespread disease involving multiple gastrointestinal sites strongly favors mantle cell lymphoma. In other extranodal sites such as the orbit <sup>134</sup> and breast, <sup>135</sup> follicular lymphoma may be more common than MALToma and should be considered in the differential diagnosis.

Although most cases of indolent nodal lymphoma can be correctly classified by morphologic criteria if good histologic sections are available, immunophenotyping studies can be helpful and are occasionally necessary for correct subclassification (see [Table 45.3-2](#)). Expression of CD5 and CD43 and lack of CD23 and (usually) CD10 are useful in distinguishing mantle cell lymphoma from CLL and follicular center lymphoma, respectively. In extranodal sites, CD5 is useful in distinguishing mantle cell lymphoma from MALToma. Staining for cyclin D1 is potentially the most specific marker for mantle cell lymphoma; Southern blot or PCR studies can also be used to detect the t(11;14).

#### DIFFERENTIAL DIAGNOSIS OF MATURE (PERIPHERAL) T-CELL LYMPHOMAS

With most peripheral T-cell lymphomas, the clinical and pathologic differential diagnosis includes an atypical reactive process, such as a viral infection, and one of the more common B-cell lymphomas. Because of the great variety of clinical presentations and morphologic features, establishing a diagnosis can be difficult and may require multiple diagnostic procedures. Since there is no reliable immunophenotypic marker for clonality in T cells, molecular genetic analysis is often necessary when the differential diagnosis includes a reactive process. These studies can often be performed on cells isolated from blood or body fluids or from needle-aspiration biopsies, if the initial diagnostic biopsy has not been processed to obtain fresh tissue. An important caveat is excluding a B-cell lymphoma; many B-cell lymphomas of

both low and high grade contain numerous reactive T cells in biopsy specimens. Therefore, simply demonstrating a predominance of T cells does not establish the diagnosis of a T-cell lymphoma; tissues should always be stained for B-cell-associated antigens and Ig.

## PRINCIPLES OF MANAGEMENT OF NON-HODGKIN'S LYMPHOMA

The principles of the management of patients with NHL have steadily evolved. The phases of patient management include obtaining an adequate biopsy for an accurate diagnosis, a careful history and physical examination, appropriate laboratory studies, imaging studies, and possibly, further biopsies to determine an accurate stage and to plan therapy. Finally, taking into account factors related to the patient, type of lymphoma, and stage and pace of disease, a treatment recommendation must be made. Treatment choices include no initial therapy, radiotherapy, cytotoxic chemotherapy, a variety of new biologic therapies, and hematopoietic stem cell transplantation.

### HISTORY AND PHYSICAL EXAMINATION

A careful history and physical examination is the basis for subsequent studies to determine the extent of the disease and key factor in the therapeutic decision. The duration of symptoms and the pace of progression of the illness should be documented. The physician should not discount the possibility that waxing and waning lymphadenopathy could be related to the lymphoma. Especially in follicular lymphomas, spontaneous regressions are frequent. The presence of specific symptoms known to have an adverse prognosis in patients with some types of lymphoma should be ascertained. These include fevers, night sweats, and unexplained weight loss. Symptoms referable to a particular organ system such as pain in the chest, abdomen, or bones might lead to identification of specific sites of involvement. History of a concurrent illness such as diabetes or congestive heart failure might modify therapeutic decisions.

A careful physical examination can lead to important observations that will direct subsequent care. Obviously, examination of all lymph node-bearing areas and a search for hepatomegaly or splenomegaly are important. Pharyngeal involvement, a thyroid mass, evidence of pleural effusion, abdominal mass, testicular mass, or cutaneous lesions are all examples of findings that might direct further investigations and subsequent therapy. Certain associations of involvement between two organ sites are worth remembering. For example, patients with involvement of Waldeyer's ring often have gastrointestinal involvement, and the converse is also true. These patients usually have mantle cell lymphoma. Patients with paranasal sinus, testicular involvement, and epidermal lymphoma are especially prone to meningeal spread and deserve a diagnostic lumbar puncture and, probably, prophylactic therapy. Patients with one testicle involved are likely to relapse on the opposite side and radiotherapy should be directed to the entire scrotum with this in mind. Patients with ocular lymphoma almost always have dissemination to other parts of the CNS in the absence of prophylactic therapy.

### LABORATORY EVALUATION

Laboratory studies should include complete blood count and screening chemistry studies to include renal and hepatic function studies, serum glucose, calcium, albumin, lactate dehydrogenase (LDH), and b<sub>2</sub>-microglobulin level. Serum protein electrophoresis is frequently appropriate. The purpose of these studies is to aid in determining the prognosis (e.g., LDH, b<sub>2</sub>-microglobulin, albumin) and identifying abnormalities in other organ systems that might complicate therapy (e.g., renal or hepatic dysfunction).

In addition to the diagnostic biopsy, almost all patients should have a bone marrow aspirate and biopsy performed. The chances of finding bone marrow involvement varies considerably among different subtypes of lymphoma (Table 45.3-9). It is present in approximately 70% of patients with SLL, lymphoplasmacytoid lymphoma, and mantle cell lymphoma. Patients with follicular lymphoma have bone marrow involvement approximately 50% of the time, while it is seen in approximately 15% of patients with diffuse large B-cell lymphoma (see Table 45.3-9).<sup>126</sup> Bone marrow involvement in patients with follicular and SLL has little prognostic import except when bone marrow is extensively involved and cytopenias or large numbers of circulating lymphoma cells are present. In patients with diffuse large B-cell lymphoma, bone marrow involvement can occur with the large cells or small B cells. Patients with large cell lymphoma in the marrow have a distinctly adverse prognosis, while marrow involvement by small cells has a much less clear effect on prognosis.<sup>136</sup>

Subtype of Non-Hodgkin's Lymphoma	Bone Marrow (%)	Gastrointestinal Tract (%)	Any Extranodal Site (%)
Follicular	42	4	64
Small lymphocytic	72	3	80
Mucosa-associated lymphoid tissue	14	50	98
Mantle cell	64	9	81
Diffuse large B-cell	16	18	71
Burkitt's	33	11	78
Lymphoblastic	50	4	82
Peripheral T-cell	36	15	82
Anaplastic large T/null cell	15	9	59

TABLE 45.3-9. Frequency of Extranodal Involvement by Non-Hodgkin's Lymphomas

## IMAGING STUDIES

### Chest Radiography and Computed Tomographic Scans

Chest radiography and computed tomographic (CT) scans of the chest, abdomen, and pelvis should be performed at the initial evaluation in almost all patients with NHL. Although the chest radiograph is abnormal in less than 50% of patients, identification of hilar or mediastinal adenopathy, parenchymal lesions, or pleural effusions is important and provides an easy method for reevaluation. CT scanning can identify both nodal and extranodal sites of involvement and provides an important approach to monitoring the response to therapy. This approach has largely replaced lymphangiography for the evaluation of retroperitoneal lymphadenopathy. This is partly because of the difficulty of performing lymphangiography. The abdominal and pelvic CT scan can identify mesenteric and retrocrural nodes and is more accurate than the lymphangiogram in determining the dimension of nodal disease.<sup>137,138</sup> Involvement of intraabdominal organs such as kidney, ovary, spleen, and liver can be identified on CT scans.

### Magnetic Resonance Imaging

The value of magnetic resonance imaging (MRI) in the staging of NHL is limited. This technique can be used in lieu of CT scanning in many patients, but its higher cost makes this impractical. MRI is particularly useful in identifying bone and CNS involvement. MRI can suggest meningeal involvement when gadolinium has been used. MRI can also identify bone marrow involvement<sup>139</sup> and might be more sensitive than bone marrow biopsy in this regard. However, it has not yet been accepted as a substitute for bone marrow biopsy.

### Nuclear Medicine Studies

The most common nuclear medicine studies used in staging patients with lymphoma are bone scans and gallium scans. Bone scans are rarely used as part of the initial staging studies. They can sometimes be useful in patients who present with or develop back pain during the course of their lymphoma, looking for vertebral involvement and potential spinal cord compression.

Gallium scans are more often used as part of the staging evaluation. This study, because it provides functional rather than purely anatomic information, has potential value in resolving difficulties in determining the response to therapy.<sup>140</sup> To be maximally valuable, high doses of gallium need to be administered and single photon emission CT needs to be used. Gallium scan results are more likely to be positive in patients with aggressive lymphoma such as diffuse large B-cell lymphomas than in more indolent lymphoma such as follicular lymphoma, but can be positive in any subtype. Gallium scans are more accurate in evaluating supradiaphragmatic rather

than infradiaphragmatic sites because of colon uptake of the gallium. Unfortunately, this test is most often needed in determining intraabdominal sites of involvement.

On rare occasions, technetium liver spleen scans can be helpful in determining the cause of splenic involvement in the patient in whom lymphoma is suspected. One of the differential diagnoses in such patients is occult liver disease. Technetium liver spleen scans that show more uptake in the spleen than liver suggest occult liver disease, and a liver biopsy should be done before considering splenectomy.

**Positron Emission Tomographic Scans**

Positron emission tomographic (PET) scanning has been increasingly applied in staging patients with lymphoma. The specificity and sensitivity of PET scanning seems to be at least that of gallium scanning. The procedure has been more widely adopted in some countries in Europe than in the United States. Despite enthusiastic reports, more large comparative trials assessing the relative merits of PET scanning, gallium scanning, and CT scanning need to be completed before PET replaces previous tests. Merely adding PET scanning to all the previous studies will only increase the cost of therapy.

**STAGING LAPAROTOMY**

Staging laparotomies became popular in the late 1960s and 1970s for evaluating patients with Hodgkin's disease. The same approach was used in patients with NHLs. Studies showed that a large proportion of patients with apparently localized follicular lymphoma would be upstaged using staging laparotomy, but this was a less common event in diffuse large B-cell lymphoma. Because of improvements in imaging studies, and the morbidity and potential mortality associated with staging laparotomy, this procedure is rarely appropriate in the initial evaluation of a patient with NHL. However, some patients with NHL are diagnosed at laparotomy, and if the diagnosis is known during the procedure, careful evaluation of other lymph nodes sites and organs by the surgeon can be valuable.

**POLYMERASE CHAIN REACTION FOR EVALUATING MINIMAL RESIDUAL DISEASE**

The use of PCR to expand small numbers of cells with a particular genetic abnormality can allow identification of cells as frequent as 1 in 10<sup>5</sup>.<sup>141</sup> This has usually been applied to studying blood and bone marrow, but could be applied in other sites. Studies to date have generally focused on the t(14;18) translocation and the associated bcl-2 gene. Several observations have been made. PCR positivity for bcl-2 gene rearrangements can be found in healthy individuals.<sup>142</sup> However, patients with lymphoma in remission who show positive results for bcl-2 gene rearrangement using PCR in the blood or bone marrow are more likely to relapse than patients who do not have this abnormality discovered.<sup>143</sup> Unfortunately, some patients that are positive do not relapse and some patients that are negative do relapse. At present, this approach is probably better considered a research tool. Planning further therapy based only on this abnormality appears risky, until the test is better standardized and the implications of an abnormal finding are better quantified.

**STAGING AND PROGNOSTIC SYSTEMS**

The goal of the initial evaluation of a patient with lymphoma is to provide information that allows intelligent planning of therapy, imparting the prognosis to the patient, and making possible comparisons between patients in clinical trials. The studies to accomplish these goals can be aimed at identifying sites of involvement, characteristics of the patient (i.e., age, performance status, and so forth), or characteristic of the lymphoma (serum LDH, serum b<sub>2</sub>-microglobulin, growth fraction, and so forth) that predict treatment outcome.

The Ann Arbor Staging System was developed for patients with Hodgkin's disease. This system<sup>144</sup> (Table 45.3-10) identifies anatomic sites of involvement by lymphoma and assigns patients into four categories based on the extent of disease dissemination. Patients are also subcategorized by the presence of unexplained fevers, night sweats, or weight loss. This system has a significant effect on prognosis and is important in treatment planning.

Stage	Description*
I	Involvement of a single lymph node region or a single extralymphatic organ or site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III) or localized involvement of an extralymphatic organ or site (IIIE) or spleen (IIIS) or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement. Bone marrow and liver involvement are

\*Identification of the presence or absence of symptoms should be noted with each stage designation: A, asymptomatic; B, fever, sweats, weight loss greater than 10% of body weight.

**TABLE 45.3-10.** Ann Arbor Staging System

Other staging systems have been identified.<sup>145,146</sup> and <sup>147</sup> These have used anatomic stage as identified by the Ann Arbor System, symptoms, performance status, serum LDH, serum b<sub>2</sub>-microglobulin, tumor size, number of sites of involvement, and bone marrow involvement. The bulk of lymphoma is an important prognostic indicator whenever it has been studied. Unfortunately, there has been no consensus on how to best measure bulk. The diameter of the largest mass has been the most common method used, but diameters of 5, 7, and 10 cm have been used by different investigators, making comparisons difficult. Even so, a greater than 10-cm mass, regardless of anatomic stage, is a serious negative prognostic factor. These patients might benefit from adjuvant radiotherapy even if the disease is disseminated.

At present, the most valuable and widely used system to stratify patients is the International Prognostic Index (Table 45.3-11).<sup>148</sup> It was developed by investigators throughout the world for use in predicting outcome for patients with diffuse aggressive NHLs treated with an anthracycline-containing combination chemotherapy regimen. Five features were found to have approximately an equal and independent effect on survival. These included age, serum LDH, performance status, anatomic stage, and the number of extranodal sites. Because of the approximately equal effect on outcome, the number of abnormalities were simply summed to develop the prognostic index. Thus, patients might have a score of 0 to 5. For patients under the age of 60, a simplified index can be applied that incorporates only anatomic stage, serum LDH, and performance status. This system was initially developed only for patients with diffuse aggressive lymphoma. However, it is clear that it applies to patients with almost all subtypes of NHL.<sup>127</sup>

Stage (Diff. Large Cell)	Group			
	Number of Patients	Survival (%)	5-Year Survival (%)	10-Year Survival (%)
<b>Patients under 60 years of age, performance status 2 or less, LDH above upper limit of normal, Ann Arbor stage II or III, 25 or more sites</b>				
I	25	47	35	23
II	27	47	36	22
III	22	35	26	17
IV	11	41	26	18
<b>Patients 60 years of age or older, performance status 2 or less, LDH above upper limit of normal, Ann Arbor stage II or III, 25 or more sites</b>				
I	22	32	26	17
II	22	35	26	18
III	22	37	28	18
IV	11	46	31	22

**TABLE 45.3-11.** International Prognostic Index for Diffuse Large Cell Lymphoma

## RESTAGING

After patients have received three or four cycles of the planned treatment regimen or at the completion of the entire regimen, reevaluation should be done to determine the response to therapy. For patients with diffuse aggressive lymphoma, reevaluation after three or four cycles of therapy can add prognostic information. Patients who have a complete response are more likely to be cured than patients who have only achieved a partial response at this point. Achieving a complete remission to therapy is the most important single prognostic factor in patients with NHL. <sup>149</sup> Documenting complete remission is important. It is particularly true since salvage treatment such as high-dose therapy and autologous or allogeneic bone marrow transplantation can sometimes cure disease in patients who fail to respond to initial therapy.

A restaging evaluation typically involves repeating all previous studies with abnormal results to document their current normal results. However, especially in sites of bulky disease, masses do not always completely regress. This does not necessarily mean that patients will have persisting lymphoma. Rebiopsy under these circumstances can be difficult and is not always accurate. If the patient was known to have a positive gallium scan or PET scan at the outset of treatment, a normal result of that test despite a residual mass raises the possibility that only residual fibrous tissue is present. Gallium avidity midtreatment cycle or at the end of treatment is associated with a much higher relapse rate than seen in patients who have negative results on gallium scanning. <sup>140</sup>

## SPECIFIC DISEASE ENTITIES

### B-CELL NEOPLASMS

#### *Precursor B-Lymphoblastic Leukemia and Lymphoma (Precursor B-Cell Acute Lymphoblastic Leukemia/ Precursor B-Lymphoblastic Lymphoma)*

**DEFINITION.** The definition is a neoplasm of lymphoblasts committed to the B-cell lineage, typically composed of small to medium-sized blast cells with scant cytoplasm, moderately condensed to dispersed chromatin and indistinct nucleoli, involving bone marrow and blood (ALL), and occasionally presenting with primary involvement of nodal or extranodal sites (lymphoblastic lymphoma).

**MORPHOLOGY.** On smears, lymphoblasts vary from small cells with scant cytoplasm, condensed nuclear chromatin, and indistinct nucleoli to larger cells with a moderate amount of cytoplasm, dispersed chromatin, and multiple nucleoli. Azurophilic granules may be present. In tissue sections, the cells are small to medium sized, with scant cytoplasm; round, oval, or convoluted nuclei; fine chromatin; and indistinct or small nucleoli. Occasional cases have larger cells. The pattern is infiltrative rather than destructive, with partial preservation of the subcapsular sinus and germinal centers. A *starry-sky* pattern may be present, but this is usually less prominent than in Burkitt's lymphoma.

**IMMUNOPHENOTYPE.** The lymphoblasts are typically positive for TdT and variably express CD19, CD22, CD20, and CD79a, as well as CD45 and CD10. The constellation of antigens defines stages of differentiation, ranging from early precursor (membrane CD19 and CD79a and cytoplasmic CD22) to common ALL (CD10+) to late pre-B ALL (CD20+, cytoplasmic  $\mu$  heavy-chain). CD34 is expressed on 40%, and coexpression of myeloid antigens is seen in up to 30%, most commonly CD13 (14%), CD33(16%), or both. <sup>150,151</sup> Expression of CD13 and CD33 is associated with rearrangement of ETV6 [t(12;21)(p12;q22),ETV6-CBFA2 or TEL-AML1], while expression of CD68, CD15, and CD33 are seen in cases with 11q23/MLL abnormalities. <sup>151</sup>

**GENETIC FEATURES.** Rearrangement of antigen receptor genes is variable in lymphoblastic neoplasms and may not be lineage specific; thus, precursor B-cell neoplasms may have either or both Ig heavy-chain and TCR g or b chain gene rearrangements, or may show no rearrangements. <sup>152,153 and 154</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is precursor B lymphoblast at varying stages of differentiation.

**CLINICAL FEATURES AND THERAPY.** Precursor B-ALL/lymphoblastic lymphoma occurs most frequently in childhood, with a second peak in the elderly. The outcome is less favorable in infants less than 1 year of age and in adults. In addition to cytogenetic features, risk groups are based on age, leukocyte count, sex, and response to therapy. In infants, many cases have translocations involving the MLL gene at 11q23, which is associated with a poor prognosis at any age <sup>155</sup>; older children more often have hyperdiploidy or t(12;21), which confers a better prognosis (85% to 90% long-term survival). <sup>156</sup> Adult precursor B-ALL is more often associated with the poor-prognosis t(9;22) or t(v11q23), and the survival is much poorer than that for childhood cases. <sup>150,157</sup> Myeloid antigen expression does not seem to be an independent prognostic factor in ALL. <sup>151,158</sup> Therapy is the same as described for T-lymphoblastic lymphoma.

#### *B-Cell Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma*

**DEFINITION.** The definition of B-CLL/SLL is a neoplasm of monomorphic, small round B lymphocytes in the peripheral blood and lymph nodes, admixed with prolymphocytes and paraimmunoblasts in lymph nodes, usually expressing CD5 and CD23. B-SLL is defined as a tissue infiltrate with the morphology and immunophenotype of B-CLL.

**MORPHOLOGY.** The lymph node infiltrate of B-CLL/SLL is composed predominantly of small lymphocytes with condensed chromatin, round nuclei, and occasionally a small nucleolus. <sup>159,160</sup> Larger lymphoid cells (prolymphocytes and paraimmunoblasts) with more prominent nucleoli and dispersed chromatin are always present, usually clustered in pseudofollicles. In some cases, the cells show moderate nuclear irregularity, which can lead to a differential diagnosis of mantle cell lymphoma. <sup>161,162</sup> Occasional cases show plasmacytoid differentiation.

**IMMUNOPHENOTYPE.** The tumor cells of B-CLL have faint SIgM, and most coexpress IgD. The antigen specificity of the SIg in many cases has been shown to be against self-antigens, and these antibodies often have broad specificity, so-called cross-reactive idiotypes. <sup>163</sup> Cytoplasmic Ig is detectable in approximately 5% of the cases. B-cell-associated antigens (CD19, CD20, CD79a) are positive, but particularly CD20 may be weak; tumor cells characteristically express both CD5 and CD23. <sup>164</sup> CD23 is particularly useful in distinguishing B-CLL/SLL from mantle cell lymphoma and should be evaluated in every case, if possible. <sup>164</sup>

**GENETIC FEATURES.** Ig heavy and light-chain genes are rearranged. Most cases (75%) in early studies did not show somatic mutation of their V regions, suggesting that they corresponded to a cell that has not yet undergone antigen selection in the germinal center. <sup>165</sup> However, more recent studies have found up to 40% of the cases to have V region mutations, consistent with exposure to the germinal center. Cases with mutations are reported to express CD38 and to be associated with a better prognosis than cases without mutations or that are CD38-. <sup>166,167</sup>

Approximately 50% of cases have abnormal karyotypes. <sup>168</sup> Trisomy 12 is reported in one-third of the cases with cytogenetic abnormalities <sup>169</sup> and correlates with atypical histology and an aggressive clinical course. <sup>162,170</sup> Abnormalities of 13q are reported in up to 25% of the cases and are associated with long survival. t(11;14) and bcl-1 gene rearrangement have been reported, <sup>171,172</sup> but many of these cases may be examples of leukemic mantle cell lymphoma; however, at least two clear-cut cases of B-CLL have been reported with bcl-1 gene rearrangement, cyclin D1 overexpression, or both; in both it was associated with an unusually aggressive clinical course. <sup>173,174</sup> Abnormalities of 11q23 are found in a small subset of cases and are associated with lymphadenopathy and an aggressive course. <sup>175,176</sup>

**POSTULATED NORMAL COUNTERPART.** Many cases of B-CLL are thought to correspond to the recirculating CD5+ CD23+ naive B cells, <sup>177</sup> which are found in the peripheral blood, primary follicle, and follicle mantle zone. <sup>178,179</sup> It has been suggested that they are an anergic, self-reactive CD5+ B-cell subset. <sup>180,181</sup> Cases that show V region mutations may correspond to a subset of peripheral blood CD5+ IgM+ B cells that appear to be memory B cells. <sup>182</sup>

**CLINICAL FEATURES.** B-CLL accounts for 90% of chronic lymphoid leukemias in the United States and Europe; nonleukemic B-SLL accounts for less than 5% of NHLs. In the International Non-Hodgkin's Lymphoma Classification Project, 6.7% of 1378 cases were diagnosed as B-CLL/SLL. The median age was 65 years, and 83% had stage IV disease, 73% with bone marrow involvement. Generalized lymphadenopathy, hepatosplenomegaly, and extranodal infiltrates may occur. Sixty-four percent had an International Prognostic Index score of 2/3. The 5-year overall actuarial survival was 51%, with a failure-free survival of 25%; for those patients with an International Prognostic Index of 0/1, the overall actuarial survival was 76%, whereas for those with an International Prognostic Index of 4/5 it was only 38%. Thus, the extent of the disease at the time of the diagnosis is the best predictor of survival; however, chromosomal abnormalities and immunophenotype may also have

prognostic importance.<sup>183</sup>

Patients with SLL can present with hypogammaglobulinemia or develop it over the course of the illness.<sup>184,185</sup> The presence of hypogammaglobulinemia is associated with an increased incidence of infections and can be managed in some patients with intermittent gamma globulin injections. Polyclonal or monoclonal hypergammaglobulinemia can also be seen.<sup>185,186</sup> Autoimmune hemolytic anemias can be seen in patients with SLL<sup>187</sup> and are particularly likely to develop in patients treated with fludarabine.<sup>188</sup> Autoimmune thrombocytopenia is not rare.<sup>189</sup> Autoimmune neutropenia and pure red cell aplasia are unusual.<sup>185</sup>

**THERAPY.** Localized SLL is unusual and was seen in only 4% of patients in a large series.<sup>127</sup> The rare patient who presents in this manner could be treated with local radiotherapy. Such patients should have their slides reviewed to make certain they do not have a MALT lymphoma.

Some patients with disseminated SLL/chronic lymphocytic leukemia have a slowly progressive or stable disorder that does not require therapy. The traditional treatment for this lymphoma has been oral chlorambucil or oral cyclophosphamide. However, it is now clear that fludarabine is the most active single agent. Several randomized trials have been completed. One study with 544 patients randomized received fludarabine, chlorambucil, or a combination of both drugs. Patients who failed to respond to an individual drug were crossed over to the other arm. The overall response rate (70% vs. 43%) and complete response rate (27% vs. 3%) favored fludarabine over chlorambucil.<sup>190</sup> Although progression-free survival also favored fludarabine, there was no difference in overall survival. Another randomized trial<sup>191,192</sup> studied 695 patients and compared fludarabine with anthracycline-containing combinations. Fludarabine had a superior response rate. It appears that combinations including fludarabine and cyclophosphamide are also active and might be more active than fludarabine alone.<sup>193</sup>

Patients with SLL/chronic lymphocytic leukemia can respond to monoclonal antibody therapy using rituximab (anti-CD20) and Campath-1 (anti-CD52). However, the response rate to rituximab appears to be on the order of 20%, perhaps because of the lower level of expression of CD20 than seen in follicular lymphoma.<sup>194,195</sup>

Combination chemotherapy using CHOP or FND produces significant response rates in SLL, but the patients almost always relapse. High-dose therapy and autologous transplantation<sup>196</sup> and allogeneic transplantation<sup>197</sup> have both been used in fairly small numbers of patients. It appears that allogeneic transplantation can probably be curative. In general, principles of therapy of SLL apply to patients with lymphoplasmacytic lymphoma.

### ***Lymphoplasmacytic Lymphoma (with or without Waldenström's Macroglobulinemia)***

**DEFINITION.** Lymphoplasmacytic lymphoma is defined as a neoplasm of small B lymphocytes, plasmacytoid lymphocytes, and plasma cells, involving bone marrow, lymph nodes, and spleen, lacking CD5, usually with a serum monoclonal protein with hyperviscosity or cryoglobulinemia. Plasmacytoid variants of other neoplasms are excluded. The name, *lymphoplasmacytoma* (REAL) has been changed to *lymphoplasmacytic* (WHO).

**MORPHOLOGY.** The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes, and plasma cells, with variable numbers of immunoblasts. In lymph nodes, sinuses are often open and may contain histiocytes reacting to secreted periodic acid–Schiff-positive Ig. In the spleen, both red and white pulp may be infiltrated. The pattern is usually diffuse, without a distinct marginal zone or nodularity in the red pulp. The bone marrow infiltrate may be either diffuse or nodular and is often interstitial and rather subtle. It is usually less massive than that of B-CLL and contains plasma cells and plasmacytoid cells in addition to small lymphocytes. Peripheral blood involvement is usually less prominent than in CLL, and the cells often have a plasmacytoid appearance.

**IMMUNOPHENOTYPE.** The cells have surface and cytoplasmic (some cells) Ig, usually of IgM type, usually lack IgD, and strongly express B-cell–associated antigens (CD19, CD20, CD22, and CD79a). The cells are CD5–, CD10–, CD23–, CD43+/-; CD25 or CD11c may be faintly positive in some cases.<sup>164,198,199 and 200</sup> Lack of CD5 and CD23, strong SIg and CD20, and the presence of cytoplasmic Ig are useful in distinguishing it from B-CLL.

**GENETIC FEATURES.** Ig heavy and light-chain genes are rearranged, and V region genes show somatic mutations, suggesting that, in contrast to B-CLL, these cells arise from a population of B cells that have undergone antigen B–driven selection.<sup>165,201,202 and 203</sup> Translocation t(9;14)(p13;q32) and rearrangement of the PAX-5 gene is reported in up to 50% of the cases. PAX-5 encodes a protein, B-cell–specific activator protein, which is important in early B-cell development. Expression of B-cell–specific activator protein is restricted to B cells and appears to be independent of the translocation.<sup>204</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is a peripheral B lymphocyte stimulated to differentiate to a plasma cell, possibly corresponding to the primary immune response to antigen, or to a post–germinal center cell that has undergone somatic mutation but not heavy-chain class switch.

**CLINICAL FEATURES AND THERAPY.** Lymphoplasmacytic lymphoma made up only 1.2% (16 of 1378) of the cases in the REAL clinical study.<sup>126</sup> Similar to B-CLL/SLL, the median age was 63 years and 53% were men; most (73%) had bone marrow involvement. Sixty-nine percent had an International Prognostic Index of 2/3. Lymph node and splenic involvement are common. A monoclonal serum paraprotein of IgM type, with or without hyperviscosity syndrome (Waldenström's macroglobulinemia), is present in most patients<sup>205</sup>; as with B-CLL, the paraprotein may have autoantibody or cryoglobulin activity.

Most cases of mixed cryoglobulinemia have been shown to be related to HCV infection, even in patients who have demonstrable B-cell lymphoma in the bone marrow.<sup>206,207</sup> Treatment of patients with HCV and cryoglobulinemia with interferon to reduce viral load has been associated with regression of the lymphoma.<sup>208</sup> HCV infection has also been documented in patients with B-cell lymphoma without cryoglobulinemia, most commonly in MALT type/monocytoid B-cell lymphomas and in lymphomas of the salivary gland and liver (two sites of chronic viral infection).<sup>78,209,210 and 211</sup> HCV is an RNA virus that cannot integrate into the host genome, but it does infect lymphocytes, and viral proteins have been detected in lymphoid cells in these patients.<sup>212</sup> It is not clear at this point whether HCV has transforming potential, or whether these neoplasms are antigen driven, similar to MALT type lymphomas.

The clinical course of LPL is indolent; in some European series it has been reported to be more aggressive than typical B-CLL,<sup>213,214</sup> but in the REAL clinical study, 5-year overall actuarial survival (58%) and failure-free survival (25%) were identical to that of CLL/SLL.<sup>126</sup> The traditional therapy for this disorder has been chlorambucil with or without prednisone.<sup>215</sup> Anthracycline-based combination chemotherapy has not been shown to be more effective. However, fludarabine and cladribine<sup>216,217</sup> are active as single agents. Combinations including fludarabine are now being studied.

### ***Extranodal Marginal Zone B-Cell Lymphoma (Low-Grade B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue)***

**DEFINITION.** Extranodal marginal zone B-cell lymphoma is defined as an extranodal lymphoma consisting of heterogeneous small B cells, including marginal zone (centrocyte-like) cells, monocytoid cells, and small lymphocytes in varying proportions, and scattered immunoblast- and centroblast-like cells, with plasma cell differentiation in 40% of the cases. The infiltrate is in the marginal zone of reactive B-cell follicles and extends into the interfollicular region.

**MORPHOLOGY.** Extranodal marginal zone B-cell (MALT) lymphoma reproduces the morphologic features of normal MALT. It is characterized by a polymorphous infiltrate of small lymphocytes, marginal zone (centrocyte-like) B cells, monocytoid B cells, and plasma cells, as well as rare large basophilic blast cells (centroblast- or immunoblast-like). Reactive follicles are usually present, with the neoplastic marginal zone or monocytoid B cells occupying the marginal zone, the interfollicular region, or both; occasional follicles may be *colonized* by marginal zone or monocytoid cells. In epithelial tissues, the marginal zone B cells typically infiltrate the epithelium, forming so-called lymphoepithelial lesions.<sup>218</sup> While blast cells are typically present, they are by definition in the minority. Clusters or sheets of blasts sufficiently large to warrant a diagnosis of large cell lymphoma are associated with a worse prognosis. In these cases, a separate diagnosis of diffuse large B-cell lymphoma should be made. The term *high-grade MALT lymphoma* should be avoided for large B-cell lymphomas in MALT sites, since it may lead to inappropriate treatment with antibiotics instead of aggressive antilymphoma therapy.<sup>130</sup>

**IMMUNOPHENOTYPE.** The tumor cells express SIg (M greater than G greater than A), lack IgD, and 40% to 60% have monotypic cytoplasmic Ig, indicating plasmacytoid differentiation. They express B-cell–associated antigens (CD19, CD20, CD22, CD79a) and are usually negative for CD5 and CD10. Immunophenotyping studies are useful in confirming malignancy (light-chain restriction) and in excluding B-CLL (CD5+), mantle cell (CD5+), and follicle center (CD10+ CD43–, CD11c–, usually clg–) lymphomas.<sup>164,219</sup>

**GENETIC FEATURES.** Ig genes are rearranged, and the variable region has a high degree of somatic mutation, as well as intraclonal diversity consistent with a post–germinal center stage of B-cell development.<sup>220,221 and 222</sup> Ig heavy-chain variable regions in the analyzed cases are those often found in autoantibodies,

consistent with prior studies showing that the antibodies produced by the tumor cells have specificity against self-antigens such as endothelial cells.<sup>222</sup> The bcl-1 and bcl-2 genes are germline<sup>223</sup>; trisomy 3 (60%) and t(11;18) (25% to 40%) are the most common reported cytogenetic abnormalities.<sup>224,225 and 226</sup> Interestingly, neither of these abnormalities is common in primary large cell lymphomas of the gastrointestinal tract.<sup>226,227</sup> Analysis of the t(11;18) breakpoint has shown fusion of the apoptosis-inhibitor gene AP12 to a novel gene at 18q21, named *MLT*, in two cases of MALT lymphoma.<sup>228</sup> A gene involved in a breakpoint in MALT lymphomas with t(1;14) has been cloned; named *BCL-10*, it is an apoptosis-promoting gene that in mutated form may cause cellular transformation.<sup>229</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is a post-germinal center B memory cell with capacity to differentiate into marginal zone, monocytoid, and plasma cells.

**CLINICAL FEATURES.** Extranodal marginal zone B-cell (MALT) lymphoma accounts for the majority of low-grade gastric lymphomas and almost 50% of all gastric lymphomas<sup>230</sup>; in other sites, such as the ocular adnexa, they make up approximately 40% of the cases,<sup>134</sup> and they account for the majority of low-grade pulmonary lymphomas.<sup>231</sup> Patients are usually older adults, although they may be in their 20s and 30s. A slight female predominance has been reported in some series.<sup>164</sup> The majority of patients present with localized stage I or II extranodal disease, involving glandular epithelial tissues of various sites. The stomach is the most frequent site, but most low-grade lymphomas (and former pseudolymphomas) presenting in the lung, thyroid, salivary gland, and orbit are of this type; skin and soft tissues may also be the presenting site. Many patients have a history of autoimmune disease, such as Sjögren's syndrome or Hashimoto's thyroiditis, or of *Helicobacter* gastritis in the case of gastric MALT lymphoma. *Acquired MALT* secondary to autoimmune disease or infection in these sites is thought to be the substrate for lymphoma development.<sup>232</sup>

Proliferation of the cells of marginal zone lymphoma at certain sites depends on the presence of activated, antigen-driven T cells; in gastric tumors, it has been shown that the T cells are driven by *Helicobacter pylori* antigens.<sup>89</sup> Therapy directed at the antigen (*Helicobacter pylori* in gastric lymphoma) results in regression of most early lesions.<sup>233,234</sup> The long-term prognosis of these patients is not known, however, and patients treated with antibiotic therapy require long and careful follow-up. The disease known as *Mediterranean abdominal lymphoma*, a *heavy-chain disease*, and *immunoproliferative small intestinal disease*, which occurs in young adults in eastern Mediterranean countries, is another example of a MALT type lymphoma that may respond to antibiotic therapy in its early stages.<sup>235</sup>

#### THErapy OF MUCOSA-ASSOCIATED LYMPHOID TISSUE LYMPHOMAS.

*Nodal and Extranodal Marginal Zone B-Cell Non-Hodgkin's Lymphoma (Mucosa-Associated Lymphoid Tissue).* The indolent extranodal lymphomas associated with MALT involve the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, lung, and less commonly other sites. As these diseases tend to remain localized for long periods of time, local treatment (surgery or local or regional irradiation) is effective at long-term control of disease and provides the opportunity for cure. In particular, low doses of radiation therapy (RT; 30 Gy) almost always control sites of disease. These doses are somewhat lower than used for patients with localized follicular grade 1 and 2 disease. Data regarding irradiation of gastric MALT suggest that doses above 30 Gy are probably not needed.<sup>236</sup>

The use of chemotherapy for MALT lymphomas has received limited attention as this indolent NHL does not routinely require the use of systemic treatment in patients with early-stage disease. In one study of 24 patients with low-grade MALT treated with daily cyclophosphamide or chlorambucil for 12 to 24 months, the complete response rate at 1 year was 75% and approximately 50% continued to be in remission at the time of the study.<sup>237</sup> Although these results are favorable, control of limited disease is superior with RT, and the use of chemotherapy should be limited to patients with advanced-stage disease.

One-half or more of patients with gastric NHL have the indolent MALT type. The optimal treatment of gastric MALT lymphoma remains to be determined. Gastric MALT lymphoma is frequently associated with chronic gastritis and *H pylori* infection. Based on clinical observations, it has been postulated that *H pylori* infection leads to the accumulation of MALT in the stomach, and that gastric MALT lymphomas arise within this *acquired MALT* tissue. This has prompted speculation that eradication of the *H pylori* infection might lead to tumor regression. Promising early results have been seen with the use of antibiotics for gastric MALT NHL. In one study from the German MALT Lymphoma Group, 33 patients with low-grade MALT were treated with antibiotics. At 1-year median follow-up more than 70% of patients remained in complete remission.<sup>238</sup> However, in a follow-up study, 22 of 31 patients in continuous complete remission (median follow-up, 16 months) had a monoclonal B-cell population on PCR analysis, leaving open the question of durability of complete response after antibiotics.<sup>239</sup> Nonetheless, the standard treatment for patients with gastric MALT who are positive for *H pylori* is antibiotics and follow-up endoscopy 3 and 6 months later. Patients who have a complete response should be followed without further treatment. Patients who have a partial response and remain *H pylori* positive should receive a second course of antibiotics before proceeding to more definitive treatment.

Patients who are negative for *H pylori* may be less likely to respond to antibiotics than *H pylori*-positive patients; initial treatment of *H pylori*-negative patients with antibiotics remains under study.<sup>240</sup> For patients who have persistent disease after antibiotics, local regional irradiation therapy is the treatment of choice. Good results have been obtained with total or partial gastrectomy; however, this approach has been associated with long-term morbidity. Local and regional radiation through the three-field approach (anterior and two lateral fields to minimize radiation to the left kidney) provides local control and relief of symptoms in greater than 90% of patients. Although more information is needed, 30 Gy appears sufficient to control disease in most patients.<sup>236</sup>

More than 80% of patients with pulmonary NHL have indolent histology; nearly 80% of these are MALT.<sup>241</sup> The 5-year survival of patients with pulmonary MALT is greater than 90%. Often surgery is the initial treatment for patients with pulmonary MALT; however, development of recurrent disease is common and moderately low-dose RT has the potential to provide durable remissions. Gastrointestinal MALT is less common than gastric MALT. Approximately 25% of patients with gastrointestinal NHL have MALT. Few data exist on the success of treatment of these patients. The most common sites are the jejunum and the ileocecum.

Patients with MALT in the salivary glands may have a history of Sjögren's disease. Because these patients often have symptoms of mild xerostomia and low doses of RT worsen the xerostomia, we recommend that the radiation fields be limited to the ipsilateral salivary gland region and draining nodes to spare as much of the remaining salivary tissue as possible.

Lymphomatous involvement occurs in the orbit and in the conjunctiva with approximately equal frequency, accounting for between 5% and 14% of all extranodal presentations. These locations should be considered individually as they are often histologically distinct and have different natural histories. Conjunctival lymphoma tends to be localized, but may be associated with advanced disease. Due to its infiltrative nature, conjunctival lymphoma recurs with a high frequency following surgical excision alone. Surgery is used for diagnosis, but local RT to the entire conjunctiva is the definitive treatment of choice. Treatment of conjunctival lymphoma can be accomplished with either electrons or with photons. We generally use electrons as the lens can be protected with daily placement of a tungsten eyeshield. Dunbar and colleagues from the Massachusetts General Hospital have recommended doses of 24 to 30 Gy for patients with conjunctival lymphoma. They saw no local recurrences in a series of 12 patients treated with electron-beam RT.<sup>242</sup>

CT scanning and MRI are useful for the evaluation of the extent of disease and important for radiation treatment planning when the orbit is involved. Various treatment field arrangements can be employed depending on the location of the disease (i.e., disease limited to the anterior portion of the orbit, involving both eyes, or involving the lacrimal glands). In treatment of orbital NHL in contrast to conjunctival NHL, it is not possible to block the lens and cataract development is more common. When disease is unilateral, a single anterior photon field can be used to avoid dose to the contralateral eye; however, this field produces a higher anterior dose and more dose than optimal to the lacrimal gland, resulting in a greater risk of some eye dryness. Alternatively, an anterior wedged pair can allow for better dose distribution within the tumor and less dose to normal tissues. Doses restricted to 30 to 36 Gy controls nearly 100% of indolent NHL of the orbit while maintaining a low risk of toxicity to the lacrimal glands and retina. With MALT lymphoma of the orbit, the dose can probably be reduced to 30 Gy.

MALT lymphomas can also be disseminated and present at an advanced stage in approximately one-third of cases.<sup>243,244 and 245</sup> Dissemination is usually to lymph nodes but can involve other extranodal sites. Patients with widespread MALT lymphoma should probably be treated in a manner similar to that described for follicular lymphoma.

#### **Nodal Marginal Zone B-Cell Lymphoma**

**DEFINITION.** Nodal marginal zone B-cell lymphoma is defined as a primary nodal lymphoma with features identical to lymph nodes involved by MALT lymphoma, but without evidence of extranodal disease. Monocytoid B cells may be prominent. This diagnosis should not be made in patients with MALT lymphoma at other sites, Sjögren's syndrome, or when another low-grade B-cell lymphoma (follicular, mantle cell) is present in the same node.

**MORPHOLOGY.** Tumors with morphologic features identical to those described for extranodal marginal zone (MALT type) lymphoma have occasionally been reported

with isolated or disseminated nodal involvement, in the absence of extranodal disease.<sup>246,247</sup> Most reported cases of nodal monocytoid B-cell lymphoma have been in patients with Sjögren's syndrome and thus represent nodal involvement by a MALT type lymphoma of the salivary gland.<sup>248,249</sup> Others have been reported as *composite* lymphomas with other histologically low-grade lymphomas, chiefly follicular lymphoma. In these cases, however, this phenomenon represents focal differentiation to marginal zone or monocytoid B cells and not a true composite lymphoma; these cases should be classified as follicular lymphoma (see [Follicular Lymphoma](#), later in this chapter).<sup>250</sup> Nonetheless, there are occasional cases that do not appear to be associated with other types of lymphoma. Two morphologic types have been described: cases that resemble MALT lymphoma and cases that more closely resemble splenic marginal zone lymphoma.<sup>251</sup> Those that resemble MALT lymphoma show aggregates of monocytoid B cells in a parafollicular, perivascular, and perisinusoidal distribution, with preserved germinal centers and mantle zones. Those that resemble SMZL had infiltrates of marginal zone cells surrounding reactive follicles with germinal centers, but with attenuated mantle zones.

**IMMUNOPHENOTYPE AND GENETIC FEATURES.** The cases that resembled splenic marginal zone lymphoma are reported to express IgD and to lack CD5, CD23, and cyclin D1. Those that resemble MALT lymphoma are IgD– and have an immunophenotype identical to those of extranodal marginal zone B-cell lymphoma (MALT).<sup>251</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is nodal monocytoid or marginal zone B cell.

**CLINICAL FEATURES AND THERAPY.** This is a rare disorder, accounting for 1% of the cases in the international study of the REAL.<sup>126</sup> The patients presented with isolated or generalized nodal disease; bone marrow was involved in 30%; rarely, peripheral blood may be involved.<sup>127,252</sup> However, when peripheral and blood involvement appears, it seems to have a poor prognosis.<sup>253</sup> The cases reported by Campo and associates were predominantly localized at the time of the diagnosis.<sup>251</sup> Although elderly women with vocalized disease have been reported much more frequently, the disease appears in both genders, and patients with advanced stage are not infrequent. Transformation to large cell lymphoma occurs and has a poor prognosis.<sup>254</sup> Of those that resembled MALT lymphoma, 44% of those with follow-up had an extranodal lymphoma, whereas those resembling SMZL did not. The overall and failure-free survivals appear to be similar to those of follicular or SLLs.<sup>127</sup> The optimal therapy for patients with monocytoid B-cell lymphoma is not known. Patients are frequently treated with regimens that are used for follicular lymphoma.

### **Splenic Marginal Zone Lymphoma with or without Villous Lymphocytes**

**DEFINITION.** Splenic marginal zone lymphoma is defined as a neoplasm of small B lymphocytes that surround and replace splenic white pulp germinal centers, merging with an outer marginal zone of larger cells with pale cytoplasm admixed with large transformed blasts; both small and large cells infiltrate red pulp, often with villous lymphocytes in the peripheral blood.<sup>255</sup>

**MORPHOLOGY.** In the spleen, the neoplastic cells occupy both the mantle and marginal zone of the splenic white pulp, usually with a central residual germinal center, which may be either atrophic or hyperplastic.<sup>219,235,256</sup> Both the mantle and marginal zones are expanded. The cells in the mantle zone are small, with slight nuclear irregularity and scant cytoplasm, while those in the marginal zone have more dispersed chromatin and abundant pale cytoplasm, resembling marginal zone cells, and are admixed with centroblasts and immunoblasts. The red pulp is also involved, with both a diffuse and micronodular pattern and sinus infiltration. Epithelioid histiocytes may be present singly or in clusters and, particularly in the bone marrow, may give rise to the differential diagnosis of an infectious process. Splenic hilar lymph nodes are often involved; the neoplastic cells form vague nodules, often without a central germinal center, and a marginal zone pattern may or may not be present.<sup>257</sup> Sinuses are often open. The marrow usually contains discrete lymphoid aggregates, without a marginal zone pattern, with or without diffuse lymphoid infiltration. When tumor cells are present in the peripheral blood they often have abundant cytoplasm with small surface *villous* projections or may appear plasmacytoid.

**IMMUNOPHENOTYPE.** The tumor cells are IgM+, IgD+, CD5–, CD10–, CD43–, CD23–, express B-cell antigens (CD19, CD20, CD22) and bcl-2, and lack CD11c and CD25.<sup>235,258</sup> In the majority of cases, lack of CD5 serves to distinguish this disorder from B-CLL, and lack of CD103 and CD25 are useful in distinguishing it from hairy cell leukemia. The cells are cyclin D1 negative by immunoperoxidase staining.<sup>259</sup>

**GENETIC FEATURES.** Analysis of the Ig variable region genes indicates a high degree of somatic mutation, consistent with a post-germinal center stage of B-cell development.<sup>260</sup> More recently, ongoing mutations of V region genes, similar to germinal center cells, has been reported.<sup>261</sup> Bcl-2 is germline. Early reports that t(11;14)(q13;132), bcl-1 rearrangement, and cyclin D1 overexpression were common are now thought to have reflected inclusion of cases of leukemic mantle cell lymphoma.<sup>262,263</sup> Trisomy 3, found in nodal and extranodal marginal zone lymphoma, is detected in only a small number of cases.<sup>224,264</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is post-germinal center, memory B cell of splenic type.

**CLINICAL FEATURES AND THERAPY.** Splenic marginal zone lymphoma accounts for only 1% to 2% of chronic lymphoid leukemia found on bone marrow examination, but up to 25% of low-grade B-cell neoplasms in splenectomy specimens.<sup>235,256,265,266</sup> It may make up the majority of chronic B-cell leukemia and low-grade splenic lymphomas that do not fit the defining criteria of B-CLL, lymphoplasmacytic lymphoma, mantle cell lymphoma, follicular lymphoma, or hairy cell leukemia. Patients typically present with weakness, fatigue, or symptoms related to splenomegaly.<sup>267</sup> Physical examination revealed splenomegaly in almost all patients, hepatomegaly in up to 40% of patients, but lymphadenopathy is rare.<sup>267</sup> Lymphocytosis is a uniform finding, but extreme lymphocytosis is unusual. Anemia and thrombocytopenia are present in a minority of patients. In some series more than one-half of the patients have been shown to have a monoclonal Ig.<sup>267</sup> Although most commonly seen in elderly men, the disease can be seen in both genders and in young patients.<sup>267,268</sup> and <sup>269</sup> Although the disease is usually confined to the spleen, bone marrow, and blood, unusual sites of involvement such as leukemic meningitis<sup>270</sup> have been described.

Most patients have an indolent course and require no immediate therapy or respond to splenectomy.<sup>267,269,271</sup> However, transformation to a large cell lymphoma with an aggressive course can be seen in some patients.<sup>267,272</sup> For patients in whom splenectomy is inappropriate, splenic radiation can be an alternative.<sup>267,269</sup> Oral alkylating agents appear to be marginally effective.<sup>269</sup> One report described four patients who achieved a complete remission with fludarabine.<sup>273</sup>

### **Follicular Lymphoma**

**DEFINITION.** Follicular lymphoma is a lymphoma of follicle center B cells (centrocytes and centroblasts), which has at least a partially follicular pattern.

**MORPHOLOGY.** The tumor is composed of follicle center cells, usually a mixture of centrocytes (cleaved follicle center cells) and centroblasts (large noncleaved follicle center cells). Centrocytes typically predominate; centroblasts are usually in the minority, but by definition are always present. Rare lymphomas with a follicular growth pattern consist almost entirely of centroblasts. Occasional cases may show plasmacytoid differentiation or foci of marginal zone or monocytoid B cells.<sup>254</sup> The proportion of centroblasts varies from case to case, and the clinical aggressiveness of the tumor increases with increasing numbers of centroblasts. Numerous criteria have been proposed for grading follicular lymphoma. The WHO Classification is adopting the cell-counting method of Mann and Berard ( [Table 45.3-12](#) ).<sup>130,274</sup> In addition to typical follicular lymphoma, two variants are recognized whose relationship to follicular lymphoma remains controversial: cutaneous follicle center lymphoma and diffuse follicle center lymphoma.

FOLLICULAR LYMPHOMA	
<b>Grades</b>	
Grade 1:	0–5 centroblasts per high-power field
Grade 2:	6–15 centroblasts per high-power field
Grade 3:	>15 centroblasts per high-power field
3a:	>15 centroblasts, but centrocytes are still present
3b:	Centroblasts form solid sheets with no residual centrocytes
<b>Variants</b>	
Cutaneous follicle center lymphoma	
Diffuse follicle center lymphoma	
Grade 1:	0–5 centroblasts per high-power field
Grade 2:	6–15 centroblasts per high-power field
<b>MANTLE CELL LYMPHOMA</b>	
Variant: blastoid	

**TABLE 45.3-12.** Follicular and Mantle Cell Lymphomas: Grading and Variants

**IMMUNOPHENOTYPE.** The tumor cells of follicle center lymphoma are usually SIg+; approximately 50% to 60% express IgM; approximately 40% express IgG; and rare cases express IgA. The tumor cells express pan-B-cell-associated antigens, approximately 60% are CD10+, and they are CD5–, CD23–/+, CD43– (most cases), and CD11c–. Tightly organized mesh works of FDCs are present in follicular areas. <sup>198,275</sup> Most cases are bcl-2+, and nuclear bcl-6 is expressed by at least some of the neoplastic cells. <sup>276,277</sup> The Ki-67+ fraction is lower than that of reactive follicles.

**GENETICS.** Ig heavy and light-chain genes are rearranged, and analysis of the Ig variable region genes shows that most cases have extensive somatic mutations and a high frequency of intraclonal diversity, indicating ongoing mutations, similar to normal germinal center cells. <sup>278,279</sup> t(14;18) and bcl-2 gene rearrangement are present in the majority of the cases.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is germinal center B cells, both centrocytes (small cleaved follicular center cells) and centroblasts (large noncleaved follicular center cells).

**CLINICAL FEATURES.** Follicular lymphoma is the second most common lymphoma in the United States and western Europe, accounting for 20% of all NHLs and up to 70% of low-grade lymphomas reported in American and European clinical trials. <sup>7,126</sup> Thus, our understanding of the clinical features and response to treatment of *low-grade lymphoma* is essentially that of follicular lymphoma. Follicular lymphoma affects predominantly older adults, with a slight female predominance. <sup>126,280</sup> Most patients have widespread disease at diagnosis, usually predominantly lymph nodes, but also spleen, bone marrow, and occasionally peripheral blood or extranodal sites. Despite the advanced stage, the clinical course is generally indolent, with median survivals in excess of 8 years; however, the disease is not usually curable with available treatment. In the international study of the REAL, the few patients (7%) with International Prognostic Index scores of 4/5 have a much worse prognosis, with a median survival of only 1 year. <sup>126</sup> In that study, cases with monocytoid B-cell differentiation had a worse prognosis than other cases. <sup>250</sup>

**THERAPY OF LOCALIZED FOLLICULAR LYMPHOMA.** There are a number of questions regarding RT and follicular grade 1 and 2 NHL. Is follicular grade 1 and 2 NHL curative with RT alone? (Yes.) What is the frequency of recurrence after 10 years? (Only approximately 10%.) Are there prognostic factors for recurrence? (Yes, age is the most influential.) What is the extent and dose of RT needed? What are the late effects of treatment? What is the role of CT in early-stage low-grade NHL? Many published studies have demonstrated the efficacy of RT in the treatment of clinically staged patients with localized follicular small cleaved cell NHL. Patients with early-stage disease are curable with local regional irradiation. The updated series from Stanford University details the results of RT in 177 patients treated from 1961 to 1994. <sup>281</sup> Out of 177 patients, 73 were stage I and 104 had stage II disease. Staging laparotomy was performed in 25% of patients and 20% of patients had extranodal presentations. Total nodal irradiation (TLI) and subtotal nodal irradiation were given to 41 patients, and involved-field or extended-field irradiation was delivered to 133 patients. Staging laparotomy and TLI were used in the early years of the study. Histology was follicular grade 1 in 57% of cases and follicular grade 2 to 3 in 43% of patients. The median follow-up was 7.7 years. The 10-year, 15-year, and 20-year survivals were 64%, 44%, and 35%, respectively. The 10-year, 15-year, and 20-year disease-free survivals were 44%, 40%, and 37%, respectively. Only 5 of 47 patients in remission for 10 years or longer have relapsed at longer intervals. This study demonstrates that a substantial percentage of patients with early-stage follicular small cleaved cell NHL never have recurrence of disease following local regional irradiation.

Several other series using local regional radiation demonstrate similar results and are shown in [Table 45.3-13](#). All the series demonstrate greater than a 40% freedom from treatment failure at 10 years. Median survival ranges from 13 to 16 years in the studies. Prognostic factors for relapse were analyzed. <sup>281,282,283,284</sup> and <sup>285</sup> Age in all studies was a significant adverse factor for relapse. Although most studies use age under and over 60, the British National Lymphoma Investigation (BNLI) study found no difference in relapse for patients in their 50s or 60s and only age 70 or greater was an adverse factor. <sup>284</sup> Other significant but less important prognostic factors for increasing recurrence risk include extranodal disease, female gender, and stage II disease. There appears to be little difference in outcome between follicular grade 1 and follicular grade 2 disease.

Center	No. of Patients	Stage	Freedom from Recurrence	Median Survival	Grade
Princess Margaret Hospital	58	I-II	45% at 10y	13y	Follicular grade 1-2
British National Lymphoma Investigation	59	I	45% at 10y	16y	Follicular grade 1-2
Stanford University	177	I-II	45% at 10y	13y	Follicular grade 1-2
Royal Marsden Hospital	31	I-II	45% at 10y	20y	Follicular grade 1-2

**TABLE 45.3-13.** Radiation Therapy Alone for Early-Stage, Low-Grade Follicular Non-Hodgkin's Lymphoma

The techniques of RT (field arrangement and size and dose) in the treatment of NHL are guided by the histologic subtype, the stage of disease, and the patterns of failure. Early-stage indolent lymphomas treated with RT alone have been shown to relapse in extranodal sites or in nodal sites distant from the radiation fields when involved-field or extended-field RT has been used. This observation led some to recommend TLI for patients with follicular small cleaved cell NHL. Several factors, however, argue against the use of such extensive RT for patients with early-stage indolent disease. On multivariate analysis, for patients with stage I to II disease, there is no evidence that the use of extended-field or TLI provided for a survival advantage compared with involved-field or regional irradiation in the Stanford study. There are concerns for increased toxicity with larger RT fields and the possibility that subsequent treatment, if needed, will be compromised as more than 50% of stage I to II patients eventually develop a recurrence and require more aggressive treatment. In addition, there is a high conversion rate of follicular small cleaved cell NHL to a more aggressive histology over time, requiring treatment with chemotherapy. <sup>286,287</sup> Prior treatment with TLI may compromise marrow reserve and limit subsequent multiagent chemotherapy given either for recurrent indolent NHL or for NHL transformed to a more aggressive histology. Also, there appears to be an increased risk of late complications including second cancers with large-field irradiation. <sup>281</sup>

There are no large prospective or randomized studies evaluating the dose and field size of RT for patients with stage I to II follicular small cleaved cell NHL. However, most centers use radiation doses between 30 and 40 Gy, and either involved-field irradiation or regional fields. Current recommendations include the use of regional RT fields. This consists of irradiating the involved nodal region plus one additional uninvolved region on each side of the involved nodes. For example, the treatment field for lymphoma of the inguinal nodes would include the ipsilateral femoral, inguinal, and external iliac nodes. The treatment of a stage I lymphoma of the right supraclavicular nodes would include the ipsilateral axilla, supraclavicular, and cervical nodes. The cervical, supraclavicular, oropharyngeal, and nasopharyngeal nodes would be irradiated in patients with involvement of Waldeyer's ring. The recommended dose for patients with follicular small cleaved cell NHL is 3000 to 3600 cGy, with a boost to areas of initial involvement to 36 to 40 Gy. When there is a possibility of significant morbidity from treatment, such as long-term xerostomia from irradiation of the salivary glands, lower doses to the uninvolved nodal areas are recommended (i.e., 25 to 30 Gy).

The role of combination chemotherapy in the management of early-stage follicular lymphoma is unclear. At least three randomized studies conducted in the 1970s failed to demonstrate that non-adriamycin-containing combination chemotherapy regimens plus RT were superior to RT alone. <sup>288,289</sup> and <sup>290</sup> A more recent BNLI study randomized 148 patients to receive either RT alone or RT plus chlorambucil chemotherapy. <sup>291</sup> There were no differences in freedom from recurrence or survival between the groups. A single-arm study of 91 stage I and II patients treated at the M. D. Anderson Cancer Center with cyclophosphamide, vincristine, and prednisone (COP) or cyclophosphamide, doxorubicin, vincristine, and prednisone-bleomycin (CHOP-Bleo) chemotherapy in addition to RT demonstrated an improved freedom from recurrence compared with historic controls but no overall survival differences. <sup>292,293</sup> In part, the choice of therapy may lie in the careful assessment of prognostic factors. Most patients with Ann Arbor clinical stage I or II follicular small cleaved cell and follicular mixed lymphomas should have a good prognosis following local regional RT alone. For patients whose prognosis is less certain, such as patients with stage II disease with multiple sites of involvement or bulky nodes, or patients with follicular large cell histology, chemotherapy followed by involved-field irradiation may provide more durable remissions.

**THERAPY OF DISSEMINATED FOLLICULAR LYMPHOMA.** The optimal treatment strategy for patients with advanced-stage follicular lymphoma is controversial. <sup>294</sup> Treatment has followed one of two divergent approaches: an aggressive approach that may include extensive RT, combination chemotherapy, or both; and a conservative approach that consists of no initial treatment followed by a palliative single-agent chemotherapy or involved-field radiotherapy when treatment is needed. Although many years of clinical investigation have failed to prove that immediate aggressive therapy improves survival compared with conservative therapy, <sup>294</sup> the median survival of only 7 to 8 years from diagnosis in patients with stage III and IV disease has prompted the continuation of aggressive treatment approaches. <sup>295,296 and 297</sup> Despite the indolent nature of the follicular lymphomas, most patients ultimately die of their disease. Of 147 previously untreated patients enrolled at St. Bartholomew's Hospital in various protocols, ranging from no initial therapy to conservative treatment with single alkylating agents, only 53 of 147 patients remain alive; 94 patients have died, and only 18 patients died from causes unrelated to lymphoma. <sup>296</sup>

RT in the treatment of patients with stage III and IV follicular lymphoma serves two roles, as palliative treatment and as part of a potentially curative approach in clinical trials. RT has much to offer as a palliative approach. For patients with isolated disease that has returned after remission or has not responded as well as other sites to chemotherapy, involved-field irradiation can allow for patients to go significant periods of time without the need for additional combination therapy. In addition, follicular lymphoma can produce troubling symptoms through bone or spine involvement, through pressure on peripheral nerves, by disfigurement via large neck or axillary nodes, by intraorbital involvement, and through many other mechanisms. Follicular lymphoma is sensitive to RT, and often nodes resistant to chemotherapy begin to shrink after four to five radiation treatments. Sometimes even a large volume of lymph nodes can be encompassed because the low doses of radiation needed results in minimal toxicity to normal tissues.

As a curative approach, TLI combined with chemotherapy has been used for the treatment of stage III patients in past studies. McLaughlin and colleagues reported on the use of CHOP chemotherapy and TLI in 74 patients with follicular lymphomas. The relapse-free survival at 5 years was 52%. This study did not provide sufficient evidence that patients were cured with this approach. <sup>298</sup> The National Cancer Institute initiated a prospective randomized study comparing conservative treatment (no initial therapy) with aggressive combined modality therapy with ProMACE/MOPP chemotherapy followed by low-dose (24 Gy) total lymphoid RT. <sup>299</sup> Eighty-nine patients were randomized. The disease-free survival was significantly higher in the combined modality therapy group at 4 years (51% vs. 12%); however, no differences in overall survival were seen. As these studies have failed to show a survival advantage for an initial aggressive approach in the management of patients with advanced-stage indolent lymphomas, new high-dose chemotherapy approaches are being developed that for the most part do not include the use of TLI.

When a decision is made to treat a patient with disseminated follicular lymphoma using cytotoxic chemotherapeutic agents, a wide variety of choices is available. These include single-agent chlorambucil, cyclophosphamide, or fludarabine, or popular combination chemotherapy regimens such as cyclophosphamide, vincristine, and prednisone (CVP), CHOP, and fludarabine, mitoxantrone, and dexamethasone (FND). Each of these approaches produces objective responses in a high proportion of patients with previously untreated follicular lymphoma. <sup>300,301,302,303 and 304</sup> In general, complete responses occur more rapidly with combination chemotherapy regimens, but it is unclear that the ultimate treatment result is superior with combinations. Approximately 20% of complete responders remain in remission for longer than 10 years. <sup>294</sup>

Patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete. <sup>305</sup> Spontaneous regressions appear most frequently in patients with predominantly follicular small cleaved cell lymphoma and least frequently in patients with follicular large cell lymphoma.

Interferon- $\alpha$  has long been known to be an active drug in the treatment of patients with follicular lymphoma and has an objective response rate of 30% to 55% when used as a single agent with relapsed disease. <sup>306,307 and 308</sup> The value of adding interferon to standard combination chemotherapy regimens has been tested in a number of clinical trials. <sup>309,310,311,312,313,314,315 and 316</sup> The dose and duration of administration of interferon- $\alpha$  varied among these studies. A significant increase in remission duration was observed in several studies, <sup>311,312 and 313,315,316</sup> and a prolongation of survival was found in one setting. <sup>312</sup> A metaanalysis of eight of the randomized trials incorporating 1756 patients has been initially reported. <sup>317</sup> This analysis found an improvement in overall survival in patients who received an anthracycline-containing chemotherapy regimen and received a dose of interferon of at least 36 MU/month.

The activity of rituximab in patients with relapsed follicular lymphoma has led to its incorporation into the initial treatment and has produced encouraging results. <sup>318</sup> Use of the radiolabeled monoclonal antibody tositumomab in previously untreated patients has also been reported to produce a high complete response rate. Two trials of autologous hematopoietic stem cell transplantation incorporated in the primary therapy of patients with follicular lymphoma have reported high complete response rates, but the observation period is too short to know if a subset of these patients will be cured. <sup>319,320</sup>

The importance of determining what has been called a molecular response in patients receiving primary therapy for follicular lymphoma has been studied. A molecular response refers to disappearance of previously apparent bcl-2 gene rearrangements detected by the PCR in the blood or bone marrow. Most studies have found a better disease-free survival in patients achieving a molecular remission. <sup>321,322 and 323</sup> At the present time, determining the molecular response is an important research tool, but since prolonged remissions have been reported in patients who are persistently positive <sup>321</sup> the practical clinical utility of this measurement is uncertain.

The subdivision of patients with follicular lymphoma into those with predominantly small cells (follicular small cleaved cell), those with an intermediate number of small and large cells (follicular mixed), and those with more large cells (follicular large cell) is difficult. <sup>126</sup> However, even considering the imprecision of the distinction, patients classified as follicular large cell lymphoma have a shorter remission duration and overall survival than patients with the other subtypes. <sup>126</sup> The incorporation of an anthracycline into the initial treatment regimen seems to be more important in patients with follicular large cell lymphoma. <sup>302,324,325</sup> A subset of patients with follicular large cell lymphoma who receive an intensive chemotherapy regimen can achieve long-term disease-free survival. <sup>326</sup>

**SALVAGE THERAPY.** Most patients with follicular lymphoma, despite complete response to initial chemotherapy, relapse and are candidates for salvage treatment. However, unlike the situation with diffuse large B-cell lymphoma or other aggressive NHLs, patients with relapsed follicular lymphoma do not necessarily pursue an aggressive course. In an asymptomatic patient, particularly if the patient is elderly, observation without treatment can be an acceptable option. In a patient with follicular lymphoma who relapses with transformation to a diffuse large B-cell lymphoma, however, treatment is almost always indicated. The majority of patients with follicular lymphoma undergoes transformation to diffuse large B-cell lymphoma. This transformation is clinically recognized in approximately 40% of patients, but present in autopsy in almost 100% of patients. <sup>327</sup> The clinical manifestations of histologic transformation to diffuse large B-cell lymphoma typically include rapidly progressive lymphadenopathy (i.e., often localized); the development of new symptoms such as fevers, night sweats, weight loss, and pain; or both. In general, histologic transformation to diffuse large B-cell lymphoma has a poor prognosis and frequently a rapidly fatal outcome. However, some patients can have complete responses to salvage chemotherapy regimens and achieve durable complete remissions. <sup>328</sup> These patients are typically left with persisting follicular lymphoma.

A wide variety of second-line chemotherapy regimens has been used in patients with follicular lymphoma. In addition to repeating standard front-line regimen, purine analogues such as fludarabine <sup>329</sup> and cladribine <sup>330</sup> are often used. However, even when the initial therapy is repeated, patients with follicular lymphoma often respond. In one series using chlorambucil, the response rate was 68% for the second course of therapy in contrast to 70% in the initial treatment. <sup>331,332</sup>

A variety of other treatment approaches has been used in patients with relapsed follicular lymphoma. Interferon- $\alpha$  used as a single agent has a 30% to 55% response rate. <sup>306,307 and 308</sup> The monoclonal antibody rituximab produces objective responses in 35% to 50% of patients with relapsed follicular lymphoma. <sup>333</sup> Radiolabeled antibodies also directed against CD20 have even higher response rates in patients with relapsed follicular lymphoma. <sup>334,335</sup> Other treatments such as use of antisense molecules <sup>336</sup> and tumor vaccines <sup>337</sup> have also been shown to produce objective responses.

Both autologous and allogeneic hematopoietic stem cell transplantations have been used for patients with relapsed follicular lymphoma. Both purged <sup>338,339</sup> and unpurged <sup>340,341</sup> autologous stem cell products have been used. The value of purging, particularly when blood stem cell products are used, remains uncertain. Autologous transplantation in patients with relapsed follicular lymphoma produces remissions durable for 5 years in approximately 50% of patients who are transplanted at the time of initial treatment failure. <sup>339,340 and 341</sup> Patients transplanted after multiple treatment failures have a poorer outcome. Use of allogeneic bone marrow transplantation is associated with a much higher treatment-related mortality and a lower relapse rate. <sup>342</sup>

## **Mantle Cell Lymphoma**

**DEFINITION.** A mantle cell lymphoma is a neoplasm of monomorphic small to medium-sized B cells with irregular nuclei, which resemble the cleaved cells (centrocytes) of germinal centers and overexpress cyclin D1; neoplastic transformed cells (centroblasts or immunoblasts) are absent. Tumor cells are typically CD5+

CD23–.

**MORPHOLOGY.** The pattern of mantle cell lymphoma may be either diffuse, nodular, or mantle zone, or a combination of the three. Some reports indicate a better prognosis for cases with a mantle zone pattern.<sup>343</sup> Most cases are composed exclusively of small to medium-sized lymphoid cells, with slightly irregular or *cleaved*, nuclei; however, the morphology in various cases can range from lymphocyte-like to large cleaved or lymphoblast-like.<sup>160,164,344,345</sup> and <sup>346</sup> Despite the small size and bland appearance, there is often more mitotic activity than in other histologically low-grade lymphomas. Single epithelioid histiocytes may be present, but clusters and granulomas are not seen. Transformed cells with basophilic cytoplasm (centroblast- or immunoblast-like cells) are extremely rare or absent.

**IMMUNOPHENOTYPE.** The tumor cells express strong SIgM and IgD, which is often of I light-chain type, strongly express B-cell-associated antigens, and coexpress CD5, similar to B-CLL/SLL, but are CD23–. Rare cases may be CD5– or CD23+.<sup>363,363a</sup> In contrast to follicle center lymphoma, mantle cell lymphoma are usually CD10– and CD43+. A prominent, irregular mesh work of FDCs is found, even in diffuse cases.<sup>164,198,275</sup> The product of the cyclin D1 gene can be detected in the nuclei of neoplastic mantle cells in paraffin-embedded tissue sections with the immunoperoxidase technique and is useful in distinguishing mantle cell lymphoma from other low-grade B-cell lymphomas.<sup>173,347</sup>

**GENETIC FEATURES.** Ig heavy and light-chain genes are rearranged. The Ig V region genes lack somatic mutations, indicating a pre-germinal center stage of differentiation, consistent with an origin from the follicle mantle.<sup>348</sup> A t(11;14) in the majority of the cases results in overexpression of a gene known as PRAD1 or cyclin D1, which encodes a cell-cycle-associated protein that is not normally expressed in lymphoid cells.<sup>173,349,350</sup> The protein is overexpressed even in cases lacking the t(11;14), suggesting that point mutations may also result in overexpression.<sup>351,352</sup> Overexpression of this protein may explain the often high mitotic index and aggressive clinical course of this histologically low-grade lymphoma. Studies have shown abnormalities in expression of other genes associated with the cell cycle, including mutations of the cdk inhibitors p16 and p17 in blastoid variants and decreased expression of p27, another cdk inhibitor, in the majority of the cases.<sup>353</sup> Cases of the blastoid variant have been reported to have a high incidence of tetraploidy and p53 gene mutations.<sup>354,355</sup> and <sup>356</sup> Acquisition of a myc translocation has been reported in some fatal cases.<sup>357</sup>

**POSTULATED NORMAL COUNTERPART.** Mantle cell lymphoma corresponds to a naive B cell of follicle mantle or germinal center origin that is distinct from both the recirculating B cell of B-CLL/SLL and the later centrocyte of follicle center lymphomas.<sup>179,198</sup>

**Clinical Features.** Mantle cell lymphoma accounts for approximately 7% of adult NHLs in the United States and Europe.<sup>126,160</sup> In a review of 376 cases of disseminated low-grade lymphoma (Working Formulation categories A through E), mantle cell lymphoma made up 10% of the cases.<sup>358</sup> It is a tumor of older adults, with a marked male predominance (75%).<sup>126</sup> The majority (70%) of patients are in stage IV at diagnosis; sites involved include lymph nodes, spleen, Waldeyer's ring, bone marrow (greater than 60%), blood (up to 50%), and extranodal sites, especially the gastrointestinal tract (lymphomatous polyposis).<sup>359</sup> The course is moderately aggressive. The median overall survival in most series is 3 years, with no plateau in the curve, and failure-free survival is around 1 year.<sup>127</sup> The blastoid variant is reported in some studies to be more aggressive.<sup>126,358,360,361,362</sup> and <sup>363</sup>

**THERAPY.** Since mantle cell lymphoma was widely accepted as an entity in only the last decade, the number of therapeutic trials are not as extensive as for some other types of NHL. Localized mantle cell lymphoma is quite rare, seen in only 13% of unselected patients in one large series.<sup>127</sup> The failure-free survival of patients treated for localized mantle cell lymphoma is quite poor, suggesting that unrecognized dissemination was usually present. The optimal treatment for these patients is not known.

Most patients present with disseminated disease. Single-agent chemotherapy has been used less commonly than in other small cell lymphomas, with chlorambucil, fludarabine, and cladribine being the most commonly used agents. The most frequently used combination regimens have been CVP and CHOP. Overall response rates have ranged between 60% and 80% and complete response rates between 30% and 60%. A randomized trial comparing CVP and CHOP showed no significant difference in overall survival (84% vs. 88%) and failure-free survival (41% vs. 58%).<sup>360</sup> A new chemotherapy regimen that was originally used for patients with leukemia called hyper-CVAD (cyclophosphamide, vincristine, dexamethasone, and doxorubicin) has been used in mantle cell lymphoma and has a high response rate.<sup>364</sup> In an historic control study from M. D. Anderson Cancer Center, hyper-CVAD had a superior 3-year event-free survival to CHOP (72% vs. 28%).<sup>364</sup>

Because of the poor long-term outlook, patients with mantle cell lymphoma who are sufficiently young and healthy often undergo autologous or allogeneic bone marrow transplantation at best response.<sup>365,366,367</sup> and <sup>368</sup> The long-term benefits of autologous and allogeneic transplantation are still uncertain, although long-term survivors with both approaches are reported. Patients who relapse and are not candidates for transplantation or those who relapse can be treated with rituximab and interferon.

Monoclonal antibody therapy for patients with mantle cell lymphoma has been attempted with rituximab.<sup>369</sup> The antibody yielded a response rate of 33% in relapsed patients. Further trials will be necessary to define the place of rituximab in the management of patients with mantle cell lymphoma. Interferon- $\alpha$  has been used in the treatment of mantle cell lymphoma. In one randomized trial including 47 patients with mantle cell lymphoma, 22 patients received interferon and 25 patients did not.<sup>370</sup> The disease-free survival was 47% for the patients receiving interferon and 27% for the patients observed without therapy. However, the number of patients and the period of follow-up were not long enough to reach a firm conclusion.

### Diffuse Large B-Cell Lymphoma

**DEFINITION.** Diffuse large B-cell lymphoma is defined as a neoplasm of large, transformed B cells with prominent nucleoli and basophilic cytoplasm, with a diffuse growth pattern and a high (greater than 40%) proliferation fraction. The cells may resemble centroblasts, immunoblasts, multilobated cells, or anaplastic large cells. Rare cases contain only scattered large cells in a background of small T cells and epithelioid histiocytes (T-cell/histiocyte-rich large B-cell lymphoma).

**MORPHOLOGY.** Diffuse large B-cell lymphomas are probably a heterogeneous group of neoplasms. They are typically composed of large cells that resemble centroblasts or immunoblasts, most often with a mixture of the two. Several morphologic variants can be recognized, but their clinical significance is debated ( [Table 45.3-14](#) ).

Intravascular large B-cell lymphoma

---

**TABLE 45.3-14.** Morphologic Variants and Subtypes of Diffuse Large B-Cell Lymphoma

**Centroblastic Variant.** The monomorphic centroblastic (large noncleaved cell) type is composed of medium to large lymphoid cells with oval to round vesicular nuclei with fine chromatin and two to four membrane-bound nucleoli. The cytoplasm is generally scanty and amphophilic to basophilic. The multilobated centroblastic type contains many large lymphoid cells with nuclei having more than three lobes. A polymorphic type shows a mixture of centroblasts and immunoblasts and may contain up to 90% immunoblasts.

**Immunoblastic Variant.** Approximately 10% of the cases of diffuse large B-cell lymphomas have over 90% immunoblasts with a prominent central nucleolus and abundant, basophilic cytoplasm. Plasmacytoid differentiation may be present. These cases are more common in immunosuppressed patients. In nonimmunosuppressed patients, they have been reported to carry a worse prognosis.<sup>371</sup>

**Anaplastic Variant.** In some cases of diffuse large B-cell lymphomas, the cells are identical to those of T/null anaplastic large cell lymphoma and strongly express CD30 (Ki-1) as well as T-cell antigens. Although these have been called *B-cellanaplastic large cell lymphoma* (B-ALCL), they do not have the same distinctive clinical or genetic features of T/null-ALCL and are considered a morphologic variant of large B-cell lymphoma in the REAL/WHO classifications. The most significant differential diagnostic problem presented by such cases is with classical Hodgkin's disease expressing B-cell antigens.

**T-Cell–Rich/Histiocyte-Rich Large B-Cell Lymphoma.** Some cases of large B-cell lymphoma have a prominent background of reactive T cells and often histiocytes, so-called T-cell or histiocyte-rich large B-cell lymphoma. They may resemble Hodgkin's disease of either lymphocyte predominance or mixed cellularity type.<sup>372,373</sup> In contrast to those with Hodgkin's disease, patients with T-cell/histiocyte-rich large B-cell lymphoma typically present with disseminated disease involving the liver and spleen and have a poor survival. The relationship of this disease to lymphocyte-predominance, classical Hodgkin's disease, or both remains to be elucidated.

**Large B-Cell Lymphoma, Lymphomatoid Granulomatosis Type.** The entity described as *lymphomatoid granulomatosis*, which had been thought to be related to nasal or angiocentric lymphoma, has been shown in most cases to be an EBV+ large B-cell lymphoma with a T-cell–rich background.<sup>374,375,376</sup> and<sup>377</sup> The infiltrates show extensive necrosis, often with only a few atypical large B cells in a background of lymphocytes; the infiltrate may be both angiocentric and angioinvasive. Patients typically present with extranodal disease, most commonly involving lung, brain, kidneys, or all three. Evidence of past or present immunosuppression may be found. Although the infiltrates may resemble those of nasal or angiocentric lymphoma, there is no biologic and little clinical overlap, since the latter is an NK cell or T-cell neoplasm that involves the upper airway and midfacial region, skin, and sometimes the gastrointestinal tract, and rarely the lung or CNS.

**IMMUNOPHENOTYPE.** Diffuse large B-cell lymphomas express one or more B-cell–associated antigens (CD19, CD20, CD22, CD79a), as well as CD45, and often but not always, surface Ig. They may coexpress CD5 or CD10.<sup>198,378</sup> Twenty-five percent to 80% in various studies express bcl-2 protein, and this may be associated with a worse prognosis.<sup>379,380,381,382</sup> and<sup>383</sup> Approximately 70% express bcl-6 protein, consistent with a germinal center origin<sup>382,383</sup>; this expression is independent of bcl-6 gene rearrangement.

**GENETIC FEATURES.** Most cases of diffuse large B-cell lymphomas have somatic mutations in the Ig variable region genes.<sup>182,384</sup> The bcl-2 gene is rearranged in 15% to 30% of diffuse large B-cell lymphomas; it is associated with nodal and disseminated disease, but is not associated with either a worse prognosis or with bcl-2 expression.<sup>379</sup> The c-myc gene is rearranged in 5% to 15%,<sup>385,386</sup> and the bcl-6 gene is rearranged in 20% to 40% of cases<sup>386,387</sup> and shows mutations in the 5' noncoding region in 70%.<sup>388,389</sup> Both the 5' noncoding mutations of the bcl-6 gene<sup>390</sup> and the Ig variable region gene mutations are found in normal germinal center cells<sup>391</sup>; their presence in diffuse large B-cell lymphomas is consistent with a germinal center or post–germinal center stage of differentiation.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is proliferating peripheral B cells, centroblasts or immunoblasts in most cases.

**DIFFERENTIAL DIAGNOSIS.** For large B-cell lymphoma, as for most of the aggressive lymphomas, the major differential diagnosis is with a nonlymphoid tumor, including poorly differentiated carcinoma, germ cell tumor, glioma, melanoma, or sarcoma. Clinically, when patients present with lymphadenopathy, lymphoma is often at the top of the differential diagnosis, but in extranodal sites, lymphoma may not be suspected. Clinical features that tend to favor lymphoma in extranodal sites include the presence of multiple, noncontiguous lesions, characteristic radiographic findings (e.g., permeative lesions in bone, ring-enhancing lesions in the CNS), involvement of lymphoid organs, and systemic symptoms such as fever and weight loss.

Histologically, the most important factor in establishing the diagnosis is a high index of suspicion and a recognition of the morphologic spectrum of diffuse large B-cell lymphoma. In this differential diagnosis, immunoperoxidase stains on paraffin sections are usually definitive; however, a panel of several antibodies must be used (e.g., cytokeratin, EMA, CD45, pan-B and pan-T antigens, Ig light-chains, and if relevant, S-100 and HMB-45).

**CLINICAL FEATURES.** Diffuse large B-cell lymphoma was the most common lymphoma in the international study of the REAL, accounting for 31% of the cases. Patients typically present with a rapidly enlarging symptomatic mass, with B symptoms in one-third of the cases.<sup>126,127</sup> Localized (stage I or II) extranodal disease occurs in up to 30%; bone marrow involvement was seen in only 16%. Up to 40% of diffuse large B-cell lymphomas are extranodal; common sites include the gastrointestinal tract, bone, and CNS. The prognosis was highly associated with the International Prognostic Index score,<sup>127</sup> but not with histologic subclassification according to either the Working Formulation or the Kiel Classification. Large B-cell lymphoma may occur as a high-grade transformation of several low-grade B-cell lymphomas (B-CLL, lymphoplasmacytic lymphoma, follicular lymphoma, MALT lymphoma, splenic marginal zone lymphoma). Diffuse large B-cell lymphoma of certain extranodal sites, such as the CNS, may be clinically distinctive and may have specific treatment protocols.

**THERAPY OF LOCALIZED DIFFUSE LARGE B-CELL LYMPHOMA.** Patients with localized diffuse large B-cell lymphoma often have extranodal disease. It now appears that patients with localized extranodal lymphoma might have a better outcome than seen for patients with equal stage nodal lymphoma.<sup>282</sup> This might be related to an occult MALT origin of the large cell lymphoma in some of these patients. The data are clearest for gastric lymphomas.

Before 1980, RT was the primary treatment for patients with localized diffuse large cell lymphoma. Approximately 50% of patients with stage I and 20% of patients with stage II disease were alive without recurrence at 5 years.<sup>392,393</sup> Among the patients who had recurrences, 15% to 20% were within the radiation field; the remainder were in distant sites. Early randomized trials, published in the 1980s, compared RT alone with RT followed by CVP or BACOP chemotherapy.<sup>288,289,394</sup> These studies demonstrated a disease-free and overall survival advantage for combined CT and RT. This dramatically changed the treatment of localized large cell lymphoma. Staging laparotomy and large-field RT became obsolete as combination chemotherapy with or without RT produced disease-free and overall survival rates equivalent to or better than those seen even in the most selected studies reporting results with RT alone.

New clinical trials were then initiated to evaluate the role of RT as adjuvant to chemotherapy in patients with stage I or II diffuse large cell lymphoma. Small retrospective studies had advocated chemotherapy alone<sup>395,396</sup> or combined chemotherapy and RT.<sup>397,398</sup> and<sup>399</sup> Several centers reported excellent results using reduced chemotherapy and involved-field irradiation. At the National Cancer Institute, more than 90% of the 49 stage I or IE patients with diffuse large cell lymphoma treated with four cycles of ProMACE-MOPP (cyclophosphamide, etoposide, doxorubicin, nitrogen mustard, vincristine, procarbazine, high-dose methotrexate with leucovorin rescue and prednisone) at reduced doses (75% of normal) followed by involved-field RT to 40 Gy remained disease free.<sup>399</sup> In a similar study from Vancouver 78 patients were treated with three cycles of CHOP chemotherapy followed by involved-field RT to a total dose of 30 to 45 Gy; at 3 years the disease-free survival was 84%.<sup>400</sup> Both studies excluded patients with bulky disease (greater than 10 cm). In a third study, which included some patients with bulky disease, 183 patients treated with four cycles of CHOP and 40 to 44 Gy involved-field RT have 5-year relapse-free and overall survival rates of 83%.<sup>401</sup>

Two prospective randomized trials have further evaluated the role of RT in patients with early-stage diffuse large cell lymphoma. The Eastern Cooperative Oncology Group randomized 365 patients with bulky stage I and patients with stage II diffuse large cell lymphoma to eight cycles of CHOP with or without involved-field RT. Patients with complete response were randomized to 30 Gy involved-field RT or no further treatment. Patients with partial response received 40 Gy. The disease-free survival (73% vs. 58%;  $P = .03$ ), freedom from recurrence (73% vs. 58%;  $P = .04$ ), and survival (84% vs. 70%;  $P = .06$ ) all favored the patients who received adjuvant involved-field irradiation.<sup>402</sup> The Southwest Oncology Group Trial randomized 401 stage I and nonbulky stage II patients to receive either three cycles of CHOP and involved-field irradiation (40 to 55 Gy) or eight cycles of CHOP alone. The 5-year progression-free survival (77% vs. 64%;  $P = .03$ ) and overall survival (82% vs. 72%;  $P = .02$ ) favored the CHOP and involved-field RT treatment arm.<sup>403</sup> As a result of these trials, combination chemotherapy and adjuvant RT has become the standard of care for patients with stage I and II diffuse large cell lymphoma.

There are no prospective trials evaluating dose of radiation when combined with chemotherapy in patients with early-stage diffuse large cell lymphoma. In general, the dose of RT should be based on the number of cycles of chemotherapy and the bulk of disease. Patients with bulky mediastinal or abdominal disease or with multiple sites of involvement have a somewhat worse prognosis; these patients should receive six cycles of CHOP combined with RT.<sup>397,404,405</sup> Prior studies support the use of three to four cycles of CHOP combined with RT in patients with more limited disease.<sup>399,400</sup> and<sup>401,403</sup> With a complete response after six cycles of CHOP we recommend 30-Gy involved-field RT for patients with favorable presentations, and 35 to 40 Gy for patients with initial bulky disease. Patients with diffuse large cell lymphoma localized to the bone should receive 40 Gy.<sup>406</sup> With a complete response after four cycles of CHOP we recommend 40 Gy. These recommendations are

derived from the studies cited previously.

**THERAPY OF DISSEMINATED DIFFUSE LARGE B-CELL LYMPHOMA.** The curability of disseminated diffuse large B-cell lymphoma using chemotherapeutic agents was reported in the early 1970s.<sup>407,408</sup> In both early reports, the majority of patients who achieved a documented complete remission at the end of planned therapy did not relapse on prolonged follow-up. These reports led to a large number of clinical trials documenting the possibility of cure for patients with disseminated diffuse large B-cell lymphoma. Principles of therapy that have evolved include the administration of highly active drugs given in combination for several cycles and then to restage the patient to document complete remission (Table 45.3-15). Two or more further cycles of chemotherapy are usually administered after complete remission is documented. In most series, 50% to 75% of completely responding patients do not relapse. It appears that patients who achieve remission promptly are most likely to be cured.<sup>409</sup>

**TABLE 45.3-15.** Combination Chemotherapeutic Regimens for Newly Diagnosed Aggressive Non-Hodgkin's Lymphoma

A great deal of effort has gone into attempts to identify the best treatment regimen for patients with advanced diffuse aggressive lymphoma. Most patients in these studies had diffuse large B-cell lymphoma. More than 40 randomized clinical trials have been reported.<sup>407,408,410,411,412,413,414,415,416,417,418,419,420,421,422,423,424,425,426,427,428,429,430,431,432,433,434,435,436,437,438,439,440,441,442,443,444,445,446,447,448,449,450,451,452</sup> and <sup>453</sup> The majority of these trials have not found a significant treatment advantage for any particular regimen.<sup>407,408,410,411,412,413,414,415,416,417,418,419,420,421,422,423,424,425,426,427,428,429,430,431,432,433,434,435,436,437,438,439,440,441,442,443</sup> and <sup>444</sup> The most widely quoted trial was carried out in the United States comparing CHOP, m-BACOD, ProMACE/CytaBOM, and MACOP-B (Table 45.3-16).<sup>410</sup> This trial was carried out because of enthusiasm generated by single-arm trials showing apparent superiority of m-BACOD, ProMACE/CytaBOM, and MACOP-B over the older CHOP regimen.<sup>419,454,455</sup> This study of 899 patients showed no improvement in failure-free or overall survival with the newer regimen, but did find increased toxicity with m-BACOD and MACOP-B.<sup>410</sup> The 6-year overall survival for the four regimens were CHOP, 33%; m-BACOD, 36%; ProMACE/CytaBOM, 34%; and MACOP-B, 32%. The conclusion from the study was that the less complicated and less expensive CHOP regimen should be considered the treatment of choice. This has been widely applied, and today most patients with diffuse large B-cell lymphoma or other aggressive lymphomas receive CHOP.

Regimen	Complete Remission (%)	Partial Remission (%)	3+ Failure-Free Survival (%)	Overall Survival (%)
CHOP	44	36	41	34
m-BACOD	48	34	46	32
ProMACE/CytaBOM	36	31	46	30
MACOP-B	31	32	41	30

\*Some patients who responded partially had only a residual mass on imaging studies and might actually have been in complete remission.  
(Data from refs. 127, 291, 292, 294, 295, and 408.)

**TABLE 45.3-16.** Treatment of Aggressive Non-Hodgkin's Lymphoma (Approximately 80% Diffuse Large B-Cell): A Comparison of Four Regimens

Several randomized trials have identified superiority of one chemotherapy regimen over another for the treatment of patients with diffuse large B-cell lymphoma.<sup>414,419,424,445,446,447,448,449,450,451,452</sup> and <sup>453</sup> The most consistent finding from these studies is the superiority of an anthracycline-containing chemotherapy regimen over regimens that do not contain an anthracycline.<sup>414,446,448,449</sup> and <sup>450</sup> This appears to be true in older as well as younger patients.<sup>446,447</sup> An anthracycline, usually doxorubicin, appears to be a key component in optimizing the chances for the cure of patients with diffuse aggressive lymphoma. Substitution of another anthracycline such as mitoxantrone or epirubicin has been controversial, with some studies finding the drugs equivalent,<sup>420,426,427,428</sup> and <sup>429</sup> whereas others have found an advantage for doxorubicin.<sup>453</sup>

The importance of duration of follow-up in interpreting comparative trials is pointed out by a study done by the Australian and New Zealand lymphoma group.<sup>411,445</sup> Investigators carried out a trial comparing CHOP with MACOP-B. Two hundred thirty-six patients were eligible for analysis and an initial report showed no significant difference in outcome between the two approaches, except for more severe toxicity with MACOP-B. The 4-year overall survival was 56% for MACOP-B and 51% for CHOP, with 3.2-year median follow-up. The authors reported the study again with 6.5-year median follow-up. At that point the failure-free survival (i.e., 42% vs. 30%) and overall survival (54% vs. 41%) favored the MACOP-B regimen.

Currently, there is no one superior regimen for the treatment of patients with disseminated diffuse large B-cell lymphoma. Unfortunately, this is because all the regimens are equally bad, rather than that they are all extremely effective. Patients with advanced-stage diffuse large B-cell lymphoma are cured with chemotherapy less than 50% of the time. New treatment approaches are badly needed. Attempts have been made to improve the response to CHOP by combining it with the monoclonal antibody rituximab. An early study of 33 patients showed a 97% response rate and a 73% complete response rate.<sup>456</sup> The place of combined chemotherapy and monoclonal antibody therapy in the management of patients with diffuse large B-cell lymphoma will be determined by subsequent comparative clinical trials.

One approach to improve treatment results in patients with disseminated diffuse large B-cell lymphoma would be the addition of adjuvant drugs, radiotherapy, high-dose therapy with transplant, immunotherapy, or antibodies after a standard chemotherapy regimen. The addition of levamisole, bacille Calmette-Guérin, or both did not improve treatment outcome.<sup>457</sup> Aviles et al. found an improved disease-free and overall survival with the use of adjuvant interferon- $\alpha$ .<sup>451</sup> A combination of standard chemotherapy regimens and monoclonal antibodies is currently being tested.

The most widely studied adjuvant therapy has involved high-dose therapy and autologous bone marrow transplantation. Attempts to shorten the standard chemotherapy regimens and substitute high-dose therapy and autologous bone marrow transplantation have been disappointing. One study that randomized slowly responding patients to continuing CHOP or to autologous transplantation found a superior overall survival in continuing CHOP (85% vs. 56%).<sup>458</sup>

Two studies have found an improved disease-free survival and overall survival in patients who underwent autologous bone marrow transplantation after achieving a remission with a standard chemotherapy regimen.<sup>459,460</sup> In both cases, benefits were restricted to patients who presented with a high International Prognostic Index score. In a French study, the disease-free survival (59% vs. 39%) and overall survival (65% vs. 52%) both significantly favored adjuvant autologous bone marrow transplantation. In an Italian study, the disease-free survival (87% vs. 48%) favored adjuvant autologous bone marrow transplantation, but there was no difference in overall survival. In another Italian study, sequential high doses of individual drugs followed by autotransplant yielded a better disease-free survival (76% vs. 49%), but

not overall survival, than MACOP-B.<sup>461</sup> An international consensus conference<sup>462</sup> reached the conclusion that autologous high-dose therapy and autotransplantation in patients with high-risk International Prognostic Index scores seemed to provide benefit.

**SALVAGE THERAPY.** The phrase *salvage therapy* encompasses subsequent treatment administered to patients who failed to achieve an initial remission and the treatment administered to patients who relapse from complete remission. A major prognostic factor for patients receiving any form of salvage therapy relates to the chemotherapy sensitivity of the lymphoma (i.e., patients who achieve an initial complete remission and then relapse generally have a better prognosis than patients who are primarily resistant to chemotherapy). Patients with lymphoma that progresses on the previous chemotherapy regimen have a poorer outlook than those who have stable or partially responding disease.<sup>463,464</sup> and <sup>465</sup> Patients who have been in complete remission and then relapsed require a rebiopsy before initiating salvage therapy. Some patients who present with diffuse large B-cell lymphoma are found to have a follicular lymphoma at the time of relapse.<sup>466</sup>

The initial step in planning salvage chemotherapy is to determine the goal of treatment. Some patients who fail to achieve an initial remission or relapse from complete remission can be cured. This is less likely in elderly patients, those with extensive disease, and those with a poor performance status. In such patients less intensive, palliative treatments might be better pursued.

Radiotherapy can frequently be used to alleviate the symptoms at a particular site of involvement in patients with relapsed diffuse large B-cell lymphoma. This can frequently be accomplished with minimal morbidity. However, the chance for cure with salvage radiotherapy is extremely small. Most patients receive second-line combination chemotherapy regimens. These regimens usually incorporate drugs such as cisplatin, ifosfamide, etoposide, and cytarabine.<sup>464,465,467,468,469,470,471</sup> and <sup>472</sup> The chances for achieving a complete remission have varied widely in different studies, but generally fall in the 20% to 40% range.<sup>464,465,467,468,469,470,471</sup> and <sup>472</sup> A subset of complete responding patients can be long-term survivors, with the overall *cure* rate for salvage chemotherapy in patients with relapsed diffuse large B-cell lymphoma being approximately 5% to 10%.<sup>464,465,467,468,469,470,471</sup> and <sup>472</sup>

Other approaches used for salvage therapy in patients with diffuse large B-cell lymphoma include the monoclonal antibody rituximab and interferon- $\alpha$ . In 30 patients with diffuse large B-cell lymphoma treated with rituximab, 11 (37%) had an objective response. Most responses were partial. The median time to progression had not been reached at the time of the report.<sup>473</sup> Responding patients were more likely to have tumors less than 5 cm in maximum diameter, and no patient with a tumor greater than 10 cm in maximum diameter responded. Occasional patients with relapsed diffuse large B-cell lymphoma respond to interferon- $\alpha$ .<sup>474</sup> These responses can be complete and durable for several years.

Because of the poor response to salvage chemotherapy in patients with relapsed refractory diffuse large B-cell lymphoma, autologous bone marrow transplantation was tested soon after its development. In a study of 100 patients with relapsed diffuse aggressive lymphoma, both complete remission and prolonged disease-free survival could be predicted by the history of previous response to chemotherapy.<sup>475</sup> Approximately 35% of patients who relapsed from complete remission but remained sensitive to chemotherapy at relapse achieved prolonged disease-free survival and apparent cure, in contrast to approximately 10% of those who were chemotherapy resistant at the time of relapse and no patients who were initially refractory to therapy and failed to achieve a complete remission.<sup>476</sup> This study formed the basis for an international randomized trial referred to as the PARMA study.<sup>477</sup> In this trial, 109 patients who had relapsed from complete remission and responded to two cycles of DHAP (dexamethasone, cytarabine, cisplatin) were randomly allocated to high-dose chemotherapy using BEAC regimen (carmustine, etoposide, cytarabine, cyclophosphamide) or continued treatment with DHAP. Both groups were to receive involved-field radiotherapy. Bone marrow transplantation was associated with a superior failure-free survival (51% vs. 12% at 5 years) and overall survival (53% vs. 32% at 5 years). At present, high-dose therapy and autologous bone marrow transplantation are the treatments of choice for patients with chemotherapy-sensitive relapse who are young enough and healthy enough to undergo the procedures.

Allogeneic bone marrow transplantation has been used less frequently for patients with diffuse large B-cell lymphoma. While occasional patients failing autologous transplantation can have prolonged survival with allogeneic transplantation,<sup>478</sup> overall results from the North American Bone Marrow Transplant Registry have favored autologous transplantation.

### **Primary Mediastinal (Thymic) Large B-Cell Lymphoma**

**MORPHOLOGY.** Primary mediastinal large B-cell lymphoma usually involves the thymus at presentation.<sup>479,480</sup> The tumor is composed of large cells with variable nuclear features, resembling centroblasts, large centrocytes, or multilobated cells, often with pale or *clear* cytoplasm. Less often, the tumor cells resemble immunoblasts. Reed-Sternberg-like cells may be present. Many cases have fine, compartmentalizing sclerosis.

**IMMUNOPHENOTYPE.** The tumor cells are often Ig $^-$ , but express B-cell-associated antigens (CD19, CD20, CD22, CD79a) and CD45.<sup>480</sup>

**GENETIC FEATURES.** Ig heavy and light-chain genes are rearranged; the *bcl-2* gene is usually germline.<sup>480,481</sup> and <sup>482</sup> *Bcl-6* gene rearrangements are uncommon.<sup>483</sup> Amplification of the *REL* oncogene has been described in a minority of the cases.<sup>484</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is putative thymic (medullary) B cell.

**DIFFERENTIAL DIAGNOSIS.** The major differential diagnoses clinically are thymoma, germ cell tumor, and Hodgkin's disease. In female subjects, germ cell tumor can be confidently excluded. Involvement of lymph nodes argues against a diagnosis of thymoma. The presence of superior vena cava syndrome argues against Hodgkin's disease. Histologically, the diagnosis depends on recognition of the characteristic morphology; immunohistochemical stains, as for other diffuse large B-cell lymphomas, are helpful.

**CLINICAL FEATURES AND THERAPY.** Primary diffuse large B-cell lymphoma of the mediastinum is a distinct clinicopathologic entity, requiring knowledge of both morphology, immunophenotype, and presenting site for the diagnosis.<sup>126</sup> It accounted for 7% of diffuse large B-cell lymphomas (2.4% of all NHL) in the international REAL study.<sup>126,127</sup> There is a female predominance and a median age in the fourth decade; patients present with a locally invasive anterior mediastinal mass originating in the thymus, with frequent airway compromise and superior vena cava syndrome.<sup>485</sup> Relapses tend to be extranodal, including liver, gastrointestinal tract, kidneys, ovaries, and CNS.

Although early studies suggested an unusually aggressive, incurable tumor, others have reported cure rates similar to those for other large cell lymphomas with aggressive therapy, usually combining chemotherapy with mediastinal irradiation.<sup>485,486</sup> With no evidence to the contrary, we recommend treating these patients similar to other patients with localized diffuse large cell lymphoma (i.e., with four to six cycles of CHOP and involved-field RT). The prognosis of patients with localized mediastinal large cell NHL is similar to other patients with poor prognosis early-stage disease; approximately 50% of patients are alive without disease at 5 years. Patients who present with a pleural effusion or who remain gallium positive after CHOP have a worse prognosis. Patients without bulky disease have a better prognosis.<sup>487</sup> Patients with disseminated disease should be treated like other patients with disseminated diffuse large B-cell lymphoma.

### **Intravascular Large B-Cell Lymphoma**

Rare cases of large cell lymphoma, usually of B-cell type, present with a disseminated intravascular proliferation of large lymphoid cells, involving small blood vessels, without an obvious extravascular tumor mass or leukemia.<sup>488,489</sup> This tumor has also been variously known as intravascular lymphomatosis, angiotropic lymphoma, and malignant angioendotheliomatosis. The neoplastic lymphoid cells are mainly lodged in the lumina of small vessels in many organs. The tumor cells are large with vesicular nuclei, prominent nucleoli, and frequent mitotic figures. Malignant cells are rarely seen in cerebrospinal fluid, blood, or bone marrow. The organs most commonly involved are CNS, kidneys, lungs, and skin, but virtually any site may be involved.

Patients present with a bewildering variety of symptoms related to organ dysfunction secondary to vascular occlusion, which may be transient. Patients often present with neurologic dysfunction.<sup>490,491</sup> and <sup>492</sup> Other presentations include pulmonary involvement,<sup>493,494</sup> syndrome of inappropriate antidiuretic hormone production,<sup>494</sup> skin lesions,<sup>495</sup> lytic bone lesions,<sup>495</sup> endocrine dysfunction,<sup>496</sup> disseminated intravascular coagulation,<sup>497</sup> edema and hypoalbuminemia,<sup>498</sup> and thrombotic thrombocytopenic purpura.<sup>499</sup> Because of the wide variety of presentations, diagnosis is often difficult, and many reported cases were diagnosed by autopsy. If a timely diagnosis is made and combination chemotherapy instituted, patients can attain a complete remission, and long-term survival appears to be possible.<sup>500</sup>

## Burkitt's Lymphoma

**DEFINITION.** Burkitt's lymphoma is a B-cell lymphoma composed of monomorphic, medium-sized cells with basophilic cytoplasm and a high proliferation fraction, characterized by translocation and deregulation of the c-myc gene on chromosome 8, which is often extranodal and occurs most often in children (endemic, sporadic) and immunocompromised hosts.

**MORPHOLOGY.** Burkitt's tumor cells are monomorphic, medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm. Cytoplasmic lipid vacuoles are usually evident on imprints or smears. There is an extremely high rate of proliferation as well as a high rate of spontaneous cell death. A starry-sky pattern is usually present, imparted by numerous benign macrophages that have ingested apoptotic tumor cells. Although most cases present no problem in diagnosis, some cases may have larger cells or an admixture of immunoblast-like cells, and there is morphologic overlap with diffuse large B-cell lymphoma. These borderline cases are often called *non-Burkitt*<sup>501</sup> or *Burkitt-like*.<sup>124</sup> In children and human immunodeficiency virus–positive patients, these often have a c-myc translocation and behave similarly to typical Burkitt's lymphoma, whereas in adults, so-called Burkitt-like lymphomas often have bcl-2 gene rearrangement and may represent an aggressive variant of diffuse large B-cell lymphoma.<sup>502</sup> In the international study of the REAL,<sup>126</sup> Burkitt-like lymphoma was a nonreproducible category, in which the pathologists agreed on the diagnosis only 50% of the time: Disagreements were equally split between large B-cell and Burkitt's lymphoma.

The most appropriate way to handle this borderline between Burkitt's lymphoma and diffuse large B-cell lymphoma has been the subject of debate in the WHO classification project: Should it continue to be a separate, nonreproducible category; should it be a subtype of large B-cell lymphoma; or should it be a subtype of Burkitt's lymphoma? From a clinical standpoint, it is important to identify patients who should be treated as though they had Burkitt's lymphoma, since patients with Burkitt's lymphoma do not do well with treatment that would be effective for large cell lymphoma. On the other hand, treatment for Burkitt's lymphoma is considerably more aggressive than that for large B-cell lymphoma and may have significant treatment-related morbidity,<sup>503</sup> so that it should not be used for usual large B-cell lymphomas. The question is how to draw the line between large cell lymphoma and Burkitt's lymphoma so that morphologically borderline cases will be assigned to the correct category?

The defining biologic feature of Burkitt's lymphoma is c-myc deregulation, as a consequence of which the tumor cells remain constantly in cycle. It is this phenomenon that results in both its morphologic homogeneity and its clinical behavior. Unfortunately, detection of c-myc translocation is not practical in all clinical specimens for technical reasons. In addition, some large B-cell lymphomas have t(8;14) and c-myc deregulation, and it is not clear if all such cases should be treated like Burkitt's lymphoma. The best practical surrogate for c-myc deregulation is proliferation fraction: In a tumor with c-myc deregulation, 100% of viable cells should be in cycle and should express Ki-67. Thus, the WHO committees concluded that a diagnosis of Burkitt-like lymphoma should only be made in a tumor with morphologic features intermediate between Burkitt's lymphoma and diffuse large B-cell lymphoma, in which the Ki-67 fraction of viable cells is at least 99%. This tumor will be considered a subtype of Burkitt's lymphoma in the WHO classification.<sup>130</sup> Cases with morphologic features of large cell lymphoma with a high proliferation fraction [or t(8;14)] and cases that are morphologically borderline between Burkitt's lymphoma and large B-cell lymphoma with a lower proliferation fraction, should be classified as diffuse large B-cell lymphoma.

**IMMUNOPHENOTYPE.** Burkitt's lymphoma cells express SIgM and B-cell–associated antigens (CD19, CD20, CD22, CD79a), as well as CD10 and CD43; they lack CD5 and bcl-2 and typically lack CD23.<sup>504</sup> They show nuclear staining for BCL-6 protein, which is independent of bcl-6 gene rearrangement.<sup>505</sup>

**GENETIC FEATURES.** Ig heavy and light-chain genes are rearranged. Studies of the Ig variable region genes show conflicting results: One study reported unmutated genes,<sup>506</sup> whereas others report somatic mutations and intracлонаl heterogeneity, consistent with ongoing mutations.<sup>507,508 and 509</sup> Most cases have a translocation of c-myc from chromosome 8 to either the Ig heavy-chain region on chromosome 14 [t(8;14)] or light-chain loci on 2 [t(2;8)] or 22 [t(8;22)]. In African (endemic) cases, the breakpoint on chromosome 14 involves the heavy-chain joining region, whereas in nonendemic cases, the translocation involves the heavy-chain switch region.<sup>510,511</sup> Mutations in the 5' noncoding region of the bcl-6 gene, similar to those seen in large B-cell lymphoma, have been reported in 25% to 50% of the cases.<sup>512</sup> Most African cases contain EBV genomes, as do 25% to 40% of the cases associated with AIDS.<sup>513</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is peripheral B cell of unknown stage: perhaps B blast of early germinal center reaction.

**DIFFERENTIAL DIAGNOSIS.** Burkitt's lymphoma must be distinguished from other primary abdominal malignancies in childhood, including Wilms' tumor, neuroblastoma, and peripheral neuroectodermal tumor. In the bone marrow, it must be distinguished from B- and T-precursor and myeloid leukemias. Morphologic features are usually sufficient for the diagnosis if adequate material is available. The presence of leukocyte-associated antigens and Ig and the lack of TdT are important in distinguishing Burkitt's lymphoma from the other tumors mentioned. Among peripheral B-cell lymphomas, the major differential diagnosis is with diffuse large B-cell lymphoma; although this is usually straightforward on histologic grounds, occasional borderline cases occur; a provisional category of *high-grade B-cell lymphoma, Burkitt-like* is used for these cases. Burkitt's lymphoma is more likely to express CD10 and to have c-myc rearrangement than is diffuse large B-cell lymphoma.

**CLINICAL FEATURES AND THERAPY.** Three distinct clinical forms of Burkitt's lymphoma can be recognized: endemic, sporadic, and immunodeficiency-associated.<sup>514</sup> Although they are histologically identical and have similar clinical behavior, there are differences in epidemiology, clinical presentation, and genetic features between the three forms. Endemic and sporadic Burkitt's lymphomas are both most common in children, but the median age is younger in endemic patients. Burkitt's lymphoma accounts for 30% of nonendemic pediatric lymphomas, but less than 1% of adult NHLs; in human immunodeficiency virus–positive patients it typically affects those with a relatively high CD4 count and no opportunistic infections. In all groups, the majority of patients are male (3 to 4:1). In endemic cases, the jaws and other facial bones are often involved, as well as the mesentery and gonads. In sporadic cases, the majority are present in the abdomen, most often involving distal ileum, cecum, mesentery, or both cecum and mesentery; ovaries, kidneys, or breasts may be involved.<sup>515</sup> Immunodeficiency-related cases more often involve lymph nodes, and both these and sporadic cases may present as acute leukemia.

Patients typically present with rapidly growing tumor masses and often have a high serum LDH. Burkitt's lymphoma is highly aggressive but potentially curable with aggressive therapy. Because of the extremely rapid progression of Burkitt's lymphoma, patients with this disease should be approached as a medical emergency. Staging should be completed quickly and therapy initiated at the earliest possible time. Because of the risk of tumor lysis syndrome, patients should be well-hydrated, receive allopurinol, and be watched closely after the initiation of therapy. Death from hyperkalemia has been reported.<sup>516,517</sup> Some patients require hemodialysis to control hyperkalemia.

Burkitt's lymphoma was one of the first malignancies to be shown to be curable with chemotherapy,<sup>518</sup> and the majority of patients should be curable today with aggressive combination chemotherapy regimens. High-dose regimens of fairly brief duration are used to treat patients with Burkitt's lymphoma.<sup>519,520,521 and 522</sup> Patients with localized disease are cured in approximately 90% of the cases with these intensive regimens, and cure rates within excess of 50% have been reported in patients with extensive disease.<sup>519</sup> When treated with similar regimens, adults and children have comparable outcomes.<sup>519</sup> Because of the propensity for CNS metastases, treatment regimens for Burkitt's lymphoma always involve prophylactic therapy to the CNS. Salvage therapy for patients with relapsed Burkitt's lymphoma has generally been unsatisfactory. However, occasional patients can be cured with autologous bone marrow transplantation.<sup>523</sup> Patients with isolated CNS relapse can sometimes be cured with bone marrow transplantation<sup>524</sup> or a combination of systemic therapy at traditional doses and intrathecal treatment.<sup>525</sup>

## T-CELL AND NATURAL KILLER-CELL NEOPLASMS

### *Precursor T-Lymphoblastic Lymphoma/Leukemia (Precursor T-Cell Acute Lymphoblastic Leukemia/ Precursor T-Cell Lymphoblastic Lymphoma)*

**DEFINITION.** A T-cell and NK-cell neoplasm is a neoplasm of lymphoblasts committed to the T-cell lineage, typically composed of small to medium-sized blast cells with scant cytoplasm, moderately condensed to dispersed chromatin and indistinct nucleoli, variably involving bone marrow and blood (precursor T-cell ALL), thymus, lymph nodes, or all (precursor T-cell lymphoblastic lymphoma).

**MORPHOLOGY.** On smears, lymphoblasts vary from small cells with scant cytoplasm, condensed nuclear chromatin, and indistinct nucleoli to larger cells with a moderate amount of cytoplasm, dispersed chromatin, and multiple nucleoli. Azurophilic granules may be present. In tissue sections, the cells are small to medium-sized, with scant cytoplasm, round, oval, or convoluted nuclei, and fine chromatin and indistinct or small nucleoli. Occasional cases have larger cells. The pattern is infiltrative rather than destructive, with partial preservation of the subcapsular sinus and germinal centers. A starry-sky pattern may be present, but is usually less prominent than in Burkitt's lymphoma.

**IMMUNOPHENOTYPE.** The lymphoblasts are typically positive for TdT and variably express CD2, CD7, CD3, CD5, CD1a, CD4, CD8, or all of these. Only CD3 is considered lineage specific. The constellation of antigens defines stages of differentiation, ranging from early or pro-T (CD2, CD7, and cytoplasmic CD3), to *common* thymocyte (CD1a, sCD3, CD4, and CD8), to late thymocyte (CD4 or CD8). Although there is some correlation with presentation and differentiation stage (cases with bone marrow and blood presentation may show earlier differentiation stage than cases with thymic presentation),<sup>526,527</sup> there is overlap.<sup>528</sup>

**GENETIC FEATURES.** Rearrangement of antigen receptor genes is variable in lymphoblastic neoplasms and may not be lineage specific; thus, precursor T-cell neoplasms may have either or both TCR b or g chain gene rearrangements and Ig heavy-chain gene rearrangements.<sup>529</sup>

Chromosomal translocations involving the TCR a and d loci at chromosome 14q11 and b and g loci at 7q34 are present in approximately one-third of the cases<sup>150,530</sup>; the partner genes are variable and include the transcription factors c-MYC (8q24), TAL1/SCL (1p32), RBTN1 (11p35), RBTN2 (11p13), and HOX11 (10q24) and the cytoplasmic tyrosine kinase LCK (1p34). In an additional 25%, the TAL1 locus at 1p32 has deletions in the 5' regulatory region.<sup>531</sup> Deletions of 9p involving deletion of the p16/*INK4a* tumor suppressor gene (cdk4 inhibitor) is also seen in T-lymphoblastic neoplasms.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is precursor T lymphoblast at varying stages of differentiation.

**CLINICAL FEATURES AND THERAPY.** Precursor T-cell neoplasia occurs most frequently in late childhood, adolescence, and young adulthood, with a male predominance; it accounts for 15% of childhood and 25% of adult ALL.<sup>157</sup> The prognosis is typically worse than that for precursor B-cell neoplasms and is not affected by immunophenotype or genetic abnormalities. Patients typically present with a high leukocyte count and often a mediastinal mass. Clinically, a case is defined as lymphoma if there is a mediastinal or other mass and less than 25% blasts in the bone marrow, and as leukemia if there are greater than 25% bone marrow blasts, with or without a mass. In children, treatment is generally more aggressive than that for precursor B-ALL and is typically the same for lymphomatous and leukemic presentations.<sup>530</sup>

Adults with lymphoblastic lymphoma seem to have an excellent prognosis when presenting with stage I or II disease.<sup>532</sup> In such patients treatment with CHOP, intrathecal methotrexate, and CNS radiotherapy, and maintenance chemotherapy with methotrexate and mercaptopurine yielded a 94% 5-year freedom from relapse rate for patients with lymph node–based disease and a normal serum LDH level.<sup>532</sup> Patients who presented with bone marrow involvement, CNS involvement, or a high serum LDH had a 5-year freedom from relapse rate of only 19%. Because of the propensity for CNS relapse, all patients with lymphoblastic lymphoma should receive prophylactic treatment to the CNS.

More intensive chemotherapy regimens of the type used to treat ALL appeared to yield better results in patients with lymphoblastic lymphoma.<sup>533,534</sup> and <sup>535</sup> Adjuvant autologous bone marrow transplantation in high-risk patients has been reported to improve the long-term disease-free survival rate.<sup>536</sup> These data have been supported by the early results from a randomized trial.<sup>537</sup> There is some evidence that allogeneic bone marrow transplantation might have a superior result to autologous bone marrow transplantation.<sup>535</sup> Some patients who relapse from remission can be cured with autologous or allogeneic bone marrow transplantation, although the overall prognosis in such patients is poor.<sup>538</sup>

#### **Mature T Cell: Mycosis Fungoides**

For a discussion of mycosis fungoides, see [Chapter 45.4](#).

#### **Adult T-Cell Lymphoma and Leukemia**

**DEFINITION.** Adult T-cell lymphoma and leukemia is defined as a peripheral T-cell neoplasm caused by HTLV-I.

**MORPHOLOGY.** Cells with hyperlobated nuclei (flower cells) are common in the peripheral blood in leukemic cases. In addition, there is a small proportion of blast-like cells with a deep basophilic cytoplasm. Bone marrow infiltrates are usually patchy, ranging from sparse to moderate. In lymph nodes, the infiltrates are diffuse with architectural effacement. Neoplastic cells are usually medium to large with nuclear pleomorphism; the cytoplasm is amphophilic, basophilic, or pale. Mitotic activity is variable. Reed-Sternberg–like cells and giant cells with convoluted or cerebriform nuclei may be present. Rare cases may be composed of small atypical lymphocytes with nuclear pleomorphism or may resemble anaplastic large cell lymphoma. In the background there is a mild to moderate proliferation of high endothelial venules.

**IMMUNOPHENOTYPE.** Tumor cells express T-cell–associated antigens (CD2, CD3, CD5), but usually lack CD7. Most cases are CD4+ and CD8–. Rare cases are CD4–, CD8+, or CD8+ and CD4+. CD25 is expressed in a majority of the cases. Anaplastic large cell types react with CD30, but are ALK (p80) negative.

**GENETICS.** Clonally integrated HTLV-I genes are found in all cases. The TCR genes are clonally rearranged.

**POSSIBLE NORMAL COUNTERPART.** The possible normal counterpart is peripheral CD4+ T cells in various stages of transformation.

**DIFFERENTIAL DIAGNOSIS.** Chronic and smoldering forms must be distinguished from benign lymphocytosis. Cutaneous involvement must be distinguished from mycosis fungoides. Lymphomatous presentations may clinically and histologically resemble large B-cell or other peripheral T-cell lymphomas. The typical acute form is clinically and morphologically distinctive, with leukocytosis and the characteristic flower cells in an Asian or Caribbean patient, often with hypercalcemia. Since the disease may be mimicked by other peripheral T-cell lymphomas, and because of its highly aggressive course, serologic evaluation for HTLV-I infection is recommended in any patient with a newly diagnosed peripheral T-cell lymphoma.

**CLINICAL FEATURES.** ATL is one manifestation of infection by HTLV-I. Tropical spastic paraparesis and HTLV-I–associated myelopathy appear to be more common manifestations of infection than ATL. The diagnosis is established when a patient with a typical clinical and pathologic syndrome is found to have antibodies to HTLV-I. Most patients are adults, although children are occasionally seen with the disorder when they received transfusions in infancy. The virus can be acquired by vertical transmission from mother to child, sexual transmission, or via blood products. Most cases occur in Japan or the Caribbean, with sporadic cases found elsewhere in the world.

In the United States the diagnosis is frequently difficult because ATL is not considered since many clinicians are not acquainted with the syndrome. Several variants have been described depending on the clinical features: acute, lymphomatous, chronic, and smoldering. The most common *acute type* presents with neoplastic cells in the blood, skin rashes, generalized lymphadenopathy, hepatosplenomegaly, and hypercalcemia. The *lymphomatous type* is characterized by prominent lymphadenopathy but no blood involvement. The *chronic type* shows skin lesions and an increased white blood cell count with absolute lymphocytosis, but no hypercalcemia. The *smoldering type* shows normal blood lymphocyte counts with  $\leq 5\%$  circulating neoplastic cells. Patients frequently have skin or pulmonary lesions, but hypercalcemia is not present. Progression from chronic and smoldering to acute types eventually occurs in up to 25% of the cases. Peripheral blood and bone marrow are the most frequent sites of involvement, although essentially any organ can be involved by the disease including gastrointestinal tract, liver, lung, and CNS.

**THERAPY.** The treatment of ATL has been unsatisfactory. Patients with the chronic or smoldering syndromes can sometimes be followed without therapy for extended periods of time. When the disease becomes asymptomatic, combination chemotherapy regimens have usually been used.<sup>145</sup> Although patients frequently respond to the initial combination chemotherapy regimen, the overall survival remains poor, with less than 10% of the patients surviving 5 years after initiating therapy. A variety of the new treatment approaches has been studied including new chemotherapeutic agents, monoclonal antibodies, and allogeneic bone marrow transplantation. One case of long-term, disease-free survival with allogeneic bone marrow transplantation has been described.<sup>539</sup>

#### **Peripheral T-Cell Lymphoma, Not Otherwise Categorized**

**DEFINITION.** In peripheral T-cell lymphoma, not otherwise categorized, a number of distinct entities have been defined, which correspond to recognizable subtypes of T-cell neoplasia. There remains a large group of predominantly nodal T-cell lymphomas, which make up the largest group of T-cell neoplasms in western countries. Although a variety of morphologic subtypes has been described, no consistent immunophenotypic, genetic, or clinical features have been associated with most of them. Therefore, for the time being, these presumably diverse cases are lumped under the heading peripheral T-cell lymphoma, not otherwise categorized, or

unspecified. This category includes heterogeneous diseases that require further definition.

**MORPHOLOGIC FEATURES.** Peripheral T-cell lymphomas typically contain a mixture of small and large atypical cells<sup>540,541</sup> and are classified as *diffuse small cleaved, mixed, large cell, and immunoblastic* in the Working Formulation.<sup>127,542</sup> Admixed eosinophils or epithelioid histiocytes may be numerous<sup>543</sup>; the term *lymphoepithelioid cell (Lennert's) lymphoma* has been used for cases rich in epithelioid cells.<sup>543</sup> Because of their relative rarity and heterogeneity, it has been impossible to arrive at a generally useful classification.<sup>541,544,545,546</sup> and<sup>547</sup> For the time being, these tumors are simply designated *peripheral T-cell lymphomas, unspecified*.

**IMMUNOPHENOTYPE.** T-cell-associated antigens are variably expressed (CD3+/-, CD2+/-, CD5+/-, CD7-/+), CD4 is more often expressed than CD8, and tumors may be CD4- and CD8-. B-cell-associated antigens are lacking.<sup>540,548</sup>

**GENETIC FEATURES.** The TCR genes are usually but not always rearranged; Ig genes are germline.<sup>540,549</sup> No specific cytogenetic or oncogene abnormality has been reported, although complex karyotypes are common in cases with larger cells.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is peripheral T cells in various stages of transformation.

**CLINICAL FEATURES.** Peripheral T-cell lymphomas accounted for only 6% of lymphomas in the international study of the REAL,<sup>126,127</sup> reflecting their rarity in American and European populations. The median age was in the seventh decade, and 65% of the patients had stage IV disease. Blood eosinophilia, pruritus, and hemophagocytic syndromes may occur<sup>550</sup>; lymph nodes, skin, liver, spleen, and other viscera may be involved.<sup>551,552</sup> The clinical course is aggressive, and relapses are more common than in large B-cell lymphoma.<sup>545,553,554,555</sup> and<sup>556</sup> In the international REAL study, this group had one of the lowest overall and failure-free survival rates.<sup>126,127</sup>

**THERAPY.** Treatment regimens used for peripheral T-cell lymphoma are the same as used for diffuse large B-cell lymphoma. Because of the poorer overall survival in peripheral T-cell lymphoma as compared with diffuse large B-cell lymphoma, bone marrow transplantation is more likely to be used as part of the primary therapy. Bone marrow transplantation may be as effective in peripheral T-cell lymphoma as in diffuse large B-cell lymphoma.<sup>557</sup>

### **Angioimmunoblastic T-Cell Lymphoma**

**DEFINITION.** Angioimmunoblastic T-cell lymphoma is a T-cell lymphoma characterized by systemic disease, a polymorphous infiltrate involving lymph nodes, and a prominent proliferation of high endothelial venules and FDCs.

**MORPHOLOGY.** The nodal architecture is effaced; peripheral sinuses are typically open and even dilated, but the abnormal infiltrate often extends beyond the capsule into the perinodal fat. There are prominent arborizing high endothelial venules, many of which show thickened or hyalinized periodic acid-Schiff-positive walls. Clusters of epithelioid histiocytes and numerous eosinophils and plasma cells may be present. Expanded aggregates of FDCs, visible on immunostained sections, surround the proliferating blood vessels and may have the appearance of *burnt-out* germinal centers. The lymphoid cells are a mixture of small lymphocytes, immunoblasts, plasma cells, and medium-sized cells with round nuclei and clear cytoplasm. B immunoblasts may be numerous.

**IMMUNOPHENOTYPE.** Tumor cells express T-cell-associated antigens and usually CD4, but many CD8+ cells are often present; expanded FDC clusters (CD21+) are present around proliferated venules.<sup>558</sup> The latter feature is useful in distinguishing this disorder from other T-cell lymphomas.<sup>547</sup> Polyclonal plasma cells and B immunoblasts may be numerous.

**GENETIC FEATURES.** The TCR genes are rearranged in 75%; IgH in 10%, corresponding to expanded B-cell clones.<sup>558,559</sup> EBV genomes are detected in many cases and may be present in either T or B cells<sup>560,561</sup>; trisomy 3, 5, or both may occur.<sup>562</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is peripheral T cell of unknown subset in various stages of transformation.

**CLINICAL FEATURES.** Angioimmunoblastic T-cell lymphoma is one of the more common peripheral T-cell lymphomas encountered in western countries. In the Kiel Registry, it accounted for 20% of all T-cell lymphomas and approximately 4% of all lymphomas.<sup>547</sup> Angioimmunoblastic T-cell lymphoma is clinically distinctive: Patients typically have generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobulinemia<sup>563</sup> and are susceptible to infections. The course is moderately aggressive, with occasional spontaneous remissions, and is not reliably predicted by the histologic appearance.

**THERAPY.** Approximately 30% of the patients may have initial remission on corticosteroids alone, but most require some form of cytotoxic chemotherapy. Median survivals range from 15 to 24 months, and curability has not been well established. Some patients develop a secondary EBV+ large B-cell lymphoma. A prospective but nonrandomized trial compared an anthracycline-based combination chemotherapy regimen with prednisone followed by combination chemotherapy only if the disease progressed. Initial chemotherapy yielded a higher complete remission rate (64% vs. 29%) and median survival (19 vs. 11 months).<sup>564</sup>

### **Extranodal Natural Killer/T-Cell Lymphoma, Nasal Type (Formerly Angiocentric Lymphoma)**

**DEFINITION.** Extranodal NK/T-cell lymphoma, nasal type, is an extranodal lymphoma, usually with an immature NK-cell phenotype and EBV+, with a broad morphologic spectrum, frequent necrosis and angioinvasion, and most commonly presenting in the midfacial region, but also in other extranodal sites. It is designated NK/T because of uncertainty regarding lineage.

**MORPHOLOGIC FEATURES.** Nasal NK/T-cell lymphoma is typically characterized by a polymorphous infiltrate composed of a mixture of normal appearing small lymphocytes and atypical lymphoid cells of varying size,<sup>565,566</sup> along with plasma cells and occasionally eosinophils and histiocytes. A characteristic feature is invasion of vascular walls and, usually, occlusion of lumina by lymphoid cells with varying degrees of cytologic atypia; however, this is not seen in all the cases. There is usually prominent ischemic necrosis of both tumor cells and normal tissue. The term *angiocentric lymphoma* has proven confusing, since angiocentricity is not evident in all cases. Since the most characteristic presentation is midfacial, and the cells have both T and NK features, the term *extranodal T/NK-cell lymphoma, nasal type*, has been proposed.<sup>567</sup>

Cases of pulmonary *lymphomatoid granulomatosis* were for a time considered to be part of the spectrum of angiocentric lymphoma. Studies suggest that most pulmonary cases are EBV-associated B-cell proliferations, and therefore a distinct disease category<sup>374,377</sup>; however, some pulmonary lymphomas with histologic features of lymphomatoid granulomatosis lack CD20+ cells and EBV and may be examples of peripheral T-cell lymphoma.<sup>377</sup> Thus, pulmonary lymphomas with angiocentric growth patterns and necrosis may be heterogeneous.

**IMMUNOPHENOTYPE.** The atypical cells in most cases are CD2+, CD56+, surface CD3-, and cytoplasmic CD3+ (Leu 4- but positive with the polyclonal anti-CD3, which detects the epsilon chain of CD3). They are typically CD4- and CD8-, but may express CD4, CD7, or both.<sup>566,568,569</sup> Most cases express cytotoxic granule proteins such as Granzyme B and TIA-1.<sup>570</sup>

**GENETIC FEATURES.** The TCR and Ig genes are usually germline; EBV genomes are usually present and are detectable in the majority of the cells in most cases by *in situ* hybridization for EBER-1.<sup>569,571</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is immature NK cell.

**CLINICAL FEATURES.** Nasal-type T/NK lymphoma is a rare disorder in the United States and Europe, but is more common in Asia and in native populations in Peru. It may affect children or adults. Extranodal sites are invariably involved, including nose, palate, upper airway, gastrointestinal tract, and skin.<sup>565,566,569,572,573</sup> The clinical course is typically aggressive, with relapses in other extranodal sites.<sup>569,574</sup> Hemophagocytic syndromes may occur. Some cases of the aggressive variant of NK-cell leukemia and lymphoma may be related to this disorder.<sup>575</sup>

**THERAPY.** Patients with localized NK/T-cell lymphoma in the nasal pharynx can be cured with a combination of chemotherapy and local radiotherapy.<sup>576</sup> With radiotherapy alone, treatment failure is frequent. Patients with disseminated NK/T-cell lymphoma have an extremely poor outlook. Occasional long-term survivors are seen using the CHOP regimen.<sup>577</sup> Less aggressive regimens have a uniformly poor outcome.

High-dose chemotherapy and autologous bone marrow transplantation can be curative in some patients after relapse from standard therapy.<sup>578,579</sup> Because of the poor results with standard chemotherapeutic approaches, incorporation of bone marrow transplantation as a primary management of patients with disseminated NK/T-cell lymphoma might improve treatment outcome.

### **Enteropathy Type T-Cell Lymphoma**

**DEFINITION.** Enteropathy type T-cell lymphoma is a tumor of intraepithelial T lymphocytes, usually associated with features of gluten-sensitive enteropathy, showing varying degrees of transformation but usually presenting as a high-grade (blastic) tumor.

**MORPHOLOGY.** This disorder was originally termed *malignant histiocytosis of the intestine*, but has since been conclusively shown to be a T-cell lymphoma.<sup>580</sup> On gross examination, circumferentially oriented jejunal ulcers are present, often multiple, and often with perforation. A mass may or may not be present. The tumors contain a variable admixture of small, medium and mixed, large or anaplastic tumor cells, often with a high content of intraepithelial T cells in adjacent mucosa. The adjacent mucosa may or may not show villous atrophy<sup>552</sup>; this varies depending on the segment analyzed, since in sprue, villous atrophy is most prominent in the proximal small intestine and may be absent in distal jejunum or ileum. Early lesions may show mucosal ulceration with only scattered atypical cells and numerous reactive histiocytes, without formation of large masses<sup>581</sup>; these lesions are nonetheless clonal. Intraepithelial lymphocytes in apparently nonneoplastic mucosa may also be clonal.<sup>582</sup> Clonal TCR gene rearrangements have been found in cases of celiac disease unresponsive to a gluten-free diet, suggesting that these cases may represent early T-cell lymphomas.<sup>583</sup> The tumor may involve liver, spleen, lymph nodes, and other viscera such as the gallbladder.

**IMMUNOPHENOTYPE.** The tumor cells are T cells expressing pan-T antigens (CD3+, CD7+), usually CD8+ and CD4-, and expressing the mucosal lymphoid antigen CD103.<sup>584</sup> CD30 may be positive in some cells. Expression of cytotoxic T-cell-associated proteins (Granzyme B, TIA-1, perforin) is seen in many of the cases.<sup>585,586</sup>

**GENETIC FEATURES.** The TCRb gene is clonally rearranged<sup>580</sup>; no specific cytogenetic abnormality has been described.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is intestinal intraepithelial cytotoxic T cells in various stages of transformation.

**CLINICAL FEATURES AND THERAPY.** This disease occurs in adults, typically with a rather brief history of gluten-sensitive enteropathy, as the initial event in a patient found to have villous atrophy in the resected intestine, or without evidence of enteropathy but with either or both antigliadin antibodies or the typical HLA type (DQA1\*0501, DQB1\*0201) of patients with celiac disease.<sup>587</sup> It is uncommon in most areas of the United States and Europe, but is seen with increased frequency in areas in which gluten-sensitive enteropathy is common. Treatment of celiac disease with a gluten-free diet effectively prevents the development of lymphoma, so that patients diagnosed with celiac disease early in life usually do not develop lymphoma, and patients with lymphoma rarely have a long history of celiac disease.<sup>136,588</sup> Patients present with abdominal pain, often associated with jejunal perforation; stomach or colon are affected less often,<sup>589</sup> and other viscera, skin, or soft tissues may be involved.<sup>590,591</sup> and <sup>592</sup> The course is aggressive, and death usually occurs from multifocal intestinal perforation due to refractory malignant ulcers. A poor response to therapy has been reported. It is probably related to the severe nutritional and immunologic abnormalities found in patients with uncontrolled celiac disease.

### **Hepatosplenic gd T-Cell Lymphoma**

**DEFINITION.** Hepatosplenic gd T-cell lymphoma is a neoplasm of mature gd T cells with sinusoidal infiltration of spleen, liver, and bone marrow.

**MORPHOLOGY.** Hepatosplenic gd T-cell lymphoma produces a sinusoidal infiltrate in liver and spleen, as well as bone marrow, of medium-sized lymphoid cells with round nuclei, moderately condensed chromatin, and moderately abundant, pale cytoplasm.<sup>593</sup> Mitotic activity is generally low.<sup>594</sup> The white pulp is atrophic. Erythrophagocytosis may be prominent in splenic and bone marrow sinuses.

**IMMUNOPHENOTYPE.** The tumor cells are CD2+, CD3+, CD5-, CD4-, CD8-, CD16+, CD56 +/-, and lack the ab TCR protein, expressing instead the gd complex. Cytotoxic granule protein TIA-1 is typically expressed, but Granzyme B and perforin are absent, indicating a nonactivated cytotoxic T-cell phenotype.<sup>595,596</sup> and <sup>597</sup>

**GENETIC FEATURES.** The TCR g and d genes are rearranged; the TCR b gene may be rearranged or germline. The tumor cells are EBV-. Isochromosome 7q and trisomy 8 have been reported in many cases.<sup>598,599</sup> and <sup>600</sup>

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is gd T cell of splenic type.

**CLINICAL FEATURES AND THERAPY.** This is a rare neoplasm, but because it has only relatively recently been characterized, its frequency is not known; cases have probably been classified as T-CLL/prolymphocytic leukemia or peripheral T-cell lymphoma unspecified. The diagnosis is often difficult. These patients frequently present as with a multisystem disease with hepatomegaly, splenomegaly, or both.<sup>594,601</sup> The absence of lymphadenopathy and the sinusoidal pattern of infiltration of the liver, spleen, and bone marrow make the diagnosis difficult. Frequently, only the demonstration of a T-cell gene rearrangement leads to the correct diagnosis.

Patients have been predominantly adolescent boys and young adult men. Although most patients were previously healthy, the disease has been described in immunosuppressed, solid organ allograft recipients.<sup>598,602</sup> Unusual sites of involvement such as skin, nasal cavity, gastrointestinal tract, lung, mucosal, and larynx<sup>603,604</sup> have been described. Although circulating neoplastic cells are usually not prominent, subtle bone marrow involvement may be present.<sup>605,606</sup>

Despite the relatively bland appearance of the cells, this is an aggressive tumor. Complete remission can occur with combination chemotherapy,<sup>594,606</sup> but most patients relapse. Long-term survival has been described with autologous bone marrow transplantation.<sup>594,606</sup>

### **Subcutaneous Panniculitis-Like T-Cell Lymphoma**

**DEFINITION.** Subcutaneous panniculitis-like T-cell lymphoma is a T-cell lymphoma that preferentially infiltrates subcutaneous tissue, with atypical cells of varying size, showing prominent tumor necrosis and karyorrhexis.

**MORPHOLOGIC FEATURES.** There is a variable mixture of small, medium, and large atypical cells, often containing irregular, hyperchromatic nuclei and pale cytoplasm. Reactive histiocytes with phagocytized nuclear debris, lipid, or both are numerous. Granulomas may be present. Individual adipocytes are rimmed by neoplastic cells.<sup>551,607</sup>

**IMMUNOPHENOTYPE.** Most cases express pan-T antigens and usually CD8, although they may be CD4+, express cytotoxic granule proteins TIA-1 and perforin, and in most cases, the a-b TCR.<sup>608</sup> Occasional cases derive from gd T cells.<sup>607</sup>

**GENETIC FEATURES.** TCR g genes are rearranged; usually b but occasionally d chain genes are rearranged.<sup>607</sup> No specific cytogenetic abnormalities have been described.

**POSTULATED NORMAL COUNTERPART.** The postulated normal counterpart is the mature cytotoxic T cell.

**CLINICAL FEATURES AND THERAPY.** Patients present with one or more subcutaneous nodules and are often misdiagnosed as having panniculitis. Hemophagocytic syndrome is common. The disease may present in an indolent fashion but typically becomes aggressive.<sup>551,607</sup> Patients may respond to combination chemotherapy regimens, but the responses are usually transient. These lymphomas are generally radiosensitive, and radiotherapy can be used to control symptoms. However, the

long-term outlook with this disorder is poor.

### **Anaplastic Large T/Null-Cell Lymphoma, Primary Systemic Type**

**DEFINITION.** Anaplastic large T/null-cell lymphoma, primary systemic type, is a neoplasm of large lymphoid cells with pleomorphic or multiple nuclei and abundant cytoplasm, a cohesive growth pattern, and sinusoidal spread in lymph nodes, expressing CD30 and either T-cell or no lineage-specific antigens, involving lymph nodes or extranodal sites, but not limited to the skin.

**MORPHOLOGIC FEATURES.** The tumor is usually composed of large blastic cells with round or pleomorphic, often horseshoe-shaped or multiple nuclei with multiple or single prominent nucleoli, and abundant cytoplasm, which gives the cells an epithelial or histiocyte-like appearance. The so-called hallmark cell has an eccentric nucleus and a prominent, eosinophilic Golgi region.<sup>609</sup> The tumor cells grow in a cohesive pattern and often preferentially involve the lymph node sinuses or paracortex.<sup>610</sup> In some cases, the tumor cells may have a more monomorphous appearance, with round to oval nuclei and no Reed-Sternberg-like cells; these cases have in common with the more anaplastic cases a low nuclear to cytoplasmic ratio, with dense, abundant cytoplasm and a cohesive, often sinusoidal growth pattern.<sup>611</sup> Lymphohistiocytic and small cell variants have been described, again, more commonly in children.<sup>612,613</sup> Study of cytogenetic and molecular genetic abnormalities as well as clinical features suggests that these cases belong to the same disease entity as the more anaplastic cases.<sup>609,614</sup>

A variant of ALCL resembling Hodgkin's disease of nodular sclerosis type has been described,<sup>615,616</sup> originally called *ALCL Hodgkin's-related* and included as a provisional entity under the name *ALCL Hodgkin's-like*, in the REAL.<sup>124</sup> This subtype is defined as having architectural features of Hodgkin's disease (nodularity and sclerosis), but cytologic features of ALCL (sheets of neoplastic cells and sinusoidal infiltration). Many patients are young adults with mediastinal masses, and the outcome was said to be intermediate between that of typical ALCL and nodular sclerosis Hodgkin's disease. Several studies suggest that these are not true borderline cases. First, most cases of ALCL Hodgkin's-like lack the t(2;5) or ALK protein.<sup>617,618</sup> Second, most cases of Hodgkin's disease are now thought to be B-cell derived, based on single-cell studies showing Ig gene rearrangement,<sup>559,619,620,621</sup> and <sup>622</sup> while ALCL is predominantly a T-cell disease; thus, there should be no true biologic borderline. Finally, a randomized study showed that patients with ALCL Hodgkin's-like responded equally well to the ABVD regimen for Hodgkin's disease as to a MACOP-B regimen for aggressive NHL,<sup>623</sup> suggesting a closer relationship to Hodgkin's disease than to typical ALCL. The current consensus is that the majority of these cases can be resolved as either Hodgkin's disease (CD15+, CD30+ T-cell antigen, ALK-) or ALCL (CD15-, CD30+ T-cell antigen +/-, ALK+/-) by a combination of morphology and immunophenotype. Thus, this category will be eliminated from the WHO classification.<sup>130</sup>

**IMMUNOPHENOTYPE.** The tumor cells are CD30+ and usually express CD25 and EMA; they are typically CD45+ and CD15-; approximately 60% express one or more T-cell-associated antigens (CD3, CD43, or CD45RO). Studies have shown cytotoxic granule proteins in many of the cases.<sup>624,625</sup> The ALK protein can be detected in 40% to 60% of the cases using the ALK1 monoclonal antibody, showing both nuclear and cytoplasmic staining in cases with the t(2;5), since nucleophosmin is a nuclear protein. ALK+ cases are more common in children and have a better prognosis than ALK- cases.<sup>617,618,626</sup>

**GENETIC FEATURES.** The majority of the cases have TCR genes rearranged; 20% to 30% have no rearrangement of TCR or Ig genes. Between 20% and 50% of primary systemic ALCL have a t(2;5),<sup>627,628</sup> which results in a fusion of the nucleophosmin gene (NPM) on chromosome 5 to a novel tyrosine kinase gene on chromosome 2, called anaplastic lymphoma kinase (ALK). The specificity of this translocation for ALCL has been debated, in part because of differing criteria for the diagnosis of ALCL. Using the reverse transcriptase-PCR or an antibody to the fusion protein, the fusion gene product can be detected in approximately 50% of ALCL of T and null type; however, it is also detected in some T-cell lymphomas without obvious anaplastic morphology.<sup>626,628,629</sup> Based on illustrations published in some of these articles, the so-called nonanaplastic cases appear to represent examples of the monomorphic, small cell, or histiocyte-rich variants.<sup>628</sup> Rare cases of B-cell lymphoma with the t(2;5) have been reported.<sup>626,630</sup> Finally, variant translocations have been described, which also result in overexpression of ALK protein but without the nuclear localization.<sup>631</sup>

Based on current information, t(2;5) and ALK expression are not considered defining features of ALCL, since negative case results exist; however, the positive case results appear clinically relatively homogeneous: young patients with a relatively good prognosis.

**DIFFERENTIAL DIAGNOSIS.** Many cases of ALCL were previously diagnosed as nonlymphoid tumors (malignant histiocytic tumors,<sup>627</sup> regressing atypical histiocytosis,<sup>632</sup> melanoma, metastatic carcinoma, sarcoma) or as lymphocyte-depleted Hodgkin's disease. A high index of suspicion is important in recognizing the tumor as lymphoid; immunophenotyping studies on paraffin sections (CD45, CD30, pan-T antigens, lack of epithelial or melanocyte-associated antigens) usually confirm the diagnosis.

**CLINICAL FEATURES.** Anaplastic large cell lymphoma represents approximately 2% of all lymphomas, but approximately 10% of childhood lymphomas and 50% of large cell pediatric lymphomas.<sup>125,126</sup> and <sup>127,547,633,634</sup>

Primary systemic ALCL may involve lymph nodes or extranodal sites, including the skin, but is not localized to the skin. Tumors that present with systemic disease (with or without skin involvement) have a bimodal age distribution in children and adults and are associated with the t(2;5), particularly in children, in 20% to 40% of the cases. Patients may present with isolated lymphadenopathy or extranodal disease in any site, including gastrointestinal tract and bone.<sup>633</sup> Anaplastic large cell lymphoma in children is characterized by frequent high stage but a good response to therapy with overall excellent survival.<sup>628,633,634</sup> In adults the tumor is aggressive but potentially curable, similar to other aggressive lymphomas.<sup>635</sup> Cases with the t(2;5) have a significantly better prognosis than cases lacking the t(2;5).<sup>626</sup>

**THERAPY.** Treatment regimens used for anaplastic large T/null-cell lymphoma of the primary systemic type are the same as used in diffuse large B-cell lymphoma. Treatment results have been excellent, with better survival in ALK+ patients (71% to 93%) than in ALK- patients (31% to 37%).<sup>636</sup> Excellent results are seen in adults as well as children.<sup>616,637</sup> One report using autologous bone marrow transplantation early in the treatment of patients with anaplastic large cell lymphoma reported an excellent treatment outcome.<sup>638</sup>

## **SPECIAL CLINICAL SITUATIONS**

### **CHILDREN**

See [Chapter 45.2](#) for a discussion of lymphomas and leukemias in children.

### **ELDERLY PATIENTS**

The incidence of NHL increases with age<sup>2</sup> and more than 50% of patients are beyond 60 years of age at diagnosis.<sup>7,639,640</sup> and <sup>641</sup> Some studies have failed to identify age as an important prognostic factor in patients who receive aggressive therapy for NHL,<sup>642</sup> although the vast majority of studies have shown that elderly patients have worse outcomes than younger patients.<sup>643,644,645,646,647,648</sup> and <sup>649</sup> The International Prognostic Index demonstrated that NHL patients older than 60 years of age had a significantly lower complete remission rate, greater chance of relapsing from remission (relative risk, 1.8), and higher risk of death (relative risk, 1.96).<sup>133</sup>

There are several explanations for the poorer outcome in elderly adults. Some analyses have shown that older patients were more likely to have mortality from chemotherapy-related toxicity than younger patients, despite similar complete remission rates.<sup>650</sup> Other studies have identified higher relapse rates in elderly patients.<sup>644</sup> Still other analyses have shown inferior survival in elderly patients to be a result of increased deaths from cardiovascular disease and other nonrelapse causes.<sup>645,648,651</sup> A Non-Hodgkin's Lymphoma Classification Project demonstrated that elderly patients were more likely to have a high International Prognostic Index than younger patients.<sup>648</sup> Other studies have shown that older patients are more likely to have poor performance status,<sup>647</sup> advanced-stage disease,<sup>652</sup> and diffuse histology<sup>647,653</sup> and are more likely to have extranodal disease.<sup>641,653</sup> Older patients are also more likely to have comorbid conditions.<sup>639,647</sup> These factors have often led to arbitrary dose reductions or use of less aggressive therapy, which may reduce the possibility of cure.<sup>639,646,647</sup> and <sup>648</sup> This is exemplified by Southwest Oncology Group studies that revealed a complete remission rate of 37% in patients 65 years of age and above who received initial 50% dose reductions of cyclophosphamide and doxorubicin.<sup>643</sup> Complete remission rates were 52%, a rate similar to younger patients, when full-dose chemotherapy was used.

Some analyses have shown that less intensive regimens may be associated with diminished mortality and equivalent outcomes when compared with more aggressive

regimens in elderly NHL patients.<sup>654</sup> These results have led to a multitude of phase II trials of chemotherapy regimens designed specifically for treatment of elderly patients with NHL. In general, these regimens have used anthracyclines with less cardiotoxicity than doxorubicin, have substituted mitoxantrone for doxorubicin,<sup>447,655,656,657</sup> and <sup>658</sup> or have used short-duration weekly therapy.<sup>657,659,660,661,662</sup> and <sup>663</sup> Although these regimens may be well-tolerated, selection bias and lack of appropriate comparisons make it difficult to determine whether these novel regimens are superior to standard regimens.

Several prospective randomized trials have examined results of NHL treatments in elderly patients. A Canadian trial compared standard CHOP administered every 3 weeks with a regimen in which CHOP was administered weekly at a one-third dose.<sup>437</sup> Patients were 65 years of age or older and had intermediate-grade NHL. No significant differences in complete response rate or progression-free survival were observed, although 2-year overall survival was 74% in the CHOP group and 51% in patients given weekly therapy ( $P = .05$ ). A Dutch trial compared CHOP and CNOP (cyclophosphamide, mitoxantrone, vincristine, and prednisone) in patients 60 years of age and older with aggressive NHL.<sup>453</sup> The complete response rate was 49% in CHOP-treated patients and 31% in patients who received CNOP ( $P = .03$ ). Overall survival at 3 years was 42% and 26%, respectively. A trial from the European Organization for Research and Treatment of Cancer randomized patients older than age 70 with aggressive NHL between treatment with CHOP and a regimen consisting of etoposide, mitoxantrone, and prednimustine.<sup>446</sup> The complete response rate was 77% in the CHOP arm and 50% in the etoposide, mitoxantrone, and prednimustine arm ( $P = .01$ ). Progression-free survival was also significantly longer in the CHOP arm and overall survival at 2 years was 65% and 30%, respectively ( $P = .004$ ). A Groupe d'Etude des Lymphomes de l'Adulte trial randomized patients beyond 69 years of age with aggressive NHL to treatment with cyclophosphamide, teniposide, and prednisolone or to treatment with cyclophosphamide, teniposide, prednisolone, and pirarubicin.<sup>447</sup> The complete remission rate was 47% in patients who received the anthracycline-containing regimen, as compared with 32% in the cyclophosphamide, teniposide, and prednisolone arm ( $P = .0001$ ). Time to treatment failure was significantly longer in patients who received the more aggressive regimen, and 5-year overall survival rates were 27% and 19%, respectively ( $P < .05$ ). A British National Lymphoma Investigation trial studied two treatment regimens in patients older than age 60 with aggressive NHL.<sup>664</sup> Patients were randomized between six-drug regimens that contained either doxorubicin or mitoxantrone. Toxic deaths were significantly less common in patients who received the mitoxantrone-containing regimen, and the complete remission rate was 62%, as compared with 55% in patients who received doxorubicin ( $P = .07$ ). Overall survival at 4 years was 55% and 35%, respectively ( $P = .0014$ ).

Another Groupe d'Etude des Lymphomes de l'Adulte prospective randomized trial compared fludarabine versus cyclophosphamide, doxorubicin, teniposide, and prednisolone (CHVP) plus interferon in patients older than age 59 with follicular lymphoma.<sup>665</sup> Higher response rates were noted in patients treated with CHVP and interferon. Two-year failure-free survival was 63% in the CHVP plus interferon arm and 49% in the fludarabine arm ( $P < .05$ ). Overall survival rates were 77% and 62%, respectively ( $P < .05$ ).

Elderly patients who participate in clinical trials may be subject to selection bias,<sup>647,666</sup> although these results suggest that these patients may be able to tolerate aggressive anthracycline-containing regimens. When adverse characteristics such as poor performance status are excluded, elderly NHL patients may have outcomes similar to younger patients.<sup>667</sup> It seems unreasonable to arbitrarily reduce drug dosages or to withhold aggressive therapy because of chronologic age alone in NHL patients with good performance status and without significant comorbidity. These patients should be treated aggressively with CHOP or similar regimens, which can be reduced in intensity at a later time if not tolerated. Other patients may still be candidates for less aggressive therapy, or even a watch and wait approach, if disease is behaving indolently. The use of colony-stimulating factors (CSFs) may allow elderly patients to receive planned chemotherapy doses, although they may be less effective for the oldest patients and do not entirely prevent neutropenic complications.<sup>668,669</sup> A randomized trial showed that granulocyte-CSF (G-CSF) was able to reduce the incidence of neutropenia and infection in elderly patients receiving an aggressive NHL regimen, although response rates and survival were not significantly different.<sup>670</sup>

## POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS

The risk of developing lymphoma is markedly increased following solid organ transplantation.<sup>671</sup> PTLDs occur in 0.8% to 20.0% of transplanted patients.<sup>672</sup> Although mortality of 60% to 80% is frequently reported, more favorable outcomes have been described.<sup>673</sup> Identical disorders are seen after allogeneic bone marrow transplantation, especially in recipients of T-cell-depleted marrow. PTLDs are almost always EBV-related, although cases unrelated to EBV have been described.<sup>674</sup> The development of PTLD results from proliferation of EBV-transformed B-cell clones when patients receive immunosuppressive therapy following transplantation.<sup>672</sup> Occasional cases of Hodgkin's disease and T-cell NHL have been reported.<sup>675</sup> Most PTLDs following solid organ transplants are host derived.<sup>676</sup>

The histologic appearance of PTLD is highly variable. Classification systems with clinical relevance have been proposed.<sup>677,678</sup> and <sup>679</sup> Lesions may be polymorphic or monomorphic. In some cases the appearance may resemble infectious mononucleosis and other cases may be indistinguishable from aggressive NHL or plasmacytomas.<sup>677,678</sup> Lesions may be polyclonal, oligoclonal, or monoclonal. Clinically, patients may have a syndrome similar to infectious mononucleosis with fevers, lymphadenopathy, tonsillar enlargement, and hepatitis. This presentation is more common in children and is frequently seen in the first year after transplantation. Other patients have nodal or extranodal presentations more typical of NHL. Involvement of the CNS and extranodal sites is common, as is involvement of the transplanted organ.<sup>671</sup>

The risk of PTLD is highest in recipients of heart-lung transplants and lowest in kidney transplant recipients, although the incidence rate is still 20 times higher than the general population.<sup>671</sup> Patients who receive the most aggressive immunosuppression are also more likely to develop PTLD,<sup>680</sup> as are patients who are EBV seronegative before transplant.<sup>672</sup> Disease that occurs more than 1 year after transplantation has been associated with worse outcome in most,<sup>671,681,682</sup> but not all, reports.<sup>683</sup> The presence of BCL-6 gene mutations may also correlate with histology and poor response to therapy.<sup>684</sup>

No prospective trials of PTLD treatment have been performed, and management decisions must be individualized. Interpretation of results is also hampered by lack of standardized histologic classification. Suggested treatment guidelines have been published.<sup>672</sup> Initial management should consist of reduction or cessation of immunosuppression. Patients who develop early-onset PTLD are most likely to benefit from this approach.<sup>681</sup> Many investigators recommend concurrent administration of acyclovir or ganciclovir, although the value of this approach has been questioned.<sup>685</sup> Surgical excision or RT may be curative for patients with localized PTLD.<sup>672,683,685,686</sup> Surgery should be considered for patients with isolated PTLD in renal transplants. Patients who fail to respond to reduction of immunosuppression can be treated with anthracycline-based combination chemotherapy. Durable remissions can be seen, although mortality is higher than nonimmunosuppressed NHL patients.<sup>683</sup> Interferon may also be considered for patients who are not progressing rapidly.<sup>685</sup>

Responses have also been reported with anti-B-cell monoclonal antibodies, including rituximab.<sup>682,687</sup> This modality may be considered before the use of chemotherapy. Autologous lymphokine-activated killer cell infusion has also been investigated for PTLD following solid organ transplantation,<sup>688</sup> and donor leukocyte infusion has become accepted therapy for patients who develop PTLD following allogeneic bone marrow transplantation.<sup>689</sup>

## HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED NON-HODGKIN'S LYMPHOMA

The risk of developing NHL is markedly increased in patients infected with human immunodeficiency virus type 1. Large cell lymphomas, small noncleaved cell NHL, and primary CNS lymphoma are considered AIDS-defining conditions.<sup>690</sup> The risk of developing NHL after another AIDS-defining diagnosis is increased 165-fold in the first 3.5 years.<sup>13</sup>

AIDS-related lymphomas are B-cell neoplasms. Virtually all primary CNS lymphomas and approximately 50% of other AIDS-related NHL are EBV-related.<sup>63</sup> Most cases are classified as small noncleaved cell histology or diffuse large cell lymphoma. The risk of low-grade NHL may also be increased, although these lymphomas are not considered to be diagnostic of AIDS. Small noncleaved cell lymphomas are associated with c-myc activation in virtually all cases and are frequently associated with p53 mutations.<sup>63</sup> Rearrangements of bcl-6 are detected in approximately 40% of diffuse large cell lymphomas. Primary effusion lymphoma is seen in 1% to 3% of AIDS patients and is associated with HHV-8.<sup>63,77</sup>

AIDS-associated NHL usually behaves aggressively. Systemic symptoms are common, along with involvement of extranodal sites.<sup>691</sup> Gastrointestinal tract involvement is common, as well as unusual sites such as anus and rectum, skin and soft tissues, and heart. Approximately 15% of cases are primary CNS lymphomas.<sup>13</sup> The prognosis for AIDS-associated NHL is poor. Median survival averages approximately 6 months and 2-year survival rates are 10% to 20%.<sup>13,692</sup> Factors associated with improved survival include higher CD4 counts,<sup>692,693</sup> and <sup>694</sup> EBV-negative lymphomas,<sup>692</sup> higher performance status,<sup>691,693,695</sup> younger age,<sup>694</sup> and low stage.<sup>694,695</sup> Patients with a history of drug abuse have worse outcomes,<sup>694</sup> and outcome is better for patients without an AIDS-defining illness before NHL.

diagnosis.<sup>691,693,695</sup>

Aggressive chemotherapy regimens are associated with significant toxicity, and the use of lower dose chemotherapy regimens have been investigated. A randomized trial comparing m-BACOD with reduced-dose m-BACOD demonstrated median survival rates of 31 weeks and 35 weeks, respectively ( $P = .25$ ), with less toxicity in the low-dose arm.<sup>696</sup> Similar survival has been noted in a phase II trial of oral lomustine, etoposide, cyclophosphamide, and procarbazine.<sup>697</sup> Median survival was 9.3 months in AIDS-associated NHL patients who received the LNH-84 regimen, which incorporates CNS prophylaxis.<sup>698</sup> Median survival was 18 months using a regimen of continuous infusion cyclophosphamide, doxorubicin, and etoposide combined with didanosine,<sup>699</sup> and median survival was 13 months using weekly methotrexate combined with zidovudine.<sup>700</sup>

The lack of randomized trials makes it difficult to reach consensus on management approaches for AIDS patients with NHL. Dose-modified regimens should be considered, although many patients can tolerate full-dose chemotherapy.<sup>696,698</sup> Other investigators have recommended CHOP or similar regimens for low-risk patients, and dose-attenuated regimens for patients with poor performance status, low CD4 counts, or a prior AIDS-defining condition.<sup>701</sup> The benefits of CSFs are uncertain, and no clear survival advantages have been demonstrated, although routine use may be justified.<sup>702,703</sup> Antiretroviral therapy and prophylactic antibiotics should be continued during therapy.<sup>698,701</sup> There are differing opinions on the use of CNS prophylaxis,<sup>698,701</sup> although patients with small noncleaved histology and those with sinus or testicular involvement should receive prophylactic intrathecal therapy.

The prognosis for AIDS patients with primary CNS lymphoma is also poor. Standard therapy has consisted of whole brain irradiation, although median survival is 3 to 4 months.<sup>698</sup> Patients may respond to high-dose methotrexate, and the role of combined modality therapy is being investigated. No standardized approaches have been developed for primary effusion lymphoma and these patients should probably be treated like other patients with AIDS-related NHL.

## EXTRANODAL SITES

### *Primary Central Nervous System Lymphoma*

Primary CNS lymphoma accounts for less than 5% of all primary brain tumors and approximately 1% to 2% of all lymphomas in immunocompetent patients.<sup>704</sup> The incidence of primary CNS lymphoma rises with age and has increased four times as rapidly as extranodal NHL as a whole, although there is controversy as to whether this increase is entirely explained by the AIDS epidemic.<sup>8</sup> Most cases are large cell lymphoma, although other histologic subtypes can be observed.<sup>705</sup> Ocular lymphoma is common and slit-lamp examination should be performed for all patients. Leptomeningeal involvement also occurs commonly. Corticosteroid administration may lead to rapid regression of primary CNS lymphoma and make it difficult to obtain diagnostic tissue. Every effort should be made to perform biopsies before corticosteroids are administered to patients with suspected CNS lymphoma.

The median survival of untreated patients is less than 4 months. Median survival was 16 months and actuarial 5-year survival was 19% in a series of 226 patients treated heterogeneously.<sup>705</sup> Overall survival is not improved after surgical resection, and surgery has little role except for diagnostic purposes. The use of RT improves overall survival, although median survival after whole brain radiation is only approximately 12 months, a rate similar to glioblastoma multiforme.<sup>706</sup> Most patients progress locally after RT despite high rates of remission.

Conventional regimens such as CHOP have little efficacy in primary CNS lymphoma.<sup>707,708</sup> Several regimens designed specifically for treatment of primary CNS lymphoma have been developed. These regimens have generally employed drugs that penetrate the CNS, such as methotrexate and cytarabine, combined with intrathecal prophylaxis, and RT.<sup>705,709,710</sup> and <sup>711</sup> It is thought that RT should be administered after chemotherapy because of evidence that neurotoxicity is enhanced if radiation is administered first. Results from these phase II studies, as well as retrospective analyses, suggest that overall survival rates are improved with the use of chemotherapy regimens containing high-dose methotrexate.<sup>708,712</sup>

Unfortunately, the use of whole brain radiation results in rates of leukoencephalopathy that may be as high as 25% 5 years after treatment.<sup>708</sup> In other studies, the rate of neurotoxicity was estimated to be nearly 80% in patients over the age of 60 who survived at least 1 year after treatment.<sup>713</sup> Few patients return to their former functional status after treatment for primary CNS lymphoma and median survival is less than 12 months for patients who develop neurotoxicity.<sup>708</sup>

Analyses of patient-related prognostic factors have consistently identified age over 60 years and poor performance status as adverse prognostic characteristics for patients with primary CNS lymphoma.<sup>706,708,712</sup> It has been suggested that improved results associated with combined modality therapy may be due to patient selection,<sup>714,715</sup> and some trials have shown that regimens using chemotherapy, without whole brain radiation, may be as good as combined modality therapy.<sup>716,717</sup> and <sup>718</sup> Other investigators have reported high response rates using osmotic blood-brain barrier disruption and intraarterial chemotherapy for patients with primary CNS lymphoma.<sup>719</sup>

We recommend that patients receive initial therapy with a regimen that uses high-dose methotrexate. It is unknown whether this eliminates the need for intrathecal therapy, although some analyses have shown that overall survival was improved using regimens that included intrathecal chemotherapy.<sup>712</sup> The use of radiation as initial therapy should be avoided, except in patients who are unlikely to tolerate chemotherapy. Because of the risk of leukoencephalopathy, withholding radiation after chemotherapy may be considered, especially in older patients who achieve a complete remission with chemotherapy.

### *Testicle*

Primary testicular NHL accounts for approximately 1% to 9% of all testicular neoplasms and is the most common testicular neoplasm in men over the age of 60.<sup>720,721</sup> Testicular lymphoma is frequently associated with involvement of Waldeyer's ring, skin and subcutaneous tissue, lung, and CNS. Involvement of the contralateral testis is common at diagnosis or later in the course of disease. Most tumors are classified as diffuse large cell histology or immunoblastic lymphoma, although Burkitt's lymphoma is common in children, and follicular lymphomas and other histologic subtypes have been described.<sup>721,722</sup> and <sup>723</sup>

Most series have reported poor outcomes with relatively few long-term survivors. Five-year overall survival was 17% in a Danish population-based study.<sup>724</sup> Median survival is less than 12 months in many series,<sup>720</sup> although somewhat better results have been reported in more recent series.<sup>725,726,727</sup> and <sup>728</sup> Nevertheless long-term disease-free survival is poor, especially for patients with advanced disease, and most series have failed to show a survival plateau. Factors reported to be associated with improved outcome have included localized disease,<sup>723,724,729</sup> low International Prognostic Index score,<sup>727,730</sup> age,<sup>725</sup> presence of sclerosis within biopsies,<sup>729</sup> tumor size,<sup>731</sup> and right-sided tumors.<sup>729,732</sup>

Orchiectomy is universally recommended as initial therapy for patients with localized disease. Although long-term disease-free survival has been described after orchiectomy alone, the vast majority of patients relapse, and this is not adequate therapy, even for patients with IE disease.<sup>720</sup> Furthermore, relapse rates exceeding 50% have been observed in the majority of reports in which adjuvant RT was used following orchiectomy. Relapses often occur in extranodal sites, and this suggests that testicular NHL is usually a systemic disease, even when clinically localized.<sup>720</sup>

These poor results have led to use of chemotherapy following orchiectomy for patients with stage IE and IIE disease. The Danish Lymphoma Study Group noted that the relapse rate was 15.4% for stage IE or IIE patients who received combination chemotherapy after orchiectomy, as compared with 63.6% for the remaining patients ( $P < .05$ ).<sup>724</sup> Median relapse-free survival was 28 months and 14 months, respectively. An analysis of men with stage IE disease at Harvard demonstrated that 5-year relapse-free survival was 75% for men who got adjuvant chemotherapy, as compared with 50% for those who received no adjuvant therapy.<sup>733</sup> However, by 10 years no difference in relapse-free survival was observed. The best results in patients with stage IE and IIE disease have been reported by the Vancouver group.<sup>734</sup> Patients were treated with a brief course of doxorubicin-based chemotherapy followed by scrotal radiation for stage IE patients and additional pelvic and paraaortic radiation for patients with stage IIE disease. The 4-year overall survival and relapse-free survival rates were 93%, as compared with 50% in a historic control group treated with orchiectomy and radiation alone. No relapses in the contralateral testis or CNS were observed, and the routine use of CNS prophylaxis was thought to be unnecessary.

However, other groups have reported CNS relapses and contralateral testis relapse after doxorubicin-based chemotherapy and RT in stage IE patients.<sup>727,728,730,733</sup> The use of adjuvant radiation has been recommended by some groups,<sup>734,735</sup> whereas others found no apparent advantage when pelvic or paraaortic radiation was

added to stage IE patients who received chemotherapy.<sup>720,733</sup> High rates of CNS relapse with aggressive combination chemotherapy have led some groups to recommend routine CNS prophylaxis<sup>724,725</sup> and <sup>726,730,735</sup> or to consider this for patients who achieve remission.<sup>720</sup> Others have questioned the value of this approach.<sup>728,734</sup> The high rate of contralateral testis recurrence has led some to recommend prophylactic scrotal radiation.<sup>723,728,730,734</sup>

### **Cardiac**

Lymphoma involving the heart is not often recognized clinically. Cardiac involvement can be primary or secondary. Patients with mediastinal involvement by a lymphoma frequently have secondary cardiac involvement, particularly pericardial disease.<sup>736</sup> In one series, 64% of the patients presenting with mediastinal lymphoma were found to have cardiac involvement, with pericardial infusions or infiltration being the most common finding.<sup>736</sup> In one series of 150 patients undergoing autopsies after death from lymphoma, cardiac involvement was found in 9%.<sup>737</sup> Cardiac involvement is most often identified by echocardiography, but MRI and radionuclide studies can be helpful.<sup>736,738</sup> Patients with secondary cardiac involvement are most likely to present with symptoms of pericardial disease, although arrhythmias have been described<sup>739</sup> as well as ventricular perforation.<sup>752</sup>

Primary cardiac lymphoma is unusual, but several cases have been described.<sup>740,741,742,743,744</sup> and <sup>745</sup> Primary cardiac lymphoma is often reported in patients with AIDS,<sup>743,744,746</sup> but is also seen in immunocompetent patients.<sup>743,745</sup> Primary cardiac lymphoma is often found at autopsy because of difficulty in diagnosis. However, responses to combination chemotherapy are possible.<sup>742</sup>

### **Thyroid and Adrenal**

Most cases of thyroid NHL arise in a background of Hashimoto's thyroiditis,<sup>54,747,748</sup> and evidence of thyroiditis is frequently detected in biopsies.<sup>749,750</sup> and <sup>751</sup> Most thyroid lymphomas are classified as diffuse large cell lymphomas and most of the remainder are MALT lymphomas.<sup>54</sup> These lymphomas may be difficult to distinguish from thyroiditis, especially when fine-needle aspirates are performed. Large cell lymphomas frequently have a small cell component, suggesting a MALT origin.<sup>747,748,751,752</sup> Factors reported to be associated with better prognosis have included lack of bulk,<sup>750,753</sup> stage IE disease,<sup>753,754</sup> and <sup>755</sup> and absence of mediastinal or retrosternal extension.<sup>749,753,755</sup>

The role of surgery in the management of thyroid NHL is controversial. Some authors have recommended complete surgical excision whenever possible,<sup>749,756</sup> while others have argued against the use of extensive resection, particularly for patients with large cell histology, except for rare cases in which disease is confined to the thyroid and resection can be accomplished without morbidity.<sup>54,753,757,758</sup> Results of RT for thyroid lymphoma vary widely, with 5-year relapse-free survival rates of 38% to 64%.<sup>54</sup> A retrospective BNLI study showed a 5-year cause-specific survival of 90% following RT of thyroid lymphomas of MALT origin, as compared with 55% for patients without MALT histology ( $P < .01$ ).<sup>759</sup> Radiation therapy alone is usually inadequate for primary large cell lymphoma, and reports have shown better outcomes with the addition of chemotherapy.<sup>750,760</sup> Patients with localized thyroid large cell lymphoma can be successfully treated with a brief course of anthracycline-based chemotherapy followed by involved-field radiation in the same manner as other localized lymphomas.<sup>403</sup> Patients with disseminated disease should receive a full course of chemotherapy.

Primary adrenal lymphoma is unusual. Most patients have diffuse large B-cell lymphoma, and the disease is sometimes bilateral.<sup>761,762</sup> The disease might present with adrenal insufficiency, but more commonly the presenting manifestation is an adrenal mass that might be found incidentally on imaging studies.

### **Pancreas**

Lymphoma presenting in the pancreas is rare. Lymphomas presenting in the pancreas are usually diffuse large B-cell lymphomas. Although rare, recognizing their presence is extremely important for the patient. Diffuse large B-cell lymphoma has a much better prognosis than adenocarcinoma of the pancreas, and failure to make an accurate histologic diagnosis keeps a patient from appropriate therapy and a chance for cure.

### **Breast**

Lymphomas presenting in the breast are rare.<sup>763</sup> Lymphomas in this site can be MALT lymphomas, diffuse large B-cell lymphoma, and Burkitt's lymphoma. Breast involvement and Burkitt's lymphoma have been seen particularly in association with pregnancy.<sup>764</sup>

### **Kidney, Ureter, Bladder, and Prostate**

Lymphomas presenting in the kidney, ureter, bladder, and prostate are rare.<sup>765</sup> The most common lymphoma seen involving the kidney is diffuse large B-cell lymphoma. Prostatic involvement by lymphoma is often related to SLL.

### **Ovary, Uterus, and Vagina**

Lymphomas presenting in the female genital tract are rare.<sup>766,767</sup> The most common has been diffuse large B-cell lymphoma, although MALT lymphoma can be seen.<sup>768</sup> An accurate histologic diagnosis is important to avoid inappropriate therapy.

### **Eye and Orbit**

Lymphomas presenting in the orbit are most often MALT lymphomas.<sup>769,770,771,772,773</sup> and <sup>774</sup> In the past, these tumors were often called *pseudolymphomas*. In one series, 80% were MALT lymphomas, 14% were diffuse large B-cell lymphomas, and rare cases of mantle cell lymphoma and lymphoplasmacytic lymphoma were seen.<sup>769</sup> Patients with MALT lymphomas in the orbit most often present with unilateral swelling and most have stage I disease. Treatments used have included observation, radiotherapy, chemotherapy, and combined modality therapy. Radiotherapy alone can produce durable remissions in the majority of patients with localized disease and is probably the treatment of choice. Patients with more aggressive subtypes of lymphoma should be treated with modalities appropriate for that subtype.

Primary ocular lymphoma most often presents with altered vision or uveitis that is refractory to therapy.<sup>775,776,777,778</sup> and <sup>779</sup> Patients might also present with photophobia, a red eye, retinal detachment, pain, glaucoma, or the symptoms of lymphoma involving other parts of the CNS. Intraocular lymphoma should be considered one presentation of primary CNS lymphoma. Treatment of these patients should include radiotherapy of the eye along with combined chemotherapy and radiotherapy to treat the entire CNS.<sup>717</sup>

### **Lung**

Lymphomas presenting in the lung are unusual and have a wide variety of histologic appearances. These include MALT lymphomas, diffuse large B-cell lymphoma, lymphomatoid granulomatosis (which is usually a manifestation of diffuse large B-cell lymphoma), and intravascular lymphomatosis.<sup>780</sup> MALT lymphomas in the lung and at other extranodal sites have an indolent course. Surgery can sometimes be curative. Patients with diffuse large B-cell lymphoma should receive aggressive combination chemotherapy regimens.

### **Bone**

NHL presenting primarily in the bone makes up as many as 5% of extranodal NHLs. Since the report by Parker and Jackson,<sup>781</sup> this has been recognized as a distinct clinical pathologic entity. The vast majority of patients have diffuse large B-cell lymphoma and present with bone pain, a palpable mass, or both.<sup>406,782,783,784,785</sup> and <sup>786</sup> As is always true in diagnosing lymphomas, an adequate biopsy is essential for accurate diagnosis.

Most patients with primary lymphoma of the bone have localized disease, often with extension to adjacent soft tissues. The masses can be quite large. Patients have been treated with radiotherapy, chemotherapy, or combined modality therapy.<sup>406,782,783,784</sup> and <sup>785,787,788,789</sup> and <sup>790</sup> There is a trend in these reports for better failure-free

survival in patients treated with combined modality therapy. Patients should be managed in conjunction with an orthopedic surgeon because of the risk of fracture. Delayed follow-up should include observation for avascular necrosis as a consequence of the therapy.

### **Pleura**

Pleural involvement in NHL is not rare, with a frequency as high as 20% being reported.<sup>791</sup> Pleural involvement can be seen at presentation of the lymphoma or develop during the course of the disease. Effusions can be seen in any subtype of NHL. Most effusions are exudative, with a few patients having chylous effusion. Cytologic examination results are often positive.<sup>792</sup> In SLL the diagnosis can be difficult because of the bland nature of the lymphoma cells in the fluid. In these circumstances, demonstration of a B-cell immunophenotype can be helpful, since most reactive pleural effusions have predominantly T lymphocytes.<sup>793,794</sup> The presence of pleural effusion at the time of diagnosis does not seem to adversely affect prognosis in comparison with other patients with similar stages.<sup>792</sup>

A distinct type of pleural involvement by lymphoma has been referred to as *pleural effusion lymphoma*.<sup>77</sup> These patients demonstrate Kaposi's sarcoma-associated herpesvirus (also known as *HHV-8*) in the lymphoma cells.<sup>77,795,796</sup> These tumors also have been associated with EBV infection.<sup>797</sup> Patients have diffuse large B-cell lymphomas, sometimes with immunoblastic or anaplastic appearance.<sup>77</sup> These lymphomas rarely express c-myc, bcl-2, or bcl-6 gene rearrangement. The tumors often remain confined to the pleura. These patients have a poor prognosis, probably in large part because of the frequent occurrence of this lymphoma in patients infected by the human immunodeficiency virus. However, this lymphoma has been reported in patients with negative results for human immunodeficiency virus.<sup>798</sup>

### **Skin**

Following the gastrointestinal tract, the skin is the second most common extranodal site primarily involved by NHL. As opposed to lymph nodes and most other extranodal sites of presentation of lymphoma, the skin is unusual in that T-cell lymphomas occur more frequently than B-cell lymphomas. The most common cutaneous T-cell lymphoma, mycosis fungoides, is dealt with in [Chapter 45.4](#). The most common presentation is a new or unusual skin lesion.

Skin lymphomas can be classified using the WHO classification. However, the European Organization for Research on the Treatment of Cancer<sup>799</sup> has also developed a classification that specifically deals with primary cutaneous lymphomas. An important feature interpreting any histologic diagnosis of a cutaneous lymphoma is to remember that the clinical behavior may be different than when the same diagnosis is identified in nodal or other extranodal sites. It is also important to realize that full-thickness biopsies usually are required for diagnosis. The diagnosis of cutaneous lymphomas can be extremely difficult, even with immunohistochemical and molecular genetics studies. Repeat biopsies are sometimes required for a definite diagnosis. In addition, the clinical history may be important in making the diagnosis. Lymphomatoid papulosis is histologically quite similar to CD30+, T/null-cell lymphomas in the skin. Often a history of chronic recurring lesions is the key to making the correct diagnosis.<sup>800,801,802</sup> and <sup>803</sup> There is a clinical spectrum of cutaneous CD30+ lymphoproliferative disorders ranging from the benign behavior of lymphomatoid papulosis to an aggressive anaplastic large cell lymphoma.<sup>804</sup> Peripheral T-cell lymphomas that are CD30- can involve the skin and typically follow an aggressive clinical course.<sup>805</sup> Tumors with a high proportion of large cells seem to be more aggressive. Angiocentric lymphomas can also have cutaneous presentations and are associated with a highly aggressive course.

Primary B-cell lymphomas in the skin are less common, but occur more frequently than previously appreciated. These can include marginal zone lymphoma and diffuse large B-cell lymphomas. Marginal zone lymphomas of the skin are typically of MALT type.<sup>806,807</sup> and <sup>808</sup> These lymphomas have an excellent survival with local therapy, although local recurrence sometimes occurs. Primary diffuse large B-cell lymphoma occurring on the trunk tends to behave indolently and can be managed with local therapy, in contrast to those that occur on the legs, which tend to follow a more aggressive course.<sup>799,809,810</sup>

### **Paranasal Sinuses**

Paranasal sinuses represent an unusual site of presentation of NHL in North America. In North America most of these patients have diffuse large B-cell lymphoma,<sup>811</sup> in contrast to frequent T-cell or NK-cell lymphoma with angiocentric involvement seen in Asia.<sup>567</sup> Patients typically present with pain, rhinorrhea, airway obstruction, swelling, epistaxis, proptosis, or diplopia. In general, patients with disease confined to the primary site should receive combined modality therapy, with a combination chemotherapy regimen including an anthracycline followed by radiotherapy. In some patients, the radiotherapy might be not given and a longer course of chemotherapy may be used because of concerns about visual toxicity or persistently dry mouth. Because this type of lymphoma has a predilection to spread to the CNS, these patients should receive prophylactic CNS treatment with intrathecal chemotherapy.

### **Gastrointestinal Tract**

Gastrointestinal tract represents the most frequent extranodal site of presentation of NHLs. Lymphomas can present in the oral pharynx,<sup>812,813</sup> and <sup>814</sup> esophagus,<sup>815</sup> stomach,<sup>816,817,818,819,820</sup> and <sup>821</sup> small intestine,<sup>822,823</sup> or rectum.<sup>824</sup> In North America, lymphomas in most of these sites are predominantly diffuse large B-cell lymphomas. In the stomach MALT lymphomas represent a minority of NHLs in the United States, but are more common in other areas in the world.<sup>20</sup> Lymphomas occurring in the small intestine can include enteropathy associated T-cell lymphomas and lymphomas arising in immunoproliferative disease of the small intestine.<sup>825,826</sup> In addition, Burkitt's lymphomas as well as diffuse large B-cell lymphoma can be seen in the rectum in patients affected with human immunodeficiency virus.<sup>824</sup> Patients presenting with multiple polyps in the colon usually have mantle cell lymphoma.<sup>827</sup>

Symptoms and signs of presentation reflect the site of involvement. The most serious presenting symptoms include perforation and bleeding. These can also be complications of therapy. Because of the seriousness of perforation of the colon, removal before the administration of systemic therapy is often appropriate. For patients presenting with diffuse large B-cell lymphoma in other sites, it is now clear that surgery, while associated with a modest chance for cure,<sup>821,828</sup> is not required for cure, and that chemotherapy with or without radiotherapy seems to yield a higher cure rate.<sup>818,819</sup> and <sup>820</sup> Patients with gastric MALT lymphoma can be treated with eradication of *H pylori* as described in the section on MALT lymphoma (see [Infectious Agents](#), earlier in this chapter). For patients with MALT lymphoma who do not respond to this treatment but have disease confined to the stomach, radiotherapy is usually curative.

## INTRODUCTION

Cutaneous T-cell lymphoma (CTCL) is a lymphoproliferative disorder of epidermotropic, neoplastic T cells with a wide range of clinical manifestations. Although previously considered as distinct clinical entities, mycosis fungoides (MF), Sézary syndrome (SS), reticulum cell sarcoma of the skin, and several other cutaneous lymphocytic dyscrasias are now recognized as different clinical presentations of CTCL.<sup>1</sup> All forms of CTCL are neoplasms of T lymphocytes, which home to skin and to the T-cell zones of lymphoid structures but generally not to bone marrow. The clinical value of the umbrella classification of CTCL is twofold. First, it highlights the relationship between distinct clinical presentations that can nevertheless evolve into one another (i.e., the plaque stage of MF can develop into the erythrodermic SS) or coexist [i.e., plaque-stage MF and lymphomatoid papulosis (LP)]. Second, the nomenclature emphasizes the clinical relevance of advances in the understanding of the biology of the malignant T cells. Recognition of the malignant clone-specific properties of the T-cell receptor (TCR) for antigen on the CTCL cells in individual patients has both provided the most sensitive diagnostic tool for the disease and offered an extraordinary target for selective immunologic attack of CTCL cells in such treatments as photopheresis. Still, it remains fairly useful for the clinician to attach the subtype of CTCL to the name (e.g., CTCL/MF), as the management scheme and prognosis for these subtypes differ.

## PATHOBIOLOGY

CTCL is a clonal neoplasm<sup>2,3 and 4</sup> of mature CD4+ helper-inducer T cells,<sup>5,6</sup> which are capable of stimulating immunoglobulin synthesis by B cells,<sup>7,8</sup> perhaps by secretion of interleukin-4 (IL-4) or other cytokines.<sup>9</sup> CTCL cells also express BE-2, a molecule related to heat-shock proteins the function of which is yet unknown; the CD45RO marker characteristic of “memory” T cells<sup>10</sup>; and cutaneous lymphoid antigen (CLA), a glycoprotein that is expressed on the surface of only a small fraction of normal T cells in cutaneous infiltrates.<sup>11</sup> Both of the last two markers are simultaneously expressed on the surface of virtually all circulating CTCL cells. The deficiency of normal T cells that can accompany the systemic dissemination of lymphoma may reflect the production of IL-10, an inhibitory cytokine produced by those CTCL cells.

CLA is the physiologic ligand of endothelial cell E-selectin, a cell adhesion molecule expressed on the surface of endothelial cells of cutaneous venules during chronic inflammation.<sup>12,13</sup> Interactions between CLA on the surface of CTCL cells and E-selectin on endothelial cells allow CTCL cells to adhere to the walls of cutaneous venules, leave the circulation, and enter the skin.

Once CTCL cells enter into the skin, their most striking trait is their profound epidermotropism.<sup>14</sup> The latter may be a consequence of neoplastic and normal T-cell production of interferon-gamma (IFN-gamma), which stimulates keratinocytes to express the intracellular adhesion molecule-1 (ICAM-1) on their surface.<sup>15</sup> Because ICAM-1 is the physiologic ligand for lymphocyte function-associated antigen-1 expressed on the surface of all T cells, CTCL cells should adhere to keratinocytes exposed to IFN-gamma.<sup>16</sup> In addition, there is evidence for avid binding of CTCL cells to keratinocytes by other, non-ICAM-1-dependent mechanisms.

In addition to producing cytokines, CTCL cells are exposed to a complex paracrine environment composed of many growth factors and cytokines elaborated by keratinocytes and stromal fibroblasts, macrophages, endothelial cells, and normal and neoplastic T lymphocytes. Preformed IL-1 may be released by proliferating keratinocytes to stimulate both keratinocytes and benign or neoplastic T cells to release granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF).<sup>17</sup> The latter two cytokines enhance the antigen-presenting capabilities of Langerhans' cells (LC) and activate resting macrophages, which respond by releasing a complex mix of cytokines active on keratinocytes, fibroblasts, and endothelial and lymphohematopoietic cells.<sup>18</sup>

In more advanced stages of disease, CTCL cells lose their dependence on epidermal cell adhesion molecules and cytokines so that their epidermotropism either is diminished (to permit the development of tumor nodules that extend deep into the dermis) or is lost completely (to permit dissemination of the neoplastic T cells to nodal and visceral sites). At this stage, the clinical presentation of CTCL may become indistinguishable from that of a peripheral T-cell lymphoma, although the broad involvement of the skin usually remains a distinguishing feature. Even at this advanced stage, the distinctive tissue distribution of the malignant cells (skin infiltration, preferential localization in interfollicular regions of lymph nodes, and avoidance of bone marrow) remains evident.

## EPIDEMIOLOGY

CTCL is a relatively rare neoplasm, and the Surveillance, Epidemiology, and End Results program<sup>19</sup> reports that the incidence had increased 3.2-fold between 1973 and 1984. The overall incidence rate is approximately 4 per 1,000,000, according to data from that program.<sup>20</sup> The actual incidence rate may be an order of magnitude higher, given possible underreporting and the difficulty and confusion in making the diagnosis. The incidence of CTCL rises with age such that the majority of patients are between 40 and 60 years old. The disease is 2.2 times more common in male than in female subjects, and incidence rates are somewhat higher in African Americans than in whites.

## ETIOLOGY

The inability to propagate CTCL cells *in vitro* after isolation from skin lesions, even from rapidly growing cutaneous tumors, has rendered molecular biologic studies of

CTCL far less informative than they have been for many other lymphoid neoplasms; to date, the molecular etiology of CTCL remains unclear. However, at least one study has implicated rearrangements or deletions of the tal-1 and NFkB2/lyt-10 encoded transcription factors in a subset of CTCL patients with very aggressive disease.<sup>133</sup> In addition, transgenic mice that constitutively synthesize IL-7 develop extensive dermal infiltrates that progress to a cutaneous lymphoma resembling CTCL—results that suggest that overexpression of IL-7 might contribute to the development of CTCLs.<sup>23,24</sup> Such infiltrates develop even when the transgene is expressed in athymic nude mice, implying that the evolution of IL-7–induced dermal lymphoma may be dependent on the skin rather than on the thymus. Although the phenotypes of the lymphomatous T cells and their distribution in the skin are not identical with those of human CTCL, a refinement of this experimental system may ultimately provide an animal model for the human disorder.

Given the inherent immunologic nature of the neoplastic cells responsible for this disorder, it has been proposed that chronic exposure to occupational chemicals, pesticides, or tobacco may predispose to the development of CTCL; however, none of these potential associations has survived scrutiny.<sup>20,21</sup> The observations that the disease is more common in African Americans than in whites and that it often presents first in areas normally shielded from the sun (i.e., “bathing trunk” distribution) together suggest that actinic exposure may actually inhibit the evolution of the malignant clone from normal “cutaneous T cells.” It is noteworthy that the epidermotropic collections of CTCL cells, referred to as *Pautrier microabscesses*, may represent congregation of malignant T cells around LC, the dendritic antigen-presenting cells (DC) of the epidermis, and that LC are fairly sensitive to ultraviolet (UV) damage. This observation has suggested that epidermotropic CTCL cells may receive growth signals from their contact with LC. Therefore, it is possible that UV damage of LC, more significant in whites than in African Americans (whose darker pigment shields the LC), may interrupt this growth signal and inhibit the replication of CTCL cells in UV-exposed skin sites. It is also intriguing that the often profound response of plaque-stage CTCL to UV treatment may reflect this phenomenon as well. The observation that individuals infected with the human T-cell leukemia virus type I (HTLV-I) often develop T-cell leukemias with skin involvement indistinguishable from those of CTCL has led some to hypothesize that CTCL may be a consequence of infection with HTLV-I or another unknown retrovirus, a possibility that remains the subject of active investigation.

## CLINICAL PRESENTATION

### MYCOSIS FUNGOIDES

The classic MF presentation of CTCL progresses through the following four distinct phases:

1. A premycotic phase with an asymptomatic, scaling erythematous macular eruption, often in sun-shielded areas (i.e., bathing trunk distribution), which lasts for months to years during which the diagnosis may be suspected but cannot be confirmed by standard clinical or histopathologic means
2. A patch phase with thin, barely palpable, erythematous and eczematous lesions the histologic features of which are at least “consistent with” the diagnosis of CTCL
3. A plaque phase with more readily palpable erythematous lesions
4. A tumor phase, in which the neoplastic infiltrate extends below the upper dermis

Painful erythroderma may arise *de novo* or during any of the earlier described phases and is not always associated with frank T-cell leukemia (SS). Infrequently, CTCL presents with cutaneous tumor nodules in the absence of patches or plaques. Patients may also present with involvement of internal organs.

### RELATED CONDITIONS

The MF presentation of CTCL often manifests alongside (and can be confused with) several related, more benign cutaneous lymphoid dyscrasias. They include LP,<sup>25,26 and 27</sup> alopecia mucinosa–follicular mucinosis (AM-FM),<sup>28,29</sup> and pagetoid reticulosis (PR).<sup>30</sup> CTCL also has features in common with two other, clearly malignant disorders: adult T-cell leukemia-lymphoma (ATLL) and CD30+ anaplastic large cell lymphoma.

LP is a dermatologic disorder that resembles pityriasis lichenoides et varioliformis acuta. LP lesions often appear as groups of erythematous brown papules that develop a scale or crust. Resolving LP lesions may leave residual pigment or superficial atrophic scars. Depending on the clinical series, from 5% to 20% of patients with LP eventually develop a non-B-cell lymphoma, most often CTCL. Regressing atypical histiocytosis is thought to be a variant of LP.

AM is an infiltrative, cutaneous T-cell dyscrasia also known as *follicular mucinosis* (FM). AM-FM is characterized by the accumulation of acid mucopolysaccharides in the sebaceous glands and root sheaths of hair follicles. When the lesions of AM-FM develop in a hair-bearing area, patchy alopecia may be their presenting sign. Overall, 15% to 30% of AM-FM patients either have or will develop CTCL.

PR, or Worringer-Kolopp disease, presents as a solitary cutaneous lesion of long duration and is characterized histologically by significant numbers of abnormal mononuclear cells infiltrating the epidermis. The underlying dermis is involved by a mixed inflammatory cell infiltrate. Clonal T-cell gene rearrangements have been observed in PR, which, in all likelihood, represents an indolent, particularly epidermotropic variant of CTCL.

### ADULT T-CELL LEUKEMIA-LYMPHOMA AND CD30+ ANAPLASTIC LARGE CELL LYMPHOMAS

ATLL is a disorder that develops in some HTLV-I-infected individuals. The clinical presentation of ATLL is often acute, with rapidly growing cutaneous lesions, hypercalcemia, marked lymphadenopathy, and infiltration of visceral organs.<sup>100,101 and 102</sup> Patients also present with systemic symptoms, such as drenching night sweats and weight loss and, in marked contrast to CTCL, the diagnosis of ATLL is usually made soon after presentation. Patients may present with a leukemic form of ATLL with extremely high white blood cell counts or may present a lymphomatous variant. ATLL patients are often severely immunocompromised and are susceptible to a variety of opportunistic pathogens. Peripheral blood and cutaneous lymphocytes often express high levels of IL-2 receptor. Current therapy for ATLL consists of simultaneous antiretroviral therapy (zidovudine) and IFN.<sup>103</sup>

Ki-1 (CD30+) anaplastic large cell lymphoma may occur primarily in the skin or with systemic involvement. Patients may present with tumor-like lesions with central ulceration, which may undergo spontaneous regression. Systemic involvement is unusual, and cutaneous lesions may be treated with radiation therapy alone. However, lesions often relapse, even though the overall clinical course may be indolent.<sup>130</sup> Patients with systemic disease, age older than 60 years, or whose tumors do not spontaneously regress appear to have a less favorable prognosis. Anaplastic (vs. nonanaplastic) cell histology does not imply a poorer prognosis; however, prognosis is poor for those patients whose tumors are CD30–.<sup>131</sup> Serum levels of CD30 may serve as a marker for response to therapy.<sup>132</sup>

## APPROACH TO PATIENTS WITH MYCOSIS FUNGOIDES

The most important clinical prognostic variables related to CTCL are the type of lesion and the percentage of the total skin surface involved, nodal involvement, dissemination to visceral sites, and the presence of CTCL cells in the circulation. These parameters have been codified in the modified TNM staging classification (Table 45.4-1) proposed by the Cutaneous T-Cell Lymphoma Workshop in 1979.<sup>31</sup> Also, this staging system has yet to be modified to incorporate the many clinical, immunologic, and molecular biologic discoveries relevant to the diagnosis and treatment of CTCL.

**TABLE 45.4-1.** TNM Classification of Cutaneous T-Cell Lymphomas

## SKIN LESIONS

Prognosis in CTCL patients depends on both the type of lesions and the extent of cutaneous involvement. All patients should have the number and distribution of each type of lesion and an estimate of the total skin surface involved by CTCL carefully recorded before initiation of therapy. Patients with patches or plaques that involve less than 10% of the body surface (stage T1) are far more likely to be palliated over the long term or cured than those with the same types of lesions occupying more than 10% of the skin surface (stage T2) (Fig. 45.4-1). Prognosis is significantly worse for patients with cutaneous tumors (T3), although it is better for patients with less than 10% of their skin surface involved by tumors than for those with more extensive involvement (Fig. 45.4-2).<sup>128</sup> Prognosis is poorer still for patients with erythroderma either alone or in addition to patches, plaques, and tumors.

**FIGURE 45.4-1.** Patch-plaque (T1 to T2 disease).

**FIGURE 45.4-2.** Tumor (T3 disease).

Skin biopsies at multiple sites may be necessary to define T-stage, as lesion morphology varies from patient to patient and for different lesions from the same patient.

However, because the histopathologic criteria for the diagnosis of early CTCL are not firmly established and there is significant interobserver variability in the pathologic interpretation of the same specimens,<sup>32</sup> accurate definition of T-stage and diagnostic correlation with pathologic material is far from routine. Such problems are especially evident for early patch or plaque lesions wherein only a small fraction of the infiltrating T lymphocytes (confined exclusively to the epidermis) are actually neoplastic. Most of the cells in the underlying, often much more impressive, dermal infiltrate are nonneoplastic, reactive CD4+ and CD8+ T lymphocytes and represent the host's immune response to the neoplastic clone. This typical histopathologic pattern can be significantly modified by prior therapy, as even topical steroids can significantly alter the intensity and appearance of both the neoplastic and nonneoplastic lymphoid infiltrates.

CTCL biopsy specimens should be reviewed by dermatopathologists with specific experience and interest in the study and diagnosis of CTCL. Specimens that exhibit epidermal collections of lymphocytes (i.e., Pautrier's microabscesses) with characteristic hyperchromatic, irregularly shaped nuclei without spongiosis are interpreted as "diagnostic" for CTCL, and those that exhibit at least two of these features (epidermal collections of lymphocytes, atypical nuclei, or absence of spongiosis) are judged "consistent with" CTCL. Histopathologic features of "transformation" to a high-grade lymphoma, such as an enlarged pale nucleus and prominent nucleoli or loss of normal T-cell markers, are all associated with a poorer prognosis.

In an attempt to quantitate more precisely the histopathologic features of CTCL, one group of investigators has attempted to use vertical measurements (analogous to the Breslow level in melanoma) to delineate the depth of the cutaneous infiltrates.<sup>33</sup> In their preliminary analysis, a positive correlation with morbidity was noted for the distance from the granular layer of the epidermis to the lower limit of the CTCL infiltrate. Cell density has also been found to correlate with clinical outcomes. Jones et al.<sup>144</sup> have demonstrated that cell density predicted remission and progression-free, overall, and cause-specific survival after total skin electron-beam therapy (TSEBT).

Skin biopsies should also be subjected to immunophenotyping to define better the identity of the benign and neoplastic cell populations present in the cutaneous lesions. Several studies have reported correlations between the immunophenotypes of the cells present in the infiltrates and stage of disease. In general, as disease progresses, fewer CD8+ cells are observed, and the relative ratio of CD4+ to CD8+ cells increases.<sup>34,35</sup> However, in one rare and clinically very aggressive form of CTCL, the neoplastic T cells are CD8-, CD4-, as they have undergone Gd- but not ab-TCR chain rearrangement.<sup>126</sup>

Immunogenotyping of skin biopsies can help to define whether an early lesion suggestive of CTCL actually contains a clonal T-cell population. Such analyses are best performed by polymerase chain reaction-based (PCR-based) techniques, as one rarely obtains sufficient neoplastic cell DNA from skin biopsies for routine Southern blot analyses. PCR analysis is performed with primers designed to amplify TCR G chain rearrangements that occur in all T cells before rearrangement of the a and b chain loci. Such PCR-based assays are able to detect clonal T-cell populations in 90% of skin biopsies that show diagnostic CTCL pathology. The 10% false-negative rate may reflect the fact that the currently available PCR primer pairs amplify only 90% of G chain variable regions. This high degree of sensitivity contrasts with the somewhat lower (79%) sensitivity of standard Southern blot techniques that require significantly more DNA.<sup>36</sup>

## LYMPH NODES

The incidence of lymphadenopathy increases with T-stage and is associated with a poorer prognosis. Imaging studies (computed tomography scan or magnetic resonance imaging) are recommended at initial evaluation for those with advanced disease and during follow-up to detect enlargement of thoracic, abdominal, or pelvic nodes. In practice, biopsy of uninvolved nodal sites is uncommon; lymph nodes are subjected to biopsy either at initial staging or afterward only if they are found to be obviously enlarged on physical examination or imaging studies.

Flow cytometry, immunophenotyping, and Southern blot (or PCR-based) genotyping for clonality are recommended for all nodal samples and may detect neoplastic T cells even in so-called reactive, dermatopathic (stage N1) nodes not obviously involved by CTCL. In a study of lymph node samples from 17 patients with stage N1

disease, eight showed evidence of clonal T-cell abnormalities consistent with CTCL on Southern blotting, and these eight patients had a poorer prognosis than those whose nodes were free of CTCL.<sup>37</sup> Another study of lymph nodes in patients with CTCL revealed that specific histologic factors were predictive of outcome. Those patients with small cell infiltrates had a median survival of 40 months, and those with high-grade immunoblastic features had a median survival of only 9 months.<sup>38</sup>

## PERIPHERAL BLOOD

The level of circulating neoplastic cells in CTCL patients correlates adversely with prognosis and is an important parameter to document and quantitate both at presentation and during follow-up. The application of nearly clone-specific, family-specific antibodies against the V $\beta$  regions of TCRs has also revealed that morphologic evaluations alone often grossly underestimate the level of circulating CTCL cells.

In normal individuals, none of the more than 50 available anti-V $\beta$  monoclonal antibodies (mAbs) react with more than 2% to 5% of the circulating peripheral T cells. As shown in Table 45.4-2, it is possible to use these mAbs to detect and quantitate precisely the levels of circulating CTCL cells. Such analyses have revealed a remarkable clinical heterogeneity within patients who present with T4 disease. In most, the level of circulating CTCL cells is actually much higher than estimated by less sensitive techniques.<sup>39</sup> In some, the expansion of the neoplastic T-cell clone is accompanied by depression of normal T cells to levels comparable with those observed in advanced acquired immunodeficiency syndrome. Such a *de facto* T-cell deficiency may both explain the susceptibility of erythrodermic CTCL patients to infection by bacterial, viral, and fungal pathogens<sup>129</sup> and contribute to the progression of the disease, which is often held in check by host immune mechanisms.

Patient	Total Lymphocyte Count <sup>a</sup>	CD4:CD8 Ratio <sup>b</sup>	Sézary Syndrome (%) <sup>c</sup>	V $\beta$ (%) <sup>d</sup>
1	7184	50	32	67
2	294	10	10	32
3	684	13	7	74
4	3276	17	9	78
5	3360	90	13	87
6	3630	14	5	39

<sup>a</sup>Normal range, 1500–3000.  
<sup>b</sup>Normal range, 0.5–3.5.  
<sup>c</sup>Sézary cells are expressed as a percentage of lymphocytes; normal range, 0–5%.  
<sup>d</sup>Percentage of lymphocytes expressing a particular  $\beta$  chain variable region; normal range, 0–5%. In patients in whom there is an identifiable V $\beta$  region, the values in this column represent the percentage of lymphocytes that are malignant.

**TABLE 45.4-2.** Peripheral Blood Values of Six Patients with Advanced Cutaneous T-Cell Lymphoma

In the absence of such specific anti-CTCL mAbs, flow cytometry and Southern blot (or PCR-based) analyses of G chain rearrangements can be used to detect and quantitate circulating CTCL more accurately. Flow cytometry should be performed with antibodies to the CD4, CD8, CD3, CD45R0, and CD20 antigens. The ratio of CD4+ to CD8+ cells is normally 0.5:3.5; elevations in this ratio correlate with total leukocyte count and with extent of skin disease in CTCL patients. An elevated ratio of CD4+ to CD8+ cells in excess of 4.5:1 reliably indicates significant levels of circulating CTCL cells, and a routine leukocyte count, manual differential, and smear supplemented by a measurement of the CD4:CD8 ratio serve as a good initial screen for circulating CTCL cells. If flow cytometric analysis reveals a marked elevation of the CD4:CD8 ratio or an elevation in the percentage of CD45R0+ cells, it is worthwhile to perform flow cytometry with anti-V $\beta$  mAbs to determine whether a clonal expansion of T cells is present.

If any of the aforementioned studies suggest the presence of circulating CTCL cells, the more laborious and expensive TCR gene rearrangement studies to confirm their presence are also worthwhile. Even standard Southern blot assay for TCR rearrangement can detect a neoplastic clone that represents only 1% of the total lymphocyte population and, thus, is far more sensitive in detecting circulating CTCL cells than any of the previously mentioned techniques, including flow cytometry. Nonetheless, in only approximately 10% of CTCL cases with circulating cells are Southern blots the only laboratory abnormality. In one study of 11 CTCL patients in whom circulating CTCL cells were documented by Southern blotting, ten also had CD4:CD8 ratios greater than 10:1. Only one patient's CD4:CD8 ratio was less than 2:1.<sup>40</sup>

## PATIENT EVALUATION

### HISTORY

The duration of the eruption and the evolution of its distribution should be carefully noted. The patient should also be asked about cutaneous integrity, temperature imbalance, fissuring, pruritus, and the use of moisturizers.

### PHYSICAL EXAMINATION

A complete physical examination should be performed with particular attention to the skin and lymph nodes. Examination of the skin should record the number of lesions, including their type (patch, plaque, tumor, or erythroderma), distribution, and the percentage of skin surface involved by CTCL lesions (i.e., by the "rule of nines" used in the evaluation of burn patients). Evaluation of the abdomen should be performed to detect hepatosplenomegaly, and the site, size, and number of palpable peripheral lymph nodes should be recorded.

### DIAGNOSTIC TESTS

#### *Dermatopathology*

At least two skin biopsies should be obtained for routine hematoxylin and eosin histopathology. Frozen specimens should be harvested for immunophenotyping for the CD2, CD3, CD4, CD5, CD7, CD8, CD19, CD20, CD25, CD30, CD45R0, CD56, bF1, and d antigens. PCR for G chain rearrangements and, if available, b chain rearrangements should be performed on either the paraffin or frozen section tissue.

#### *Peripheral Blood Evaluation*

A complete blood cell count with differential and smear examination supplemented by a flow cytometric analysis of peripheral blood lymphocytes screen for circulating CTCL cells. Flow cytometric analysis can measure peripheral blood involvement by revealing an elevation of the CD4:CD8 ratio, an increase in CD4+CD7– lymphocytes, or an elevation of CD45R0+ lymphocytes. The interpretation of these findings is facilitated by the demonstration of the malignant clone by PCR testing for gene rearrangement in the peripheral blood. The latter, in turn, is facilitated by similar PCR testing on the patient's skin biopsy. If the clone is detectable in skin, the test is useful in the peripheral blood. If the clone is undetectable by PCR, this method is not interpretable when performed on the peripheral blood.

#### *Other Studies*

A posteroanterior and a lateral chest radiograph should be performed in all patients. Computed tomography or magnetic resonance scans should be carried out of the chest, abdomen, and pelvis both to evaluate mediastinal, retroperitoneal, and pelvic nodes as well as to supplement physical examination of the axillary and inguinal nodes in patients with T3 and T4 disease.<sup>122</sup> The location of pathologically enlarged nodes should be noted and their size recorded. Such enlarged nodes should undergo biopsy (preferably by excision rather than needle sampling) to document both the presence of neoplastic T cells and the histopathologic pattern of involvement (i.e., dermatopathic adenopathy vs. more extensive replacement). The latter can be supplemented by immunophenotypic and TCR rearrangement analyses to document the presence of neoplastic T cells. Bone marrow evaluation is not routinely performed unless abnormalities are noted on complete blood cell count or smear.

## PRINCIPLES OF THERAPY

The therapy for CTCLs is fairly distinct from that of other lymphomas. Hence, many therapeutic strategies that have proved successful with localized and disseminated B-cell lymphomas have often been found to be inappropriate for CTCL. CTCL is first and foremost a disease of cutaneous lymphocytes. Hence, early-stage disease that is localized to the skin has an excellent chance of cure with therapies directed to the skin alone. However, disease that has disseminated and become established in lymph nodes or visceral sites (liver, lung, central nervous system) can be palliated but rarely cured, even with the most aggressive regimens of systemic chemotherapy. This result contrasts with that seen in B-cell lymphomas in which patients with extensive nodal and visceral disease are often cured by aggressive combination chemotherapy or bone marrow or stem cell transplantation.

Effective therapies for CTCL include both skin-directed and systemic therapies ( [Table 45.4-3](#)). Skin-directed therapy includes topical chemotherapy with such agents as carmustine (BCNU) and nitrogen mustard (NM), systemically administered psoralens activated in the skin by psoralen and ultraviolet A light (PUVA) therapy, and local and generalized superficial ionizing radiation that includes both electron-beam and x-ray therapy.

<b>PATIENTS WITH T1 DISEASE (PATCHES OR PLAQUES &lt;10% OF SURFACE)</b>
Topical chemotherapy
PUVA
Localized external-beam radiotherapy
<b>PATIENTS WITH T2 DISEASE (PATCHES OR PLAQUES &gt;10% OF SURFACE)</b>
PUVA
Topical chemotherapy
TSEBT
<b>PATIENTS WITH T3 DISEASE (TUMORS)</b>
TSEBT
TSEBT and PUVA
TSEBT and ECP
Investigational modalities
<b>PATIENTS WITH T4 DISEASE (DEEP/DERMAL)</b>
ECP
TSEBT and ECP
Interferon
Investigational modalities
<b>PALLIATION OF VISCERAL DISEASE</b>
Systemic chemotherapy (methotrexate derivatives)
Photon irradiation
ECP, extracorporeal photopheresis; PUVA, psoralen and ultraviolet A therapy; TSEBT, total skin electron-beam therapy.

**TABLE 45.4-3.** General Management of Cutaneous T-Cell Lymphoma

All skin-directed therapies exert their primary effects on disease confined to the skin. All are capable of destroying CTCL cells directly, probably by triggering T-lymphocyte apoptosis,<sup>127</sup> and all interfere with the local production of cytokines by epithelial and stromal cells necessary for neoplastic T-cell survival and proliferation.

Photopheresis, a systemic immunologic therapy, acts both directly by killing T lymphocytes by the cytotoxic actions of UVA light/psoralen and indirectly by eliciting anti-CTCL cell immune responses. Similarly, other systemic agents, such as retinoids and the biologic response modifiers (IFN- $\alpha$  and - $\gamma$ ) may exert their therapeutic effects by modifying production by keratinocytes and dermal fibroblasts of cytokines necessary for neoplastic T-cell survival and proliferation. This is in addition to any direct cytotoxic or cytostatic effects they exert on benign and neoplastic T lymphocytes.<sup>41</sup>

### TOPICAL CHEMOTHERAPY

Therapy for T1 and T2 CTCL can be carried out with either topical mechlorethamine (NM) or BCNU, both potent DNA-alkylating agents. Topical NM therapy is generally administered daily with a fresh solution of 10 mg in 50 mL tap water, which is applied to the entire body surface. Because NM is a potent irritant, patients should wear protective plastic gloves while applying the solution. Topical NM therapy results in delayed hypersensitivity reactions in up to 40% of patients, who often require at least temporary cessation of therapy. Such reactions can be circumvented by induction of tolerance to NM by topical desensitization or by PUVA-induced suppression of the hypersensitivity reaction. Ointment-based NM is less likely to induce allergic reactions and, in its typical formulation of 10 mg/dL, NM in Aquaphor is stable at room temperature.

Other side effects of topical NM therapy include induction of second cutaneous malignancies (e.g., squamous cell carcinomas), hyperpigmentation, and hypopigmentation. Between 64% and 90% of NM-treated patients with T1 and T2 CTCL can achieve a complete response (CR) to therapy. In one series of 243 patients, the median survival of treated patients was 8 years, and the response rate was better in those with less extensive disease.<sup>42</sup> Although some patients appear to be cured by topical NM therapy, seven of eight patients experience relapse within 3 years unless a maintenance topical NM regimen has been instituted. Maintenance topical NM can also be used to prevent or delay relapse of cutaneous lesions in patients who have achieved a CR to TSEBT or to treat minimal patch or plaque recurrences after such therapy.<sup>75,149</sup>

Another topical chemotherapeutic agent useful in the treatment of CTCL is BCNU. Because topical BCNU is not immunologically cross-reactive with NM, this agent can be used in patients who have developed allergies to NM. Topical BCNU can be formulated either as a 10- to 40-mg/dL ointment stable indefinitely at room temperature or as a 25- to 50-mg/dL solution in dilute alcohol, which is stable for at least 3 months when refrigerated.

Cutaneous hypersensitivity reactions to topical BCNU are rare and, in one series, such reactions interfered with continuation of therapy in only 10 of 152 patients. However, significant erythema in the treated areas and posttreatment telangiectasia occur in one of three patients. Also, as a small fraction of the drug is absorbed, marrow suppression can occur but is unusual unless the total dose exceeds 600 mg (in increments of 20 to 25 mg).<sup>43</sup> Therefore, hematologic monitoring is necessary when using BCNU.

### PSORALEN AND ULTRAVIOLET A THERAPY

Cutaneous photochemotherapy with orally administered PUVA irradiation of the skin, or PUVA therapy, kills cutaneous lymphocytes and interferes with antigen presentation and cytokine production in the skin. PUVA therapy is also able to induce complete remissions as reliably as TSEBT therapy in CTCL patients with patches or thin plaques. In patients with thicker plaques or tumors, PUVA therapy alone is unlikely to produce a CR but may be used to maintain the CRs induced by other skin-directed therapies, including TSEBT.

PUVA therapy requires the ingestion of 0.6 mg/kg of 8-methoxypsoralen (8-MOP) 1 to 2 hours before the exposure of the skin surface to UVA light (320 to 400 nm). To induce remission, treatments should begin three times per week at doses that are minimally phototoxic. After most of the lesions have cleared, the frequency of PUVA can be decreased to twice weekly until the patient has achieved a CR.<sup>44</sup> Such a schedule of multiple treatments per week must be maintained for a minimum of 3 months and a maximum of 6 months. If a CR has not been achieved by this time, several strategies can be used to supplement or enhance the efficacy of PUVA. We have often used local spot x-ray or electron-beam therapy to treat lesions refractory to PUVA, particularly in regions anatomically shielded from receiving the full UVA dose. Addition of such "PUVA boosters" as IFNs, retinoids, or oral methotrexate can also be considered.

### INTERFERON

IFN- $\alpha$  at doses of 3 to 6 MU can help to clear skin lesions refractory to PUVA alone.<sup>45</sup> However, the systemic side effects of such therapy can be troublesome, although some patients experience no significant toxicity. Retinoids also have a role as adjunctive agents in achieving remission or palliating symptoms. Retinoids for acne and psoriasis have been used in the past. However, the ability of bexarotene to improve CTCL as monotherapy<sup>46</sup> suggests that it will supplant other retinoids in the adjunctive role with PUVA and other therapies. If such boosters are successful, maintenance PUVA therapy alone should be sufficient to maintain disease-free status.

Once a CR has been achieved, PUVA is administered once weekly as maintenance therapy for 1 year. If the remission is sustained, the interval between treatments can be extended to 2 weeks for a total of 26 sessions per year for an additional year. If there is still no evidence of relapse, the interval between treatments can be extended to 3 weeks and continued for another 2 years. Interruptions of maintenance PUVA due to intercurrent illness or injury can be followed by recurrence of

disease, sometimes within 1 or 2 months. After 5 years of maintenance therapy, consideration can be given to cessation of therapy or to extending the interval between PUVA treatments to 4 to 6 weeks.

Patients may be free of disease at this stage, but studies of patients treated with TSEBT have noted relapses at times more than 5 years later, particularly in those with T2 disease.<sup>64</sup> Whether such late relapses are the consequence of the persistence and regrowth of the original neoplastic clone or are “true” second primary CTCLs has not yet been defined. It is also not known whether such “late” recurrences or second primaries will also be observed in patients who have received 5 years of maintenance PUVA. However, patients should probably not be considered “cured” until they have remained disease-free for at least 5 years after completing therapy. Some reports suggest that PUVA therapy may result in true “cures,” because the mortality rate from early disease was decreased after the adoption of PUVA as the standard therapy for CTCL in Scandinavia.<sup>47</sup>

## LOCAL EXTERNAL-BEAM IRRADIATION

Local x-ray therapy for CTCL lesions was first reported in 1902 by Scholtz, less than a decade after the discovery of x-rays by Roentgen.<sup>48</sup> The cutaneous lesions of CTCL are extremely radioresponsive, and a dose-response relationship has been demonstrated.<sup>49,50</sup> and <sup>51</sup> Superficial [30 to 125 kV(p)] and orthovoltage [125 to 500 kV(p)] x-rays as well as electrons can be used to treat localized primary or recurrent patches, plaques, and tumors.<sup>52</sup> Doses between 20 and 36 Gy are effective in fractional sizes of 1 to 2 Gy, depending on the size and location of the lesions. Such therapy is rarely first-line but can be considered for the unusual patient with very localized primary patches, plaques, or tumors. Local x-ray or electron-beam therapy in similar doses is also fairly effective in clearing isolated lesions that fail to respond to PUVA or recur after CR to PUVA or TSEBT.

Local treatment of isolated lesions is very effective, and the CR rate is in excess of 90% for both plaques and tumors. Cotter et al.<sup>51</sup> demonstrated that none of nine patients failed when treated with doses in excess of 30 Gy, with a minimum of 1 year follow-up. Approximately 5% of patients with stage IA disease will present with a solitary cutaneous lesion or several in close proximity. Wilson et al.<sup>145</sup> have found that the rate of clinical remission after local external-beam radiotherapy is 97%. A total of 21 patients were evaluated with a minimum follow-up of 1 year and treated to a median dose of 20 Gy. Seventeen of the 21 patients received 20 Gy or higher. The median follow-up was 36 months. The actuarial disease-free survival (DFS) rates at 5 and 10 years were 75% and 64%, respectively, with a local control rate of 75% at 10 years. Acute and chronic toxicities were minor, and such treatment does not preclude TSEBT in the future. For metastatic disease (e.g., nodes, central nervous system and spine and lung involvement), radiation with 4 to 20 Gy may provide a meaningful palliative response.

## TOTAL SKIN ELECTRON-BEAM THERAPY

### Principles of Application

Treatment of the entire cutaneous surface with TSEBT is technically much more challenging than local x-ray therapy and should be attempted only in centers with appropriate equipment and in which a close working relationship has been established between dermatologists and radiation oncologists committed to and experienced in the treatment of patients with CTCL. TSEBT is excellent treatment for patients with diffuse involvement with thick plaques or cutaneous tumors and is also suitable for patients with symptomatic erythroderma (T4 disease). TSEBT is also an excellent alternative for patients with extensive patches or thin plaques refractory to PUVA or other skin-directed therapies.

The application of TSEBT for the treatment of CTCL was first reported by Trump et al.<sup>52</sup> in 1953, and since that time, a variety of fractionation schedules and techniques have been implemented.<sup>53,54,55,56,57,58,59,60,61,62,63</sup> and <sup>64</sup> In 1960, Karzmark et al.<sup>55</sup> described the details of the “Stanford technique” for the administration of TSEBT, which was later modified to a six-field array to improve the homogeneity of dose delivered to the total skin surface.<sup>65,66,67</sup>

Electrons ranging in energy between 4 and 7 MeV are used to treat the epidermis and dermis homogeneously. Structures below the deep dermis are spared, as most of the dose (80%) is delivered within the first 1.0 cm, and less than 5% beyond 2.0 cm depth. Blood and superficial lymph nodes may receive 20% to 40% of the skin surface dose.

At Yale, treatment is offered via a Varian 6-MeV linear accelerator at a treatment distance of 7 m, with a single incident beam energy of 3.9 MeV at the skin. Therapy is delivered via six fields, and supplemental local boosts to the scalp, perineum, and soles of the feet are administered with 120-kV(p) x-rays. Treatment is delivered to the six fields over a 2-day cycle, with three of six fields (anteroposterior, left posterior oblique, right posterior oblique) treated on the first day and the remaining three (posteroanterior, left anterior oblique, right anterior oblique) on the second. External and internal eye shields are used sequentially throughout, and the hands and feet are shielded for 50% of the treatment course. Patients receive TSEBT 4 days per week for a total of 9 weeks, and the boost fields are treated concurrently.

The dose to the skin surface is 36 Gy, 4 Gy/wk and usually fractionated over 4 days and two cycles. Photon contamination to the body is 1.2% of the electron dose. Supplemental boosts to the scalp, perineum, and soles of the feet are 6 Gy (2 Gy/d), 20 Gy, and 20 Gy (1 Gy/d), respectively. Areas “shadowed” from the electron beam by large pendulous breasts, abdominal panniculi, or other deep skin folds receive similar boosts with 15 to 20 Gy (1 to 2 Gy/d) of electron-beam or orthovoltage x-ray therapy. Gross tumor lesions that have not completely regressed by the completion of TSEBT should also be evaluated for supplementary boost via x-ray or electron-beam therapy.

More commonly, a dual-beam six-field arrangement has been used.<sup>143</sup> Although the techniques differ between Yale and Hamilton, for example, the dosimetry is similar, as are the clinical results.<sup>140</sup> Regardless of technique, it should be noted that 4 MeV electron energy and more than 30 Gy to the skin surface are recommended. Jones and Thorson<sup>146</sup> have demonstrated (as have other investigators) that improved progression-free, cause-specific, and overall survival are related to these parameters.

## Results

Clinical CR rates for patients with T1 or T2 (patch or plaque) disease range from 71% to 98% and are higher in patients with less extensive disease. Representative data on disease-free and overall survival are presented in [Table 45.4-4](#) and [Table 45.4-5](#). In our institution, patients with T1 and T2 disease treated with TSEBT have disease-free and overall survivals of 50% to 65% and 80% to 90%, respectively, at 5 years, although patients with antecedent or coexisting LP or AM-FM appear to have shorter DFS after TSEBT than those who do not.<sup>64</sup> Patients with more advanced T3 and T4 disease fare significantly worse, with 5-year disease-free and overall survivals of approximately 20% and 50%, respectively. However, those T3 patients with less than 10% of the total skin surface involved by CTCL have significantly better disease-free and overall survival after TSEBT than those with more extensive disease.<sup>128</sup>

**TABLE 45.4-5.** Overall Survival at 5 and 10 Years for Mycosis Fungoides Patients after Total Skin Electron-Beam Therapy

For patients with erythrodermic MF (T4) who are managed with TSEBT alone (32 to 40 Gy), without concomitant or neoadjuvant therapy, the CR rate is 74%. The 5-year progression-free, cause-specific, and overall survivals are 26%, 52%, and 38%, respectively. <sup>147</sup>

Palliation of adenopathy or visceral involvement in patients with N3 disease can be accomplished by the use of appropriate high-energy orthovoltage or megavoltage photons to doses of 20 to 30 Gy. Even 6 to 8 Gy in 3 fractions is sufficient if added during TSEBT. Combinations of TSEBT with total nodal irradiation have been investigated. Although feasible, such combinations do not appear to prolong survival and may be associated with hematologic toxicities not observed with TSEBT alone. <sup>68,69</sup>

**TOXICITY.** TSEBT is well tolerated by most patients, and acute sequelae either during or within the initial 6 months after treatment may include pruritus, desquamation, epilation, hypohidrosis, xerosis, erythema, lower-extremity edema, bullae of the feet, and onychoptosis. Chronic changes can include atrophy of the skin, telangiectasia, alopecia, hypohidrosis, and xerosis. <sup>70</sup> Because of the superficial penetration of the electron beam, patients do not experience gastrointestinal or hematologic toxicities. Second malignancies, such as squamous and basal cell carcinomas, as well as malignant melanomas have been observed in patients treated with TSEBT, and such risk is likely increased by other mutagenic, skin-directed therapies, such as PUVA or mechlorethamine (or both). It is interesting that additional x-ray or electron-beam irradiation after TSEBT does not appear to increase the risk of second cutaneous malignancies. <sup>71,72</sup>

**REPEAT TREATMENT.** For patients who have diffuse cutaneous recurrences after TSEBT not amenable to other skin-directed therapies, a second course of TSEBT is both feasible and worthwhile. <sup>60,73,74</sup> At Yale, a total of 14 patients have received two, and five patients have received three courses of TSEBT. The median total dose after these additional courses was 57 Gy, and 86% of the patients achieved a CR after the second course, with a median disease-free interval of 11.5 months. Median dose was 36 Gy for the first course, 18 Gy for the second, and 12 Gy for the third. <sup>73</sup> A similar experience was reported from Stanford, where 15 patients were identified who had been treated with a second course of TSEBT (median dose, 20 Gy), with a CR rate of 40%. Nine of these patients had a partial response to therapy, and the median total dose for the entire group was 56 Gy. In both series, repeat courses were relatively well tolerated, and sequelae were similar to those observed during and after the first course of therapy. <sup>74</sup> Both studies also support the contention that the palliative benefits of additional courses of TSEBT outweigh their risks in appropriately selected patients. Criteria for retreatment include an extended disease-free interval after the first course of TSEBT, a CR to the initial course, diffuse cutaneous involvement, and the failure of other palliative modalities.

**COMBINED AND SEQUENTIAL THERAPY.** Several other CTCL therapies, including topical NM, systemic chemotherapy, etretinate, PUVA, and extracorporeal photochemotherapy (ECP) have been administered concomitantly with or adjvantly after TSEBT with varying degrees of success. <sup>75,76,77</sup> and <sup>78</sup>

We have observed that the adjuvant use of PUVA after TSEBT in patients with T1 and T2 disease significantly decreases cutaneous relapse. Patients treated with adjuvant PUVA after TSEBT had a 5-year DFS of 85%, compared to 50% for those not receiving PUVA ( $P < .02$ ). The median DFS for the T1 patients receiving adjuvant PUVA was not reached at 103 months, versus 66 months for the non-PUVA group ( $P < .01$ ). For those with T2 disease, the DFS figures were 60 and 20 months, respectively ( $P < .03$ ). <sup>78,148</sup> Adjuvant topical NM also appears able to delay cutaneous recurrence after TSEBT. At Stanford, the median DFS of patients was prolonged from 29 to 37 months by the addition of topical NM therapy after TSEBT. <sup>75</sup> In 1999, Chinn et al. <sup>149</sup> from Stanford showed that TSEBT with or without NM provided improved response rates as compared to mustard alone for those patients with T2 and T3 level disease, respectively (76% vs. 39%;  $P = .03$  for T2; 44% vs. 8%;  $P < .05$  for T3). For those with patch-plaque (T2), adjuvant mustard offered improved freedom from relapse after TSEBT as compared to no adjuvant treatment. No significant survival difference was noted between the groups. <sup>149</sup>

Concurrent use of systemic chemotherapy with TSEBT was evaluated in a randomized clinical trial conducted by Kaye et al., <sup>79</sup> in which a combination of TSEBT (30 Gy) and combination chemotherapy was compared with a regimen of sequential skin-directed therapies followed by TSEBT if cutaneous lesions progressed. Those patients who received concurrent TSEBT and chemotherapy experienced considerable hematologic toxicity but had a significantly higher CR rate than those who did not. However, there was no statistically significant difference between the two groups with respect to either DFS (12.9 vs. 21.3 months;  $P = .19$ ) or overall survival (91 vs. 76 months) at 75 months.

Several nonrandomized studies have suggested that the adjuvant use of single or combination systemic therapy after TSEBT might be of benefit in the treatment of CTCL. <sup>80,81,82,83</sup> and <sup>84</sup> In a study of adjuvant doxorubicin-cyclophosphamide after TSEBT, the DFS was longer for those patients who received adjuvant chemotherapy for the first 2 to 3 years of follow-up. <sup>85</sup> However, this early advantage was no longer apparent after 5 years.

In contrast, ECP administered during and after TSEBT appears to improve survival ( $P < .06$ ) for patients with T3 or T4 disease who have achieved a CR to TSEBT, but the group of treated patients is small, and the data are retrospective. <sup>76</sup> We currently do not administer adjuvant systemic chemotherapy after TSEBT but are developing a randomized clinical trial to evaluate the potential utility of adjuvant ECP in patients with T3 and T4 CTCL. Wilson et al. <sup>150</sup> have found a significant improvement in cause-specific survival for erythrodermic patients treated with the combination of TSEBT and ECP as compared to those not treated with ECP. The 2-year progression-free, cause-specific, and overall survival for those receiving TSEBT/ECP were 66%, 100%, and 88%, respectively, versus 36%, 69%, and 63% for those not managed with the combination. These data should be interpreted with caution, though, as the total number of patients was low and the series was nonrandomized.

## SYSTEMIC THERAPIES

Systemic therapy for CTCL initially consisted of single- and multiple-agent cytotoxic chemotherapy regimens, often modeled after those that have been used with great success in the treatment of advanced B-cell lymphomas. In most clinical settings, however, cytotoxic chemotherapy has been supplanted by a variety of immunologically based therapies, including ECP (also known as *photopheresis*), IFNs, mAbs, and an investigational agent, the diphtheria toxin/IL-2 hybrid, DABIL-2.

### Basic Principles: Photopheresis

Given the intrinsic immunologic nature of the cells responsible for CTCL, it is reasonable that agents that either directly or indirectly modulate T-cell function or other aspects of host immune response should be applied to the therapy of CTCL. The efficacy of most chemotherapeutic and topical treatments used to treat CTCL has never been directly evaluated by U.S. Food and Drug Administration advisory committees, but the agency has approved three systemic therapies for the specific indication of CTCL. The earliest, ECP, received approval in 1988 and was the first such sanctioned selective immunotherapy for any malignancy. More recently, Ontak (diphtheria toxin conjugated to IL-2) and Targretin (Bexarotene) have become available.

Development of Ontak followed Waldmann's original investigation <sup>139</sup> of an mAb against IL-2 that had shown efficacy in preliminary studies. Activated T cells may develop avid receptors for this growth factor. By attaching a toxin to a carrier that binds to the IL-2 receptor, targeted malignant T cells can then be destroyed, sparing non-IL-2 receptor-bearing bystander cells. Some limitations to the approach are that usually only a minority of CTCL cells, even in an actively expanding tumor, are

IL-2 receptor–positive.

ECP, or photopheresis, involves systemic pretreatment with oral or parenteral psoralens, removal of a portion of the patient's blood, pheresis of white blood cells away from red blood cells, and exposure to UVA of the white blood cells that have undergone pheresis in an effort to photoactivate intercalated, DNA-bound psoralen to produce psoralen monoadducts and diadducts in DNA. The irradiated cells are then reinfused back into the patient.

The reinfusion of the killed, irradiated CTCL cells appears to stimulate host immune responses selectively against neoplastic T cells. Evidence that such clone-specific immunization actually occurs has come from several different lines of investigation.

Some observations with V $\beta$ -family–specific antibodies have demonstrated that only a minority of infiltrating T cells in patches and plaques are actually neoplastic,<sup>86</sup> and of the benign T cells found in CTCL plaques, approximately 20% are CD8+ cells.<sup>87</sup> When studied *in vitro*, these reactive, nonneoplastic CD8+ T cells have been shown to produce large amounts of IFN- $\gamma$  and tumor necrosis factor- $\alpha$ .<sup>88</sup> Both of the last two cytokines increase benign and neoplastic T-cell surface expression of major histocompatibility complex (MHC) class I molecules and presentation of bound peptide antigens to other CD8+ cells, including cytotoxic T lymphocytes. In this context, it is interesting to note that the CD8+ T cells of several patients who underwent photopheresis were found to be cytotoxic only for autologous CTCL cells.

Similarly, others have demonstrated that exposure of murine T-cell lymphoma cells to 8-MOP and UVA in an experimental protocol analogous to photopheresis, and reinfusion of the treated cells into syngeneic mice protects them against subsequent challenge with this cell line. In theory, such anti-CTCL cell “immunization” should occur after any therapy that selectively kills a significant number of neoplastic T cells; however, certain animal studies suggest that ECP may accomplish this by a unique mechanism.

*Ex vivo* exposure of a lymphocytic murine tumor line to 8-MOP (at the temperature at which photopheresis is conducted) appears to block normal intracellular insertion of cytoplasmic peptides into the peptide antigen-binding groove of MHC class I molecules, resulting in the unusual expression of “empty” class I molecules at the cell surface. In theory, such empty class I molecules are free to bind any extracellular peptides that are recognized by the specific amino acid sequence of the antigen-binding groove.

If such exogenous peptides happen to be derived from protein components of other dying, neoplastic T cells (i.e., the neoplastic clone's TCR), such MHC class I–peptide antigen presentation should facilitate the expansion of clones of CD8+ “killer” and “suppressor” cells specifically directed against the neoplastic clone and immunize the host against its own CTCL cells. Evidence that such phenomena actually occur *in vivo* in patients undergoing photopheresis has come from studies of the peptide fractions eluted from the MHC class I molecules of CTCL patients who underwent photopheresis. Such peptide fractions appear to be unique and characteristic only of the patient's neoplastic T cells and are not observed on nonneoplastic T cells or B lymphoblasts.

Currently, ECP is frequently used as monotherapy for CTCL, but its combination with other therapies such as TSEBT is currently under study. ECP is initially administered on a once-a-month schedule, with therapy continued until maximal clearing is established. An additional 6 months of therapy may be administered to consolidate the clinical response. After the patient's disease has stabilized, the interval between ECP treatments is gradually prolonged by 1 week per cycle every three cycles. After the interval between treatments has reached 8 weeks for three cycles, therapy can be discontinued.

Patients may experience transient responses 1 to 2 days after photopheresis but begin to show sustained clinical improvement as early as the second month of therapy. However, some do not clear or achieve their maximal response until 12 months after starting therapy. On the average, after 4 to 6 months of therapy, a sustained decrease in erythema, scaling, and pruritus is observed. Patients often notice more subtle changes, such as the return of body hair, loss of rigors, and return of the ability to sweat.

Previous reports suggest that conventional systemic therapies are ineffective in prolonging the survival of patients with erythrodermic CTCL. A population-based estimate in one tumor registry survey revealed a 31-month median survival for patients with erythematous skin related to CTCL. A similar analysis of erythrodermic patients in the Mycosis Fungoides Cooperative Group yielded a 30-month survival. In contrast, patients in the original cohort of ECP patients were found to have a median survival of 60 months, or twice as long as had been obtained with prior conventional systemic therapies.<sup>89,90,91,92,93 and 94</sup>

No side effects of ECP that compromises its continued administration have been observed in more than 7 years of follow-up. Patients with CTCL in the original cohort treated with ECP have also been carefully studied to determine whether this therapy exerted any adverse effects on host immune response, but none were found. Lymphocyte and leukocyte counts never decreased to low levels. Lymphocyte stimulation studies showed no evidence of immunosuppression, even after years of therapy. Delayed hypersensitivity tests revealed improvement in recall responses after photopheresis; in fact, most of the patients had to experience significant improvement in their erythroderma to allow the skin testing studies to be performed.

In the treatment of T4 CTCL, particularly in patients with markedly elevated white blood cell counts and immunosuppression, ECP has been combined with a variety of other therapies, including IFNs, methotrexate, etoposide, and TSEBT. TSEBT can be particularly useful in producing prompt remissions of symptomatic erythroderma, and results suggest that T4 patients treated with TSEBT and ECP have longer survival than those treated with either modality alone.<sup>76,150</sup>

The mechanism of response to this immunotherapy appears to involve the simultaneous induction of large numbers of DCs and apoptotic CTCL cells. Passage through the UV exposure apparatus, at a film thickness of only 1 mm, causes blood monocytes to adhere transiently to the plastic surface, thereby activating these cells. Over the next few days, at least one-third of the treated monocytes are stimulated in this way to evolve into fully functional DC, the most efficient antigen-presenting cells in the body. This effect is UV-independent, in contrast to the induction of apoptosis of CTCL cells by the photoactivated 8-MOP. The apoptotic CTCL cells are ingested by the newly formed DC, a phenomenon that can be greatly enhanced by delaying the return of the treated blood for 1 day and cocultivating the young DC with the damaged CTCL cells. The CTCL antigens are processed by the DC through the class I MHC pathway and presented to anti-CTCL CD8 T cells, perhaps accounting for the observed enhanced antitumor responses. Trial of this variation on the conventional ECP approach has led to encouraging results in a preliminary study and merits extended study before it becomes more widely used.

### **Interferons**

Whereas all three IFNs—G,  $\beta$ , and  $\alpha$ —have been studied in CTCL, most clinical studies have been performed with IFN- $\alpha$ . Early studies have reported a CR rate of 10% to 27% with response duration of less than 6 months with doses ranging from 3 to 12 MU/m<sup>2</sup> three times weekly (with the lower dose being the best tolerated).<sup>95</sup> As with other therapies, the extent of prior treatment correlated inversely with the clinical response. With IFN- $\gamma$ , partial responses were attained in one-third of the patients, and improvements in the therapeutic response to PUVA have also been observed, as mentioned. Kuzel et al.<sup>141</sup> reported a series of 39 patients (stages I to IV) treated with IFN- $\alpha_{2e}$  in combination with phototherapy and found a 90% response rate (62% CR), with a median duration of 28 months and survival of 62 months.

All IFNs induce similar toxicities. The first week of IFN therapy may be complicated by flu-like syndrome with fever, myalgia, fatigue, and listlessness. After these acute symptoms remit, patients are often left with residual mild, chronic fatigue. Long-term toxicities of concern include neuropathy, dementia, and myelopathy. IFN therapy can also be complicated by such autoimmune phenomena as proteinuria, thrombocytopenia, and anemia.<sup>95,96</sup>

### **Retinoids (Vitamin A Derivatives)**

Retinoids have found a role in the management of several malignancies, including all-*trans*-retinoic acid therapy of acute promyelocytic leukemia and topical allitretinoin in the treatment of Kaposi's sarcoma. Each retinoid has distinct binding patterns with respect to the major classes of retinoid receptors: RAR and RXR. Initial studies in CTCL demonstrated that the retinoids approved for acne and psoriasis (binding both RAR and RXR) could produce responses in CTCL.<sup>117,118 and 119</sup> These nonspecific retinoids had also been combined with other therapies, such as PUVA,<sup>120</sup> TSEBT,<sup>121</sup> and IFN.<sup>123,124 and 125</sup> Bexarotene is an oral RXR-selective retinoid. In a clinical trial of heavily pretreated, refractory CTCL, oral monotherapy with bexarotene had a 50% response rate in a group of 94 patients with plaque, tumor, or erythrodermic CTCL.<sup>46</sup> The ideal starting dose is 300 mg/m<sup>2</sup> as a single dose taken with a meal. The most frequent toxicity is hypertriglyceridemia necessitating antilipemic therapy in the majority of patients. Hypothyroidism occurred in approximately one-third of patients, and supplemental thyroid hormone was needed. In one report of nine patients with erythrodermic CTCL, there were rapid palliative and remitting responses induced (within 12 weeks) by monotherapy with oral bexarotene. The nine patients with erythrodermic CTCL included those with SS and those without circulating atypical cells. Two achieved CR, and the other seven showed partial responses.<sup>46</sup> As a treatment of erythroderma, this agent could be considered as monotherapy but, in the management of plaque and tumor disease, bexarotene will most likely be combined with skin-directed therapies, including topical steroids. Given the high rate of partial responses with bexarotene

monotherapy, it would be anticipated that the combination treatments could achieve a CR, the desired goal of therapy.

### Monoclonal Antibodies

Several forms of mAbs have been used in the treatment of CTCL. Miller and Levy<sup>134</sup> have studied the anti-CD5 antibody, and although preliminary study demonstrated partial responses, subsequent investigations were less promising, with no CRs in 34 patients.<sup>135,136</sup> and<sup>137</sup> Anti-CD4 therapy has been shown by Knox et al.<sup>138</sup> to be effective in seven of eight patients, with a mean freedom from progression of 25 weeks. Seven of the eight patients had plaque disease, and no patient had visceral or SS involvement.<sup>142</sup> Anti-Tac therapy has been studied by Waldmann<sup>139</sup> and, in an effort to enhance the effect, anti-TAC was used in concert with toxins and a and b emitters. Of 17 patients studied, 11 had a partial or CR to such therapy.

### Fusion Toxin

The efficacy of fusion toxin therapy was established in a trial treating patients with refractory CTCL. Fusion toxins are a family of targeted drugs that are recombinant proteins generated by fusing the gene for the targeting factor (with CTCL, the T-cell growth factor IL-2 was used) with the gene for diphtheria toxin. The recombinant peptide is selectively toxic for IL-2 receptor-positive T cells at picometer to nanomolar concentrations. This specific killing can be blocked by the addition of excess IL-2 or mAb to the p55 portion of the IL-2 receptor. Patients are given intravenous infusions of the fusion toxin over a 30-minute period for 5 consecutive days and repeated every 3 weeks. Using doses of 9 µg/kg/d and 18 µg/kg/d, it was possible to demonstrate the dose responsiveness of the efficacy of IL-2 fusion toxin in treating CTCL. The toxicities were also dose-responsive. A vascular leak syndrome occurred at severe levels in 13% of patients. Pretreatment with systemic corticosteroids appears to minimize this complication. Overall, the response rate in heavily treated patients was 30%.<sup>97</sup> Almost all responses occurred within the first three infusion cycles and were maximal at eight cycles. Tumor and plaque lesions appeared to be the most responsive. Patient selection for fusion toxin therapy traditionally depends on skin biopsy or flow cytometry demonstration of lymphocytes expressing the high affinity IL-2 receptor (CD25). However, dramatic responses have occurred in CD25-negative CTCLs. The level for CD25 expression to confer toxicity from the fusion toxin is below the level of detection from immunoperoxidase. Thus, the ultimate screening test for a response to fusion toxin is to monitor the patient over two to three cycles and then continue for a full eight cycles to optimize a response. In those patients with remission, retreatment has recaptured the response.

### Systemic Chemotherapy

Chemotherapy has been traditionally associated with increased toxicity in the management of CTCL.<sup>79</sup> Presumably, the immunosuppressive effects of advancing CTCL render patients particularly prone to the suppressive effects of chemotherapy. In addition, central lines in patients with CTCL tend to become infected, owing to the continuous seeding by bacteria from the open skin lesions. Thus, there are two strategies with chemotherapy in the management of CTCL: traditional intravenous chemotherapy and low-dose oral chemotherapy. There have not been any formal studies comparing these two distinct dosing regimens. The oral agents used in managing CTCL patients are methotrexate,<sup>98</sup> etoposide,<sup>104</sup> and chlorambucil.<sup>105,106</sup> Methotrexate is probably the most commonly used, at doses of 15 to 50 mg/wk.<sup>98</sup> If chlorambucil or etoposide is used, the peripheral blood cell count must be carefully monitored. More intense intravenous regimens with cytotoxic chemotherapy palliate patients with CTCL. Single-agent therapy can yield CRs in approximately 30% of patients, but the response durations are relatively short.<sup>84</sup> Commonly used agents have included cyclophosphamide, doxorubicin, vincristine, etoposide, and prednisone.

Several studies have reported that the adenine nucleotide derivatives 2'-deoxycoformycin, 2-chlorodeoxyadenosine, and fludarabine might be useful in the treatment of CTCL.<sup>104,105,106,107,108,109,110,111,112,113</sup> and<sup>114,151</sup> Although these agents are active against T lymphocytes through their inhibition of the enzyme adenosine deaminase, their clinical utility in CTCL has been less than initially hoped. In early studies, response rates of approximately 40% were reported for both 2'-deoxycoformycin and 2-chlorodeoxyadenosine, whereas fludarabine was somewhat less effective. The duration of these responses was relatively short, however, and severe myelosuppression was often observed. Combinations of these agents with IFN have been studied, but preliminary results reveal no significant advantages over either modality alone.<sup>115,116</sup>

Overall, combination systemic therapy yields CR rates of 35% to 50% in CTCL, but there is no significant advantage in the use of drug combinations over single-agent therapy. Chemotherapy may be helpful for patients who are in need of symptomatic palliation when other modalities have proven ineffective or when visceral disease is symptomatic. The use of high-dose systemic chemotherapy with stem cell or bone marrow rescue is investigational, and preliminary results have been discouraging.<sup>99</sup>

## INTRODUCTION

*Primary central nervous system lymphoma* (PCNSL) is the term applied to non-Hodgkin's lymphoma (NHL) arising in and confined to the central nervous system (CNS). In the past, this tumor was called *microglioma*, *reticulum cell sarcoma*, or *perivascular sarcoma*, but its lymphocytic origin, usually the B cell, is now well established.<sup>1,2</sup> and<sup>3</sup> How a lymphoma can develop within the CNS, which lacks lymph nodes and lymphatics, remains unanswered; however, lymphocytes do normally traffic in and out of the CNS, and these lymphocytes may be the source of PCNSL.

PCNSL was formerly a rare tumor, accounting for only 0.5% to 1.2% of all intracranial neoplasms, and usually associated with congenital, acquired, or iatrogenic immunodeficiency states such as Wiskott-Aldrich syndrome or renal transplantation.<sup>2,4,5</sup> The highest incidence has been reported in patients with the acquired immunodeficiency syndrome (AIDS), in whom it is seen in 1.9% to 6.0%.<sup>6,7</sup> One autopsy study demonstrated an overall risk of 12%, but only one-half of patients were suspected to harbor CNS disease before death.<sup>8</sup> There is a strong clinical impression among experienced clinicians that widespread use of highly active antiretroviral therapy has reduced the incidence of PCNSL in the AIDS population, but this has yet to be confirmed by formal epidemiologic studies. However, there has been a clear and dramatic increase in the incidence of PCNSL among apparently immunocompetent individuals. An epidemiologic study in the United States revealed a threefold increase in the incidence of PCNSL between 1973 and 1984; a tenfold increase has been observed in southeast England.<sup>9,10</sup> This increase far exceeds the 3% to 4% per year increase seen in systemic NHLs during the same period.<sup>11</sup> Not all epidemiologic studies indicate an increased incidence, and it is unclear if these geographic variations contain important etiologic clues.<sup>12</sup> Currently, PCNSL has an incidence of 0.31 per 100,000 person years, suggesting that approximately 800 new cases occur in the United States every year.<sup>11</sup> This change in incidence cannot be attributed to new diagnostic techniques or the adoption of a uniform nosology, and the reason for this marked rise in PCNSL is unknown.

## CLINICAL FEATURES

### GENERAL

PCNSL affects all ages, from the very young to the elderly. Its peak incidence occurs in the sixth and seventh decades in immunocompetent patients and younger in immunosuppressed patients.<sup>13</sup> Among apparently immunocompetent individuals, there is a 3:2 male to female ratio, but in the AIDS population, more than 90% of patients are men.<sup>14</sup>

By definition, PCNSL is limited to the nervous system and has not metastasized there from a systemic site. Metastatic NHL typically involves the leptomeninges, rarely the brain, and usually occurs in the setting of advanced disseminated disease.<sup>15</sup> Systemic staging of PCNSL patients has yielded only a 3% to 4% incidence of systemic disease.<sup>16,17</sup> In all patients, the systemic site was extranodal and identified by bone marrow biopsy or abdominopelvic computed tomographic scan, suggesting that these are the only tests necessary for a systemic evaluation.

### BRAIN

Most PCNSLs present with symptoms of an intracranial mass lesion. The specific presenting symptoms and signs reflect the location of the tumor, with focal cerebral deficits occurring in approximately one-half of patients<sup>13</sup>; however, the presentation of PCNSL has some differences from that of other brain tumors. Because the frontal lobe is the most frequently involved region of the brain and multiple lesions are often seen, changes in personality and level of alertness are common presenting symptoms. Headaches and symptoms of increased intracranial pressure are also seen frequently. Seizures are less common than in patients with other types of brain tumors, occurring in approximately 10% of patients as a presenting sign, because most PCNSLs involve deep brain structures rather than seizure-prone cerebral cortex. PCNSL is a rapidly growing tumor, and symptoms are usually present for only weeks to a few months before a diagnosis is made. Staging for PCNSL should include the following tests:

- Cranial magnetic resonance imaging (MRI) with gadolinium
- Lumbar puncture
- Ophthalmologic examination with slit lamp
- Spinal MRI with gadolinium (when appropriate)
- Abdominal computed tomographic scan
- Bone marrow testing
- Chest radiography
- Human immunodeficiency virus-1 serology

PCNSL is often disseminated within the nervous system at diagnosis. Brain lesions are multifocal in 40% of immunocompetent patients and almost 100% of AIDS patients. Multiple lesions often cause diagnostic confusion with brain metastases, particularly as 13% of PCNSL patients have a history of a prior systemic malignancy.<sup>18</sup> Many lesions are periventricular, allowing tumor cells to easily gain access to the CSF. At least 42% of patients have demonstrable leptomeningeal seeding based on a positive CSF cytologic examination, pathologic leptomeningeal invasion, or unequivocal radiographic evidence of subarachnoid tumor, but patients rarely have symptoms or signs of leptomeningeal lymphoma.<sup>19</sup> At autopsy, 100% of patients have leptomeningeal tumor from either direct invasion into the ventricular system by periventricular tumor or local involvement of the leptomeninges overlying a cortical lesion.<sup>20</sup> In addition, approximately 20% of PCNSL patients have ocular involvement at diagnosis.<sup>21</sup>

### EYE

The eye, a direct extension of the brain, is a common site of disease in PCNSL. Lymphoma can originate within the eye, and 50% to 80% of these patients eventually develop cerebral lymphoma, usually after several years of latency.<sup>22,23</sup> Ocular lymphoma typically involves the vitreous, retina, or choroid, but optic nerve infiltration can also occur.<sup>22,23</sup> and<sup>24</sup> Disease outside of the globe but within the orbit is not a feature of ocular lymphoma; it represents systemic NHL. Ocular lymphoma can

present with blurred vision or floaters, or it may be clinically silent; it may begin unilaterally, but most patients eventually develop bilateral, but asymmetric, disease. A cellular infiltrate of the vitreous can be visualized only by slit-lamp examination, and choroidal or retinal lesions often require indirect ophthalmoscopy. Lymphoma can be identified in vitrectomy specimens<sup>22</sup>; false-negative biopsy results may occur when patients have too few vitreal lymphocytes for the pathologist to examine or if the patient has been given corticosteroids to treat a presumed uveitis.<sup>24,25</sup>

## LEPTOMENINGES

Primary leptomeningeal lymphoma, in the absence of a parenchymal brain mass, is rare, accounting for approximately 7% of PCNSLs.<sup>26,27</sup> and <sup>28</sup> Patients can present with progressive leg weakness, urinary incontinence or retention, cranial neuropathies, increased intracranial pressure, confusion, or a combination of these symptoms. Symptoms are usually present for only 2 to 3 months before diagnosis, but occasionally a patient can have symptoms for 1 to 2 years before being diagnosed.<sup>26</sup> Diagnosis is established by demonstrating malignant lymphocytes in the CSF or on meningeal biopsy. The CSF invariably shows an elevated protein concentration and a lymphocytic pleocytosis often in excess of 100 cells/ $\mu$ L; CSF glucose is low in approximately one-third of patients. A gadolinium MRI scan of the head or spine reveals meningeal enhancement, hydrocephalus, or multiple intradural nodules.

## SPINAL CORD

Primary spinal cord lymphoma is even less common than primary leptomeningeal lymphoma.<sup>28,29,30</sup> and <sup>31</sup> Lymphoma in the spinal cord parenchyma can occur in isolation or with brain lymphoma. Patients present with painless bilateral limb weakness, usually involving the legs; sensory symptoms and signs may initially follow a radicular pattern, but eventually a sensory level may be found. CSF may be normal or have a mildly elevated protein concentration with a few lymphocytes. Prognosis has been poor, with patients surviving only a few months from the onset of symptoms, but this is often because the diagnosis was not made until autopsy and no appropriate therapy was administered.

## DIAGNOSTIC TESTS

### CRANIAL IMAGING

MRI scanning is the standard imaging technique for any patient with a cerebral neoplasm. The MRI of PCNSL is usually quite distinctive, and the diagnosis may be suspected on the basis of the radiographic appearance alone. The tumor has an isointense signal on the pregadolinium T1 MRI, and after contrast is administered, there is dense and diffuse enhancement.<sup>32,33</sup> The lesions often have indistinct borders, and the amount of surrounding edema is quite variable. Unlike brain metastases or malignant gliomas, ring enhancement is rarely seen.

Prominent contrast enhancement is characteristic of PCNSL, occurring in more than 90% of patients; however, nonenhancing lesions may be seen in 10% or fewer patients, particularly at recurrence.<sup>34</sup> Nonenhancing tumor can occur in the absence of corticosteroid administration, particularly in immunosuppressed patients, although it is also seen in immunocompetent patients. At its extreme, nonenhancing PCNSL can rarely present as lymphomatosis cerebri, with diffuse infiltration of the entire brain, usually presenting as a progressive dementia.<sup>35</sup> Although it is a minor component of disease in most patients, nonenhancing PCNSL has important therapeutic implications, indicating tumor behind a relatively intact blood-brain barrier.

The radiographic features of PCNSL in the immunosuppressed patient differ from the characteristic image seen in immunocompetent individuals.<sup>33</sup> In the AIDS patient, ring enhancement is typical, reflecting the higher incidence of necrosis seen pathologically in this group. Consequently, it is impossible to distinguish PCNSL from more common cerebral infections, such as toxoplasmosis, on the basis of MRI. However, positron emission tomography or single photon emission computed tomographic imaging can reliably differentiate PCNSL from toxoplasmosis in most patients, frequently eliminating the need for histologic confirmation.<sup>36,37</sup> and <sup>38</sup>

### LUMBAR PUNCTURE

Lumbar puncture should be part of the diagnostic evaluation of every patient with PCNSL. The protein concentration is elevated in 85% of patients, although rarely above 150 mg/dL.<sup>19,20,39,40</sup> The glucose concentration is usually normal, but can be low when florid leptomeningeal tumor is present. A CSF pleocytosis is seen in more than one-half of patients and always consists of lymphocytes, either reactive or malignant. An unequivocally positive CSF cytology eliminates the need for a brain biopsy. This may be particularly important in the immunosuppressed or desperately ill patient at increased risk for a surgical complication. Occasionally, immunohistochemical stains of CSF demonstrate a monoclonal population of cells establishing the neoplastic nature of the pleocytosis even if the cells appear to be cytologically benign.<sup>41</sup> Tumor markers, such as b<sub>2</sub>-microglobulin, lactic acid dehydrogenase isoenzymes, and b-glucuronidase, when their levels are elevated, provide circumstantial evidence for tumor invasion of the leptomeninges.

Systemic lymphomas in immunocompromised patients are often associated with the Epstein-Barr virus (EBV); the virus is believed to be oncogenic in these patients.<sup>42</sup> Using *in situ* hybridization and the polymerase chain reaction, EBV has been detected in the tumor tissue of most AIDS-related PCNSLs and some non-AIDS tumors as well.<sup>43,44</sup> EBV may play an important role in the development of this tumor in immunosuppressed patients, comparable with its presumed role in systemic polyclonal and monoclonal lymphoid proliferations in the immunocompromised host. Regardless of its role in the genesis of the neoplasm, it may serve a useful diagnostic function. With polymerase chain reaction, EBV DNA has been detected in the CSF of AIDS patients with PCNSL, but not in the CSF of AIDS patients without PCNSL; this approach offers a simple, noninvasive diagnostic alternative to brain biopsy in the AIDS population,<sup>37,38,45,46</sup> and when combined with a positive positron emission tomography or single photon emission computed tomographic scan result, provides 100% specificity for a diagnosis of PCNSL.<sup>37,38</sup>

## PATHOLOGY

PCNSL is a NHL, usually of an intermediate malignant subtype.<sup>2,28</sup> Most are diffuse large cell lymphomas or diffuse large cell immunoblastic lymphomas. Response to treatment or prognosis is not related to pathologic subtype; however, most series contain so few patients in any given category that a relationship may be missed. Further prospective studies with a large number of patients may reveal differences comparable with that seen for systemic lymphomas. At this time, all PCNSLs are treated in the same manner, regardless of subtype or cell of origin.

Macroscopically, PCNSL is usually a brownish space-occupying mass involving the deep white matter.<sup>2</sup> In some cases, only a thickened corpus callosum may occur without discoloration, and in occasional patients the brain is grossly normal, but diffuse infiltration is seen microscopically. Histologically, PCNSL can grow as sheets of cells, but a characteristic vasocentric growth pattern with tumor infiltrating the brain parenchyma between involved blood vessels is found in virtually all cases. Neither necrosis nor hemorrhage is a dominant histologic feature. In autopsy specimens, tumor is always found in multiple regions of the CNS that appeared normal on neuroimaging studies.

Several investigators have demonstrated the B-cell nature of this tumor, with immunohistochemistry showing monoclonal immunoglobulin heavy- or light-chain production or identifying B-cell markers.<sup>3,28,47</sup> Immunoglobulin gene rearrangement has also been shown and may be diagnostically useful in some patients.<sup>48</sup> A study of adhesion molecules revealed an identical pattern of expression for PCNSL and systemic lymphomas.<sup>49</sup> Bc rearrangements have not been detected in PCNSL, and no unique molecular marker has been identified to discriminate PCNSL from its systemic counterparts.<sup>49</sup> Rare, T-cell PCNSLs seem to have a predisposition to develop in the leptomeninges.<sup>50,51</sup> and <sup>52</sup> Reports suggest a rising incidence in the number of T-cell PCNSLs.<sup>53</sup> This may be a result of newer immunohistochemical techniques, or it may be an artifact of the difficulties interpreting immunohistochemical studies. In both the CSF and the tumor itself, these neoplasms may be accompanied by a reactive lymphocytosis.<sup>54</sup> These reactive cells are T cells and can make interpretation of special stains difficult. For the most part, one can clearly distinguish the cytologically malignant cells, which are usually B cells, from the reactive lymphocytes, which are T cells. In lesions partially treated by corticosteroids, however, the reactive T cells may be all that is apparent on a biopsy specimen, making accurate diagnosis difficult.

## MANAGEMENT

The appropriate management of a patient with PCNSL requires a correct diagnosis. This may be difficult because the clinical presentation of PCNSL is not distinctive and other primary and secondary brain tumors are much more common; however, the method outlined here can aid in the approach to a patient who harbors this

tumor.

When an MRI scan reveals an intracranial mass, the radiographic appearance may strongly suggest PCNSL; multiple lesions, deep or periventricular location, diffuse and dense contrast enhancement, and poorly defined borders are common imaging characteristics. In addition, the clinical setting in which the tumor arises may point to the diagnosis (e.g., an immunocompromised patient). If PCNSL is a strong diagnostic consideration, corticosteroids should be withheld unless the patient is in imminent danger of herniation, a rare situation. Corticosteroids may alter or even eliminate the ability to establish the diagnosis pathologically. Histologic confirmation is essential, by stereotactic biopsy, lumbar puncture demonstrating leptomeningeal lymphoma, or vitreous biopsy demonstrating lymphomatous cells. If the patient requires the immediate use of corticosteroids, or if PCNSL was not considered originally and the patient was placed on corticosteroids, a repeat MRI scan should be done to evaluate for possible resolution or marked shrinkage of the lesion or lesions. Biopsy should still be considered if the lesions are reduced in size but still evident; however, nondiagnostic tissue may be obtained. Corticosteroid-induced resolution of an intracranial mass does not establish the diagnosis of PCNSL, because nonneoplastic contrast-enhancing processes such as multiple sclerosis or sarcoidosis can resolve after corticosteroid administration.

Using the clinical staging criteria developed for systemic lymphomas, PCNSL corresponds to stage IE (i.e., disease confined to a single extranodal site). Systemic stage IE disease has a 100% complete response rate and at least a 70% 10-year survival, or cure, rate with focal radiotherapy.<sup>55</sup> Surprisingly, the prognosis for PCNSL is poor. Despite the highly responsive nature of PCNSL to initial treatment, median survival is only 12 to 18 months with cranial radiotherapy,<sup>21,28,39,40,56</sup> and the 5-year survival rate is only 3% to 4%. This short survival is a result of recurrence of PCNSL after an initial response to cranial irradiation. Relapse occurs primarily in the brain, often in regions remote from the original site but within the prior radiation port; it also occurs in the leptomeninges and eye. Systemic lymphoma is found in only 7% to 8% of autopsied patients, and the vast majority of these patients have a single focus of clinically silent disease, thought to represent a systemic metastasis from recurrent nervous system tumor.<sup>21,39</sup>

Because of its poor prognosis, new treatment approaches have been developed. The therapeutic strategies differ, depending on the immunologic status of the patient. Most data regarding effective therapies have been accumulated in immunocompetent patients. The presence of significant immunosuppression may compromise the patient's ability to tolerate more vigorous forms of treatment. Thus, we divide the descriptions of existing and potential treatment regimens for PCNSL into treatments for the immunologically intact patient and those for patients with diminished immune systems from a preexisting condition.

## IMMUNOLOGICALLY NORMAL PATIENTS

### *Corticosteroids*

A unique feature of PCNSL compared with other brain tumors is its exquisite sensitivity to corticosteroids. In at least 40% of patients, tumor masses significantly shrink or disappear on MRI scan after corticosteroids are administered.<sup>28,32,57</sup> This apparent remission is a direct result of the cytotoxic effect of corticosteroids, comparable with their effect in systemic lymphoma. Experimentally, corticosteroid receptor-like molecules have been identified on mouse lymphoma cells, and their presence correlates with cell lysis after exposure to corticosteroids.<sup>58</sup> Clinically, disappearance of PCNSL lesions is accompanied by improvement, which may last long after the corticosteroids have been discontinued. There are isolated reports of patients being cured or having prolonged survival after treatment with corticosteroids alone.<sup>57</sup> Regardless of apparent tumor regression, corticosteroid-induced remission is short-lived in most patients and is not definitive treatment. Biopsy after corticosteroid administration often yields normal or nondiagnostic tissue. Occasionally, biopsy results are misleading as the corticosteroids can lyse the malignant B cells, leaving the reactive T cells behind, which may be interpreted as an inflammatory process.

### *Surgery*

Surgery is an important means of confirming the histologic diagnosis, but it has no therapeutic role. Mean survival of patients with PCNSL with supportive care alone is 1.8 to 3.3 months.<sup>1,4,39</sup> Surgical resection adds little, prolonging the average survival to only 3.3 to 5.0 months.<sup>39,59,60</sup> Unlike malignant glioma, for which extensive resection is an important component of therapy, PCNSL's multifocal and infiltrative nature makes surgical extirpation difficult. Furthermore, the deep location of many PCNSLs leaves the patient susceptible to severe postoperative deficits if a complete resection is attempted.<sup>32</sup> Therefore, the diagnostic method of choice is stereotactic biopsy, which also allows for biopsy of deep lesions that cannot be approached safely by conventional surgery. If craniotomy is undertaken because the diagnosis of PCNSL is not considered preoperatively, an intraoperative frozen section often establishes the diagnosis of PCNSL; the procedure can then be terminated, because further resection is unnecessary.

### *Radiotherapy*

Whole brain radiotherapy (WBRT), combined with corticosteroids, was the conventional treatment for PCNSL, yielding median survivals of 12 to 18 months. There is no clear radiotherapy dose-response relationship in PCNSL.<sup>61</sup> The Radiation Therapy Oncology Group conducted a prospective study of patients with PCNSL treated with 4000 cGy WBRT plus a 2000-cGy boost to the involved area, to assess whether dose intensification improved outcome.<sup>56,61</sup> Median survival was only 12.2 months, and most recurrences were in the boosted field. This is comparable with our experience at Memorial Sloan-Kettering Cancer Center, where relapses occurred with equal frequency in a boosted region receiving a total of 5440 cGy and in other areas of the brain treated with only 4000 cGy.<sup>62</sup> Because the added radiotherapy does not improve local control and can contribute to late neurologic sequelae, we have eliminated the boost and use 4500-cGy WBRT in our current protocol.

The primary treatment of ocular disease is radiotherapy to the globe.<sup>23,24,63</sup> 3500 to 4000 cGy over 4 to 5 weeks is the recommended total dose. Because ocular lymphoma is predominately a binocular process, both eyes should be irradiated, even when only monocular disease can be detected on slit-lamp examination. Most patients experience both symptomatic improvement and resolution of cells in the vitreous after radiotherapy; however, some have vitreal clearing without improved vision, and others may not respond to radiotherapy. The incidence of long-term ocular toxicity from radiotherapy in this disease is unknown, but it may increase with improved survival because many of the complications are delayed. Accelerated cataract formation is almost a certainty after these doses of radiation therapy. Conjunctivitis, dry eyes, retinal atrophy, and vitreous hemorrhage have all been reported in PCNSL patients after ocular radiotherapy.<sup>63</sup> However, most patients tolerate a fractionated dose of 3600 cGy to both eyes without significant acute or permanent delayed complications.

Craniospinal irradiation has been proposed as the initial therapy for PCNSL because of the high incidence of clinically evident meningeal tumor at recurrence and the invariable demonstration of leptomeningeal infiltration at autopsy. Few data exist to evaluate this approach, although results in the few patients treated with neuraxis radiotherapy suggest improved survival over WBRT alone.<sup>64</sup> However, irradiation of such a large portion of the bone marrow compromises the patient's ability to tolerate subsequent systemic chemotherapy that is likely to be necessary at relapse. Administration of intrathecal chemotherapy at diagnosis is an effective alternative to neuraxis radiotherapy in treating leptomeningeal lymphoma, and it is associated with less systemic toxicity.

### *Chemotherapy*

No large prospective trials have compared chemotherapy plus radiotherapy with radiotherapy alone, but accumulating data from multiple phase II studies clearly document the chemosensitivity of PCNSL to systemic chemotherapy and superior outcomes with combined modality therapy. It is improbable that a phase III trial will ever be mounted to study this issue given the small number of patients with PCNSL and the long time needed to complete such a protocol.

Most studies have focused on the use of preradiation chemotherapy for two reasons:

1. It permits assessment of response to treatment. Almost all patients have a complete, although short-lived, response to radiotherapy; therefore, no measurable disease is present to assess adjuvant chemotherapy. This is particularly important in PCNSL because we are still trying to identify active agents and cannot simply adopt regimens effective against comparable systemic NHLs.
2. The administration of drugs, particularly methotrexate, before radiotherapy may reduce the synergistic toxicity of combining chemotherapy with cranial irradiation. Although methotrexate has been best studied, the enhanced neurotoxic potential of chemotherapy after cranial radiotherapy may apply to other agents as well. Cranial irradiation opens the blood-brain barrier, and this may persist for weeks to months after radiotherapy is completed. This enhanced permeability of the blood-brain barrier permits greater drug concentrations to accumulate in normal brain tissue. Completing chemotherapy before cranial irradiation is started should minimize brain exposure to potentially neurotoxic agents.

Several investigators have used chemotherapeutic regimens for PCNSL that were successful in treating systemic NHL. The combinations of preradiation cyclophosphamide, doxorubicin, and vincristine with prednisone (CHOP) or dexamethasone (CHOD) have been studied most extensively. Stewart and associates

were the first to note responses of brain lesions to CHOP, although patients quickly developed florid leptomeningeal tumor. <sup>65,66</sup> Lachance and associates noted initial responses, but patients rapidly developed multifocal brain recurrence in sites distant from the original location of disease before chemotherapy could be completed. <sup>67</sup> In contrast to these data, isolated patients have been reported to experience prolonged survival with CHOP plus WBRT. <sup>68,69</sup> However, two prospective, multicentered trials clearly established the poor efficacy and high toxicity of CHOP/CHOD for PCNSL. <sup>70,71</sup> The Radiation Therapy Oncology Group conducted a study in which patients received three cycles of CHOD followed by cranial irradiation. <sup>70</sup> The median survival was only 16.1 months for the 52 patients treated. A separate multiinstitutional trial of preradiation CHOP included 46 evaluable patients with an estimated median survival of approximately 9.5 months. <sup>71</sup> Only 54% of patients completed two cycles of CHOP before beginning radiotherapy; in the others disease progression or toxicity occurred, with a 15% mortality. Furthermore, it appears that, when effective, CHOP is associated with a high incidence of delayed neurologic toxicity. <sup>69</sup> In addition to CHOP, Brada and associates studied methotrexate, 400 mg/m<sup>2</sup>, with doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (MACOP-B) preceding cranial radiotherapy, but median survival was only 14 months. <sup>72</sup> When added to radiotherapy, neither CHOP nor MACOP-B improved survival over that seen with radiotherapy alone.

Although the agents in these regimens should have excellent activity against PCNSL cells, they are unable to penetrate an intact blood–brain barrier. Adequate drug concentrations are likely to be achieved in areas of bulky disease seen on MRI scan where the blood–brain barrier is disrupted by tumor, which accounts for the initial resolution of tumor masses; however, the drugs are unable to reach microscopic disease, which persists behind a relatively preserved blood–brain barrier. Drug delivery issues may only partially explain the difficulty of treating PCNSL, but these data strongly argue for the use of drugs that can permeate the blood–brain barrier (Table 45.5-1).

<b>SURGERY</b>
Biopsy for diagnosis
Resection should be avoided
<b>CHEMOTHERAPY</b>
Should be considered at diagnosis for every patient
Must penetrate the blood–brain barrier
Lipophilic (e.g., procarbazine)
High-dose with central nervous system penetration (e.g., methotrexate)
Must have antilymphoma activity
Should be given before radiotherapy
<b>RADIOTHERAPY</b>
Must be whole brain, if used
4500 cGy; boost not necessary
3600 cGy to eyes, if indicated
May be deferred in some patients who have a complete response to chemotherapy

**TABLE 45.5-1.** Management of Primary Central Nervous System Lymphoma

High-dose methotrexate has emerged as the most important drug for the treatment of PCNSL. Two large retrospective studies have convincingly demonstrated that methotrexate is the single most active agent for PCNSL. <sup>73,74</sup> and <sup>75</sup> A number of years ago, we treated PCNSL patients at Memorial Sloan-Kettering Cancer Center with systemic, 1 g/m<sup>2</sup>, and intra-Ommaya methotrexate followed by radiotherapy and high-dose cytarabine. <sup>62</sup> An analysis of this original cohort confirms a cause-specific median survival of 42 months, with a 22% 5-year survival, a significant improvement over radiotherapy alone <sup>76</sup> (Fig. 45.5-1 and Table 45.5-2). Age older than 50 years was a poor prognostic factor for response and survival. Others have confirmed that age and performance status are important prognostic factors, regardless of treatment type. <sup>56,70,71,73,74</sup> Additional regimens using nitrosoureas, procarbazine, cyclophosphamide, and doxorubicin have all been used in a few patients, with reported success. <sup>68,77,78</sup> and <sup>79</sup>

**FIGURE 45.5-1.** Kaplan-Meier curve demonstrating cause-specific survival for 31 patients treated with chemotherapy plus cranial irradiation. Median survival was 42 months, and the 5-year survival rate was 30%.

Regimen	Median Survival (mo)	5-Y Survival Rate (%)	Reference
High-dose methotrexate	42	22	76
Blood-brain barrier disruption and intrathecal methotrexate	40	30	62
Cyclophosphamide, doxorubicin, and vincristine with prednisone or dexamethasone	15-18	10	70,71
Methotrexate with doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin	14	10	72
Whole brain radiotherapy alone	15-18	5	70

**TABLE 45.5-2.** Chemotherapy Regimens for Primary Central Nervous System Lymphoma

The history of treatment for systemic NHL documents the superiority of combination chemotherapy over single agents. Consequently, new regimens for PCNSL are combining multiple agents that can penetrate the blood–brain barrier (Table 45.5-3). An intergroup trial with the Radiation Therapy Oncology Group and the Southwest Oncology Group, using a 10-week preradiation regimen of high-dose methotrexate, 2.5 g/m<sup>2</sup>, procarbazine, and vincristine has just been completed. Preliminary results show a median survival of 30 months <sup>80</sup> (Fig. 45.5-2). This is the first multicentered trial to demonstrate an improved outcome over radiation therapy alone.

Site	Number of Patients with Response to Treatment									
	1	2	3	4	5	6	7	8	9	10
Brain	1	1	1	1	1	1	1	1	1	1
Spinal cord	1	1	1	1	1	1	1	1	1	1
Other	1	1	1	1	1	1	1	1	1	1

**TABLE 45.5-3.** Active Chemotherapy Regimens

**FIGURE 45.5-2.** Gadolinium-enhanced magnetic resonance imaging scans demonstrating a complete response of primary central nervous system (CNS) lymphoma to high-dose methotrexate, procarbazine, and vincristine. The prominent and diffuse enhancement pattern and periventricular location are characteristic of primary CNS lymphoma.

In an effort to circumvent the blood–brain barrier and deliver multiagent treatment, Dahlborg and coworkers used blood–brain barrier disruption followed by intraarterial methotrexate, combined with systemic cyclophosphamide, procarbazine, and dexamethasone without cranial irradiation.<sup>81</sup> Their 39 patients treated at the time of diagnosis had a median survival of 40 months; however, 31% required WBRT. Neither the rate of relapse nor failure of the regimen was reported.

Although most studies have focused on preradiation chemotherapy, the question of adjuvant chemotherapy in patients who have completed WBRT and not received prior chemotherapy often arises. It is unknown if adjuvant chemotherapy is equivalent to a preradiation drug, but preliminary data suggest it is superior to radiotherapy alone. Chamberlain and Levin followed WBRT with procarbazine, lomustine, and vincristine, achieving a 41-month median survival in 16 patients.<sup>82</sup> Therefore, four to six cycles of procarbazine, lomustine, and vincristine after WBRT is completed seem to be reasonable in patients who have received no prior chemotherapy. We have avoided methotrexate in this setting because of potential CNS toxicity.

The prolonged survival seen with combined modality regimens has led to greater appreciation of treatment-induced late neurologic toxicity. Mercht and associates first reported radiation necrosis in a patient with PCNSL treated with radiotherapy alone.<sup>83</sup> Liang and associates noted a high incidence of late toxicity in survivors treated with CHOP and intrathecal methotrexate plus WBRT.<sup>84</sup> Long-term follow-up of our original cohort of patients reveals that almost 100% of patients older than the age of 60 years at diagnosis experience significant late sequelae within 4 years of treatment, whereas only 30% of younger patients have similar problems after a 7.5-year latency.<sup>76</sup> Mass and associates report no toxicity with intraarterial therapy; however, their own experimental work clearly demonstrates damage of normal brain structures when chemotherapy follows blood–brain barrier disruption.<sup>84</sup> These issues led to an exploration of systemic chemotherapy alone as effective treatment for PCNSL. Glass and associates reported long-term survival in a few patients treated with high-dose methotrexate alone.<sup>85</sup> We, and others, have treated elderly patients with a multiagent chemotherapeutic regimen.<sup>86,87 and 88</sup> The response rate was greater than 90%, with most patients having a complete response. Median survival for patients older than age 60 years was 33 months, superior to a median of 7.1 months for radiation therapy alone in a comparable age group.<sup>56</sup> Furthermore, no patient developed neurotoxicity. Similar results were observed in 14 patients treated by Sandor et al. with a high-dose methotrexate-based regimen without radiation therapy.<sup>89</sup> These preliminary data suggest that good disease control can be achieved by chemotherapy alone.

There are few examples of ocular lymphoma being treated with chemotherapy. Barr and associates used cyclophosphamide and then vincristine in one patient with metastatic ocular lymphoma without effect.<sup>90</sup> Sullivan and Dallow reported both systemic and ocular remission in a patient with a systemic histiocytic lymphoma and a ciliary body metastasis, after treatment with procarbazine, CCNU, and vincristine.<sup>91</sup> Baumann and coworkers reported a patient with lymphomatous uveitis who relapsed after ocular irradiation.<sup>92</sup> Treatment with intravenous cytarabine, 500 mg, and methotrexate, 200 mg, had no effect; however, high-dose cytarabine, 3 g/m<sup>2</sup>, produced a complete response that was long lasting. Furthermore, therapeutic cytarabine levels were documented in both aqueous and vitreous humor 90 minutes after infusion was completed. Strauchen and associates treated six patients with primary ocular lymphoma with high-dose cytarabine, obtaining a response in five.<sup>93</sup> We have observed responses of ocular lymphoma to high-dose methotrexate before ocular radiotherapy. In addition, Valluri and coworkers used our original PCNSL regimen to treat three patients with ocular lymphoma, two of whom had concurrent CNS disease; these patients remained in CNS and ocular remission 30 to 40 months after diagnosis.<sup>94</sup> The role of chemotherapy in treating ocular involvement in PCNSL remains to be clarified; however, these reports suggest that some agents or combination regimens may prove useful in the future. Intravitreal injection of methotrexate was described as effective treatment for recurrent ocular lymphoma.<sup>95</sup> Although this approach eliminates systemic toxicity from intravenous chemotherapy, it requires frequent intraocular injections.

## IMMUNOCOMPROMISED PATIENTS

The treatment modalities for PCNSL in immunocompetent patients are also used to treat AIDS-related PCNSL, although they are generally less effective and more toxic in immunodeficient patients. The initiation of treatment first requires a histologic diagnosis of PCNSL. In the non-AIDS immunocompromised patient a stereotactic biopsy should be performed when an intracranial mass lesion is first diagnosed. In AIDS patients, a noninvasive diagnosis can often be achieved with the use of positron emission tomography or single photon emission computed tomographic imaging and the detection of EBV DNA in CSF. In the absence of a definitive circumstantial diagnosis, biopsy should be performed. Toxoplasmosis continues to be the most common cause of an intracranial mass in an AIDS patient, but PCNSL is the second most common. However, empiric treatment with 2 to 3 weeks of antitoxoplasmosis therapy is an unacceptable diagnostic trial because most PCNSL patients markedly deteriorate during this time, severely limiting subsequent treatment options.

Corticosteroids and cranial irradiation are the mainstays of treatment for PCNSL in immunosuppressed patients. Use of corticosteroids should be limited because they can contribute to the underlying immunosuppression; however, they are still valuable for short-term control of neurologic symptoms and may be necessary during the course of WBRT. AIDS patients with PCNSL do respond to cranial irradiation, but median survival is only 2 to 5 months because most die of systemic or coexistent CNS infections.<sup>96,97,98 and 99</sup>

Chemotherapy for PCNSL has been used infrequently in immunodeficient patients. Intrathecal methotrexate for leptomeningeal lymphoma was reported to be effective in a single patient with immunoglobulin A deficiency, although the benefit was of short duration.<sup>100</sup> Potent intravenous chemotherapy programs are often inappropriate for immunosuppressed patients, particularly those with AIDS. However, there is a subset of AIDS patients who benefit from a vigorous approach.<sup>101,102</sup> Typically, these are patients with a good performance status, no active comorbid conditions, and a relatively high CD4 cell count (200/μL or more). Such patients do have prolonged survival when chemotherapy is added to WBRT, often surviving more than 1 year and occasionally for many years. Again, high-dose methotrexate is the agent of choice.<sup>103</sup> There are isolated reports of patients with AIDS-related PCNSL who have been successfully treated with antiviral and biologic agents or reconstitution of their immune system using highly active antiretroviral therapy.<sup>104,105</sup> These reports open new therapeutic avenues for what has been a virulent and deadly

complication of human immunodeficiency virus-1 infection. Furthermore, monitoring the level of CSF EBV DNA may prove helpful in assessing treatment response, in addition to conventional imaging techniques. <sup>106</sup>

## HISTORY

A great deal has been written about the life and accomplishments of Thomas Hodgkin.<sup>1</sup> In his historic paper entitled “On Some Morbid Appearances of the Exorbitant Glands and Spleen,” presented to the Medical Chirurgical Society in London on January 10, 1832, Hodgkin described the clinical history and postmortem findings of the massive enlargement of lymph nodes and spleens of six patients studied at Guy's Hospital in London and of a seventh patient who had been seen by Carswell in 1828.<sup>2</sup> Without a microscope, Hodgkin recognized that these patients had a disease that started in the lymph nodes located along the major vessels in the neck, chest, or abdomen, rather than from an inflammatory condition.

In 1856, Sir Samuel Wilks, a Guy's Hospital pathologist, described ten postmortem cases that had “a peculiar enlargement of the lymphatic glands frequently associated with disease of the spleen.” By 1865, Dr. Wilks had collected 15 cases, which were published in a second paper entitled “Cases of the Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease) with Remarks.”<sup>3</sup> This linked Hodgkin's name permanently to this newly identified disease. Wilks's initial descriptions gave us some of our earliest understanding of Hodgkin's disease (HD). He described the disease as a cancer that started and remained in the lymph nodes for a long time, perhaps years, before involving the spleen and then spreading to other organs. He also noted anemia, weight loss, and fevers in some of the patients with HD.

Although other physicians had provided descriptions of the characteristic giant cells present in the lymph nodes and spleens of patients with HD, Dr. W. S. Greenfield in 1878 was the first to contribute drawings of them from a low microscopical magnification of a lymph node specimen.<sup>4</sup> Despite Greenfield's findings, Dr. Carl Sternberg (in 1898) and Dr. Dorothy Reed (in 1902) are credited with the first definitive microscopical descriptions of HD.<sup>5,6</sup>

Both Sternberg and Reed, along with many other physicians, believed that HD was caused by an associated infection rather than by a separate malignant process of the lymph nodes. Proponents of the infectious theory cited the frequent association of HD with tuberculosis. Eight of Sternberg's thirteen cases of HD had coexistent tuberculosis, and he believed HD to be a variant of tuberculosis. Other physicians believed that HD was a cancer of the lymph nodes. Clinical and pathologic studies, available in the early twentieth century, helped to confirm their view.<sup>7</sup> Despite the very strong evidence for the malignant nature of HD over the last century, it has only recently been shown that Hodgkin's-Reed-Sternberg (H-RS) cells are clonal, confirming their origin from a single malignant cell.<sup>8</sup>

## ETIOLOGY AND EPIDEMIOLOGY

Approximately 7500 new cases of HD are diagnosed each year in the United States. Slightly more men than women develop this malignancy (1.4:1). In economically developed countries, there is an age-related bimodal incidence for HD. The first peak occurs in the third decade of life, and a second rise in incidence occurs after the age of 50 years. The incidence of HD by age also differs by histologic subtype.<sup>9</sup>

*Mycobacterium tuberculosis* was first suspected of being the etiologic organism for HD because of the high coexistence of tuberculosis in these patients.<sup>5</sup> This theory

was later discounted when it was appreciated that HD was associated with deficits in the immune system that accounted for the increased presence of associated infections.<sup>10</sup> Several studies in the 1970s suggested that HD might be contagious because of reports of clustering of the disease. The first reports, by Vianna and Poln,<sup>11</sup> noted clustering among high school students exposed to HD. However, population-based studies, using cancer registries in Connecticut and California, convincingly made the argument that the reported clusters occurred by chance alone, and a study that repeated the methodology of Vianna and Poln<sup>11</sup> in a different location failed to confirm their findings.<sup>12</sup>

A number of studies have suggested that a genetic predisposition for HD exists. There is an increased incidence in Jews and also among first-degree relatives.<sup>13</sup> Siblings appear to have a two- to fivefold increased risk; in siblings of the same gender, there is as much as a ninefold increased risk.<sup>14</sup> An increased risk among parent-child pairs but not among spouses again suggests a genetic predisposition. Also, HD has been linked with certain HLAs.<sup>15,16</sup>

There is less support for most other potential causes of HD. In contrast to other malignancies, HD rarely is seen as a second malignancy and does not appear to be increased in patients with illness- or treatment-related chronic immunosuppression. Although HD has been noted in patients with the acquired immunodeficiency syndrome (AIDS), evidence for a direct correlation with the immunosuppression associated with AIDS is lacking.<sup>17</sup>

In contrast, increasing evidence suggests a viral etiology for HD. In economically developed countries, studies report an association between HD in younger patients and increased maternal education, decreased numbers of siblings and playmates, early birth order, and single-family dwellings in childhood.<sup>18,19</sup> This association between HD and childhood factors that decrease exposure to infectious agents at an early age has led investigators to propose that the epidemiologic features of HD appear to mimic those of a viral illness that has an age-related host response to infection.

Epstein-Barr virus (EBV) is the leading viral candidate for HD causation.<sup>20</sup> There is a twofold to threefold excess in the incidence of HD among patients with a history of mononucleosis, a disease caused by EBV. In addition, there appears to be an altered antibody pattern to EBV in patients before presenting clinically with HD, with elevated titers against the viral capsid antigen and against the EBV nuclear antigen (EBNA) as compared to controls.<sup>21</sup> This suggests that such patients may have had more severe initial EBV infections or more frequent viral replication associated with the development of HD.

Patients in nonindustrialized countries and from lower socioeconomic groups, as well as children, who develop HD are more likely to have EBV-positive HD than are patients with high socioeconomic backgrounds in the young adult age group.<sup>20,22</sup> In these groups, even nodular sclerosis HD (NSHD) has a higher incidence of EBV positivity than it does in the young adult cases.

Some cellular and molecular biology data have provided additional support for the association of EBV and HD.<sup>23</sup> Through the use of sensitive molecular probes, including Southern blot, *in situ* hybridization, and polymerase chain reaction (PCR) assays, 30% to 50% of HD specimens have been found to contain EBV genome fragments in the diagnostic RS cells.<sup>24</sup> In the United States and Western Europe, the tumor cells of classic HD (CHD) are EBV-positive in approximately 50% of the cases. The positivity rate is lower in NSHD (15% to 30%) and higher in mixed-cellularity HD (MCHD) (60% to 70%) (Table 45.6-1).<sup>25</sup>

EBV-Positive Cases	NS (%)	Total (%)	MC (%)
Japan	—	25	—
United States-Europe	35	40	65
Mexico	50	70	80
Other Latin American	—	70-100	—
Africa	80	80	100
China	50	60	90-100
Children	—	80	—
HIV	—	80	—

EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; MC, mixed cellularity; NS, nodular sclerosis.

**TABLE 45.6-1.** Hodgkin's Disease: Differences in EBV Association (Approximate)

EBV genome status appears to be stable over time when studied in initial biopsies and at relapse. The latent gene products, latent membrane protein (LMP) and EBNA2, have important roles in EBV-induced cell transformation *in vitro*. EBV genome-positive RS cells express the phenotype LMP1 and LMP2+/EBNA1+ EBNA2-, a phenotype found in EBV genome-positive nasopharyngeal carcinoma and in a small portion of T-cell non-Hodgkin's lymphomas (NHLs). LMP1 has transforming activity for B cells, and its expression should give a survival advantage to infected cells. Because EBV is capable of immortalizing B cells, and because all the cells in infected cases carry the same clone of EBV and express the most potent transforming protein (LMP1), the obvious conclusion is that EBV must play some role in the pathogenesis of HD. However, the fact that EBV is not present in all the cases leaves open the question of the pathogenesis of EBV-negative cases and, more important, the question of whether EBV is important even in positive cases.

Patients with autoimmune disease who are treated with rather mild immunosuppression with methotrexate occasionally develop a Hodgkin's-like lesion, which is EBV-positive in nearly 50% of the cases.<sup>26</sup> Taken together, these observations suggest that immunosuppression *per se* does not predispose to the development of HD but that, when it does develop, it is likely to be of mixed-cellularity (MC) or lymphocyte-depleted (LD) type and EBV-positive.<sup>27</sup>

H-RS cells show a specific expression pattern of the viral latent genes with expression of EBNA1 and LMP.<sup>28</sup> This pattern is identical to that found in nasopharyngeal carcinoma endemic in the southwest of China. It differs from such other EBV-associated neoplasias as endemic Burkitt's lymphoma and immunoblastic B-cell NHLs of immunocompromised patients. Except for EBNA1, all latent viral proteins represent targets for cytotoxic T lymphocytes (CTLs). Thus, EBV-infected cells either express the complete set of latent viral genes in an immunocompromised host (immunoblastic NHL) or they down-regulate these proteins except EBNA1 (Burkitt's lymphoma), possibly to escape the host's immune response. Thus far, it remains unclear how the specific latent viral gene expression pattern in HD (EBNA2- and LMP-positive) and the pronounced T-cell proliferation in affected lymph nodes relate to each other.

The functional relevance of LMP expression in H-RS cells is not understood. LMP has a transforming potential: Transformation of epithelial cells after transfection of LMP has been described. In lymphocytes, apoptosis can be prevented by LMP via up-regulation of the *bcl-2* gene. LMP is also a target for CTLs. In addition, it up-regulates (partly in cooperation with EBNA2) numerous cellular genes [e.g., activation-associated antigens (CD23, CD30, CD39)] and adhesion molecules [intracellular adhesion molecule-1 (ICAM-1), lymphocyte function-associated antigen 3 (LFA-3)]. Thus it may render a cell indirectly more susceptible for a T-cell response. Knecht et al.<sup>29</sup> described in some HD cases mutations in the carboxy-terminal part of the LMP1 gene identical to those previously reported in LMP isolates from Chinese nasopharyngeal carcinoma. These authors discussed an association of these mutations with a clinically more aggressive HD phenotype.

At least three hypotheses can be advanced to explain EBV-negative cases of HD. First, another virus could be involved in these cases; however, studies to date have failed to identify another virus.<sup>30</sup> Second, EBV may be involved in all the cases but may remain undetectable in some; this has been called the *hit-and-run theory*. In this scenario, EBV infects the cell, alters the DNA in some way, and then is eliminated, leaving the cell either transformed or susceptible to transformation. Elimination of EBV, with its immunogenic proteins, might be expected to occur most commonly in patients with active immune systems, such as the young women with NSHD. However, a third possibility, and the one perhaps best supported by epidemiologic data, is that EBV is not important in the pathogenesis of any of the cases of HD and that its presence in some cases simply reflects the presence of a larger reservoir of latently EBV-infected cells in these individuals.

Examination of the epidemiology of EBV-associated HD reveals several paradoxes, which cast doubt on the causative role of EBV in many cases. First, the group in which EBV had been predicted most likely to be involved—young women from high socioeconomic groups with NSHD—proved to have the lowest incidence of EBV in tumor tissue.<sup>20</sup> Second, there is no correlation between a history of either infectious mononucleosis or unusually high titers of antibodies to EBV and detectable EBV in HD tissues.<sup>31</sup> Thus, in contrast to what one would expect if most HD cases were caused by EBV, populations in which HD is common (young women in affluent societies) have EBV-negative HD and populations in which HD is rare (young children in underdeveloped countries, older individuals, and immunosuppressed patients) have EBV-positive HD.<sup>20</sup> These apparent paradoxes force us to at least consider the possibility that EBV may be merely an epiphenomenon in HD, reflecting

a high incidence of EBV-infected B cells in the patient, rather than an etiologic factor.

In summary, despite data that suggest an etiologic role for EBV in HD, direct evidence of a causative role is lacking. The lack of an animal model and the difficulties in studying the malignant cells in HD continue to frustrate investigators. Additional epidemiologic, serologic, and molecular data are needed to determine whether EBV is a causative agent.

## BIOLOGY AND CELL OF ORIGIN

### LINEAGE, ORIGIN, AND CLONALITY OF HODGKIN'S-REED-STERNBERG CELLS

#### *Specific Morphologic Features of Hodgkin's Disease*

Lymph nodes affected by HD consist of a heterogeneous mixture of lymphocytes, histiocytes, eosinophils, plasma cells, fibroblasts, and other cells. The mononuclear Hodgkin's cells and their polynucleated counterparts, the RS cells, which have long been considered to represent the malignant substrate of the disease, represent only 0.1% to 1.0% of the entire cell population in CHD [i.e., lymphocyte-rich CHD (LRCHD) and the NS, MC, and LD subtypes].<sup>40</sup> Similarly, in lymphocyte-predominant HD (LPHD, nodular paragranuloma), the pathognomonic lymphocytic and histiocytic (L&H) cells represent only a small minority of the total cell population. This scarcity of the putative tumor cells was one of the major obstacles for understanding the nature of these cells. Whereas in the LP subtype of HD, H-RS cells consistently express B-cell-specific surface antigens (CD19, CD20), in CHD H-RS cells express, in the majority of cases, the activation markers Ki-1 (CD30), the Leu-M1 antigen (CD15), the interleukin-2 (IL-2) receptor (CD25), the transferrin receptor (CD71), and HLA class II molecules (HLA-DR), but not surface antigens, which helped to determine their physiologic counterpart.<sup>32</sup> Until recently, the application of conventional molecular-genetic methods for a more detailed analysis of H-RS cells was not possible owing to their scarcity. In addition, these cells could not be enriched from tissue affected by HD, presumably due to their fragility. Thus, over decades, the cell of origin of the H-RS cells remained an enigma.

#### *Cell Lines and Animal Models*

The establishment of permanently growing cell lines permitted the biologic and genetic characterization of the tumor cell population in numerous human neoplasias. In contrast, outgrowth of a cell line is extremely rare in HD. The first two permanent cell lines (designated L428 and L540) were established in 1979 from patients with advanced-stage HD [clinical stage (CS) IVB].<sup>33</sup> These cell lines grew from a pleural effusion and bone marrow. With few exceptions, all subsequently established cell lines were also obtained from body fluids (bone marrow, pleural effusion, peripheral blood) of advanced-stage patients.<sup>34</sup> This observation may reflect an *in vivo* adaptation of the cells to the conditions of suspension culture as prerequisite for *in vitro* outgrowth. Thus far, only 15 cell lines have been established that may be regarded as HD-derived. Analysis of immunophenotype, karyotype, immunoglobulin (Ig), or T-cell receptor gene rearrangements of these cell lines revealed, in analogy to analysis of primary tissue, heterogeneous results, not allowing any conclusion to be drawn on the cell of origin of HD. In addition, their derivation from primary H-RS cells could not be determined unequivocally.<sup>34</sup> A novel EBV-negative cell line (L1236) has been established from the peripheral blood of a patient with advanced HD of the MC subtype.<sup>35</sup> Using H-RS single-cell PCR, it could be shown that the genomic sequences of the Ig gene rearrangements of the H-RS cells in the patient's bone marrow were identical to those detected in L1236 cells.<sup>36</sup> Thus, in this cell line, the H-RS cell origin is definitely proven on the molecular level.

HD-derived cell lines were used successfully for the discovery of H-RS cell-associated antigens, which include CD30 (Ki-1), CD70, and Ki-27,<sup>37,38</sup> for cloning the CD30 gene,<sup>39</sup> and for studying the CD30 signal transduction pathway. They also enabled the *in vitro* testing of new immunotherapeutic modalities such as Ricin A-linked anti-CD30 immunotoxins,<sup>40</sup> Saporin-linked anti-CD30 immunotoxins,<sup>41</sup> and anti-CD16/CD30 bispecific antibodies.<sup>42</sup>

Though none of these HD-derived cell lines could be grown reproducibly in thymus-aplastic T-cell-deficient nude mice, the HD-derived cell lines L540, HD-MyZ, and L1236 have been shown to disseminate intralymphatically after inoculation into T- and B-cell-deficient severe combined immunodeficient (SCID) mice.<sup>35,43</sup> The SCID mouse model is used for the preclinical *in vivo* testing of new experimental therapeutic approaches.<sup>43</sup> However, no reproducible growth of primary H-RS cells has been observed after transplantation of biopsy material.<sup>44</sup>

#### *Results of Single-Cell Analysis: Hodgkin's-Reed-Sternberg Cells Are Clonal B Cells*

A methodologic breakthrough for the biologic analysis of H-RS cells was achieved by the establishment of micromanipulation of immunophenotyped single cells from frozen sections, allowing the amplification and analysis of genes derived from a single cell. Küppers et al.<sup>45</sup> amplified rearranged Ig heavy-chain genes from single H-RS cells micromanipulated from two cases of CHD and one case of LPHD. Sequence analysis revealed the clonal B-cell origin of the H-RS cells in all three cases. In 14 of 15 additional cases of CHD, again clonally rearranged Ig genes were detected in the H-RS cells. Clonal Ig gene rearrangements in H-RS cells of CHD were also found by others using micromanipulation and single-cell PCR.<sup>46</sup> Similarly, using the new method, clonally related Ig gene rearrangements were detected in L&H cells isolated from frozen tissue sections of LPHD.<sup>47</sup> Thus, there is overwhelming evidence that at least a substantial proportion of cases (if not all cases) of CHD and LPHD represent monoclonal B-cell disorders.

#### *Germinal Center Derivation of H-RS Cells*

The site of physiologic contact between a specific antigen and a B lymphocyte is the germinal center (GC) of a lymph node. This contact results in somatic mutations accumulating in the Ig genes and leading to the expression of antibodies with a higher affinity due to amino acid exchanges. However, somatic mutations might also result in a lower affinity of the antibody or even in generation of a stop codon. When B cells lose their ability to express an antibody or when they express an antibody with lower affinity, they subsequently undergo apoptosis within the GC. All other B cells accumulating favorable mutations are rescued from apoptosis by expressing the *bcl-2* gene. These B cells clonally expand and can accumulate further mutations to improve the affinity of their antibody. After leaving the GC, they differentiate into B memory cells or plasma cells. In a substantial proportion of LPHD cases, the clonal L&H cells revealed ongoing mutations, which provides evidence that L&H cells are GC-derived B cells that depend on antigen binding and selection.<sup>47</sup> In this context, L&H cells are comparable with follicular lymphoma (FL) cells. Whereas FL cells frequently harbor the chromosomal translocation t(14;18), resulting in activation of the *bcl-2* gene, the transforming event in L&H cells remains unknown. H-RS cells of CHD differ from FL as well as from LPHD in that they accumulate crippling somatic mutations within potentially functional Ig gene rearrangements, which prevent further antibody expression.<sup>36</sup> These crippling mutations do not necessarily have to be located within the coding region of Ig genes. One case of MCHD has been described in which a somatic mutation within a regulatory element of the IgH promoter was associated with down-regulation of Ig gene expression.<sup>48</sup> The detection of crippling mutations rendering potential functional Ig gene rearrangements nonfunctional suggests that H-RS cells, as a rule, grow independently from antigen selection and even antibody expression. Indeed, no Ig gene expression in H-RS cells could be demonstrated by several groups. The mechanism preventing apoptosis of the H-RS cells within the GC still is unknown.

## GENETIC ALTERATIONS IN HODGKIN'S DISEASE

Conventional karyotype analysis of Hodgkin's and RS cells is hampered by the low number of obtainable mitoses from lymph node suspensions and their poor chromosome-banding qualities. In addition, karyotypes cannot be unequivocally attributed to malignant cells, as the cellular compartment with the highest mitotic index in affected tissue is that of nonmalignant lymphocytes in the neighborhood of the H-RS cells. Thus, proliferating cells with a normal karyotype most probably represent reactive lymphoid cells.<sup>49</sup> Depending on the histologic subtype, between 75% (NS) and 42% (LP) of cases studied yielded evaluable metaphases. In karyotype analyses performed by different groups, the percentage of abnormal karyotypes varied considerably, between 22% and 83%. Although numeric and structural cytogenetic abnormalities were observed, a specific chromosomal marker of HD—as, for instance, the Burkitt's lymphoma-specific chromosomal translocations—has not yet been defined.<sup>50</sup> In a study of 60 lymph nodes obtained from untreated patients with HD, numeric or structural aberrations (or both) were found in approximately one-half of the analyzable cases.<sup>51</sup> Among HD-associated chromosomal abnormalities, aneuploidy (100%) with hyperdiploidy (70%) is the most frequent. Chromosomes 1, 2, 5, 12, and 21 are often triplicated. In a few cases, a loss of chromosomes is reported; for example, chromosomal translocations or deletions were found in two-thirds of cases.<sup>51</sup>

Analysis of whole tissue sections for genomic alterations or deregulated expression of the oncogenes MYC, JUN, RAF, and RAS did not reveal any characteristic pattern.<sup>52</sup> Because the t(14;18) translocation results in overexpression of the *bcl-2* protein preventing apoptotic death of FL cells, many attempts were made using PCR to detect breakpoints in the major breakpoint region (mbr) of t(14;18) in H-RS cells. In several studies, the t(14;18) translocation was found in 0% to 39% of HD cases. Whether the translocation was localized in the H-RS cells remained unproven in these positive cases, however, particularly as the detection of the *bcl-2*

protein by immunohistochemistry *in situ* was not congruent with the detection of the translocation itself in all cases. In one report using micromanipulation of single H-RS cells followed by PCR, the t(14;18) was shown to be localized in nonmalignant bystander B cells and not in a single case in the H-RS cells.<sup>53</sup> Mutations in the p53 tumor suppressor, which are commonly found in a variety of human cancers, also could not be detected in H-RS cells using single-cell analysis.<sup>54</sup> In view of the derivation of H-RS cells from the GC of lymph nodes, putative mechanisms preventing apoptosis of their precursors are of special interest for understanding the transforming events. The nuclear transcription factor NFκB might be involved in prevention of apoptosis. Indeed, constitutive expression of NFκB has been found in HD-derived cell lines as well as in primary H-RS cells *in situ*.<sup>55</sup> It also has been suggested that defects in the inhibitory molecule IκB might underlie the overexpression of NFκB, at least in some cases of HD. So far, however, the mechanisms preventing apoptosis in H-RS cells are not understood.<sup>56</sup>

## IMMUNOLOGY OF HODGKIN'S DISEASE

### Cellular Immunodeficiencies

HD is associated with a complex deficiency in cellular immunity, including impairment of delayed cutaneous hypersensitivity, enhanced Ig production, high levels of circulating immune complexes, production of antilymphocyte and anti-Ia antibodies, decreased natural killer (NK) cell cytotoxicity, enhanced sensitivity to suppressor monocytes and T suppressor cells, and a variety of other disorders of serum factors, including high levels of circulating IL-2 receptors. *In vitro*, peripheral blood lymphocytes show spontaneous DNA and IgG synthesis and depressed proliferative response to T-cell mitogen stimulation, with impairment of lymphokine production.

Increasing numbers of long-term survivors provided the opportunity to restudy energy and *in vitro* lymphocyte responsiveness in patients who have been successfully treated. Studies at the National Cancer Institute (NCI), in a population of uniformly staged and treated patients, showed that energy did not influence prognosis within a given stage. After successful treatment, energy to recall antigens was reversible, although response to neoantigens remained suppressed. This defect appears to be disease-related, as patients with other types of lymphomas did not show this defect. Unlike the defects in delayed hypersensitivity, most studies have shown that the antibody response of B cells and the B-cell numbers are normal in HD patients, except in those with advanced disease.

### Antigen-Presenting Phenotype of Hodgkin's-Reed-Sternberg Cells

In affected lymph nodes, the rare H-RS cells are surrounded by a majority of nonmalignant bystander cells. The majority of lymphocytes in affected lymphatic tissue are activated T helper cells (CD4+, CD45RO+, CD45RB).<sup>57</sup> These lymphocytes represent the population with the highest mitotic index in affected lymph nodes. The lymph nodes often grow slowly and show fluctuations in their size in early disease stages. These observations point toward a cellular immune reaction as the primary reason for the lymph node enlargement in HD. In contrast to benign lymphoproliferative lesions (e.g., reactive lymph nodes), the immune reaction in HD is not self-limited. One reason might be the inability of the immune system to eliminate the malignant cells expressing the target antigen.<sup>58</sup> The recently established HD-derived cell line L1236 expresses HLA class I and II molecules, B7.1 and B7.2 (CD80, CD86), and the adhesion molecules ICAM-1 (CD54) and LFA-3 (CD58).<sup>59</sup> All of these molecules are essential for efficient T-cell recruitment (accessory molecules). Expression of HLA antigens and of B7.1 molecules has also been described on H-RS cells in biopsy specimens and on other HD-derived cell lines (L428, L540; unpublished observation). The expression pattern of the surface antigens on H-RS cells thus points toward an antigen-presenting functional phenotype.

Antigen-presenting cells and, in particular, dendritic cells play a major role in the recruitment and activation of antigen-specific T cells, which is mainly attributed to their ability effectively to present antigens and to provide costimulatory signals via CD40, members of the B7 family (CD80, CD86), and adhesion molecules (CD11a, CD11c, LFA-3, ICAM-1). Furthermore, immunoregulatory cytokines such as IL-12, secreted by dendritic cells, promote the development of Th1 T cells, which play a major role in tumor-specific T-cell responses (Fig. 45.6-1).

**FIGURE 45.6-1.** Antigen-presenting cell–like functional phenotype of a B-cell–derived tumor cell. Ag, antigen; H-RS, Hodgkin's-Reed-Sternberg; IL-10, interleukin-10; MHC, major histocompatibility complex; TARC, thymus and activation regulated chemokine; TCR, T-cell receptor; TGF-β, transforming growth factor-β; Th2, T helper cell 2.

### Hodgkin's Disease and Immunity against Epstein-Barr Virus

In one study, it was shown that the H-RS cell population was uniformly HLA class I–positive in at least 75% of cases of EBV genome–positive HD, whereas the figure was much lower in EBV genome–negative tumors.<sup>60</sup> More than one-half of the EBV genome–negative tumors had no detectable HLA class I expression in tumor cells. Analyses of transporter associated with antigen processing (TAP) expression in H-RS cells found that almost all HD cases, regardless of EBV status, were positive for TAP1 and for TAP2. Furthermore, it has been shown that in the HD-derived cell line L1236, the LMP2 can be processed and presented through the HLA class I pathway. Although TAP expression in L1236 is not down-regulated, processing of the LMP2-derived target epitope might also have occurred via a TAP-independent route.

### Nerve Growth Factor Superfamily: Relevant Molecules?

The CD30 antigen, a member of the nerve growth factor superfamily, has been defined by a cluster of antibodies raised first against the HD-derived cell line L428.<sup>61</sup> Initially, the expression of CD30 seemed to be related exclusively to H-RS cells, thus representing a tumor-specific antigen. Subsequently, the CD30 antigen was also found on activated T and B cells as well as on activated and differentiated macrophages. The highest CD30 expression is seen on HD lymphoma cells, CD30+ large cell lymphomas (LCLs) with T-cell phenotype, and acute lymphocytic leukemia T cells.

The CD30/CD30 ligand (CD30/CD30L) interaction probably plays a central role in the complex interaction between H-RS cells and their microenvironment. A CD30L has been described<sup>62</sup> that exerts pleiotropic effects on different lymphoma subtypes *in vitro* and is expressed only on the bystander cells (T cells, monocytes, granulocytes) but not on the H-RS cells. In tissue culture experiments, some biologic functions of the CD30/CD30L interaction have been characterized that point toward a cytokine receptor function of the CD30 antigen. It remains to be established whether the pleiotropic effects of CD30/CD30L interaction in different cell types are due to a different intracellular signaling or whether they reflect sequence differences in the CD30 gene.

The soluble form of CD30 (sCD30) is detectable in the serum of patients with advanced stages of HD. This has been considered to reflect a prognostic factor for an unfavorable outcome.<sup>62</sup> It has been shown *in vitro* that CD40/CD40L signaling is able to down-regulate BCL-6 in B cells with a GC phenotype. A similar effect is exerted *in vitro* also by LMP1, which is functionally homologous to CD40. It thus may be postulated that CD40 ligation is the major determinant of the phenotype of the RS cell. The BCL-6+/syn-1- profile associates with 100% nodular LPHD (NLPHD), thus corroborating the notion that nodular lymphocyte predominance (NLP) is a relatively homogeneous disorder closely reflecting the GC phenotype.<sup>63</sup> The BCL-6-/syn-1+ profile associates with the majority of CHD (NS and MC), indicating that RS cells frequently are represented by post-GC B cells that have undergone preterminal differentiation.<sup>64</sup> Whereas CD40 is consistently expressed by both L&H and RS cells, the abundance and distribution of CD40L+ T lymphocytes varies markedly in different HD categories. In CHD, CD40/CD40L signaling between neoplastic and reactive cells seems to be a prominent feature that is associated with RS cells displaying the BCL-6-/syn-1+ phenotype.

## Chronic Secretion of Cytokines

IL-2 receptor levels and other inflammatory cytokines are elevated in the sera of patients. The (deregulated?) expression of cytokines may at least partially explain the complex interaction between H-RS and bystander cells. For instance, eosinophilia in HD is caused by IL-5, and fibrosis may be triggered by IL-1 and transforming growth factor- $\beta$  (TGF- $\beta$ ). IL-1, IL-6, and IL-9, which are produced by H-RS cells, may act as autocrine growth factors and as paracrine growth stimulators for T cells.<sup>65</sup> Vice versa, the T cells may stimulate H-RS cells via IL-2 and IL-6. Many cytokines, including IL-1, IL-5, IL-6, IL-9, IL-10, and TGF- $\beta$ , are produced by RS cells, and it is suspected that constitutive nuclear expression of NF $\kappa$ B is responsible for this phenomenon.<sup>58</sup>

IL-10 is a pleiotropic cytokine with potent inhibitory effects toward Th1 cells and is mainly produced by Th2 cells, activated monocytes and macrophages, stimulated B cells, and mast cells. It has been suggested that IL-10 is involved in the pathogenesis of malignant B-cell lymphomas. HD is characterized by an abnormal or unbalanced secretion or production of cytokines, including IL-10, which supports growth of both neoplastic Hodgkin's and Reed-Sternberg (H-RS) cells and their surrounding reactive bystander cells.

In untreated HD patients, 13% were found to be seropositive for IL-10 before therapy, whereas IL-10 was not detectable in a healthy control population. HD patients whose disease was at an advanced clinical stage (stage III or IV) were found to have higher IL-10 serum levels. A univariate analysis indicated a correlation of elevated IL-10 serum levels with early relapse and reduced long-term survival. The group of IL-10-seropositive HD patients showed a significant correlation of elevated IL-10 serum level with a reduced relapse-free survival. Thus, the increased production of IL-10 in HD could be associated with a poor clinical prognosis and may serve as a prognostic factor.<sup>66</sup>

## PATHOLOGY

### DEFINITION OF HODGKIN'S DISEASE

The clinical features and responses to treatment of HD differ dramatically from those of most so-called NHLs, suggesting that a specific immunologic reaction is important not only in the definition but also in the clinical behavior of this disease. Studies in the 1980s showed that in NLPHD, the RS cell variants expressed B-cell-associated antigens,<sup>67</sup> whereas these cells in most cases of NSHD and MCHD lacked these antigens.<sup>68</sup> This difference in immunophenotype, together with the observation that NLPHD follows a more indolent clinical course,<sup>69</sup> led to the suggestion that NLPHD was a low-grade B-cell lymphoma and should be removed from the category of HD and placed with the NHLs. However, both immunophenotypic and, more recently, molecular genetic studies have shown that CHD of the NS and MC types can express B-cell-associated antigens and, similar to NLPHD, have rearranged Ig genes.<sup>70,71</sup> Furthermore, NLPHD and CHD share the feature of having a small number of neoplastic cells in a reactive background, which distinguishes both from most B-cell NHLs. Thus, although it is now known that the neoplastic cells in most cases of both LPHD and CHD are monoclonal B cells, their distinctive pathologic and clinical features still warrant placing them together in a separate category from other lymphoid neoplasms.<sup>72</sup> It is important for both pathologists and oncologists to recognize that HD is two distinct diseases. Therefore, current classifications include two main categories of HD: CHD (NS, MC, and LD) and NLPHD. In summary, the Hodgkin's lymphomas are defined as lymphomas containing one of the characteristic types of RS cells in a background of nonneoplastic cells; cases are subclassified according to the morphology and immunophenotype of the RS cells and the composition of the cellular background. The differences in the morphology of the RS cells and the composition of the cellular background have formed the basis for the pathologic subclassification of HD ( [Table 45.6-2](#) ).

Jackson and Parker <sup>73</sup>	Lukes and Butler <sup>74</sup>	Rye Conference <sup>74</sup>	REAL Classification <sup>75</sup>	WHO Classification <sup>75</sup>
Paragranuloma	Lymphocytic or histiocytic, nodular	Lymphocyte predominant	Nodular lymphocyte predominant, non-class HD	Lymphocyte predominant, nodular class HD
	Lymphocytic or histiocytic, diffuse	—	Lymphocyte-rich class HD	Lymphocyte-rich class HD

TABLE 45.6-2. Classifications of Hodgkin's Disease

### CLASSIFICATIONS OF HODGKIN'S DISEASE

The early classification by Jackson and Parker<sup>73</sup> recognized three categories of HD: paragranuloma, granuloma, and sarcoma. The distinction among the three categories was based on the ratio of neoplastic to normal cells, which increased from paragranuloma to granuloma to sarcoma, and predicted decreasing survival. In 1966, Lukes et al.<sup>74</sup> recognized that the category of granuloma could be subdivided into two categories—NS and MC—which were characterized by distinctive morphology and clinical features. Lukes et al.<sup>74</sup> also recognized that there were two variants of what they called *lymphocytic* or *histiocytic predominance type* (replacing paragranuloma)—a nodular and a diffuse variant—which they found differed in prognosis. The Lukes and Butler classification was modified and simplified at the Rye conference in 1966.<sup>74</sup> The Rye classification has remained the standard classification since that time.

In 1994, the International Lymphoma Study Group introduced an updated classification, incorporating new immunologic and molecular data, as part of the Revised European-American Lymphoma (REAL) Classification.<sup>75</sup> These concepts have been incorporated into the new World Health Organization (WHO) classification of hematologic malignancies, a joint effort of the Society for Hematopathology and the European Association of Hematopathologists.

Several major differences exist between the REAL/WHO classification of HD and older classifications. Most important is the recognition that there are two distinct diseases that have been called HD: CHD, which consists predominantly of NS and MC, and NLPHD ( [Table 45.6-3](#) ). Simply a predominance of lymphocytes in the background is not sufficient to classify a case as NLPHD; cases that have the RS-cell morphology and immunophenotype of CHD, even if they contain predominantly lymphocytes, are classified as lymphocyte-rich classic Hodgkin's disease (LRCHD). A second difference is that, in the Lukes-Butler and Rye classifications, MC was a heterogeneous category, including both typical cases and all other cases that did not fit into one of the other categories. We now recommend that MC be restricted to typical cases and that unclassifiable cases be categorized as HD unclassifiable. Finally, it is now clear that immunophenotype is important in the subclassification of HD, both in distinguishing NLPHD from classic types and in distinguishing HD from NHL; thus, the immunophenotype is included in the definitions of HD in the REAL/WHO classification. Typical freedom-from-treatment-failure (FFTF) and survival curves for the main histologic subtypes are illustrated in [Figure 45.6-2](#) using German Hodgkin's Lymphoma Study Group data.

	Class HD	NLPHD
Nodes	Diffuse, interfollicular, nodular	Nodular, at least in part
Small cells	Dispersed B cells, nonreactive or inactive cells	Likely "regener" cells
Background	Lymphocytes, histiocytes, eosinophils, plasma cells	Lymphocytes, histiocytes
Fibrosis	Common	Rare
CD15	+	-
CD20	-	+
CD22	+	-
CD24	-	+
EBV	+	-
EBV in EB cells	+	-
Background lymphocytes	T cells > B cells	B cells > T cells
CD3+T cells	+	-
Ig genes (high-d PCR)	Rearranged, clonal, normal, "typical"	Rearranged, clonal, normal, ongoing

EBV, Epstein-Barr virus; EBV, Epstein-Barr virus antigen; EB, Epstein-Barr virus; HD, Hodgkin's disease; Ig, immunoglobulin; LAR, lymphocyte and histiocyte; NLPHD, nodular lymphocyte predominant; NS, nodular sclerosing; PCR, polymerase chain reaction.

**TABLE 45.6-3.** Morphologic and Immunophenotypic Features of Nodular Lymphocyte-Predominant and Classic Hodgkin's Disease

**FIGURE 45.6-2.** **A:** Reviewed histologic subtype: freedom from treatment failure in the German Hodgkin's Study Group trials, 1988 through 1998, all stages. Significant ( $P \leq .01$ ) comparisons: NS1 vs. NS2,  $P = .0012$ ; LP vs. LD,  $P = .0088$ ; NS1 vs. LD,  $P = .0017$ . **B:** Reviewed histologic subtype: survival in the German Hodgkin's Study Group trials, 1988 through 1998. Significant ( $P \leq .01$ ) comparisons: NS1 vs. NS2,  $P = .0021$ . LD, lymphocyte-depleted ( $n = 35$ ); LP, lymphocyte-predominant ( $n = 144$ ); NS1, nodular sclerosis grade 1 ( $n = 1397$ ); NS2, nodular sclerosis grade 2 ( $n = 361$ ); MC, mixed-cellularity ( $n = 596$ ).

### Nodular Lymphocyte-Predominant Hodgkin's Disease

**MORPHOLOGIC FEATURES.** NLPHD is defined as having at least a partially nodular growth pattern; diffuse areas are present in a minority of cases, and it is controversial whether purely diffuse cases exist.<sup>76</sup> The RS-cell variants differ from mononuclear and classic RS cells: They have vesicular, polylobed nuclei and distinct but small, usually peripheral nucleoli, without perinucleolar halos; these have been called *L&H cells* (after Lukes and Butler) or *popcorn cells*, because of the resemblance of their nuclei to an exploded kernel of corn.<sup>74</sup> In fact, they resemble “exploded” centroblasts. Although popcorn cells may be very numerous, usually no classic, diagnostic RS cells are found. In occasional cases, however, the RS cells may resemble classic or lacunar types; in such cases, immunophenotyping is helpful in establishing the diagnosis. The background is predominantly lymphocytes; clusters of epithelioid histiocytes may be numerous; plasma cells, eosinophils, and neutrophils rarely are seen and, if present, are not numerous.<sup>77</sup> Occasional sclerosis may cause some cases to resemble NSHD.

**PROGRESSIVE TRANSFORMATION OF GERMINAL CENTERS.** A distinctive type of follicular lymphoid hyperplasia, known as *progressive transformation of germinal centers* (PTGCs), is seen focally in approximately 20% of lymph nodes involved by NLPHD and may be seen in the absence of HD in other lymph nodes in the same patient.<sup>78</sup> PTGCs are enlarged follicles that contain numerous small B cells of mantle zone type; these follicles may closely resemble the nodules of NLPHD. This phenomenon has given rise to speculation that NLPHD may arise from PTGCs. PTGCs usually are seen as single or only a few enlarged follicles in a setting of nonspecific reactive follicular lymphoid hyperplasia; however, on occasion, they may be numerous and associated with prominent lymph node enlargement, particularly in adolescents and young adults.<sup>79</sup>

**NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN'S DISEASE AND LARGE B-CELL LYMPHOMA.** Patients with NLPHD have a slightly higher risk of developing NHL than do patients with other types of HD.<sup>80</sup> Transformation of NLP to LCL, usually with a B-cell phenotype and often monoclonal with respect to Ig (both phenotype and genotype), is most common. Hansmann et al.<sup>81</sup> reported 2.6% in a series of 537 cases, and the British National Lymphoma Investigation (BNLI) reported a 2% incidence in 182 cases<sup>80</sup>; the range in recent reports is from 2% to 6.5%.<sup>82</sup> The LCL does not necessarily consist of typical L&H cells and usually resembles other diffuse, large B-cell lymphomas (DLBCLs).<sup>81</sup> Most cases studied have had a B-cell immunophenotype, with B-lineage antigen expression in the majority and monotypic Ig expression in approximately 30% to 50%. In some cases, a clonal relationship between the LP and the DLBCL has been shown by molecular genetic analysis.<sup>83</sup>

In addition to the cases that progress to DLBCL, NLP may be composite with DLBCL in the same lymph node, at the time of either diagnosis or relapse.<sup>84</sup> In reported cases, the prognosis of these patients appears to be significantly better than that for usual DLBCL, and patients who respond to treatment may later relapse with only NLP.<sup>84</sup>

**IMMUNOPHENOTYPE.** The immunophenotype is an important part of the definition of NLP. In contrast to CHD, the atypical cells are CD45+, express B-cell-associated antigens (CD19, CD20, CD22, CD79a) and epithelial membrane antigen (EMA), but lack CD15 and CD30. In contrast to typical B-cell lymphomas, however, they are usually Ig-negative by routine techniques. J-chain has been demonstrated in many cases.<sup>85</sup> Studies using *in situ* hybridization for light-chain messenger RNA (mRNA) have shown clonal expression in the atypical cells.<sup>86</sup> Popcorn cells also express the nuclear protein encoded by the *bcl-6* gene, which is associated with normal GC B-cell development, and the activation-associated molecules CD40 and CD86 (B7/BB1), which are involved in B-cell interaction with T cells.<sup>87</sup>

The nodules of LP are actually altered follicles or GCs. The small lymphocytes in the nodules are a mixture of polyclonal B cells with a mantle zone phenotype (IgM and IgD+), and numerous T cells, many of which are CD57+, similar to the T-cell population in normal and progressively transformed GCs.<sup>88</sup> T cells in NLP may exhibit significant nuclear enlargement and irregularity, resembling centrocytes. In contrast to the T cells in reactive or progressively transformed follicles, which are scattered singly and often concentrated in the light zone or at the junction with the mantle zone, the T cells in NLP form small aggregates, often giving the follicle a broken-up, moth-eaten, or irregular contour. They typically surround the neoplastic B cells, forming rings, rosettes, or collarettes. Although several reports suggest that the T cells surrounding popcorn cells are mostly CD57+,<sup>89,90</sup> this can be difficult to demonstrate in many cases, and absence of CD57+ cells in the rosettes does not argue against the diagnosis. A prominent concentric meshwork of follicular dendritic cells (FDCs) is present within the nodules. The interfollicular region contains predominantly T cells; when there are diffuse areas, the background lymphocytes are also predominantly T cells, and the FDC meshwork is lost.<sup>91</sup>

**CLINICAL FEATURES.** NLPHD accounts for 4% to 5% of the cases of HD in most series. The median age of patients is in the mid 30s, but cases may be seen both in children and the elderly. The male-female ratio is 3:1 or greater. NLPHD usually involves peripheral lymph nodes, with sparing of the mediastinum. Nearly 80% of the patients in most series are stage I or II at the time of the diagnosis, but rare patients may present with stage III or IV disease, with a concomitantly worse prognosis. More than 90% of the patients have a complete response to therapy, and 90% are alive at 10 years. The cause of death is often NHL, other cancers, or complications of treatment, rather than HD.<sup>82,92</sup>

### Classic Hodgkin's Disease

CHD is defined by the presence of classic, diagnostic RS cells in a background of NS, MC, or LD, with classic immunophenotype (CD15+, CD30+, T- and B-cell-associated antigens usually negative). CHD includes NS, MC, and LD, as well as the proposed new category of LRCHD. Because the immunophenotype, genetic features, and postulated normal counterpart are the same for all of the classic types, these will be discussed together at the end of this section.

**NODULAR SCLEROSIS HODGKIN'S DISEASE.** NSHD, by definition, has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases; diffuse areas are common, as is necrosis. The characteristic cell is the lacunar type RS cell, which may be very numerous. These are cells with characteristically multilobed nuclei and small nucleoli, with abundant, pale cytoplasm that retracts in formalin-fixed sections, producing an empty space, or lacuna. Diagnostic RS cells also are present but may be rare. The background usually contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils.<sup>74</sup>

In some cases with characteristic lacunar cells and a nodular or diffuse pattern, fibrous bands may be absent, and differentiating this type from NLP may be difficult. These cases have been called the *cellular phase* of NS<sup>74</sup>; in one series, the clinical course of these cases was slightly worse than that for typical cases.<sup>93</sup> Another morphologic variant, syncytial NS, has been described, in which, focally, the NS pattern is lost and large sheets of cells resembling lacunar RS-cell variants are seen.

The prognosis of this variant was not reported to be different from that of typical NS. However, some studies have suggested that NS with lymphocyte depletion is associated with large mediastinal masses, advanced stage, and poor response to radiotherapy alone.<sup>94</sup>

**Grading.** The BNLI developed a system for grading NSHD (grade 1 and grade 2), based on the number and atypia of the RS cells in the nodules.<sup>95</sup> Cases of grade 2 NS overlap with the syncytial and LD variants already described. Based on this system, approximately 75% to 85% of the cases in most series are grade 1 and 15% to 25% are grade 2. In the BNLI series, grade 2 (NS2) tumors were associated with a worse prognosis than grade 1 (NS1) tumors, with NS2 tumors having an increased rate of relapse, shorter survival, and worse response to initial therapy (see Fig. 45.6-2). The BNLI studies have been criticized because some series included patients who were not pathologically staged and because, as compared to some other series, their patients had a relatively poor outcome.

Results from American and European centers have conflicted, showing either no influence on outcome or a significantly worse outcome for NS2 patients.<sup>96,97</sup> In general, when a center reports either a relatively high rate of relapse or relatively poor survival, NS2 patients are found to have a significantly worse outcome than NS1 patients; conversely, when overall relapse rates are low and survival high, grade has no impact on outcome.<sup>97</sup> This phenomenon was illustrated most clearly in a study of 195 patients treated in the Netherlands<sup>98</sup>; for patients treated between 1972 and 1980, when overall survival was relatively poor, grade 2 patients had a significantly worse outcome (5-year overall survival for NS1 and NS2, 83% and 43%, respectively), whereas for those treated between 1981 and 1992, grade had no impact on outcome (5-year overall survival for NS1 and NS2, 81% and 82%, respectively).

The impact of NS2 on survival is most evident in patients who experience relapse; those with NS2 have significantly shorter survival after relapse than do those with NS1. Taken together, these results suggest that more aggressive therapy benefits grade 2 patients; they also suggest the possibility that patients with NS1 could be treated less aggressively and still do as well. It could be argued that in future studies, NS should be consistently graded and that trials of less aggressive initial treatment for NS1 might be appropriate.

**Clinical Features.** NSHD is the most common subtype of HD in developed countries (60% to 80% in most series). It is most common in adolescents and young adults but can occur at any age; the number of affected female individuals equals or exceeds the number of affected male persons. The mediastinum and other supradiaphragmatic sites are commonly involved.

**MIXED-CELLULARITY HODGKIN'S DISEASE.** In MCHD, the infiltrate is usually diffuse or, at best, vaguely nodular, without band-forming sclerosis, although fine interstitial fibrosis may be present. RS cells are of the classic, diagnostic type and usually are easily identified. Many mononuclear variants are also usually present; rare lacunar cells may be seen. Diagnostic RS cells are large cells with bilobed, double, or multiple nuclei, with a large, eosinophilic, inclusion-like nucleolus in at least two lobes or nuclei. The infiltrate typically contains lymphocytes, epithelioid histiocytes, eosinophils, and plasma cells.<sup>74</sup>

**Clinical Features.** MCHD is accountable for 15% to 30% of HD cases in most series; it may be seen at any age and lacks the early adult peak of NSHD. Involvement of the mediastinum is less common than in NSHD, whereas abdominal lymph node and splenic involvement are more common.

**LYMPHOCYTE-DEPLETED HODGKIN'S DISEASE.** The infiltrate in lymphocyte-depleted HD (LDHD) is diffuse and often appears hypocellular, due to the presence of diffuse fibrosis and necrosis; there are large numbers of RS cells and bizarre sarcomatous variants, with a paucity of other inflammatory cells. Confluent sheets of RS cells and variants may occur and rarely predominate (reticular variant or Hodgkin's sarcoma).<sup>74</sup> Before the availability of immunophenotyping studies, many cases diagnosed as LDHD were, in reality, cases of large B-cell lymphoma or T-cell lymphomas, often of the anaplastic large cell lymphoma (ALCL) type. Cases of the reticular variant of LDHD may be difficult to distinguish from ALCL.<sup>99</sup>

**Clinical Features.** LDHD is the least common variant of HD, accounting for fewer than 1% of the cases in recent reports. It is most common in older people, in human immunodeficiency virus–positive (HIV-positive) individuals,<sup>27</sup> and in nonindustrialized countries. LDHD frequently presents with abdominal lymphadenopathy and spleen, liver, and bone marrow involvement, without peripheral lymphadenopathy.<sup>100</sup> The stage is usually advanced at diagnosis; however, response to treatment is reported not to differ from that of other subtypes of comparable stage.<sup>94</sup>

**IMMUNOPHENOTYPE OF CLASSIC HODGKIN'S DISEASE.** In most cases of NSHD, MCHD, and LDHD, the tumor cells are CD15+, CD30+, and CD45–. The frequency with which CD15 and CD30 are detected varies in reported series, probably because of technical problems. With microwave antigen retrieval and use of an anti-IgM secondary antibody, the German Hodgkin's Study Group (GHSG) reported 83% of 1751 cases to be positive for CD15, 96% positive for CD30, and 5% positive for CD20. Expression of B-cell antigens has been reported in a varying number of cases, usually only weakly and in a minority of the cells.<sup>101</sup> Thus, expression of B-cell antigens does not exclude a diagnosis of HD if the morphologic features are typical.

The diagnosis of HD still is made on routine sections, and immunophenotyping studies are an adjunct to the diagnosis. In a morphologically typical case, immunophenotyping studies are not absolutely necessary; however, they are becoming more standard practice. Failure to detect CD15 or CD30 or expression of a B-cell–associated antigen does not preclude a diagnosis of HD; however, absence of both CD15 and CD30 and expression of CD20 should prompt reexamination of the slides and consideration of either NLPHD or LRCHD. Expression of T-cell antigens is distinctly unusual, and should prompt both re-review of the slides and molecular genetic analysis of the T-cell receptor gene.

In addition to CD15 and CD30, RS cells express CD25, HLA-DR, ICAM-1, CD95 (apo-1/fas), and both CD40 and CD86 (B7), molecules associated with B-cell activation and interaction with T cells. T cells surrounding the RS cells express both CD40L and CD28, the ligand for CD86. In contrast to NLPHD, the RS cells of CHD lack the nuclear bcl-6 protein associated with follicle center B cells.<sup>102</sup> In EBV-positive cases, the tumor cells express EBV LMP but not EBNA2.

**CLINICAL BEHAVIOR OF CLASSIC HODGKIN'S DISEASE.** Several studies have addressed the impact of immunophenotype on the survival of patients with CHD, with varying results. The GHSG study found that cases that lacked CD15 but expressed CD30 had a significantly worse freedom from relapse and overall survival than did CD15+ cases. Coexpression of CD20 with CD15 or CD30 (or both) had no impact on outcome, but cases that expressed CD20 alone had poor survival; this result is similar to that reported by McBride et al.<sup>103</sup> and raises the question whether these may represent cases of T-cell–rich large B-cell lymphoma (see later, in [Differential Diagnosis of Classic Hodgkin's Disease](#)).

**LYMPHOCYTE-RICH CLASSIC HODGKIN'S DISEASE.** Some cases of HD with RS cells of the classic type, both by morphology and immunophenotype, may have a background infiltrate that consists predominantly of lymphocytes, with rare or no eosinophils. The term *lymphocyte-rich classic Hodgkin's disease* was proposed for these cases in the REAL classification. Some cases of LRCHD have a nodular pattern, with remnants of regressed GCs in the nodules and RS cells and variants located within the mantle zones and interfollicular regions,<sup>104</sup> mimicking NLPHD. This has been termed *follicular Hodgkin's lymphoma* or *nodular LRCHD*.<sup>105</sup>

Of 426 cases initially diagnosed as LPHD, review and immunophenotyping by a panel formed by the European Task Force on Lymphoma (ETFL) revealed that only 51% were confirmed as NLPHD, whereas 27% were LRCHD with a nodular pattern, with RS cells in the mantles of reactive follicles and in the interfollicular regions.<sup>105</sup> In a study from the GHSG, a similar rate of misdiagnosis of NLPHD was found; only 44% of 208 cases considered by at least one pathologist as LPHD had the immunophenotype of LPHD, whereas 56% were CHD. When the expert panel reclassified the cases by morphology alone, only 75% of the cases classified as LPHD and 88% of the cases classified as CHD were confirmed by immunophenotyping. Thus, cases of LRCHD may very closely resemble NLPHD and require immunophenotyping for differential diagnosis.

**Immunophenotype.** Cases of LRCHD have the immunophenotype of CHD, with expression of CD15 and CD30 by the RS cells; similar to other types of CHD, CD20 is coexpressed in 3% to 5% of cases.<sup>105</sup> In nodular areas, the background lymphocytes are predominantly B cells, similar to LPHD, and follicular meshworks of FDC are seen with antibodies to CD21 or CD35. Staining for FDC often reveals a small, dense aggregate of FDC consistent with a regressed GC, associated with a broad mantle zone with more loosely spaced FDC processes. The RS cells are found within the mantle area or at the junction of the mantle and interfollicular regions. CD57+ T cells may also be present and may rim the RS cells; thus, it is actually the immunophenotype of the RS cells that distinguishes LRCHD from NLPHD.

**Clinical Features.** The frequency of LRCHD among cases classified as HD can be roughly calculated from the two GHSG reports.<sup>106</sup> Of 1959 cases of HD with immunophenotyping for CD15, CD30, and CD20, LRCHD comprised 6% of cases (116) and LPHD 5% (92). In the ETFL and GHSG series, the clinical features at presentation of LRCHD seem to be intermediate between those of LPHD and CHD: similar to those with NLPHD, patients had early-stage disease and lacked bulky disease or B-cell symptoms; as in patients with either NLPHD or MCHD and in contrast to those with NLPHD, they lacked mediastinal disease and were predominantly male and, like MCHD patients, their median age was older than either NLPHD or NSHD patients. In the ETFL series, the overall survival for both LPHD and LRCHD patients was excellent but not significantly different from that for other types of HD. However, patients with NLPHD had an increased frequency of

multiple relapses and better survival after relapse, as compared with LRCHD, NSHD, and MCHD patients. In the GHSG study, the overall survival of LRCHD was significantly worse than that of NLPHD. These data do not clearly define LRCHD as a distinct entity but are consistent with either an early phase of MCHD or a novel subtype. It is suggested that this category continue to be recognized within the classification of HD, so that additional data can be collected.

**ASSOCIATION OF CLASSIC HODGKIN'S DISEASE WITH OTHER LYMPHOMAS.** CHD may be associated with other lymphomas, most often of the B-cell type.<sup>107</sup> These lymphomas may occur before, simultaneously with, or after HD. Patients treated for HD are at risk for development of high-grade B-cell lymphomas (DLBCL or Burkitt's or Burkitt-like lymphoma), which have been presumed to arise in a setting of immunosuppression secondary to therapy for HD; the estimated risk ranges from 1% to 5%. However, EBV has not been demonstrated in the secondary lymphomas, in contrast to the situation in most immunosuppression-associated NHLs. Numerous cases of CHD associated with FL or DLBCL have been reported; the HD may precede, follow, or occur simultaneously with the NHL.<sup>107,108</sup> Two cases of HD occurring with NHL (one case of composite HD and FL and one case of DLBCL followed by HD) have been studied by single-cell PCR; a common clone was found in HD and NHL in both cases.<sup>109</sup> Rare cases of B-cell chronic lymphocytic leukemia (CLL) may contain cells with the morphology and immunophenotype of classic RS cells, whereas other patients with typical CLL may go on to develop HD—a so-called HD variant of Richter's syndrome.<sup>110</sup> Several such cases have been studied using single-cell PCR; in the majority of the cases, the RS cells were of the same clone as the CLL cells, though in one case, they were clonally unrelated.<sup>111</sup> Finally, cases of mycosis fungoides or lymphomatoid papulosis associated with HD have been reported.<sup>112</sup> Thus, it is clear that patients with CHD are at some increased risk for development of NHL. In some patients, a single neoplastic B cell can give rise to both HD and NHL, whereas in other patients, it appears that either immunosuppression or other unknown factors can give rise to two independent malignancies.

#### DIFFERENTIAL DIAGNOSIS OF CLASSIC HODGKIN'S DISEASE

Two lymphomas have been described that have significant morphologic overlap with HD and may cause problems in differential diagnosis ( Fig. 45.6-3): T-cell/histiocyte-rich large B-cell lymphoma (T/HRLBCL) and T-cell ALCL. In addition, DLBCLs with anaplastic cytology may be difficult to distinguish from HD with LD (Table 45.6-4).

**FIGURE 45.6-3.** Differential diagnosis of Hodgkin's disease (HD). There is morphologic overlap between classic HD, T-cell/histiocyte-rich large B-cell lymphoma (T/HRLBCL), B-cell anaplastic large cell lymphoma (B-ALCL), and T-cell anaplastic large cell lymphoma (T-ALCL). Immunophenotyping can be useful in the differential diagnosis. DLBCL, diffuse large B-cell lymphoma; LDHD, lymphocyte-depleted HD; LRCHD, lymphocyte-rich classic HD; NLPHD, nodular lymphocyte-predominant HD.

Disease	Morphology (Exp. Cells)	Immunophenotype (Exp. Cells)	TGF Exp	Grains Southern Blot
NLPHD	Diffuse cells	CD20- CD15- CD20- CD15-	-	Ig <sup>+</sup> stained
Class. HD lymphocytic	Class. B cells	CD20- CD15- CD20- CD15-	-	Ig <sup>+</sup> stained
FLC	Centric	CD20- CD15- CD20- CD15-	-	Ig <sup>+</sup> stained
DLBCL lymphoma	Centric	CD20- CD15- Ig <sup>+</sup> stained	-	Ig <sup>+</sup> stained
T-cell, histiocyte-rich large B-cell lymphoma	Centric, immunoblastic, popcorn cells	CD20- CD15- CD20- Ig <sup>+</sup> stained	-	Ig <sup>+</sup> stained
Anaplastic large cell lymphoma (T-cell)	Reactive-appearing nuclei, popcorn cells	CD20- CD15- CD20- T- Ig <sup>+</sup>	-	Tk <sup>+</sup> stained
Large B-cell lymphoma, anaplastic stage	Reactive large cells, B-like cells	CD20- CD15- CD20- Ig <sup>+</sup>	-	Ig <sup>+</sup> stained

**TABLE 45.6-4.** Differential Diagnosis of Hodgkin's Disease

#### T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

In the late 1990s, several groups reported an unusual type of lymphoma with morphologic features reminiscent of diffuse LPHD or MCHD, with a predominance of small T lymphocytes and scattered large neoplastic cells that express B-cell antigens. Patients typically present with advanced-stage disease and have a poor prognosis.<sup>103</sup> The term *histiocyte-rich* or T-cell-rich large B-cell lymphoma has been used for these cases. The cases that resemble HD are different from earlier cases reported as T-cell-rich B-cell lymphoma, many of which are simply B-cell lymphomas of follicle center or large cell type in which T cells compose 50% or more of the infiltrate. Whether T/HRLBCL constitutes a distinct disease or is simply an aggressive variant of LPHD is not clear. However, it is important to distinguish it from either NLPHD or CHD because of its aggressive clinical course.

T/HRLBCL is a diffuse lymphoma with a lymphocyte-rich background, with small clusters of epithelioid histiocytes and scattered large mononuclear cells, suggesting either LPHD or CHD. The large cells may resemble popcorn cells, immunoblasts, or centroblasts, or all three.

The neoplastic cells express CD20 and other pan-B antigens, may or may not express cytoplasmic light chains, and may or may not have detectable Ig gene rearrangement by Southern blot or whole section PCR. Like LPHD, they are often EMA-positive but are CD15-, CD30-, and EBV-negative. The background lymphocytes are T cells that are CD57-negative, and FDC aggregates are not seen.

The immunophenotype of the large cells is of limited value in the differential diagnosis with LPHD, as it is similar; however, readily detectable Ig light chains would tend to favor a diagnosis of T/HRLBCL. In addition, staining for CD20 may reveal a nodular pattern and a B-cell-rich background, which would favor NLPHD. Follicular aggregates of FDC (anti-CD21) also favor NLPHD, as do large numbers of CD57+ cells. In distinguishing T/HRLBCL from CHD, immunophenotyping is essential and helpful. If the large cells express CD20 and lack CD15 and CD30, the diagnosis of T/HRLBCL is strongly favored, whereas expression of either CD15 or CD30 strongly favors a diagnosis of CHD. Furthermore, in cases diagnosed as CHD that express only CD20, the prognosis appears to be significantly worse than for cases expressing CD15 or CD30, with or without CD20.<sup>103,106</sup>

#### Anaplastic Large-Cell Lymphoma

ALCL is a T-cell lymphoma characterized by large malignant cells with prominent nucleoli and abundant cytoplasm, which may resemble mononuclear or multinucleated RS-cell variants.<sup>113</sup> However, the tumor cells grow in cohesive sheets and frequently involve lymph node sinuses, a pattern that is unusual in HD. In addition, the neoplastic cells usually are smaller than RS cells, have less conspicuous nucleoli, without perinucleolar halos, and often have bean-shaped or horseshoe-shaped nuclei, with a prominent paranuclear hof, in contrast to the round nuclei of mononuclear RS cells.<sup>114</sup> ALCL has a bimodal age distribution, with one peak in childhood and another in adulthood.

A subtype of ALCL, called *Hodgkin's-related ALCL*, has been described (modified to *Hodgkin's-like* in the REAL classification; a provisional entity).<sup>115</sup> This variant was characterized by cytologic features similar to common ALCL—confluent sheets of tumor cells, a cohesive growth pattern, and sinusoidal infiltration—but with architectural features that resemble HD of the NS type, with nodular growth of tumor cells and occasional fibrous bands. The immunophenotype of ALCL-HD was reported to be similar to that of common ALCL, but some cases had CD15 expression and EBV infection. There has been an ongoing debate about whether ALCL Hodgkin's-like is a variant of HD, a variant of ALCL, a heterogeneous mixture of the two, or a distinct disease.

Analysis of the t(2;5) associated with ALCL has helped to resolve this problem. Studies of the translocation have shown that it is absent in cases of typical HD.<sup>116,117</sup> In immunophenotyping studies using antibodies to either the ALK protein or the p80 fusion product of the t(2;5), several groups have found the protein to be present in a subset of ALCL but not in HD. Cases diagnosed as ALCL-HD typically lack the ALK protein.<sup>118</sup>

Most hematopathologists now believe that cases reported in the literature as ALCL Hodgkin's-like are heterogeneous. Some represent LD variants of HD—either NSHD (syncytial, LD, or NS grade 2) type or LD (LDHD; Hodgkin's sarcoma)—whereas others are cases of ALCL with a nodular growth pattern. Most cases can be resolved as either HD (CD45–, CD15+, T-cell antigen–, CD20–/+, t(2;5)–, ALK1–, EMA–) or ALCL (CD45+, CD15–, T-cell antigen+, CD20–, t(2;5)+, ALK1+, EMA+).

In cases that are histologically borderline between HD and T-ALCL, immunophenotyping on paraffin sections with CD45, CD15, CD30, CD20, EMA, pan-T antigens, ALK1 and, if necessary, genetic studies should be undertaken to resolve the differential diagnosis. Expression of CD15 or CD20 tends to exclude a diagnosis of T-ALCL (CD20+ cases may be either HD or DLBCL), whereas expression of CD45, T-cell antigens, ALK1, or EMA tend to exclude HD. Southern blot or whole section PCR analysis showing T-cell antigen receptor gene rearrangement would tend to exclude HD and confirm the diagnosis of ALCL. Ig gene rearrangement by these techniques would not usually be detectable in HD and would favor DLBCL, but a weak band would not exclude HD. Cases that cannot be resolved by immunophenotype or genetic studies should be considered unclassifiable; clinical judgment should be used in deciding whether to perform another biopsy or to treat for either HD or ALCL. The category of ALCL Hodgkin's-like will be eliminated from the proposed WHO classification.

In summary, the data currently available suggest that there is no true borderline between HD and ALCL of the T-null type as defined in the REAL classification: HD is, in most cases, a B-cell neoplasm, whereas ALCL is a T-cell neoplasm. There is morphologic but not biologic overlap between HD and ALCL. HD may resemble ALCL by having areas of LD—that is, it may be ALCL-like—but this is a morphologic resemblance only, not a true biologic borderline. Similarly, ALCL may resemble HD by having areas of nodularity, sclerosis, or granulocyte infiltration—that is, it may be Hodgkin's-like—but again, this is not a true biologic borderline. In contrast, because HD is a B-cell neoplasm, there may be a true biologic borderline between B-cell lymphomas and HD of any type, between DLBCL and NLPHD, between T/HRLBCL and either MC or LPHD, and between large B-cell lymphoma, anaplastic, CD30+ type and lymphocyte-depleted variants of CHD. It is these latter areas that present the most challenging differential diagnoses currently.

## DIAGNOSIS AND STAGING

### NATURAL HISTORY AND PATTERNS OF SPREAD

The Swiss radiotherapist Gilbert is credited with first reporting that HD spread by contiguity from one lymph node chain to adjacent chains.<sup>10,119</sup> His work was extended by Peters,<sup>120</sup> Kaplan,<sup>121</sup> and others, who evaluated the use of prophylactic radiotherapy to lymph nodes adjacent to those involved with disease. The development of new radiographic studies and the routine use of staging laparotomy improved understanding of the presentation and evolution of HD.<sup>121,122</sup> Although there is strong evidence that HD begins in a single group of lymph nodes and then spreads to contiguous lymph nodes, eventually the malignant cells become more aggressive, may invade blood vessels, and spread to organs in a manner similar to other malignancies. This is more likely to occur in patients with stage III than with stage I or II HD.

Most patients with NSHD or MCHD have a central pattern of lymph node involvement (cervical, mediastinal, paraortic). In contrast, certain nodal chains (mesenteric, hypogastric, presacral, epitrochlear, popliteal) seldom are involved. Occult adenopathy in patients with negative radiographic staging ranges from 6% to 35%. The spleen is involved more frequently in patients with adenopathy below the diaphragm, systemic symptoms, and MC histology. Involvement of the liver in an untreated patient is rare and almost always occurs with concomitant splenic involvement. Infiltration of the bone marrow is usually focal and almost invariably associated with extensive disease, systemic symptoms, and unfavorable histology. In the great majority of patients, the initial pattern of spread occurs nonrandomly and predictably via lymphatic channels to contiguous lymph node chains. This important observation, first made in the 1930s, continues to form the basis for prophylactic irradiation of adjacent lymph node-bearing regions in patients with apparently localized HD treated with radiotherapy alone.

### STAGING CLASSIFICATIONS

Prior experience with staging laparotomy, the advent of new imaging modalities, and the frequent use of combined modality treatment have made staging procedures simpler and less invasive. The latest international staging classification was proposed in 1989 during a meeting held in Cotswolds, England.<sup>123</sup> The Cotswolds classification ([Table 45.6-5](#)) is a modification of the Ann Arbor classification using information from staging and treatment over the 1970s and 1980s.

Stage I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, testis, thymus, Waldeyer's ring) or involvement of a single extralymphatic site
Stage II	Involvement of two or three lymph node regions on the same side of the diaphragm (IIa) or two, when separated by the diaphragm, or two or three lymph node regions on one side of the diaphragm (IIb). Two extralymphatic sites are considered involved for purposes of a subscript (e.g., II <sub>1</sub> )
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of one or both spleen (III <sub>s</sub> ) or by localized extralymphatic involvement of one or both sites (III <sub>1</sub> , III <sub>2</sub> )
III <sub>s</sub>	With or without involvement of spleen, testis, or other sites
III <sub>1</sub>	With involvement of paranasal, oral, and extracranial sites
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement
<b>DESIGNATIONS APPLICABLE TO ANY DISEASE STAGE:</b>	
A	No symptoms
B	Fever (temperature >38°C), abnormal night sweats, unexplained loss of >10% body weight within the preceding 6 months
C	Bulky disease (a nodal mass of >10 cm or a nodal mass with a maximum dimension >10 cm)
E	Involvement of a single extralymphatic site that is contiguous or proximal to the disease nodal site
CS	Extent of stage
FS	Histologic stage (as determined by histology)

**TABLE 45.6-5.** Cotswolds Staging Classification for Hodgkin's Disease

Some of the recommended modifications include adding criteria for clinical involvement of the spleen and liver, including evidence of focal defects with two imaging techniques, eliminating consideration of abnormalities of liver function, adding the suffix X to designate bulky disease (larger than 10 cm maximum dimension), adding a new category of response to therapy (i.e., unconfirmed or uncertain complete remission) to accommodate the difficulty of persistent radiologic abnormalities of uncertain significance after primary therapy, and separately classifying certain selected patients with localized extranodal disease (e.g., lung, pleura, chest wall, bone) contiguous to involved nodes as the appropriate lymph node system stage followed by the subscript E. The E designation excludes multiple extranodal deposits or bilateral lung extension, which constitute stage IV disease. Recommended staging procedures are listed in [Table 45.6-6](#). An adequate surgical biopsy, possibly of more than one intact lymph node, is required for histopathologic examination.

---

Adequate surgical biopsy reviewed by an experienced hematopathologist
Included history with attention to the presence or absence of systemic symptoms
Careful physical examination, emphasizing node chains, size of liver and spleen, and Waddley's ring inspection
Routine laboratory tests (complete blood cell count, erythrocyte sedimentation rate, and liver function tests)
Chest radiograph (posteroanterior and lateral) with measurement of mediastinal ratio
Chest and abdominal computed tomography scans
Radioisotopic evaluation with <sup>67</sup> Ga or positron emission tomography when the results of other conventional diagnostic procedures are not conclusive
Care needle biopsy of bone marrow from the posterior iliac crest in patients with stage IIIb-IV disease
Needle or surgical biopsy of any suspicious extranodal (e.g., hepatic, osseous, pulmonary, cutaneous) lesion
Cytologic examination of any effusion
Staging laparotomy (with splenectomy, needle and wedge biopsy of the liver, and biopsies of paraaortic, mesenteric, portal, and splenic hilar lymph nodes) in rare circumstances in early-stage Hodgkin's disease in which the use of limited radiotherapy alone depends on pathologic staging

---

**TABLE 45.6-6.** Recommended Staging Procedures

## RADIOGRAPHIC STAGING ABOVE THE DIAPHRAGM

More than 60% of patients with newly diagnosed HD have radiographic evidence of intrathoracic involvement. Frontal and lateral chest radiographs should be routinely ordered and also represent the ideal for subsequent surveillance.

Massive mediastinal adenopathy [large mediastinal adenopathy (LMA)] has been arbitrarily defined as the ratio greater than one-third between the largest transverse diameter of the mediastinal mass over the transverse diameter of the thorax at the diaphragm on a standing posteroanterior chest radiograph.<sup>123</sup> Alternatively, others have defined extensive mediastinal disease as greater than 35% of the thoracic diameter at T5-6, or as measuring greater than 5 to 10 cm in width. Patients with LMA have an increased risk of relapsing in nodal and extranodal sites above the diaphragm after radiotherapy alone.<sup>124,125</sup> These patients make up 20% to 25% of CS I to II patients, generally present with involvement of multiple supradiaphragmatic nodal chains, and may have extension of tumor into the lung, pericardium, or chest wall.<sup>124</sup> Systemic symptoms frequently are present.

Staging with thoracic computed axial tomographic (CAT) scanning can more precisely identify sites of initial involvement.<sup>126</sup> CAT scanning is especially apt at detecting pulmonary disease, pleural or pericardial involvement, apical cardiac nodal enlargement, and extension into the chest wall, and in defining the extent of involved axillary lymph nodes. Such information has considerable potential to alter clinical management.<sup>127</sup> Identification of the extent of thoracic disease will help to define the use of combination chemotherapy and the dose, extent, and need for radiotherapy.

With improved gamma camera resolution, several investigators have described the ability of <sup>67</sup>Ga scanning to detect intrathoracic lymphadenopathy, though the reported sensitivities and specificities are somewhat less than those of CAT scanning. Today, the primary role for <sup>67</sup>Ga scanning in the thorax is to answer specific questions that arise after treatment (e.g., whether a residual mass represents viable tumor rather than necrosis or fibrosis). As an alternative to gallium scanning, positron emission tomography is being explored in Europe and in the United States.<sup>128</sup>

Some investigations suggest that the ability of magnetic resonance imaging (MRI) to detect tumor in mediastinum or hilar lymph nodes is not superior to that of CAT scanning.<sup>129</sup> Although, MRI can probably function as an alternative to CAT scanning in the thorax, particularly at the level of chest wall involvement, its continuing high cost and lack of clinical data prevent this modality from being used routinely.

## RADIOGRAPHIC STAGING BELOW THE DIAPHRAGM

CAT scanning, lymphangiography (LAG), MRI, and <sup>67</sup>Ga scanning all have limitations in the radiologic evaluation of abdominal nodes. No single study is reliable for detecting HD in normal-size nodes, and all studies have a 20% to 25% false-negative rate due to the inability to detect occult HD in the spleen.<sup>130,131</sup> Ninety percent of patients who are up-staged have splenic involvement either alone or in addition to other infradiaphragmatic nodal sites.<sup>130</sup> Head-to-head comparisons of bipedal LAG and CAT scanning suggests that LAG has a small statistical advantage over CAT, particularly in the presence of small lymphadenopathies, because it provides useful information on lymph node architecture. On the other hand, CAT scanning can better evaluate adenopathy in the celiac axis, splenic hilus, porta hepatis, and mesentery, relying almost exclusively on increases in the size of the nodes. CAT scanning can also demonstrate foci of HD in the liver and spleen; however, the false-negative results are too numerous to allow one to rely heavily on CAT assessment of these organs.

During the late 1990s, LAG gave way to CAT scanning as the examination of choice. MRI may be more sensitive than CAT scanning in the evaluation of abdominal nodes, but information on its usefulness is still limited. MRI appears to be a potentially valuable tool in investigating bone marrow involvement and can help in directing image-guided biopsies. Gallium scanning can also complement LAG or CAT scanning, but its use in the abdomen may be hampered by normal uptake in the liver, spleen, and bowel. With the infrequent use of staging laparotomy and splenectomy in the staging of HD, the risk of overstaging based on a single radiographic test of abdominal involvement (false-positive outcome) has greater potential consequences. Therefore, we recommend that two separate studies (i.e., CAT scanning and <sup>67</sup>Ga scanning) be used to assess abdominal involvement and that positive findings on both tests be required to confirm abdominal involvement for the routine radiographic staging of HD.

## STAGING LAPAROTOMY

Staging laparotomy was extensively used when radiotherapy was the only potentially curative treatment for early-stage HD and when it was mandatory to define the extent of abdominal disease to help determine the extent of radiation needed below the diaphragm. With the increasing use of combination chemotherapy, staging laparotomy gradually evolved into a tool that aids in determining whether radiotherapy or chemotherapy should be selected as definitive treatment. With many groups using prognostic factors to determine treatment for HD, laparotomy has disappeared as a routine staging procedure. Its use now is reserved for patients with limited disease who are to receive limited treatment.

## CLINICAL PRESENTATION

First reports about clinical manifestations of HD and patterns of its course of spreading were conducted by Gilbert,<sup>132</sup> Peters,<sup>120</sup> and others. Their findings that HD spreads by contiguity from one lymph node chain to adjacent chains were extended by the use of prophylactic radiotherapy to lymph node regions adjacent to those involved with HD. The understanding of the presentation and evolution of HD has been improved by the development of new radiographic studies and the use of staging laparotomy.<sup>130</sup> Although there is evidence that the course of HD is characterized by its onset in a single lymph node or group of lymph nodes, followed by spreading to contiguous lymph nodes, there are indications that the disease can spread to organs similar to other malignancies by invading blood vessels.<sup>121</sup> Most convincing data for contiguous spread in HD were found for NS and MC histology. In NS and MC histologic subtypes, a central pattern of lymph node involvement (cervical, mediastinal, paraaortic) was more common than nodal involvement of mesenteric, hypogastric, presacral, or popliteal regions.

In general, HD patients present with peripheral lymphadenopathy. The nodes usually are not tender, and changes in the overlying skin are not the norm. Otherwise, tenderness and skin changes are believed to reflect rapid growth with stretching of nodal capsules. In most cases, the nodes are discrete and freely movable. Occult presentation with central (chest and abdomen) lymphadenopathy, visceral involvement, or systemic symptoms of the disease is uncommon. The most characteristic clinical presentation of HD is enlarged superficial lymph nodes in young adults, the most frequent locations being cervical and supraclavicular (60% to 80%), high in the neck or axillary. Less often, such enlarged nodes are found in the inguinal-femoral region.

Mediastinal involvement is discovered often by routine staging chest radiography, and even fairly large masses may occur without producing local symptoms. Otherwise, symptoms of retrosternal chest pain, cough, or shortness of breath may be clinical signs of an intrathoracic disease presentation. A bulky mediastinal mass is not uncommonly associated with small amounts of pericardial and pleural fluid, but malignant effusions, diagnosed by thoracentesis or pleural biopsy, are rare.

Involvement of the liver in a patient with newly diagnosed HD is uncommon and occurs almost always with concomitant splenic involvement. HD limited to the spleen

is rare. Patients may present with abdominal swelling secondary to hepatomegaly or splenomegaly or, rarely, with ascites. Infradiaphragmatic lymphadenopathy may give rise to discomfort and pain in the retroperitoneum or the paravertebral or loin regions, particularly in the supine position, by nodular compression of nerves or nerve roots. Advanced intraabdominal disease may be associated with obstruction of the ureters or compression of the renal vein, with or without ascites.

Bone marrow infiltration is usually focal and, in most cases, is associated with extensive disease, including systemic symptoms. Laboratory findings such as leukopenia, anemia, thrombocytopenia, and an elevated alkaline phosphatase level may give indications of bone marrow infiltration.

Involvement of the central nervous system is rare, although invasion of the epidural space can occur by nodular extension from the paraaortic region through the intervertebral foramina, presenting neurologic symptoms and pain as leading clinical features.<sup>133</sup> Several paraneoplastic neurologic syndromes have been reported in association with HD, but all are very rare.

Complaints due to extranodal manifestations of disease may occur, such as cough from pulmonary infiltration, jaundice from hepatic involvement, or abdominal pain from disease adjacent to the bowel. Gastrointestinal involvement is an extremely rare event and might occur as infiltration from mesenteric lymph nodes. Initial symptoms of disease limited to extranodal tissue are much rarer in HD than in NHLs.

A significant proportion of patients with undiagnosed HD present systemic symptoms before the discovery of enlarged lymph nodes. Typical symptoms are fever, drenching night sweats, and weight loss (so-called B-symptoms, relating to the Ann Arbor classification). This characteristic HD-associated fever occurs intermittently and recurs at variable intervals for several days or weeks. Fever and drenching night sweats are found in 25% of all patients at first presentation, increasing to 50% of patients with more advanced disease. Other nonspecific symptoms are pruritus, fatigue, and the development of pain shortly after drinking alcohol. This pain usually is transient at the site of nodal involvement and may be severe. Pruritus, although currently not a defined B-symptom, may be an important systemic symptom of disease but occurs infrequently, in fewer than 20% of patients. It often occurs months or even a year before HD is first diagnosed.<sup>134</sup> The underlying pathophysiologic mechanisms leading to pruritus are unknown but may be due to an autoimmune reaction in which a number of cytokines are activated by tumor lysis.

## TREATMENT METHODS

### RADIOTHERAPY

#### Principles

The early treatment of HD with crude x-irradiation in 1901 followed the discoveries by Roentgen, Becquerel, and the Curies at the end of the eighteenth century. The first reports of x-ray treatments that would dramatically shrink enlarged lymph nodes produced great excitement and premature predictions for the successful treatment of HD.<sup>135,136</sup> During the first two decades of the twentieth century, physicians mainly used two methods to treat HD with radiation. Small doses of radiation were administered to the entire trunk at weekly intervals for many weeks or were given as a single massive dose just to the tumor. Neither method controlled the HD, and both caused severe side effects.<sup>10</sup> Enlarged nodes usually shrank with both techniques, but recurrence and spread to previously uninvolved nodes invariably followed. After several courses of radiotherapy, the HD became more resistant to treatment, and very few patients survived 5 years from diagnosis. These multiple recurrences were not attributed to poor radiotherapeutic techniques but were viewed as inherent to the HD itself. Consequently, by 1920, most physicians had stopped using radiation as a means of curing HD. For the next 40 years, in most centers, treatment was mainly palliative, to shrink large nodes that were painful or interfered with movement, eating, or breathing.

The development of modern radiotherapeutic techniques for the treatment of HD began with the work of Gilbert,<sup>137</sup> a Swiss radiotherapist, in the 1920s. He advocated treatment to apparently uninvolved adjacent lymph node chains that might contain suspected microscopic disease, as well as to the evident sites of lymph node involvement. Peters also adapted this technique at the Princess Margaret Hospital in the late 1930s and early 1940s. In her historic paper published in the *American Journal of Roentgenology* in 1950, Peters<sup>120</sup> provided evidence that patients with limited HD could be cured with aggressive radiotherapy that treated involved nodal disease as well as adjacent nodal sites. She did this by identifying a group of patients with limited-stage HD that was cured with high-dose, fractionated radiotherapy. She reported 5-year and 10-year survival rates of 88% and 79%, respectively, for patients with disease limited to a single lymph node region, rates that were notably high for a disease in which virtually no one survived 10 years. Nevertheless, the concept that early-stage HD might be curable with radiotherapy using higher doses and larger fields was slow to be accepted. Before the 1960s, most patients with limited HD were not treated at all or with only small doses of radiation.

No one deserves more credit than Henry Kaplan for the development of successful modern treatment for HD. His accomplishments are many and include pioneering work on developing the linear accelerator,<sup>121,138</sup> defining radiation field sizes and doses for a curative approach for early HD,<sup>121</sup> refining and improving diagnostic staging techniques, developing models for translating laboratory findings into clinical practice, and promoting early randomized clinical trials in the United States.

### TECHNIQUES

Excellent results in the treatment of early-stage HD have been achieved through careful delineation of disease and meticulous attention to technique.<sup>139</sup> Treatment-machine generated verification films should be used to ensure proper alignment. Daily doses of no more than 180 to 200 cGy to the mantle field (unless the treatment field includes the entire heart or entire lung, in which case the dose should be limited to 150 cGy/d or less) reduces risks to both the heart and lungs. Adjusting treatment on the basis of off-central axis dose calculations can reduce dose inhomogeneity from differences in patient separation within the large mantle field. Extended source-to-skin distances of 110 cm or greater, rather than a source-to-skin distance of 100 cm, also reduces tissue inhomogeneity. Proper use of megavoltage energies will ensure that superficial nodes are not underdosed in the buildup region. A 4- to 6-MeV linear accelerator should be used for mantle and pelvic fields, whereas higher energies (10 to 15 MV) can be used for treating paraaortic nodes.

The mantle field encompasses the submandibular, cervical, supraclavicular, infraclavicular, axillary, mediastinal, subcarinal, and hilar lymph nodes. A total dose of 3000 cGy to the entire mantle field is sufficient for patients with supradiaphragmatic HD when radiotherapy alone is used. Areas of initial involvement should receive a total dose of 3600 to 4000 cGy through the addition of a cone-down field. Reduction of the radiation dose to 3000 cGy to areas of initial involvement is recommended for patients receiving combined modality therapy, especially when there has been a good response confirmed by CAT scanning. When at least four cycles of chemotherapy have been given, radiation to initial uninvolved prophylactic sites probably is not needed. Further reduction to 1500 to 2500 cGy may be desirable in prepubertal patients receiving combined modality treatment or, occasionally, in patients with extensive nodal involvement who are receiving treatments to large radiation fields after chemotherapy.

There is an increasing use of involved field irradiation after chemotherapy in the treatment of early-stage HD. Involved field irradiation should encompass the entire involved lymph node region, as defined initially by Stanford University Medical School.<sup>10</sup> For example, the ipsilateral cervical and supraclavicular nodes and the inguinal and femoral nodes constitute single regions.

Mantle paraaortic-splenic irradiation after a negative laparotomy occasionally is used as a radiotherapy-alone approach for early-stage disease patients who have not had a staging laparotomy. The paraaortic field encompasses the paraaortic nodes down to the fourth to fifth lumbar vertebral interspace (L4-5). Without staging laparotomy and splenectomy, the entire spleen must be irradiated. A CAT scan should be used to localize the position of the spleen and enable blocking of as much of the left kidney as is possible. The dose to the paraaortic lymph nodes should be 3000 cGy when there is no known disease, and radiotherapy alone is used. Beam divergence from the mantle and paraaortic fields creates the potential for an overdose at the spinal cord. A number of different matching techniques have been published.<sup>140</sup>

Prophylactic pelvic irradiation is used rarely in the modern-day treatment of supradiaphragmatic HD. However, pelvic irradiation continues to be used for patients presenting with stage I or II infradiaphragmatic HD. Iliac wing blocks to spare bone marrow and a pelvic block to shield the bladder and central pelvic organs should be part of the treatment technique (which includes irradiation of inguinal and femoral nodes). Loss of fertility in both men and women is a risk with the use of pelvic irradiation for subdiaphragmatic HD, and techniques should be used to reduce this risk whenever possible.<sup>141</sup>

### CHEMOTHERAPY

The development of chemotherapeutic programs for HD is a story of success. After the discovery of the cytotoxic effects of nitrogen mustard in the 1940s, a number of different drugs—including chlorambucil, cyclophosphamide, procarbazine, vinblastine, and vincristine—were developed and showed efficacy in HD. Response rates

were approximately 50% to 60% with 10% to 30% complete response. However, relapse was seen in almost all cases, and no cure could be achieved.

On the basis of a murine leukemia cell line, Skipper et al.<sup>141a</sup> postulated a model of tumor cell kill based on the logarithmic cell growth and a logarithmic response to cytotoxic agents. From this model, the authors predicted that response to chemotherapy would depend on tumor burden, drug dose, and kinetics of residual tumor cells. It was further postulated that the simultaneous use of several drugs with different modes of action might yield superior results. The combination of drugs might be tolerated if the toxicities were nonoverlapping. Initial attempts with two-drug combinations revealed the potential of this approach.

However, the relevance of this model was realized in 1967, when DeVita et al.<sup>141b</sup> reported on a four-drug combination chemotherapy program, MOPP [mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone]. This combination established the curability of more than 50% of patients with stage III or IV disease.

The development of MOPP was a milestone in oncology, demonstrating that advanced-stage HD could be cured. The differences in survival between historic controls and MOPP-treated patients were so dramatic that randomized clinical trials were not needed to validate these results. Further information on chemotherapy is provided in [Advanced-Stage Disease](#) later in this chapter.

### **Combined Modality Chemotherapy**

In addition to the many factors that affect either chemotherapy or radiotherapy when used alone, there are several issues that arise specifically because of potential interaction and summing of effects when they are combined. It is important to remember that the purpose of adding a second modality is to overcome resistance to the first and, in the case of adding irradiation to chemotherapy for HD, it seems likely that full-dose irradiation may be needed to overcome primary resistance to chemotherapy. Of particular interest are two German trials recently summarized,<sup>142</sup> in which patients with stage IA+B, IIA+B, and stage IIIA disease with extensive mediastinal or splenic involvement or E lesions were treated with two-course cyclophosphamide, Oncovin, procarbazine, and prednisone (COPP) and doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) followed by irradiation. In the first trial (HD1), responders to chemotherapy then were given extended-field irradiation with a dose to nonbulky sites assigned randomly to be either 20 Gy or 40 Gy. In the second trial (HD5), a similar group of patients received 30 Gy to the nonbulky sites. Bulky sites received 40 Gy in each trial. Failure-free survival was the same in all groups, strongly implying that after optimal chemotherapy, irradiation dose, at least to nonbulky sites, can be reduced without sacrificing efficiency.

The risk of two important late complications of irradiation may be reduced by lowering the dose. Studies of late sequelae of treatment for HD suggest that the risk of second neoplasms, especially breast cancer in women, may be reduced by lower radiation dose.<sup>143</sup> The other late toxicity possibly associated with radiation dose is cardiovascular. Stanford University investigators found that a higher dose of irradiation to the mediastinum was associated with increased mortality from cardiac disease.<sup>144</sup>

An alternative approach to reduce toxicity from irradiation when used in combined modality treatment is to reduce not the dose but the extent of the field encompassed. Several trials involving patients with limited-stage HD have shown that results comparable to those achieved with irradiation alone to an extended field can be achieved when chemotherapy is combined with involved field irradiation.<sup>125,145</sup> The ability to preserve efficacy while limiting toxicity by reducing the size of the treatment fields is one of the most attractive aspects of using combined modality treatment.

The same theoretic considerations that apply to irradiation are relevant when one considers reduction of the dose of chemotherapy used in combined modality treatment. The section [Choice of Treatment](#) examines these results in more detail.

In theory, either the chemotherapy or the radiotherapy could come first in the sequence of combined modality treatment. In practice, it is almost always desirable for chemotherapy to precede radiotherapy. The reason for this includes early effective treatment of disseminated disease, delay in induction of irreversible loss of bone marrow function, and the opportunity to use smaller, potentially less toxic radiation treatment fields after chemotherapy has induced tumor regression.

### **High-Dose Chemotherapy Plus Stem Cell Support**

**PRINCIPLES.** High-dose chemotherapy (HDCT) has been used extensively in patients with relapsed and refractory HD. Implicit in the rationale for this approach is the assumption of a steep dose-response relation for lymphoma patients subjected to chemoradiotherapy. Although care must be exercised in interpreting clinical results, both animal models and clinical studies support the existence of such a relationship.<sup>146</sup>

The use of autologous bone marrow or peripheral blood stem cells (PBSCs) to support intensification of chemotherapy as salvage treatment has changed the options available for relapsed patients. Autologous transplantation involves the replacement of hematopoietic stem cells that have been irreversibly injured by HDCT or radiotherapy (or both). This can be accomplished either with bone marrow cells obtained by multiple aspirations from the posterior iliac crest under anesthesia or with PBSCs collected by apheresis. The use of PBSCs has surpassed the use of bone marrow, and PBSCs may be used exclusively in the future. The advantage of using PBSCs includes avoiding general anesthesia and more rapid hematopoietic reconstitution.

**CONDITIONING REGIMENS.** Several conditioning regimens have been used and summarized previously.<sup>147</sup> The most commonly used are cyclophosphamide, etoposide (VP-16), and BCNU (CVB) or BCNU, etoposide, cytarabine (arabinoside), and melphalan (BEAM) given in different dose schedules. When BCNU-containing regimens are used, careful clinical monitoring to detect early signs of delayed lung toxicity is important, particularly when BCNU doses of 450 mg/m<sup>2</sup> are given. Mucositis and enterocolitis represent the most significant nonhematologic toxicities associated with high-dose melphalan. Total body irradiation has been used only in a few studies, owing to the fact that many HD patients have already received thoracic irradiation by the time they have reached the transplantation stage and to the high treatment-related mortality of patients prepared by total body irradiation-containing regimens.<sup>148,149</sup> Although the toxicity profiles differ with these regimens, there currently is no evidence to support the superiority of any particular regimen in HD.

Sequential HDCT is increasingly being used in the treatment of solid tumors and lymphoma. First results from phase II studies show that this kind of therapy is safe and effective.<sup>150,151</sup> In accordance with the Norton-Simon hypothesis, after initial cytoreduction, a few non-cross-resistant agents are given in short intervals.<sup>152</sup> In general, the transplantation of autologous stem cells and the use of growth factors allow application of the most effective drugs in highest doses in intervals of 1 to 3 weeks. Sequential HDCT permits the highest possible dosing in minimum time.

**INCORPORATING RADIOTHERAPY IN HIGH-DOSE CHEMOTHERAPY PROGRAMS.** Radiotherapy is a very effective locoregional treatment modality in HD. The rationale for incorporation of radiotherapy into HDCT programs stems from the observation that disease progression after HDCT often occurs in sites of prior involvement. Several investigators showed that in 65% to 95% of cases, the sites of failure are involved immediately before HDCT.<sup>148,153</sup> Retrospective analysis suggests that radiotherapy may be incorporated as cytoreductive treatment before HDCT or as a consolidative therapy after HDCT.<sup>154,155</sup> However, no prospective clinical trial has yet answered the questions regarding the extent of the radiation field, the timing of treatment, and the appropriate dose to use. The complementary role of radiotherapy in salvage HDCT is uncertain and remains to be investigated.

## **CHOICE OF TREATMENT**

### **PROGNOSTIC FACTORS AND TREATMENT GROUPS**

A prognostic factor is a measurement or classification of an individual patient, performed at or soon after diagnosis, that gives information on the likely outcome of the disease. This information will generally be phrased in terms of probabilities—for instance, the probability of cure for various values of a prognostic factor. It may be used for informing the patient or, in the context of clinical trials, for defining or describing the study population or adjusting the data analysis; however, for the clinician, the most important role of the prognostic factor is to help in selecting an appropriate treatment strategy.

In HD, patients have traditionally been divided into two or three prognostic groups, chiefly according to stage and B-symptoms but also taking various other factors into consideration. Most basically, patients with stage IIIB or IV (advanced-stage) disease have been associated with the poorest prognosis and assigned an intensive chemotherapy protocol, sometimes followed by adjuvant radiotherapy. Further prognostic factors often were used to assign stage IIIA or stage IIB patients to the advanced-stage group. Among the remaining patients with early-stage disease who had previously continued to receive radiotherapy alone, an “unfavorable”

subgroup often was defined to select patients for combined modality therapy. Each group has thus been associated with a typical standard treatment strategy:

- Early stages, favorable: radiation alone (extended field)
- Early stages, unfavorable: moderate amount of chemotherapy (typically four cycles) plus radiation
- Advanced stages: extensive chemotherapy (typically eight cycles) with or without consolidating (usually local) radiation

These “typical” strategies are not uniformly applied, and the investigation of alternatives (e.g., the use of chemotherapy in favorable early stages) is continuing. In the scheme just listed, two divisions between the three prognostic groups must be noted, each division possibly being defined by a different set of factors. Furthermore, the attempt has been made to identify advanced-stage patients with a particularly high risk of failure for intensified therapy (e.g., early HDCT with stem cell support).<sup>156</sup> The selection of factors and the definition of the prognostic groups vary among institutions, as does the choice of treatment.

Prognostic factors are rarely the subject of specific clinical studies but are discovered and evaluated using data from large cohorts of uniformly treated, well-documented, and reliably followed-up patients, usually from large clinical trials.<sup>157,158</sup> The diversity of diagnostic and treatment strategies used for the early stages, as well as statistical problems caused by the low rate of treatment failure events, has led to the reporting and use of different prognostic factors by different institutions and trial groups.

In the following few sections, recognized prognostic factors are described for early stages treated with radiotherapy alone, for early stages treated with chemotherapy, and for advanced stages (treated with chemotherapy), respectively. Such factors are required to show independent prognostic value in multivariate analyses of large numbers of patients. This account refers in general to clinically staged patients, because laparotomy is now rarely performed. The use of these factors to define prognostic groups for treatment purposes, as practiced by various institutions and study groups, are described.

**Prognostic Factors for Early-Stage Disease (Clinical Stage I or II) Treated with Radiotherapy Alone**

For those patients with early-stage (CS I or II) disease who are to be treated by radiotherapy alone, recognized adverse factors are (1) advanced age (which correlates with the presence of occult abdominal disease and with poor results of salvage therapy and may also be associated with treatment complications, leading to reduced or delayed treatment); (2) male gender (which has a small effect only); (3) histologic subtype MC (which is associated with the presence of occult abdominal disease); (4) the presence of B-symptoms (which is associated with the presence of occult abdominal disease); (5) presence of a large mediastinal mass (LMM), for which there is some evidence of an increased relapse rate in the thorax (although there are few data, as few LMM patients were treated with radiotherapy alone); (6) the number of involved nodal regions; (7) an elevated erythrocyte sedimentation rate (ESR); (8) presence of anemia; and (9) a low serum albumin level.

These factors are relevant to the decision as to which early-stage patients should be classed as unfavorable and receive combined modality therapy because their prognosis with radiotherapy alone is relatively poor. Major study groups have used criteria as described next. Favorable patients were generally given radiation only, although the additional application of mild chemotherapy has increased.

The European Organization for the Research and Treatment of Cancer (EORTC) has, since 1982, defined CS I and II (supradiaphragmatic only) patients as unfavorable if any of the following factors applied: age older than 50 years, asymptomatic with ESR in excess of 50, B-symptoms with ESR in excess of 30, and LMM, based on the results of earlier EORTC trials H1 and H2. In previous trials, stage II, MC or LD histology, and number of involved regions also were counted as adverse factors.<sup>159</sup>

The GHSG has, since 1988, assigned combined modality treatment to CS I and II patients with any of the following adverse factors: (1) LMM, (2) number of regions (3), (3) elevated ESR, (4) localized extranodal infiltration (so-called E-lesions), or (5) massive splenic involvement.<sup>160</sup> Owing to the rarity of splenectomy, the last-mentioned factor was seldom reported and was abandoned for the present trial generation. It can be difficult to distinguish consistently between E-lesions and stage IV disease, and varying assessments of the prognostic value of this feature have been obtained by different investigators ( Table 45.6-7). Stanford began in 1980 to give combined modality treatment to CS I and II patients with LMM or multiple E-lesions.

Treatment Group	GHSG Risk Factors	EORTC/GELA Risk Factors
	A Large mediastinal mass	I Large mediastinal mass
	B Extensive disease	II Age >50
	C Elevated ESR	C Elevated ESR
	D ≥ 2 involved regions	D ≥ 2 involved regions
Empiric performance	N2/N3 histology in CS I-II with no RF	N2/N3 histology in supradiaphragmatic CS I-II
Early stage favorable	CS I-II with no RF	CS I-II supradiaphragmatic with no RF
Early stage unfavorable	CS I, CS II with one or more RF; CS III with 0-2 RF	CS I-II supradiaphragmatic with one or more RF without LMM
Advanced stage	CS III with 1-3, CS IV-II	CS III-II

CS, clinical stage; EORTC, European Organization for Research and Treatment of Cancer; ESR, erythrocyte sedimentation rate; GELA Group (Fédération de Chimie des Tumeurs de l'Abdomen, German Hodgkin's Lymphoma Study Group, NCI); nodal/empiric performance (nodal) disease; RF, risk factor; supradiaphragmatic sites (SF) without or (SF) with (B-symptoms).

**TABLE 45.6-7.** Definition of Treatment Groups in Two Large Cooperative Trial Groups

The EORTC has investigated the use of localized radiotherapy in a “very favorable” subgroup of early-stage patients. Inclusion criteria were a stage IA female patient younger than 40 years, with disease of NS or LP histology, without elevated ESR or LMM. A 30% long-term failure rate was observed, however, and this policy was not continued.

**Prognostic Factors for Early-Stage Disease (Clinical Stage I or II) Treated with Chemotherapy**

Despite the different mode of action of chemotherapy as compared with radiotherapy, similar prognostic factors have emerged from analyses of cohorts treated with radiation and with combined modality therapy. All the factors listed for radiation-treated patients have also been reliably confirmed in cohorts who also received chemotherapy,<sup>161,162</sup> either in early or in advanced stages. This similarity of prognostic effects is supported by the observation from a metaanalysis of radiotherapy versus combined modality treatment in early stages that the size of the difference in failure-free survival between these two treatment strategies was essentially constant over different prognostic groups.<sup>163</sup>

As a consequence, the prognostic factors relevant to the division between unfavorable early and advanced-stage cases (i.e., between moderate and extensive chemotherapy) are essentially the same as those listed for the division between favorable and unfavorable disease categories. However, generally only stage IIB or III patients are given “advanced-stage” treatment owing to the presence of these factors.

The EORTC includes in its advanced-stage cohorts stages III and IV only, without regard to other factors, as did the U.S. NCI and several U.S. cooperative groups.

In the GHSG, all stage III and IV patients plus stage IIB with LMM or E-lesions are included in the advanced-stage group. Earlier trials included in the unfavorable early-stage category either all stage IIIA patients or just those without any of the five GHSG factors listed. This gradual shift to use of more intensive therapy was based on prognostic factor analyses.

Certain other trial groups include further stage I and II patients in the advanced prognostic group (e.g., IB and IIB or bulky stage II disease).<sup>164</sup>

**Prognostic Factors for Advanced-Stage Disease**

The more uniform treatment modality and the greater frequency of treatment failure events has permitted more conclusive and generally applicable results for prognostic factor analyses for the advanced stages, as compared with early stages. The results of the International Prognostic Factors Project,<sup>161</sup> though not

necessarily including all possible factors, can be taken as reliable ( [Table 45.6-8](#)).

Factor	Log Hazard Ratio	P Value	Relative Risk
Serum albumin <4 g/dL	0.40 ± 0.10	<.001	1.49
Hemoglobin <10.5 g/dL	0.30 ± 0.11	.006	1.35
Male gender	0.30 ± 0.09	.001	1.35
Stage IV disease	0.25 ± 0.09	.011	1.26
Age ≥45 y	0.33 ± 0.10	.001	1.39
White blood cell count ≥15,000/mm <sup>3</sup>	0.34 ± 0.11	.001	1.41
Lymphocyte count <600/mm <sup>3</sup> or <8% of white blood cell count	0.31 ± 0.10	.002	1.38

(From ref. 161, with permission.)

**TABLE 45.6-8.** Final Cox Regression Model

All these factors were highly significant in the multivariate analysis of data from 5141 patients treated in 25 centers, and their prognostic power was confirmed in an independent sample. Note that factors 1, 2, 4, and 5 are also prognostic for early-stage patients. All seven factors were associated with similar relative risks of between 1.26 and 1.49. Therefore, Hasenclever and Diehl<sup>161</sup> recommended combining these factors into a single score by simply counting the number of adverse factors, thus giving an integer prognostic score between 0 and 7. However, even patients exhibiting five or more factors (7% of cases) had a 5-year failure-free rate of more than 40%. The best failure-free rate was close to 80% for those with, at most, one factor (29% of cases), suggesting that a group of advanced-stage patients with a relatively favorable prognosis could be recognized (1618 patients included in the final analysis for FFTF, according to whether the prognostic score was 0 to 2 or 3 or higher) ([Fig. 45.6-4](#)).

**FIGURE 45.6-4.** International prognostic score split at three prognostic factors.

A number of other factors have been shown to correlate with prognosis in advanced stages, but their independent importance is not proven due to conflicting results or lack of confirmation in a large data set. These include pathologic grade in NSHD, presence of tissue eosinophilia, elevated inguinal involvement, high serum lactate dehydrogenase level, and b<sub>2</sub>-microglobulin.

Factors relevant to advanced-stage patients may be used to identify patients for either treatment intensification or treatment reduction. Reduction can be achieved by creating a modified protocol or by including these patients in the early-stage group. Concerning intensification, various investigators have treated a poor-prognosis subset of advanced-stage patients, who had attained a remission by conventional chemotherapy, with HDCT accompanied by hematologic stem cell support.<sup>156,165</sup> Proctor et al.<sup>165</sup> constructed a continuous numeric index for this purpose as a weighted sum of the variables age, stage, lymphocyte count, hemoglobin, and presence of bulky disease, and included patients with an index greater than 0.5 in the poor-prognosis subset. Carella et al.<sup>231</sup> included patients with two or more of the following factors: high lactate dehydrogenase level, very large mediastinal mass, two or more extranodal sites, inguinal involvement, low hematocrit, and bone marrow involvement. However, none of these methods could consistently select a subset with a failure rate of less than 40% with conventional therapy. This means that the early high-dose approach is unlikely to show a clinically relevant long-term survival benefit as compared with conventional treatment.<sup>166</sup>

Concerning treatment reduction, the short-duration, reduced-dose Stanford V chemotherapeutic regimen (mechlorethamine, Adriamycin, vinblastine, vincristine, etoposide, bleomycin, and prednisone)<sup>194</sup> with or without radiotherapy is currently being tested in patients with bulky stage II or advanced-stage disease who have, at most, two International Prognostic Factor Project adverse factors.<sup>167</sup> Stanford V is, however, not merely a reduction of therapy but rather a rescheduling with lower total doses but greater dose intensities. No data are available on the results of treatment reduction in a favorable subset of the advanced-stage patients.

In conclusion, the three-level scheme of division into early-stage favorable, early-stage unfavorable, and advanced-stage cases remains valid according to current knowledge (see [Table 45.6-7](#)). Separation of very favorable early-stage or poor-risk advanced-stage patients for especially mild or intensive therapy, respectively, does not appear justified. Several prognostic factors, other than clinical stage, are used in the divisions among favorable, unfavorable, and advanced cases, and no universally valid set of factors has been determined. Nevertheless, the list of reliably confirmed, independent prognostic factors just reviewed encompasses most of the factors used by the major institutions and study groups. For early-stage and advanced-stage disease patients receiving radiotherapy or chemotherapy or both, the set of relevant factors is fairly similar.

A number of other factors have been shown to correlate with prognosis in advanced stages, but their independent importance is not proven due to conflicting results or lack of confirmation in a large data set. These include both clinical factors, such as inguinal involvement, and biologic factors, such as pathologic grade in NSHD, presence of tissue eosinophilia, high serum lactate dehydrogenase, and high b<sub>2</sub>-microglobulin. The search for biologically specific factors directly related to tumor activity is now an important research goal.

## EARLY-STAGE FAVORABLE DISEASE

### Reduction of Staging or Treatment: Ongoing and Recently Completed Trials

Increasing concern for the long-term consequences of treatment has prompted many investigators to reexamine the aggressive approaches developed for the staging and treatment of early-stage HD in the 1970s and 1980s. Many of the ongoing and recently completed studies were developed in an attempt to reduce the long-term complications of treatment without increasing mortality from HD. These include studies that look at reduction of radiation dose or reduction of field size in pure radiotherapy; seek an optimal, short, or less toxic chemotherapeutic regimen; explore an optimal radiation volume in combined modality therapy; or evaluate chemotherapy alone.

### Clinical Trials of Radiotherapy Alone

**RADIATION DOSE REDUCTION.** Although a few studies have comprehensively reviewed dose-response data for HD, only one prospective randomized study is available.<sup>168</sup> This multicenter trial by the GHSG evaluated the tumoricidal doses for subclinical involvement by HD.<sup>169</sup> A total of 376 laparotomy-staged favorable-prognosis IA to IIB HD patients were enrolled. Only patients without risk factors were included in the trial. Any one of the following risk factors was cause for exclusion: presence of LMA, massive splenic involvement, extranodal disease, an ESR of more than 30 and B-symptoms, an ESR of more than 50 and no

B-symptoms, or more than three regions of involvement. Patients were randomized to receive either 40-Gy extended-field radiotherapy or 30-Gy extended-field radiotherapy followed by an additional 10 Gy to involved lymph node regions.

The 5-year FTF results favored the 30-Gy extended-field plus 10 Gy arm over the 40-Gy extended-field arm (81% vs. 70%, respectively;  $P = .026$ ). The 5-year FTF and survival rates were (nonsignificantly) higher in the reduced-dose arm, suggesting that 30 Gy is sufficient for treating subclinical involvement of HD with radiotherapy alone.<sup>169</sup>

#### **RADIATION FIELD SIZE REDUCTION.**

*Mantle Irradiation Alone in Clinical Stage IA to IIA Patients.* The use of mantle irradiation alone for early-stage HD is attractive because all treatment is completed within 5 weeks, patients avoid the long-term risks of radiation to the upper abdomen, and the potential for salvage with combination chemotherapy is not compromised. Results of prospective and retrospective studies of mantle irradiation alone for unselected CS I and II patients have been disappointing. The EORTC H1 trial, one of the first studies to evaluate the role of chemotherapy in the treatment of early-stage HD, randomized clinically staged I and II patients to receive mantle irradiation alone or combined with vinblastine chemotherapy. All CS I and II patients were enrolled. Fewer recurrences were seen in patients who received both mantle irradiation and vinblastine chemotherapy. However, relapse rates were high in both groups. The freedom from recurrence was only 38% in the mantle-alone group, and the 15-year survival rate was only 58%. This suggests that mantle irradiation alone is not adequate treatment for unselected patients with CS I to II HD and that vinblastine is only partially effective in eliminating recurrences, many of which occurred below the diaphragm.<sup>170</sup> Similarly, the Toronto series reported a 10-year rate of freedom from recurrence of only 54%.<sup>171</sup> These high recurrence rates in unselected patients are not surprising, as more than 20% of CS I to II patients have occult abdominal involvement, and absence of treatment of potential abdominal disease (with radiotherapy or chemotherapy) will result in higher recurrence rates than are achieved with more extensive treatment. When mantle irradiation was restricted to clinically staged, asymptomatic patients in whom a single lymph node region was involved (CS IA), better results have been seen, with 10- to 15-year freedom-from-recurrence rates of 58% to 81%.<sup>172</sup>

*Clinically Staged Patients with a Very Low Risk of Abdominal Involvement.* Clinically staged patients with a very low risk of abdominal involvement include female patients with CS IA NSHD, patients with CS IA LP histology, and CS IA patients with interfollicular HD.<sup>130</sup> A similar subgroup of patients was defined by the EORTC (women <40 years of age with CS IA lymphocytic predominance or NS histology and an ESR <50 mm) and treated with mantle irradiation alone without staging laparotomy in the EORTC H7VF (very favorable) and H8VF trials. In the H7VF trial, 40 patients were treated with mantle irradiation alone; complete remission was achieved in 95%. However, 23% of patients experienced relapse, yielding a 6-year event-free survival rate of 66%, a relapse-free survival rate of 73%, and overall and cause-specific survival rates of 96%.<sup>173</sup> The relapse rates were thought to be unacceptably high in this selected subgroup of stage IA patients. The very favorable subgroup now is treated according to the EORTC strategy for the favorable subgroup.

*Mantle Irradiation Alone in Favorable-Prognosis Stage IA and IIA Patients.* To determine the role of prophylactic abdominal irradiation in early-stage HD, the EORTC H5 trial (1977 through 1982) compared the use of mantle and paraaortic-splenic pedicle irradiation to mantle irradiation alone in patients with favorable early-stage HD.<sup>159,170</sup> This study included only patients with NS or LP histology, aged 40 years or younger, with prognostically staged (PS) I or II disease with mediastinal adenopathy, and an ESR of less than 70. No differences were seen in disease-free survival or overall survival between the two treatment groups with or without paraaortic irradiation. A 1997 update of this trial shows no statistical difference between the two treatment arms, either for treatment failure probability ( $P = .62$ ) or overall survival ( $P = .69$ ).

In 1989, a single-arm prospective trial was initiated at the Harvard University Medical School Joint Center for Radiotherapy of mantle irradiation alone in laparotomy-staged IA to IIA HD patients. The objectives were to identify patients most suitable for mantle irradiation alone, to establish guidelines for follow-up after treatment, to evaluate the requirement for staging laparotomy, and to provide an assessment of risk versus gain for the reduction of treatment in early-stage HD. The eligibility criteria for the study included a negative laparotomy, the absence of LMA and B-symptoms, and NS or LP histology. Thoracic CAT scanning and <sup>67</sup>Ga scanning were required to establish the extent of thoracic involvement, and patients with HD in hilar, subcarinal, or cardiophrenic lymph node regions were not eligible for the trial. Eighty-four patients have been enrolled. The 5-year actuarial rate of freedom from recurrence exceeds 80%. These excellent results with mantle irradiation alone also have been seen in other retrospective studies.<sup>174</sup>

#### **Clinical Trials of Combined Chemoradiotherapy**

Some randomized trials of combined modality therapy are based on the premise that this approach results in a very high freedom from recurrence in early-stage HD and that efficacy can be maintained when using less toxic chemotherapeutic and radiotherapeutic regimens.

**LESS TOXIC CHEMOTHERAPY WITH RADIATION: COMPARISON WITH RADIATION ALONE.** These trials use chemotherapeutic regimens given for four or six cycles in combination with radiotherapy. The regimens are combined with involved-field or regional (mantle) radiotherapy with the premise that the drugs being tested will be able to control both adjacent prophylactic sites and occult abdominal disease in clinically staged patients without upper abdominal and splenic irradiation. Analysis of patterns and frequency of failure eventually will provide better guidelines for designing optimal regimens to control occult HD not appreciated on physical examination or radiographic evaluation. If successful, these regimens should reduce treatment-related morbidity and mortality by reducing both the amount and toxicity of chemotherapy and by using smaller radiation volumes.

With the objective of reducing acute toxicity and chronic morbidity (sterility, increased risk of leukemia), Horning et al.<sup>175</sup> developed a “nontoxic” chemotherapeutic regimen—vinblastine, bleomycin, and methotrexate (VBM)—which was tested in a randomized trial of PS IA to IIB and PS IIIA patients. The trial compared subtotal or total nodal irradiation to involved-field irradiation (44 Gy) followed by VBM.<sup>175</sup> Data on freedom from disease progression at 9 years favored involved-field irradiation and VBM (98%) over subtotal or total nodal irradiation (78%) ( $P = .01$ ). No differences were seen in overall survival ( $P = .09$ ). The BNLI has confirmed the efficacy of VBM with involved-field irradiation but, in that group's experience, this approach produced unacceptable pulmonary and hematologic toxicity.<sup>176</sup> Favorable results with VBM and extended-field radiotherapy in CS IA to IIA HD also have been reported by the Gruppo Italiano per lo Studio dei Linfomi.<sup>177</sup> In that study of 50 patients, the 5-year progression-free survival rate was 82%. Sixteen percent of patients in the trial experienced pulmonary toxicity.

Based on the Stanford trial results reported above,<sup>175</sup> a follow-up Stanford University trial has been completed.<sup>145</sup> Patients with CS IA to IIA HD (staging laparotomy and splenectomy were eliminated) were treated either with subtotal nodal and splenic irradiation or two cycles of VBM, followed by regional (mantle) irradiation, followed by four additional cycles of VBM (with a reduced bleomycin dose). No differences in 4-year freedom from disease progression or survival were noted between the two arms of the trial.

Epirubicin, bleomycin, vinblastine, and prednisone (EBVP) and involved-field irradiation ( $n = 168$ ) versus mantle and paraaortic-splenic irradiation ( $n = 165$ ) for favorable-prognosis CS IA to IIA patients was tested in the EORTC H7F trial (1988 through 1993). The EORTC EBVP II regimen (one dose per cycle) was proposed as a potentially less toxic but similarly effective regimen as compared to ABVD. In the H7F trial for patients with favorable disease, six cycles of EBVP were combined with involved-field radiation and were randomly compared with subtotal nodal and splenic irradiation in favorable CS I and II patients. At 6 years, the relapse survival rate was significantly higher for patients on the combined chemoradiotherapy arm than for those on the radiotherapy-alone arm (92% vs. 81%, respectively;  $P = .004$ ). The 6-year survival rate was excellent in both treatment arms (98% vs. 96%, respectively;  $F = .156$ ).<sup>178,179</sup> In contrast, in the H7U trial for patients with unfavorable disease, EBVP and involved-field radiotherapy was inferior to MOPP and ABV and involved-field radiotherapy, suggesting that the use of prognostic factors is crucial in selecting patients for treatment with reduced chemotherapeutic and radiotherapeutic regimens.

**REDUCED NUMBER OF CHEMOTHERAPY CYCLES.** The trials noted here use combination chemoradiotherapy with fewer than four cycles of chemotherapy. Although the primary goal of these trials is to evaluate the efficacy of short courses of chemotherapy, new regimens are also being tested [i.e., Stanford V; vincristine, Adriamycin, prednisolone, etoposide, cyclophosphamide, and bleomycin (VAPEC-B)]. The optimal extent of radiotherapy needed is less certain in the short-course trials. For example, there are at least limited data that four to six cycles of chemotherapy are sufficient to control occult abdominal disease in the majority of CS I to II patients.<sup>124,180</sup> With short-course chemotherapy, very few data are available on the effectiveness of different regimens to control HD outside of the involved regions, as defined by physical examination or radiographic evaluation. This uncertainty is reflected in some of the trial designs that use subtotal nodal and splenic irradiation rather than involved-field or mantle irradiation in combination with chemotherapy. Ongoing and recently completed short-course trials are listed in [Table 45.6-9](#).

Trial	Eligibility	Treatment/Regimen	No. of Patients	Outcome
GHSB HD7	CS IA to IIB HD with or without splenic irradiation	A: 2 cycles of ABVD + subtotal nodal and splenic irradiation B: 4 cycles of ABVD + subtotal nodal and splenic irradiation	643	FFTF 97% vs 87%
GHSB HD10	CS IA to IIB HD with or without splenic irradiation	A: 2 cycles of ABVD + 20-Gy involved-field radiotherapy B: 4 cycles of ABVD + 20-Gy involved-field radiotherapy	Open	Open
BNLI	CS IA to IIA HD with or without splenic irradiation	A: 4 cycles of VAPEC-B + subtotal nodal and splenic irradiation B: 20-Gy involved-field radiotherapy	Open	Open
SWOG/CALGB	CS IA to IIA HD with or without splenic irradiation	A: 3 cycles of adjuvant doxorubicin and vinblastine + subtotal nodal and splenic irradiation B: 4 cycles of adjuvant doxorubicin and vinblastine + subtotal nodal and splenic irradiation	Open	Open
EORTC H8F	CS IA to IIA HD with or without splenic irradiation	A: 3 cycles of MOPP/ABV hybrid + subtotal nodal and splenic irradiation B: 4 cycles of MOPP/ABV hybrid + subtotal nodal and splenic irradiation	Open	Open
Stanford V	CS IA to IIA HD with or without splenic irradiation	A: 12 weeks of Stanford V regimen + subtotal nodal and splenic irradiation B: 8 weeks of Stanford V regimen + subtotal nodal and splenic irradiation	Open	Open

**TABLE 45.6-9.** Clinical Trials in Favorable-Prognosis Stage I–II Hodgkin's Disease: Trials to Identify the Optimal Number of Chemotherapy Cycles

The GHSB HD7 trial (1994 through 1998) randomized 643 favorable CS IA to IIB HD patients to subtotal nodal and splenic irradiation alone or to two courses of ABVD and the radiotherapeutic regimen. A preliminary analysis of 365 patients showed an advantage in FFTF in the patients receiving ABVD (96%) as compared to those treated with irradiation alone (87%;  $P = .05$ ) (see [Table 45.6-9](#)).<sup>181</sup>

Several questions are raised by this study. First, with an expected long-term FFTF in favorable CS IA to IIA HD of approximately 70% to 75% with radiotherapy alone, is the added benefit in FFTF with two cycles of ABVD worth the extra risk from the doxorubicin and bleomycin? Second, is it more difficult to salvage patients whose disease recurs after subtotal nodal and splenic irradiation and two cycles of ABVD than after subtotal nodal and splenic irradiation alone? These are questions that can be answered only with longer follow-up.

The GHSB HD10 trial (opened in 1998) has essentially the same eligibility criteria as does the GHSB HD7 trial. Patients are to be randomized to four arms, namely the four combinations of two or four cycles of ABVD followed by 20- or 30-Gy involved-field radiotherapy. This trial should help to determine the number of cycles of ABVD needed to control occult HD in the abdomen and to prevent recurrence of HD in apparently uninvolved sites adjacent to known HD (adjacent to the irradiated involved site). It should also help to determine the dose of radiation needed to control HD when combined with limited chemotherapy.

In a Manchester pilot study and a BNLI trial, VAPEC-B chemotherapy is given for 4 weeks, followed by involved-field irradiation or mantle irradiation alone. Preliminary reports from the Manchester pilot study using the relatively brief 4-week VAPEC-B regimen in early-stage HD provide background data for the ongoing BNLI trial. In the Manchester study, 111 CS IA to IIA patients without mediastinal bulk have been randomized since 1989 to receive either limited radiotherapy alone or VAPEC-B followed by local irradiation only to the involved regions. With a median follow-up time of 3.3 years, there have been only two recurrences in the VAPEC-B-plus-local irradiation arm (progression-free survival rate at 3 years, 91%).<sup>182</sup> The current BNLI study has a similar design; however, the radiotherapy-alone arm includes full mantle irradiation rather than a more limited field (see [Table 45.6-9](#)).

The Southwest Oncology Group–Cancer and Leukemia Group B (SWOG/CALGB) study of three cycles of adjuvant doxorubicin and vinblastine plus subtotal nodal and splenic irradiation versus subtotal nodal and splenic irradiation alone in CS IA to IIA HD patients is ongoing (see [Table 45.6-9](#)). As of June 1998, 284 patients have been enrolled in the study (information provided courtesy of Dr. Todd Wasserman, CALGB update, June 1998). Of these, 162 patients have been evaluated for short-term toxicity. The questions raised by this study are similar to those for the GHSB HD7 study, including the potential extra toxicity of the doxorubicin and vinblastine in a group of patients with an expected favorable prognosis with treatment by radiotherapy alone and the overall strategy in trial design of giving enough chemotherapy to eliminate the need for abdominal irradiation.

The EORTC H8F trial (1993 through 1998), which compares three cycles of MOPP/ABV hybrid and involved-field irradiation to mantle and paraaortic-splenic irradiation for favorable-prognosis CS IA to IIA patients, was activated in 1993 (see [Table 45.6-9](#)). This trial should answer the following important questions: Are three cycles of standard chemotherapy sufficient to control subclinical HD in favorable-prognosis CS IA to IIA patients? Can patients who experience relapse after three cycles of MOPP/ABV and involved-field radiotherapy be cured with an alternative treatment, short of HDCT and stem cell rescue? The one concern of the trial is the use of the hybrid regimen, which confers some risk of sterility and leukemogenesis in these favorable-prognosis HD patients. ABVD and EBVP are proposed for the H9 trials.

The modified Stanford V trial for early-stage favorable-prognosis HD involves a relatively short, but intensive, chemotherapeutic regimen given for 12 weeks to patients with poor-prognosis stage I to II disease.<sup>183</sup> A modification of this trial has been opened for favorable-prognosis CS IA to IIA patients using 8 weeks of the Stanford V regimen and modified involved-field irradiation to sites of initial involvement (identified radiographically as nodal enlargement of  $\geq 1.5$  cm). The chemotherapeutic regimen includes mechlorethamine (6 mg/m<sup>2</sup> in weeks 1 and 5), doxorubicin (25 mg/m<sup>2</sup> in weeks 1, 3, 5, and 7), vinblastine (6 mg/m<sup>2</sup> in weeks 1, 3, 5, and 7), prednisone (40 mg/m<sup>2</sup> on days 1 through 36, followed by tapering), vincristine (1.4 mg/m<sup>2</sup> in weeks 2, 4, 6, and 8), bleomycin (5 mg/m<sup>2</sup> in weeks 2, 4, 6, and 8), and VP-16 (60 mg/m<sup>2</sup> on days 15 and 16 and days 43 and 44). This regimen will evaluate the ability of brief but intense chemotherapy to control HD outside of initially involved sites in favorable-prognosis CS I to II patients.

**RADIATION VOLUME AND DOSE.** Two ongoing trials in favorable-prognosis early-stage HD are evaluating radiation dose to involved sites after chemotherapy. The GHSB initiated a trial, HD10, that compares 30-Gy with 20-Gy irradiation after two cycles of ABVD, as described previously in the section [Reduced Number of Chemotherapy Cycles](#) (see [Table 45.6-9](#)). The EORTC H9F trial is evaluating 36-Gy or 20-Gy irradiation or no radiation to involved sites in patients who have achieved a complete remission after six cycles of EBVP.

### Clinical Trials of Chemotherapy Alone

Probably the first published experience of the use of MOPP chemotherapy alone in early stages of childhood HD comes from Uganda, where no radiotherapy was available.<sup>184</sup> Several small, retrospective studies have also reported treatment with MOPP alone.<sup>185</sup> On the basis of this limited experience, two randomized studies were devised to compare radiotherapy alone to MOPP chemotherapy alone in laparotomy-staged patients; both studies have median follow-up times of 7.5 to 8 years. Although both studies now are dated because of the use of the MOPP regimen and the requirement for staging laparotomy, results from these trials provide valuable information for the design of future protocols.

**CHEMOTHERAPY VERSUS RADIATION.** The NCI study was initially designed to include patients with intermediate-prognosis HD.<sup>186</sup> Although the trial included patients with favorable-prognosis PS IIA disease, the most favorable patients (PS IA patients with peripheral sites) were not included in the trial and were treated with radiotherapy alone. Patients with an unfavorable prognosis (B-symptoms, LMA, and limited stage III disease) were included in the trial. Patients were randomized to 6 months of MOPP chemotherapy alone or to subtotal nodal irradiation alone. After researchers recognized that patients with massive mediastinal involvement and PS IIIA disease were not optimal candidates for radiotherapy alone, the randomization criteria were changed while the study was ongoing. No difference in disease-free or overall survival was seen at 10 years.

The Italian prospective study randomized patients with PS IA to IIA HD to receive either 6 months of MOPP alone or subtotal nodal irradiation alone.<sup>187</sup> There were no differences in freedom from progression. However, the survival rate was significantly higher in patients treated with radiotherapy alone (93%) than in those treated with chemotherapy alone (56%). The difference in survival was attributed to the inability to salvage patients who experienced relapse after MOPP chemotherapy; these results are similar to the poor results of salvage ABVD in patients who experienced relapse after MOPP for advanced HD.

Both the NCI and the Italian studies demonstrated greater acute toxicities in patients who received MOPP chemotherapy. In the Longo et al.<sup>186</sup> study, more than 50% of patients treated with MOPP had at least one hospital admission for fever and neutropenia.

The NCIC CTG HD6 study (unpublished data) is a modification of the NCI and Italian studies, with randomization of clinically staged, rather than pathologically staged, patients and the use of ABVD as the chemotherapeutic regimen. Favorable-prognosis patients (NS or LP histology, age <40 years, ESR <50, one to three sites of involvement) are randomized to subtotal nodal irradiation and splenic irradiation versus four cycles of ABVD alone. This study will test the efficacy of four

In the EORTC trial, the recurrence rate was high enough to result in early closure of the trial. Although, in favorable-prognosis stage I to II HD, less toxic and less intense chemotherapeutic regimens have been effective in combined modality therapy programs, this does not appear to be the case for patients with unfavorable-prognosis disease. In the GATLA trial, the event-free survival was 66% for doxorubicin, vincristine, prednisone, and etoposide versus 85% for CVPP (  $P = .009$ ).<sup>188</sup> In the EORTC trial, the event-free survival was 68% for EBVP II and involved-field radiotherapy versus 90% for MOPP/ABV (  $P = .0001$ ).<sup>178</sup>

Several nonrandomized trials also have evaluated alternative chemotherapeutic regimens using a reduced number of cycles of chemotherapy or modified chemotherapeutic regimens.<sup>192,193</sup> It is worth noting one recent trial: At Stanford, the Stanford V regimen, administered for 3 months, was followed by involved-field irradiation to 36 Gy in 38 patients with large mediastinal disease. No patients have experienced relapse or died (median follow-up, 40 months).<sup>194</sup>

Based mainly on trials in advanced HD, ABVD has become the standard regimen used in patients with CS I to II disease. A number of current trials compare combined modality therapy using ABVD with more intense, novel regimens. Both the EORTC H9U and GHSG HD11 studies of combined modality therapy are comparing four cycles of ABVD with four cycles of BEACOPP.<sup>181</sup> In the Eastern Cooperative Oncology Group (ECOG) 2496 trial of combined modality therapy, six cycles of ABVD are being compared to 3 months of the Stanford V regimen.<sup>194</sup>

### **Trials to Identify the Optimal Number of Cycles of Chemotherapy**

Two large, randomized trials are currently evaluating whether four cycles of combination chemotherapy and radiotherapy is sufficient treatment as compared to six cycles of chemotherapy and radiotherapy. The recently closed EORTC H8U study randomized patients to combined modality therapy with four or six cycles of MOPP/ABV, but the results have not yet been reported (see [Table 45.6-10](#)). The new EORTC H9U trial randomizes patients to four and six cycles of ABVD.<sup>181</sup> A number of retrospective or prospective single-arm studies have evaluated the role of the number of cycles of chemotherapy in patients with large mediastinal disease.<sup>193,195,196</sup> The results vary, and the number of patients studied is small; a more definitive answer will need to come from the large, randomized trials currently under way.

### **Trials to Identify the Appropriate Radiotherapy Volume**

Several randomized trials have addressed the question of radiotherapy volumes in combined modality programs. The French trial reported by Zittoun et al.<sup>197</sup> randomized 218 stage I to II unfavorable-prognosis patients to six cycles of MOPP sandwiched around involved-field (40-Gy) or extended-field (40-Gy) irradiation. The 6-year disease-free survival rates were 87% and 93%, respectively (  $P = .15$ ). The Milan study reported by Hoppe et al.<sup>197a</sup> incorporated only 4 months of chemotherapy (ABVD), followed by involved-field (36-Gy) or subtotal nodal irradiation (30 to 36 Gy). The 5-year freedom-from-progression rates were 96% and 93%, respectively ([Table 45.6-11](#)).

Trial	Eligible	Treatment Regimens	No. of Patients	Outcome*
French Group no 97b/98	CS I-II and age 16 to 75 without prior therapy	A: 1 MOPP + 1 BE + 1 BE + 1 MOPP B: 1 MOPP + 1 BE + 1 BE + 1 MOPP	42	DFS: 87% vs 93% NS
Milan 1997-2002	CS I-II	A: 4 ABVD + 1 BE B: 4 ABVD + 1 BE	45	FFP: 96% vs 93% NS
EORTC 2496 HD11	CS I-II and age 16 to 75 without prior therapy	A: 4 ABVD + 1 BE + 1 BE + 1 MOPP B: 4 ABVD + 1 BE + 1 BE + 1 MOPP	45	FFP: 96% vs 93% NS
GHSG HD11	CS I-II and age 16 to 75 without prior therapy	A: 1 MOPP + 1 BE + 1 BE + 1 MOPP B: 1 MOPP + 1 BE + 1 BE + 1 MOPP	45	FFP: 96% vs 93% NS

**TABLE 45.6-11. Randomized Clinical Trials in Unfavorable Prognosis Stage I–II Hodgkin's Disease: Trials to Identify the Appropriate Radiation Volume**

The three-arm EORTC/Groupe d'Etude les Lymphomes de l'Adulte H8U trial, randomized patients to four cycles of MOPP/ABV plus involved-field irradiation or subtotal nodal irradiation.<sup>197b</sup> The GHSG HD8 trial, conducted between 1993 and 1998, used two cycles (4 months) of COPP/ABVD followed by either involved-field or extended-field irradiation to 30 Gy (see [Table 45.6-11](#)).<sup>197b</sup> Preliminary evidence from these randomized trials as well as from several nonrandomized studies suggests that radiation fields may be safely limited to involved regions in most combined modality programs when chemotherapy is given over 4 months or more.<sup>198,199</sup>

### **Trials of Chemotherapy Alone versus Combined Modality Therapy**

Only one prospective trial of chemotherapy alone versus combined modality therapy in unfavorable-prognosis stage I to II disease patients has been reported. The GATLA randomized 104 patients with unfavorable disease characteristics to six cycles of CVPP alone or six cycles of CVPP sandwiched around involved-field irradiation (30 Gy).<sup>200</sup> The 7-year survival rates were 66% and 84%, and the freedom-from-relapse rates were 34% and 75% (  $P < .001$ ), both favoring combined modality treatment.

The ongoing NCI of Canada (NCI-C) HD6 trial evaluates patients with unfavorable disease characteristics but excludes patients with LMA or bulky disease. Patients are randomized to receive combined modality therapy with two cycles of ABVD followed by irradiation (an extended mantle plus splenic irradiation or mantle plus paraaortic and splenic irradiation) or four to six cycles of ABVD alone (depending on the rapidity of response).

### **Recommendations and Future Directions**

The outcome of treatment for patients with unfavorable-prognosis stage I to II HD has improved dramatically since the 1970s. Mainly, this is due to the use of combined modality therapy, as historically either radiotherapy alone or chemotherapy alone was associated with recurrence rates of approximately 50%. Current clinical trials are exploring new combinations of radiotherapy and chemotherapy to try to reduce late morbidity and mortality while maintaining a high probability of freedom from first recurrence.

## **ADVANCED-STAGE DISEASE**

### **Basic Regimens: MOPP and ABVD**

**MECHLORETHAMINE, VINCRISTINE (ONCOVIN), PROCARBAZINE, AND PREDNISONE.** Initially the four-drug MOPP program was administered with each drug given at full dose over 2 weeks, resulting in a complete remission rate of 81%. Complete remission rates of 73% to 81%, long-term freedom from progression of 36% to 52%, and long-term overall survival of 50% to 64% were obtained in major trials of MOPP in advanced-stage HD.<sup>201,202 and 203</sup>

Despite the good initial results with MOPP therapy, several groups investigated alternative regimens to improve the efficacy or reduce toxicities. The CALGB showed that omission of the alkylating agents nitrogen mustard or procarbazine from the MOPP regimen were associated with inferior complete remission rates.<sup>204</sup> Thus, the four-drug principle was considered a standard at that time, to which all alternative combinations had to be compared.

Modifications of the MOPP scheme included the substitution of an alkylating agent such as cyclophosphamide or chlorambucil for mechlorethamine (COPP) or a vinca alkaloid such as vinblastine or vincristine for Oncovin (MVPP), as well as alteration of the doses of procarbazine and prednisone.

The ECOG developed a five-drug regimen containing BCNU, cyclophosphamide, vinblastine, procarbazine, and prednisone (BCVPP) with MOPP.<sup>205</sup> Their results showed that BCVPP had a significantly higher freedom-from-progression rate (50% vs. 33%) and overall survival rate (83% vs. 75%) than did MOPP at 5 years.

However, the interpretation of these results is complicated by the inclusion of previously treated patients.

In the United Kingdom, the MVPP combination was used, which revealed comparable results to MOPP, with complete remission rates of 60% to 80% and 5-year overall survival rates of 70% to 80%.<sup>206,207</sup> Also in the United Kingdom, the chlorambucil, vinblastine, procarbazine, and prednisone (ChIVPP) regimen was developed and showed similar efficacy with less acute toxicity as compared to MOPP, although a randomized comparison was not performed. The BNLI performed a randomized trial to compare chlorambucil (Leukeran), Oncovin, procarbazine, and prednisone (LOPP) with MOPP. No significant differences were observed in complete remission or overall survival rates.<sup>208</sup> Taken together, several MOPP-like regimens showed similar efficacy with less acute gastrointestinal and neurologic toxicities.

**ADRIAMYCIN, BLEOMYCIN, VINBLASTINE, AND DACARBAZINE.** MOPP and its derivatives had two limitations: Only approximately 50% of patients could be cured, and the alkylating agent–based combination was associated with an increased risk of sterility and acute leukemia. In an attempt to develop a regimen for patients in whom MOPP had failed, Bonadonna et al.<sup>209</sup> introduced the ABVD regimen. Vinblastine had demonstrated high activity as a single agent and lacked cross-resistance with vincristine in human tumors. Both doxorubicin and bleomycin were very active drugs and showed objective responses in approximately 50% of patients. Dacarbazine was added because it was active as a single agent and also showed synergism with doxorubicin.

The Milan group compared three cycles of MOPP or ABVD followed by extended-field irradiation and three additional cycles of the same chemotherapy.<sup>210</sup> A significant difference in favor of ABVD could be achieved, with freedom-from-progression rates of 63% for MOPP versus 81% for ABVD.

Both MOPP and ABVD were highly active regimens and had nonoverlapping toxicities. It was therefore straightforward to test combinations of MOPP and ABVD to further increase treatment results. The Milan group randomized patients with stage IV disease to MOPP or MOPP/ABVD for up to 12 cycles. The results were emphatically in favor of the alternating program, with a statistically significant difference in freedom from progression at 8 years (36% MOPP vs. 65% MOPP/ABVD;  $P < .005$ ).<sup>205</sup> Subsequently, three large cooperative trial groups (ECOG,<sup>211</sup> CALGB,<sup>211a</sup> and EORTC<sup>212</sup>) have confirmed these results and demonstrated superior results with the combination of MOPP/ABVD over MOPP or a MOPP derivative. ECOG compared the MOPP derivative BCVPP with MOPP followed by ABVD. Both complete remission and overall survival rates were superior with the MOPP/ABVD combination.

The CALGB tested, in a three-arm trial, six to eight cycles of MOPP, six to eight cycles of ABVD, and 12 cycles of MOPP alternating with ABVD.<sup>211</sup> At 10 years, the failure-free survival rates were 38% for MOPP, 55% for ABVD, and 50% for MOPP/ABVD, with a probability value of .02. Overall survival was not significantly different among the three arms, although there was a trend in favor of ABVD or MOPP/ABVD as compared to MOPP alone.<sup>211</sup>

The EORTC compared two courses of MOPP alternating with two courses of ABVD to a total of eight courses.<sup>212</sup> Radiotherapy was given to initial bulk or residual masses after chemotherapy. MOPP/ABVD showed a significantly higher failure-free survival rate at 6 years (43% MOPP vs. 60% MOPP/ABVD).<sup>212</sup>

Thus, ABVD alone and MOPP/ABVD are more effective than MOPP alone. In addition, ABVD alone offers the advantage of less acute and long-term toxicities.

**DURATION OF THERAPY.** In the original NCI studies of MOPP, two additional monthly cycles were given after a complete remission was achieved.<sup>213</sup> Viviani et al.<sup>164</sup> initially applied up to 12 cycles of MOPP and later, in the alternating program, eight cycles without reduction in efficacy. The CALGB trial demonstrated that eight cycles of ABVD was comparable to 12 cycles of alternating MOPP/ABVD.<sup>214</sup> A total of eight to 12 cycles of chemotherapy was given in the more recent phase III trials. Thus, although the optimal duration is not known precisely, eight cycles of MOPP, ABVD, or a combination appear to be sufficient.

### **Hybrid Regimens**

The theoretic basis for multidrug regimens is the predicted advantage of the early introduction of all active agents to avoid resistant tumor cell clones. This idea is based on a model proposed by Goldie and Coldman,<sup>215</sup> who related the drug sensitivity of tumors to their spontaneous mutation rate. The model formed the basis of “hybrid” schemes, which were tested by several groups in advanced-stage HD.

Groups in Vancouver and Milan independently designed two hybrids of MOPP and ABVD to test the Goldie-Coldman hypothesis prospectively.<sup>215</sup> The NCI-C compared the MOPP-ABV hybrid with alternating MOPP/ABVD in patients with stage IIIB or IV HD. At 5 years, there was no significant difference in the overall survival rates between both arms, although the hybrid regimen was associated with higher hematologic and nonhematologic toxicities.<sup>216</sup>

The Milan group compared their MOPP/ABV hybrid with alternating MOPP/ABVD. Freedom-from-progression and overall survival rates at 10 years revealed no significant difference between the hybrid and alternating arms.<sup>164</sup>

The GHSG compared a new hybrid scheme—COPP, ABV, and ifosfamide, methotrexate, and etoposide (IMEP) with their standard COPP/ABVD. Complete remissions, FFTF, and overall survival rates showed no statistically significant difference between the two treatment arms.<sup>217</sup>

A second intergroup trial<sup>217a</sup> that compared an MOPP/ABV hybrid with ABVD was performed in the United States, recruiting a total of 856 patients with stage III or IV HD or recurrent disease after radiotherapy. This study was prematurely stopped by the Data and Safety Monitoring Board because an excess of treatment-related deaths and second malignancies with the hybrid regimen was observed. At 3 years, similar failure-free survival rates were observed for ABVD (65%) and MOPP/ABV (67%). From this trial, it was concluded that ABVD and MOPP/ABV are equally effective but that ABVD is less toxic and should remain the standard treatment.

The potential relevance of scheduling was exemplified in a recent BNLI study in which a significant difference was found between a LOPP and etoposide, vincristine, and Adriamycin (EVA) hybrid and LOPP alternating with EVA that contained identical total doses. The complete remission was significantly less in the hybrid arm, and the trial was stopped prematurely.<sup>218</sup>

To summarize, the Goldie-Coldman hypothesis could not be proven in advanced-stage HD, although this could be due to the fact that the optimal hybrid regimen has not been identified thus far. ABVD has emerged as the standard against which newer treatments must be compared. With ABVD, 60% to 70% of patients will be free of disease at 5 years. ABVD is much less likely to cause severe myelotoxicity, acute leukemia, or sterility than are treatment programs that contain significant doses of alkylating agents.

### **New Chemotherapeutic Regimens**

The success of ABVD in the CALGB and in the intergroup trials indicated that alkylating agents are not essential for curative treatment for advanced HD. However, the pulmonary toxicity of bleomycin, which is especially pronounced in children and in combination with mediastinal irradiation, remains a major concern with ABVD. A number of drugs showing high efficacy in relapsed HD have become candidates for use in first-line therapy. The topoisomerase inhibitor etoposide has gained special interest among several groups, as a 20% to 60% response rate in refractory HD was reported with single-agent etoposide.<sup>219</sup> On the basis of these considerations, several etoposide-containing drug regimens have been developed.

At Stanford, the five-drug regimen Stanford V was developed.<sup>183</sup> The program was applied weekly over a total of 12 weeks. Sophisticated consolidative radiotherapy to sites of initial bulky disease was used. In this phase II trial, 126 patients had been recruited. The estimated 5-year freedom-from-progression rate was 89%, and the overall survival was 96% at a median observation time of 4.5 years in this single-center study. Reduced long-term toxicities with preserved fertility was a major goal and could be achieved both in men and women. An intergroup trial of Stanford V versus ABVD has been initiated in selected patients with low-risk advanced HD.

Similarly, the Manchester group developed an abbreviated, 11-week chemotherapeutic program, VAPEC-B. In a randomized trial, VAPEC-B and the hybrid ChIVPP/EVA were compared with radiotherapy applied to previous bulky disease or residual disease.<sup>220</sup> This study was stopped after 26 months owing to a threefold increase in the rate of progression after VAPEC-B.

The Southampton group developed another abbreviated, weekly chemotherapeutic regimen consisting of PACE-BOM.<sup>221</sup> Radiotherapy was applied to residual disease. A 64% failure-free survival was reported after a median observation time of 5 years.

Caution should be exercised when comparing results of different trials; particularly the amount of consolidative radiation, can vary widely. Large, randomized trials

provide the only reliable comparisons between regimens. [Table 45.6-12](#) shows the doses and scheduling of polychemotherapeutic regimens in HD.

**TABLE 45.6-12.** Polychemotherapy Regimens Used in Hodgkin's Disease

### ***Dose and Dose Intensity***

In several animal models, a clear relationship between chemotherapy dose and tumor response has been demonstrated. In HD, retrospective analyses of drug delivery with MOPP chemotherapy showed that patients receiving less than the optimal doses had inferior results. [222](#) Such dose effects were detected independently with mustard, procarbazine, and vincristine.

Until recently, no prospective randomized trials to analyze the role of dose intensity in the treatment of advanced HD had been conducted. There are two principal ways to test dose intensity: Doses of cytotoxic drugs can be intensified by increasing individual drug dose or by shortening the interval between treatments (or both). Gerhartz et al. [223](#) compared COPP/ABVD with a dose- and time-escalated COPP/ABVD regimen given with granulocyte-macrophage colony-stimulating factor support. The delivered dose intensity in the dose-intensified arm was 1.22, as compared with 0.92 in the standard arm (1.0 = standard intended dose). The preliminary analysis revealed a higher complete remission rate in the intensified arm, but definite results have not been reported yet.

The GHSG has conducted a series of clinical trials to address the role of dose intensity in advanced HD in a comprehensive way. A mathematic model of tumor growth and chemotherapeutic effects was developed and fitted to the data from 705 patients treated by the GHSG. [224](#) This model predicted that moderate dose escalation would increase tumor control by 10% to 15% at 5 years. The BEACOPP regimen was devised and used as a standard combination for dose escalation. [225](#) After establishing excellent tolerability as well as efficacy in a pilot trial, a second study of escalated BEACOPP was performed in which doxorubicin was increased to a fixed level and doses of cyclophosphamide and etoposide were increased in a stepwise fashion with granulocyte colony-stimulating factor support. [226](#) Maximum practicable doses were found to be 190% of cyclophosphamide and 200% of etoposide.

The GHSG then designed a three-arm study comparing COPP/ABVD, standard BEACOPP, and escalated BEACOPP in patients with advanced HD. [227](#) Radiotherapy was prescribed for bulky disease at diagnosis or for residual disease after eight cycles of chemotherapy, and approximately two-thirds of patients received consolidative radiotherapy. In 1996, at the time of a planned interim analysis, the COPP/ABVD arm of this trial was closed to accrual because of superior outcomes in the combined BEACOPP arms. [227](#) In a subsequent interim analysis, with 1070 patients evaluated, superior FFTR results were seen with escalated BEACOPP (88%) versus standard BEACOPP (79%) and COPP/ABVD (69%). A major difference was observed in the rate of primary progressive disease during initial therapy, which was significantly lower with escalated BEACOPP (2%) versus BEACOPP (8%) and COPP/ABVD (12%). Although there was a trend in the overall survival rate in favor of BEACOPP, this was significant only at the time of this interim analysis.

As expected, escalated BEACOPP was associated with greater hematologic toxicity, including a greater use of both red blood cell and platelet transfusions. Second malignancies, including acute myeloid leukemia possibly related to etoposide, were reported with BEACOPP. However, the rate of secondary high-grade NHLs was similarly reduced after escalated BEACOPP. The mature data from this important study, particularly with survival as an end point, are awaited with great interest.

HDCT frequently is used in patients with first or later relapses of HD. Numerous phase II trials and two randomized trials from the BNLI and the GHSG have shown superior results with a high-dose program as compared to conventional treatment. [228](#), [229](#) and [230](#) In advanced-stage HD, limited data concerning the role of HDCT are available. The Genua group of Carella et al. [231](#) conducted a phase II trial of myeloablative therapy and autografting among patients with poor-risk features as described by Straus et al. [232](#) Subsequently, the European Bone Marrow Transplant Registry (EBMT) initiated a prospective study in poor-risk patients comparing HDCT and autografting with additional chemotherapy after four cycles of ABVD-containing chemotherapy. Proctor et al. [165](#) have used their previously published model to identify patients at risk for an ongoing study in which patients are randomized to additional chemotherapy or HDCT and autografting after three cycles of a hybrid regimen and radiotherapy to bulky sites. [232](#) No interim results of these studies have yet been published.

### ***Role of Radiotherapy***

The ability of radiotherapy to provide local control in HD is well established. Furthermore, radiotherapy is non-cross-resistant with standard combination chemotherapy. However, the role of radiotherapy in advanced-stage HD is still controversial. Despite this uncertainty, most large trial groups include some radiotherapy as an integral part of their advanced-stage treatment strategy.

The potential contribution of radiotherapy depends on a variety of factors, including patient parameters (e.g., age, stage of the disease, and tumor mass) and the chemotherapy program. The field and dose influence efficacy and toxicity. Radiotherapy in advanced HD can be considered in three clinical settings. First, radiotherapy may be used as an adjuvant after complete remission with standard chemotherapy. Second, radiotherapy may be an integrated component of a combined modality program, possibly with reduced or brief chemotherapy. Finally, radiotherapy can serve as a non-cross-resistant treatment for patients with partial or uncertain response after chemotherapy.

There have been several reports indicating that patients treated with chemotherapy alone failed to completely respond or progressed, primarily in previously involved nodal sites. In the SWOG study, 80% of relapses after MOP-BAP chemotherapy were detected in initially involved sites. [233](#) A number of authors have reported that approximately 30% of selected patients who experienced relapse after chemotherapy can achieve long-term remissions with radiotherapy. However, the benefits of consolidative radiotherapy must be balanced against the risk for serious side effects, particularly second malignancy in the irradiated field.

A number of phase III trials investigated the role of consolidative radiotherapy after primary chemotherapy, with divergent results. After MOP-BAP chemotherapy, 61% of patients who achieved complete remission were randomized to low-dose involved-field radiotherapy or to no further treatment in a SWOG study. [233](#) In this trial, no significant differences in remission duration or overall survival were detected.

The GHSG analyzed the role of low-dose (20-Gy) involved-field radiotherapy versus two cycles of additional chemotherapy consolidation in 288 patients in complete remission after initial chemotherapy with COPP/ABVD. There was no significant difference in freedom-from-progression or overall survival rates between the treatment arms. [234](#)

To overcome the insufficient power of the randomized studies with too few patients to detect a relevant difference, Loeffler et al. [235](#) performed a metaanalysis of 14 studies involving more than 1700 patients in total. Two study designs were compared: In the additional design, the same chemotherapy with and without additional irradiation was compared, whereas in the parallel design, irradiation following chemotherapy was compared with further cycles of chemotherapy.

In the additional design, radiotherapy reduced the hazard rate by approximately 40%. The benefit of irradiation was more pronounced among patients with mediastinal involvement and provided no reduction in relapse among patients with stage IV disease. There was no survival benefit detected by radiotherapy in any subgroup analyzed. In the parallel design, there was no significant difference in disease-free survival. However, overall survival was significantly higher among patients treated

disease after salvage treatment is vital, because salvage therapies generally are more intense and more toxic than are first-line regimens. In salvage therapy studies, the response criteria usually are defined as in first-line therapies. In most series reported, however, a minimum duration of response of 4 weeks after the end of a salvage therapy is required.

### Prognostic Factors

The likelihood of successful salvage therapy is determined by biologic features, which may be linked to certain clinical features. Adverse prognostic factors for patients with treatment failure include the treatment modality used in first-line therapy, patient age, relapse sites, quantity of disease at relapse, and presence or absence of systemic symptoms. In addition, the duration of first remission is a major determinant of a second complete response.

It was first noted in 1979 that the length of a remission after first-line chemotherapy had a marked effect on the ability of patients to respond to subsequent salvage treatment.<sup>241</sup> In 1992, the NCI updated their experience with the long-term follow-up of patients who experienced relapse after polychemotherapy.<sup>242</sup> Derived primarily from investigations involving failures after MOPP and MOPP variants, the conclusions are relevant to other chemotherapeutic programs. On this basis, chemotherapy failures can be divided into three subgroups:

- Primary progressive HD (approximately 10% of all cases)—that is, patients who never achieved a complete remission
- Early relapses within 12 months of complete remission (approximately 15% of all cases)
- Late relapses after complete remission lasting longer than 12 months (approximately 15% of all cases)

Using conventional chemotherapies for patients with primary progressive disease, virtually no patient survives more than 8 years. In contrast, for patients with early relapse or late relapse, the projected 20-year survival was 11% and 22%, respectively.<sup>242</sup>

Patients in whom treatment with first-line radiotherapy, combination chemotherapy, or combined modality therapy fails can be divided into two groups and their treatment selected accordingly: relapse after irradiation for early-stage disease and relapse after primary chemotherapy.

**RELAPSE AFTER IRRADIATION FOR EARLY-STAGE DISEASE.** Primary radiotherapy alone has been used more extensively in the past than in current practice. The survival of patients treated with conventional chemotherapy after relapse of irradiated early-stage disease is at least equal to that of advanced-stage patients initially treated with chemotherapy. Overall survival and disease-free survival range from 57% to 71%.<sup>163,243,244</sup>

Patients who experience relapse after radiotherapy alone for localized HD (stage I and II) have satisfactory results with combination chemotherapy and are not considered candidates for HDCT and autologous stem cell transplantation (ASCT). The relapse rates after radiotherapy varied from 19% to 35%, the highest rates being in the series that included only clinical rather than laparotomy staging. The majority of patients in these series had salvage treatment based on MOPP or similar regimens. The range of 10-year survival was 57% to 71%, resembling the results of primary treatment with MOPP in patients with advanced disease. This suggests that prior radiotherapy does not cause drug resistance or a clinically significant compromise of chemotherapy dose intensity.

Stage at relapse is an important prognostic variable in radiotherapy failures. A study from Stanford including more than 100 patients with relapsed HD after subtotal or total nodal irradiation showed that conventional salvage chemotherapy is sufficient in patients with limited-stage disease having no systemic symptoms on recurrence (stage IA and IIA); after 10 years, 90% of these patients remained disease-free.<sup>244</sup> In contrast, the 10-year disease-free survival for those with stage III and IV disease or with B-symptoms (all stages) at the time of relapse was 58% and 34%, respectively. An analysis using the International Database on Hodgkin's Disease showed a worse prognosis for patients whose relapse included an extranodal site and stage IV at relapse and for those patients older than 40 years.<sup>245</sup>

Patients with LP or NS histology fared better than did those with MC or LD histology: Ten-year freedom from relapse for patients with favorable histologies was 67% versus 47% ( $P = .04$ ) for patients with unfavorable histologies.<sup>243,246,247</sup>

The original experience using systemic therapy for radiation failures was based on the use of MOPP. The likelihood of freedom from second relapse was 57% at 10 years.<sup>248</sup> However, sufficient data from doxorubicin-based regimens indicate that the principles for selecting a salvage regimen for a relapse after radiotherapy are the same as the principles for selecting a primary treatment for advanced disease. On the basis of the available evidence, ABVD has superior effects as compared with MOPP for radiation recurrence. The Milan Cancer Institute observed a disease-free survival rate of 81% with ABVD variants, as compared to 54% with MOPP.<sup>249</sup>

**RELAPSE AFTER PRIMARY CHEMOTHERAPY.** Treating recurrence after primary chemotherapy is a difficult issue. The choices available are salvage radiotherapy, conventional salvage chemotherapy, and HDCT followed by ASCT.

**Salvage Radiotherapy.** There are relatively few instances in which radiotherapy alone would be considered the standard salvage treatment because the perception is that recurrence indicates disseminated disease. However, salvage radiotherapy offers a potentially curative option with low morbidity for a subset of selected patients. Salvage radiotherapy is a valid treatment alternative in patients without B-symptoms who have not been given radiation previously or who experience relapse locally outside the initial radiation field.

This approach has been reported in series of more than 100 patients. Wirth et al.<sup>250</sup> reported the experience of salvage radiotherapy in 51 patients with relapsed or refractory HD. Twenty-three patients (45%) achieved a complete response after irradiation. Five-year failure-free survival and overall survival rates were 26% and 57%, respectively. Significant prognostic factors for failure-free survival were B-symptoms at the time of salvage radiotherapy, extranodal involvement, and histology. For overall survival, significant factors were B-symptoms, patient age, and number of prior chemotherapeutic regimens. For patients who relapsed in supradiaphragmatic nodal sites without B-symptoms, 5-year failure-free survival and overall survival rates were 36% and 75%, respectively.

**Table 45.6-16** demonstrates that selected patients who experience relapse after chemotherapy in an isolated nodal site without systemic symptoms can be salvaged by radiotherapy alone. Comparing radiotherapy with other types of salvage treatment is difficult, because the selection criteria for the different forms of treatment vary and no randomized study exists.

No. of Patients	FFP	OS	Prognostic Factor for FFP	Reference
53	26% (5 y)	57% (5 y)	B-symptoms, extranodal sites, histology	250
44	38% (5 y)	48% (5 y)	Extranodal sites	349
28	40% (5 y)	63% (5 y)	Duration of response	350
10	38% (5 y)	60% (5 y)	nc	351

FFP, freedom from progression; nc, not evaluated; OS, overall survival.

**TABLE 45.6-16.** Salvage Radiotherapy Alone for Relapse after Chemotherapy

**Conventional Salvage Chemotherapy.** Since 1990, a number of new salvage chemotherapeutic regimens have been tested that incorporate drugs not used in the initial combination. Because most first-line management programs use MOPP, ABVD, or combinations of both, new salvage regimens have been designed anticipating resistance to these drugs in patients who have relapsed.<sup>251,252,253 and 254</sup>

Primary progressive disease and early relapse suggest cellular resistance to conventional doses of drugs. Patients with primary refractory HD on treatment with MOPP or alternative regimens usually respond poorly to second or third induction attempts and have a particularly poor prognosis (life expectancy <1.5 years). Fewer

than 50% of patients who experience relapse after a short initial remission achieve a second complete remission, even when treated with non-cross-resistant regimens, with a median survival of 2.5 to 4.0 years. For the vast majority of these patients, second-line chemotherapy followed by HDCT is required. In contrast, more than 80% of patients with late relapse achieve a second complete remission with MOPP or alternative regimens, having a median survival of less than 4 years.<sup>242</sup> The Milan and NCI data suggest that late relapse does not necessarily imply resistance, as retreatment with the initial first-line regimen may result in response. An important goal for any retreatment in late relapse is the achievement of a second complete response, as nearly 50% of second complete responses will result in prolonged progression-free survival.<sup>242,255</sup>

Table 45.6-17 lists the second-line salvage regimens for HD published since 1985. Detailed analysis and interpretation are difficult because, in some trials, the number of patients is small, the clinical status of patients varied, the duration of first remission is heterogeneous, and a large number of these patients also received subsequent HDCT plus ASCT. No randomized trial exists comparing the effectiveness of different conventional salvage chemotherapeutic regimens.

TABLE 45.6-17. Salvage Regimens for Hodgkin's Disease at Conventional Dosages

**High-Dose Chemotherapy Plus Stem Cell Support.** Most clinical results are derived from transplantation centers where a great deal of selection is used in referral and in the decision for HDCT and ASCT. The encouraging results from numerous phase II studies and analyses using transplantation registry data, as well as the reduction of early transplant-related mortality to less than 5%, have led to widespread acceptance of HDCT as an important component in the management of progressive and relapsed HD. HDCT followed by ASCT has been shown to produce 30% to 70% long-term disease-free survival in selected patients with primary progressive and relapsed disease.<sup>153,256,257</sup>

Although results with HDCT have generally been better than those observed after conventional-dose salvage therapy, the validity of this comparison has been questioned because of the lack of randomized trials. The most compelling evidence for the superiority of high-dose therapy in relapsed HD comes from two reports from the BNLI and the GHSG together with the EBMT. In the BNLI trial, patients with relapsed or refractory HD were treated with a combination of BEAM at a conventional-dose level (mini-BEAM) or a high-dose level (BEAM) with autologous bone marrow transplantation. The actuarial 3-year event-free survival was significantly better in patients who received HDCT (53% vs. 10%).<sup>258</sup>

The largest randomized, multicenter trial was performed by the GHSG/EBMT to determine the benefit of HDCT in relapsed HD. Patients with relapse after polychemotherapy were randomized between four cycles of dexamethasone-BEAM and two cycles of the dexamethasone-BEAM regimen followed by HDCT (with BEAM) and ASCT. The interim analysis of 142 evaluable patients revealed that for 115 patients with partial or complete response after two cycles of chemotherapy, the FFTF in the HDCT group was 53%, as opposed to 39% for the patients receiving an additional two cycles of conventional chemotherapy (Table 45.6-18).<sup>259</sup>

No. of Patients	Treatment	Outcome	P	Follow-Up	Reference
41	3 × Mini-BEAM	11% EFS	.05	3 y	258
	BEAM	53% EFS			
142	4 × Deca-BEAM	39% FFTF	.05	3 y	259
	2 × Deca-BEAM + BEAM	53% FFTF			

BEAM: BCNU, etoposide, arabinoside, and methylprednisolone; Deca-BEAM: dexamethasone, BCNU, etoposide, arabinoside, and methylprednisolone; EFS, event-free survival; FFTF, freedom from treatment failure.

TABLE 45.6-18. Randomized Studies in Relapsed Hodgkin's Disease: High-Dose Chemotherapy versus Conventional Salvage Therapy

**High-Dose Chemotherapy in Primary Progressive Hodgkin's Disease.** Patients with primary progressive disease, defined as progression during induction treatment or within 90 days after the end of treatment, have a particularly poor prognosis. Treatment of patients with primary progressive HD has consisted of salvage chemotherapy, radiotherapy, and HDCT with ASCT. Conventional salvage regimens have given disappointing results in the vast majority of patients: Response to salvage treatment is low, and the duration of response is often short. The 8-year overall survival ranges between 0% and 8%. FFTF in second remission is 0% at 4 to 8 years in small series reported.<sup>242,260</sup> Extensive disease often limits the use of radiotherapy.

In contrast, the data on HDCT and ASCT in these patients are more promising. The EBMT reported its analysis of 175 patients with primary progressive disease who received HDCT and ASCT.<sup>261</sup> The 5-year actuarial progression-free and overall survival rates were 32% and 36%, respectively. The Autologous Blood and Marrow Transplant Registry recently reported a progression-free survival of 38% and an overall survival of 50% at 3 years in 122 patients with primary induction failure.<sup>262</sup> In single-institution series evaluating the efficacy of HDCT exclusively in induction failures, Reece et al.<sup>263</sup> reported a 42% progression-free survival at a median of 3.6 years. Similarly, an updated report from Stanford University showed an event-free survival of 49% at 4 years.<sup>229</sup> Gianni et al.<sup>151</sup> reported an event-free survival of 31% at 4 years. The studies by Yuen et al.<sup>264</sup> and André et al.<sup>265</sup> reported improved outcome after HDCT and ASCT as compared with historical control groups given conventional chemotherapy for induction failures. Thus, HDCT and ASCT should be considered for HD patients with primary induction failure.

The GHSG retrospectively analyzed 206 patients with progressive disease to determine outcome after salvage therapy and to identify prognostic factors.<sup>266</sup> The 5-year freedom-from-second-failure and overall survival rates for all patients were 17% and 26%, respectively. As reported from transplantation centers, the 5-year freedom-from-second-failure and overall survival rates for patients treated with HDCT were 42% and 48%, respectively, but only 33% of all patients received HDCT. A high proportion of those patients will rapidly succumb to progressive disease. Life-threatening severe toxicity on salvage treatment occurred in 11% of the patients. Insufficient stem cell harvest, poor performance status, and older age had also contributed to ineligibility for HDCT. In a multivariate analysis, the Karnofsky performance score at progress ( $P < .0001$ ), age ( $P = .019$ ), and attainment of a temporary remission to first-line chemotherapy ( $P = .0003$ ) were significant prognostic factors for survival. In conclusion, HDCT is an effective treatment for a proportion of patients with primary progressive HD.<sup>267</sup> Owing to the poor outcome of HD patients with progressive disease, future trials must aim at identifying patients at very high risk for induction failure and modifying primary treatment in this group to avoid progressive disease.

**High-Dose Chemotherapy in Early and Late Relapsed Hodgkin's Disease.** Patients who receive transplantation at first relapse from complete remission can often be cured with HDCT and ASCT.<sup>257,268,269</sup> At present, patients with early relapse are good candidates for HDCT followed by ASCT. A report from Stanford in which historical controls were used found a 4-year event-free survival of 56% for patients with early relapse, as compared to 19% in patients who received standard-dose salvage chemotherapy.<sup>264</sup> In addition, the HDR-1 study showed improved FFTF for patients with early relapse after HDCT, as compared with conventional

chemotherapy.<sup>259</sup> Although the results reported with HDCT in patients with late relapse have been superior to those reported in most series of conventional chemotherapy, the use of HDCT in late relapses has been an area of controversy. Patients with late relapse have high second complete remission rates even with conventional chemotherapies and overall survival rates ranging from 40% to 55%. The HDR-1 study of the GHSG showed improved FFTF and overall survival after HDCT as compared with conventional chemotherapy in patients with late relapses. Therefore, HDCT should be considered as standard treatment even for patients with late relapses.<sup>259</sup>

Several published studies have evaluated the importance of prognostic factors for patients with HD undergoing HDCT with subsequent ASCT.<sup>228,257,270</sup> Adverse prognostic factors identified by multivariate analysis included age, chemoresistance, disease status, poor performance status, extranodal disease, female gender, elevated lactate dehydrogenase level, and failure of more than two prior regimens. An important variable that affects outcome is the ability of conventional salvage chemotherapy to reduce tumor volume before HDCT. Patients who experience relapse after chemotherapy but respond to subsequent conventional salvage therapy make up most of the long-term survivors in transplantation programs. Nevertheless, the role of conventional salvage chemotherapy before HDCT has not been clearly defined. Several studies have confirmed that a subset of patients with disease resistant to conventional salvage therapy clearly benefit from HDCT, with reported long-term survival of 10% to 31%.<sup>228,262,268,271</sup> The number of patients with chemoresistant disease who benefit from HDCT and ASCT largely depends on the definition of chemoresistance or the number and intensity of courses of chemotherapy administered to reduce the tumor burden. Accordingly, chemoresistant patients should not routinely be excluded from transplantation programs.

Allogeneic stem cell transplantation has clear advantages as compared with autologous transplantation: Donor cells uninvolved by malignancy are used, avoiding the risk of infusing occult lymphoma cells, which, despite purging, may contribute to relapse in patients who undergo autologous transplantation. In addition, donor lymphoid cells can potentially mediate a graft-versus-lymphoma effect. As in all allograft studies, issues of donor availability and age constraints have limited its use. Moreover, in all reports using allogeneic stem cell transplantation, a high treatment-related mortality rate of up to 75% was observed in patients with HD, which casts doubt on the feasibility of this approach in larger series.<sup>272,273</sup> and <sup>274</sup> In most circumstances, allogeneic transplantation from HLA-identical siblings is not recommended for patients with HD. The reduced relapse rate associated with a graft-versus-tumor effect is offset by lethal graft-versus-host toxicity.

In conclusion, patients who experience relapse after radiotherapy alone for localized HD have satisfactory results with combination chemotherapy and are not considered candidates for HDCT with ASCT. Current data support the use of HDCT with ASCT for patients with relapse and refractory HD after combination chemotherapy (Table 45.6-19).

Relapse after first-line radiotherapy	Conventional chemotherapy
Nodal relapse (CS I + II)	Salvage radiotherapy
No B-symptoms	
No prior radiotherapy	
Primary progressive disease	HDCT + ASCT
Early relapse	HDCT + ASCT
Late relapse	HDCT + ASCT

ASCT, autologous stem cell transplantation; CS, clinical stage; HDCT, high-dose chemotherapy.

**TABLE 45.6-19.** Recommendations for Treatment of Relapsed and Primary Progressive Hodgkin's Disease

### SPECIAL CASES: LYMPHOCYTE-PREDOMINANT HODGKIN'S DISEASE

The early-stage characteristics, indolent course, and relatively good prognosis of LP variants of HD have been recognized since the 1930s.<sup>275</sup> Earlier studies consistently demonstrated that patients with an LP variant of HD enjoyed a better prognosis than did those with other forms of the disease.<sup>276</sup> However, the introduction of clinical staging showed that the extent of disease was a more important prognostic factor than was histology and that the localized nature of LPHD could well account for the good prognosis of this subtype.<sup>277</sup> In addition, modern therapeutic strategies were able to improve survival and cure rates for all types of patients, and prognostic differences due to histology often were no longer evident.<sup>93,278</sup> The clinical relevance of the recent REAL<sup>75</sup> and WHO classifications, particularly the distinction between LPHD and LRCHD, has been clarified by the international retrospective study of the ETFL.<sup>279</sup> The many smaller studies of LPHD paint a similar picture.<sup>280,281</sup> and <sup>282</sup>

### CLINICAL FEATURES

LPHD patients show a similar age distribution to MC patients and are somewhat older, on average, than NS patients (Table 45.6-20). Approximately 75% of patients are male, again similar to MC and different from NS (approximately 50%). Of LPHD patients, 53% had stage I and only 6% had stage IV disease. Thus, the proportion of early stages is consistently high in comparison with CHD, and stage IV is consistently rare, although not negligible. B-symptoms were present in only 10% of cases, far less than in CHD. LPHD seems to favor the peripheral upper neck and inguinal node sites and to occur relatively seldom in central sites such as the mediastinum and upper abdomen.<sup>283</sup>

	LPHD (n = 219)	NSHD (n = 599)	MCHD (n = 174)
Median age (y)	35	30	35
Male gender (%)	74	49	73
Stage I (%)	53	10	21
Stage II (%)	28	47	32
Stage III (%)	14	29	35
Stage IV (%)	6	14	13
B-symptoms (%)	10	42	35

LPHD, lymphocyte-predominant Hodgkin's disease; NSHD, nodular sclerosis Hodgkin's disease; MCHD, mixed-cellularity Hodgkin's disease.

**TABLE 45.6-20.** Characteristics of 219 Cases Confirmed as LPHD in the European Task Force on Lymphoma Project Compared with Nodular Sclerosis and Mixed-Cellularity Cases in the 1988–1994 Trials of the German Hodgkin's Study Group

### TREATMENT RESULTS

There is some evidence to support the hypothesis that certain LPHD patients do well without any therapy beyond excision. Among the 51 nodular LP cases reported by Miettinen,<sup>284</sup> 31 were given no treatment except possibly surgical removal of the tumor, as malignant disease was not suspected. After 7 years' median follow-up, only seven of the untreated patients died. These results must be cautiously interpreted, as it is likely that especially mild examples would predominate in this retrospective sample. Most LPHD patients have received first-line therapy similar to that prescribed for CHD patients. LPHD cases appear to relapse just as frequently as other subtypes, but the relapse is less aggressive, resulting in frequent multiple relapses and good survival rates (see Fig. 45.6-2).

## TRANSFORMATION TO NON-HODGKIN'S LYMPHOMA

The possibility of occurrence of an NHL after primary LPHD is clinically important for several reasons. The treatment should be chosen to prevent development or progression of NHL; it should avoid inducing a secondary NHL; and a monitoring and diagnostic strategy should be chosen to detect and correctly identify recurrent and secondary tumors. In an analysis from the International Database on Hodgkin's Disease,<sup>285</sup> a significantly higher risk for secondary NHL, increased by a factor 1.8, was found for LP patients as compared with NS and MC patients. Several smaller LPHD studies report secondary NHL, indicating a rate of 2% to 3% on average. Miettinen et al.<sup>284</sup> reported four secondary NHLs among 31 cases of untreated LPHD, suggesting that some, if not all, such NHLs develop independently of treatment.

## CONSEQUENCES FOR FUTURE TREATMENT

Although, the prognosis superiority of LPHD as compared with CHD is scarcely discernible under modern treatment, the relatively good prognosis of LPHD cases under earlier, less intensive treatment does indicate a potential for treatment reduction. Furthermore, as many LPHD patients died of fatal treatment-related secondary leukemias and solid tumors as died from HD directly. This suggests that current treatment strategies might be too intensive, particularly when other late effects, such as cardiac and pulmonary complications, are taken into account. Disadvantages of treatment reduction could include the greater risk of disease progression or of development of NHL.

Caution is needed in identifying those patients for whom treatment reduction is an option. First, immunostaining is needed for a reliable differential diagnosis among LPHD, CHD, and certain NHL variants. Second, patients with advanced-stage LPHD (20% to 25%) had an overall survival and tumor-free survival that was substantially worse than that of patients with early-stage LPHD and was similar to advanced-stage CHD patients.<sup>279</sup> This implies that thorough staging and, in the case of advanced-stage disease, aggressive treatment are needed irrespective of histologic subtype.

A watch-and-wait treatment strategy, in which patients are monitored without treatment until the disease shows signs of progression, has been advocated for LPHD and for other indolent lymphomas. However, most authors report only anecdotal untreated cases.<sup>284</sup> A prospective study with explicit inclusion criteria is required to assess the feasibility, risks, and benefits of a watch-and-wait strategy. The EORTC is currently adopting a watch-and-wait approach for stage I supradiaphragmatic LPHD after complete resection of the tumor; the involved field is to be irradiated only if the disease progresses. The GHSG is now treating CS IA LPHD without risk factors with involved-field irradiation.

Involved-field radiotherapy has been shown to be inferior to more extensive irradiation in early-stage CHD but might be adequate for the very localized, less aggressive LP subtype. Two study groups, the EORTC and the GHSG, are currently treating certain early-stage LPHD patients with involved-field irradiation.

A new development potentially relevant to LPHD is the use of immunotherapy. The monoclonal antibody Rituximab, in particular, is directed against the B-cell-restricted CD20 antigen; this antigen is expressed by the L&H cells of LPHD but rarely by the H-RS cells of CHD. First experiences with indolent follicular B-cell lymphomas have shown good results, with nearly 55% overall responses even in heavily pretreated patients.<sup>286</sup> This therapy is now being tested by the GHSG in relapsed and refractory LPHD.

## HODGKIN'S DISEASE IN THE ELDERLY PATIENT

HD treatment results, reflected in complete remission, relapse, and survival rates, tend to worsen with increasing age of the patient at diagnosis. There is no definite threshold age for the onset of this effect, although many authors report changes appearing at approximately age 60 years and older.

HD rarely occurs in patients older than 60 years. Two basic problems in the management of elderly patients emerge as a recurrent theme: a high rate of toxicities during treatment and frequent early relapses. At least two factors are considered to contribute to this poor prognosis. First, older patients differ from younger patients in disease characteristics: Advanced clinical stage and MC histology<sup>287</sup> are more frequent. Second, the older patient may be more likely to experience treatment complications, which in turn influence the given intensity of therapy.

The patient's physical and mental condition, disease history, and the presence of concurrent disorders influence the treatment strategy. Age, in general, is not a contraindication for aggressive treatment. Biologically young patients in good physical and mental condition should be treated by stage-adapted regimens, analogous to conventional treatment protocols. In this subgroup, complete remission rates and relapse-free and overall survival appear to be as good as in younger cohorts.<sup>288</sup> Combined modality treatment with a mild chemotherapeutic regimen and limited radiation (i.e., two cycles of ABVD plus involved-field radiotherapy) is increasingly considered the standard therapy in favorable early-stage HD. If no chemotherapy can be administered, mantle or inverted-Y fields should be irradiated, possibly at a reduced dose. For the patients with intermediate-stage (unfavorable early-stage) disease, two to four cycles of chemotherapy may be administered before involved-field radiotherapy is undertaken.

In advanced-stage disease, treatment should also be given with curative intent. The well-established ABVD combination (six to eight cycles) represents a safe regimen, whereas protocols with severe hematologic toxicities should be avoided. The time-intensified BEACOPP regimen, which has proved especially effective in advanced-stage HD patients aged up to 65 years, appears to be too toxic for patients older than 65.<sup>289</sup> Support with hematopoietic growth factors (granulocyte colony-stimulating factor) should be given liberally, as infectious complications due to prolonged neutropenia are common. Close monitoring of toxicity (i.e., electrocardiography, echocardiography, pulmonary function tests) and response to treatment are important for adjusting treatment at an early juncture.

Treatment for those patients with impairment of lung, liver, heart, or kidney should be individually adapted. Depending on preexisting impairment of organs, single drugs with organ-specific toxicities (i.e., bleomycin, Adriamycin) may be omitted from the chemotherapeutic regimen, replaced, or modified in dose. Involved-field radiotherapy, oral combination therapy (CCNU, etoposide, prednimustine), or less aggressive drugs, such as gemcitabine<sup>290</sup> in the initial treatment as well as the combination of vinblastine, bleomycin, and methotrexate,<sup>291</sup> present possible treatment alternatives.

## HODGKIN'S DISEASE DURING PREGNANCY

The peak incidence of HD occurs at female reproductive age. Therefore, the association with pregnancy is not uncommon. One case of HD has been reported per 1000 to 6000 deliveries, making it the fourth most common cancer diagnosed during pregnancy.<sup>292</sup> Several studies have shown that pregnancy does not worsen the clinical course of the disease and that the 20-year survival of pregnant women with HD is not different from that of nonpregnant women.<sup>293</sup>

The clinical presentation of HD is not influenced by pregnancy. However, there are significant limitations on staging and treatment of the pregnant patient. CAT scanning should be avoided because it exposes the fetus to ionizing radiation. Ultrasonography, which is without known adverse fetal effects, is helpful not only for assessing fetal development but also for detecting the presence of lymphadenopathy. MRI will complete the radiologic staging because it appears to be free from genetic hazards. Decisions about the need for chest radiography should be made on the basis of clinical examination.

If HD is diagnosed in the first trimester, most experts agree that a therapeutic abortion should be encouraged. If the woman wishes to continue her pregnancy, treatment should be deferred until the second trimester at least, because the options for therapy at the beginning of pregnancy are rather limited. If therapy is indicated, supradiaphragmatic irradiation with doses less than 10 Gy or vinblastine chemotherapy for more advanced disease may be commenced.

In the second or third trimester, a stage I to II disease may be closely observed, and treatment should be postponed until an early delivery, usually at approximately 32 to 34 weeks' gestation. If there is any sign of rapid disease progression, in supradiaphragmatic lymphadenopathy radiotherapy alone is recommended. Most studies indicate doses of 10 to 44 Gy to the classic mantle field or the involved field, with abdominal shielding to protect the fetus. In the second and third trimesters, the risk of adverse sequelae for the fetus by supradiaphragmatic radiation is low. In infradiaphragmatic lymphadenopathy and in stage III to IV disease, combination chemotherapy will be the choice of treatment. Because most chemotherapeutic agents freely cross the placenta and enter the fetal circulation, both the patient and the fetus must be closely monitored. Chemotherapy administered in the second and third trimester may increase the risk of intrauterine growth retardation, microcephaly, and mental retardation.<sup>294</sup> Application of cytotoxic drugs shortly before birth may be particularly hazardous, as the placenta is also the primary means of drug elimination, and metabolism and excretion will be delayed in the neonatus. The current concept is that antimetabolites, especially methotrexate, confer a high risk of teratogenesis, whereas alkylating agents, Adriamycin, bleomycin, etoposide, and the vinca alkaloids would appear acceptable.<sup>294</sup> The ABVD regimen may be

used when chemotherapy is indicated beyond the first trimester. Because chemotherapeutic agents reach significant levels in milk, mothers are best advised not to breast feed during treatment.

## HODGKIN'S DISEASE IN HUMAN IMMUNODEFICIENCY VIRUS-POSITIVE PATIENTS

### EPIDEMIOLOGY AND CLINICAL PRESENTATION

The majority of recent studies demonstrate a slight increase in the incidence of HD in young adult and middle-aged homosexual men. They also suggest that, with regard to a certain risk behavior, HD associated with HIV infection occurs preferentially in intravenous drug users. An increased incidence of HD among such other risk groups as hemophiliacs or women with an increased risk for AIDS has not been convincingly demonstrated.

Several data support the thesis that EBV probably represents a relevant factor involved in the pathogenesis of HIV-associated HD. First, EBV is found in H-RS cells in nearly 80% to 100% of HD tissue specimens from HIV-infected patients, in contrast to the HIV-negative population with EBV in 50% to 70% of HD cases.<sup>295</sup> Second, a pathogenetic role of EBV in HIV-associated HD is supported by the fact that tumor cells of virtually all cases of HIV-associated HD express EBV-encoded LMP1.<sup>296</sup>

A characteristic of HD in HIV-infected patients is the predominance of unfavorable histologic subtypes.<sup>297</sup> Most studies from Europe and the United States reported MC to be the most frequent histologic subtype among HIV-infected patients (40% to 100%). NS was less frequent (0% to 40%) in the HIV population than in HIV-negative persons. The incidence of the LP subtype was rather low (0% to 4%); in contrast, more than 20% of all cases were classified as LD.<sup>298</sup>

At the time of diagnosis, 70% to 90% of all patients with HIV-associated HD present with advanced disease. Extranodal involvement is frequent (60%), the most common sites being bone marrow, liver, and spleen. In contrast to non-HIV-related HD in the general population, in which the involvement of contiguous lymph node groups is typical and dissemination and infiltration of extranodal sites are late occurrences, in HIV-infected patients noncontiguous spread of lymphoma, such as liver involvement without splenic disease or lung involvement without mediastinal adenopathy, can be observed. Bone marrow involvement occurs in 40% to 50% of patients and may be the first indicator of the presence of HD in nearly 20% of cases.<sup>299</sup> HD tends to develop as an earlier manifestation of HIV infection, presenting in patients with a median CD4+ cell count in a range of 275 to 306/ $\mu$ L.<sup>17</sup> At the time of diagnosis, the majority of patients have persistent generalized lymphadenopathy and, in 50% of cases, lymphoma may be concurrently present with persistent generalized lymphadenopathy in the same lymph node group.<sup>300</sup> Therefore, it is important to be aware of HIV-associated HD as a differential diagnosis.

### TREATMENT

Treatment is difficult, considering the underlying immunodeficiency caused by HIV itself, and may increase the risk of opportunistic infections by inducing further immunosuppression. Survival of patients with HIV-associated HD is short, typically 12 to 18 months, and the incidence of opportunistic infections is increased owing to standard therapeutic regimens. Because most patients have advanced HD, they have been treated with combination chemotherapeutic regimens such as MOPP and ABVD, but the response was poor in comparison with HIV-unrelated HD. Retrospective evaluations show a complete response rate far below that of HIV-negative patients with HD, poor tolerance of chemotherapy, and necessity of dose reduction or delay of treatment.<sup>301</sup> Other prospective studies show that tailored chemotherapeutic regimens having moderate bone marrow toxicity (e.g., epirubicin, bleomycin, and vinblastine) in combination with antiretroviral treatment with zidovudine result in a substantial decrease of opportunistic infection, yet overall survival was not significantly improved.<sup>302</sup> Improvement of response rate and median survival could be achieved by full-dose regimens like EBVP<sup>303</sup> or ABVD<sup>304</sup> combined with antiretroviral treatment, prophylaxis of the most common opportunistic infection, *Pneumocystis carini*, and the use of granulocyte colony-stimulating factor.<sup>305</sup> Preliminary data with BEACOPP showed promising results regarding complete remission, toxicity, and median survival.<sup>306</sup>

In summary, treatment of HIV-associated HD demands a special approach. Therefore, it will likely be the combination of unconventional chemotherapy, antiretroviral agents, prophylaxis of opportunistic infections, and hematopoietic growth factors that will lead to cure of HIV-associated HD. However, the individual components of the recipe are not yet defined.

### SEQUELAE

Long-term complications of mantle irradiation include lung, heart, and thyroid dysfunction, second primary cancers, and Lhermitte's syndrome ( [Table 45.6-21](#)). Complications such as transverse myelitis and constrictive pericarditis should not occur with the use of modern radiotherapeutic techniques. Other long-term toxicities are not totally avoidable but can be reduced in severity or frequency.

---

Potentially fatal
Acute myelomonocytic leukemia
Diffuse, high-grade non-Hodgkin's lymphoma
Solid tumors (mostly lung and breast cancer)
Overwhelming bacterial sepsis after splenectomy or spleen irradiation (OPSI)
Serious
Myocardial damage from radiation and anthracyclines
Lung fibrosis from radiation plus bleomycin
Sterility in men and women
Growth abnormalities in children and adolescents
Opportunistic infections
Psychological problems
Minor
Chemical or clinical hypothyroidism
Long-term alteration of lymphocyte function

---

**TABLE 45.6-21.** Treatment-Related Complications after Curative Therapy for Hodgkin's Disease

### PULMONARY COMPLICATIONS

Radiation pneumonitis typically occurs 1 to 6 months after completion of mantle irradiation. Once it resolves, usually there are no long-term sequelae. A mild, nonproductive cough, low-grade fever, and dyspnea on exertion characterize symptomatic radiation pneumonitis. The overall incidence of symptomatic pneumonitis is less than 5% after mantle irradiation; patients with LMA or who receive combined chemotherapy and radiotherapy have a two- to threefold greater risk (10% to 15%).<sup>307</sup> Radiographically, pneumonitis is characterized by the formation of infiltrates confined to the original radiation fields. Infection rather than pneumonitis is more likely if the infiltrates extend into areas of the lung initially protected from radiation. Severe pneumonitis may require treatment with steroids.

Various cardiac complications, including arrhythmias, myocardial infarction, and coronary artery disease, pericarditis, myocarditis, pericardial effusion, and tamponade have been documented after radiotherapy to the mediastinum.<sup>307,308</sup> In many early studies, these complications were related to treatment techniques that resulted in a high radiobiologic dose to the anterior mediastinum and heart. Current practice, which limits the dose to the whole heart, blocks the subcarinal region part-way into treatment, delivers treatments equally from front and back, and uses a lower overall radiation dose and smaller treatment volumes by the use of preradiation chemotherapy, has yielded more satisfactory results. Some studies have shown a modest increase in cardiac mortality after mantle irradiation. Boivin and Hutchison<sup>309</sup> have demonstrated an increased, age-adjusted risk of death from myocardial infarction after mediastinal irradiation. When analyzed by year of diagnosis of HD, the risk was much greater for patients treated in 1966 or earlier (relative risk, 6.33; confidence interval, 1.73 to 23.16) as compared to 1967 or later (relative risk, 1.97; confidence interval, 0.75 to 5.17), suggesting an important role for modern treatment techniques in reducing the risk of complications.

### CARDIAC COMPLICATIONS

The risk of chronic cardiomyopathy appears to increase as the cumulative dose of doxorubicin exceeds 400 to 450 mg/m<sup>2</sup>. It is still unknown whether there is an increased risk of cardiomyopathy at lower cumulative doses (as commonly given with ABVD) in patients treated with mediastinal irradiation before or after

chemotherapy. Careful cardiac evaluation of patients treated with combined radiotherapy and chemotherapy is recommended because of concerns that mediastinal irradiation may predispose to accelerated coronary arteriosclerosis, and this risk may be further increased by the administration of anthracyclines. Consideration should also be given to using lower doses and blocking the lower portion of the heart whenever possible.

## SECONDARY NEOPLASIA

The occurrence of second malignancies, including acute leukemia, NHL, and a variety of solid tumors, has become a well-acknowledged reality that adversely affects survival of some patients cured of HD. Some of these cases may represent chance association. However, physicians should be aware that HD patients are at higher risk of developing a second neoplasm.

A number of reports have stressed the possibility that the occurrence of acute nonlymphocytic leukemia is closely related to drug combinations containing alkylating agents. The use of ABVD in chemotherapeutic regimens for HD has reduced the risk of leukemia. In most studies, the use of radiotherapy in combination with chemotherapy does not increase the risk over chemotherapy alone, although there may be an increased risk when chemotherapy is combined with extensive irradiation (i.e., total nodal irradiation). There does not appear to be an increased risk of developing acute nonlymphoblastic leukemia after radiotherapy alone.

The total incidence of acute leukemia, which usually occurs within the first 10 years after initial treatment, is reported in most published series to range from 2% to 6%.<sup>310,311</sup> The classic form of treatment-related leukemia is characterized by a relatively long latency period, namely 3 to 5 years, a preceding myelodysplastic phase, trilineage bone marrow dysplasia, and abnormalities of chromosome 5 or 7 (or both). Topoisomerase II inhibitors—primarily the epipodophyllotoxins, but also anthracyclines when given in combination with alkylating agents—have been implicated in the development of a clinically and cytogenetically distinct form of secondary acute myeloid leukemia in both adult and pediatric patients.<sup>312</sup>

Nearly all cases of NHL occurring after HD are of intermediate-grade or high-grade histology and are similar to lymphomas seen in patients with immunodeficiency diseases or under chronic immunosuppression for organ transplantation or autoimmune disorders. These lymphomas have a cumulative risk of 1.2% to 2.1% at 15 years.<sup>313,314</sup>

The actual incidence of solid tumors, which have not revealed a particular histopathologic pattern, is unknown, as the full extent of the expression of risk of a second neoplasm may not be appreciated for another decade. The solid tumors tend to occur in the second decade after treatment and, thus far, appear to represent a hazard of both radiotherapy and chemotherapy. The major risks appear to be lung cancer (mostly in smokers) and breast cancer among women when irradiated young.<sup>310,315</sup> Other cancers include sarcomas, melanomas, connective tissue and bone tumors, and salivary, stomach, and skin cancers.<sup>314,316</sup>

A major argument against the use of radiotherapy as primary or adjunct therapy in HD has been its potential induction of secondary solid tumors by radiation.

The large study from the BNLI of 2846 patients included 987 patients who were treated with chemotherapy alone.<sup>317</sup> The BNLI study showed that the relative risk of developing a secondary solid tumor after chemotherapy alone was 5.7. This was not significantly different from the relative risk after radiotherapy alone (4.8) or after combined modality therapy (5.8). Furthermore, a case-control study from a collaborative group of population-based registries and cancer centers that maintains data on 25,665 cases of HD<sup>318</sup> showed that HD patients treated with chemotherapy alone were at approximately twice the risk of developing lung cancer as were those treated by radiotherapy alone or by both modalities. Most of these data are from cases involving MOPP or MOPP-like regimens; little is known of the use of ABVD and the risk of second solid tumors.

## GONADAL DYSFUNCTION

Many patients who complete successful treatment for HD go on to raise normal children. However, under some circumstances, gonadal dysfunction is an important iatrogenic toxicity that considerably affects the quality of life of patients after HD. Three to six cycles of MOPP or MOPP-like chemotherapy induces azoospermia in 50% to 100% of male patients. This finding is associated with germinal hyperplasia and increased follicle-stimulating hormone levels, with normal levels of luteinizing hormone and testosterone. Only 10% to 20% of patients will eventually show recovery of spermatogenesis after a long interval. After MOPP alternated with ABVD, the incidence of permanent azoospermia is approximately 50%. With full-course MOPP chemotherapy, nearly half of women become amenorrheal, with occurrence of age-dependent premature ovarian failure (>30 years, 75% to 85%; <30 years, ~20%).

The Milan Cancer Institute has reported that the administration of ABVD chemotherapy produces only limited and transient germ cell toxicity in men and no drug-induced amenorrhea.<sup>319</sup> To circumvent chemotherapy-induced sterility, the use of drug regimens not containing alkylating agents, procarbazine, or nitrosourea derivatives is highly recommended. An alternative for men undergoing MOPP or MOPP/ABVD therapy is sperm storage before chemotherapy. The usefulness of the administration of analogues of gonadotropin-releasing hormone in men or oral contraceptives in premenopausal women remains to be fully defined; however, limited data have been discouraging.

## OTHER COMPLICATIONS

Minor complications can be summarized as follows: Hypothyroidism is a common event (~30%) after mantle-field irradiation, typically picked up by means of an elevated thyroid-stimulating hormone level.<sup>307</sup> Hormone replacement therapy is required. Herpes zoster is another common complication, self-limited and usually occurring in one to two contiguous dermatomes within the first 2 years after treatment and affecting 15% to 20% of patients treated with radiotherapy or chemotherapy alone, but the incidence appears higher in patients treated with combined radiotherapy and chemotherapy. Cutaneous dissemination and visceral involvement from this virus are rare. Early treatment with antiviral agents may limit the intensity and duration of the infection. Acute transient radiation myelopathy or Lhermitte's sign (paresthesias down the dorsal portion of the extremities when the neck is flexed) occurs in approximately 10% to 15% of patients after mantle irradiation. This particular complication typically occurs 6 weeks to 3 months after radiotherapy and is self-limited, resolving in weeks to months. Xerostomia is a temporary complication of mantle irradiation; saliva returns to normal usually within 6 months of treatment. However, xerostomia may be prolonged in patients older than 40 years at treatment, or if Waldeyer's ring is treated. Fluoride supplementation and careful dental care will minimize the risks of radiation caries. The risk of postsplenectomy sepsis can occur particularly in children,<sup>320</sup> but it can be minimized by immunization with pneumococcal vaccine; in more recent years, vaccines have been developed against *Haemophilus* and *Neisseria* species, the other microorganisms associated with small but finite risks of overwhelming postsplenectomy sepsis.

## QUALITY OF LIFE

A review of most randomized clinical trials in HD reveals that quality of life has been neglected as a primary or even a secondary outcome measure. After a review of the literature in pediatric oncology, Bradlyn et al.<sup>321</sup> demonstrated that only 3% of all randomized clinical trial reports reviewed (n = 70) include quality-of-life data. However, mainly retrospective analyses of long-term survivors of HD have been performed.<sup>322,323</sup> These analyses showed that a substantial subgroup of patients still shows serious sequelae of the disease and its treatment even many years after treatment has ended. In one study, men who have experienced serious illness since treatment and who earn less than \$15,000 U.S. annually, are currently unemployed, are single, or are less educated were found to be at high risk for maladaptation years after treatment. Furthermore, 22% of the 273 patients studied met the criterion suggested for psychiatric diagnosis.<sup>322</sup> Currently, it remains unclear at which point in the course of the disease patients with a good coping capacity can be distinguished from those without such a capacity. To characterize phases of readaptation and maladaptation more precisely, quality-of-life assessment has to be implemented in prospective, randomized clinical trials. To obtain completeness of data, quality-of-life investigations should be a mandatory component of the clinical trial design and part of the inclusion criteria.<sup>324</sup>

The assessment of quality of life has become an essential tool in clinical trials, in particular in the evaluation of therapies given to patients with chronic illness such as cancer. Although survival and survival without disease have long been used as the sole end points in clinical trials, these limits are no longer accepted today because other characteristics now are considered to be as important as survival by both patients and physicians. Among these, treatment burden, treatment-related toxicity, and the psychological and social impacts of disease and treatment are of great importance.

Obviously, this change originates from the dramatic improvement in the efficacy of cancer treatments, particular in HD. Effective therapies, however, have several drawbacks that might limit their use. Chemotherapy and radiotherapy induce severe acute and late toxicities, which may diminish the long-term benefit of curative treatment. Several studies including a quality-of-life approach have highlighted the difficulties that survivors may experience even long after the treatment, such as

general fatigue, poor health, and social problems.

## NEW DRUGS IN HODGKIN'S DISEASE

### VINORELBINE

Vinorelbine belongs to the family of vinca alkaloids and is a semisynthetic analogue of vinblastine (5'-nor-anidro-vinblastine). The main side effect of vinorelbine is myelosuppression. WHO grade III to IV neutropenia occurs in up to 70% of patients but is of very short duration, with a low incidence of infectious complications.<sup>325</sup> Vinorelbine used as single-agent therapy in HD was administered in all studies in a weekly schedule with 30 mg/m<sup>2</sup>. Devizzi et al.<sup>326</sup> report on 22 patients with HD refractory or resistant to at least two chemotherapeutic regimens, of which 50% (n = 11) showed an objective response (complete remission, n = 3; partial remission, n = 8) with a median duration of 6 months. Benckekroun et al.<sup>327</sup> evaluated the response to vinorelbine in untreated patients with advanced HD. Thirty-two patients received four weekly doses of vinorelbine before MOPP/ABVD chemotherapy, and 90% achieved a partial remission.

### IDARUBICIN

Idarubicin is a semisynthetic drug that was first purified in 1976. Idarubicin differs from its parent drug daunorubicin only by the replacement of the C-4 methoxyl group in the D ring with a hydrogen atom. This modification has major consequences for the pharmacokinetic characteristics: Idarubicin is much more lipophilic and can be administered orally. Its main metabolite idarubicinol is as active as the parent compound. In addition, idarubicin has shown greater cytotoxicity than daunorubicin or doxorubicin *in vitro*. Idarubicin exhibits less cardiotoxicity at equi-effective doses as compared with other anthracyclines, whereas hemotoxicity and mucositis appear to be more pronounced. The GHSG is currently conducting a clinical phase II study in which idarubicin (8 mg/m<sup>2</sup>, days 1 and 2) is administered together with etoposide (60 mg/m<sup>2</sup>, days 1 to 4), ifosfamide (1000 mg/m<sup>2</sup>, days 1 to 4 continuous infusion), and dexamethasone (20 mg/m<sup>2</sup>, days 1 to 4) in patients with relapsed or refractory HD.

### GEMCITABINE

Gemcitabine is a new pyrimidine antimetabolite with unique metabolic and mechanistic properties among the nucleoside analogues.<sup>328</sup> It is a derivative of deoxycytidine, with fluorine substituted for the two hydrogen atoms in the 2'-position of the deoxyribose sugar. Although structurally similar to cytarabine, gemcitabine differs pharmacokinetically and pharmacologically. It acts as a competitive substrate for incorporation into the DNA, where it leads to chain termination. Based on the impressive results in solid tumors such as non-small cell lung cancer and pancreatic cancer, gemcitabine was given in a multicenter clinical phase II study in patients with multiple relapsed or refractory HD who had received at least two prior chemotherapeutic regimens.<sup>290</sup> Gemcitabine was administered in a weekly schedule of 1250 mg/m<sup>2</sup> on days 1, 8, and 15 of a 28-day cycle. An interim analysis of this trial showed an overall response of 39%, with 2 of 23 complete remissions and 7 of 23 partial remissions. Another ten patients had stable disease. Myelosuppression was the main toxicity.

## IMMUNOTHERAPY

Tumor cells that survive intensive therapy in small quantities are defined as minimal residual disease. These partially dormant, chemoresistant lymphoma cells might be eradicated by new immunotherapeutic strategies with a different mechanism of action. Current approaches comprise passive immunotherapy with antibody-based regimens for specific targeting of malignant cells as well as active immunotherapy with modulation of the cellular immune response using cytokines, tumor vaccines, or gene transfer. The combination of immunotherapeutic strategies with standard chemotherapeutic regimens seems to be most promising: Owing to different mechanisms of action, cross-resistance of malignant cells is expected to be rare. Furthermore, the side effects of these two treatment modalities differ, so that toxicity will not usually be additive.

### PASSIVE IMMUNOTHERAPY

Systemically administered chemotherapeutic agents kill all rapidly dividing cells, whereas monoclonal antibodies can target tumor cells selectively. Normal cells that lack specific tumor antigens are not harmed. For a variety of reasons, Hodgkin's lymphoma seems to be an ideal target for antibody-based therapeutic approaches: First, H-RS cells express many different cell surface antigens, such as CD15, CD25, CD30, CD40, and CD80 (B7-1), which are present on only a minority of normal human cells.<sup>113</sup> Due to low cross-reactivity with healthy human tissue, side effects are rare. Second, because many different markers can be detected on the surface of Hodgkin's cells, "cocktails" (i.e., a combination of various antibody conjugates targeting different Hodgkin's-specific antigens) might be useful for selective immunotherapy. If one malignant antigen-deficient cell clone is resistant to one antibody, cells might still be targeted by the second or third antibody conjugate administered at the same time. Third, the number of malignant cells that must be killed is small, as the majority of cells in the involved lymph nodes are reactive bystander cells. Fourth, lymphomas are well vascularized,<sup>329</sup> so that intravenously administered antibody conjugates can easily reach their target cells. Therefore, chemotherapy or radiotherapy (or both) can be used for treatment of bulky disease, whereas immunotherapeutic agents are applied thereafter to eliminate minimal residual disease and thus prevent relapses.

#### **Native Monoclonal Antibodies**

Ideally, the antibody targets with high specificity an antigen present only on the tumor cells and has no cross-reactivity with normal human tissue. The mechanisms of action of native antibodies include complement activation, antibody-dependent cellular toxicity, phagocytosis of antibody-coated target cells, inhibition of cell-cycle progression, and induction of apoptosis. In early phase I and II trials, native antibodies have exhibited moderate adverse effects, such as chills, fever, dyspnea, nausea, diarrhea, and myalgia. Toxicity usually was related to the number of circulating tumor cells and the development of human anti-mouse antibodies. New chimeric antibodies that consist of human constant and murine variable regions rarely induce human anti-mouse antibody formation.<sup>286</sup>

Engert et al.<sup>330</sup> evaluated more than 40 different monoclonal antibodies for their antitumor activity toward Hodgkin's-derived cell lines *in vitro*. Thus far, it has not been possible to identify monoclonal antibodies against Hodgkin's-associated antigens that exhibit potency *in vitro* or *in vivo* when used in native form. The chimeric monoclonal anti-CD20 antibody Rituximab (IDEC-C2B8) has been approved by the U.S. Food and Drug Administration for treatment of patients with relapsed advanced follicular NHL after a pivotal trial demonstrated response rates up to 50% in 166 patients.<sup>331</sup> Because the CD20 antigen is expressed on all malignant cells in paraneoplastic or LPHD, this entity might be a good target for treatment with Rituximab. An international study currently is investigating the safety and efficacy of Rituximab in patients with relapsed or refractory LPHD and other multiple relapsed CD20-positive cases of HD.

#### **Immunotoxins**

Immunotoxins generally consist of a binding moiety and a toxin moiety, which are either covalently linked via a chemical linker or generated by recombinant fusion technology. The binding domain is usually a monoclonal antibody, a Fab' fragment, a single-chain variable fragment, or a cytokine, whereas the toxin is of bacterial or plant origin. Recombinant toxins are constructed by fusing coding regions of toxins such as diphtheria toxin or *Pseudomonas* exotoxin-A to ligand genes.<sup>332</sup> Immunotoxins can bind selectively to their target cells. After internalization of the construct by endocytosis, the toxin is transferred to the ribosomal subunits, where it interferes with protein synthesis, thus killing the tumor cell.

Another interesting target for selective immunotherapy in HD is the IL-2 receptor (CD25), which is expressed on the majority of H-RS cells. In a phase I study, 15 patients with refractory Hodgkin's lymphoma were treated with the anti-CD25 immunotoxin RFT5.dgA.<sup>333</sup> All patients in this trial were heavily pretreated with a mean of five prior chemotherapeutic regimens, including autologous bone marrow transplantation. Most side effects were related to vascular leak syndrome. Clinical response included two partial remissions, one minor response, and three stable diseases. Promising approaches include deleting immunodominant epitopes and humanizing the antibody moiety of the immunotoxin.

A variety of monoclonal antibodies have been evaluated for their potential clinical use as ricin A chain immunotoxin against HD.<sup>334</sup> The most potent anti-CD30 immunotoxin, Ki-4.dgA, is currently being investigated in a clinical dose escalation trial.<sup>335</sup> In humans, sequential application of anti-CD30 antibodies linked to distinct ribosome-inactivating proteins might prevent formation of human antibodies against the individual toxins.

## Radioimmunoconjugates

Radioimmunoconjugates are constructed by linking a monoclonal antibody to radioisotopes without significantly altering the immunologic specificity of the protein. The most important advantage of these constructs as compared to all other antibody-based therapeutic strategies is that  $\beta$ -particles emitted by radionuclides can kill adjacent tumor cells through a crossfire effect, regardless of whether cells express the target antigen. As opposed to external-beam radiotherapy, radiolabeled antibodies deliver radiation continuously at a low dose rate to the whole body, including occult micrometastases.<sup>336</sup> Currently, both nonmyeloablative and myeloablative strategies involving radiolabeled antibodies are investigated for imaging and treatment of HD.

Low-energy radionuclides are coupled to monoclonal antibodies either for diagnostic use (immunoscintigraphy) or for low-dose radioimmunotherapy without severe myelosuppression. A phase I trial was initiated to investigate the safety of the  $^{99m}\text{Tc}$ -labeled anti-CD30 antibody Ber-H2 for immunoscintigraphy and possible immunotherapy in patients with refractory HD and large cell anaplastic lymphoma. Preliminary results suggest good tolerance of the therapy with no major side effects and satisfactory efficacy for imaging or detecting HD lesions. Future trials involving modern radioisotopes ( $^{111}\text{In}$ ,  $^{90}\text{Y}$ ,  $^{186}\text{Re}$ ) are warranted.<sup>337</sup>

Stem cell support for hematopoietic recovery might be necessary in high-dose radioimmunotherapy. A phase I to II study with  $^{90}\text{Y}$ -labeled polyclonal antiferritin antibodies for refractory Hodgkin's lymphoma followed by autologous bone marrow transplantation was performed by Vriesendorp et al.<sup>338</sup> Of 17 patients, seven achieved complete remissions lasting 2 to 26 or more months, and four patients achieved partial remissions (2 to 6 months). Twelve patients received a reduced dose (20 mCi) due to bone marrow involvement or unsuccessful marrow harvest. Complete remissions were observed in two and partial remissions in five of them. For all doses, response rates were better in patients with small tumor burden. Based on these encouraging results, radioimmunotherapy appears to be a new promising option, either alone or in combination with other chemotherapy or immunotherapy (or both).

## Bi-Specific Monoclonal Antibodies

Bi-specific monoclonal antibodies contain two different recognition sites, one for antigens on tumor cells and another for antigens on immunologic effector cells, such as macrophages, T lymphocytes, or NK cells. For treatment of HD with NK-cell-activating bi-specific antibodies, a CD16/CD30 bi-specific antibody was constructed using hybridoma technology.<sup>42</sup> Heavily pretreated patients with refractory HD received intravenous infusions of the CD16/CD30 (A9/HRS-3) antibody four times every 3 or 4 days.<sup>339</sup> Fifteen patients with refractory HD were treated with escalating doses. Side effects were rare and consisted of short-lasting fever, pain in involved lymph nodes, and a maculopapular rash. A total of one complete and one partial remission (lasting 16 and 3 months, respectively), three minor responses (1 to 11+ months), and one mixed response was observed.

## ACTIVE IMMUNOTHERAPY

Therapeutic strategies modulating the cellular immune response have been investigated in lymphoma patients for more than 25 years. As immunotherapy with Bacillus Calmette-Guérin had suggested therapeutic effects when combined with chemotherapy in patients with acute myelocytic leukemia and breast cancer, several randomized clinical trials were initiated in patients with advanced Hodgkin's lymphoma as well.<sup>340</sup> Because of a documented lack of therapeutic benefit and a higher frequency of unacceptable toxicity, trials investigating Bacillus Calmette-Guérin treatment were discontinued.

IL-2 was one of the first immunotherapeutic agents used for anticancer therapy. Several clinical studies were performed to investigate the efficacy of IL-2 alone or in combination with autologous lymphokine activated killer cells (adoptive immunotherapy) in patients with refractory Hodgkin's lymphoma.<sup>341,342</sup> and <sup>343</sup> Toxicity was mild, mainly comprising fever, rash, hypotension, and anemia. In these clinical pilot trials, several transient partial remissions were achieved in heavily pretreated patients with relapsed or refractory disease. IL-2 is currently under clinical investigation as maintenance therapy alone or in combination with other cytokines after HDCT.

Case reports of a few patients who received interferon for treatment of viral infection noted minor responses of Hodgkin's lymphoma. Therefore, some pilot studies were conducted to investigate the efficacy of interferon in the salvage or maintenance therapy of HD. Preliminary results suggest a limited activity of interferon- $\alpha$  in patients with relapsed or refractory HD.<sup>344</sup>

## GENE THERAPY

Modulation of EBV-directed T-cell activity might be another interesting new immunotherapeutic option: Heslop et al.<sup>345</sup> developed EBV-specific CTLs for treatment of EBV-associated lymphoma after bone marrow transplantation. Donors' blood samples were used for generation of EBV-transformed B-cell lines (LCLs) and for production of CTLs.<sup>345</sup> Incubation of activated CTLs with LCLs of the same probe induced formation of EBV-specific CTLs. In three of ten patients, elevated levels of EBV DNA after allogeneic transplantation normalized after infusion of the EBV-specific CTLs. EBV-specific CTLs were isolated for an adoptive transfer in patients with EBV-positive HD.<sup>346</sup> Nine patients with active, relapsed HD and four who were in complete remission after first or subsequent therapy were treated with autologous EBV-specific CTLs: A 100-fold reduction of EBV DNA was observed in all patients; in two of them, B-symptoms ceased.

## MOLECULAR BIOLOGY OF LEUKEMIAS

Leukemia can be broadly defined as a disease whose malignant cell is derived from the hematopoietic system and manifests its expansion in the bone marrow with or without peripheral blood involvement. The cytogenetic study of these malignant cells has revealed that recurrent chromosomal changes occur in over one-half of all cases of leukemia. Most commonly, these are structural changes classified as translocations, inversions, or deletions. Further, it is usually the disruption or deregulation of specific genes at the chromosome breaks that in turn contributes to the process of leukemogenesis.<sup>1,2</sup> In many instances, these genes have also been found to be directly or indirectly involved in the normal development or maintenance of the hematopoietic system. Thus, leukemia results, at least in part, from the disruption or deregulation of genes that normally regulate blood cell development, blood cell homeostasis, or both.<sup>1,2,3,4</sup> and <sup>5</sup> In this sense, the molecular biology of leukemia is consistent with the paradigm established for cancer in general: Genes that predispose to human cancer (i.e., oncogenes and tumor suppressor genes) are altered or inactivated versions of genes normally involved in the regulation of cell growth, cell development, and cell death.<sup>4,6</sup>

Several generalizations about the molecular biology of leukemia can be made.<sup>7</sup> First, the chromosomal aberrations that result in the disruption or deregulation of genes occur in somatic tissues (i.e., hematopoietic cells) and are not found in nonleukemic cells. The genetic mishap often occurs at a specific point in normal hematopoiesis, giving rise to leukemia of a specific lineage that has arrested at a distinct maturational stage. This strongly suggests that the gene or genes altered in a particular type of leukemia are important in a specific stage of development or homeostasis of its normal cell counterpart. There are, however, some notable exceptions to this, such as the myeloid-lymphoid leukemia (*MLL*) gene that can be involved in leukemia of different or mixed lineages.

The mechanisms by which disrupted or deregulated genes cause leukemia can be broadly classified into two categories. The first is gene fusion, whereby a distinct protein, usually either a transcription factor or receptor tyrosine kinase, fuses with an unrelated gene to create a unique *chimeric* fusion protein that then critically contributes to malignant transformation of the cell. This mechanism predominates in the genesis of myeloid leukemia, but is also found in lymphoid leukemia. The second is gene activation, whereby a gene that normally controls transcription within the cell is inappropriately placed under the control of an active promoter/enhancer from another gene, usually the immunoglobulin (Ig) or T-cell receptor (TCR) promoter/enhancer during the process of antigen receptor gene rearrangement. Chromosomal translocations that result in gene activation usually occur in lymphoid tissue and lead to a deregulation in gene expression.<sup>1,3,4</sup> and <sup>5</sup> As discussed in this chapter, more recently it has been appreciated that other genetic and epigenetic events, such as point mutations, gene deletions, and DNA methylation, usually in tumor suppressor genes, can also contribute to the initiation or progression of leukemia.

The improved techniques for the study of chromosomes and the explosive growth in molecular biology are rapidly facilitating the elucidation of genes involved at chromosomal breakpoints in cases of leukemia, and the list of oncogenes is increasing almost daily in the literature. [Table 46.1-1](#) provides the reader with some examples of genes involved in leukemogenesis by either gene fusion or gene activation, their chromosomal location and name derivation, a general description of their function, if known, and the type of leukemia with which they are associated. However, it should be noted that nearly one-half of all cases of leukemia do not have cytogenetic evidence of recurrent structural chromosomal rearrangements, but instead have changes only in chromosome number (e.g., monosomy 7 or trisomy 8), or completely normal cytogenetics. This severely restricts the molecular biologist's ability to focus in on *hot spots* in the genome where evidence of gene fusion or gene activation is likely to be found. Advances in a fraction of such cases have revealed that comparable genetic mechanisms of leukemogenesis are operative even in the absence of structural cytogenetic abnormalities.

**TABLE 46.1-1.** Selected Examples of Cytogenetic and Molecular Abnormalities in Leukemia

In this chapter, we review the most common genetic disruptions that result from the recurrent cytogenetic aberrations in acute and chronic leukemia, and where possible, provide an explanation as to how such alterations contribute to the molecular pathogenesis of the disease. In addition, we review instances in which the molecular basis for leukemia has been determined in the absence of structural cytogenetic abnormalities. Finally, we discuss other genetic alterations, mostly in tumor suppressor genes, that are likely to contribute to the genesis or progression of leukemia. We proceed with a molecular description of leukemia that simply follows the list of the more common molecular defects provided in [Table 46.1-1](#). There is little or no attention to the more traditional revised histologic classification of leukemia to put more emphasis on the genetic basis of leukemia.<sup>8</sup> Derivations of abbreviations used for the genes discussed in the text can be found in [Table 46.1-1](#).

## GENE FUSIONS IN LEUKEMIA

## GENE FUSIONS INVOLVING CORE-BINDING FACTOR IN LEUKEMIA

Core-binding factor (CBF) is a heterodimeric transcription factor, composed of CBFA2 and CBFb, that is involved in the regulation of hematopoiesis ( Fig. 46.1-1A). The CBFA2 protein (originally described as AML1) has an amino terminus domain with homology to the *Drosophila* runt protein, which is an early acting factor that regulates the expression of genes involved in segmentation during fly development.<sup>9</sup> The runt homology domain of CBFA2 confers at least two properties to the protein. The first is a DNA-binding domain that recognizes the sequence TGT/cGGT, an enhancer core motif that serves as a regulatory element in several genes important in hematopoiesis, such as *LCK*, *myeloperoxidase*, *granulocyte-macrophage colony-stimulating factor*, *interleukin-3*, *colony-stimulating factor*, *neutrophil elastase*, and *TCRa*, *b*, and *g*.<sup>10</sup> The second important function of the runt homology domain of CBFA2 is that it is required for heterodimerization of CBFA2 with its normal partner CBFb. CBFb does not directly bind to DNA, but its binding to CBFA2 is thought to increase the heterodimeric transcription factor's affinity and stability for the target DNA-binding sequence.<sup>9</sup> More recently, the carboxyl terminus of CBFA2 was discovered to contain a transactivation domain that binds the transcriptional coactivator p300, a transcriptional regulator that has been shown to promote transcription via acetylation of histone proteins associated with targeted genes (see Fig. 46.1-1A).<sup>11</sup>

**FIGURE 46.1-1. A:** Schematized representation of the wild-type CBFA2-CBFb transcription factor complex. The DNA-binding domain of CBFA2 (originally described as AML1) recognizes the enhancer core motif of the target gene via its domain that has homology to the *Drosophila* runt protein. The CBFA2 runt domain is also required for heterodimerization with CBFb (originally described as CBFb), which in turn increases the affinity and stability of CBFA2 binding to the core enhancer sequence, thereby promoting efficient activation of target gene transcription. Additional factors that act as coactivators of transcription participate in this complex formation (e.g., p300), depending on the particular target gene promoter or enhancer involved (e.g., myeloperoxidase, CSF-1 receptor, etc). **B:** Schematized representation of the transcription factor complex that results from the *CBFA2-CBFA2T1* (originally described as *AML1-ETO*) gene fusion in t(8;21)(q22;q22) acute myeloid leukemia. The CBFA2 runt domain is left intact following the fusion, allowing it to (1) recognize and bind to the enhancer core motif of the target gene and (2) heterodimerize with wild-type CBFb. However, its fusion partner, CBFA2T1, forms either a homodimer or a heterodimer (not shown) that then interacts with the nuclear corepressors (N-COR) and SIN3A, which complex with histone deacetylase 1 (HDAC1). This entire complex then facilitates repression of transcription by altering chromatin structure via histone deacetylation. (Adapted from ref. 7.)

The CBF complex is the most frequent target of chromosomal translocations and inversions in human acute leukemia. At the molecular level, the t(8;21)(q22;q22) generates a chimeric gene fusing *CBFA2* with the *CBFA2T1* gene (originally described as *ETO*) at chromosome band 8q22.<sup>12</sup> The reciprocal *CBFA2T1-CBFA2* fusion, on the derivative chromosome 21, is often not expressed and thus does not appear to be essential for leukemogenesis. The *CBFA2-CBFA2T1* fusion protein retains the runt homology domain and therefore its protein-protein binding (to CBFb) and its DNA-binding properties. However, the fusion of *CBFA2* with nearly the entire *CBFA2T1* coding sequence does create a protein that lacks the CBFA2 carboxyl terminal transactivation domain and may therefore interfere with CBF-mediated transcriptional activation of hematopoiesis through a dominant-negative mechanism ( Fig. 46.1-1B).<sup>13</sup>

The CBFA2T1 protein binds to the human homologue of the murine nuclear receptor corepressor (N-COR). N-COR forms a complex with mammalian SIN3A and histone deacetylase 1 (HDAC1) and facilitates repression of transcription by altering chromatin structure via histone deacetylation.<sup>14,15</sup> It is thus possible that in t(8;21) acute myeloid leukemia (AML), the N-COR/SIN3A/HDAC1 complex is recruited to the CBF complex by the CBFA2-CBFA2T1 protein, thereby inducing repression of transcription by deacetylation of CBFA2-targeted genes (see Fig. 46.1-1B). This process may result in the disruption of normal hematopoiesis and may also inactivate tumor suppressor genes and other factors important for neoplastic transformation.<sup>10,16</sup> In support of such a hypothesis, there are data demonstrating that inhibitors of histone deacetylase can reverse CBFA2T1-mediated transcriptional repression and can induce differentiation of *CBFA2-CBFA2T1* leukemia cells.<sup>17</sup>

At the molecular level, inv(16)(p13q22) and t(16;16)(p13;q22) both result in the fusion of the *CBFB* gene, the normal partner of *CBFA2* shown in Fig. 46.1-1A and located at chromosome 16q22, with the *MYH11* gene from chromosome 16p13.<sup>18</sup> The *MYH11* gene encodes a smooth muscle form of the myosin heavy chain, and it is the fusion of its carboxyl terminus with almost the entire *CBFB* gene, including its *CBFA2*-binding domain, that appears important for leukemogenesis. The genomic fusion between these two genes is quite variable, and at least eight different sized fusion transcripts have been described, the biologic and clinical significance of which are unclear.<sup>19</sup> The mechanism whereby the *CBFB-MYH11* fusion gene contributes to malignant transformation remains to be fully elucidated. *In vitro* analyses show that the CBFB-MYH11 chimeric protein can bind to the CBFA2 protein, which in turn can bind its TGT/cGGT core enhancer DNA sequence element, albeit with reduced DNA-binding activity. The carboxyl terminus of MYH11 does contain a functional domain, the myosin long tail, that might mediate homodimerization of the CBFB-MYH11 fusion protein into high-molecular-weight structures. It may therefore be possible that the CBFB-MYH11 homodimers could sequester CBFA2 subunits into a nonfunctional complex, thereby inhibiting the transcriptional activation of genes important for hematopoiesis. Indeed, Adya et al. provided compelling *in vitro* evidence in support of such a hypothesis, demonstrating that the CBFB-MYH11 homodimers could colocalize with the CBFA2 protein in actin filaments outside of the nucleus.<sup>20</sup> These data would therefore support a dominant negative mechanism of CBFA2 gene inactivation by the CBFB-MYH11 fusion protein, leading to dysregulated hematopoiesis.

Mice have been generated with *Cbfb+Cbfb-MYH11* embryonic stem cells.<sup>21</sup> The *Cbfb+Cbfb-MYH11* mice are chimeric, in that they have hematopoietic stem cells with and without the knocked-in *Cbfb-MYH11* gene in the marrow. The mice have defective myeloid and lymphoid differentiation; however, they did not develop any malignancies in their first year of life. To test the hypothesis that additional genetic events might be required, the mice were injected with a single sublethal dose of N-ethyl-N nitrosourea, a potent DNA alkylating mutagen. Within 2 to 6 months after treatment, 84% of the treated *Cbfb+Cbfb-MYH11* chimeric mice developed acute myelomonocytic leukemia, whereas none of the control populations (*Cbfb+Cbfb-MYH11* chimeras without injection or wild-type mice with injection) developed leukemia. Leukemic cells expressed the *Cbfb-MYH11* fusion gene and, importantly, the mice did not show evidence of malignancy in other tissues where the *Cbfb-MYH11* fusion gene was not expressed. The data from this elegant experimental model and from others not discussed suggest that alterations in the CBF complex serve to block hematopoietic differentiation, while a *second hit* that targets these particular cells may be necessary to induce frank leukemia. The molecular analysis of human familial platelet disorder (FPD) with predisposition to AML (familial platelet disorder/AML) perhaps reveals the first clinical evidence in support of the mouse model. Patients with familial platelet disorder/AML have haploinsufficiency of *CBFA2*, which causes an autosomal dominant congenital platelet defect and may predispose to the acquisition of additional mutations that cause leukemia.<sup>22</sup>

There are other examples of fusion with *CBFA2* that lead to dysregulation of myeloid hematopoiesis and leukemic transformation. The t(3;21)(q26;q22) noted in myelodysplastic syndromes (MDS), AML, and blast crisis of chronic myeloid leukemia (CML) results in a fusion of *CBFA2* with the *EVI1* gene, where the zinc finger DNA-binding domains of *EVI1* fuse with the amino terminus (runt homology) domain of *CBFA2*, similar to that described previously for *CBFA2-CBFA2T1*.<sup>23,24</sup> However, like the *CBFA2* fusion partner *CBFA2T1*, *EVI1* also has properties that may contribute to leukemogenesis. Using the first zinc finger domain of *EVI1*, the *CBFA2-EVI1* fusion product has been shown to interact with SMAD3 and block transforming growth factor- $\beta$ -mediated growth inhibition of myeloid cells.<sup>25</sup> Thus, myeloid hematopoietic cells rendered unable to differentiate because of disrupted CBF function may be further induced toward malignant transformation by interference with transforming growth factor- $\beta$ -induced growth-inhibitory signals from the marrow stroma. It appears likely that additional *CBFA2* partner genes will be cloned from patients with *de novo* and secondary AML and MDS.<sup>26</sup>

An important example of *CBFA2*'s involvement in lymphoid malignancies is the *TEL-CBFA2* fusion that is associated with pediatric B-lineage acute lymphoblastic leukemia (ALL). The *TEL* gene, also known as *ETV6*, is a member of the ETS family of transcription factors that are defined by their highly conserved, 90-amino acid,

winged helix-turn-helix DNA-binding domain, also known as the *ETS domain*, that recognizes the consensus motif C/A GGA A/T.<sup>27</sup> A role for the *TEL* gene in human hematopoiesis appears likely, as mice chimeric with *Tel* embryonic stem cells were unable to establish hematopoiesis in the bone marrow, as opposed to other sites of hematopoietic activity during development.<sup>28</sup>

The *TEL-CBFA2* fusion of childhood B-lineage ALL results from the t(12;21)(p13;q22). However, it is best identified by fluorescence *in situ* hybridization, because the juxtaposition of bands 12p13 and 21q22 is usually unrecognizable in banded metaphase preparations. The *TEL-CBFA2* fusion occurs in approximately 25% of cases of pediatric ALL and is therefore the most common gene rearrangement in any childhood cancer.<sup>29,30</sup> The fusion product contains the helix-loop-helix (HLH) homooligomerization domain near the amino terminus of *TEL* linked to, essentially, the full-length *CBFA2* gene, including both the runt homology domain as well as the carboxyl terminus transactivation domain. Indeed, this is the only *CBFA2* fusion in human leukemia currently known to incorporate the transactivation domain. It is likely that the *TEL-CBFA2* fusion contributes to a reduction in normal *CBFA2* function via a dominant negative mechanism.<sup>31</sup> However, in addition, this fusion invariably leads to the loss of the remaining wild-type *TEL* allele, suggesting that this might be an important contributor to leukemogenesis as well.<sup>29,32</sup> The mechanism by which such a contribution might occur remains unknown.<sup>33</sup>

The disruption of the CBF complex in t(8;21), inv(16), and t(12;21) confers a favorable prognosis on patients whose leukemic blasts harbor the consequent molecular alterations.<sup>33,34</sup> This does not appear to be the case for the t(3;21). The molecular basis for this clinical observation largely remains obscure, but there is at least preliminary evidence that downstream genes that could confer resistance to standard induction chemotherapy might be dysregulated by disruptions in the CBF complex.<sup>35</sup>

#### ADDITIONAL GENE FUSIONS WITH TEL

There are several chromosomal translocations in myeloid leukemia that disrupt the *TEL* gene, which, unlike the *TEL-CBFA2* fusion noted in ALL, do not involve the CBF complex. In some cases, the amino terminus of the *TEL* protein, which includes the HLH oligomerization domain, appears to be required for leukemogenesis, whereas in other cases it is the DNA-binding *ETS* domain of *TEL* that appears to be relevant. Further, there is little, if any, homology or functional similarity between most of the *TEL* fusion partner genes. While *TEL* gene rearrangements in myeloid malignancy are not frequent, their characterizations have revealed a multitude of possible mechanisms whereby *TEL* may contribute to leukemogenesis.<sup>36</sup>

*TEL* was first identified when the t(5;12)(q33;p13) associated with chronic myelomonocytic leukemia was cloned.<sup>37</sup> This translocation produces an in-frame fusion of the amino terminus of *TEL*, which includes the HLH oligomerization domain, with the transmembrane and tyrosine kinase domains of the platelet-derived growth factor receptor- $\beta$  (PDGFR- $\beta$ ), a receptor tyrosine kinase. The *TEL-PDGFR- $\beta$*  fusion results in both constitutive activation of the truncated receptor tyrosine kinase as well as its ectopic expression, and both properties are dependent on *TEL* and its HLH domain.<sup>38,39</sup> In model systems it has been demonstrated that at least some of the downstream effector molecules normally induced by PDGF, such as *MYC*, are induced by the *TEL-PDGFR- $\beta$*  protein and are required for transformation.<sup>40</sup>

The t(9;12)(q34;p13) fuses the *TEL* gene with another tyrosine kinase called *ABL*, named after its homologue, the Abelson leukemia virus oncogene.<sup>41</sup> *ABL* is best known as the fusion partner with *BCR* (breakpoint cluster region) in CML (see [Philadelphia-Positive Chronic Myeloid Leukemia and Acute Lymphoblastic Leukemia Result from a Fusion of BCR with the Tyrosine Kinase ABL](#), later in this chapter). The *TEL-ABL* fusion is strikingly similar to the *TEL-PDGFR- $\beta$*  fusion, in that the in-frame fusion joins the HLH domain of *TEL* with the catalytic (kinase) domain of *ABL*. Once again, the HLH domain serves to oligomerize the *ABL* kinase, with subsequent constitutive *ABL* kinase activation. The fusion has been characterized in acute undifferentiated myeloid leukemia, atypical CML, and ALL. The similarities between the roles of *TEL* and *BCR* in their fusion with *ABL* are striking. They both appear to function by primarily inducing *ABL* oligomerization and consequent activation, i.e., a gain-of-function mechanism. Indeed, comparison of *TEL-ABL* and *BCR-ABL* transformation properties and downstream signal transduction events suggests that the fusion proteins are indistinguishable.<sup>42</sup>

The t(12;22)(p13;q11) is found in AML and in MDS. In contrast to the two fusions of *TEL* with tyrosine kinases noted previously, in which the HLH domain of *TEL* functions to oligomerize and activate the kinase, this translocation fuses the carboxyl terminus-containing *ETS* domain of *TEL* with the *MN1* gene that encodes a nuclear protein whose function is unknown. Two types of *MN1-TEL* fusion transcripts have been identified, one that includes the *TEL* HLH domain as well and one that disrupts the *TEL* HLH domain. This suggests that the oligomerization is not likely important in the process of malignant transformation, but rather that the DNA-binding or *ETS* domain is, and that *MN1-TEL*-mediated leukemic transformation occurs via a molecular pathway that normally involves *TEL*. The reciprocal *TEL-MN1* fusion products are not known to contain any functional domains, suggesting little or no contribution of this protein to leukemogenesis.<sup>43</sup>

#### MLL GENE: FUSIONS WITH MULTIPLE PARTNERS RESULT IN ACUTE LEUKEMIA

In our discussion of the *TEL* gene at chromosome band 12p13, we reviewed how *TEL* can fuse with a variety of partners, in a variety of ways, and participate in the genesis of both lymphoid and myeloid leukemias. However, the best example of a *promiscuous* partner in leukemia is the *MLL* gene located at chromosome band 11q23. This gene fuses with an extraordinary number (over 30) of diverse partner genes, examples of which are shown in [Table 46.1-1](#). The fusions manifest in myeloid, lymphoid, or mixed lineage leukemias (defined by markers of more than one hematopoietic lineage) of infants, children, or adults, the clinical details of which are provided in subsequent chapters. Further, the leukemias involving *MLL* may be *de novo* or primary, but also account for as many as 80% of secondary leukemias that develop in patients who were successfully treated for other tumors at an earlier time with regimens that included topoisomerase II inhibitors.<sup>44,45</sup> and <sup>46</sup> Collectively, the clinical and correlative laboratory data support the notion that *MLL* is important for early pluripotent and lineage-specific hematopoiesis, and that disruption of *MLL* at 11q23 can give rise to leukemias of mixed or multiple lineages.

*MLL* (also known as *ALL1*, *HRX*, and *HTRX1*) was cloned by four independent groups and found to contain at least 36 exons that encode 3968 amino acids with a predicted molecular mass of 431 kD.<sup>47,48,49</sup> and <sup>50</sup> The various names for the single gene at 11q23 are derived from its association with *MLL*, its initial identification in a case of ALL (*ALL1*), and because of its strong homology to the *Drosophila* trithorax protein (*HRX* and *HTRX1*). This trithorax homology includes a highly conserved domain covering the carboxyl terminus known as SET, because it is also found in *suvar3-9*, *enhancer-of-zeste*, and *trithorax* proteins ([Fig. 46.1-2A](#)).<sup>49,50,51,52</sup> and <sup>53</sup>

**FIGURE 46.1-2. A:** The *MLL* protein and its known fusion partners with various motifs identified. Protein motifs are indicated in black. The shaded gray regions in *ENL* and *AF9* indicate known regions of homology. Fusion breakpoints are indicated by arrows. *AF1q* is unique in that its fusion breakpoint occurs six nucleotides upstream of its open reading frame, resulting in a fusion protein without functional domains. Protein motifs are indicated in black. AT, AT hooks; bromo, bromodomain; CREB, cAMP response element-binding protein site; DH, *Dbi* homology domain; DPF, aspartic acid-proline-phenylalanine repeat; GLGF, glycine-leucine-phenylalanine domain; HAT, histone acetyltransferase activity; LZ, leucine zipper; MCBBD, methyl-CpG binding domain; NLS, nuclear localization signal; PDZ, PDZ domain; PH, pleckstrin homology domain; SH3, *Src* homology domain; TH, trithorax homology (SET domain); ZF, zinc fingers. **B:** The genomic structures of *MLL* and *MLL* with an exon 6–exon 2 partial tandem duplication (PTD) are shown. Exons are indicated by vertical lines and boxes, and introns are indicated by the horizontal line for each structure. Vertical arrow indicates point of unique self-fusion that results from the PTD. The predicted protein structure for *MLL* with the 6-2 PTD is illustrated below and can be compared with the wild-type protein at top of the figure (**A**).

Collectively, the structural and functional data accumulated thus far strongly suggest that wild-type *MLL* is a maintenance factor for gene expression. For example, in

*Drosophila*, trithorax (the MLL fly homologue) maintains homeobox gene expression, critical for normal development of the head, thorax, and abdomen.<sup>52</sup> Gene-targeting studies in mice demonstrated that MLL is a positive regulator of homeobox (*Hox*) gene expression and maintenance.<sup>53,54</sup> Mammalian *Hox* genes encode DNA-binding, homeodomain-containing, helix-turn-helix transcription factors that appear critical in both skeletal and blood cell development.<sup>55</sup> The *Mill*<sup>-/-</sup> mouse completely lacks *Hox* gene expression, has defects in yolk sac hematopoiesis, and is lethal to the embryo, while the *Mill*<sup>+/-</sup> mouse has a disruption in *Hox* gene expression and various consequent defects in skeletal, neural, craniofacial, and hematopoietic development.<sup>53,56</sup> *In vitro*, *Mill*<sup>-/-</sup> embryonic stem cells fail to undergo hematopoietic differentiation.<sup>57</sup> Structure function studies suggest that the SET domain of MLL is required for proper regulation of *Hox* gene expression.

Virtually all of the translocations involving *MLL* at 11q23 in human acute leukemia consistently disrupt the gene within an 8.5-kb region located between exons 5 and 11, joining the amino-terminal half of *MLL* to the partner gene. The large *MLL* fusion gene on the derivative 11 chromosome includes the AT hook minor groove DNA-binding motifs, a methyl-CpG binding domain (MCBD), the nuclear localization domain, and all or part of the overlapping transcriptional repression domain. Missing are the two protein-binding zinc finger domains in the mid region and the *trithorax* homology located in the SET domain at the carboxyl terminus of the protein (see Fig. 46.1-2A). This derivative chromosome 11 (der 11) thus contains the *MLL* promoter and the amino terminus of *MLL* fused to the carboxyl terminus encoded by the gene at the breakpoint of the partner chromosome and is always the one that is transcribed by the leukemic clone.<sup>58</sup>

In contrast to many of the other common translocations discussed in this chapter, we have thus far learned little about the mechanisms of *MLL*-associated leukemogenesis from the study of its many fusion partners (see Table 46.1-1 and Fig. 46.1-2A). There is limited similarity in protein structure between the partner genes currently known to fuse with *MLL* in acute myeloid, lymphoid, or mixed lineage leukemia. To date, 18 *MLL* fusion partner genes have been cloned and sequenced (see Fig. 46.1-2A), and there is no one structure-function that can unify their role in the malignant transformation of hematopoietic cells. Most of the cloned partners are novel genes and inference about their functions comes from the study of their homologies or *in vitro* systems. Several partners, such as *AF4*, *ENL*, *AF9*, *CBF*, and *P300* have evidence for transcriptional activation or coactivation domains, suggesting that replacement of the MLL zinc finger and SET domains by these partners could result in uncontrolled expression of MLL target genes, possibly within some lineage-specific, transcriptional context (e.g., *MLL-AF4* in lymphoblasts).<sup>59</sup> However, this alone cannot be the only pathway to malignant transformation, as other partner genes (e.g., *AF1q*) lack homology to any known protein sequence and contribute a minimal portion of its carboxyl terminus to the MLL fusion protein (see Fig. 46.1-2A), suggesting this fusion may only contribute through haploinsufficiency or possibly via a dominant negative effect.<sup>60</sup>

The multitude of partners that fuse with *MLL* in acute leukemia led us to hypothesize that the *MLL* gene might be rearranged without structural cytogenetic evidence of translocations, inversions, or deletions at 11q23. We therefore looked for evidence of *MLL* gene rearrangements in cases of AML without cytogenetic abnormalities involving 11q23, including cases with normal cytogenetics. Rearrangement of *MLL* was initially observed in cases of AML with trisomy 11 (+11) as a sole abnormality and in cases of AML with normal cytogenetics.<sup>61</sup> These rearrangements were subsequently not found to result from cryptic fusions with other partner genes, but rather from a partial tandem duplication (PTD) of *MLL* spanning exons 2 through 6 or exons 2 through 8 (see Fig. 46.1-2B).<sup>62,63</sup> The putative partially duplicated protein includes duplication of the AT hooks and MCBD, without loss of the carboxyl portion of the protein containing the SET domain. Molecular analysis of the chromosomes in a limited number of cases with +11 or normal cytogenetics and the *MLL* PTD revealed that only one of the alleles carries the rearrangement.<sup>64</sup> Sequence analysis of the genomic fusion in nine cases of *MLL* PTD indicated that the rearrangement is most likely the result of *Alu*-*Alu*-mediated homologous recombination events within the involved introns.<sup>63,65,66</sup> This is the first demonstration of homologous recombination between *Alu* elements as a consistent mechanism for gene rearrangement in somatic tissue.

The PTD of *MLL* has been found to be present in the majority of AML patients with +11 as a sole cytogenetic abnormality, as well as in some patients with +11 accompanied by additional cytogenetic abnormalities,<sup>67,68</sup> and is the first consistent gene rearrangement associated with recurrent trisomy in human cancer. In a study of 98 AML patients with normal cytogenetics, 11% of patients had rearrangement of *MLL*, and in eight of eight cases in which additional material was available, the *MLL* PTD was documented. In patients with AML and normal cytogenetics, a rearranged *MLL* gene was associated with a poorer prognosis compared with the remaining AML patients with normal cytogenetics.<sup>69</sup> These adverse prognostic data were confirmed in a separate study, but with a lower percentage (6%) of the *MLL* PTD in AML cases with normal cytogenetics.<sup>70</sup> Thus, the *MLL* PTD is an example of a novel gene fusion detectable in a significant fraction of AML patients without structural cytogenetic abnormalities.

*MLL* gene rearrangements are seen in 80% of infant ALL cases and in approximately 50% of infant AML cases.<sup>71</sup> There have now been several elegant reports of infant twins developing acute leukemia with 11q23 translocations involving *MLL in utero*.<sup>72,73</sup> and<sup>74</sup> The concordance rate for the development of 11q23-related acute leukemia in monozygotic twins with shared circulation approaches 100%, with the disease manifesting quickly (i.e., 5 to 24 months of age). The concordance rate for monozygotic twins with shared circulation who develop childhood common ALL, including those with the *TEL-CBFA2* fusion, is estimated to be less than or equal to 5%, with the leukemia often developing 3 to 4 years after birth.<sup>75</sup> These twin studies suggest that proliferating pluripotent progenitor cells in the developing bone marrow are uniquely susceptible to malignant transformation by *MLL*-associated chimeric fusion proteins. Further, the identical *MLL* gene rearrangements found within each pair of twins suggests the leukemic clone arose in one infant and spread via the placental circulation to the other twin infant.

Approximately 80% of leukemias that develop secondarily in patients treated with DNA-topoisomerase II inhibitors such as the epipodophyllotoxins (e.g., etoposide) and the anthracyclines are associated with a chimeric gene fusion involving *MLL*.<sup>44,45</sup> and<sup>46</sup> While the *MLL* fusions in secondary AML occur within the 8.5-kb breakpoint cluster region, they are more often distributed in the telomeric region, compared with the more centromeric region in cases of primary AML. Interestingly, the telomeric region has scaffold attachment regions and topoisomerase II consensus binding sites.<sup>76,77</sup> The DNA-topoisomerase II inhibitors stabilize the DNA-topoisomerase II complex after it cleaves double-stranded DNA, allowing for the accumulation of double-strand DNA breaks that are then presumably more susceptible to *MLL* translocations via nonhomologous recombination events. Acute leukemia then develops within 6 to 24 months after diagnosis of the primary malignancy, and typically without antecedent MDS. This is in distinct contrast to the secondary acute leukemias that develop following exposure to alkylating agents, which lack an association with *MLL*, have a chromosome 7q- or 5q- karyotype, have a latency period of 5 to 10 years, and are more often associated with an antecedent MDS.<sup>78</sup>

The short latency noted with *MLL*-associated infant and secondary acute leukemia suggests that the molecular defect itself might be all that is required for malignant transformation, or might predispose the affected hematopoietic stem cells to rapidly undergo additional secondary mutations. For example, if the fusion with an *MLL* partner gene protected against apoptosis or promoted enhanced cell growth, the stimulation from marrow stromal factors in the developing fetus or in the patient recovering from topoisomerase II inhibitor chemotherapy-induced aplasia might lead to the rapid acquisition of additional genetic alterations associated with full transformation of the leukemic clone.<sup>79</sup>

## RETINOIC ACID RECEPTOR GENE REARRANGEMENTS IN ACUTE PROMYELOCYTIC LEUKEMIA

Acute promyelocytic leukemia (APL) is one of the best examples of how a molecular characterization of leukemia can provide insights into the pathogenesis and the success of a serendipitous treatment approach. A unique molecular defect, the *PML/RAR-a* fusion, segregates with a single phenotype, FAB M3 APL, and identifies a set of patients who are essentially all initially responsive to differentiation therapy with all-*trans*-retinoic acid (ATRA).<sup>80</sup> *RAR-a* is located on chromosome 17 and encodes a transcriptionally active protein that contains two zinc finger DNA-binding domains and a ligand-binding domain that interacts with retinoic acid derivatives. The promyelocytic leukemia (*PML*) gene is located on chromosome 15 and encodes a protein that also has zinc finger motifs.<sup>81,82</sup> *PML* proteins are normally localized to macromolecular nuclear organelles called PML oncogenic domains (PODs). With the t(15;17)(q22;q12-21), the resultant *PML/RAR-a* fusion protein contains each of the functional domains described previously, yet appears to act as a dominant negative inhibitor of wild-type *RAR-a* function, and disrupts the PODs into a dispersed microparticulate pattern, preventing localization of *PML*. Both of these effects likely lead to an arrest in myeloid differentiation at the promyelocyte stage, and the subsequent development of APL, but the molecular details of this process are not yet clear.<sup>83</sup> One mechanism for the transcriptional inhibitory effect on myeloid differentiation is the *PML/RAR-a* fusion protein's ability to bind DNA and form complexes with N-COR and HDAC1, as was shown for the CBFA2-CBFA2T1 fusion protein in Figure 46.1-1B. The complex in turn alters chromatin conformation in such a way that transcription of target genes responsible for myeloid differentiation is repressed.<sup>84,85</sup> ATRA appears to overcome the dominant negative actions of the *PML/RAR-a* fusion protein and allows *PML* to relocalize to the PODs. It releases the N-COR and HDAC1 complex from the *PML/RAR-a* DNA-bound protein, allowing *RAR-a*-mediated transcription and myeloid differentiation to proceed.<sup>86</sup> The serendipitous introduction of ATRA for the treatment of APL turned out to be the first truly effective targeted therapy for the treatment of acute leukemia and has had a profound effect on improving the cure rate for this disease (see Chapter 46.2). Resistance to ATRA likely involves the up-regulation of cellular retinoic acid-binding proteins as well as increased cellular degradation of ATRA.

The disruption of the *RAR-a* locus and its fusion with other nuclear proteins via chromosome translocation is responsible for the APL phenotype (see Table 46.1-1). One of several variant translocations involving *RAR-a* is the t(11;17)(q23;q21), which fuses the *PLZF* (for promyelocytic leukemia zinc finger) gene with *RAR-a* and results in APL that is not responsive to ATRA.<sup>87</sup> When fused with *RAR-a*, *PLZF* itself is capable of forming complexes with N-COR and HDAC1<sup>88</sup> that in turn inhibit the

transcription of target genes responsible for myeloid differentiation. However, unlike PML, PLZF does not disassociate from the complex on exposure to ATRA, thus maintaining a repressed chromatin conformation and consequent inhibition of transcription in the presence of this treatment. <sup>86</sup>

### GENE FUSIONS IN B-LINEAGE ACUTE LYMPHOBLASTIC LEUKEMIA INVOLVING THE *E2A* Gene

The *E2A* gene encodes a basic HLH (bHLH) transcription factor that was originally discovered to regulate Ig kappa gene expression, <sup>89</sup> but was subsequently found to have three differentially spliced products involved in multiple regulatory aspects of B-cell development. <sup>90</sup> The amino terminus of the *E2A*-encoded protein contains two transcriptional activation domains, <sup>91</sup> and the carboxyl terminus contains the bHLH domain. The latter is responsible for both DNA binding and homodimerization or heterodimerization with other bHLH proteins. The various protein partners normally dimerizing with the *E2A* gene products determine its DNA-binding specificity and consequent gene activation during development. <sup>92</sup> The *E2A* homodimer is itself critically important during normal B-cell development. <sup>93,94</sup> It is the carboxyl end of *E2A* that is disrupted by distinct partner genes in two important gene fusions associated with B-lineage ALL (see [Table 46.1-1](#)). Both of the fusion proteins invariably contain the two transcriptional activation domains at the amino terminus of *E2A*.

The t(1;19)(q23;p13) occurs in childhood pre-B-cell ALL and fuses the amino terminus of *E2A*, including the two transactivation domains, to the homeodomain of *PBX1*, a member of the TALE (three-amino acid extension) family of homeodomain proteins. <sup>95,96</sup> *PBX1* is normally not expressed during B-cell development. The inclusion of the *PBX1* homeodomain in the fusion protein is likely critical to leukemogenesis, as it allows complex formation with HOX proteins, substituting for the severed bHLH DNA-binding protein interaction domain of *E2A*. Thus, although *PBX1*, by itself, has no transactivating ability, its fusion with the strong *E2A* transactivating domains bestows this property on the novel chimeric protein, <sup>97</sup> allowing for activation of genes normally controlled by *PBX1*-HOX complexes, but with inappropriate expression in the pre-B cell. Indeed, the first of such genes (*WNT-16*, <sup>EB-1</sup>) have been identified and will likely provide additional insights into the mechanism by which this fusion transcript induces malignant transformation of human pre-B cells. <sup>98,99</sup>

*E2A* also fuses with the hepatic leukemia factor (*HLF*) gene in the t(17;19)(q22;p13) in a small subset of ALL patients with the proB-cell (CD45R+) phenotype and only partial rearrangement of a functional heavy chain gene. <sup>100,101</sup> *HLF* is a basic region/leucine zipper (bZIP) transcription factor whose protein product has structural similarity to the proapoptotic gene product of *Caenorhabditis elegans*, *CES-2* (for cell-death specification-2). <sup>102</sup> *In vitro* studies demonstrate that the *E2A*-*HLF* fusion protein induces strong antiapoptotic gene expression in pro-B cells, <sup>103</sup> and that amino terminus-containing transactivation domains of *E2A* are critical for this function, while the DNA-binding and protein dimerization motifs of *HLF* are not. <sup>104</sup> It thus appears that *E2A*-*HLF* contributes to leukemogenesis by interfering with an evolutionarily conserved lineage-specific suicide pathway in pro-B cells, leading to prolonged survival and subsequent malignant transformation of genetically altered cells normally programmed for cell death. <sup>104</sup>

### PHILADELPHIA-POSITIVE CHRONIC MYELOID LEUKEMIA AND ACUTE LYMPHOBLASTIC LEUKEMIA RESULT FROM A FUSION OF *BCR* WITH THE TYROSINE KINASE *ABL*

The Philadelphia chromosome <sup>105</sup> is produced by a t(9;22)(q34;q11) <sup>106</sup> that results in a fusion of the phosphoprotein *BCR* with the truncated *ABL* tyrosine kinase protooncogene on chromosome 22. <sup>107,108</sup> and <sup>109</sup> The t(9;22) and subsequently the fusion oncoprotein were first noted in patients with CML, and then in 30% to 40% of adults and 3% to 5% of children with ALL. <sup>110</sup> In CML and in ALL, the *ABL* gene consistently fuses within its first intron to *BCR*, thus always contributing its complete tyrosine kinase domain. However, in CML, *BCR* fuses to *ABL* within a 5.8-kb region known as the major breakpoint cluster region that spans exons 12 through 16 to produce a chimeric oncoprotein product known as p210*bcr-abl*, while in ALL and a minority of patients with CML, *ABL* fuses with *BCR* at various sites within its first intron known as the minor breakpoint cluster region to produce a chimeric oncoprotein product known as p185*bcr-abl* or p190*bcr-abl*. A larger *BCR*-*ABL* fusion protein (p230*bcr-abl*) has been found in a subgroup of CML patients with a more indolent clinical course (reviewed in reference <sup>111</sup>).

The ability of the *BCR*-*ABL* fusion protein to transform cells has been studied in a host of elegant *in vitro* and *in vivo* systems by numerous investigators and has provided insight into what regions of the fusion protein are required for transformation of cell lines and which signal transduction pathways are likely involved in mediating this transformation. A comprehensive review of this work has been carefully undertaken. <sup>112</sup> The first 63 amino acids of *BCR* are responsible for the tetramerization of the fusion protein, which is necessary for tyrosine kinase activation and activation of the F-actin binding function within *ABL*. Tyrosine 177 in the *BCR* portion of the fusion protein is required for transformation because once phosphorylated by the *ABL* tyrosine kinase it serves as a docking site for the SH2 domain of Grb-2. <sup>113</sup> The phosphoserine-threonine domain located between amino acids 192 and 413 of *BCR* may be responsible for activation of the *ABL* kinase.

The three regions in the *ABL* portion of the fusion protein that are required for transformation are the SH2 domain, the SH1 tyrosine kinase domain, and the F-actin binding domain. <sup>112</sup> Three properties of the fusion protein appear to contribute critically to its *in vitro* transforming ability: First, *BCR*-*ABL* has constitutive and elevated tyrosine kinase activity; second, this dysregulated kinase activity is confined to the cytoplasm, in distinct contrast to the wild-type *ABL* that moves between the nucleus and the cytoplasm <sup>114,115</sup>; and third, its constitutive activation of the tyrosine kinase domain in the cytoplasm results in the activation of a multitude of both cytoplasmic and nuclear signaling pathways that enhance the cell's growth and survival ( [Fig. 46.1-3](#)). The substrates activated as a consequence of this signaling include CRKL, CBL, RIN, RAS, RAF, phosphatidylinositol-3-kinase, JUN, MYC, STAT5, PAXILLIN, and FAK (reviewed in references <sup>111</sup> and <sup>112</sup>). However, although these studies reveal the complexity by which the *BCR*-*ABL* fusion protein can transform *in vitro*, it is unclear how much of this dysregulation is responsible for the clinical disease we know as CML. The use of different promoters to drive the expression of the oncoprotein, the absence of the *ABL*-*BCR* gene, and the presence of two wild-type *BCR* and *ABL* alleles may, among other *in vitro* conditions, all serve to sufficiently alter the dose or function of *BCR*-*ABL* in the transduced cell lines such that it may bear only some resemblance to what may actually happen *in vivo*. The specific oral *ABL* kinase inhibitor STI571 was tested in chronic phase CML patients who had failed to respond to interferon therapy, and complete hematologic response (i.e., normalization of counts for greater than or equal to 4 weeks) was obtained in 23 of 24 (96%) patients on treatment for at least 4 weeks, with minimal side effects. A significant fraction of these patients have also achieved a complete cytogenetic response as well, again emphasizing how specific targeting of molecular defects is likely to have a significant effect on treatment outcome (see [Chapter 46.3.1](#)). <sup>116</sup>

**FIGURE 46.1-3.** Promiscuous cell signaling by the *BCR*-*ABL* oncoprotein. The t(9;22)(q34;q11) results in the fusion of the phosphoprotein *BCR* with the truncated *ABL* tyrosine kinase protooncogene. The first 63 amino acids of *BCR* are responsible for the fusion protein tetramerization and consequent constitutive and elevated tyrosine kinase activity that is restricted to the cytoplasm. This activation results in phosphorylation of a multitude of cellular and nuclear signaling molecules (some of which are shown) whose pathways ultimately affect cell growth, differentiation, and cell survival. PI3-K, phosphatidylinositol-3 kinase; TK, tyrosine kinase.

### GENE FUSIONS INVOLVING THE NUCLEOPORIN FAMILY OF PROTEINS

Nucleoporins (NUP) make up the nuclear pore complex (NPC), which promotes the selective transportation of both RNA and protein between the nucleus and the cytoplasm in a bidirectional fashion. <sup>117</sup> In the past several years, a series of gene fusions involving two NUPs have been described in *de novo* AML, treatment-related AML, and in T-cell ALL. The first such fusion to be cloned was *DEK*-*CAN*, found in children and young adults with t(6;9)(p23;q34) AML (see [Table 46.1-1](#)). <sup>118</sup> *CAN*, also called *NUP214*, is an NPC protein that contains multiple NUP-specific Phe-Gly (FG) peptide sequence motifs that mediate protein-protein interaction thought to be required for nuclear-cytoplasmic transport, cell-cycle control, and cell survival. <sup>119,120</sup> *NUP214* fuses with the amino terminus of *DEK*, a putative DNA-binding transcription factor. *NUP214* has also been shown, in a single case of inv(9)(q34q34) AML, <sup>118</sup> to fuse with *SET*, a nuclear protein that is thought to regulate G<sub>1</sub>/S

transition by modulating the activity of cyclin E–cyclin-dependent kinase-2 activity via p21 *Cip1*.<sup>121</sup> *SET-NUP214*, like *DEK-NUP214*, is located exclusively in the nucleus, leaves the FG repeat-rich motif intact, and therefore presumably interacts with the same cellular proteins likely to be important in leukemogenesis.<sup>119</sup>

The other important NPC gene involved in leukemogenesis is *NUP98*, located at chromosome 11p15, which, like *NUP214*, lends its amino terminus FG repeat domains to fuse in frame to a variety of partners in acute leukemia. *NUP98* was first identified as part of the t(7;11)(p15;p15), associated primarily with AML.<sup>122</sup> In this instance, *NUP98* fuses with the carboxyl terminus of *HOXA9*, located at chromosome 7p15, a homeobox gene that regulates hematopoietic differentiation. Evidence suggests that this fusion transcript requires the *HOXA9* domains for DNA binding and interaction with PBX proteins, while the FG repeats of *NUP98* act as transactivators of gene transcription and recruit cAMP response element (CREB)–binding protein and p300 as requisite transcriptional coactivators. Thus, the properties of the *NUP98-HOXA9* fusion protein collectively result in a deregulation of HOX-responsive genes with consequent induction of AML.<sup>123</sup> The other fusion partners of *NUP98* have not yet shed additional light on the mechanism of FG-rich NPC protein–mediated leukemogenesis, but do provide supporting evidence that *NUP98* is a recurrent target primarily in treatment-related AML/MDS.

## GENE ACTIVATION IN LEUKEMIA

### GENE ACTIVATION INVOLVING IMMUNOGLOBULIN GENES IN B-CELL LEUKEMIA AND LYMPHOMA

In the t(8;14)(q24;q32), the prototypic bHLH/bZIP transcription factor *MYC* is juxtaposed to a region of strong Ig heavy chain enhancer elements. Two variants have also been described in which regulatory portions of the *Igk* gene on chromosome 2 or the *Ig lambda* ( $\lambda$ ) gene on chromosome 22 are juxtaposed to the *MYC* locus of chromosome 8 (see [Table 46.1-1](#)). In each instance, the B cell experiences a deregulation of *MYC* gene expression because of its inappropriate activation and control by Ig regulatory elements whose expression is B-cell specific. This resultant malignant B-cell transformation takes the form of either Burkitt's lymphoma or ALL. The earliest of these studies were the first to demonstrate that rearrangement of specific genes that resulted from chromosomal translocations were actually at the heart of malignant transformation.<sup>124,125</sup>

*MYC* is capable of activating gene transcription by forming a heterodimer with *MAX*, which normally homodimerizes with itself or heterodimerizes with *MAD* or *MXI-1* to repress transcription. Therefore, the overexpression of *MYC* in B lymphocytes, carrying the t(8;14)(q24;q32) or one of its variants, functions to disrupt the normal equilibrium that *MAX* shares with its partners, ultimately leading to the inappropriate overexpression of a multitude of downstream genes activated by the *MYC-MAX* heterodimer. How the activation of these downstream events in turn induces the malignant B-cell transformation is still incompletely understood and an area of intense study (reviewed in references [126](#) and [127](#)).

### GENE ACTIVATION INVOLVING T-CELL RECEPTOR GENE IN T-CELL LEUKEMIA AND LYMPHOMA

A comparable group of transcription factors, normally active during early hematopoiesis, but not during more committed T-cell development, are rearranged via chromosome translocation to lie near enhancers within the T-cell receptor *TCRb* (chromosome 7q34) and *TCRa/d* (chromosome 14q11) loci. As a consequence, these regulatory genes become inappropriately expressed, and their protein products contribute to T-cell leukemogenesis. They include the bHLH *TAL1/SCL*,<sup>128,129</sup> *TAL2/SCL2*,<sup>130</sup> *LYL1*,<sup>131</sup> as well as *MYC*.<sup>132,133</sup> and <sup>134</sup> Each of these specific translocations are listed in [Table 46.1-1](#).

Rearrangements involving *TAL* account for up to 25% of childhood cases of T-cell ALL and T-cell lymphoma, but are seen infrequently in adults. *TAL1* is normally coexpressed with another transcription factor called *LMO2*, and both are part of a larger transcriptional complex that includes the zinc finger transcription factors *GATA1* and *E2A*. The complex is likely to be important for normal erythropoiesis.<sup>135</sup> *LMO2* and *LMO1* are both rearranged near the regulatory elements of *TCR* loci in T-cell ALL (see [Table 46.1-1](#)).<sup>136,137</sup> and <sup>138</sup> The mouse *Hox11* gene is a homeobox transcription factor that is likely critical for lymphocyte development and survival, in that it prevents apoptosis of splenocytes in the mouse.<sup>139</sup> Further, *Hox11* interacts with a protein serine-threonine phosphatase, PP1C, allowing bypass of the G<sub>2</sub> checkpoint following injury and progression to the M phase.<sup>140</sup> Thus, its juxtaposition within the regulatory regions of the *TCRb* and *TCRa/d* loci<sup>141</sup> results in its ectopic expression in T cells, which likely contributes to T-cell ALL via its inhibition of normal programmed cell death and disruption of normal cell cycling, two processes that facilitate tumor progression.

T-cell prolymphocytic leukemia (T-PLL) is a rare form of mature T-cell leukemia characterized by chromosomal inversions and translocations involving chromosome band 14q11, containing the *TCRa/d* gene. The inv(14)(q11q32.1) and the t(14;14)(q11;q32) each juxtapose the T-cell leukemia-1 (*TCL1*) gene at 14q32.1 to *TCRa/d*, and the rarely seen t(7;14)(q35;q32.1) juxtaposes *TCL1* to the *TCRb* gene.<sup>142,143</sup> The t(X;14)(q28;q11) rearranges another gene, *MTCP1*, within the *TCRa/d* locus as well in T-PLL.<sup>144</sup> While the function of *TCL1* and *MTCP1* remain unknown, they share 40% amino acid identity, and with the elucidation of the three-dimensional structure of *MTCP1* showing a compact eight-stranded b-barrel structure, it appears that these two gene products are the first members of a b-barrel family of proteins.<sup>145</sup>

## TUMOR SUPPRESSOR GENES IN LEUKEMIA

### INACTIVATION OF TUMOR SUPPRESSOR BY GENE MUTATION

Mutations in tumor suppressor genes that result in functional inactivation likely contribute to the process of malignant transformation by disrupting the signals that normally inhibit cell growth (see [Chapter 6](#)). This process normally requires disruption of both copies of relevant tumor suppressor genes, which can occur by such genetic alterations as point mutation, frame-shift mutation, and deletion, or by epigenetic alterations such as hypermethylation.<sup>146,147</sup> Approximately 10% to 20% of patients with B-cell chronic lymphocytic leukemia have mutations in *p53*, a tumor suppressor gene, with an increase in frequency as the disease progresses and a correlation with poor clinical outcome.<sup>148</sup> *p53* can also be inactivated by *MDM2*, itself an oncoprotein that is up-regulated by *p53* and then serves to bind and inactivate it in a negative feedback loop without gene mutation. An increased expression of *MDM2* in chronic lymphocytic leukemia has been correlated with progressive disease.<sup>149</sup>

### INACTIVATION OF TUMOR SUPPRESSOR BY GENE DELETION

The frequent deletion of the human chromosome 9p21 region in leukemia and other cancers led to the search and ultimate discovery of two tumor suppressor genes at this locus, *p16* and *p15*. *p16* blocks cell-cycle progression by inhibiting cyclin-dependent kinase, as does *p15*, whose expression can be induced by transforming growth factor- $\beta$ .<sup>150,151</sup> and <sup>152</sup> A review of the literature on the frequency of *p15* and *p16* deletions (*p15del* and *p16del*, respectively) in leukemia showed they were frequently deleted in T-lineage ALL, ranging between 47% and 64%, as well as in B-lineage ALL, with a frequency between 20% and 27%. Likewise, in CML lymphoid blast crisis, the frequency of *p15del* was noted to be 27%, while *p16del* was 35%. There was little difference in frequency between children and adults with ALL, but *p15del* and *p16del* were absent from infants with ALL. The frequency of *p15del* and *p16del* was noted to be low in chronic T- and B-cell leukemias and is uncommon in AML, MDS, or CML (i.e., less than or equal to 2%).<sup>153</sup>

*ATM* is a kinase and putative tumor suppressor gene thought to have a role in cell-cycle checkpoint control. Indeed, patients with the genetic disease ataxia-telangiectasia have a loss of *ATM*, an increased frequency of translocations and inversions involving *TCL1*, and a clonal excess of mature T cells. This develops years before a significant fraction of these patients progress to T-PLL.<sup>154,155</sup> This finding is consistent with a model by which the deregulation of *TCL1* could serve as a tumor initiator, and loss of tumor suppressor genes might function to further promote progression of T-PLL. In strong support of this model and in support of *ATM* as a tumor suppressor gene, a large fraction of sporadic T-PLL cases, many with rearrangements of *TCL1*, have been shown to contain inactivating deletions and missense mutations of *ATM*.<sup>156</sup>

### INACTIVATION OF TUMOR SUPPRESSOR BY HYPERMETHYLATION

Methylation of CpG islands located in the 5' regulatory region of genes can lead to the repression of gene transcription and illustrates an epigenetic mechanism for inactivation of tumor suppressor genes.<sup>147</sup> Multiple known tumor suppressor genes have been shown to be inactivated via hypermethylation in leukemia, including *p15* and *p16*. While *p16* is often inactivated by hypermethylation in epithelial tumors, it is *p15* that is frequently inactivated by hypermethylation in hematologic malignancies, most notably in AML and MDS, but also in ALL. Intriguingly, *p16* is not inactivated in these cases by either deletion, methylation, or point mutation.<sup>157,158</sup> and <sup>159</sup> In AML, and possibly in MDS, the density of *p15* methylation (i.e., the percent of CpG dinucleotides that are methylated on each allele) appears to correlate

best with the degree of gene silencing and may increase as the disease progresses.<sup>157,160</sup> Other candidate tumor suppressor genes, such as *p73* in ALL,<sup>161</sup> have also been shown to be inactivated by hypermethylation.

While most investigations of aberrant CpG island methylation in human cancer have primarily taken a candidate gene approach, we performed a global analysis of the methylation status of 1184 unselected CpG islands in each of 98 primary human tumors including AML using a technique termed *restriction landmark genomic scanning*. This approach showed that an average of 608 CpG islands were aberrantly methylated in these tumors (range, 0 to 4500), and it allowed the identification of patterns of CpG island methylation that were shared within each tumor type, together with a pattern that was specific for acute leukemia. Which tumor suppressor genes are systematically silenced by this process has not yet been determined. However, these data suggest that the methylation of particular subsets of CpG islands has specific consequences for leukemogenesis and is likely an important event in disease progression.<sup>162</sup> One of the exciting avenues being pursued by several laboratories is the reversal of methylation status with pharmacologic agents such as 5-azacytidine, which often results in reexpression of the target gene.

## MOLECULAR MONITORING OF LEUKEMIA

### ASSESSMENT OF MINIMAL RESIDUAL DISEASE

Molecular analysis can not only play a role in the diagnosis and treatment of leukemia, but may also prove to be useful for monitoring a patient's response to therapy. Both the exponential amplification of small fragments of DNA and RNA by polymerase chain reaction (PCR) and reverse transcription PCR, respectively, and the growing discovery of the unique gene fusions and *Ig* and *TCR* gene rearrangements in leukemia, form the basis for our ability to detect the presence of these genetic alterations while a patient is in complete morphologic and clinical remission. There have been at least two important observations made with the advancement of this technology and the explosion of literature on the subject of minimal residual disease (MRD) in leukemia. First, in some instances (e.g., *MLL* PTD, *BCR-ABL*), the fusion transcripts can be detected in bone marrow, blood samples, or both from normal individuals.<sup>163,164,165,166</sup> and <sup>167</sup> The reasons for this are not entirely clear, but in some cases the fusions in normal individuals are clearly distinct from the malignant gene fusions and likely occur through entirely different mechanisms.<sup>66,164,165</sup>

Second, the persistence of *PCR-detectable* chimeric or rearranged genes is not at all a guarantee of persistent functional disease or eventual relapse in either CML<sup>168</sup> or some types of AML (e.g., *CBFA2-CBFA2T1*).<sup>169,170</sup> The reasons for this are also not known, but likely involve the presence of the fusion transcript in a normal parental clone, immunologic suppression of MRD by the host, or the absence of additional genetic alterations that were required for tumor initiation, progression, or both.<sup>171</sup> There are some striking examples of how the detection of MRD by PCR can predict relapse in ALL<sup>172</sup> and APL<sup>173</sup> but most of these studies have yet to be confirmed in large prospective trials with standardized criteria for quantitative methodologies and uniform evaluation intervals. The ability to accurately quantify these genes and gene products using more fully automated technologies<sup>174</sup> might ultimately identify levels of MRD above which relapse is probable and below which relapse is unlikely. However, as we learn more about the evolutionary history of the leukemic clone and the seemingly high likelihood that in many instances, a multitude of genetic alterations are required for leukemogenesis, the simultaneous detection of several such alterations may prove to be more predictive of outcome following the achievement of a clinical complete remission. The incorporation of genetic profiling with cDNA microarray technology is likely to have a significant effect on unraveling the molecular complexity of leukemia for the purposes of diagnosis, classification, treatment, and monitoring clinical outcome.<sup>175</sup>

### Acknowledgments

The authors would like to thank Tamra Brooks, John Byrd, Megan Cooper, Todd A. Fehniger, Peter J. Kourlas, Guido Marcucci, Krzysztof Mrózek, Laura Rush, Matthew P. Strout, and Susan P. Whitman for their assistance. This work was supported in part by grants P30 CA16058, U10 CA37027, and T32 CA09338, National Cancer Institute, Bethesda, MD, and the Coleman Leukemia Research Fund.

## INTRODUCTION

Leukemias are clonal, neoplastic proliferations of immature cells of the hematopoietic system, which are characterized by aberrant or arrested differentiation. Leukemia cells accumulate in the bone marrow cavity, ultimately replacing most of the normal hematopoietic cells, thus resulting in the signs and symptoms of the disease. These include most prominently, bone marrow failure and its consequences of anemia, hemorrhage, and infection. Leukemia cells circulate into the blood and other tissues throughout the body, with patterns characteristic of the particular type of leukemia. The acute leukemias, which can be broadly grouped as either lymphoblastic or myelogenous, can be identified phenotypically and genetically and are characterized by a rapid clinical course usually necessitating immediate treatment. Acute leukemias are derived from, and biologically resemble, primitive hematopoietic progenitor cells; in contrast, chronic leukemias have the phenotype and biologic character of more mature cells. Chronic myeloid leukemia (CML), however, over time may transform to an acute, blastic phase and thereafter more closely resembles an acute leukemia in its biology, clinical course, and need for therapy.

The acute lymphoblastic leukemias (ALLs) are distinguished generally from the lymphomas because the latter resemble more mature lymphoid cells and typically inhabit the lymph nodes, spleen, or other extramedullary sites before spreading to involve the blood or bone marrow. Certain lymphomas, such as lymphoblastic lymphomas and Burkitt's lymphomas, retain features of both the leukemias and lymphomas, but are derived from immature cells and require therapy similar to that used for ALL. Other lymphomas, and sometimes multiple myelomas, however, may spread widely into the blood and bone marrow, and in such a phase, can be described as *leukemic*, but are not true leukemias.

Leukemia (meaning *white blood*) was originally described in 1845 by Virchow.<sup>1</sup> Although acute leukemias are relatively rare cancers, these leukemias are the most carefully studied and best characterized neoplasms. Numerous subtypes have been defined based on morphology, genetics, immunophenotype, and biologic behavior. Oncogenes responsible for leukemogenesis are beginning to be identified, and there is an enlarging body of knowledge regarding the factors regulating leukemia cell growth and function. Multiple drugs capable of killing leukemia cells are now available. Therapeutic strategies that have been developed often result in clinical remissions of adult leukemias and, in a smaller fraction of patients, result in cures. Despite these advances, acute leukemia remains, for most patients, a fulminant and incurable disease, requiring immediate diagnosis and treatment. The course of patients with acute leukemia is often complicated by the severity of the treatments themselves (Fig. 46.2-1).

**FIGURE 46.2-1.** Overall survival for up to 25 years of follow-up in adults treated on protocols at Memorial Hospital, New York City. Patients older than 60 years of age have a substantially worse prognosis for both acute lymphoblastic leukemias (ALL) and acute myelogenous leukemias (AML). Patients treated on more recent protocols have a similar outcome to those on earlier protocols. (Data accrued by B. D. Clarkson, C. Little, D. Tyson, L. Megharian, and D. A. Scheinberg.)

## EPIDEMIOLOGY AND ETIOLOGY

## INCIDENCE

The acute leukemias are rare diseases, but have a disproportionately large effect on cancer survival statistics among children and younger adults. Although the acute leukemias account for less than 3% of all cancers, these diseases are the leading cause of death due to cancer in the United States in persons younger than 35 years of age.<sup>2,3</sup> The incidence rate of acute myelogenous leukemias (AMLs) in the United States is approximately 2.5 per 100,000 persons; for ALL, the rate is approximately 1.3 per 100,000 persons. AML has a slight male predominance (1.5:1.0) and accounts for 25% of both acute and chronic leukemias. AML affects approximately 9000 people a year in the United States. ALL affects approximately 4000 people, with a similar predominance of male subjects. The incidences of acute leukemias in the United States have not changed substantially since the 1980s, although there is a slight trend upward among those diagnosed with ALL and a slight decrease in the number of diagnoses of AML in this time period. Incidence rates for acute leukemia are similar worldwide. In ALL, the incidence rates in African Americans are approximately one-half that seen in whites; in AML, rates are similar between these two groups. Age-specific incidences differ dramatically between ALL, which has a median age at diagnosis of 10 years, and AML, which has a median age of 65 years. AML is rare below the age of 40, but the incidence increases progressively with age from approximately 1 per 100,000 at age 40 to more than 15 per 100,000 at age 75 or older. In contrast, ALL has its peak incidence at less than 10 years and has a second smaller increase in persons older than 70 ( Fig. 46.2-2).

**FIGURE 46.2-2.** Age-specific incidence of acute myelogenous leukemias (AML) (circles) and acute lymphoblastic leukemias (ALL) (squares) in the United States. (Adapted from ref. 3.)

## SECONDARY LEUKEMIAS

For most patients with acute leukemia, the cause of the disease is unknown. Because leukemias are the result of a genetic alteration in a clonogenic cell, which can often be identified by a chromosomal translocation, deletion, or mutation, known and suspected carcinogens have been explored as causative agents in acute leukemia. A clear cause of leukemia can be found in the minority of patients with a history of prior chemotherapy or radiation therapy. Such secondary leukemias, more than 90% of which are myeloid, are notoriously difficult to treat. The chromosomal abnormalities often observed in these secondary leukemias are associated with a poor prognosis, even when observed in patients without a history of prior therapy or toxic exposure.

Secondary myeloid leukemias first became apparent in the early survivors of Hodgkin's disease.<sup>4,5</sup> Studies initially linked the use of alkylating agents such as nitrogen mustard to the increased risk. Among a large cohort of patients treated with chemotherapy and radiotherapy for Hodgkin's disease, 163 cases of secondary leukemia were found.<sup>6</sup> There were dose-related increases in secondary leukemia. More recent studies have not linked radiotherapy, when used alone, to an increased risk.<sup>7</sup> Mechlorethamine (nitrogen mustard), procarbazine, cyclophosphamide, lomustine, teniposide, and chlorambucil were all implicated in the increased risk. The risk for secondary AML was greatest between 2 and 9 years after therapy, with 85% of cases occurring before the tenth year.<sup>6,7</sup>

Curative therapy for childhood ALL has a risk of inducing secondary AML as well.<sup>8,9 and 10</sup> The increased risk of AML occurred within 6 years and was originally associated with a T-cell phenotype of the original ALL<sup>8</sup> and use of an epipodophyllotoxin (etoposide or teniposide)<sup>9</sup> or alkylating agent.<sup>10</sup> The risk from epipodophyllotoxins was proportional to the dose intensity of the drug, rather than the cumulative dose, with the highest risks associated with weekly or twice weekly administration.<sup>9</sup> In contrast, secondary AML was not increased in pediatric ALL protocols in which epipodophyllotoxins were not used.<sup>11</sup>

Several additional studies in both adults and children have confirmed the association between treatment with epipodophyllotoxins and secondary AML,<sup>12,13 and 14</sup> in particular, monocytic leukemias with abnormalities of chromosome 11q23. Promyelocytic leukemias with t(15;17) have also been associated with etoposide and with other chemotherapeutic agents, such as doxorubicin, that target topoisomerase II.<sup>15</sup>

Dose-dependent risks for secondary AML have also been observed in adults treated with alkylating agents, including platinum-based drugs and radiotherapy for breast cancer<sup>16</sup> and ovarian cancer,<sup>17</sup> and for a variety of neoplasms treated with an autologous bone marrow transplant (BMT) after high-dose radiation and alkylating agent therapy.<sup>18</sup> Among the alkylating agents, cyclophosphamide appears to hold less risk; a study of the incidence of secondary leukemia in patients with breast cancer treated with moderate doses of cyclophosphamide confirms this lower level of risk.<sup>19</sup>

## OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

The clear relationship between the atomic bomb radiation<sup>20</sup> or use of carcinogenic therapies and the development of secondary leukemias has led to the exploration of the possible leukemogenic role of other potential carcinogens in the environment, such as low-dose radiation, chemicals, cigarette smoke, and electromagnetic radiation.<sup>21</sup>

Although electromagnetic fields have received considerable attention as a possible carcinogen, the actual risk of leukemia from exposure to commercial and residential power fields remains controversial.<sup>21,22 and 23</sup> There are a large number of conflicting reports, but there is a lack of clear dose-response relationships, and a causal relationship between leukemia and electromagnetic fields, either as a consequence of occupational exposure or residential power use, has little current support.<sup>21,22 and 23</sup>

Both ALL and AML risks increased as a result of exposure to the atomic bomb.<sup>20</sup> Risks associated with occupational exposure to low-dose radiation are controversial. Early suspicions that paternal exposure at power plants resulted in an increased risk for subsequent children of the exposed workers have been disputed.<sup>24,25</sup>

Cigarette smoke contains numerous carcinogens and has been linked in a dose-dependent manner to leukemia,<sup>26,27 and 28</sup> particularly in patients older than 60 years and to specific chromosomal alterations known to be associated with chemical mutagens. As much as 20% of AML may be attributable to smoking.<sup>27</sup>

Occupational exposure to benzene has been established as a cause of AML,<sup>29</sup> but low-level exposure in the workplace (e.g., less than 10 parts-per-million) has not been clearly established as a risk. Other occupational exposures to solvents, such as toluene or butadiene in the shoe and rubber industries, or hair dyes, have not been shown conclusively to increase leukemia risk.<sup>21</sup>

## OTHER RISK FACTORS

Viruses, and in particular, RNA retroviruses, have been found to cause many neoplasms in experimental animals, including leukemia of mice<sup>30</sup> and cats; a human retrovirus, human T-cell lymphotropic virus-1, has been identified as the cause of a mature T-cell lymphoma and leukemia in humans.<sup>31</sup> A clear retroviral cause for acute leukemia in humans has not been identified. Epstein-Barr virus, a DNA virus, has been associated with oncogenesis in acute B-cell leukemias, Burkitt's lymphomas, especially those of endemic origin, and human immunodeficiency virus-associated lymphomas.<sup>31</sup> Epstein-Barr virus may function by increasing lymphoid

proliferation in patients; this provides a setting in which a second oncogenic event, possibly *myc* oncogene activation, can result in the clonal, neoplastic proliferation.<sup>32</sup> It has not been demonstrated, however, that simple infection with either an RNA- or DNA-based virus alone is a cause of acute leukemia.

Although leukemias are acquired disorders, there may be significant genetic and immunologic predispositions that allow their occurrence. Several genetic syndromes are associated with increased risk of leukemias, including Down syndrome, Fanconi's anemia, Bloom's syndrome, and ataxia-telangiectasia.<sup>33</sup> and<sup>34</sup> Down syndrome is associated with 20-fold increased risk of leukemia; this is typically a megakaryoblastic leukemia in children younger than 3 years of age and a pre-B ALL in children who are older.<sup>35</sup> These true leukemias must be differentiated from a transient abnormal myeloproliferative disorder.<sup>36</sup> Patients with transient abnormal myeloproliferative disorder are neonates with hepatosplenomegaly, modest elevations in blasts, and pancytopenia. Although transient abnormal myeloproliferative disorder is a clonal disorder, in two-thirds of cases the disease has a benign course.

An immunologic predisposition for acute leukemia has not been clearly delineated. However, analyses of HLA types with specific cytogenetically defined subgroups of AML have pointed to associations between certain HLA A, B, C, and DR types and common chromosomal translocations or deletions.<sup>37</sup> These correlations may become increasingly important as an understanding of the immune response to these breakpoints becomes clear.<sup>38</sup>

## BIOLOGY OF ACUTE LEUKEMIAS

More is known about the pathobiology of the acute leukemia cell than about any other neoplasm. This is the consequence of a confluence of discoveries regarding hematopoietic growth factors, hematopoietic stem cells and progenitor cells, oncogenes, and transcription factors. These discoveries were made possible by the availability of acute leukemia cell lines capable of immortal growth in culture, reliable assays for hematopoietic cell growth, and sensitive tests for specific gene expression and protein expression. The important concepts about leukemia cell growth and function are likely to be useful paradigms that will aid in understanding all cancers.

Cell lines derived from and biologically resembling AML and ALL have been available since the 1980s and have allowed careful study of the growth of leukemia cells under controlled conditions and of the effects of antileukemic agents.<sup>39</sup> Mouse models mimicking human leukemias can be prepared by oncogene transfections.<sup>40</sup> In addition, both cell lines and fresh acute leukemias have been propagated in immunocompromised nude or severe combined immunodeficiency (SCID) mice, thus also allowing controlled study of new therapies under conditions *in vivo* as well.<sup>41</sup> Fresh normal and neoplastic hematopoietic cells can also be grown in intermediate-term cultures or colony-forming assays (over 2 to 8 weeks), in which maturation into specific lineages can be observed and modulated by use of exogenous growth factors, drugs, and differentiating agents.<sup>42,43</sup> and<sup>44</sup> This has allowed the elucidation of the sequence and importance of the various growth factors and adhesion molecules during normal and leukemia cell growth and cell death (apoptosis),<sup>45</sup> the identification and isolation of primitive normal stem cells, and the partial reconstitution of normal hematopoiesis *ex vivo*.<sup>42,43,44,45,46</sup> and<sup>47</sup> The growth of myeloid leukemia cells *in vitro* appears to be dependent on interleukin (IL)-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), or macrophage colony-stimulating factor (M-CSF) and may be regulated by IL-6 and tumor necrosis factor as well.<sup>43,47,48</sup> Autocrine production of colony-stimulating factors or mutations in their receptors by cells that also express the appropriate receptors on their cell surfaces may allow unregulated proliferation in the absence of exogenous factors.<sup>43,49,50</sup> Comparable assays *in vivo* using immunosuppressed mice that allow spleen colony formation or complete bone marrow reconstitution have demonstrated that viable hematopoiesis for an entire animal may require as few as 30 hematopoietic stem cells.<sup>51,52</sup>

Enzyme marker studies using glucose-6-phosphate dehydrogenase have shown that leukemia cells derive from a single clonogenic cell.<sup>53,55</sup> Depending on the cell of origin, the leukemia clone may involve cells of more than one lineage (e.g., erythroid and myeloid) or only one lineage. Unlike normal hematopoiesis, the clonogenic leukemia cell generally retains only a limited ability to differentiate into different lineages.<sup>56</sup> The cells responsible for leukemia colony growth *in vitro* represent a more primitive subset of the entire leukemia cell population.<sup>57</sup>

There is considerable aberrancy in the differentiation of leukemia cells, as compared with normal cells, when the cell is examined for surface protein phenotype.<sup>58</sup> There may also be abnormalities in apoptosis, or programmed cell death, that leads to persistence of the leukemic clone<sup>45,59</sup> or abnormalities in telomerase, which promotes longevity.<sup>60</sup> Apoptotic death may still be induced with appropriate growth factors *in vitro*, or in the case of promyelocytic leukemia, by clinical use of retinoic acid (see [Acute Promyelocytic Leukemia](#), later in this chapter). It is likely that many leukemogenic translocations or mutations (see [Chapter 46.1](#), and [Chapter 45.1](#)) result in dysregulation of the cell cycle.<sup>61</sup>

Heterogeneity of the cells that make up the leukemic population is frequently seen.<sup>53,54,57</sup> Although the leukemic clone may involve multiple lineages, typically leukemia blasts are phenotypically of one lineage; within this lineage, stages of maturation may vary, suggesting incomplete control of differentiation. The phenotypic heterogeneity of the leukemia colony-forming cell also suggests that leukemias may arise at various stages of differentiation. This concept was surmised based on the morphologic and phenotypic characteristics of different leukemias; evidence supporting the concept has been demonstrated in patients with acute promyelocytic leukemia (APL), in which the leukemia clone can be positively identified by use of sensitive polymerase chain reaction (PCR) techniques for the t(15;17). In most cases, the most primitive hematopoietic cells remained normal, whereas more mature progenitors contained the neoplastic translocation.<sup>62</sup>

Despite the achievement of a complete clinical remission after therapy of acute leukemia, normal hematopoiesis derived from cells originally involved with the leukemic clone is sometimes present.<sup>63</sup> Apparently normal granulocytes have exhibited persistence of chromosomal markers of the original leukemia.<sup>64</sup> The continued presence of clonal hematopoiesis may suggest the existence of a preleukemic clone of cells that has a proliferative advantage to other normal cells.<sup>63</sup> In spite of this, hematopoiesis in patients in remission is usually polyclonal or oligoclonal.<sup>65</sup>

## DIAGNOSIS AND CLASSIFICATION OF ACUTE LEUKEMIAS

### CLINICAL PRESENTATION

Although the signs and symptoms are relatively nonspecific, the diagnosis of acute leukemia is usually made easily with the history of the illness, the physical examination, and an examination of the blood smear and bone marrow aspirate smear. Additional laboratory examinations (complete blood cell counts, coagulation profile, chemistry profile) or diagnostic imaging (chest radiography, abdominal sonography) are important in the management of the disease, but are not usually necessary for diagnosis. Patients with acute leukemia typically present with a 1- to 3-month history of fatigue or malaise, easy bruisability or frank bleeding, dyspnea, minimal to modest weight loss, fever, bone pain, or abdominal pain ([Table 46.2-1](#)). Excessive bleeding after a minor dental procedure or severe epistaxis may bring the patient to the physician's attention. In adults with an antecedent myelodysplastic syndrome, symptoms may date back for up to a year or more.

Signs and symptoms
Fatigue, malaise, dyspnea
Easy bruisability, weight loss
Bone pain, or abdominal pain (less common)
Neurologic symptoms (rare)
Signs
Anemia and pallor
Thrombocytopenia, hemorrhage, ecchymoses, petechiae, purpura
Leukocytosis
Fever and infection (parotitis, sepsis, bacterial abscess)
Adenopathy, hepatosplenomegaly, mediastinal mass
Edema or skin induration (rare)
Bluish cyanosis and hyperthermia (rare)
Central nervous system (rare)
Immunologic laboratory and diagnostic tests
Complete blood cell count and differential composition studies, including fibrinogen
Bluish cyanosis and hyperthermia, including creatinine, urea, acid, calcium, phosphorus
Examination of the peripheral blood smear
Examination of the bone marrow aspirate smear and biopsy
Examination of the cell surface phenotype, cytogenetics (cell molecular genetics if indicated)
Examination of the serologic and histologic (cell surface) tests using immunofluorescence, immunohistochemistry, or other serologic tests
Examination, study of induction
Comparative morphology of the cells (in peripheral blood, bone marrow, or at the site of the tumor) with acute lymphoblastic leukemia
Examination
Examination, antigen typing (less common practice)

TABLE 46.2-1. Diagnosis and Evaluation of Acute Leukemia

The physical examination typically shows pallor, consistent with anemia, and hemorrhage (in the gums, as epistaxis, in the stool, in the skin as petechiae or

ecchymoses, or as fundal hemorrhage). Less commonly, there is hepatic or splenic enlargement and lymphadenopathy. Fever and infection, usually of respiratory origin are frequent; sepsis may occur. Neurologic signs and symptoms are infrequent at presentation, occur more commonly with ALL, and typically include cranial neuropathies, nausea and vomiting, and headache.

The laboratory evaluation is notable for anemia and thrombocytopenia in most patients, with severe thrombocytopenia (less than 50,000/ $\mu$ L) in more than one-half of patients. The white blood cell (WBC) count can be normal, reduced, or elevated; less than 20% of patients have greater than 100,000 cells per  $\mu$ L, and an equal number of patients have less than 5000 cells per  $\mu$ L. Acute monocytic leukemias and T-cell leukemias may have the highest WBC counts. Examination of the peripheral blood smear shows blasts in almost all cases. Peripheral blood blasts may be absent in some patients with lymphoblastic or Burkitt's lymphoma. Peripheral blood myeloblast levels in excess of 100,000/ $\mu$ L represent a medical emergency requiring prompt reduction in the blast level to prevent leukostasis. The prothrombin time and partial thromboplastin time may be elevated; in APL, this coagulopathy is often associated with reduced fibrinogen and other evidence of disseminated intravascular coagulation (DIC) and is another medical emergency that must be treated urgently (see [Principles of Clinical Management of Acute Leukemia](#), later in this chapter). Subclinical DIC may be present in any form of acute leukemia.

Blood chemistry results are typically normal, but in advanced disease, or in infiltrative cases such as with monocytic leukemias, there may be evidence of renal dysfunction (elevated creatinine). Renal infiltration and enlargement can be documented with ultrasonography. In cases of high cell turnover and cell death, such as in patients with mature B-cell ALL (ALL-L3), there may be evidence of tumor lysis syndrome at presentation; this syndrome is more commonly seen during the rapid lysis of large numbers of ALL cells, and less often AML cells, during chemotherapy. The laboratory picture of tumor lysis syndrome consists of hypocalcemia, hyperkalemia, hyperphosphatemia, increased lactate dehydrogenase, hyperuricemia and renal insufficiency; if untreated, this syndrome can be fatal (see [Principles of Clinical Management of Acute Leukemia](#), later in this chapter).

The clinical presentation of AML cannot usually be distinguished from ALL without examination of the blasts for immunophenotype and morphology (see [Morphology and Cytochemistry](#) later in this chapter). There are signs and symptoms, however, that are more frequent with certain disease subgroups than with others. Bone pain is more common in ALL, as are signs and symptoms of central nervous system (CNS) infiltration. Lymph node and organ infiltration and enlargement are also more common in ALL and in monocytic subtypes of AML. Gum involvement is seen most frequently in acute monocytic leukemia (AML-M5). Mediastinal masses are found in greater than 50% of patients with T-cell ALL. However, the overlap in symptoms and signs among the leukemia subtypes requires a pathologic diagnosis to be made in all cases. Therefore, a bone marrow aspirate and biopsy, with appropriate cytochemical, immunochemical, and genetic evaluations, must be done in all cases.

The differential diagnosis of acute leukemia includes other neoplastic hematopoietic disorders, such as lymphomas, myelodysplastic syndromes, multiple myeloma, aplastic anemia, severe megaloblastic anemia due to folate or B<sub>12</sub> deficiency, severe lymphocytosis due to infection, such as with Epstein-Barr virus; severe monocytosis due to tuberculosis; and bone marrow failure with release of early cells, such as in myelophthisis, due to carcinoma. Examination of the bone marrow nearly always excludes the nonhematopoietic conditions because of the presence of increased numbers of blasts. Careful morphologic examination and immunophenotyping of the cells then excludes virtually all the hematopoietic conditions based on lineage and maturational stage; one exception is the myelodysplastic syndromes, which often differ from the acute leukemias only in the percentage of blasts in the marrow. Up to one-third of AMLs in patients older than the age of 60 years have evolved from a prior myelodysplastic syndrome or other hematologic disorder, suggesting that the distinction between refractory anemia with excess blasts or refractory anemia with excess blasts in transformation and true AML after myelodysplasia may be clinically unimportant. These conditions each respond more poorly to chemotherapy than *de novo* AML, and progressive leukemia and bone marrow failure leading to death is the typical outcome.

## CLASSIFICATION OF ACUTE LEUKEMIA

Modern classifications of acute leukemia must answer three questions to be diagnostically and prognostically useful: (1) What is the lineage? (2) What is the maturational stage? (3) What is the genotype? Although traditional classifications relied primarily on morphology and cytochemistry, <sup>66,67,68</sup> and <sup>69</sup> these limited characterizations are not always adequate for classifying leukemias into groups that assign the most appropriate therapy or predict outcome. Knowledge of the exact immunophenotype and the genotype, either via cytogenetic analysis or molecular analysis, is critically important before commencing the most appropriate definitive treatment, such as high-dose consolidation chemotherapy, BMT, or prolonged maintenance therapy.

## MORPHOLOGY AND CYTOCHEMISTRY

The French-American-British (FAB) group has proposed a widely used classification of eight different types of AMLs (M0 to M7) and three types of ALLs (L1 to L3) based on morphology and cytochemistry<sup>66,67,69</sup>; monoclonal antibody-based immunophenotype is also used in undifferentiated cases in which morphology and cytochemistry are inconclusive<sup>69,70</sup> ([Table 46.2-2](#)). Because the treatments of ALL and AML may differ significantly, the most important first step in the diagnostic assignment is to distinguish the lymphoid and myeloid lineages to assign therapy. Among the lymphoid neoplasms, the distinction of FAB L3-ALL (Burkitt's type; mature B cell) is a second important step, as treatment strategies and prognosis differ with this subgroup. Among the myeloid leukemias, identification of FAB M3-AML (APL) is necessary because retinoic acid differentiation therapy is instituted instead of, or concurrently with, chemotherapy. Moreover, there is a significant risk of highly morbid coagulopathy associated with APL. Because current therapies for all subtypes of AML, except APL, are generally similar, and outcomes are typically poor, the advantages of the FAB classification are limited. In addition, morphology and cytochemistry are not diagnostic in 10% to 15% of cases or can be misleading in a small percentage of patients. Moreover, concordance of diagnosis among reviewers may only be 70% to 85%. For these reasons, the FAB classification should always be accompanied by immunophenotypic and genotypic analysis.<sup>70,71</sup> and <sup>72</sup>

**TABLE 46.2-2.** Classification of Acute Leukemia

The FAB classification of AML, as modified by the National Cancer Institute,<sup>71</sup> is based on morphologic examination for lineage, confirmation of lineage by cytochemical stains, quantitation of the number of blasts, and estimation of the degree of differentiation of the cells (see [Table 46.2-2](#)). Myeloid leukemia blasts are typically large with round or irregular, smoothly grained nuclei, and with moderate cytoplasm often containing granules or Auer rods; the Auer rods are pathognomonic for myeloblasts. In contrast, lymphoid blasts are typically small with more regular nuclei, clumpier chromatin, and scant, agranular cytoplasm. A cytoplasmic tail, making the cell resemble a hand mirror is sometimes seen. B-lineage leukemia blasts are not distinguishable from T-lineage leukemia blasts based on morphology alone, except if they are mature B-cell type (Burkitt's type, FAB L3) blasts, which have characteristic voluminous, vacuolated, deeply basophilic cytoplasm. Myeloblasts are graded according to the number of and quality of granules (e.g., a type I blast has no granules; a type II blast has up to 15 delicate granules; a type III blast has numerous azurophilic granules). The blasts associated with chronic myelogenous leukemia in blast crisis cannot be distinguished on morphologic or phenotypic grounds alone.

The most important stains for determining lineage initially include myeloperoxidase, which can be positive (golden brown), even in the absence of visible primary azurophilic granules, and Sudan black B, which stains primary and secondary granule lipids black. Myeloid differentiation is inferred if either of these stains are positive in 3% or more blasts. AS-D chloroacetate esterase is another stain (red or blue) for maturing myeloid granules; a-naphthyl butyrate esterase staining (red/brown) is indicative of monocytic differentiation. Acid phosphatase is generally most useful in T-cell ALL, where it stains as a block or patch.

In the small subset of cases in which lineage cannot be indicated by morphology or cytochemistry, immunophenotyping using specific monoclonal antibodies usually determines lineage to be myeloid.<sup>69,70,73</sup> This group is designated AML-M0. The poorer prognosis of this subgroup makes their distinction from L2-ALL and other AML subtypes important.

Another subgroup that is difficult to classify due to its pleomorphic morphology and unhelpful cytochemistry is acute megakaryoblastic leukemia (AML-M7).<sup>67,74</sup> The lineage can sometimes be identified by cytoplasmic blebs; electron microscopy for platelet peroxidase is confirmatory, although this is not a routinely or rapidly available test. Monoclonal antibodies to platelet-specific antigens CD41 and CD61 are usually helpful, but false-positive results are seen often.<sup>67,70,71</sup> This disease is often associated with bone marrow fibrosis and pancytopenia that obscures the percentage of blasts in aspirates and necessitates the use of a bone marrow biopsy for morphologic diagnosis.<sup>67,71</sup>

The FAB classification of ALL into L1 and L2 subtypes is based on an examination of blasts for nuclear cytoplasmic ratio, the number and appearance of nucleoli, the regularity of the nuclear membrane outline, and cell size.<sup>68</sup> In general, L1 has a small size in greater than 50% of cells, a high nuclear cytoplasmic ratio in greater than 75% of cells, up to one small, ill-defined nucleoli in greater than 75% of cells, and a regular nuclear membrane in greater than 75% of cells. L2 generally has the opposite characteristics. L1-type blasts are found more often among children and denote a better prognosis. L2 is more common in adults, but has little prognostic significance in this population. L3-ALL is easily distinguished by its homogeneous large cells and basophilic cytoplasm with prominent vacuolization. L3-ALL cells usually express cell surface immunoglobulin. The ALLs are usually distinguished by the absence of myeloid-specific immunophenotypic markers or cytochemical stains and by the presence of lymphoid immunophenotypic patterns.

Additional diagnostic subgroups not classified by the FAB criteria include mixed lineage (biphenotypic) leukemias, mast cell leukemias, the histiocytoses, juvenile chronic myelogenous leukemia, and eosinophilic leukemias.

## IMMUNOPHENOTYPING OF ACUTE LEUKEMIAS

Approximately 160 antigen groups, known as *clusters of differentiation* (CDs), have been identified on the surface of hematopoietic cells by monoclonal antibodies. These antigens are predominantly cell surface glycoproteins, and rarely carbohydrates or glycolipids. Although no leukemia-specific antigens have been identified, the CD antigen characterization of hematopoietic cells using a panel of antibodies can establish lineage with reasonable certainty and may suggest maturational stages of cells. Expression on a cell population of antigens not usually found together can also provide strong evidence for neoplasia. Currently, immunophenotyping plays an important role in the understanding of hematopoietic biology and in the diagnosis of leukemia. The immunophenotype is used (1) to confirm the diagnosis in cases in which the classification is clear; (2) to make a diagnosis when morphology and cytochemistry are equivocal, as in M0-AML; (3) to identify biphenotypic leukemias; (4) to characterize aberrant antigen expression, which can be used to identify a neoplastic clone, even when found as minimal residual disease, as in clinical remission; and (5) to assist in assigning leukemias into prognostic groups.

The lineage and state of maturation of normal hematopoietic cells may be identified by use of a flow cytometer to determine the cell size, granularity, and the presence or absence of a panel of cell surface or cytoplasmic differentiation antigens (designated by their CD numbers). Such analyses, termed *multidimensional* or *multiparameter flow cytometry*, are available at most cancer centers or commercial laboratories. Pathways describing the phenotype of normal B, T, and myeloid cells have been constructed<sup>70,75,76,77</sup> and <sup>78</sup> (Fig. 46.2-3). Acute leukemias can also be characterized by a similar panel of markers, and in general, lineage can be assigned by examination of expression of the same antigens as those found in normal cells.<sup>58,70,79</sup>

**FIGURE 46.2-3.** Schematic diagram of selected important antigens expressed on normal hematopoietic cells and acute leukemia cells throughout the differentiation and maturation of the normal cells. Acute leukemia cells may express these antigens aberrantly as described in the text. (Adapted from ref. 78.)

Acute lymphoid leukemias of T-cell lineage are characterized by expression of the T-cell markers CD2, CD5, CD7, and sometimes CD1 or dual staining of CD4 and CD8. T-cell ALL or lymphoblastic lymphoma may also express the B-lineage markers CD10 and CD21. Acute lymphoid leukemias of B-cell lineage express CD19, CD10, CD22, and, depending on maturational stage, CD20, and surface immunoglobulin. Acute myeloid leukemias express CD13, CD15, CD33, and, more often if monocytoid, CD14. Terminal deoxyribonucleotidyl transferase is expressed by most lymphoid blasts and approximately 20% of myeloid blasts. CD34 can be expressed by blasts of all lineages, especially if the cells are primitive. HLA-DR is found on virtually all B-lineage leukemias, most myeloid and monocytic leukemias (except FAB M3), and on a rare T-cell ALL.

The pathways of antigen expression, with regard to maturational stage, however, are often aberrant in leukemias.<sup>58,70,78,79</sup> In some cases, there is also abnormal expression of antigens not expected to be found in the lineage.<sup>81,82,83</sup> and <sup>84</sup> Although such infidelity of antigen expression may prevent exact assignment of the maturational stage of the leukemia cell, it may distinguish that cell as neoplastic from within a larger population of normal cells. Thus, aberrant antigen expression, which can be an antigen of the wrong lineage, the simultaneous expression of antigens of different stages of maturation, or the lack of an expected antigen, can provide a useful diagnostic marker for the leukemia cells.<sup>79,81</sup> In addition, such a marker may allow the flow cytometric detection of the leukemia cells at a level of 1 cell in 1000 to 10,000 normal cells, even in patients who have apparently normal bone marrow and blood examination by morphologic criteria.<sup>85</sup> The prognostic significance of this detection is not yet clear, but is likely to predict relapse.<sup>86</sup>
