

**Cancer: Principles and Practice of Oncology 6th edition (July 2001):** by Vincent T. DeVita (Editor), Samuel Hellman, Steven A. Rosenberg (Editor) By Lippincott Williams & Wilkins Publishers

By OkDoKeY

CONTENTS

[Editors](#)

[Dedication](#)

[Contributing Authors](#)

[Preface](#)

[Acknowledgment](#)

[Dermatology Atlas](#)

[Video Library](#)

---

[Part 1](#)

[Part 2](#)

[Part 3](#)

[Part 4](#)

---

**PART 1**

**ESSENTIALS OF MODERN ONCOLOGIC SCIENCE**

[Chapter 1 Essentials of Molecular Biology: Basic Principles](#)

LANCE A. LIOTTA  
EDISON T. LIU

[Chapter 2 Essentials of Molecular Biology: Genomics and Cancer](#)

LANCE A. LIOTTA  
EDISON T. LIU

[Chapter 3 Essentials of Signal Transduction](#)

CHRISTOPHER L. CARPENTER  
LEWIS C. CANTLEY

[Chapter 4 Essentials of Immunology](#)

NICHOLAS P. RESTIFO  
JOHN R. WUNDERLICH

**PART 2**

**PRINCIPLES OF ONCOLOGY**

[Chapter 5 Molecular Biology of Cancer: Cytogenetics](#)

MAZIN B. QUMSIYEH PEINING LI

[Chapter 6 Molecular Biology of Cancer: The Cell Cycle](#)

MICHAEL B. KASTAN  
STEPHEN X. SKAPEK

[Chapter 7 Molecular Biology of Cancer: Apoptosis](#)

STANLEY J. KORSMEYER  
SANDRA S. ZINKEL

[Chapter 8 Molecular Biology of Cancer: Invasion and Metastases](#)

WILLIAM G. STETLER-STEVENSON  
DAVID E. KLEINER, JR.

[Chapter 9 Biology of Cancer: Angiogenesis](#)

ISAIAH J. FIDLER  
ROBERT S. KERBEL  
LEE M. ELLIS

**Chapter 10 Etiology of Cancer: Viruses**

[Section 10.1 RNA Viruses](#)

ERIC M. POESCHLA  
GARY L. BUCHSCHACHER, JR.  
FLOSSIE WONG-STAAAL

[Section 10.2 DNA Viruses](#)

PETER M. HOWLEY  
DON GANEM  
ELLIOTT KIEFF

[Chapter 11 Etiology of Cancer: Chemical Factors](#)

STUART H. YUSPA  
PETER G. SHIELDS

[Chapter 12 Etiology of Cancer: Physical Factors](#)

ROBERT L. ULLRICH

[Chapter 13 Etiology of Cancer: Cancer Genetics](#)

ALLEN E. BALE  
SUZANNE J. BROWN

**Chapter 14 Epidemiology of Cancer**

**Section 14.1 Epidemiologic Methods**

MARGARET A. TUCKER

**Section 14.2 Descriptive Epidemiology: Cancer Statistics**

PHILIP COLE  
BRAD RODU

**Section 14.3 Analytic Epidemiology: Cancer Causes**

PHILIP COLE  
BRAD RODU

**Chapter 15 Principles of Cancer Management: Surgical Oncology**

STEVEN A. ROSENBERG

**Chapter 16 Principles of Cancer Management: Radiation Therapy**

SAMUEL HELLMAN

**Chapter 17 Principles of Cancer Management: Chemotherapy**

EDWARD CHU  
VINCENT T. DEVITA, JR.

**Chapter 18 Principles of Cancer Management: Biologic Therapy**

STEVEN A. ROSENBERG

**Chapter 19 Pharmacology of Cancer Chemotherapy**

**Section 19.1 Pharmacokinetics and Pharmacodynamics**

MARK J. RATAIN

**Section 19.2 Cancer Drug Development**

**Section 19.2.1 Cancer Drug Development: Identification and Screening of New Agents**

EDWARD CHU  
MICHAEL R. GREVER  
BRUCE A. CHABNER

**Section 19.2.2 Cancer Drug Development: Combinatorial Chemistry**

DAVID J. AUSTIN

**Section 19.3 Antitumor Alkylating Agents**

OLIVER MICHAEL COLVIN

**Section 19.4 Cisplatin and Its Analogues**

STEVEN W. JOHNSON  
JAMES P. STEVENSON  
PETER J. O'DWYER

**Section 19.5 Antimetabolites**

EDWARD CHU  
AUGUSTO C. MOTA  
MIKLOS C. FOGARASI

**Section 19.6 Topoisomerase Interactive Agents**

CLINTON F. STEWART  
MARK J. RATAIN

**Section 19.7 Antimicrotubule Agents**

ERIC K. ROWINSKY  
ANTHONY W. TOLCHER

**Section 19.8 Miscellaneous Chemotherapeutic Agents**

BRUCE D. CHESON

**Chapter 20 Pharmacology of Cancer Biotherapeutics**

**Section 20.1 Interferons**

JOHN M. KIRKWOOD

**Section 20.2 Interleukin-2**

JAMES W. MIER  
MICHAEL B. ATKINS

**Section 20.3 Hormonal Therapies**

CHARLES ERLICHMAN  
CHARLES L. LOPRINZI

**Section 20.4 Differentiation Agents**

RAYMOND P. WARRELL, JR.

**Section 20.5 Therapeutic Monoclonal Antibodies: General Principles**

LOUIS M. WEINER  
GREGORY P. ADAMS  
MARGARET VON MEHREN

**Section 20.6 Antiangiogenesis Agents**

JUDAH FOLKMAN

**Chapter 21 Clinical Trials in Cancer**

**Section 21.1 Design and Analysis of Clinical Trials**

RICHARD SIMON

**Section 21.2 Research Data Management**

DOUGLAS HAGEMAN  
DIANNE M. REEVES

**PART 3**

**PRACTICE OF ONCOLOGY**

**Chapter 22 Cancer Prevention: Preventing Tobacco-Related Cancers**

HOWARD K. KOH  
CHRISTINE KANNLER  
ALAN C. GELLER

**Chapter 23 Cancer Prevention: Diet and Chemopreventive Agents**

**Section 23.1 Fat**

WALTER C. WILLETT

**Section 23.2 Dietary Fibers**

PETER GREENWALD

**Section 23.3 Retinoids, Carotenoids, and Micronutrients**

SUSAN TAYLOR MAYNE  
SCOTT M. LIPPMAN

**Section 23.4 Naturally Occurring Dietary Anticarcinogens**

PETER GREENWALD

**Section 23.5 Dietary Carcinogens**

PETER GREENWALD

**Section 23.6 Aspirin and Other Nonsteroidal Antiinflammatory Drugs and the Risk of Cancer Development**

MICHAEL J. THUN  
CHARLES H. HENNEKENS

**Section 23.7 Physical Activity and Body Weight**

GRAHAM A. COLDITZ

**Chapter 24 Cancer Prevention: Role of Surgery in Cancer Prevention**

RICHARD M. SHERRY

**Chapter 25 Cancer Screening**

BARBARA K. RIMER  
JOELLEN SCHILDKRAUT  
ROBERT A. HIATT

**Chapter 26 Cancer Diagnosis: Molecular Pathology**

JOSE COSTA  
CARLOS CORDON-CARDO

**Chapter 27 Cancer Diagnosis: Imaging**

**Section 27.1 Computed Tomography**

ELLIOT K. FISHMAN  
BRUCE A. URBAN

**Section 27.2 Magnetic Resonance Imaging**

ARTHUR E. LI  
DAVID A. BLUEMKE

**Section 27.3 Functional and Metabolic Imaging**

MARTIN G. POMPER

**Section 27.4 Interventional Radiology**

JEAN-FRANCOIS H. GESCHWIND

**Section 27.5 Ultrasound**

ULRIKE M. HAMPER

**Section 27.6 Radionuclide Imaging**

E. EDMUND KIM

**Chapter 28 Cancer Diagnosis: Endoscopy**

ROBERT C. KURTZ  
ROBERT J. GINSBERG

**Chapter 29 Specialized Techniques in Cancer Management**

**Section 29.1 Laparoscopy**

ALAN T. LEFOR

**Section 29.2 Vascular Access and Specialized Techniques of Drug Delivery**

STEVEN K. LIBUTTI  
MCDONALD K. HORNE III

**Section 29.3 Isolation Perfusion**

H. RICHARD ALEXANDER

**Section 29.4 Intensity-Modulated Radiation Therapy**

C. CLIFTON LING  
CHEN CHUI  
THOMAS LOSASSO  
CHANDRA BURMAN

MARGIE HUNT  
GIGAS MAGERAS  
HOWARD IRA AMOLS  
MICHAEL J. ZELEFSKY  
ZVI Y. FUKS  
STEVEN A. LEIBEL

## **Chapter 30 Cancer of the Head and Neck**

### **Section 30.1 Molecular Biology of Head and Neck Tumors**

DAVID SIDRANSKY

### **Section 30.2 Tumors of the Nasal Cavity and Paranasal Sinuses, Nasopharynx, Oral Cavity, and Oropharynx**

STIMSON P. SCHANTZ  
LOUIS B. HARRISON  
ARLENE A. FORASTIERE

### **Section 30.3 Tumors of the Larynx and Hypopharynx**

ROY B. SESSIONS  
LOUIS B. HARRISON  
ARLENE A. FORASTIERE

### **Section 30.4 Tumors of the Salivary Glands and Paragangliomas**

ROY B. SESSIONS  
LOUIS B. HARRISON  
ARLENE A. FORASTIERE

### **Section 30.5 Rehabilitation after Treatment for Head and Neck Cancer**

SUSAN D. MILLER  
ROY B. SESSIONS

## **Chapter 31 Cancer of the Lung**

### **Section 31.1 Molecular Biology of Lung Cancer**

YOSHITAKA SEKIDO  
KWUN M. FONG  
JOHN D. MINNA

### **Section 31.2 Non–Small Cell Lung Cancer**

ROBERT J. GINSBERG  
EVERETT E. VOKES  
KENNETH ROSENZWEIG

### **Section 31.3 Small Cell Lung Cancer**

JOHN MURREN  
ELI GLATSTEIN  
HARVEY I. PASS

## **Chapter 32 Neoplasms of the Mediastinum**

ROBERT B. CAMERON  
PATRICK J. LOEHRER  
CHARLES R. THOMAS, JR.

## **Chapter 33 Cancers of the Gastrointestinal Tract**

### **Section 33.1 Molecular Biology of Gastrointestinal Cancers**

ERIC R. FEARON

### **Section 33.2 Cancer of the Esophagus**

DAVID S. SCHRUMP  
NASSER K. ALTORKI  
ARLENE A. FORASTIERE  
BRUCE D. MINSKY

### **Section 33.3 Cancer of the Stomach**

MARTIN S. KARPEH  
DAVID P. KELSEN  
JOEL E. TEPPER

### **Section 33.4 Cancer of the Pancreas**

DOUGLAS B. EVANS  
JAMES L. ABBRUZZESE  
CHRISTOPHER G. WILLETT

### **Section 33.5 Cancer of the Liver and Biliary Tree**

YUMAN FONG  
NANCY KEMENY  
THEODORE S. LAWRENCE

### **Section 33.6 Cancer of the Small Intestine**

DANIEL G. COIT

### **Section 33.7 Cancer of the Colon**

JOHN M. SKIBBER  
BRUCE D. MINSKY  
PAULO M. HOFF

### **Section 33.8 Cancer of the Rectum**

JOHN M. SKIBBER  
PAULO M. HOFF  
BRUCE D. MINSKY

### **Section 33.9 Cancer of the Anal Region**

BRUCE D. MINSKY  
JOHN P. HOFFMAN  
DAVID P. KELSEN

## **Chapter 34 Cancers of the Genitourinary System**

### **Section 34.1 Molecular Biology of Genitourinary Cancers**

W. MARSTON LINEHAN  
BERTON ZBAR  
FREDRICK LEACH  
CARLOS CORDON-CARDO  
WILLIAM ISAACS

### **Section 34.2 Cancer of the Kidney and Ureter**

W. MARSTON LINEHAN  
BERTON ZBAR  
SUSAN E. BATES  
MICHAEL J. ZELEFSKY  
JAMES C. YANG

### **Section 34.3 Cancer of the Bladder**

HARRY W. HERR  
WILLIAM U. SHIPLEY  
DEAN F. BAJORIN

### **Section 34.4 Cancer of the Prostate**

PETER R. CARROLL  
KEITH L. LEE  
ZVI Y. FUKS  
PHILIP W. KANTOFF

### **Section 34.5 Cancer of the Urethra and Penis**

HARRY W. HERR  
GUIDO DALBAGNI  
DEAN F. BAJORIN  
WILLIAM U. SHIPLEY

## **Chapter 35 Cancer of the Testis**

GEORGE J. BOSL  
DEAN F. BAJORIN  
JOEL SHEINFELD  
ROBERT J. MOTZER  
R. S. K. CHAGANTI

## **Chapter 36 Gynecologic Cancers**

### **Section 36.1 Molecular Biology of Gynecologic Cancers**

SETSUKO KUKI CHAMBERS

### **Section 36.2 Cancer of the Cervix, Vagina, and Vulva**

PATRICIA J. EIFEL  
JONATHAN S. BEREK  
JAMES T. THIGPEN

### **Section 36.3 Cancers of the Uterine Body**

THOMAS W. BURKE  
PATRICIA J. EIFEL  
FRANCO M. MUGGIA

### **Section 36.4 Gestational Trophoblastic Diseases**

FRANCO M. MUGGIA  
PATRICIA J. EIFEL  
THOMAS W. BURKE

### **Section 36.5 Ovarian Cancer, Fallopian Tube Carcinoma, and Peritoneal Carcinoma**

ROBERT F. OZOLS  
PETER E. SCHWARTZ  
PATRICIA J. EIFEL

## **Chapter 37 Cancer of the Breast**

### **Section 37.1 Molecular Biology of Breast Cancer**

ROBERT B. DICKSON  
MARC E. LIPPMAN

### **Section 37.2 Malignant Tumors of the Breast**

ERIC P. WINER  
MONICA MORROW  
C. KENT OSBORNE  
JAY R. HARRIS

### **Section 37.3 Rehabilitation after Treatment for Cancer of the Breast**

JOSEPH J. DISA  
JEANNE A. PETREK

## **Chapter 38 Cancer of the Endocrine System**

### **Section 38.1 Molecular Biology of Endocrine Tumors**

TERRY C. LAIRMORE  
SAMUEL A. WELLS, JR.  
JEFFREY F. MOLEY

### **Section 38.2 Thyroid Tumors**

DOUGLAS L. FRAKER  
MONICA SKARULIS  
VIRGINIA LIVOLSI

### **Section 38.3 Parathyroid Tumors**

DOUGLAS L. FRAKER

### **Section 38.4 Adrenal Tumors**

JEFFREY A. NORTON  
HOP N. LE

**Section 38.5 Pancreatic Endocrine Tumors**

H. RICHARD ALEXANDER  
ROBERT T. JENSEN

**Section 38.6 Carcinoid Tumors and the Carcinoid Syndrome**

ROBERT T. JENSEN  
GERARD M. DOHERTY

**Section 38.7 Multiple Endocrine Neoplasias**

GERARD M. DOHERTY  
ROBERT T. JENSEN

**Chapter 39 Sarcomas of the Soft Tissue and Bone**

**Section 39.1 Soft Tissue Sarcoma**

MURRAY F. BRENNAN  
KALED M. ALEKTIAR  
ROBERT G. MAKI

**Section 39.2 Sarcomas of Bone**

MARTIN M. MALAWER  
MICHAEL P. LINK  
SARAH S. DONALDSON

**Chapter 40 Benign and Malignant Mesothelioma**

**Section 40.1 Molecular Biology of Mesothelioma**

JOSEPH R. TESTA  
HARVEY I. PASS  
MICHELE CARBONE

**Section 40.2 Management of Mesothelioma**

KAREN H. ANTMAN  
HARVEY I. PASS  
PETER B. SCHIFF

**Chapter 41 Cancer of the Skin**

**Section 41.1 Molecular Biology of Skin Cancer**

DOUGLAS E. BRASH  
ALLEN E. BALE

**Section 41.2 Management of Skin Cancer**

DAVID J. LEFFELL  
JOHN A. CARUCCI

**Section 41.3 Skin Cancer Atlas**

DAVID J. LEFFELL

**Chapter 42 Melanoma**

**Section 42.1 Molecular Biology of Cutaneous Melanoma**

MEENHARD HERLYN  
KAPAETTU SATYAMOORTHY

**Section 42.2 Cutaneous Melanoma**

MICHAEL T. LOTZE  
RAMSEY M. DALLAL  
JOHN M. KIRKWOOD  
JOHN C. FLICKINGER

**Section 42.3 Intraocular Melanoma**

JOSÉ A. SAHEL  
ARTHUR S. POLANS  
MINESH P. MEHTA  
RICHARD M. AUCHTER  
DANIEL M. ALBERT

**Chapter 43 Neoplasms of the Central Nervous System**

**Section 43.1 Molecular Biology of Central Nervous System Neoplasms**

DAVID N. LOUIS  
WEBSTER K. CAVENEE

**Section 43.2 Neoplasms of the Central Nervous System**

VICTOR A. LEVIN  
STEVEN A. LEIBEL  
PHILIP H. GUTIN

**Chapter 44 Cancers of Childhood**

**Section 44.1 Molecular Biology of Childhood Cancers**

LEE J. HELMAN  
DAVID MALKIN

**Section 44.2 Solid Tumors of Childhood**

DAVID H. EBB  
DANIEL M. GREEN  
ROBERT C. SHAMBERGER

NANCY J. TARBELL

## **Chapter 45 Lymphomas**

### **Section 45.1 Molecular Biology of Lymphomas**

RICCARDO DALLA-FAVERA  
GIANLUCA GAIDANO

### **Section 45.2 Leukemias and Lymphomas of Childhood**

HOWARD J. WEINSTEIN  
NANCY J. TARBELL

### **Section 45.3 Non-Hodgkin's Lymphomas**

JAMES O. ARMITAGE  
PETER M. MAUCH  
NANCY LEE HARRIS  
PHILIP BIERMAN

### **Section 45.4 Cutaneous T-Cell Lymphomas**

LYNN D. WILSON  
GLENN W. JONES  
BARRY M. KACINSKI  
RICHARD L. EDELSON  
PETER W. HEALD

### **Section 45.5 Primary Central Nervous System Lymphoma**

LISA M. DEANGELIS  
JOACHIM YAHALOM

### **Section 45.6 Hodgkin's Disease**

VOLKER DIEHL  
PETER M. MAUCH  
NANCY LEE HARRIS

## **Chapter 46 Leukemias**

### **Section 46.1 Molecular Biology of Leukemias**

CLARA D. BLOOMFIELD  
MICHAEL A. CALIGIURI

### **Section 46.2 Acute Leukemias**

DAVID A. SCHEINBERG  
PETER MASLAK  
MARK WEISS

### **Section 46.3 Chronic Leukemias**

#### **Section 46.3.1 Chronic Leukemias: Chronic Myelogenous Leukemia**

HAGOP M. KANTARJIAN  
STEFAN FADERL  
MOSHE TALPAZ

#### **Section 46.3.2 Chronic Leukemias: The Chronic Lymphocytic Leukemias**

BRUCE D. CHESON

### **Section 46.4 Plasma Cell Neoplasms**

NIKHIL C. MUNSHI  
GUIDO TRICOT  
BART BARLOGIE

### **Section 46.5 Myelodysplastic Syndromes**

HAGOP M. KANTARJIAN  
ELIHU ESTEY

## **Chapter 47 Paraneoplastic Syndromes**

SUSANNE M. ARNOLD  
ROY PATCHELL  
ANDREW M. LOWY  
KENNETH A. FOON

## **Chapter 48 Cancer of Unknown Primary Site**

FRANK A. GRECO  
JOHN D. HAINSWORTH

## **Chapter 49 Peritoneal Carcinomatosis**

DAVID L. BARTLETT

## **Chapter 50 Immunosuppression-Related Malignancies**

### **Section 50.1 AIDS-Related Malignancies**

ROBERT YARCHOAN  
RICHARD F. LITTLE

### **Section 50.2 Transplantation-Related Malignancies**

STANLEY R. RIDDELL

## **Chapter 51 Oncologic Emergencies**

### **Section 51.1 Superior Vena Cava Syndrome**

JOACHIM YAHALOM

**Section 51.2 Spinal Cord Compression**

BRIAN G. FULLER  
JOHN D. HEISS  
EDWARD H. OLDFIELD

**Section 51.3 Metabolic Emergencies**

RAYMOND P. WARRELL, JR.

**Section 51.4 Urologic Emergencies**

McCLELLAN M. WALTHER

**Chapter 52 Treatment of Metastatic Cancer**

**Section 52.1 Metastatic Brain Cancer**

PATRICK Y. WEN  
PETER MCLAREN BLACK  
JAY S. LOEFFLER

**Section 52.2 Metastatic Cancer to the Lung**

JOE B. PUTNAM, JR.

**Section 52.3 Metastatic Cancer to the Liver**

H. RICHARD ALEXANDER  
CARMEN J. ALLEGRA  
THEODORE S. LAWRENCE

**Section 52.4 Metastatic Cancer to the Bone**

HOLLY K. BROWN  
JOHN H. HEALEY

**Section 52.5 Malignant Pleural and Pericardial Effusions**

DAO M. NGUYEN DAVID S. SCHRUMP

**Section 52.6 Malignant Ascites**

FRANCESCO M. MARINCOLA  
DOUGLAS J. SCHWARTZENTRUBER

**Chapter 53 Hematopoietic Therapy**

**Section 53.1 Transfusion Therapy**

PETER L. PERROTTA  
EDWARD L. SNYDER

**Section 53.2 Autologous Stem Cell Transplantation**

DENNIS L. COOPER  
STUART SEROPIAN

**Section 53.3 Allogeneic Stem Cell Transplantation**

RICHARD W. CHILDS

**Section 53.4 Hematopoietic Growth Factors**

JAMES D. GRIFFIN

**Chapter 54 Infections in the Cancer Patient**

BRAHM H. SEGAL  
THOMAS J. WALSH  
STEVEN M. HOLLAND

**Chapter 55 Adverse Effects of Treatment**

**Section 55.1 Nausea and Vomiting**

ANN M. BERGER  
REBECCA A. CLARK-SNOW

**Section 55.2 Oral Complications**

ANN M. BERGER  
THOMAS J. KILROY

**Section 55.3 Pulmonary Toxicity**

DIANE E. STOVER  
ROBERT J. KANER

**Section 55.4 Cardiac Toxicity**

LAUREL J. STEINHERZ  
JOACHIM YAHALOM

**Section 55.5 Hair Loss**

CLAUDIA A. SEIPP

**Section 55.6 Gonadal Dysfunction**

MARVIN L. MEISTRICH  
RENA VASSILOPOULOU-SELLIN  
LARRY I. LIPSHULTZ

**Section 55.7 Second Cancers**

FLORA E. VAN LEEUWEN  
LOIS B. TRAVIS

**Section 55.8 Miscellaneous Toxicities**

RAYMOND B. WEISS

**Chapter 56 Supportive Care and Quality of Life**

**Section 56.1 Management of Cancer Pain**

KATHLEEN M. FOLEY

**Section 56.2 Nutritional Support**

J. STANLEY SMITH  
WILEY W. SOUBA

**Section 56.3 Sexual Problems**

PATRICIA A. GANZ  
MARK S. LITWIN  
BETH E. MEYEROWITZ

**Section 56.4 Genetic Counseling**

ELLEN T. MATLOFF  
ALLEN E. BALE

**Section 56.5 Psychological Issues**

MARY JANE MASSIE  
LISA CHERTKOV  
ANDREW J. ROTH

**Section 56.6 Community Resources**

BONNIE A. INDECK  
PHYLLIS M. SMITH

**Section 56.7 Specialized Care of the Terminally Ill**

FREDERICK A. FLATOW  
SCOTT LONG

**Chapter 57 Rehabilitation of the Cancer Patient**

LYNN GERBER  
JEANNE HICKS  
JAY SHAH

**Chapter 58 Advanced Practice Nurses and Physician Assistants in Oncology Care**

M. TISH KNOBF  
SUSAN ANDERSON

**Chapter 59 Ethical Issues in Oncology and Clinical Trials**

CHRISTOPHER DAUGHERTY  
MARK SIEGLER

**Chapter 60 Information Systems in Oncology**

SUSAN MOLLOY HUBBARD

**Chapter 61 Complementary, Alternative, and Unproven Methods of Cancer Treatment**

JEFFREY D. WHITE

**PART 4**

**NEWER APPROACHES IN CANCER TREATMENT**

**Chapter 62 Genetic Therapy**

**Section 62.1 Gene Therapy**

PATRICK HWU

**Section 62.2 Molecular Therapy**

ALBERT B. DEISSEROTH  
AMANDA PSYRRI  
DAVID J. AUSTIN

**Chapter 63 Cancer Vaccines**

**Section 63.1 Preventive Cancer Vaccines**

DOUGLAS R. LOWY  
JOHN T. SCHILLER

**Section 63.2 Therapeutic Cancer Vaccines**

NICHOLAS P. RESTIFO  
MARIO SZNOL  
WILLEM W. OVERWIJK

**Chapter 64 Image-Guided Surgery**

NICK BRYAN  
STEVEN K. LIBUTTI

**Chapter 65 Proton Beam Radiation Therapy**

IRA J. SPIRO  
ALFRED R. SMITH  
ANTHONY LOMAX  
JAY S. LOEFFLER

### **James L. Abbruzzese, MD**

Annie Laurie Howard Research Distinguished Professor  
Department of Gastrointestinal Medical Oncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

### **Gregory P. Adams, PhD**

Assistant Member  
Department of Medical Oncology  
Fox Chase Cancer Center  
Philadelphia, Pennsylvania

### **Daniel M. Albert, MD, MS**

F. A. Davis Professor and Chair; Lorenz E. Zimmerman Professor  
Department of Ophthalmology and Visual Sciences  
University of Wisconsin Center for Health Sciences  
Madison, Wisconsin

### **Kaled M. Alektiar, MD**

Assistant Attending  
Department of Radiation Oncology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

### **H. Richard Alexander, MD**

Head, Surgical Metabolism Section  
Surgery Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

### **Carmen J. Allegra, MD**

Chief, Medicine Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

### **Nasser K. Altorki, BCh, MB**

Professor of Cardiothoracic Surgery  
Weill Medical College of Cornell University  
New York, New York

### **Howard Ira Amols, PhD**

Professor of Physics in Radiology  
Weill Medical College of Cornell University  
Memorial Sloan-Kettering Cancer Center  
New York, New York

### **Susan Anderson, BSN, MFA**

Director, Clinical Trials Office  
Yale Cancer Center  
Yale University School of Medicine  
New Haven, Connecticut

### **Karen H. Antman, MD**

Wu Professor of Medicine and Pharmacology  
Herbert Irving Comprehensive Cancer Center  
Columbia University College of Physicians and Surgeons  
New York, New York

### **James O. Armitage, MD**

Professor of Medicine  
Dean of the College of Medicine  
University of Nebraska Medical Center  
Omaha, Nebraska

### **Susanne M. Arnold, MD**

Assistant Professor of Medicine  
Department of Hematology and Oncology  
Lucille P. Markey Cancer Center  
University of Kentucky Chandler Medical Center  
Lexington, Kentucky

### **Michael B. Atkins, MD**

Associate Professor of Medicine  
Department of Hematology/Oncology  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Richard M. Auchter, MD**

Clinical Assistant Professor of Human Oncology  
University of Wisconsin Medical School  
Madison, Wisconsin

**David J. Austin, PhD**

Assistant Professor of Chemistry  
Yale University School of Medicine  
New Haven, Connecticut

**Dean F. Bajorin, MD**

Professor of Medicine  
Weill Medical College of Cornell University  
Attending Physician  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Allen E. Bale, MD**

Associate Professor of Genetics  
Yale University School of Medicine  
New Haven, Connecticut

**Bart Barlogie, MD, PhD**

Professor of Medicine and Pathology  
Director, Arkansas Cancer Research Center  
University of Arkansas for Medical Sciences  
Little Rock, Arkansas

**David L. Bartlett, MD**

Surgery Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

Professor of Gynecologic Oncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Chandra Burman, PhD**

Associate Attending Physicist  
Department of Medical Physics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Michael A. Caligiuri, MD**

Professor of Medicine  
Ohio State University College of Medicine and Public Health  
Arthur James Cancer Hospital and Research Institute  
Columbus, Ohio

**Robert B. Cameron, MD**

Assistant Professor of Surgery  
University of California, Los Angeles, UCLA School of Medicine  
Los Angeles, California

**Lewis C. Cantley, PhD**

Professor of Cell Biology  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Michele Carbone, MD, PhD**

Associate Professor of Pathology  
Department of Pathology/Cancer Immunology  
Loyola University Medical Center  
Maywood, Illinois

**Christopher L. Carpenter, MD, PhD**

Assistant Professor of Medicine  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Peter R. Carroll, MD**

Professor and Chair, Department of Urology  
University of California, San Francisco, School of Medicine  
San Francisco, California

**John A. Carucci, MD, PhD**

Clinical Instructor of Dermatology  
Yale University School of Medicine  
New Haven, Connecticut

**Webster K. Cavenee, PhD**

Professor of Medicine  
University of California, San Diego, School of Medicine  
Director, Ludwig Institute for Cancer Research  
Center for Molecular Genetics; University of California Laboratory of Tumor Biology  
La Jolla, California

**Bruce A. Chabner, MD**

Professor of Medicine  
Harvard Medical School  
Department of Hematology/Oncology  
Massachusetts General Hospital  
Boston, Massachusetts

**R. S. K. Chaganti, PhD**

Member and William E. Snee Chair  
Human Genetics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Setsuko Kuki Chambers, MD**

Professor of Obstetrics and Gynecology  
Division of Gynecologic Oncology  
Yale University School of Medicine  
New Haven, Connecticut

**Lisa Chertkov, MD**

Fellow in Psychiatry and Behavioral Sciences  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Bruce D. Cheson, MD**

Clinical Professor of Medicine  
Georgetown University School of Medicine  
Vincent T. Lombardi Cancer Research Center  
Washington, DC  
Head, Medicine Section  
Cancer Therapy Evaluation Program  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Richard W. Childs, MD**

Senior Investigator  
Hematology Branch  
National Heart, Lung, and Blood Institute, National Institutes of Health  
Bethesda, Maryland

**Edward Chu, MD**

Associate Professor of Medicine and Pharmacology  
Yale Cancer Center  
Yale University School of Medicine  
Director, Veterans Administration Connecticut Cancer Center  
New Haven, Connecticut

**Chen Chui, PhD**

Associate Professor of Medical Physics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Rebecca A. Clark-Snow, RN, BSN, OCN**

Director of Clinical Services  
Oncology and Hematology Associates of Kansas City  
Kansas City, Missouri

**Daniel G. Coit, MD**

Chief of Gastric and Mixed Tumor Service  
Department of Surgery  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Graham A. Colditz, MD, DrPH**

Professor of Medicine  
Harvard Medical School  
Brigham and Women's Hospital  
Boston, Massachusetts

**Philip Cole, MD, PhD**

Professor Emeritus  
Department of Epidemiology  
University of Alabama School of Medicine  
Birmingham, Alabama

**Oliver Michael Colvin, MD**

Professor of Hematology/Oncology  
Director, Duke Comprehensive Cancer Center  
Duke University Medical Center  
Durham, North Carolina

**Dennis L. Cooper, MD**

Associate Professor of Medicine  
Yale University School of Medicine  
Department of Medical Oncology  
Yale-New Haven Hospital  
New Haven, Connecticut

**Carlos Cordon-Cardo, MD, PhD**

Member and Director, Division of Molecular Pathology  
Department of Pathology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**José Costa, MD**

Professor of Pathology  
Yale University School of Medicine  
Yale-New Haven Hospital  
New Haven, Connecticut

**Guido Dalbagni, MD, FACS**

Assistant Professor of Urology  
Weill Medical College of Cornell University  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Riccardo Dalla-Favera, MD**

Uris Professor of Pathology and Genetics  
Director, Institute of Cancer Genetics  
Columbia University College of Physicians and Surgeons  
New York, New York

**Ramsey M. Dallal, MD**

Resident of Surgery  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania

**Christopher Daugherty, MD**

Assistant Professor of Medicine  
University of Chicago Pritzker School of Medicine  
Chicago, Illinois

**Lisa M. DeAngelis, MD**

Chair, Department of Neurology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Albert B. Deisseroth, MD, PhD**

Ensign Professor of Medicine

Department of Internal Medicine  
Yale University School of Medicine  
New Haven, Connecticut

**Vincent T. DeVita, Jr., MD**

Director, Yale Cancer Center  
Professor of Medicine  
Professor of Epidemiology and Public Health  
Yale University School of Medicine  
New Haven, Connecticut

**Robert B. Dickson, PhD**

Professor of Oncology  
Georgetown University School of Medicine  
Vincent T. Lombardi Cancer Research Center  
Washington, DC

**Volker Diehl, MD PhD**

Professor of Medicine  
Department of Internal Medicine I  
University Hospital Cologne  
Köln, Germany

**Joseph J. Disa, MD**

Assistant Attending Surgeon  
Department of Surgery/Plastic Surgery  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Gerard M. Doherty, MD**

Associate Professor of Surgery  
Washington University School of Medicine  
St. Louis, Missouri

**Sarah S. Donaldson, MD, FACR**

Professor of Radiation Oncology  
Stanford University School of Medicine  
Stanford, California

**David H. Ebb, MD**

Assistant Professor of Pediatrics  
Harvard Medical School  
MassGeneral Hospital for Children  
Boston, Massachusetts

**Richard L. Edelson, MD**

Professor and Chair, Dermatology  
Yale University School of Medicine  
New Haven, Connecticut

**Patricia J. Eifel, MD**

Professor of Radiation Oncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Lee M. Ellis, MD**

Associate Professor of Surgery and Cancer Biology  
Department of Surgical Oncology and Cancer Biology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Charles Erlichman, MD, FRCP(C)**

Professor of Oncology  
Department of Medical Oncology  
Mayo Medical School  
Mayo Clinic  
Rochester, Minnesota

**Elihu Estey, MD**

Professor of Medicine  
Department of Leukemia  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Douglas B. Evans, MD**

Professor of Surgery  
Department of Surgical Oncology

The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Stefan Faderl, MD**

Assistant Professor of Medicine  
Department of Leukemia  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Eric R. Fearon, MD, PhD**

Associate Professor of Internal Medicine, Human Genetics, and Pathology  
Department of Internal Medicine, Division of Medical Genetics  
University of Michigan Medical School  
Ann Arbor, Michigan

**Isaiah J. Fidler, DVM, PhD**

Professor of Cancer Biology and Urology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Elliot K. Fishman, MD**

Professor of Radiology and Oncology  
Johns Hopkins University School of Medicine  
Johns Hopkins Hospital  
Baltimore, Maryland

**Frederick A. Flatow, MD, FACP**

Assistant Clinical Professor of Medicine  
Department of Oncology  
Yale University School of Medicine  
New Haven, Connecticut  
Medical Director, The Connecticut Hospice  
Branford, Connecticut

**John C. Flickinger, MD**

Professor of Radiation Oncology and Neurological Surgery  
Department of Radiation Oncology  
University of Pittsburgh Medical Center– Presbyterian Hospital  
Pittsburgh, Pennsylvania

**Miklos C. Fogarasi, MD**

Senior Fellow in Medicine, Section of Medical Oncology  
Yale University School of Medicine  
Yale Cancer Center  
New Haven, Connecticut

**Kathleen M. Foley, MD**

Professor of Neurology, Neuroscience, and Clinical Pharmacology  
Weill Medical College of Cornell University  
Attending Neurologist  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Judah Folkman, MD**

Andrus Professor of Pediatric Surgery  
Professor of Cell Biology  
Harvard Medical School  
Children's Hospital  
Boston, Massachusetts

**Yuman Fong, MD**

Attending Surgeon  
Memorial Hospital  
Member, Memorial Sloan-Kettering Cancer Center  
New York, New York

**Kwun M. Fong, MD**

Hamon Center for Therapeutic Oncology Research  
University of Texas Southwestern Medical Center at Dallas  
Dallas, Texas

**Kenneth A. Foon, MD**

Professor of Medicine  
Department of Internal Medicine  
University of Cincinnati College of Medicine  
Director, Barrett Cancer Center  
Cincinnati, Ohio

**Arlene A. Forastiere, MD**

Professor of Oncology  
Johns Hopkins University School of Medicine  
Baltimore, Maryland

**Douglas L. Fraker, MD**

Jonathon Rhoads Associate Professor of Surgery  
Chief, Division of Surgical Oncology  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

**Zvi Y. Fuks, MD**

Department of Radiation Oncology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Brian G. Fuller, MD**

Senior Investigator  
Radiation Oncology Branch  
National Cancer Institute, Radiation Oncology Sciences Program  
National Institutes of Health  
Bethesda, Maryland

**Gianluca Gaidano, MD, PhD**

Department of Medical Sciences Division of Internal Medicine  
Amedeo Avogadro University of Eastern Piedmont  
Novara, Italy

**Don Ganem, MD**

Professor of Microbiology and Medicine  
Howard Hughes Medical Institute  
University of California, San Francisco, School of Medicine  
San Francisco, California

**Patricia A. Ganz, MD**

Professor, School of Medicine and Public Health  
Department of Medicine (Hematology-Oncology) and Health Services  
University of California, Los Angeles, UCLA School of Medicine  
University of California, Los Angeles, Jonsson Comprehensive Cancer Center  
Los Angeles, California

**Alan C. Geller, MPH, RN**

Research Assistant Professor of Dermatology  
Boston University School of Medicine  
Boston, Massachusetts

**Lynn Gerber, MD**

Clinical Professor of Medicine  
Georgetown University School of Medicine  
Chief, Rehabilitation Medicine Department  
Clinical Center, National Institutes of Health  
Bethesda, Maryland

**Jean-Francois H. Geschwind, MD**

Assistant Professor of Radiology and Surgery  
Johns Hopkins University School of Medicine  
Director, Interventional Radiology Research  
Department of Radiology and Surgery  
Johns Hopkins Hospital  
Baltimore, Maryland

**Robert J. Ginsberg, MD, FRCS(C)**

Professor of Surgery  
Weill Medical College of Cornell University  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Eli Glatstein, MD**

Professor of Radiation Oncology  
University of Pennsylvania School of Medicine  
Hospital of the University of Pennsylvania  
Philadelphia, Pennsylvania

**Frank A. Greco, MD**

Director, Sarah Cannon Cancer Center  
Centennial Medical Center

Nashville, Tennessee

**Daniel M. Green, MD**

Professor of Pediatrics  
Roswell Park Cancer Institute  
University at Buffalo School of Medicine and Biomedical Sciences  
Buffalo, New York

**Peter Greenwald, MD, DrPH**

Director, Division of Cancer Prevention  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Michael R. Grever, MD**

Professor of Internal Medicine and Hematology and Oncology  
Chairman, Department of Internal Medicine  
Program Leader for the Experimental Therapeutics Program  
James Comprehensive Cancer Center  
The Ohio State University  
Columbus, Ohio

**James D. Griffin, MD**

Professor of Medicine  
Harvard Medical School  
Brigham and Women's Hospital  
Department of Adult Oncology  
Dana-Farber Cancer Institute  
Boston, Massachusetts

**Philip H. Gutin, MD**

Chief of Neurosurgery; Fred Lebow Chair of Neurooncology  
Division of Surgery  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Douglas Hageman, MPA**

Chief, Office of Clinical Informatics  
Division of Clinical Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**John D. Hainsworth, MD**

Director, Clinical Research  
Sarah Cannon Cancer Center  
Centennial Medical Center  
Nashville, Tennessee

**Ulrike M. Hamper, MD, MBA**

Associate Professor of Radiology and Oncology  
Johns Hopkins University School of Medicine  
Baltimore, Maryland

**Jay R. Harris, MD**

Professor of Radiation Oncology  
Harvard Medical School  
Chief of Radiation Oncology  
Brigham and Women's Hospital, Children's Hospital  
Dana-Farber Cancer Institute  
Boston, Massachusetts

**Nancy Lee Harris, MD**

Professor of Pathology  
Massachusetts General Hospital  
Boston, Massachusetts

**Louis B. Harrison, MD**

Professor of Radiation Oncology  
Albert Einstein College of Medicine of Yeshiva University  
Chair, Radiation Oncology  
Beth Israel Medical Center  
St. Luke's-Roosevelt Hospital Center  
New York, New York

**Peter W. Heald, MD**

Associate Professor of Dermatology  
Yale University School of Medicine  
New Haven, Connecticut

**John H. Healey, MD**

Chief, Orthopaedic Surgery Service  
Department of Surgery  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**John D. Heiss, MD**

Staff Physician  
Surgical Neurology Branch  
National Institute of Neurological Disorders and Stroke  
National Institutes of Health  
Bethesda, Maryland

**Samuel Hellman, MD**

A. N. Pritzker Distinguished Service Professor  
Department of Radiation and Cellular Oncology  
University of Chicago  
Chicago, Illinois

**Lee J. Helman, MD**

Chief  
Pediatric Oncology Branch  
Division of Clinical Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Charles H. Hennekens, MD, DrPH**

Visiting Professor  
Department of Medicine and Epidemiology and Public Health  
University of Miami School of Medicine  
Miami, Florida

**Meenhard Herlyn, DVM, DSc**

The Wistar Institute  
Philadelphia, Pennsylvania

**Harry W. Herr, MD**

Attending Surgeon  
Department of Urology  
Weill Medical College of Cornell University  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Robert A. Hiatt, MD, PhD**

Deputy Director, Division of Cancer Control and Population Sciences  
National Cancer Institute, National Institutes of Health  
Rockville, Maryland

**Jeanne Hicks, MD.**

Associate Professor of Internal Medicine  
George Washington University School of Medicine and Health Sciences  
Associate Professor of Rehabilitation Medicine  
Department of Orthopedic Surgery  
Georgetown University School of Medicine  
Washington, DC  
Deputy Chief, Department of Rehabilitation Medicines  
National Institutes of Health  
Bethesda, Maryland

**Paulo M. Hoff, MD**

Assistant Professor  
Department of Gastrointestinal Medical Oncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**John P. Hoffman, MD**

Professor of Surgery  
Temple University School of Medicine  
Senior Member, Fox Chase Cancer Center  
Philadelphia, Pennsylvania

**Steven M. Holland, MD**

Senior Clinical Investigator, Laboratory of Host Defenses  
National Institute for Allergies and Infectious Diseases and Warren Grant Magnuson Clinical Center  
National Institutes of Health  
Bethesda, Maryland

**McDonald K. Horne III, MD**

Senior Clinical Investigator, Clinical Pathology Department  
Warren Grant Magnuson Clinical Center, National Institutes of Health  
Bethesda, Maryland

**Peter M. Howley, MD**

George Fabyan Professor of Comparative Pathology  
Department of Pathology  
Harvard Medical School  
Boston, Massachusetts

**Susan Molloy Hubbard, RN, MPA**

National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Margie Hunt, MS**

Assistant Attending  
Department of Medical Physics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Patrick Hwu, MD**

Senior Investigator, Division of Clinical Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Bonnie A. Indeck, MSW**

Clinical Instructor of Medicine  
Department of Social Work/Oncology  
Yale University School of Medicine  
Yale-New Haven Hospital  
New Haven, Connecticut

**William Isaacs, PhD**

Professor of Urology and Oncology  
Johns Hopkins University School of Medicine  
Baltimore, Maryland

**Robert T. Jensen, MD**

Chief, Digestive Diseases Branch  
National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health  
Bethesda, Maryland

**Steven W. Johnson, PhD**

Research Assistant Professor of Pharmacology  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

**Glenn W. Jones, MD, FRCPC, MSc**

Associate Professor of Medicine  
Department of Radiation Oncology  
McMaster University Undergraduate Medical Programme School of Medicine  
Hamilton, Ontario, Canada

**Barry M. Kacinski, MD, PhD**

Professor of Therapeutic Radiology, Obstetrics/Gynecology, and Dermatology  
Yale University School of Medicine  
New Haven, Connecticut

**Robert J. Kaner, MD**

Associate Professor of Clinical Medicine  
Department of Medicine, Division of Pulmonary and Critical Care Medicine  
Weill Medical College of Cornell University  
New York Presbyterian Hospital  
New York, New York

**Christine Kannler, MD, MPH**

Medical Resident, Internal Medicine Program  
Boston University School of Medicine  
Boston, Massachusetts

**Hagop M. Kantarjian, MD**

Professor of Medicine  
Chair, Department of Leukemia

The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Philip W. Kantoff, MD**

Associate Professor of Medicine  
Harvard Medical School  
Director, Lauk Center for Genitourinary Oncology, Adult Oncology  
Dana-Farber Cancer Institute  
Boston, Massachusetts

**Martin S. Karpeh, MD**

Assistant Attending  
Department of Surgery, Gastric and Mixed Tumor Service  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Michael B. Kastan, MD, PhD**

Member and Chair, Department of Hematology/Oncology  
St. Jude Children's Research Hospital  
Memphis, Tennessee

**David P. Kelsen, MD**

Professor of Medicine  
Weill Medical College of Cornell University  
Chief, Gastrointestinal Oncology Service  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Nancy Kemeny, MD**

Professor of Medicine  
Weill Medical College of Cornell University  
Attending Physician  
Department of Medicine, Solid Tumor Division, Gastrointestinal Oncology Service  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Robert S. Kerbel, PhD**

Professor and Director  
Department of Medical Biophysics  
Division of Cancer Biology Research  
University of Toronto Faculty of Medicine  
Sunnybrook and Women's College Health Sciences Centre  
Toronto, Ontario, Canada

**Elliott Kieff, MD, PhD**

Albee Professor  
Department of Medicine and Microbiology and Molecular Genetics  
Harvard Medical School  
Brigham and Women's Hospital  
Boston, Massachusetts

**Thomas J. Kilroy, MD**

Director of Dental Oncology  
Porter Care Hospital  
Denver, Colorado

**E. Edmund Kim, MD, MS**

Professor of Radiology and Medicine  
Department of Nuclear Medicine and Diagnostic Radiology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**John M. Kirkwood, MD**

Professor of Medicine, Division of Hematology/Oncology  
University of Pittsburgh School of Medicine  
Vice Chair for Clinical Research  
Director Melanoma Center  
University of Pittsburgh Cancer Institute  
Pittsburgh, Pennsylvania

**David E. Kleiner, Jr., MD, PhD**

Director, Clinical Operations  
Laboratory of Pathology  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**M. Tish Knobf, RN, PhD**

Associate Professor

American Cancer Society Professor of Oncology Nursing  
Adult Advanced Practice Program  
Yale University School of Nursing  
New Haven, Connecticut

**Howard K. Koh, MD, MPH**

Adjunct Professor  
Boston University School of Medicine, School of Public Health  
Commissioner of Public Health, Commonwealth of Massachusetts  
Boston, Massachusetts

**Stanley J. Korsmeyer, MD**

Sidney Farber Professor of Pathology  
Professor of Medicine  
Harvard Medical School  
Investigator, Howard Hughes Medical Institute  
Director, Program in Molecular Oncology  
Department of Cancer Immunology and AIDS  
Dana-Farber Cancer Institute  
Boston, Massachusetts

**Robert C. Kurtz, MD**

Professor of Clinical Medicine  
Department of Medicine  
Weill Medical College of Cornell University  
Attending Physician  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Terry C. Lairmore, MD**

Associate Professor of Endocrine and Oncologic Surgery  
Washington University School of Medicine  
St. Louis, Missouri

**Theodore S. Lawrence, MD, PhD**

Isadore Lampe Professor and Chair  
Department of Radiation Oncology  
University of Michigan Medical School  
Ann Arbor, Michigan

**Hop N. Le, MD**

Fellow in Surgery  
University of California, San Francisco, School of Medicine  
San Francisco, California

**Fredrick Leach, MD, PhD**

Urologic Oncology Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Keith L. Lee, MD**

Research Fellow in Prostate Cancer  
Department of Urology  
University of California, San Francisco, School of Medicine  
San Francisco, California

**David J. Leffell, MD**

Professor of Dermatology and Surgery  
Yale University School of Medicine  
New Haven, Connecticut

**Alan T. Lefor, MD, MPH**

Associate Professor of Clinical Surgery  
University of California, Los Angeles, UCLA School of Medicine  
Director, Division of Surgical Oncology  
Cedars-Sinai Medical Center  
Los Angeles, California

**Steven A. Leibel, MD**

Chair, Department of Radiation Oncology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Victor A. Levin, MD**

Professor of Neurooncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Arthur E. Li, MD**

Post-Doctoral Fellow in Radiology  
Johns Hopkins Hospital  
Baltimore, Maryland

**Peining Li, PhD**

Assistant Director, Cytogenetics Laboratory  
Department of Genetics  
Yale University School of Medicine  
New Haven, Connecticut

**Steven K. Libutti, MD**

Senior Investigator  
Surgery Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**W. Marston Linehan, MD**

Chief, Urologic Surgery  
Urologic Oncology Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**C. Clifton Ling, PhD**

Enid Haupt Chair  
Department of Medical Physics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Michael P. Link, MD**

Professor of Pediatrics  
Chief, Division of Hematology, Oncology and Bone Marrow Transplantation  
Stanford University School of Medicine  
Stanford, California

**Lance A. Liotta, MD, PhD**

Chief, Laboratory of Pathology  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Marc E. Lippman, MD**

Professor of Oncology and Medicine  
Georgetown University School of Medicine  
Director, Vincent T. Lombardi Cancer Research Center  
Georgetown University Hospital  
Washington, DC

**Scott M. Lippman, MD**

Professor of Medicine and Cancer Prevention  
Department of Thoracic/Head and Neck Medical Oncology; Department of Clinical Cancer Prevention  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Larry I. Lipshultz, MD**

Professor of Urology  
Chief, Division of Male Reproductive Medicine and Surgery  
Baylor College of Medicine  
Houston, Texas

**Richard F. Little, MD, MPH**

Senior Clinical Investigator  
HIV and AIDS Malignancy Branch  
Division of Clinical Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Mark S. Litwin, MD, MPH**

Associate Professor of Urology and Health Services  
University of California, Los Angeles, UCLA School of Medicine  
Los Angeles, California

**Edison T. Liu, MD**

Director, Division of Clinical Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Virginia Livolsi, MD**

Professor of Pathology and Laboratory Medicine  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

**Jay S. Loeffler, MD**

Director, Northeast Proton Therapy Center  
Department of Radiation Oncology  
Massachusetts General Hospital  
Boston, Massachusetts

**Patrick J. Loehrer, MD**

Professor of Medicine  
Section of Hematology Oncology  
Indiana University School of Medicine  
Indianapolis, Indiana

**Anthony Lomax, MSc, PhD**

Doctor of Radiation Medicine  
Paul Scherrer Institut  
Villigen, Switzerland

**Scott Long, MD, PhD**

Assistant Clinical Professor of Medicine  
Yale University School of Medicine  
New Haven, Connecticut  
Physician, The Connecticut Hospice  
Branford, Connecticut

**Charles L. Loprinzi, MD**

Professor and Chair  
Department of Medical Oncology  
Mayo Medical School  
Mayo Clinic  
Rochester, Minnesota

**Thomas LoSasso, MD**

Memorial Sloan-Kettering Cancer Center  
New York, New York

**Michael T. Lotze, MD**

Professor of Surgery, Molecular Genetics, and Biochemistry  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania

**David N. Louis, MD**

Associate Professor of Pathology  
Department of Pathology and Neurosurgical Service  
Harvard Medical School  
Massachusetts General Hospital  
Boston, Massachusetts

**Andrew M. Lowy, MD**

Chief of Surgical Oncology  
Associate Medical Director  
Barrett Cancer Center  
University of Cincinnati Medical Center  
Cincinnati, Ohio

**Douglas R. Lowy, MD**

Chief, Laboratory of Cellular Oncology  
Division of Basic Sciences  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Gigas Mageras, PhD**

Associate Attending Physicist  
Department of Medical Physics  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Robert G. Maki, MD, PhD**

Clinical Assistant Physician  
Department of Medicine  
Memorial Sloan-Kettering Cancer Center

New York, New York

**Martin M. Malawer, MD, FACS**

Professor of Orthopedic Surgery  
George Washington University School of Medicine and Health Sciences  
Washington Hospital Center, Washington Cancer Institute  
Washington, DC  
Consultant, Surgery Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**David Malkin, MD**

Associate Professor of Pediatrics  
Division of Hematology/Oncology  
University of Toronto Faculty of Medicine  
The Hospital for Sick Children  
Toronto, Ontario, Canada

**Francesco M. Marincola, MD**

Senior Investigator  
Surgery Branch  
National Cancer Institute, National Institutes of Health  
Bethesda, Maryland

**Peter Maslak, MD**

Assistant Professor  
Medicine and Clinical Laboratories  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Mary Jane Massie, MD**

Professor of Clinical Psychiatry  
Weill Medical College of Cornell University  
Attending Psychiatrist  
Department of Psychiatry and Behavioral Science  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Ellen T. Matloff, MS**

Associate Research Scientist  
Department of Genetics  
Yale University School of Medicine  
Yale Cancer Center  
New Haven, Connecticut

**Peter M. Mauch, MD**

Professor of Radiation Oncology  
Harvard Medical School  
Brigham and Women's Hospital  
Boston, Massachusetts

**Susan Taylor Mayne, PhD, FACE**

Associate Professor of Epidemiology and Public Health  
Yale University School of Medicine  
Yale Cancer Center  
New Haven, Connecticut

**Minesh P. Mehta, MD**

Associate Professor  
Interim Chair  
Department of Human Oncology  
University of Wisconsin Medical School  
Madison, Wisconsin

**Marvin L. Meistrich, PhD**

Professor of Experimental Radiation Oncology  
The University of Texas M. D. Anderson Cancer Center  
Houston, Texas

**Beth E. Meyerowitz, PhD**

Professor of Psychology  
University of Southern California School of Medicine  
Los Angeles, California

**James W. Mier, MD**

Associate Professor of Medicine  
Harvard Medical School  
Beth Israel Deaconess Medical Center

Boston, Massachusetts

**Susan D. Miller, PhD**

Assistant Professor of Otolaryngology  
Georgetown University School of Medicine  
Washington, DC

**John D. Minna, MD**

Professor of Internal Medicine and Pharmacology  
Director, Hamon Center for Therapeutic Oncology Research  
University of Texas Southwestern Medical Center at Dallas  
Dallas, Texas

**Bruce D. Minsky, MD**

Professor and Vice Chair  
Department of Radiation Oncology  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Jeffrey F. Moley, MD**

Associate Professor of Surgery  
Washington University School of Medicine  
St. Louis, Missouri

**Monica Morrow, MD**

Professor of Surgery  
Northwestern University Medical School  
Director, Cancer Department of the American College of Surgeons  
Chicago, Illinois

**Augusto C. Mota, MD**

Senior Fellow in Medicine  
Section of Medical Oncology  
Yale University School of Medicine  
Yale Cancer Center  
New Haven, Connecticut

**Robert J. Motzer, MD**

Associate Attending Physician  
Department of Medicine  
Memorial Sloan-Kettering Cancer Center  
New York, New York

**Franco M. Muggia, MD**

The Anne Marnick and David H. Cogan Professor of Oncology  
New York University School of Medicine  
New York, New York

**Nikhil C. Munshi, MD**

Professor of Medicine  
University of Arkansas for Medical Sciences

## PREFACE

---

The rapid pace of change in knowledge of the scientific basis and clinical practice of oncology presents a daunting challenge to the oncologist. The extraordinary increase in understanding of the molecular basis of cellular processes, the rise of biotechnology, and the steady refinement of each of the major treatment approaches have impacted every phase of the care of the cancer patient. In addition, an increased appreciation of the coordinated role of each of the main treatment modalities in the care of an individual cancer patient has emphasized the need for oncologists to be familiar with developments in all treatment modalities. Each edition of this text, first published in 1982, has attempted to help the oncologist keep pace with these changes.

In this sixth edition of *CANCER: Principles and Practice of Oncology*, we have again attempted to provide a comprehensive resource describing the science underlying recent clinical developments as well as complete information to aid the clinician in the panorama of clinical care ranging from cancer prevention to the care of the terminally ill patient. To accomplish this, the book has been divided into four parts.

**PART 1: Essentials of Modern Oncologic Science** presents a summary of the major areas of modern bioscience carefully distilled to provide the background necessary for an understanding of recent developments in oncology. Thus chapters on molecular biology, genomics, proteomics, signal transduction, and immunology present a primer for the oncologist in these important areas.

**PART 2: Principles of Oncology** has been reorganized to present in further detail the specific scientific areas of greatest relevance to the oncologist, including new chapters on cytogenetics, the cell cycle, apoptosis, and angiogenesis, as well as chapters on the etiology of cancer, and a clear description of modern epidemiologic methods and the incidence of and mortality from cancer.

Chapters on the principles underlying the four modalities of cancer treatment—surgery, radiotherapy, chemotherapy, and biologic therapy—present the basis for continuing changes in the development and application of these treatments. The pharmacology of cancer chemotherapeutics is presented, and a new section is introduced on the rapidly changing area of cancer biotherapeutics as these agents have entered into the practice of oncology.

The final chapter in PART 2 deals with the design and analysis of clinical trials as well as research data and management. As more and more patients are entering clinical trials, knowledge of these areas by the practicing oncologist is of special importance.

**PART 3: Practice of Oncology** provides the practicing clinician with the specific, practical information needed for the management of each cancer patient. Increased emphasis on cancer prevention relating to diet, tobacco, chemopreventive agents, fat, exercise, retinoids, naturally occurring dietary anticarcinogens, and many other areas are covered in detail. A new chapter on the role of surgery in cancer prevention details the emerging use of surgery in preventing cancer in high-risk individuals. Modern techniques of cancer screening, molecular pathology, imaging, and endoscopy are detailed in this section as well.

The hallmark of this book from its inception to the present and a major reason it has gained worldwide acceptance as a definitive source of cancer information has been the description of the treatment of cancer patients by stage of presentation with a tightly coordinated description of the role of each of the treatment modalities in the care of individual patients. To ensure a balanced multidisciplinary approach, each of the major treatment chapters is co-authored by a surgeon, a medical oncologist, and a radiation oncologist. Each of the major treatment sections is preceded by an updated, brief chapter describing the molecular biology of that cancer and the prospects this new information holds for the improved management of cancer patients.

Increased emphasis on supportive care, palliative care, and the quality of life of the cancer patient has led to an enlargement of sections dealing with these areas, including increased information on pain control and the nutritional, sexual, and psychosocial management of the cancer patient as well as issues related to the specialized care of the terminally ill.

**PART 4: Newer Approaches in Cancer Treatment** looks to the future of developments in oncology with special sections on gene therapy, molecular therapy, preventive and therapeutic cancer vaccines, image-guided surgery, and proton beam radiation therapy. In this section, we have attempted to identify those areas that we think will be of increasing value in the several years after the appearance of this text.

As we enter the twenty-first century, both the incidence and mortality of many of the major cancers are beginning to decline. We believe that the dissemination of carefully coordinated information of the scientific foundation and practice of oncology has played and will continue to play an important role in decreasing the devastating impact of cancer on modern society. We present the sixth edition of *CANCER: Principles and Practice of Oncology* to provide the practicing oncologist with the practical as well as cutting-edge information needed to provide the best possible care for each individual patient.

## **ACKNOWLEDGMENTS**

---

The editors are grateful to Zia Raven for her excellent help and energy in coordinating all of the contributions to this book and the many organizational details involved in its assembly. We are also grateful to Ruth Crawford, who played an important role in the compilation of many of the manuscripts.

We especially thank Stuart Freeman, Senior Editor, Oncology Program, Lippincott Williams & Wilkins, whose efforts and exceptional talents have been an important part of the preparation of this book through six editions.

## STORAGE AND TRANSMISSION OF GENETIC INFORMATION

### NUCLEIC ACIDS

The genetic material of all known organisms is nucleic acid: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Nucleic acids act as an information storehouse. They also actively participate in the reading and transmission of stored information within the cell and from one cell generation to the next. The usual flow of genetic information is from DNA to RNA to protein. The transition from DNA to RNA is called *transcription*, and the transition from RNA to protein is called *translation*. The direction of flow from DNA to RNA to protein was considered the “central dogma” in biologic sciences because most organisms exhibit this directionality in the expression of genetic information. However, it was found that some viruses, including retroviruses and the virus that causes autoimmune deficiency syndrome, transmit information from RNA to DNA using an enzyme called *reverse transcriptase*. Nucleic acids are polymers comprised of nucleotides (generally four different types) chemically linked together in chains that can be many millions of units long. The number of possible nucleic acid combinations  $n$  units long is thus  $4^n$ . A nucleic acid only 10 units in length therefore has  $4^{10}$  possible sequences.

Each nucleotide in the chain contains a nitrogenous base, a five-carbon sugar, and a phosphate group. The sequence of bases is the form in which the genetic information is coded.

There are two types of bases: pyrimidines and purines. Pyrimidines are six-membered rings and include cytosine (C), thymine (T), and uracil (U). Purines are fused five- and six-membered rings and include adenine (A) and guanine (G). The chemical structures of the bases is shown in [Figure 1-1](#). Bases C, A, and G are found in both DNA and RNA. T is specific to DNA, and U is specific to RNA.

FIGURE 1-1. Purines and pyrimidines.

Nucleosides are constituted by a nitrogenous base linked to a five-carbon sugar (pentose). The linkage is from the N1 position of the pyrimidines or from the N9 position of the purines to the carbon at position 1 on the pentose. DNA and RNA use different pentose sugars. The sugar in DNA is deoxyribose, and the pentose in RNA is ribose. The difference in the two sugars is a hydroxyl group at the 2' position on the sugar.

Nucleotides are nucleoside phosphates. A nucleotide is formed when a phosphate group is added to the 5' position on the pentose. The nucleotides that form the nucleic acid chain are connected in a very specific way: The 5' position of one pentose ring is connected to the 3' position of the next pentose ring by a phosphate group. The connection is called a *phosphodiester bond*.

### DNA

The DNA backbone is made up of bonded sugar and phosphate groups in which a phosphate group connects the 5' carbon of one sugar to the 3' carbon of the next sugar in the chain by a phosphodiester bond. As shown in [Figure 1-2](#), the beginning of the DNA chain has a phosphate group attached to the 5' carbon of deoxyribose, whereas the end of the chain has an OH group on the 3' carbon of deoxyribose.

**FIGURE 1-2.** The backbone of DNA is made of bonded sugar and phosphate groups in which a phosphate group connects the 5' carbon of one sugar to the 3' carbon of the next sugar in the chain. The beginning of the chain has a phosphate group attached to the 5' carbon of deoxyribose.

DNA is a double helix. It is a double-stranded polymer. The bases of each chain face inward, with the restriction that a purine is always paired opposite to a pyrimidine; thus, a G on one strand is paired with a C on the other, and an A is paired with a T. The sugar phosphates are on the backbone of the helix. The resulting negative charge on the outside of the helix is neutralized in the chromosome by metal ions or positively charged proteins.

The two polynucleotide chains in the double helix are connected by hydrogen bonds between the bases. As noted earlier, G hydrogen-bonds specifically with a C, whereas an A can only hydrogen-bond with a T. The resulting base pairs are said to be *complementary*. As shown in [Figure 1-3](#), the GC base pair has three hydrogen bonds, and the AT base pair has only two hydrogen bonds. Each strand can serve as the template for the synthesis of the other, enabling faithful reproduction of the genetic code.

**FIGURE 1-3.** Base pairs are formed by hydrogen bonds. T=A; G=C.

The two polynucleotide chains of the DNA double helix run in opposite directions (antiparallel). Thus, as one strand runs in the 5' to the 3' direction, the partner strand runs in the 3' to 5' direction, as in the following example:

DNA can be methylated in the carbon-5 position of cytosine to form 5-methylcytosine. This occurs in animals in DNA locations where the cytosine is followed on the same strand by guanine. The pattern of methylation is passed on when the DNA replicates.

## RNA

In RNA, the pyrimidine uracil replaces the DNA base thymine, and the pentose ribose is used instead of deoxyribose in DNA. During the synthesis of RNA from a DNA template, adenine in DNA is transcribed into uracil in RNA.

Because the pentose ribose is used in RNA instead of deoxyribose, this produces a ribonucleotide having a 2' OH group on the sugar, whereas the 2' OH group is not present in DNA. The important consequence is that RNA is much less stable than DNA. RNA is highly base labile. Although RNA can have a complex secondary structure, it is single stranded, not double stranded like DNA.

RNA is *transcribed* from a DNA template and is the first step by which the genetic information of DNA is converted into the synthesis of specific proteins. A single strand of RNA is generated that is identical in its sequence to one of the strands of the DNA. The DNA strand that has the same sequence (with T instead of U) as the messenger RNA (mRNA) is the coding, or positive, strand; the opposite antiparallel strand is the anticoding, or negative, strand. The RNA itself then becomes the template (mRNA) for translation into the sequence of amino acids that comprise the protein polypeptide.

Three main types of RNA are present in the cell: mRNA, ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA encodes the sequence for all cellular proteins; however, most initial transcripts of mRNA contain large pieces of intervening sequences, or introns, that must be spliced out to leave the coding sequences, or exons. At the 3' end of most mRNA molecules is a poly(A) tail of 150 to 250 adenine nucleotides. The mRNA also has an untranslated leader and trailer sequence at both ends. rRNA does not code for protein. Instead, it comprises part of the machinery that decodes the information in the mRNA. tRNA also does not code for protein. It reads off the mRNA triplet code and matches it with the correct amino acid. tRNA contains specific bases not found in other RNAs: inosine, pseudouridine, and dihydrouridine. At the end of each tRNA is an acceptor arm whose free end is aminoacylated, or carries the specific amino acid. Another arm on the tRNA contains the anticodon, which recognizes the complementary mRNA codon. Thus, mRNA functions as a transportable copy of the blueprint for the synthesis of protein, and tRNA functions as part of the protein synthetic assembly line.

## NUCLEASES AND POLYMERASES

Endonucleases are enzymes that cleave bonds within a nucleic acid chain. They may be specific for RNA, DNA, or hybrids of RNA-DNA or DNA-DNA. Restriction enzymes are a special class of endonucleases that recognize specific short sequences of DNA and cleave the DNA at or next to the recognition sequence. These enzymes are isolated from bacteria and are named after the genus (first letter) and species (second two letters) of the bacteria they are derived from. Because a bacteria can make more than one restriction enzyme, the specific member is designated by a roman numeral (e.g., EcoRI: *Escherichia coli*, strain R, first enzyme from that strain). Restriction enzymes cut DNA at palindromes. The palindrome is a sequence of DNA that is the same when one strand is read left to right (5' to 3') or the other is read right to left (still 5' to 3' because of the antiparallel rule). An example for EcoRI is

Restriction endonucleases are now standard tools in molecular biology and permit the cutting of large stretches of DNA at very precise points. They allow fragments of DNA to be "fingerprinted" by the size of the cleaved fragments. Moreover, a restriction enzyme can cleave the DNA so as to leave blunt ends, or staggered "sticky" ends with 5' or 3' overhangs. Because of this property, restriction enzymes are powerful tools to analyze DNA sequences and to create cleaved pieces of DNA that

can be shuffled, recombined, and reannealed in the process of DNA cloning.

Polymerases are enzymes that synthesize nucleic acid chains. RNA polymerases synthesize RNA, and DNA polymerases synthesize DNA. All polymerases require a template (nucleic acid strand to be synthesized), which is complementary to the strand being synthesized. They also need a primer, which is a short sequence (oligonucleotide) that is complementary to the 3' end of the template. This provides a free 3' OH end at which the polymerase starts to build a new chain.

Reverse transcriptase is a special polymerase that has, as its primary function, the ability to use RNA as a template to generate a copy in the form of DNA. It is an important enzyme in the life cycle of the human immunodeficiency viruses that cause autoimmune deficiency syndrome and other disorders, and as such, is a prime target for anti-human immunodeficiency virus therapeutics. Reverse transcriptase is also a unique reagent that can be used to create complementary DNA (copy) from mRNA extracted from cells, and therefore it is used in complementary DNA cloning.

The genetic code is a series of three mRNA nucleotides; each is a codon that encodes one amino acid ( Fig. 1-4). Three codons are nonsense or termination codons. The genetic code is degenerate, with more than one codon for most amino acids.

## GENES AND THEIR EXPRESSION

A gene is a unit of inheritance that carries the information representing a polypeptide or a structural RNA molecule. Genes are stable information packets transmitted from one generation to the next.

A gene includes “control” regions that precede and follow a central coding region and that include the sequences encoding the protein product. The coding region is preceded by a leader sequence and followed by a trailer. The leader and trailer are not translated into protein and represent the 5' and 3' untranslated regions of the mRNA that often function in regulating the half-life of the mRNA or in controlling translation.

The coding region is divided into alternating exons and introns. The exons, which are represented in the mature spliced RNA product, are interrupted or intervened by the introns. The introns are spliced out and do not encode amino acids. The reason for the introns is not obvious, but it is a hallmark of all higher order species in evolution. A gene family is a set of genes whose exons are related. A gene cluster is a group of genes related to each other that are adjacent.

Transcription is the process by which a single-stranded RNA is generated that is identical in sequence with the coding strand of the DNA. A transcription unit is a sequence of DNA that can be transcribed by RNA polymerase into a single RNA, beginning at an initiation start point and ending at a terminator.

Three types of genes are found in eukaryotes that are differentiated from each other by the type of RNA polymerase that transcribes the gene: RNA polymerase I, II, and III. RNA polymerase II produces heterogeneous nuclear RNA, which becomes mRNA after processing and splicing.

Proteins are encoded by mRNA. In the vast majority of cases, therefore, it is the protein product of a polymerase II gene that finally determines gene activity. The genetic code that transfers nucleotide sequences into amino acid sequences is organized as triplets of nucleotides forming a codon. Each codon is recognized by the translational machinery as representing an amino acid. Some codons are used as traffic signals that tell the machinery to start and stop translation (therefore their designation as *start* and *stop codons*). Mutations in important tumor suppressor genes, such as the breast cancer gene BRCA1 and the colon cancer gene APC, are frequently mutations that convert a codon that normally encodes an amino acid to a stop codon. This results in a prematurely truncated and, therefore, inactive protein.

A series of potential points for control of gene expression and functional protein production exist. These include activation of the gene chromatin complex, initiation of transcription, processing and capping of the RNA transcript, splicing of the RNA, polyadenylation of the RNA transcript, transport of the RNA to the cytoplasm, degradation of the RNA, translation of the mRNA into protein, correct folding and posttranslational modifications of the protein, transport and secretion of the protein, cleavage of the protein, or combination with inhibitors or activators.

In the nucleus, DNA exists in a complex with proteins to form chromatin. Structural changes occur to the chromatin to activate the regions of the DNA and unwind regions of the DNA. The eukaryotic chromatin is made from nucleosomes. A nucleosome contains approximately 200 base pairs (bp) of DNA that is wrapped around an octamer of histone proteins. In between the nucleosomes are linker regions that can be digested by DNAases. Transcribable active DNA is particularly sensitive to DNAases.

Between 2% and 7% of cytosines in animal DNA are modified by methylation, most often in sites where a C is followed by a G (CpG doublets). Methylation most often appears in genes that are not being expressed. DNA that is actively transcribed is often undermethylated. CpG-rich islands are often found upstream of constitutively transcribed genes near or at the promoters. This fact has been used by molecular geneticists to identify potential transcription units in large stretches of sequenced genomic DNA.

## TRANSCRIPTION CONTROL: PROMOTERS AND ENHANCERS

A promoter is a region of DNA that is involved in binding of RNA polymerase (and associated factors) to initiate transcription and are therefore *cis*-acting sites. Promoters for polymerase I and II are usually located upstream of the transcription unit (initiation start point). Promoters for polymerase III are located downstream.

Transcription factors are *trans*-acting elements that recognize specific *cis*-acting sites in the promoter. *Cis*-acting sites can be spread over regions of DNA that are greater than 100 bp. In general, they can be tentatively identified by footprinting experiments that localize sequences covered by transcription factors. In this type of experiment, a putative promoter DNA binding sequence is allowed to bind to the transcription factor. The DNA is radioactively labeled, digested with nucleases, and then electrophoresed on a sequencing gel. In the region of the binding site, access to nuclease digestion is blocked because of the “footprint” of the transcription factor. Once a candidate promoter sequence is mapped, it is possible to directly test its ability to regulate expression of a reporter gene that is positioned downstream.

Promoters are characterized by short consensus sequences called *boxes*. The TATA box is usually located approximately 25 bp upstream from the start point of transcription. This consensus sequence of AT base pairs (e.g., TATAAAA) is important in the correct positioning of the RNA polymerase II (in concert with a series of transcription factors) at the beginning of the initiation site. The CAAT box (often GGCCAATCT) is located approximately 80 bp upstream of the transcription start point. A large number of different transacting factors recognize the CAAT box. Its role is to determine the strength (frequency or rate of initiation events) of the promoter. The GC box comprises the sequence GGGCGG. It is found in multiple copies in either orientation. The GC box, usually upstream of the TATA box, is the

binding site for the Sp1 transcription factor, which regulates the strength of the promoter.

Enhancers are sequences that enhance initiation but may be located at a considerable distance from the start point upstream or downstream. Some enhancers have even been found within introns. Some transcription factors can bind to both promoters and enhancers. In retroviruses, enhancers are located in the viral long terminal repeats and are important for pathogenesis. Papillomaviruses contain enhancer elements that are specific for keratinocytes and thereby contribute to the specific tropism of the virus to these cells. Another example is the immunoglobulin cellular enhancer, which stimulates transcription in specific immune cell types.

Response elements are consensus sequences that allow specific transcription factors to coordinate the transcription of a whole group of genes that all have the consensus sequences. Examples are the heat shock response element, which responds to heat; the glucocorticoid response element, which responds to glucocorticoids; the metal response element; and the tumor promoting element (TRE). The TRE is a response element to TPA the carcinogenic promoting agent. It has the sequence TGACTCA. In response to TPA or phorbol ester, AP-1 transcription factors (a plurifunctional family including Jun and Fos) bind to the TRE.

## PROCESSING OF THE RNA TRANSCRIPT

A cap is a complex methylated structure at the 5' end of mRNA that is essential for translation. The first base of a gene that is transcribed into an mRNA molecule is usually a purine (A or G). Almost immediately after transcription starts, a nuclear enzyme guanylyl transferase catalyzes the addition of a 5' G to the first transcribed base of the mRNA. This step is followed by a series of methylation events. The final cap structure maintains the stability of the mRNA transcript as it is forming.

Processing of RNA includes termination and polyadenylation. All eukaryotic mRNAs (except histone genes) contain a poly(A) tail at their 3' end, which is added by poly(A) polymerase. A consensus sequence called the *polyadenylation signal AAUAAA* is located 10 to 30 bases upstream of the poly(A) tail. The polymerase transcribes through the polyadenylation signal, and after termination, an endonuclease cleaves the transcribed RNA at a site 10 to 30 bases downstream of the polyadenylation signal. The site of this event involves small nuclear ribonuclear particles. Once the cleavage occurs, the poly(A) polymerase adds A residues one by one to the 3' free end of the RNA. The poly(A) tail added to the end of the cleaved mRNA may assist the mRNA export out of the nucleus and may also be involved in the stability and lifespan of the mRNA molecule.

Processing of the transcribed RNA is required to remove the introns and produce a continuous linear sequence as a template for translation into the protein polypeptide. The coding region of a gene consists of exons and introns. Splicing is the mechanism by which the introns are removed from the precursor RNA to form a mature mRNA.

Splicing mechanisms differ depending on the type of RNA being spliced. Splicing of heterogeneous nuclear RNA requires a cap structure and is not complete until a poly(A) tail is added. The ends of the intron conform to the GT-AG rule, meaning that each intron in the gene begins with GT and ends with AG. The left 5' site is the donor site, and the right 3' site is the acceptor site. *Alternative splicing* refers to the possibility that there are variations in which exons are spliced together. A large complicated gene with many exons and introns can use alternative splicing to encode different proteins that are generated by different combinations of exons. Cellular genes for structural proteins, such as collagen, fibronectin, and myelin basic proteins, use alternative splicing to produce different proteins with different biologic functions. In this manner, a single gene can produce a number of protein isoforms using sequences within its "start" and "stop" borders.

Translation is the process by which the nucleotide sequence of mRNA is converted into a sequence of amino acids to make a protein. As mentioned, the genetic information of the RNA is organized into triplets of bases called *codons*. Translation requires ribosomal RNA that combines with ribosomal protein to form ribosomes. The ribosomes are docking sites for adaptor molecules, such as tRNA, that can recognize specific codons and the correct amino acid specified by that codon. Thus, the tRNA translates the base sequence of the mRNA into the different language of the amino acid sequence of the protein.

## REPAIR OF DNA

Correction of DNA sequence errors is critical to survival. Environmental factors, including radiation, mutagenic chemicals, and thermal energy, can induce errors in the DNA sequence. In addition, errors are occasionally introduced by DNA polymerases during replication. A certain low level of random DNA errors may be required to generate genotype variation to fuel Darwinian evolution. Nevertheless, if most errors were left uncorrected, then both proliferating and nonproliferating cells would accumulate so much genetic damage that they would no longer be viable. Moreover, damage of DNA in germ cells can prevent normal offspring from developing.

Although a significant body of knowledge has been accumulated about DNA polymerase proofreading and excision repair in *E coli*, many of the enzymes required for repairing DNA damage in eukaryotic cells are now being characterized. DNA repair mechanisms have significant roles in carcinogenesis (see [Chapter 2](#)).

## READING THE GENETIC CODE AND PRODUCTION OF ENCODED PROTEINS

### GENETIC CODE

The genetic code refers to triplets of DNA or RNA and the amino acids they specify. A triplet code specifies  $4^3$  words; thus, there are  $4^3$  codons. The code is redundant because more than one codon can specify the same amino acid.

An open reading frame is a string of codons that are flanked on the 5' side by an initiation codon and on the 3' side by a termination codon. All proteins start with methionine. The codon AUG specifies methionine and is therefore the initiation codon. Termination or nonsense codons are stop signals for the end of a protein chain. They include the codons UAA, UAG, and UGA. Protein synthesis proceeds from the amino-terminus (N-terminus) to the carboxy-terminus (C-terminus).

Because of the triplet codon, each stretch of mRNA contains three potential open reading frames. The reading frame can be shifted by moving the starting point one or two bases to the right or left. Mutations in which a base is deleted or inserted within an exon are called *frameshift mutations*, because they would alter the reading frame of the sequence.

### RIBOSOMES

Ribosomes are the protein synthesizing machinery that brings together the mRNA template and the charged tRNAs. The ribosomes contain two subunits. The small subunit is 40s; it contains an 18s rRNA and 40 proteins and is responsible for binding the tRNAs and the mRNAs. The large subunit, which catalyzes peptide bonds between amino acids on the growing polypeptide chain, has three rRNAs of 28S, 5.8S and 5S, as well as 50 proteins.

Every tRNA has two properties: It can covalently link to the amino acid it recognizes to form a charged aminoacyl-tRNA, and it contains an anticodon that is complementary to the codon recognizing its amino acid. The anticodon recognizes the codon by complementary base pairing. Some of the base pairs in the third position can be nonstandard or can wobble. This permits one tRNA to recognize more than one codon.

### PROTEIN SYNTHESIS: INITIATION, ELONGATION, AND TERMINATION

There are three general steps of protein synthesis: initiation, elongation, and termination. Initiation is the recognition by a specific initiating tRNA for the small ribosome subunit, along with guanosine triphosphate (GTP), and the initiating codon of the mRNA. A special tRNA<sup>met</sup> binds to the small ribosome subunit, and a molecule of GTP correctly positions the initiating AUG codon of the mRNA on the ribosomal subunit. In concert with several initiating factors, the large ribosomal subunit now binds to the small subunit, met ferrying-tRNA<sup>met</sup> becomes localized to the ribosome at the P site (peptidyl-tRNA).

Elongation is the extension of the amino acid chain by introducing a second aminoacyl-tRNA to the proper site on the ribosome called the *A site*. With the help of elongation factors, the growing polypeptide chain is attached to the tRNA that brought in the previous amino acid. A peptide bond is formed between the carboxyl group of the methionine and the amino group of the incoming amino acid to make a dipeptide that is attached to the new tRNA. Peptide bond formation requires GTP hydrolysis, which furnishes energy for the reaction. Thus, each elongation step requires two GTPs. Elongation is continued with each new charged tRNA binding to the A site, peptide bond formation, and translocation of the peptidyl-tRNA to the P site (with displacement of the now uncharged tRNA from the P site). In each translocation, the ribosome moves three nucleotides downstream of the mRNA; therefore, more than one polypeptide chain can be produced from one mRNA

simultaneously (Fig. 1-5).

**FIGURE 1-5.** Synthesis of secretory proteins on the endoplasmic reticulum (ER). An elongated signal recognition particle (SRP) binds to the signal sequence, and then the SRP, nascent polypeptide, and ribosome bind to the ER membrane through the SRP receptor. The signal sequence inserts into the ER membrane and is elongated. The signal sequence is cleaved in the ER lumen by signal peptidase. Carbohydrates are added to asparagine residues by enzymes on the luminal surface. After synthesis is complete, the ribosomes are released and the remaining C-terminus is transferred to the ER lumen. mRNA, messenger RNA.

Termination occurs when the ribosome reaches the termination codon of the mRNA. A termination factor supports the recognition of the nonsense codon, the release of the last tRNA, and the dissociation of the subunits. This final step also requires GTP hydrolysis.

Once mRNA is transcribed and translated, several factors affect its stability. Degradation of mRNA is a regulated process. Several sequence elements have been detected on mRNAs that regulate decay. An example is the ARE (AU-rich elements) that contain the consensus sequence AUUUA repeated once or several times within the 3' untranslated region.

## PROTEIN STRUCTURE AND FUNCTION

### AMINO ACIDS

The result of the transcription-translation process is the generation of a protein polypeptide. Proteins, the working molecules of the cell, catalyze a diverse range of chemical reactions, act as information sensors, provide structural scaffolding for cells and extracellular tissue components, control membrane permeability, transduce signals, recognize and covalently bind other molecules, cause motion, and control gene function.

This breadth of tasks are performed by biomolecules constructed from 20 different amino acids. A 100-amino acid protein has  $20^{100}$  possible structures. This enormous potential for variation means that cells and organisms can differ greatly in structure and function even though they are built from a limited number of biopolymer subunits using similar biochemical reactions.

Nineteen of the 20 amino acids contain an amino group (-NH<sub>2</sub>) and an acidic carboxyl group (-COOH). Proline has an imino group (-NH-) instead of an amino group. All amino acids have a central carbon atom, called an *alpha carbon*, which is bonded to an amino (or imino) group, to the carboxyl group, to a hydrogen atom, and to one variable group called a *side chain* or *R group*. The side chains give the amino acids their individual characteristics. Amino acids with polar but uncharged R groups are serine, threonine, asparagine, and glutamine. Amino acids with positively charged R groups are lysine, arginine, and histidine. Those with negatively charged R groups are glutamic acid and aspartic acid. Amino acids with hydrophobic R groups include alanine, isoleucine, leucine, methionine, phenylalanine, tryptophan, valine, and tyrosine. Special amino acids are cysteine, glycine, and proline.

### PROTEIN FOLDING INTO A COLLECTION OF FUNCTIONAL MOTIFS

Peptides are polymers composed of amino acids connected by peptide bonds. The peptide bond joins the carboxyl group of one amino acid to the amino group of the next amino acid. The nature of the peptide bond limits rotation around the alpha carbon and contributes to the three-dimensional spacing and folding of the protein. The newly synthesized protein adopts a three-dimensional conformation through noncovalent (ionic, hydrogen, van der Waals, and hydrophobic) interactions among the amino acids. The final conformation is stabilized by covalent disulfide bonds between cysteines in different parts of the chain, or between two different chains. Multiple different polypeptide chains can interact with each other by noncovalent forces or by covalent bonds, but polypeptide chains are never branched.

Thus, remarkably, the complete three-dimensional shape of a protein is determined by its primary structure, which is the linear sequence of amino acids. The secondary structure of a protein pertains to the folding of parts of the protein into regular structures, such as a helices and  $\beta$  pleated sheets. The tertiary structure describes the interaction of these regular structures into compact domains. The quaternary structure is the final organization of several polypeptide chains (originally encoded by separate genes) into a single protein molecule. The final protein can fold to form a long structural support rod, such as collagen, or a compact ball (globular protein), as in many proteins that catalyze chemical reactions.

Large polypeptides often fold into several globular units rather than one huge unit. Most domains contain between 50 and 300 amino acids. In a water fluid environment, the domains of proteins usually contain a hydrophobic interior and a hydrophilic surface. A regular substructure that occurs in different domains is a motif. Specific motifs are associated with specific functions.

A good example is transcription factor proteins, which have characteristic DNA binding motifs in the protein primary and secondary structure. The helix-turn-helix structure exhibits an a helix, a turn, and a second a helix. An example is the homeodomain in homeobox proteins that regulate development and differentiation. Zinc finger proteins contain tandem repeats of a 30-residue motif that contains cysteine and histidine residues that bind zinc. The zinc finger binds to a consensus sequence GCGTGGGCG on the DNA. Steroid receptors display a zinc binding domain different from the zinc finger and respond to steroid hormones (e.g., estrogen), retinoids, thyroid hormones, and vitamin D. The leucine zippers protein domain appears in many general transcription factors, including Jun and Fos. The zipper itself is a leucine-rich stretch of amino acids in a 30- to 40-amino acid region. The leucines are separated at regular intervals by six amino acids. A conserved repeat of hydrophobic residues is present three residues to the N-terminal side of the leucines (valine or isoleucine). In addition, the leucine zipper proteins have a basic region that is rich in arginines and lysines. The basic region binds to the DNA, and the leucine zipper region forms two parallel a helices in a coiled-coil arrangement. In addition to DNA binding, the leucine zipper plays a role in protein dimerization. Molecules that bind with themselves form homodimers, and those that couple with other proteins form heterodimers. Examples are the homodimers Jun-Jun and the heterodimers Jun-Fos, members of the AP-1 binding proteins involved in transcriptional control.

### PROTEIN POSTTRANSLATIONAL MODIFICATIONS

Proteins undergo several types of covalent and noncovalent modifications. These include the cleavage of the N-terminal methionine, the formation of disulfide bridges between two cysteine residues, or cleavage of a precursor polypeptide region. A large number of stable protein modifications can be made, including hydroxylation of proline and lysine in collagen, acetylation of lysine, methylation of histidine, attachment of carbohydrate groups to asparagine, presence of serine or threonine side chains, linkage to lipids, and addition of various groups to the N-terminus.

Protein functions during cell signaling are also controlled by reversible side-chain modifications. A key modification is phosphorylation, which is the substitution of phosphate groups for hydroxyl groups on serine, threonine, or tyrosine. The activity of many critical enzymes in cancer biology is regulated by their state of phosphorylation (e.g., src, HER2/neu, RET, and the retinoblastoma gene product). In fact, phosphatase and kinase enzymes themselves can be regulated by phosphorylation. The phosphorylation is mediated by enzymes called *kinases* and removed by enzymes called *phosphatases*. Thus, the phosphorylation cascade provides a simultaneous means of information exchange, amplification, pathway channeling, and regulation. Its importance in cancer is the fact that many oncogenes are themselves mutated kinases that are rendered constitutively active [e.g., epidermal growth factor receptor (EGFR), bcr-abl] (Fig. 1-6). Moreover, some tumor

suppressor genes are strong regulators of kinases (e.g., p16, p27).

**FIGURE 1-6.** Oncogenes can arise from protooncogenes that encode cell-surface receptors. On the left, the epidermal growth factor (EGF) receptor becomes oncogenic by loss of the coding region for the extracellular domain. On the right, the *neu* ERB-2 oncogene encodes a protein with a single amino acid substitution in the transmembrane domain.

## SUBCELLULAR MOLECULAR STRUCTURE

### PLASMA MEMBRANE

Both prokaryotic and eukaryotic cells are enclosed in a plasma membrane. In addition, most eukaryotic cells contain extensive internal membranes interconnected to the plasma membrane. These internal pockets and sacs define a collection of subcellular organelles. The largest organelle is the nucleus. Examples of other organelles are mitochondria (oxidation of small molecules to generate adenosine triphosphate); rough and smooth endoplasmic reticula, a network of membranes in which glycoproteins and lipids are synthesized; Golgi vesicles, which channel membrane constituents to correct locations in the cell; and lysosomes, which degrade proteins. The organelles maintain a specific, demarcated, confined chemical environment (such as an acid pH in the case of lysosomes) and contain a host of bound enzymes that catalyze requisite chemical reactions.

### NUCLEUS

Chromosomal DNA in eukaryotic cells is wrapped in a set of five different positively charged proteins called *histones*. Histone-DNA interactions occur at regular intervals. Every sequence of 150 to 180 bp of DNA is bound to one molecule of histone H1 and to two molecules each of histones H2A, H2B, H3, and H4.

The eukaryotic nucleus is surrounded by two membranes containing phospholipids. The outer membrane is continuous with the cytoplasmic membrane system. The space between the inner and outer membrane communicates with the lumenal cavity of the rough endoplasmic reticulum. The inner membrane defines the nucleus proper. Fibrous proteins called *lamins* form a two-dimensional network on the inner surface of the inner membrane. Ring-like nuclear membrane pores, formed from a special set of membrane proteins, are regulated channels for the movement of material between the nucleus and the cytoplasm.

The nucleolar organizer, a region of one or more chromosomes in the nucleolus, is a focal point for synthesis of ribosomal RNA. Generated ribosomal subunits pass through the nuclear pores into the cytoplasm.

### CYTOPLASM

The cytoplasm is the region outside the nucleus of eukaryotic cells, and it contains an array of fibrous proteins collectively constituting the cytoskeleton. The most abundant cytoskeleton components are microfilaments, which are built of actin; slightly wider microtubules, made of tubulin; and intermediate filaments, built of a set of rod-shaped protein subunits. The cytoskeleton is not just a structural scaffolding. It plays critical roles in cell movement, differentiation, intracellular trafficking, cell division (microtubules mediate chromosome movement), and signal transduction. Some of the most active chemotherapeutic agents, such as the taxanes and the vinca alkaloids, directly affect microtubular assembly as their primary mode of action.

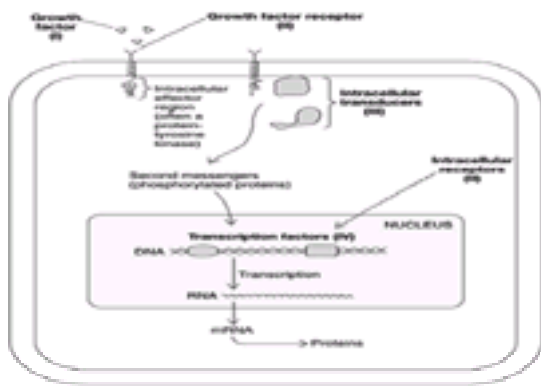

The plasma membrane surface is highly specialized to interact with the environment according to the functional requirements of the individual differentiated cell. Protuberances and extensions of the plasma membrane, such as cilia, pseudopods, and villi, contain cores of specialized cytoskeletal extensions and have broad functions in locomotion and macromolecule uptake. The plasma membrane contains embedded receptors and anchor points that bind to the extracellular matrix, surrounding cells, or soluble cytokines.

### MEMBRANE PROTEINS

Proteins interact with membranes using a variety of mechanisms. Integral membrane proteins contain amino acid residues with hydrophobic side chains that interact with the fatty acyl groups of the membrane phospholipids. Other integral proteins contain covalently bound fatty acids that function as anchors in the hydrophobic lipid bilayer. An important example is the farnesyl residue of the oncogene p21 ras (the mutant of the normal cellular small g protein) and the myristate residue of the v-src tyrosine kinase oncogene (the mutant of the normal cellular protein c-src). The farnesyl residue is linked by a thioester bond to a cysteine residue four amino acids from the C-terminus of the protein, and then the three C-terminal residues are cleaved off. Myristate is bound by an amide linkage to the glycine residue found at the N-terminus. Cancerous transformation by such oncogenes requires the membrane-attachment function of these covalently attached lipids.

### MOLECULAR ONCOGENESIS: CELLULAR SIGNAL TRANSDUCTION

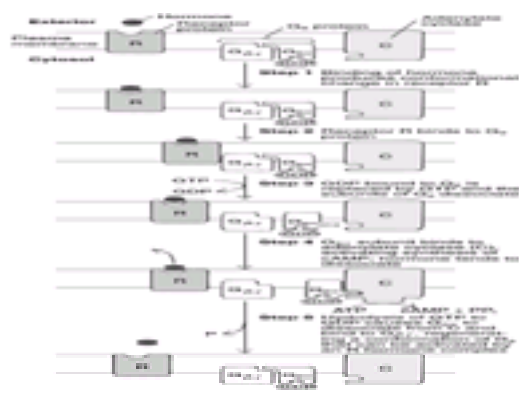

Mutations that cause cancer are mainly those that alter the ability of the cell to maintain genetic stability, such as mutations in repair genes, or those that alter the transmission of signals that control the machinery of cell growth and survival ( Fig. 1-7). The transmission of signals within the cell and from inside and outside the cell is called *signal transduction*. Surface receptors are the sensors providing the cell's window to the outside environment. Most receptors fall into one of three general types depending on the signal transduction mechanism used. Channel-linked receptors are ligand gated ion channels involved in rapid synaptic signaling. These receptors belong to a family of homologous multipass transmembrane proteins. Catalytic receptors are activated by a ligand to operate directly as enzymes. Most of the known catalytic receptors are transmembrane proteins with a cytoplasmic domain that normally accepts controlled signals from outside the cell and transmits signals to the inside of the cell. Many of these proteins function as a tyrosine-specific protein kinase. An important example is the receptor for the EGF-related ligands (EGFR). Included in the EGFR family is the ERB2/Neu receptor, which plays a major role in the biology of human breast cancers. When mutated, the RET oncogene is activated and associated with both hereditary and sporadic thyroid cancers, and overexpression of the MET protooncogene leads to increased cell motility and metastatic potential. Conversely, the normal function of the transforming growth factor- $\beta$  pathway is to suppress growth and oncogenesis. When mutated, the inactivation of the ligand or receptor renders the cell susceptible to transformation. Intracellular kinases that do not transmit signals across the cell membrane but potentially within the cell are also important in oncogenesis. The ABL kinase is activated when participating in the bcr-abl translocation. The majority of these transmembrane receptors normally transduce signals through the controlled phosphorylation of intracellular substrates, usually on tyrosine, serine, or threonine residues that function as signaling nodes in a complex intracellular communications network. The control of phosphorylation and dephosphorylation events are used by cells to relay signals, amplify signals, and regulate pathways and to act by changing the conformation and, therefore, the function of the phosphorylated protein. Any member of a signaling cascade can be a potential target for oncogenic mutation.

**FIGURE 1-7.** Control points in cellular regulation that can be targets for carcinogenic events. The following classes can become oncogenes: growth factors (I), receptors (II), transducers (III), and gene regulation factors (IV). mRNA, messenger RNA.

A third class of receptors is the G protein–linked receptors. These sensors indirectly activate or inactivate a separate membrane-bound enzyme or ion channel. The interaction takes place through an intermediary protein, the GTP-binding regulatory protein (G protein). The G protein–linked receptors activate a cascade of downstream intracellular messengers. The messengers in turn activate or regulate other target proteins in the cell. Important intracellular messengers are calcium ions, cyclic adenosine monophosphate, and phospholipids.

The Gs protein functions as a shuttle between two membrane proteins: the receptor for the stimulus and the downstream effect enzyme (adenyl cyclase), which generates the second messenger. Thus, Gs is a signal transducer, relaying to the recipient enzyme the conformational change in the receptor triggered by the ligand binding to the receptor (Fig. 1-8). The Gs protein cycles between active and resting forms, which are determined by the state of its subunits. Gs is composed of three polypeptides: an  $\alpha$  chain Gsa, which binds and hydrolyzes GTP and activates adenyl cyclase, and a tight complex of a  $\beta$  chain and a  $\gamma$  chain Gbg, which anchors Gs to the cytoplasmic face of the plasma membrane. In the resting state, Gsa contains bound guanosine diphosphate (GDP) and is coupled to Gbg. When GTP binds to Gsa, it is hydrolyzed to GDP by the reaction:  $Gsa + GTP \rightarrow Gsa + GDP + \text{inorganic phosphate}$ . The change in the receptor conformation is passed on through the G $\alpha$  to the Gsa and causes GDP to be replaced by GTP. When GTP is bound to Gsa, the Gsa dissociates from the Gbg subunits. The Gsa, with its bound GTP, undergoes a conformational change that enables it to bind and activate adenyl cyclase. In a resting cell, most Gs molecules contain GDP. Binding to a hormone or agonist changes the conformation of the receptor protruding on the inner surface of the membrane. The altered receptor can now bind Gs, causing GDP to be displaced and GTP to be bound. The GTP-bound form of Gsa then acts as a shuttle that translocates to bind adenyl cyclase and activate it to hydrolyze adenosine triphosphate to cyclic adenosine monophosphate and inorganic phosphate. Immediately after activation of adenyl cyclase, Gsa hydrolyzes bound GTP to GDP and returns to its coupled state with Gbg.

**FIGURE 1-8.** Cascade of molecular exchange events involved in the transduction of a signal through G protein–linked receptors. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; P<sub>i</sub>, inorganic pyrophosphate.

All receptors that interact with a G protein share a common stretch of 22 to 24 hydrophobic amino acids that generate seven back and forth *trans* membrane  $\alpha$  helices. A large loop between helices 5 and 6 protrudes into the cytosol and interacts with the G protein.

In cancer, the most important G proteins are found in the ras family of oncogenes: N-ras, K-ras, and H-ras. Specific mutations of the normal cellular ras protein causes it to be activated by disarming its GTPase activity. This renders the protein incapable of converting its active GTP-bound form into the inactive GDP-bound form. Thus, mutant ras proteins are constitutively “on” and are oncogenic. The downstream consequences of ras activation are through the induction of cellular proliferation and in enhancing cell motility. Ultimately, these membrane and cytoplasmic signaling molecules all converge to alter cellular transcription through the activation of transcription factors (see Fig. 1-7). Oncogenesis can be initiated by a molecular lesion that disrupts this cascade at any level, from the ligand or receptor all the way to the nuclear transcription factor (Table 1-1). In cancer biology, there is ample evidence of direct mutational activation of transcription factors in the genesis and maintenance of the cancerous state. Myc, AML1, MLL, and the homeobox proteins are all examples of altered transcriptional machinery in the induction of human cancers.

**TABLE 1-1.** Selected Oncogenes and Their Proteins

## DIFFERENT PATHWAYS TO CANCER

### PERTURBATIONS IN SIGNALING

Viral oncogenes were the first evidence that host genes can directly cause cancer. Normal cellular genes (protooncogenes, identified by the *c* prefix) are “picked up” or transduced by the retrovirus and mutated through the error-prone process of the retroviral replication. This results in a viral oncogene (*v- onc*) that is functionally arrested in a biochemically activated form. Early studies revealed that the oncogene precursors, the protooncogenes, act as biochemical switches in the command and control processes of a cell, specifically transmitting signals from the outside of the cell to the nucleus. The normal and controlled transfer of extracellular signals is bypassed when one of the relay members is mutated and is made constitutively activated, resulting in the characteristic of a cancer cell—unmanaged growth. In

nature, one finds oncogenic mutations in members of signaling pathways. For example, the receptor tyrosine kinase (EGFR; mutated or overexpressed in brain and epithelial cancers; related retroviral oncogene, *v-erbB*), when stimulated with one of its ligands, transforming growth factor- $\alpha$  (overexpressed in some human cancers), interacts with *ras* (retroviral homologue, *v-H-ras* or *v-K-ras*; mutated in 10% to 20% of human cancers) through bridging proteins. *Ras* is controlled by GTPase-activating proteins (oncogenic homologue is NF1, the gene involved in neurofibromatosis) and transmits signals by activating *raf* (retroviral homologue, *v-raf*). Stimulation of the *ras/raf* pathway results in increased expression of the nuclear proteins *jun*, *fos*, and *myc* (retroviral homologues, *v-jun*, *v-fos*, *v-myc*; *myc* is mutated and rearranged in lymphoid malignancies and amplified in breast cancers), which are proteins that can induce the expression of other genes (called *transcription factors*). Thus, every relay node in this signal transduction pathway is a potential site for oncogenic conversion. The complexity of the transformation process is reflected in the multiple parallel signaling pathways that are promiscuous in their selection of biochemical partners. For example, the receptor tyrosine kinase HER-2 physically associates with itself or with related receptor tyrosine kinases, such as EGFR, HER-3, and HER-4; *ras* can be regulated by either *ras*-GTPase-activating proteins or NF1; and stimulation of the *ras* pathway activates a number of mitogen-activated protein kinases.

## THE WRONG PLACE AT THE WRONG TIME

In human cancers, mutations in protooncogenes result in altered function. However, inappropriate expression of structurally normal proteins that have no role in the biology of a specific tissue can also lead to cancer. Several transcription factors are in this category: *myc*, *tal-1/SCL*, *lyl-1*, *Ttg-1*, and *Ttg-2*. These oncoproteins are structurally identical to their normal forms but are either inappropriately expressed in the cell cycle or in inappropriate tissues. *myc* is expressed in all cells and plays a role in cell division and differentiation. Activation of *myc* due to the t(8;14)(q24;q32) seen in Burkitt's lymphomas and B-cell acute lymphocytic leukemias deregulates *myc* expression, and the exquisite control of *myc* transcription is lost. In lymphoid tissues, this leads to the expansion of pre-B cells in transgenic mice inappropriately expressing *myc*, which ultimately results in the emergence of a lymphoid malignancy. Other members on this list (*tal-1/SCL*, *lyl-1*, *Ttg-1*, and *Ttg-2*) are linked to T-cell acute lymphocytic leukemia. In this group, oncogenic activation is through expression in an inappropriate cell type: *tal-1* is normally expressed in erythroid and myeloid precursors and not in T cells; *lyl-1* is expressed only in myeloid and B-lymphoid cells; and *Ttg-2* transcripts are found in liver, spleen, and kidney but not in activated T cells. In these examples, the inappropriate expression of a transcription factor serves as a molecular switch to induce a malignancy.

## RELEASE OF SUPPRESSION

Whereas protooncogenes are identified by a gain of function after mutational damage, another class of cancer genes, tumor suppressor genes, contribute to cancer induction by a loss of function. To this end, tumor suppressor genes, such as the retinoblastoma gene (*Rb-1*) and p53, block cellular proliferation, and each appears to function through distinct pathways. *Rb-1* negatively regulates the important transcription factor E2F, and the deletion of the *Rb* gene (seen in congenital retinoblastoma) releases the suppression of E2F. p53 enhances the expression of p21/CIP1, which is a suppressor of cell-cycle regulatory kinases [cyclin-dependent kinases (CDKs)]. Activation of these CDKs is necessary for progression through the cell cycle, and CDK inhibitors, such as p21/CIP1, block this process. Thus, the loss of p53 and the attenuation of p21/CIP1 expression result in unmanaged progression through the cell cycle.

That both *Rb* and p53 are involved in the genesis of cancer is evidenced by the identification of germline mutations of these genes in individuals with cancer predisposition syndromes, such as congenital retinoblastoma (*Rb*) and the Li-Fraumeni multicancer syndrome (p53). As with oncogenes, the presence of a single abnormal tumor suppressor allele alone is insufficient for cancer to develop; lesions at other genetic lesions are necessary. For example, both *Rb* and p53 may need to be inactivated for some normal cells to be rendered immortal. The DNA tumor virus, the human papillomavirus (HPV) that is the causative agent in many cervical, anal, and penile carcinomas, inhibits both these critical proteins through binding with and inactivation by the HPV viral proteins E6 and E7. In this manner, HPV biochemically achieves the same outcome that carcinogens accomplish through inactivating genetic mutations. In colon cancers, mutations in p53 are frequently associated with other genetic lesions, including those involved in cytoskeletal organization (APC), signal transduction (*ras*), and cell motility (DCC) in the progress toward an invasive cancer.

A tumor suppressor gene can be defined as any gene whose loss of function contributes to cancer progression. One category of suppressor genes are the inhibitors of the CDKs, which are enzymes that control the progression through the cell cycle. They, in turn, are controlled by protein activators (called *cyclins*) and inhibitors (called *CDK inhibitors*). The attenuation of expression of CDK inhibitors, such as p16, p27, and p57, has been associated with a diverse range of cancers, from lung to head and neck, breast, and pancreas cancers, as well as melanoma. In malignant melanoma, the loss of both p16 alleles is found in most primary tumors, and inactivating germline mutations in p16 segregate with familial melanoma syndromes. Therefore, CDK inhibitors, such as p16, maintain the normal cellular state by regulating cell proliferation, and disruption of its inhibitor function leads to cancer.

## CELL DEATH

Earlier on, the study of molecular oncogenesis concentrated on processes that stimulated growth. However, the accumulation of cancer cells can also be accomplished by a decrease in cell loss as well as by an increase in cell proliferation. Current evidence suggests that the abrogation of programmed cell death (apoptosis) is an important mechanism for neoplastic transformation. Certain cellular processes, such as cytokine signaling (e.g., tumor necrosis factor, interleukin-3 withdrawal) or DNA damage, can trigger a cascade of events culminating in activation of intracellular proteases. These activated proteases then lead to the regulated cleavage of cellular components, including proteins and DNA, and ultimately to cell death. The cell exerts exquisite control of this process using redundant systems to induce or block apoptosis, and some of these control switches are involved in cancer and cancer treatment.

The clearest example of an oncogene modulating the apoptotic process is *bcl-2*, found to be the oncogene involved in the t(14q;18q) translocation frequently found in follicular lymphomas. *bcl-2* blocks apoptosis when overexpressed or inappropriately expressed, and in lymphomas, translation involving *bcl-2* may be among the earliest oncogene abnormalities that act to prolong the lifespan of cells that are prone to accumulate genetic mutations. In experimental lymphomas, *bcl-2* does not cause cancer directly but is followed by rearrangements at other oncogenes, such as the *c-myc*, which result in accelerated progression of the lymphoma. This *bcl-2/myc* interaction highlights another principle of oncogene action—that is, more than one cancer gene must be perturbed for a malignancy to arise. Other *bcl-2*-related proteins have been identified, all of which are capable of physically interacting with each other as homo- or heterodimers. *bcl-X<sub>L</sub>*, like *bcl-2*, is antiapoptotic; overexpression of *bax*, *bak*, *bcl-X<sub>s</sub>*, and BAD, however, actually induces apoptosis. Thus, the ratio of antiapoptotic to proapoptotic factors determine the cell's "set point" triggering apoptosis. Significantly, this set point can modulate a cell's responsiveness to radiation and chemotherapy.

More recently, growth factor receptors and other surface signaling molecules have been shown to directly affect the apoptotic process. Many receptor kinases, such as platelet-derived growth factor receptor and *Met*, recruit and activate the phosphatidylinositol 3 kinase (PI3-kinase). PI3-kinase activates the *Akt* protein kinase, which supports cell survival through its phosphorylation and inactivation of BAD, one of the *bcl-2*-related proteins that promotes cell death. Therefore, augmented *Akt* function induced by ligand receptor interactions is predicted to have an antiapoptotic effect. It is not clear why certain tumors genetically alter *bcl-2* to alter apoptotic potential whereas others use alternative biochemical pathways to accomplish the same ends. Nevertheless, it is clear that normal cells have self-policing mechanisms that activate suicide programs. When the mutational load of a cell exceeds a critical level, self-destruct processes are activated. Cancer, however, may result when genetically abnormal cells are not cleared but are allowed to proliferate, thus accumulating mutations potentially in important cancer genes.

## GENETIC INSTABILITY

A characteristic of a cancer cell is its ability to generate and to sustain genetic mutations. Normal cells not only have the ability to identify and repair DNA damage, but also to prevent the expansion of mutation-laden daughter cells by suicide mechanisms such as apoptosis. Defects in DNA repair found in rare disorders such as xeroderma pigmentosum and ataxia-telangiectasia are associated with cancer risk. More recently, however, common human cancers have been linked to abnormalities in repair processes. One example is the hereditary nonpolyposis colon cancer (HNPCC) syndrome. HNPCC is an inherited syndrome characterized by increased risk for colon cancer without the associated polyposis seen in carriers of another heritable cancer syndrome, adenomatous polyposis coli. Affected individuals with HNPCC show signs of a defect in the repair of DNA mismatches. Additions or reductions in the number of two nucleotide repeats found in human DNA (called *microsatellite instability*) were clonally detected in their tumors. This type of DNA abnormality is a signature for a form of repair defect previously studied in bacteria and yeast. When incorrectly paired nucleotides occur in a DNA duplex, either through misincorporations or nucleotide damage, cells use a mismatch repair system to identify and remove the mismatch. This recognition and cleavage is mediated by the protein products of the MSH2, MSH3, MSH6, MLH1, PMS1, and PMS2 genes. HNPCC patients have primarily mutations in MSH2 and MLH1, although mutations in the other mismatch repair genes also are found. The clinical consequence of this molecular defect in humans is the emergence of colon cancers that differ from the sporadic variety and that are characterized by fewer *ras* and p53 mutations, as well as fewer allelic losses. Moreover, colon cancer in HNPCC patients appear to have a better prognosis than their sporadic counterparts.

Advances in molecular biology and their application to cancer research have yielded a wealth of new knowledge uncovering molecular mechanisms that can trigger and sustain uncontrolled growth. From the clinical perspective, it is astonishing that the molecular pathways that lead to cancer can be different in different types of

neoplasms, in different tissues, and even in the same type of pathology. Nevertheless, elucidating each new molecular pathway involved in cancer provides strategies for diagnosis, intervention, and treatment. Thus, a molecular understanding of cancer clarifies why curing this disease is so difficult, while at the same time, this knowledge provides more precise targets for treatments in the future.

#### UNDERSTANDING CANCER AT THE MOLECULAR LEVEL: THE NEW FRONTIER

Genomic and proteome research is a new frontier for the molecular characterization of cancer. The ongoing revolution in molecular medicine can be divided into three phases. The first phase is gene discovery, in which the tools of molecular biology are applied to identify and sequence previously unknown genes. Identification of most of the expressed human genes will be accomplished before 2002. The second phase is molecular fingerprinting, which correlates the genomic state, the cDNA expression pattern, and the protein repertoire with the functional status of the cells or tissue. The promise of this phase is that expression profiles can uncover clues to functionally important molecules and will generate information to tailor a treatment to the individual patient. The third phase is the synthesis of proteomic information into functional pathways and circuits in cells and tissues. This must take into account the dynamic state of protein posttranslational modifications and protein–protein or protein–DNA interactions. Through an integrated genomic and proteomic analysis, the ultimate outcome will be an actual functional understanding of the molecular events underlying normal development and disease pathophysiology. This higher level of functional understanding will be the basis for true rational therapeutic design.

Progress in these three phases of molecular medicine is largely driven by new technologies. The development of polymerase chain reaction (PCR), high throughput sequencing, and bioinformatics has been a driving force in the first phase. In the second phase, microhybridization arrays applied to genetic analysis and gene expression are a powerful new tool that has entered the commercial sector and is becoming widely available to researchers. As more genes are identified, it is likely that specialized arrays will be offered that are specific for a tissue type (e.g., mammary gland chip), physiologic process (e.g., apoptosis chip, angiogenesis chip, invasion chip), or class of genes (e.g., suppressor gene chip, oncogene chip).

#### GENETIC MECHANISMS OF CANCER PROGRESSION: CANCER IS A GENETIC DISEASE

Cancer is a genetic disease. Progression from normal tissue to invasive cancer takes place over 5 to 20 years and is influenced by hereditary genetic factors as well as somatic genetic changes (Fig. 2-1). Cancer progression is driven by a series of accumulating genetic changes. Some genetic oncogenic changes contribute to uncontrolled growth or loss of senescence. Some oncogenes cause uncontrolled growth by activating persistent growth stimulatory signal transduction pathways. Some oncogenes cause uncontrolled growth by altering critical nodes in the cell cycle. Uncontrolled growth can be caused by deregulation at the level of DNA transcription factors.

**FIGURE 2-1.** Molecular progression of cancer. Microscopic premalignant lesions originate within a background of hereditary predisposition. Genetic instability leads to molecular derangements that drive somatic genetic progression. Host interactions enable the cancer lesions to expand, vascularize, and metastasize. Diagnosis usually takes place at a late stage when there is a high probability of metastasis.

Separate genetic changes (beyond those causing uncontrolled growth) are required for tumor invasion and metastasis. Invasion and metastasis form a multistep cascade involving positive and negative regulatory pathways. Cancer invasion and angiogenesis are an uncontrolled version of physiologic invasion.

Genetic instability may predispose the premalignant cell to generate malignant offspring. Instability can take place at the macro level (chromosome karyotype), as well as the micro level (DNA sequence copy fidelity repair). Chromosomal rearrangement can activate silent oncogenes or delete regions containing suppressor genes. Loss of heterozygosity is a hallmark of suppressor gene inactivation in cancer progression. Telomerase defects may affect growth control as well as genetic instability. Mutations in cellular DNA can activate oncogenes or inactivate suppressor genes. Defects in DNA repair mechanisms contribute to the accumulation of genetic defects fueling cancer progression. Genetic defects causing an inhibition of cell death pathways are an important mechanism in tumorigenesis.

#### CANCER GENES: MODELS OF ACTION

Genetic alterations involved in cancer can activate inductive processes (oncogenes) or block negative pathways (suppressor genes). Early models of cancer genetics categorized cancer genes into oncogenes, which are growth inducing, and tumor suppressor genes, which are growth suppressing. Thus, mutations in oncogenes activate a promoting function, but lesions in tumor suppressors inactivate an inhibitory function. Examples of these models were the ras oncogene and the retinoblastoma (rb) tumor suppressor gene. Mutations in codons 12, 13, and 61 in the ras gene result in biochemical activation of the protein product and an induction of its transforming activity. Deletions or inactivating mutations in the rb gene lead to a compromised suppressor protein that is incapable of inhibiting cell growth. Aberrations in both genes are found as somatic mutations in human cancers and, in the case of rb, also in the germline of individuals at risk for cancer.

Dominant oncogenes play a significant role in human cancers. Ras mutations are found in 10% of cancers and appear frequently in colon and lung adenocarcinomas. Ret is a receptor tyrosine kinase in which activating single nucleotide mutations are associated with hereditary thyroid carcinomas. Myc, encoding a nuclear oncoprotein, is involved in the t(8;14) translocation, which is etiologic for Burkitt's lymphoma. Inappropriate overexpression of myc is sufficient for transformation of lymphocytes in transgenic models. Similarly, amplification and overexpression of the HER2/neu receptor tyrosine kinase not only causes mammary malignancies, but is prognostic in human breast cancers. Although originally these oncogene abnormalities were thought to induce cancer primarily through unregulated growth, other cellular phenotypes such as enhanced survival and motility may be equally important contributors to the cancer state.

It was also originally thought that tumor suppressor genes function mainly by inhibiting cell growth. Later, this was expanded to genes that block the emergence of a tumor, but not growth in culture. More recent studies, however, have uncovered other mechanisms unrelated to growth by which *tumor suppressor* genes act to inhibit cancer formation. In fact, it now seems that the inhibition of growth may not be the most important function of these genetic suppressors. Wild-type (or the normal) p53

is able to slow the proliferation of cancer cells in culture, and naturally occurring mutants of p53 lose this capability. However, many cell lines grow well with both normal p53 and rb genes, suggesting that they are not necessary for cellular proliferation (reviewed in [Chapter 1](#)). In the case of p53, one of its major roles is in DNA repair. As it appears, the regulation of growth is coupled with the regulation of DNA repair. When cells suffer DNA damage, cellular *hibernation* manifested by an arrest at the G<sub>1</sub> or G<sub>2</sub> checkpoints permits repair to take place and prevents the accumulation of mutant sequences.<sup>1</sup> Cells harboring mutant p53 genes lose the ability to arrest in G<sub>1</sub> after exposure to gamma irradiation or other genotoxins.<sup>2</sup> Mice with p53 gene disruptions are completely viable, but exhibit an enhanced rate of tumor formation, and the abrogation of the G<sub>1</sub> checkpoint after exposure to DNA-damaging agents.<sup>3,4</sup> In addition, p53 appeared to be involved in two other critical functions: genomic stability and apoptosis. Cells without a functional p53 show an increased ability to amplify their DNA. This measure of genetic plasticity is characteristic of cancer.<sup>5</sup> In addition, a mutant p53 renders cells less likely to undergo apoptosis after cellular stress including gamma irradiation and chemotherapeutic agents. Normal cells that experience a high level of DNA damage, overwhelming their repair capabilities, trigger cell death. This appears to be a mechanism to prevent the accumulation of cells harboring mutant genes. Taken together, these data suggested that the primary role of p53 is not to regulate growth, but to maintain the genetic integrity of a cell.

We know that other important tumor suppressors have similar policing functions. BRCA1 and BRCA2 are structurally unrelated genes with converging clinical effects: Disabling mutations in either gene render an individual more susceptible to breast and ovarian cancers. Although both genes carry the hallmarks of a tumor suppressor gene, their main function is not growth regulation. In gene transfection experiments, BRCA1 is able to inhibit cellular growth only under limited conditions, possibly in cells with an intact retinoblastoma gene product.<sup>6,7</sup> In other experiments, however, BRCA1 and BRCA2 paradoxically appear to be associated with signs of growth promotion. Both are increased at S phase, and mouse embryos that have either gene disrupted die *in utero* exhibiting an increase in the cell-cycle inhibitor p21, a decrease in cyclin E, and a reduction in proliferating cells.<sup>8</sup> These data suggest that BRCA1 and BRCA2 serve to support rather than to suppress proliferation. More important, however, is the finding that BRCA1 and BRCA2 are both associated with each other and with DNA repair proteins RAD51 and PCNA, especially after DNA damage.<sup>9</sup> The functional consequences of this association are exemplified by the experimental data. Cells from a BRCA1 null mouse are defective in transcription-coupled DNA repair.<sup>10</sup> BRCA2 null cells are exquisitely sensitive to gamma irradiation<sup>11</sup> and to chemotherapeutic agents.<sup>12</sup> It is remarkable that two structurally dissimilar proteins interact with the same biochemical entities and lead to similar disease phenotypes. Thus, the fundamental lesson learned from BRCA1 and BRCA2 is that the primary causes of breast cancer may be related to DNA damage and repair and not to excessive growth.

The primacy of repair over growth regulation is also seen in the MLH1 and MSH2 genes that are responsible for the syndrome of hereditary nonpolyposis colorectal cancer. The respective gene products are involved in the recognition and repair of mismatches between complementary DNA strands: When these mismatch repair (MMR) genes are mutated, the mechanism for the correction of nucleotide mismatches is defective. This defect leads to an increased risk of gastrointestinal (especially colorectal) and endometrial cancers.<sup>13</sup>

Oncoproteins such as p53 not only act to induce a cell-cycle arrest in order for DNA repair to complete, but also promotes apoptosis to eliminate damaged cells with a high cancer potential. Therefore, an attenuation of the apoptosis mechanism is therefore likely to support transformation. The cancer susceptibility gene, PTEN/MMAC, is an example of a genetic *guardian* whose primary function is to regulate cell death and survival. PTEN, localized to 10q23, was identified through position cloning as the gene responsible for Cowden's syndrome. Cowden's is a syndrome characterized by gastrointestinal hamartomas, cutaneous trichilemmomas, and increased rates of breast (25% to 50%) and thyroid cancers (3% to 10%), as well as uterine leiomyomas. Although germline PTEN mutations are distinctive for a relatively rare disorder, somatic mutations leading to the loss of PTEN function are detected in a large number of sporadic cancers including high-grade gliomas, thyroid cancers, and endometrial cancers.<sup>14</sup> Transfection of the wild-type PTEN cDNA inhibits growth in established cell lines, and mice with one disrupted PTEN allele exhibit high rates of tumor formation, especially lymphomas, teratocarcinomas, and liver and prostatic cancer.<sup>15</sup> Thus, PTEN fulfills the classic criteria of a tumor suppressor.

Functionally, PTEN is as a multifunctional phosphatase that removes phospho groups from tyrosine and serine residues as well as from phospholipids such as phosphatidylinositol second messengers. The most important biochemical consequence of PTEN is to disarm the PI3'-kinase/AKT pathway.<sup>16</sup> AKT is a pivotal member of a pathway that induces cell survival and motility and was originally found as a retroviral oncogene, v-akt, causing lymphomas in infected mice. More recently, the AKT protooncogene was also found to be amplified in human ovarian cancers. It is thought that AKT phosphorylates BCL2 proapoptotic homologue BAD, resulting in a block to apoptosis.<sup>17</sup> Mutations in PTEN result in an increase in AKT activity, rendering cells more resistant to cell death signals. This mode of cancer induction is similar to the antiapoptotic effects of the bcl2 oncogene. Augmented levels of bcl2 expression associated with the t(14;18) translocation render affected B cells less sensitive to apoptotic signals and more susceptible to be transformed. Thus, activation of the PI3'-kinase/AKT pathway, either through crippling the tumor suppressing phosphatase, PTEN, or augmenting the activity of the AKT kinase, can lead to cancer. This is but one example of the biochemical intersect between classic tumor suppressor and oncogenes that blur the taxonomic distinctions.

Our current state of knowledge of tumor suppressors shows a picture of complex interactions between multiple suppressor genes with oncogenes to generate the malignant state. A dramatic example of the convergence of oncogenic processes is seen in the analysis of the transforming growth factor- $\beta$  (TGF- $\beta$ ) pathway in gastrointestinal carcinogenesis. It has been long understood that the peptide factor TGF- $\beta$  can inhibit tumor formation, and that tumor progression is associated with loss of response to TGF- $\beta$ . This loss of response now appears to be due to the disruption of the type II TGF- $\beta$  receptor. TGF- $\beta$  functions by inducing heterodimers between the cognate type I and II receptors (TGF- $\beta$ R1 and TGF- $\beta$ R2), resulting in the phosphorylation of the type I receptor and activation of downstream pathways. Markowitz and colleagues found that many tumors, especially colorectal cancers, harbor frameshift mutations in a short polyadenine tract within the gene that generates a truncated TGF- $\beta$  protein bearing defective kinase activity.<sup>18</sup> Interestingly, this frameshift mutation occurs most commonly in cancers with concomitant aberrations in mismatch repair (MMR) as is seen in patients with hereditary nonpolyposis colorectal cancer. Moreover, this mutational *switch* occurs during the conversion from colonic adenoma to malignant carcinoma.<sup>19</sup> Further downstream, the TGF- $\beta$  signaling pathway requires engagement by the activated receptors and phosphorylation of cytoplasmic SMAD proteins. Activated SMADs form heterodimers between SMAD1 or SMAD2 with SMAD4 and are transported to the nucleus where they interact with DNA-binding proteins to induce transcription of TGF- $\beta$ -responsive genes.<sup>20</sup> The importance of this pathway is that SMAD4, which is an essential component in the TGF- $\beta$  signaling pathway, has been found to be disrupted in 50% of human pancreatic cancers and to a lesser extent in gastric, breast, ovarian, and prostatic cancers.<sup>21,22</sup> Thus, the TGF- $\beta$  pathway alone engages three functional nodes with significant roles in human cancers: mismatch repair, TGF- $\beta$ R2, and SMAD4. The complexity lies in the fact that these elements are connected not only by biochemistry, but genetics and peculiarities in DNA sequence. It is, therefore, with the use of many of the analytical tools described previously that these relationships can be uncovered.

## MOLECULAR PROFILING: PROGNOSIS AND TREATMENT TAILORED TO THE INDIVIDUAL PATIENT

The concept of employing tumor characteristics such as histologic features as a predictor of best treatments has long been part of the practice of oncology. For example, not only are the natural histories of the lymphomas different, but the requirements for optimal therapy are distinct: Burkitt's lymphomas require high-dose alkylator chemotherapy to achieve optimal cure rates, whereas doxorubicin-based therapies are optimal for large cell lymphomas.<sup>23</sup>

A significant refinement of this histology-based approach to selection of therapeutics has been the application of molecular markers and is best exemplified in the use of markers in the treatment of human leukemias. With the availability of effective chemotherapy, it was observed that cytogenetic profiles could discern those who are likely to respond. In acute myeloid leukemia (AML), patients with t(8;21), inv(16), and t(15;17) show the best overall survivals, whereas patients with del(5q)/5q-, del(7q)/7q-, and inv(3) show the lowest complete response rates. Patients with 11q23/+11 abnormalities exhibit average remission rates, but a high probability of relapse and low overall survival.<sup>24</sup>

Many of the genes involved in these leukemia translocations have now been cloned and biochemically characterized. The t(9;22), characterizing common chronic myelogenous leukemia, involves the translocation between bcr on chromosome 22 and the tyrosine kinase abl on chromosome 9. The chimeric bcr-abl oncoprotein activates the abl kinase and the ras pathway and blocks apoptotic processes in hematopoietic precursors.<sup>25</sup> In acute lymphoid leukemias, one of the major discerning factors also appears to be the presence of the bcr-abl rearrangement as exemplified by the t(9;22) translocation. The Philadelphia chromosome (Ph1) and the resultant bcr-abl fusion gene is the single most common abnormality in adult ALL, accounting for up to 50% of the B-lineage disease.<sup>26</sup> Although bcr-abl-positive ALL cases easily achieve complete remissions, relapse is uniform and the potential for cure using standard forms of chemotherapy is low. By contrast, bcr-abl translocations occur only in 5% of pediatric ALL cases, and the low frequency of this adverse prognostic marker may explain some of the differences in survival rates between pediatric and adult ALL.

In AML, the key gene involved in the t(8;21)(q22;q22) translocation found in AML-M2 through positional cloning is AML1, which is related to the *Drosophila* pair rule gene, *runt*. *Runt* is a transcription factor that regulates the expression of specific patterns of the homeobox genes.<sup>27</sup> The human homologues of these homeobox genes have been implicated in hematopoietic differentiation.<sup>28</sup> The normal AML1 binds to a protein partner called CBF $\beta$  to exert its physiologic function as a transcription factor. Coincidentally, translocations of CBF $\beta$  are also involved in leukemias harboring inv(16) that generates the fusion protein CBF $\beta$ -MYH11. This

biochemical interaction between the principal gene products of the t(8;21) and the inv(16) rearrangements is even more remarkable in that both translocations are associated with favorable clinical outcomes, although the exact mechanism explaining this association remains unclear. Rearrangements involving chromosome 11q23, however, are uniformly associated with poor outcome and with short durations of remission. Initially described in the uncommon translocation t(4q21;11q23) observed in both AML and ALL, this rearrangement creates a fusion oncogene mutating the ALL1/MLL gene (residing on 11q23). ALL1 is the human homologue of another *Drosophila* gene, *trithorax*, a transcription factor that maintains specific expression patterns of the homeobox genes. Once the exact genetic mutation for the chromosomal rearrangement was identified, other abnormalities at chromosome 11q such as trisomy 11 were found to contain perturbations in ALL1.<sup>29</sup> Moreover, the importance of 11q aberrations in leukemias was further raised when a syndrome characterized by 11q23 translocations in secondary leukemias resulting from etoposide treatment was recognized.<sup>30</sup> In every case, the clinical syndrome linked with 11q abnormalities and its associated ALL1 lesion is characterized by poor clinical outcome.

For solid tumors, the development of tumor markers for the prediction of therapeutic response has been much slower. One impressive positive example, however, has been the HER2/neu gene. HER2 gene encodes a 185-kD protein, which belongs to transmembrane type I tyrosine kinase receptor family including the EGF receptor, HER3, and HER4. Clear evidence from clinical studies demonstrates that HER2 amplification or overexpression is a marker for poor prognosis for node-positive patients. A major question, however, has been whether this poor prognosis is irrevocable or can be bypassed by some intervention. In 1994, the national cooperative group, Cancer and Leukemia Group B (CALGB) published a preliminary study on 442 patients suggesting that the poor clinical outcome of node-positive breast cancer patients with HER2 overexpression can be overcome by adequately dose-intensive regimens of cyclophosphamide, doxorubicin (Adriamycin), and 5-fluorouracil. The HER2-negative group, however, experienced no benefit from the cyclophosphamide, Adriamycin, and 5-fluorouracil dose escalation. Thus, the beneficial effect of dose intensification was present only for the HER2-positive cohort but absent for the HER2-negative patients. In a parallel study, in which node-positive patients were treated with cyclophosphamide, methotrexate, fluorouracil, vincristine, and prednisone (CMFVP) for four cycles, then randomized to completing CMFVP or to vinblastine (Velban), Adriamycin, thiotepa, and fluoxymesterone (Halotestin), patients treated only with CMFVP showed worse survival if their tumors overexpressed HER2. By contrast, patients given Velban, Adriamycin, thiotepa, and Halotestin showed no differential survival between the HER2-positive and -negative groups. These data raised the possibility that the adverse effects of HER2 overexpression can be specifically overcome by effective doses of Adriamycin.

The most definitive test of the HER2–doxorubicin interaction was seen in two studies: the reanalysis of the National Surgical Adjuvant Breast Project trial B-11, and the 10-year follow-up of the analysis of the complete cohort in CALGB 8541.<sup>31</sup> In B-11, node-positive breast cancer patients were randomized between L-PAM and fluorouracil versus L-PAM, Adriamycin, and fluorouracil so that the only treatment variable was doxorubicin. Of the 638 patient tumors, 37.5% were scored as positive for HER2 protein overexpression. After a mean time of study of 13.5 years, clinical benefit from the addition of doxorubicin to L-PAM and fluorouracil was apparent only for HER2-positive patients. The *completion* study of CALGB 8869/8541 conducted by the CALGB looked at over 900 cases from the original CALGB 8869/8541 study with a median follow-up of 9.5 years.<sup>32</sup> Important in the analysis was that the HER2 determination was rigorously validated by concurrent analysis by immunohistochemistry, differential PCR, and fluorescent *in situ* hybridization. Patients with HER2-positive tumors responded with improved overall survival when treated with dose-intensive cyclophosphamide, Adriamycin, and 5-fluorouracil chemotherapy, whereas HER2-negative patients showed no benefit with dose escalation. Although the mechanism of this interaction and putative resistance is unclear, there is evidence that inhibition of HER2 signaling is associated with a decreased ability of the cell to repair DNA damage such as is seen after chemotherapeutic exposure.<sup>33</sup>

Thus far, we have centered on examples of how the molecular profile of a cancer may give information pertinent to response to standard chemotherapeutic agents. In most cases, however, the mechanism for this oncogene-associated relative resistance or sensitivity is uncertain. However, many of the markers that define the profile may themselves be suitable targets for molecularly based therapeutics. Given the surface location of HER2 on cells, and the overexpression that occurs mainly in cancerous states, the HER2 oncoprotein represented one such attractive target for antibody-directed therapeutics. One such antibody, 4D5, suppressed cancer cell growth both in *in vitro* and *in vivo* animal studies.<sup>34</sup> When coupled with standard chemotherapeutic agents, 4D5 showed additive and potentially synergistic antiproliferative effects. The humanized form of the murine 4D5 antibody (Herceptin) was developed for clinical applications, and the initial phase II data showed promise: As a single agent in pretreated individuals, Herceptin showed a 16% response rate with 4% complete responders, and a median time to relapse of 9.1 months.<sup>35</sup> The subsequent phase III study was also significant. The study randomized individuals with metastatic breast cancer to chemotherapy alone or chemotherapy plus weekly Herceptin. The results showed that patients treated with chemotherapy alone had a response rate of 32%, a duration of response at 5.9 months, and time to disease progression of 4.6 months. Those treated with chemotherapy and Herceptin exhibited an improvement in all measures: response rate of 49% (vs. 32% with chemotherapy alone), median duration of response of 9.3 months (vs. 5.9 months with chemotherapy alone), and time to progression at 7.6 months (vs. 4.6 months with chemotherapy alone).<sup>36</sup> Thus, as predicted in the *in vitro* investigations, the combination of chemotherapy and Herceptin led to a more favorable outcome.

Since oncogenes are signaling molecules that rely on protein–protein interactions to conduct their signals, interruption of these interactions was predicted to disrupt critical pathways that maintain the cancerous state. Inhibition of the enzymatic activity of certain oncogenes, such as ras proteins and kinases, with small chemically derived molecules has been both an attractive and ultimately successful approach. Some of the most notable clinical successes have been in the treatment of leukemias. Acute promyelocytic leukemia is characterized by the uniform presence of a cytogenetic signature, the reciprocal translocation of chromosomes 15 and 17 [t(15;17)], which generates a fusion between the PML gene and the retinoic acid receptor- $\alpha$  gene (PML/RARA). The resultant fusion protein places the DNA-binding domain of a nuclear protein PML adjacent to a truncated RARA that retains its ligand-binding domain. This observation immediately suggested a molecular explanation for why acute promyelocytic leukemia occasionally responded to available retinoids.<sup>37</sup> This hypothesis was supported by dramatic reports showing clinical remissions to an isomer of retinoic acid, all-*trans*-retinoic acid. In patients with newly diagnosed or relapsing acute promyelocytic leukemia, a 90% complete response rate was seen with single-agent all-*trans*-retinoic acid.<sup>38,39</sup> This response is highly specific: all-*trans*-retinoic acid is ineffective in the absence of the PML-RARA fusion protein. Another significant development has been the Novartis compound, the 2-phenylaminopyrimidine derivative STI571. Derived to inhibit the activity of the activated BCR-ABL tyrosine kinase, STI571 was found to render remissions in the majority of patients with chronic myelogenous leukemia. In both leukemic conditions, other standard chemotherapeutic agents are equally effective. However, the specificity of the drugs significantly avoided the side effects of chemotherapy and underscored the potential of inhibiting a single molecular target to control extensive cancer conditions.

There is currently a rich developmental pipeline for these kinase inhibitors with many potential agents that will be ready for or have been in clinical testing. The targets include the ras proteins PDGF and EGF and the VEGF receptors. The number and diversity of targets, however, make molecular profiling a necessary adjunct to therapeutic decision making. Thus, a comprehensive approach for target detection will no longer remain solely of academic interest, but is predicted to become a clinical necessity.

## POSTGENOME CHALLENGE FOR MOLECULAR MEDICINE

Sequencing the human genome will provide new tools and insights that will enhance our understanding of the genetic mechanisms underlying cancer.<sup>40,41</sup> A major objective of the Human Genome Project is the identification of the complete set of human genes. A leading method for rapid gene discovery is single-pass partial sequencing of cDNA clones from one or both ends to generate expressed sequence tags. This strategy has been widely and successfully applied to humans and other species. Before 1991 and the development of the expressed sequence tag method, sequence data existed for fewer than 3000 human genes.<sup>40,41</sup> Now that the entire human genome sequence has been completed, the effect on science and society will be incalculable.<sup>42,43</sup> The combination of data on gene expression and putative gene functions inferred from sequence similarities and motif analysis will provide a powerful means of assessing the transcriptional activity of the genome in the cells and tissue before, during, and after disease. For the next generation of scientists and clinicians, identification of a new gene will be as rare as finding a new species of mammal.

Completion of the human genome sequence is just the beginning. The current challenge is to generate a comprehensive understanding of the *software and the hardware* of the cell and the organism.<sup>44</sup> Less than 2% of the noninfectious human disease burden is monogenic in nature. The rest (98%) is polygenic (caused by multiple genes at once) or is epigenetic (caused by nongenetic or postgenetic alterations in cellular molecules). Consequently, elucidating disease mechanisms and full penetration of the causal mechanisms driving carcinogenesis and cancer progression will require analysis tools ranging from direct DNA sequencing, mRNA expression monitoring, protein sequencing, protein localization studies, and finally to metabolic or physiologic profiling.

A further essential phase will be a description of the normal range of human polymorphisms (base variations in the genome), which may provide a starting point for correlating genetic variance with disease states. The final physiologic state is further complicated because biologic diversity causally associated with disease may be due to posttranslational processes regulated by the cellular environment. These changes cannot be inferred from known DNA variance. Thus, a complete understanding of the molecular basis of cancer depends on a multidisciplinary approach combining genetics, pathology, protein structure and function, cell biology, and clinical medicine.

Finding all the expressed human genes is a different task from sequencing the genome itself. This is because only a small proportion of the genome actually makes

up the actual expressed genes and their regulatory elements. The actual number of expressed human genes may be 100,000. However, at any point in time, for any individual cell in any given tissue, the amount of genes *in use* may be as few as 10,000. Of this 10,000, only a proportion may be susceptible to the influence of carcinogenic events. Thus, an important goal for molecular profiling of cancer is to identify a subset of expressed genes that is correlated with, or causally related to, the development and progression of cancer. Setting aside hereditary susceptibility, it is likely that the majority of cancers may originate in tissue that starts with a completely normal genome. Carcinogenic events produce heritable genetic alterations that expand in microscopic premalignant states such as hyperplasia and dysplasia, before frank malignant cancer ensues. Identification of the important genetic derangements and the causally important genes and proteins will depend on direct analysis of actual human cancer tissues, combined with insights gained using animal and cell culture methods. The massive profiling of genes associated with cancer progression is now possible using new technology for microdissection and array hybridization.

## cDNA MICROARRAYS ARE A NEW TOOL TO ANALYZE GENE EXPRESSION PATTERNS IN HUMAN CANCER

Every oncologist is daily faced with the biologic heterogeneity of cancer emergence, aggressiveness, and treatment response in individual patients. Every pathologist is daily faced with the enormous histologic diversity of human neoplasms. We assume that the morphologic microscopic appearance (e.g., staining pattern, nuclear shape and contour, cellular configuration and pleomorphism) of a particular neoplastic lesion that spells cancer is the outward manifestation of molecular changes that are occurring inside the interacting tissue cell populations. Scores of molecules and genes can be involved in the behavior of an individual patient's tumor. The clinical heterogeneity of cancer mirrors the underlying molecular heterogeneity of the cancer cell. This is evident in the variable presence of chromosomal translocations, deletions of suppressor genes, and numbers of chromosomes. Consequently, it is critical for molecular oncology of the future to adopt high-throughput technology to survey panels of genes, ranging from hundreds to even the whole human expressed gene set, and apply this technology to the classification of tumor pathologic entities in individual patients.

In response to this challenge, investigators in both the public and private sectors have been perfecting gene-chip arrays that can be used to survey great patterns of gene expression.<sup>45,46,47,48,49</sup> and 50 The change in the pattern can then be correlated with histomorphology, clinical behavior, or response to treatment. Typically, the analysis takes the form of rows and rows of oligonucleotide strands lined up in dots on a miniature silicon chip or glass slide or sheet of nitrocellulose. The microarrays work as follows. First, the RNA is extracted from the tumor tissue, amplified, and labeled with a fluorescent or radioactive probe. This of course assumes that the highly labile RNA is preserved when the tissue is extracted. The labeled total RNA, containing the mRNA of the expressed genes, is applied to the surface of the chip or sheet. After appropriate hybridization, the relative intensity of the signal for each spot on the chip corresponds to the abundance of its matching mRNA species and hence reflects the expression level for its gene. With appropriate pattern recognition software it is then possible to assemble a global score for the gene study set represented on the substratum.

Tremendous progress has been made in the use of DNA arrays to analyze gene expression patterns in human cancer cell lines and human cancer tissue. Perou et al. used cDNA microarrays to study 60 cancer cell lines used by the National Cancer Institute to screen anticancer drugs.<sup>48</sup> When they classified the cell lines based on the gene expression subclasses, they obtained a correspondence to the ostensible cell type origin of the cancer cell line (i.e., epithelial or fibroblast or hematopoietic). Specific features of the cell line expression pattern appeared to correlate with the growth rate in culture or drug metabolism. These investigators then went on to use the cultured cell gene expression pattern as a template for comparison with RNA extracted from actual pieces of cancer tissue. They found that the gene pattern of the cancer tissue varied greatly from one cancer type to the next. Moreover, the pattern of a carcinoma gene expression appeared to correspond with the cell lines that had an epithelial origin. This study provided direct evidence that tissue pathology was heterogeneous at the level of gene expression patterns and offered hope that this information could potentially be applied to predict patient outcome.

The first major clinical correlation of gene expression patterns with disease outcome was provided by Alizadeh et al.<sup>45</sup> Diffuse large B-cell lymphoma, the most common subtype of non-Hodgkin's lymphoma, is clinically heterogeneous. Sixty percent of the patients succumb to the disease, whereas the remainder respond well to the current therapy and have prolonged survival. This variability in natural history correlated with a distinct pattern of gene expression revealed by DNA arrays. The group identified two molecularly distinct forms of diffuse large B-cell lymphoma (Fig. 2-2): One had a gene expression pattern indicative of a B-cell differentiation pattern. The second type expressed genes induced during *in vitro* activation of peripheral B cells. Patients with the germinal B-like diffuse large B-cell lymphoma had a significantly better overall survival (see Fig. 2-2). This provides evidence that the molecular classification of tumors into general categories of gene expression can potentially identify previously undetected and clinically significant subtypes of cancer.

**FIGURE 2-2.** Diffuse large B-cell lymphoma (DLBCL) clinical subtypes elucidated by DNA chip profiling. Hierarchical clustering of data from the chip profiling of thousands of lymphocyte-relevant genes reveals gene patterns associated with lymph node germinal center B cells (GC B) and activated B cells. The patients with activated B-like profiles underwent a much poorer overall survival. CLL, chronic lymphocytic leukemia; FL, follicular lymphoma.

## TECHNOLOGY FOR TISSUE MICRODISSECTION BRINGS MOLECULAR ANALYSIS TO THE TISSUE CELL LEVEL

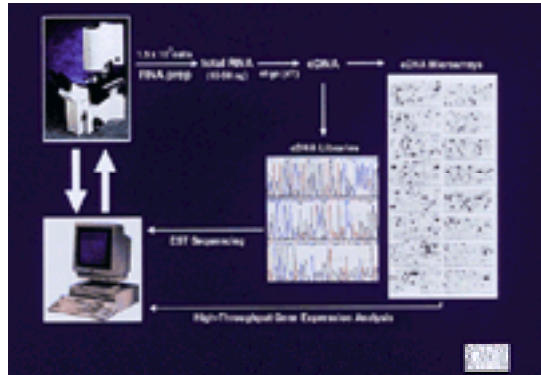

Molecular analysis of pure cell populations in their native tissue environment will be an important component of the next generation of medical genetics. Accomplishing this goal is much more difficult than just grinding up a piece of tissue and applying the extracted molecules to a panel of assays. This is because tissues are complicated three-dimensional structures composed of large numbers of different types of interacting cell populations. The cell subpopulation of interest may constitute a tiny fraction of the total tissue volume. For example, a biopsy of breast tissue harboring a malignant tumor usually contains the following types of cell populations: (1) fat cells in the abundant adipose tissue surrounding the ducts, (2) normal epithelium and myoepithelium in the branching ducts, (3) fibroblasts and endothelial cells in the stroma and blood vessels, (4) premalignant carcinoma cells in the *in situ* lesions, and (5) clusters of invasive carcinoma. If the goal is to analyze the genetic changes in the premalignant cells or the malignant cells, these subpopulations are frequently located in microscopic regions occupying less than 5% of the tissue volume. Following the computer adage *garbage in, garbage out*, if the extract of a complex tissue is analyzed using a sophisticated technology, the output will be severely compromised if the input material is contaminated by the wrong cells. Culturing cell populations from fresh tissue is one approach to reduce contamination. However, cultured cells may not accurately represent the molecular events taking place in the actual tissue they were derived from. Assuming methods are successful to isolate and grow the tissue cells of interest, the gene expression pattern of the cultured cells are influenced by the culture environment and can be quite different from the genes expressed in the native tissue state. This is because the cultured cells are separated from the tissue elements that regulate gene expression, such as soluble factors, extracellular matrix molecules, and cell-cell communication. Thus, the problem of cellular heterogeneity has been a significant barrier to the molecular analysis of normal and diseased tissue. This problem can now be overcome by new developments in the field of tissue microdissection.

Laser capture microdissection (LCM) has been developed to provide scientists with a fast and dependable method of capturing and preserving specific cells from tissue, under direct microscopic visualization<sup>50</sup> (Fig. 2-3). With the ease of procuring a homogeneous population of cells from a complex tissue using the LCM, the approaches to molecular analysis of pathologic processes are significantly enhanced. The mRNA from microdissected cancer lesions has been used as the starting material to produce cDNA libraries, microchip microarrays, differential display, and other techniques to find new genes or mutations (Fig. 2-4).

**FIGURE 2-3.** Laser capture microdissection. This new technology enables the investigator or clinician to directly procure pure tissue cell subpopulations under microscopic visualization. A transparent polymer film is placed in contact with the surface of the tissue section. A laser beam activates the film over the selected cells to actively capture the cells of interest and leave all the unwanted cells behind.

**FIGURE 2-4.** RNA isolated from tissue is reverse transcribed to cDNA. The sample cDNA is used to prepare cDNA libraries of the expressed genes *in use* by the tissue cells or to probe cDNA arrays of known pathways. EST, expressed sequence tags.

Sgroi et al.<sup>51</sup> have combined LCM of breast cancer tissue with cDNA arrays, as an approach to the identification of genes that change their expression during the progression of breast cancer. The group monitored gene expression in LCM-procured pure normal epithelium, invasive cancer, and metastatic tissue cell populations. Differences in the *in vivo* gene expression profile were verified and validated by real-time quantitative PCR and immunohistochemistry. The combined use of LCM and cDNA microarray analysis revealed genes specifically associated with the progression from normal to metastatic breast cancer cells ( Fig. 2-5). Since normal breast epithelium is a minor component of breast tissue, this analysis could not be done with simple ground-up whole breast tissue samples. This study demonstrated that *in vivo* gene expression profiling can be done on specific tissue cell populations, and that the results of the cDNA arrays correlated well with the real-time quantitative PCR analysis and immunohistochemistry. Consequently, cDNA arrays can be used to uncover patterns that correlate with the biology and find lead candidate genes that may serve as future markers or drug targets.

**FIGURE 2-5.** Molecular profiling of cancer premalignant progression. Invasive metastatic cancer emerges after a long premalignant phase that occurs in microscopic regions of the tissue epithelium. Microdissection makes it possible to profile the molecular patterns that track all the way through from normal epithelium to metastatic cancer in the same patient.

The development of the LCM allows investigators to determine specific gene expression patterns from tissues of individual patients. Pure populations of cells can be obtained, RNA extracted, copied to cDNA, and hybridized to thousands of genes on a cDNA microchip microarray. In this manner, an individualized molecular profile can be obtained for each histologically identified pathology. Using such multiplex analysis, investigators will be able to correlate the pattern of expressed genes with the etiology, premalignant progression (see Fig. 2-5), and response to treatment. A patient's risk for disease and appropriate choice of treatment could, in the future, be personalized based on the profile. A growing clinical database of such results could be used to develop a minimal subset of key markers that will lead to a revolutionary approach for early detection and accurate diagnosis of disease.

Efficient coupling of LCM of serial tissue sections with multiplex molecular analysis techniques <sup>52,53,54,55,56 and 57</sup> should lead to sensitive and quantitative methods to visualize three-dimensional interactions between morphologic elements of the tissue. For example, it will be possible to trace the gene expression pattern along the length of a prostate gland or breast duct in order to examine the progression of neoplastic development. The end result will be a new era in the integration of molecular biology with tissue morphogenesis and pathology.

## TUMOR TISSUE ARRAYS

Once a putative marker (or set of markers) is identified by cDNA array analysis of cancer tissue samples, the next step is to validate these markers in a large population of human tumors. In the past, immunohistochemistry or *in situ* hybridization has been the method of choice to evaluate an individual patient's tissue sections *one slide at a time*. Consequently, in order to screen hundreds of patient specimens, it was necessary to laboriously stain hundreds of microscopic glass slides. This exhaustive process has now been telescoped into a high-throughput miniaturized tissue array.<sup>52</sup> The array consists of 1000 cylindrical tissue biopsies, each from a different patient, all distributed on a single glass slide. Thus, each tumor is represented by a minute disk-shaped tissue section 0.6 mm in diameter and 4 to 8  $\mu$ m in thickness (Fig. 2-6). Tumor arrays are ideal for comparing large numbers of solid tumor samples. Full automation of tumor array creation and screening is envisioned as a means to expeditiously correlate marker levels over large study sets of tumors.

**FIGURE 2-6.** Tumor tissue arrays. Paraffin-embedded fixed tumor tissue in blocks is sampled with a punch to generate cylindrical cores. The cores are packed together into a new block that contains a core from one of hundreds of different patients. The composite array block is sliced into sections that are placed on a glass slide. The slide now contains hundreds of different tumor samples.

## BEYOND FUNCTIONAL GENOMICS TO CANCER PROTEOMICS

While DNA is an information archive, proteins do all the work of the cell. The existence of a given DNA sequence does not guarantee the synthesis of a corresponding protein. The DNA sequence is also not sufficient to describe protein structure, function, and cellular location.<sup>53</sup> This is because protein complexity and versatility stems from context-dependent posttranslational processes such as phosphorylation, sulfation, or glycosylation. Moreover, the DNA code does not provide information about how proteins link together into networks and functional machines in the cell. In fact, the activation of a protein signal pathway causing a cell to migrate, die, or initiate division can immediately take place before any changes occur in DNA/RNA gene expression. Consequently, the technology to drive the molecular medicine revolution into the third phase is emerging from protein analytical methods. An important goal will be to apply this knowledge at the level of human tissue itself ( [Fig. 2-7](#)).

**FIGURE 2-7.** Tissue proteomics. Proteins extracted from microdissected tissue subpopulations can be applied to quantify known proteins, to discover new proteins, and ultimately to reconstruct signal pathways. PSA, prostate-specific antigen; SELDI, surface-enhanced laser desorption and ionization.

The term *proteome*, which denotes all the proteins expressed by a genome, was first coined in late 1994 at the Siena two-dimensional gel electrophoresis meeting. *Proteomics* is proclaimed as the next step after genomics. A goal of investigators in this exciting field is to assemble a complete library of all the proteins. Only a small percentage of the proteome has been cataloged in 2000. Since PCR for proteins does not exist, sequencing the order of 20 possible amino acids in a given protein remains relatively slow and labor intensive, compared with nucleotide sequencing. Although a number of new technologies are being introduced for high-throughput protein characterization and discovery,<sup>54</sup> the mainstay of protein identification continues to be two-dimensional gel electrophoresis.<sup>53,54,55</sup> and<sup>56</sup> Two-dimensional electrophoresis can separate proteins by molecular weight in one dimension and charge in second dimension. When a mixture of proteins is applied to the two-dimensional gel, individual proteins in the mixture are separated out into signature locations on the display, depending on their individual size and charge. Each signature is a *spot* on the gel that can constitute a unique single protein species. The protein spot can be procured from the gel and a partial amino acid sequence can be read. In this manner, known proteins can be monitored for changes in abundance under treatment or new proteins can be identified. An experimental two-dimensional gel image can be captured and overlaid digitally with known archived two-dimensional gels. In this way it is possible to immediately highlight proteins that are differentially abundant in one state versus another (e.g., tumor vs. normal or before and after hormone treatment).

Two-dimensional gels have traditionally required large amounts of protein starting material equivalent to millions of cells. Thus, their application has been limited to cultured cells or ground-up heterogeneous tissue. Not unexpectedly, this approach does not provide an accurate picture of the proteins that are in use by cells in real tissue. Tissues are complicated structures composed of hundreds of interacting cell populations in specialized spatial configurations. The fluctuating proteins expressed by cells in tissues may bear little resemblance to the proteins made by cultured cells, which are torn from their tissue context and are reacting to a new culture environment. Proteins extracted from ground-up tissue represent an averaging of proteins from all the heterogeneous tissue subpopulations. For example, in the case of breast tissue, the glandular epithelium constitutes a small proportion of the tissue: The vast majority is stroma and adipose. Thus, it has previously been impossible to obtain a clear snapshot of gene or protein expression within normal or diseased tissue cell subpopulations.

To address the tissue-context problem, new technology is again coming to the rescue; *tissue proteomics* is an exciting expanding discipline (see [Fig. 2-7](#)). Two major technologic approaches have been successfully used to sample macromolecules directly from subpopulations of human tissue cells. The first technology is LCM, a technology for procuring specific tissue cell subpopulations under direct microscopic visualization of a standard stained frozen or fixed tissue section on a glass microscope slide. Tissue cells procured by LCM have been used for highly sensitive and reproducible proteomic analysis using two-dimensional gels and other analytical methods.

A second major approach to isolate tissue cell subpopulations is affinity cell sorting of disaggregated cells from pieces of fresh tissue. A highly notable application of this technology in the field of breast physiology is the result of a collaboration between Oxford Glycosciences and the Ludwig Institute. In this study the investigators separated and purified normal human breast luminal and myoepithelial from reduction mammoplasty specimens using double-antibody magnetic affinity cell sorting and magnetic bead sedimentation.<sup>55</sup> After using enzymatic treatments and various incubation, separation, and washing steps, the investigators obtained purified luminal and myoepithelial cells in yields of  $5 \times 10^6$  to  $2 \times 10^7$ . Proteins from these cell populations were then analyzed by two-dimensional gels. A master image for each cell type comprising a total of 1738 distinct proteins was derived. The investigators found 170 protein spots that were elevated twofold or more between the two populations. Fifty-one of these were further characterized by tandem mass spectroscopy. The proteins preferential to the myoepithelial cells contained muscle-specific enzymes and structural proteins consistent with the contractile muscle-related derivation of these cell types.

A pathologic hallmark of early cancer progression from carcinoma *in situ* to invasive cancer is the loss or redistribution of myoepithelial cells. The conspicuous absence of myoepithelial cells in breast cancer progression could mean that these cells produce suppressor proteins that normally keep the malignant cells in check. Thus, one or more of the proteins identified in tissue myoepithelial cells could be candidate cancer prevention molecules.

The complicated changing pattern of protein expression should contain important information about the pathologic process taking place in the cells of the actual tissue. This pattern of protein information could provide correlates with pathologic state or response to therapy. Using a protein biochip which classified protein populations into molecular weight classes, Paweletz et al.<sup>58</sup> showed distinct protein patterns of normal, premalignant, and malignant cancer cells microdissected from human tissue.

Furthermore, they reported that different histologic types of cancer and tissue (ovarian, esophageal, prostate, breast, and hepatic) exhibited distinct protein profiles.

Such a means to rapidly display a pattern of expressed proteins from microscopic tissue cellular populations ( Fig. 2-8) will potentially be an important enabling technology for pharmacoproteomics, molecular pathology, and drug intervention. Proteomic array technologies of the future will be used to rapidly generate displays of signal pathway profiles (see Fig. 2-7). Investigators will be able to assess the status of defined pathways that control mitogenesis, apoptosis, survival, and a host of other physiologic states. The information flow through these circuits, separately or through cross-talk, may dictate clinical behavior and susceptibility to therapy.

**FIGURE 2-8.** Surface-enhanced laser desorption and ionization (SELDI) analysis of laser capture microdissection microdissected microscopic stages of human prostate cancer. This technology generates a protein fingerprint consisting of the distribution of molecular weights. In the example study set, the ratios of specific protein peaks change specifically in the invasive carcinoma compared with the normal epithelium.

### INTRODUCTION

Signal transduction is the chemistry that allows communication at the cellular level. Cells sense signals from both the outside environment and other cells and, in response, they regulate protein expression and function. Protein expression is controlled by rates of transcription, translation, and proteolysis, whereas protein activities are affected by location, covalent modifications, and noncovalent interactions. Signal transduction pathways regulate all aspects of cell function, but most pathways target five primary processes: metabolism, cell division, death, differentiation, and movement.

In single-celled organisms, signal transduction pathways determine chemotaxis, mating, and adaptation to varying food sources. In multicellular organisms, signal transduction pathways are necessary for embryonic development, and they regulate differentiation, division, and death in both the mature and developing organism. Signal transduction pathways also control the particular functions of specialized cells (e.g., synthesis and secretion of insulin by the pancreas, migration and phagocytosis by neutrophils) and the abnormal behavior of diseased cells (e.g., invasion and growth of cancer cells).

To emphasize the essentials of signal transduction, we have focused on the variety of solutions to the two common problems faced by cells and organisms in signal transduction: (1) How is a signal sensed and (2) how are the levels and activities of proteins modified in response to the signal? Most signals are transmitted by ligands and are sensed by the receptors to which they bind. Binding of a ligand to a receptor stimulates the activities of proteins necessary to continue the transmission of the signal. Often, this involves the formation of multiprotein complexes and the generation of small-molecule second messengers. Integration of signals from multiple pathways determines the cell's responses to competing and complementary signals.

### THE SENSORY MACHINERY: LIGANDS AND RECEPTORS

#### SIGNALS

Signal transduction pathways have evolved to respond to an enormous variety of stimuli and to generate an equally extensive number of signals. Molecules that initiate signaling cascades include proteins, peptides, amino acids, lipids, nucleotides, gases, and light ( [Table 3-1](#)). Most extracellular signals, such as growth factors, bind to receptors on the plasma membrane, but others, such as cortisol, diffuse into the cell and bind to receptors in the cytoplasm and nucleus. Single-celled organisms respond primarily to signals that arise from the environment rather than the organism, but they are capable of generating signals, as illustrated by the mating pathway in yeast.<sup>1</sup> Multicellular organisms respond to diverse signals produced from within. Signals can be a direct reaction to a stimulus, such as the secretion of insulin by pancreatic  $\beta$  cells in response to increases in blood glucose. Signal release can be triggered by the nervous system in response to either external or internal cues, as in the release of epinephrine by the adrenal glands in response to stress. Signals also can be continuous, such as those sent by the extracellular matrix. Usually, signaling molecules are stored in the cell and are released to provide communication with other cells under specific conditions. Some ligands are stored outside the cell (e.g., in the extracellular matrix) and become accessible in response to tissue damage or remodeling. Cells also respond to signals that arise from within. Important examples include the checkpoint pathways that ensure the orderly progression of the cell cycle and the pathways that sense and repair damaged DNA.<sup>2,3</sup> When activated, these pathways lead either to cell-cycle arrest, so the damage can be repaired, or to cell death. Exactly how DNA damage and cell-cycle abnormalities are sensed is not yet known, but many components of the pathways that transmit the signals are understood.

Types of Ligands	Examples
<b>PROTEINS</b>	
Soluble	Insulin
Matrix	Fibronectin
Bound to other cells	Ephrins
<b>AMINO ACIDS</b>	Glutamate
<b>NUCLEOTIDES</b>	
Soluble	Adenosine triphosphate
DNA	Double-strand breaks
<b>LIPIDS</b>	Prostaglandins
<b>GASES</b>	Nitric oxide
<b>LIGHT</b>	Rhodopsin, visual system

TABLE 3-1. Ligands That Stimulate Signal Transduction Pathways

#### RECEPTORS

Usually, signaling pathways begin with binding of a ligand to a receptor ( [Table 3-2](#)). Receptors can be located either on the cell surface or intracellularly. Ligands that are on the cell surface or cannot transverse the membrane bind to receptors on the plasma membrane, whereas some ligands (e.g., retinoids or nitric oxide) that are membrane-permeable bind to receptors inside the cell. Usually, cells are exquisitely sensitive to ligand-receptor binding. The affinity of receptors for ligands generally is found to be in the pM to nM range, and very few receptors have to be occupied to transmit a signal. Many cytokine-responsive cells express only a few hundred receptors on the cell surface. (Signal amplification, which allows signals to propagate to the entire cell, is discussed later in [Efficiency and Specificity: Formation of Multiprotein Signaling Complexes](#).)

Type of Receptor	Example	Type of Ligand
Tyrosine kinase	PDGF, EGF, FGF, insulin	Peptide growth factors
Serine kinase	TGF- $\beta$	Activin
Microsomal G protein-coupled	Thrombin, smell receptors	Thrombin
Receptors bound to tyrosine kinases	IL-2, interferon	IL-2
TNF family	Fas receptor	Fas
Notch	Notch	Delta, Serrate, LAG-2
Guanine cyclase		Activin, serotonin, factor, NO
Tyrosine phosphatase	CD45, LAR	Connectin
Nuclear receptors	Retinoids, progesterone	Estrogen
Adhesion receptors	Integrins, CD41	Fibrinogen, hyaluronic acid

EGF, epidermal growth factor; FGF, fibroblast growth factor; IL-2, interleukin-2; PDGF, platelet-derived growth factor; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF, tumor necrosis factor.

**TABLE 3-2.** Receptors in Signal Transduction

Both receptors and ligands are multifunctional. Often, ligands can activate more than one receptor, and receptors can bind more than one ligand. The stimulation of most receptors leads to the activation of several downstream pathways that either function cooperatively to activate a common target or stimulate distinct targets. Generally, some of the pathways activated are counter-regulatory and serve to attenuate the signal.

Binding of ligands to receptors leads to a conformational change in the receptor that initiates signaling or oligomerization (or both). As a result of ligand binding, the intrinsic activity of the receptor or of associated proteins is stimulated. Receptors can have intrinsic enzymatic activity or can associate with protein kinases, guanine nucleotide exchange factors, and transcription factors. The receptor families used by eukaryotic cells in signal transduction illustrate both the diversity of receptor type and how signaling is initiated.

### Receptor Tyrosine Kinases

Receptor tyrosine kinases are transmembrane proteins that have an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic tyrosine kinase domain.<sup>4</sup> The ligands for these receptors are proteins or peptides. Most receptor tyrosine kinases are monomeric, but the insulin receptor family are heterotetramers in which the subunits are linked by disulfide bonds. Receptor tyrosine kinases have been divided into six classes, primarily on the basis of the sequence of extracytoplasmic domain. Examples of tyrosine kinase receptors include the insulin receptor, platelet-derived growth factor receptor, the epidermal growth factor receptor family, and the fibroblast growth factor receptor family.

Activation of receptor tyrosine kinases requires tyrosine phosphorylation of the receptor. Receptor tyrosine kinases transmit signals both by autophosphorylation of the receptor and by phosphorylation of other substrates. Receptor phosphorylation occurs on multiple sites, some of which stimulate the kinase activity of the receptor and others of which allow binding of downstream-signaling molecules. Ligand-dependent oligomerization of receptors brings the kinase domains into close proximity so that they cross-phosphorylate. Often, this transphosphorylation locks the kinase into a high-activity conformation.

Ligands stimulate receptor oligomerization in a variety of ways (Fig. 3-1). Some ligands, such as platelet-derived growth factor, are dimeric, so that the ligand is able to bind two receptors simultaneously.<sup>5</sup> Other ligands, such as growth hormone, are monomeric but have two receptor-binding sites that allow them to induce receptor dimerization.<sup>6</sup> Fibroblast growth factors (FGF) also are monomeric but have only a single receptor-binding site. FGF molecules bind to heparin sulfate proteoglycans, which promotes dimerization of FGF and the FGF receptor.<sup>7</sup> Epidermal growth factor (EGF) also is monomeric, but it may have a second low-affinity receptor-binding site, or receptor-ligand dimers may bind to a second receptor to allow receptor-receptor interaction and transphosphorylation.<sup>8,9</sup> Ligands not only stimulate receptor-dependent signaling; some ligand-receptor interactions result in signaling by the ligand. Ephrins are ligands for the protein tyrosine kinase EPH receptors. Ephrins are expressed on the surface of adjacent cells, and interaction of EPH receptors and ephrins both activates the tyrosine kinase activity of the receptor and leads to stimulation of signaling by the ligand in the adjacent cell.<sup>10,11</sup> The insulin receptor is an exception to the idea of dimerization leading to activation. The insulin receptor is a heterotetramer before ligand binding, and likely a conformational change brings the cytoplasmic tails in proximity or stimulates kinase activity (or does both).

**FIGURE 3-1.** Dimerization of tyrosine kinase receptors. Most tyrosine kinase receptors are activated by ligand-induced dimerization. Some ligands, such as platelet-derived growth factor (PDGF), are dimeric and induce dimerization using the two receptor-binding domains. Other ligands, such as growth hormone, contain two receptor-binding domains in the same molecule. The fibroblast growth factors (FGF) rely on proteoglycans to aid the formation of ligand dimers. Some ligands, such as the ephrins (EPH), are present on nearby cells and, when the cells come into contact, bind to the receptors and promote clustering.

Studies of the EGF receptor family illustrate some important concepts in signal transduction. The EGF-signaling pathways involve four known receptors (EGF receptor, erbB2, erbB3, and erbB4) and many ligands.<sup>12</sup> EGF can stimulate homodimerization of the EGF receptor but, under certain conditions, heterodimerization with other family members also occurs. The same ligand can activate different signaling pathways, depending on the subgroups of EGF receptor family members expressed in a cell. For example, heparin-binding EGF-like growth factor stimulates mitogenesis but not chemotaxis when it activates the EGF receptor but is both a mitogen and chemotactic factor when it activates Erb4.<sup>13</sup> Recent work also suggests that different ligands binding to the same receptors can activate distinct downstream-signaling pathways.<sup>14</sup> These findings suggest that different ligands may cause distinct conformational changes that lead to the phosphorylation of different sets of tyrosine residues on the receptor and could lead also to phosphorylation of distinct sets of substrates.

**RECEPTORS THAT ACTIVATE TYROSINE KINASES.** A number of receptors do not have intrinsic enzymatic activity but stimulate associated tyrosine kinases. The cytokine and interferon receptors associate constitutively with members of the Jak family of tyrosine kinases.<sup>15</sup> The kinases appear to be inactive in the absence of ligand but, as happens in receptors with intrinsic tyrosine kinase activity, signaling is initiated by ligand-stimulated heterodimerization of the receptors.<sup>16</sup> Dimerization of the receptors brings the Jak kinases in proximity to each other or to other tyrosine kinases, and transphosphorylation leads to their activation. Downstream signaling is dependent on the active Jak kinases phosphorylating the receptors and other substrates.

**SERINE-THREONINE KINASE RECEPTORS.** The transforming growth factor- $\beta$  (TGF- $\beta$ ) family of receptors are serine-threonine kinases.<sup>17</sup> These receptors are transmembrane proteins that have an extracellular ligand-binding domain, a transmembrane domain, and an intracellular serine kinase domain. TGF- $\beta$  ligands are dimers that lead to oligomerization of type I and type II receptors. The type I and type II receptors are homologous but distinctly regulated. The type II receptors seem to be constitutively active but do not normally phosphorylate substrates, whereas the type I receptors are normally inactive. On ligand-mediated dimerization of the type I and type II receptors, the active type II receptor phosphorylates the type I receptor and converts it to an active kinase. Subsequent signal propagation is dependent on the kinase activity of the type I receptor and the phosphorylation of downstream substrates.

## Receptor Phosphotyrosine Phosphatases

Like kinases, receptor protein tyrosine phosphatases (RPTPs) have an extracellular domain, a single transmembrane-spanning domain, and cytoplasmic catalytic domains.<sup>18</sup> The extracellular domains of many receptor tyrosine phosphatases contain fibronectin and immunoglobulin repeats, suggesting that some of these receptors may recognize adhesion molecules as ligands. Several RPTPs are capable of homotypic interaction, but no true ligands are yet known for RPTPs. Most receptor tyrosine phosphatases have two catalytic domains, and both are active in at least some receptors. Both functional and structural evidence suggests that the phosphatase activity of some of these receptors is inhibited by dimerization. Normally, these receptors might be active as tyrosine phosphatases but lose that activity after ligand binding. In this way, constitutive or stimulated tyrosine kinase activity becomes enhanced. Signaling by RPTPs is complicated because they do not always function in opposition to tyrosine kinases. For example, CD45 is necessary for signaling by the B-cell receptor, which also requires tyrosine kinase activity.<sup>19</sup>

**G PROTEIN-COUPLED RECEPTORS.** G protein-coupled receptors (GPCRs) are by far the most numerous receptors. Of the 19,000 genes in *Caenorhabditis elegans*, approximately 800 (or nearly 5% of the genome) are GPCRs, and nearly 2000 mammalian GPCRs are known.<sup>20,21</sup> The number of GPCRs is so high because they encode the light, smell, and taste receptors, all of which require great diversity. These receptors have seven membrane-spanning domains: The N-terminus, and three of the loops are extracellular, whereas the other three loops and the C-terminus are cytoplasmic. A wide variety of ligands bind GPCRs, including proteins and peptides, lipids, amino acids, and nucleotides. No common binding domain exists for all ligands, and interactions of ligands with GPCRs are fairly distinct.<sup>22</sup> In the case of the thrombin receptor, thrombin cleaves the N-terminus of the receptor, freeing a new N-terminus that self-associates with the ligand pocket, leading to activation. Amines and eicosanoids bind to the transmembrane domains of their GPCRs, whereas peptide ligands bind to both the transmembrane domains and the extracellular loops of their GPCRs. Neurotransmitters and some peptide hormones require the N-terminus for binding and activation.

The receptor appears to be kept in an inactive conformation by intramolecular bonds involving residues in the transmembrane or juxtamembrane regions.<sup>23</sup> In the inactive state, the receptor is bound to a heterotrimeric G protein, which also is inactive. Agonist binding results in a conformational change that activates the guanine nucleotide exchange activity of the receptor. Exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the a subunit of heterotrimeric G proteins initiates signaling. Though GPCRs all activate heterotrimeric G proteins, this action ultimately results in the stimulation of other signaling pathways, including protein tyrosine and serine kinases, phospholipases (PLCs A, C, and D) and ion channels.<sup>24</sup> Important recent work has shown that certain GPCRs activate receptor tyrosine kinases. Often, stimulation of GPCRs leads to activation of the EGF receptor, which is necessary for the GPCR to activate the mitogen-activated kinase (MAP kinase) pathway.

**NOTCH FAMILY OF RECEPTORS.** The Notch receptor has a large extracellular domain, a single transmembrane domain, and a cytoplasmic domain. Ligands for the Notch receptor are proteins expressed on the surface of adjacent cells, and the primary target of notch signaling is activation of the transcription factor SuH in *Drosophila* species or CBF-1 in mammals. Though the mechanisms by which Notch transmits signals have not been worked out definitively, it appears to be fairly different from other receptors.<sup>25</sup> Current evidence suggests that the cytoplasmic domain of the Notch is proteolytically cleaved and translocated to the nucleus, where it interacts directly with transcription factors.

**GUANYLATE CYCLASES.** Cyclic nucleotides are important second messengers and allosteric regulators of enzyme activities. The synthesis of cAMP by adenylate cyclase is regulated principally by heterotrimeric G proteins, but the synthesis of cGMP is regulated directly by ligands. Plasma membrane guanylate cyclases are receptors for atrial natriuretic hormone, and nitrous oxide binds to soluble guanylate cyclases in the cytoplasm.<sup>26</sup> Both stimuli increase cGMP levels.

**TUMOR NECROSIS FACTOR RECEPTOR FAMILY.** The tumor necrosis factor family of receptors has a conserved cysteine-rich region in the extracellular domain, a transmembrane domain, and a domain called the *death domain* in the cytoplasmic tail.<sup>27</sup> The receptors undergo oligomerization after ligand binding, which is necessary for signaling. These receptors are distinct in several respects. Stimulation of the receptor leads to recruitment of cytoplasmic proteins that bind to each other and the receptor through death domains.<sup>28</sup> They activate a protease, caspase 8, that initiates apoptosis, although they also can stimulate antiapoptotic signals. This family of receptors also includes “decoys” or receptors that are missing all or part of the cytoplasmic tail and thus cannot transmit a signal.<sup>29</sup> This feature provides a unique mechanism for inhibiting and further regulating signaling.

**NUCLEAR RECEPTORS.** Some ligands diffuse into the cell and bind to receptors either in the cytoplasm or the nucleus. These ligands include steroids, eicosanoids, retinoids, and thyroid hormone.<sup>30</sup> The receptors for these ligands are transcription factors that have both DNA and ligand-binding domains. The unliganded receptor is bound to heat-shock proteins, from which they release after ligand binding. Release from the chaperone complex and ligand binding allow the DNA-binding domain to contact DNA and the receptors to regulate transcription directly.

**ADHESION RECEPTORS.** Cell adherence via integrins either to the extracellular matrix or to other cells is mediated by receptors that function mechanically and stimulate intracellular signaling pathways, primarily through tyrosine kinases.<sup>31</sup> Integrins are composed of heterodimers of a and b subunits and bind to an arginine, glycine, aspartate (RGD) motif found in matrix molecules. Activation of integrin signaling involves both binding to ligand and clustering of integrins. Ligand binding can be stimulated also by intracellular signals, presumably by a change in conformation of the integrin. Integrin signaling is necessary for cell movement but, in contrast to many other pathways, adherence provides a continuous signal to cells. This signal appears to be necessary for survival of many cell types. The ability to circumvent the requirement for adherence-dependent survival plays a major role in the development of human cancers by allowing tumor survival in inappropriate locations.

## PROPAGATION OF SIGNALS TO THE CELL INTERIOR

Eukaryotic cells use a varied collection of receptors and ligands to initiate cell signaling. Binding of ligands to receptors may stimulate an intrinsic enzymatic activity of the receptor-like protein tyrosine or serine kinases or the guanine nucleotide exchange activity of GPCR. Other receptors do not have intrinsic enzymatic activity, but ligand binding results in activation of downstream enzymes (e.g., proteases by the tumor necrosis factor receptor family or protein tyrosine kinases by the cytokine receptors). Signals are transmitted by all receptors by affecting the function of downstream proteins (Table 3-3). The function of intracellular signaling proteins is regulated by covalent modifications, by noncovalent binding of other proteins and small molecules, and by the level of protein expression.

Enzyme Class	Examples
<b>PROTEIN KINASES</b>	
Tyrosine	Jak
Serine, threonine	ERKs
<b>PROTEIN PHOSPHATASES</b>	
Tyrosine	SH-PTP
Serine, threonine	Cdk/cyclin
<b>LIPID KINASES</b>	
Phosphatidylinositol	PI3-kinase
<b>LIPID PHOSPHATASES</b>	
Phosphatidylinositol	SHIP, PTEN
<b>PHOSPHOLIPASES</b>	
A	PLA2
C	PLA2
D	---
<b>G PROTEINS</b>	
Heterotrimeric	Gs, Gi
Ras/Raf	Ras, Raf
<b>NUCLEOTIDE CYCLASES</b>	
Adenylate	---
Guanylate	---

TABLE 3-3. Enzyme Classes Stimulated by Active Receptors

## REGULATION OF PROTEIN KINASES

Proteins undergo many covalent modifications, but phosphorylation is the most common covalent modification involved in the regulation of protein function. Both phosphorylation by kinases and addition of a phosphate moiety in the form of GTP exchange for GDP result in conformational changes that regulate protein activity (Fig. 3-2). Proteolysis is less common in the activation of signaling pathways but is necessary for some pathways (e.g., apoptosis) and also is an important pathway by which signals are attenuated.

**FIGURE 3-2.** Regulation of protein activity by phosphate. The activity of many proteins is regulated by phosphate. The exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to G proteins induces an activating conformational change dependent on the additional  $\gamma$  phosphate of GTP. This reaction is catalyzed by guanine nucleotide exchange factors. GTPase-activating proteins (GAP) accelerate the hydrolysis of GTP to GDP to remove the  $\gamma$  phosphate and attenuate G protein signaling. Protein kinases add phosphate to proteins that can result in conformational changes and changes in enzymatic activity. The phosphate can be removed by protein phosphatases to inhibit the signal. Both G proteins and protein kinase substrates undergo a similar cycle of phosphate addition and removal to regulate their activity. ADP, adenosine diphosphate; ATP, adenosine triphosphate; GEF, guanine nucleotide exchange factor.

The balance between kinase and phosphatase activity controls protein phosphorylation.<sup>32</sup> Protein kinases themselves, transcription factors, and cytoskeletal components are a few examples of proteins regulated by phosphorylation. Most protein kinases in eukaryotic cells are divided into three classes on the basis of residues they phosphorylate: protein tyrosine kinases, protein serine-threonine kinases, and dual-specificity kinases that phosphorylate serine, threonine and tyrosine residues. Important issues in understanding the role and regulation of protein phosphorylation are how specificities of kinases and phosphatases are determined and how phosphorylation alters the function of proteins. Recent work at both the structural and functional levels provides preliminary answers to these questions.

Most signal transduction pathways activate tyrosine kinases, either directly (as in the case of receptor tyrosine kinases) or indirectly. Phosphorylation of proteins on tyrosine can result in either the stimulation or inhibition of enzymatic activity or can provide sites for protein-protein interaction. An example of how tyrosine phosphorylation regulates enzymatic activity is the Src family of protein tyrosine kinases, which are regulated both positively and negatively by tyrosine phosphorylation.<sup>33</sup> Phosphorylation of a tyrosine residue in the C-terminus leads to an intramolecular bond involving this phosphotyrosine and the Src homology 2 (SH2) domain that blocks access of substrate to the catalytic domain. In contrast, phosphorylation of a tyrosine in the T loop of the catalytic domain stimulates the kinase activity by stabilizing the catalytic pocket in an active conformation.

A common theme in the regulation of the activity of both tyrosine and serine-threonine protein kinases is phosphorylation of the T loop as a mechanism of activation. The T loop forms a lip of the catalytic pocket and may occlude the active site, preventing access of the substrate. In the case of the insulin receptor, the unphosphorylated T loop also appears to interfere with adenosine triphosphate (ATP) binding.<sup>34</sup> Crystallographic studies indicate that the T loop is mobile and thus probably is not always in an inhibitory confirmation; hence, a kinase has some constitutive activity. This low level of activity is sufficient to phosphorylate a nearby kinase (e.g., autophosphorylation of a partner in a dimeric receptor). After phosphorylation, the T loop undergoes a conformational change that allows substrate access to the catalytic site.

Once a protein kinase is active, only specific substrates are phosphorylated. This specificity rests on two properties: colocalization of the kinase with the substrate (discussed later in [Efficiency and Specificity: Formation of Multiprotein Signaling Complexes](#)) and the presence of sequences in a potential substrate that can be phosphorylated by the kinase. Though protein kinases appear to phosphorylate many substrates *in vitro*, particular motifs have been identified that in some cases govern absolutely whether a protein will be a substrate, such as a proline following a serine or threonine for substrates of MAP kinases.<sup>35,36</sup> In other cases, particular motifs are favored as phosphorylation sites.<sup>37,38</sup> Likely these motifs fit best into the catalytic cleft of the kinase. In some cases, sequences distant from the site of phosphorylation can mediate low-affinity association of a kinase with a substrate and thus can enhance phosphorylation.

Most signaling pathways also activate serine kinases, but a higher level of constitutive phosphorylation of proteins occurs on serine and threonine. Still unclear is how much of this basal phosphorylation is involved in regulation of the activity or location of proteins and how much might be irrelevant. Myriad cellular functions are regulated by serine phosphorylation ranging from the activity of transcription factors and enzymes to the polymerization of actin. Serine kinases themselves are regulated in a variety of ways. Mammalian serine-threonine kinases have been subdivided into 11 subfamilies, on the basis of primary sequence homology, which has been predictive also of related function.<sup>39</sup> Location, phosphorylation, and ligand binding regulate serine kinases. Activation by ligand binding separates some classes of serine protein kinases. For example, cyclic nucleotides (e.g., cAMP) activate the protein kinase A (PKA) superfamily.<sup>40</sup> Calcium and diacylglycerol activate members of the protein kinase C family.<sup>41</sup> The akt family is activated by phosphatidylinositol phosphate products of phosphoinositide 3-kinases (PI3-kinase), which allows phosphoinositide-dependent kinase 1 (PDK1) to phosphorylate the activation, or T loop.<sup>42</sup> Association with cyclins activates the cyclin-dependent kinase family, and the calcium-calmodulin-dependent kinases are activated by calcium.<sup>43,44</sup> Kinase cascades also are important in allowing multiple levels of regulation and amplification of serine kinase activity. For example, MAP kinases are activated by phosphorylation of the T loop after activation of upstream kinases: Activation of Raf leads to phosphorylation and activation of MEK1, which phosphorylates and activates the ERKs ([Fig. 3-3](#)).<sup>45</sup>

**FIGURE 3-3.** Activation of the MAP kinase pathway. Many receptors activate the mitogen-activated protein kinases (MAP kinases). Most receptor tyrosine kinases stimulate the activity of the Ras guanine nucleotide exchange factor son of sevenless (SOS), which associates with the linker proteins Shc and Grb2. The activation of Ras by SOS stimulates a protein serine kinase cascade initiated by Raf, which stimulates MEK. MEK then activates the MAP kinases. MAP kinases phosphorylate transcription factors to regulate gene expression. GDP, guanosine diphosphate; GTP, guanosine triphosphate.

## REGULATION OF PROTEIN PHOSPHATASES

Protein phosphatases remove the phosphate residues from proteins and can either activate or inactivate signaling pathways, depending on the sites that are dephosphorylated. Protein phosphatases can be divided into the same three groups as are the kinases, on the basis of their substrates: tyrosine phosphatases, serine-threonine phosphatases, and dual-specificity phosphatases. Tyrosine phosphatases and dual-specificity phosphatases use a cysteinylphosphate intermediate, whereas the serine-threonine phosphatases are metal-requiring enzymes that dephosphorylate in a single step.<sup>46,47</sup>

Recent structural work has revealed how the activity of some nonreceptor tyrosine phosphatases is regulated. The SHP-2 phosphatase has, in addition to the catalytic domain, two SH2 domains. These domains (discussed in more detail in [Domains That Mediate Protein-Protein Binding](#)) mediate binding to other proteins by direct association with phosphorylated tyrosine residues. In the inactive state, the catalytic cleft of SHP-2 is blocked by the N-terminal SH2 domain.<sup>48</sup> Binding of the

N-terminal SH2 domain to a phosphotyrosine residue of a target protein induces a conformational change that allows substrate access to the catalytic domain. Tyrosine phosphatases act both to attenuate signals that require tyrosine phosphorylation and to activate pathways inhibited by tyrosine phosphorylation. An example of the negative regulatory function of tyrosine phosphatases is the role of SHP-1 (a homolog of SHP-2) in inhibiting cytokine and B-cell receptor signaling. In contrast, SHP-2 is necessary for cytokine stimulation of cells. On the basis of the ability of phosphatase inhibitors (e.g., vanadate) to activate tyrosine kinase-dependent signaling in the absence of ligands, acute inactivation of specific tyrosine phosphatases may play a more important role than previously appreciated in regulating the balance of tyrosine phosphorylation and dephosphorylation that controls signaling pathways.

Protein phosphatase 1 (PP1), PP2A, PP2B, and PP2C are the major serine-threonine phosphatase activities *in vivo*.<sup>49</sup> Both PP1 and PP2A are composed of catalytic and regulatory subunits. PP1 is involved in regulating many pathways, from glycogen metabolism to the cell cycle. PP2B binds to calmodulin and is regulated by calcium. Phosphorylation of either the regulatory or catalytic subunit regulates the activity of many serine phosphatases. More than 100 PP1 regulatory subunits function to target the catalytic domain to different cellular locations and mediate activation or inhibition. This action provides an example of how a single catalytic activity can perform multiple specific functions as a result of targeting by a regulatory subunit.

## GUANOSINE TRIPHOSPHATE-BINDING PROTEINS

Just as covalent modification as a mechanism of protein activity regulation is important, so is noncovalent binding to proteins. A number of small molecules regulate protein function, as does protein-protein interaction. G proteins are the best-studied protein mediators that regulate other proteins.

GTP-binding proteins function as digital switches. They are inactive when bound to GDP, but GTP binding results in a conformational change that allows binding to effector molecules and transmission of a signal (see Fig. 3-2). GTP-binding proteins regulate the same molecules activated by receptors: protein and lipid kinases, phosphatases, and phospholipases. GTP-binding proteins are categorized into two large classes: the heterotrimeric GTP-binding proteins and the Ras-like GTP-binding proteins. Activation of GTP-binding proteins is regulated by guanine nucleotide exchange factors that catalyze the release of GDP and allow GTP to bind to and activate the protein. GTPase-activating proteins (GAPs) accelerate GTP hydrolysis and regulate inactivation of GTP-binding proteins. All GTP-binding proteins have lipid modifications that promote membrane association.

Heterotrimeric GTP-binding proteins have three subunits and are activated by GPCR.<sup>23</sup> In the inactive state, the  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits are associated as a heterotrimer. In mammalian cells, 20  $\alpha$  subunits, 6  $\beta$  subunits, and 12  $\gamma$  subunits are known. The heterotrimeric forms are divided into four classes on the basis of function.  $G_s$  stimulates adenylate cyclase,  $G_i$  inhibits adenylate cyclase,  $G_q$  activates phospholipase C  $\beta$ , and  $G_{12}$  and  $G_{13}$  form a group whose function is not yet known. Activation of GPCR allows them to catalyze GDP/GTP exchange of the  $\alpha$  subunit of heterotrimeric G proteins. In response to GTP loading of the  $\alpha$  subunit, the  $\alpha$  and  $\beta/\gamma$  subunits dissociate. The  $\beta$  and  $\gamma$  subunits do not dissociate *in vivo*. Both the  $\alpha$  subunit and the  $\beta/\gamma$  complex send signals. The  $\alpha$  subunit undergoes a conformational change in response to GTP that allows it to bind to effectors.<sup>50</sup> The  $\beta/\gamma$  dimer does not undergo a conformational change, but release from the  $\alpha$  subunit exposes surfaces that allows it to bind to effectors.<sup>51-52</sup> Both the  $\alpha$  and  $\beta/\gamma$  subunits affect the activity of a wide range of downstream effectors, including ion channels, protein kinases, and phospholipases. Domains termed *regulators of G protein signaling* act as GAPs toward the  $\alpha$  subunit and attenuate the signal by catalyzing hydrolysis of GTP to GDP.<sup>53</sup>

Ras-like GTP-binding proteins are monomeric and of lower molecular weight than are the heterotrimeric GTP-binding proteins. Ras-like GTP-binding proteins are classified into five families: the Ras, Rho, Rab, Arf, and Ran families.<sup>54</sup> The Ras and Rho families regulate cell growth, transcription, and the actin cytoskeleton; the Arf family regulates phospholipase D and vesicle trafficking; the Rab family regulates vesicle trafficking; and the Ran family regulates nuclear import.<sup>55,56,57,58</sup> and 59 Ras-like GTP-binding proteins are activated in a manner similar to that of the  $\alpha$  subunit of heterotrimeric G proteins.<sup>60</sup> Exchange of GTP for GDP results in a conformational change that promotes binding to effector molecules.<sup>61</sup> In contrast to heterotrimeric G proteins, nucleotide exchange for Ras-like GTP-binding proteins is not catalyzed by receptors. Specific exchange factors are activated downstream of receptors or in response to specific cellular events. Signals are attenuated by the action of GAPs, analogous to regulators of the G protein–signaling domain-containing proteins that catalyze GTP hydrolysis.

GTP-binding proteins affect the activity of their targets by causing conformational changes and perhaps by serving to localize the target. Recent crystal structures of the catalytic domain of adenylate cyclase bound to G proteins illustrate the conformational change.<sup>62</sup>  $G_{s\alpha}$  binds to the C2a domain of adenylate cyclase, causing rotation of the C1a domain, which likely positions the catalytic residues more favorably for conversion of ATP to cAMP. Though crystal structures of small G proteins bound to portions of their targets also have been solved, the effect on the activity of target molecules as a result of binding has not yet been explained. Studies of the role of Ras in the interaction of Raf suggest that an important role of Ras is localization of Raf to the membrane, but Ras also may help to activate Raf directly.<sup>63</sup>

## SMALL-MOLECULE SECOND MESSENGERS

Many small molecules transmit signals by binding noncovalently to protein targets and affecting their function. Many of these molecules are called *second messengers* because they are generated within the cell in response to a first messenger, such as a growth factor, binding to a cell surface receptor. Both the generation and attenuation of small-molecule signals is regulated. Our review of the role of several small molecules in signal transduction pathways is not meant to be comprehensive.

cAMP was the first second messenger discovered.<sup>64</sup> Adenylate cyclase, activated by heterotrimeric G proteins, catalyzes the synthesis of cAMP from ATP.<sup>65</sup> The primary target of cAMP is protein kinase A, and the activation of protein kinase A by cAMP demonstrates how second messengers function.<sup>4c</sup> The inactive form of protein kinase A is a tetramer of two catalytic and two regulatory subunits; the regulatory subunit inhibits the activity of the catalytic subunit. The regulatory subunit contains two cAMP-binding sites. Binding of cAMP to the first site causes a conformational change that exposes the second site. Binding of cAMP to the second site causes dissociation of the regulatory and catalytic subunits. The free catalytic subunits are then active.

Many activated receptors stimulate phospholipases C.<sup>66</sup> All three families of phospholipases C (PLC)— $\beta$ ,  $\gamma$ , and  $\delta$ —are activated by calcium. PLC  $\beta$  is activated by both the  $\alpha$  and the  $\beta/\gamma$  subunits of heterotrimeric G proteins, and PLC  $\gamma$  is activated by tyrosine phosphorylation. The regulation of PLC  $\delta$  is not as well understood. Phospholipases C cleave PtdIns-4,5- $P_2$  to produce diacylglycerol and inositol-1,4,5-trisphosphate, resulting in a bipartite signal. Diacylglycerol interacts with the C1 domain of protein kinases C to mediate their membrane localization and activation. Inositol-1,4,5-trisphosphate binds to a calcium channel in the endoplasmic reticulum (ER) and stimulates the release of calcium from intracellular stores.<sup>67</sup> The initial increase in cytoplasmic calcium is followed by an influx of extracellular calcium via capacitive calcium channels at the plasma membrane.<sup>68</sup> Still unclear is how the capacitive calcium channels are activated. In unstimulated cells, cytosolic calcium is much lower than in the extracellular space or ER (100 nM versus 1 mM), so opening channels in the endoplasmic reticulum or plasma membrane allows calcium to flood into the cytoplasm, temporarily raising the cytoplasmic calcium to micromolar concentrations. Ultimately, calcium returns to basal levels as a result of closing the channels, which increases extracellular transport and pumping calcium into intracellular sites in the ER and mitochondria. Calcium has a multitude of cellular effects, including directly regulating enzymatic activities, ion channels, and transcription. Several calcium-binding domains are known, including the C2 domain and EF hands. Calcium binds directly to enzymes and regulates their activity or it can bind to regulatory subunits, such as calmodulin.

Eicosanoids are ubiquitous signaling molecules that bind to both GPCR and transcription factors. Eicosanoid synthesis occurs in response to a number of stimuli and is an example of rapid cell-to-cell signaling. Unlike most second messengers, eicosanoids produced in one cell can escape that cell and diffuse to nearby cells and either bind to receptors or be metabolized further. Eicosanoid synthesis is regulated by the production of arachidonic acid, which can be produced from diacylglycerol (DAG) via diglyceride lipases or from phospholipids by phospholipases A.<sup>69</sup> Phospholipases A2 cleave the sn-2 acyl group of phospholipids to produce a free fatty acid and a lysophospholipid. The calcium-regulated form of PLA2 shows a preference for substrates containing arachidonic acid. The further metabolism of arachidonic acid results in the synthesis of prostaglandins and leukotrienes.

## EFFICIENCY AND SPECIFICITY: FORMATION OF MULTIPROTEIN SIGNALING COMPLEXES

### COMPARTMENTATION

The ability of a signal transduction pathway to transmit a signal or to stimulate flux through a pathway is dependent on the probability that a protein finds its target. The likelihood of any two proteins coming into contact is proportional to their concentrations. Recruiting a protein to a specific compartment of a cell allows the local concentration of that protein to be increased markedly, thereby increasing the probability that it will interact with other proteins or small molecules that are recruited to or generated in the same compartment. Colocalization of proteins in a signaling pathway is achieved by recruitment to the same membrane surface or organelle (e.g., plasma membrane versus ER) and ultimately by protein-protein interactions. Conversely, separating proteins or second messengers (or both) into distinct

compartments turns off signaling pathways.

The regulation of transport of signaling proteins into the nucleus is important in a number of signal transduction pathways and illustrates the concept of colocalization in the same organelle.<sup>70</sup> Nuclear transport proceeds through nuclear pores that can be transversed by diffusion of proteins of less than 40 kD. Transport of larger molecules requires a nuclear localization signal to which the importin proteins bind. The importins target the protein to the nuclear pore, and the complex is transported into the nucleus. The Ran G protein dissociates the importins from their cargo once they are in the nucleus. Regulated export of proteins from the nucleus is similar to import. A nuclear export signal (NES) is recognized by the protein exportin which then transports the cargo out of the nucleus.

Regulation of nuclear localization of the transcription factor nuclear factor of activated T cells (NFAT), required for its transcriptional activity, is an example of the importance of nuclear localization in signal transduction.<sup>71</sup> In response to T-cell activation and a rise in intracellular calcium, NFAT is dephosphorylated by the calcium-responsive phosphatase calcineurin. Dephosphorylation allows the nuclear localization signal in NFAT to bind to the importins, and NFAT, along with calcineurin, is imported into the nucleus. NFAT also contains a NES, and phosphorylation appears to allow the NES to bind to exportin, resulting in transport to the cytoplasm.

Protein compartmentation can also occur on a smaller scale. Proteins in a signal transduction cascade can exist in a preformed but inactive complex, such as the yeast MAP kinase module composed of the Ste11, Ste7, and MAP kinases bound to the scaffolding protein Ste5.<sup>72</sup> Pheromone signaling activates a G protein, which in turn activates the Ste20 kinase. Ste20 phosphorylates and activates the Ste11, which activates the kinase cascade on Ste5. Once the first kinase in the cascade is activated, the other kinases are phosphorylated quickly and are activated because of their proximity.

A similar scaffolding probably functions in the activation of the Jnk kinase pathway in mammalian cells. The enzymes in the mammalian MAP kinase cascades are homologues of the yeast proteins. A protein originally thought to inhibit Jnk kinase (JIP-1, jnk inhibitory protein) binds to MLK1, MKK7, and Jnk and facilitates the activation of Jnk, presumably by localizing the components in the cascade.<sup>73</sup> Other examples of scaffolding proteins are the A kinase-anchoring proteins.<sup>74</sup> This family of proteins binds the regulatory subunit of protein kinase A and localizes it to such diverse intracellular locations as ion channels, centrosomes, and mitochondria. This activity results in the preferential activation of PKA at specific intracellular locations where the relevant substrates are.

### DOMAINS THAT MEDIATE PROTEIN-PROTEIN BINDING

Another way in which signal transduction pathways commonly are stimulated is through regulated assembly of protein-protein complexes. Most often, these interactions are mediated by conserved domains found in many signal transduction proteins that recognize phosphorylated tyrosine or serine residues or proline-rich sequences (Table 3-4).

Motifs	Domains That Bind Motif	Examples of Proteins That Contain the Domain
Phosphotyrosine	SH2	Src, PI3-kinase, SHP-2
	PTB	IRS family, SHC
Phosphoserine	WD40	Telomerase, AFAF-1, costamer
	14-3-3	—
	WW	Pin1
	FHA	Rad55
Proline-rich	SH3	Src, PI3-kinase
	WW	YAP, dystrophin
	EVH1	VASP, ENA, WASp
C-terminal sequences	PDZ	ZO-1, lim kinase

TABLE 3-4. Protein-Protein Interaction Domains and Motifs

Both SH2 domains and phosphotyrosine-binding (PTB) domains bind to motifs containing phosphorylated tyrosine residues.<sup>75</sup> Tyrosine kinases and phosphatases regulate the formation of complexes involving these domains. Tyrosine kinases themselves can serve as docking sites for other proteins, which is most evident with tyrosine kinase receptors that recruit such proteins as PI3-kinase, p120 Ras GAP, PLC  $\gamma$ , and SHP-2 through SH2 domain-dependent interactions. Tyrosine kinases also phosphorylate other proteins. Tyrosine phosphorylation of the insulin receptor substrate 1 protein by the insulin receptor leads to recruitment of SH2 domain-containing proteins to insulin receptor substrate-1.<sup>76</sup> In addition to mediating protein-protein interactions, binding of SH2 domains to phosphotyrosine residues stimulates the enzymatic activities of such proteins as PI3-kinase and Src kinases.<sup>77,78</sup> In some cases, such as Src kinases, the SH2 domain binds to an intramolecular phosphotyrosine to regulate catalytic activity. Usually, this type of regulation is inhibitory. The crystal structures of several SH2 domains have been determined and reveal a pocket that binds the phosphotyrosine and a groove that determines binding specificity based on the fit of the residues C-terminal (or, in a few cases, N-terminal) to the phosphotyrosine.<sup>79</sup>

PTB domains are functionally analogous to SH2 domains in that they bind phosphotyrosine residues to assemble multiprotein complexes, but they have no sequence or structural similarity to SH2 domains.<sup>80</sup> Thus, they represent an independent evolutionary solution to phosphotyrosine-dependent assembly of protein complexes. A few PTB domains bind to a tyrosine-containing motif in the absence of phosphorylation.

In the last few years, it has become evident that recognition of phosphoserine motifs is also an important means of protein-protein interaction. Forkhead-associated domains, 14-3-3 proteins, and some WD40 and WW domains bind to regions of proteins containing phosphoserine.<sup>81,82,83 and 84</sup> WD40 domains in proteins that are members of the F-box and WD40 repeat family are important in regulating ubiquitination and subsequent proteolysis of proteins, such as the inhibitor of  $\kappa$ B (I $\kappa$ B), which regulates the activity of the transcription factor nuclear factor  $\kappa$ B (NF $\kappa$ B). 14-3-3 proteins are a family of small proteins whose primary function appears to be binding to phosphoserine motifs. An example of the importance of this interaction is the role of 14-3-3 in regulating the nuclear location of the phosphatase Cdc25 that regulates the cell cycle.<sup>85</sup> Binding of 14-3-3 to phosphorylated Cdc25 leads to its export from the nucleus and a block in the cell cycle.

Src homology 3 (SH3), WW, and ena-vasp homology domains are structurally distinct, but all bind to proline-rich sequences.<sup>86,87 and 88</sup> Still not clear is how the interaction of these domains with proline-rich regions in other proteins is regulated. Many proteins that contain SH3 domains also have proline-rich regions that could be involved in intramolecular binding, suggesting that a conformational change in the protein could disrupt intramolecular binding and allow the SH3 domain to interact with other proteins. Similarly, the accessibility of proline-rich regions to SH3 domains may be regulated by conformational changes that expose the proline-rich region or disrupt an intramolecular interaction.

PDZ domains recognize motifs in the C-termini of proteins.<sup>89,90</sup> These domains are found in cytoplasmic proteins, and many contain multiple PDZ domains. PDZ domain-containing proteins often function to aggregate transmembrane proteins, such as the glutamate receptor. Group I PDZ domains bind to a consensus sequence, T/S-X-V/I, where V/I is the C-terminus of the protein.<sup>91</sup> Phosphorylation of the S or T in this motif can disrupt PDZ binding in some cases. For example, phosphorylation of this serine in the  $\beta_2$ -adrenergic receptor was shown to lead to a loss of PDZ domain-mediated binding to EBP50, which regulates endocytic sorting of the receptor.<sup>92</sup>

### DOMAINS THAT MEDIATE PROTEIN BINDING TO MEMBRANE LIPIDS

Localization of proteins to membranes greatly limits the space in which proteins can diffuse and increases the probability that enzymes and substrates will contact each other. C1 domains present in protein kinases C (PKC) bind to DAG and thereby recruit PKC to the membrane.<sup>41</sup> Membrane recruitment of PKC is aided also by the C2 domain, which binds to anionic phospholipids in the presence of calcium. This pathway is controlled by DAG production, and the primary source is DAG produced by PLC hydrolysis of PtdIns-4,5-P<sub>2</sub>.

Domains homologous to a region in pleckstrin (PH) are present in a number of proteins and bind to phosphoinositides, thereby targeting proteins to the plasma

membrane.<sup>93</sup> Both the accessibility of the PH domain and availability of phosphatidylinositol (PtdIns) phosphates likely regulate this interaction. Phosphoinositide kinases regulate the production of phosphoinositides.<sup>94</sup> PtdIns 4-kinases synthesize PtdIns-4-P from PtdIns. Type I phosphatidylinositol phosphate kinases (PIPKs) phosphorylate PtdIns-4-P at the 5 position to make PtdIns-4,5-P<sub>2</sub>. PtdIns 3-kinases phosphorylate PtdIns, PtdIns-4-P, and PtdIns-4,5-P<sub>2</sub> at the 3-position of the inositol ring to make PtdIns-3-P, PtdIns-3,4-P<sub>2</sub>, and PtdIns-3,4,5-P<sub>3</sub>, respectively. Phosphoinositide levels also are regulated by phosphatases. The recessive oncogene PTEN has significant homology to tyrosine phosphatases but recently was shown to remove the phosphate from the 3 position of PtdIns-3,4,5-P<sub>3</sub> and less well from PtdIns-3,4-P<sub>2</sub> and PtdIns-3-P.<sup>95</sup> PTEN thus counteracts PI3-kinase signals, and cells from which PTEN is absent have increased signaling through PI3-kinase-dependent pathways.<sup>96</sup> A family of phosphatases that removes the phosphate from the 5 position of PtdIns-3,4,5-P<sub>3</sub>, the SH2 inositol phosphatases, also regulates phosphoinositide signaling pathways.<sup>97</sup>

Some PH domains bind best to PtdIns-4,5-P<sub>2</sub>, and others bind best to PtdIns-3,4-P<sub>2</sub> or PtdIns-3,4,5-P<sub>3</sub>.<sup>98</sup> Thus, acute production of specific phosphoinositides in a membrane compartment results in the recruitment of proteins containing a PH domain that recognizes the phosphoinositide. Colocalization of a subset of proteins allows them to interact more efficiently. A recent example of the role of PH domains in such a pathway is the activation of akt by PDK1. PDK1 and akt are protein serine-threonine kinases that contain PH domains that bind PtdIns-3,4-P<sub>2</sub> or PtdIns-3,4,5-P<sub>3</sub>. Activation of PI3-kinase leads to local synthesis of PtdIns-3,4-P<sub>2</sub> and PtdIns-3,4,5-P<sub>3</sub> recruitment of akt and PDK1 to the same membrane location. This activity facilitates phosphorylation and activation of akt by PDK1.<sup>99</sup> Other domains unrelated to PH domains also bind phosphoinositides. For example, FYVE domains are present in several proteins involved in vesicle trafficking, and they bind to PtdIns-3-P.

Cellular membranes are not uniform and appear to be highly organized. One of the principal structures in the plasma membrane is lipid rafts.<sup>100</sup> They are composed of regions of the membrane that are rich in sphingolipids and cholesterol on the extracellular side of the plasma membrane. The lipid component of the cytoplasmic face of lipid rafts is not known, but some evidence suggests that PtdIns-4,5-P<sub>2</sub> is enriched. Glycophosphatidylinositol-linked proteins, transmembrane proteins, and src family members have been found to localize to lipid rafts. Both the Fce receptor and the T-cell receptor cluster in lipid rafts, which is necessary for their signaling. The basis of protein recruitment to rafts is not yet known.

## REGULATION OF PROTEIN LEVELS: TRANSCRIPTION, TRANSLATION, AND PROTEOLYSIS

In addition to influencing the activity of proteins in the cell, signal transduction pathways also regulate the type and levels of proteins expressed in cells. This sort of regulation is necessary for differentiation and the specific function of distinct cell types. Whether a protein is expressed at all in a cell is regulated at the transcriptional level, whereas transcription, translation, and proteolysis have a role in determining the amount of an expressed protein present in a cell.

Ultimately, many signal transduction pathways regulate gene transcription and, thus, the level and type of proteins expressed in the cell. The magnitude of the effect of a signaling pathway on the transcriptional output of a cell is illustrated by the effects of serum on levels of particular mRNAs in fibroblasts.<sup>101</sup> Of 8600 genes analyzed in this study, more than 500 underwent substantial changes in response to serum stimulation. The ability to transcribe a gene is regulated at many levels, including the structure of chromatin in the region of the gene, modifications of the promoter regions, and the activity of transcription factors and coactivators. Signal transduction pathways regulate histone acetylases and deacetylases that determine the accessibility of chromatin to the transcriptional apparatus. Recent work has shown that a number of signals lead to histone hyperacetylation that disrupts the nucleosome to allow transcription. For example, the Rho family small G protein Cdc42 and one of its effectors, Jnk, lead to histone hyperacetylation.<sup>102</sup> Likely these pathways cooperate with the activation of transcription factor to induce transcription.

Signal transduction pathways activate transcription factors by many different means. The binding of ligands to the nuclear receptor family of transcription factors causes dissociation of the receptor from a complex with heat-shock proteins and allows the receptor to bind to DNA. Tyrosine phosphorylation of the STAT family of transcription factors by Jak kinases in response to stimulation of cytokine receptors allows them to dimerize through their SH2 domains and enter the nucleus to bind DNA.<sup>15</sup> TGF- $\beta$  receptors activate transcription by phosphorylating SMAD proteins on serine residues.<sup>17</sup> Phosphorylation of SMAD proteins promotes heterodimerization with SMAD4 and exposes the DNA-binding domain. Activated SMADs translocate to the nucleus, complex with a protein called *Fast1*, and bind to DNA to regulate transcription.

Activation of transcription factors also can occur much further downstream from the receptor. Stimulation of the transcriptional activity of Elk-1 by EGF requires activation of a Ras exchange factor, which leads to activation of Ras. Active Ras promotes the stimulation of Raf activity. Raf in turn phosphorylates and activates MEK1, which phosphorylates and activates ERK. Active ERK translocates to the nucleus and phosphorylates and stimulates the activity of the transcription factor elk-1.

Translation also is controlled at many levels.<sup>103</sup> The sequence of the RNA can result in stable tertiary structures that bind proteins to regulate location or translation. Often, the ability of these types of RNAs to be translated is regulated by protein kinase cascades. A common target of signal transduction pathways is phosphorylation of initiation factor eIF-4E and availability of eIF-4E. p70<sup>S6</sup> kinase regulates the translation of specific RNAs containing a 5' terminal oligopyrimidine tract by phosphorylation of the ribosomal S6 protein.<sup>104</sup> This increases the ability of the ribosome to process such messages.

The levels of proteins also are regulated by proteolysis, which can occur via either the proteasome or the lysosome. Ubiquitination targets proteins to the proteasome.<sup>105</sup> An example of the role of ubiquitination is the regulation of inhibitor of  $\kappa$ B (I $\kappa$ B) levels. Phosphorylation of I $\kappa$ B is stimulated by a number of receptor-mediated signaling pathways. This action leads to its dissociation from the transcription factor nuclear factor  $\kappa$ B (NF $\kappa$ B) and allows NF $\kappa$ B to enter the nucleus and bind DNA. After phosphorylation, the  $\beta$  transducin repeat-containing protein binds to I $\kappa$ B, recruiting ubiquitin ligase that catalyzes the ubiquitination of I $\kappa$ B and leads to its recognition and degradation by the proteasome.<sup>106</sup>

The second major pathway of protein degradation is the lysosomal pathway, which is important also in signal transduction. An early response to the stimulation of receptors is their internalization into endosomes; some evidence suggests that signaling persists at this location after endocytosis.<sup>107</sup> In the case of receptor tyrosine kinases, ligand-dependent kinase activity is necessary for endocytosis, mediated by clathrin-coated pits. After endocytosis, either receptors may recycle to the plasma membrane or the endosomes may fuse with lysosomes, leading to degradation of the receptor.

### INTRODUCTION

Potentially harmful challenges to the body include viruses, bacteria, unicellular and multicellular pathogens, and cancer cells. In response to these challenges, the body has evolved active defenses that compose the immune system. While the immune system is composed of a wide range of distinct cell types, lymphocytes play a central role by providing the specificity of immune recognition. Through its various appendages, the immune system is capable of interacting, directly or indirectly, with nearly every cell in the body.

There is a central division in the immune system between the humoral branch, which is largely composed of B lymphocytes and their products, and the cellular branch, many functions of which are performed by T lymphocytes. The humoral (from the Latin word *umor* meaning “fluid”) branch of the immune system is involved with the production of antibodies that are capable of neutralizing or destroying harmful challenges to the body. Immune functions classically regarded as cellular immune responses include delayed-type hypersensitivity<sup>1</sup> and rejection of foreign grafts<sup>2</sup> or tumors.<sup>3</sup> As techniques for isolating and identifying cells associated with immune responses developed, it became clear that T cells, or thymus-derived lymphocytes, are the cells essential for cellular immune responses. Thus, understanding the principles of cellular immunity has largely come to mean understanding the development, function, and regulation of T cells.

There are fundamental differences in the ways that the cellular and humoral immune systems recognize antigens ( [Table 4-1](#)). B cells can recognize antigens not presented in the context of other molecules. T cells, on the other hand, generally recognize antigens in the context of a “self” (major) histocompatibility complex (MHC) molecule on the surface of a cell. T cells use structures on their surfaces called *T-cell receptors* (TCRs) to recognize antigen-MHC molecule complexes; B cells use immunoglobulin (Ig) molecules to react specifically to antigenic stimuli. Whereas Ig is secreted, sometimes in extremely large quantities, few, if any, TCRs are shed by T cells. Underlying the difference in the molecules used for recognition is an important difference in the types of antigens recognized: While B cells can recognize antigen in its native conformation, T cells generally recognize antigen that has been “processed” by another cell and then presented on the surface of the cell by MHC molecules. More specifically, antigen is denatured, cleaved within the cell, and transported into specific subcellular compartments where it is bound by MHC molecules. After a complex of antigen and MHC completes its journey to the cell surface, it is potentially recognizable by a T cell.

	Humoral	Cellular*
Recognizing cell	B lymphocyte	T lymphocyte
Recognizing molecule	Immunoglobulin	T-cell receptor
Self-molecules required?	No	Yes
Chemical identity of antigen	Protein, nucleic acid, polysaccharide, other	Protein
Phase of antigen	Fluid or solid	Solid
State of antigen	Native or denatured	“Processed”

\*Various exceptions are presented in the text.

**TABLE 4-1.** Toward a Molecular Understanding of Immune Recognition of Antigen

We use *antigen* in this chapter for a substance that binds specifically to the combining site of an antibody or a TCR. Some of these substances elicit immune

responses (immunogens), whereas others do not. There are exceptions to this terminology, such as *superantigens*, which are discussed later in the section [Stimulation of T-Cell Receptors by Superantigens](#). Also, T cells commonly recognize MHC-peptide complexes, but both the peptide and its parent protein often are termed *antigens* in the literature.

## T CELLS AND CELLULAR IMMUNITY

T lymphocytes were first identified as a functional subset of lymphocytes, the development of which depends on the existence of a thymus.<sup>4,5 and 6</sup> In conditions of congenital absence of the thymus or following neonatal thymectomy in animal models, a number of immune responses were found to be impaired, including cell-mediated killing and transplantation reactions such as graft-versus-host disease and allograft rejection. Subsequent to this functional definition of T lymphocytes, differentiation antigens on T cells were identified using antibodies. The ability to identify T cells and thus to isolate T cells and their subsets, and the ability to grow these cells selectively in culture, has resulted in a body of experimental evidence concerning the mechanisms of maturation, activation, and effector function of this population.

Early experiments showed that the growth of a syngeneic tumor in a mouse could be prevented by prior immunization with that same tumor.<sup>7,8,9,10 and 11</sup> Since then, the mechanisms involved in the antitumor immune response have been partially elucidated,<sup>12,13</sup> and T cells have been shown to play a critical role.<sup>14,15 and 16</sup> Guided by results from animal model studies, human T cells have been shown to be capable of specifically lysing autologous tumor cells *in vitro*.<sup>17,18</sup> T cells can also specifically secrete cytokines, such as interleukin-2 (IL-2), interferon-g (IFN-g), granulocyte-macrophage colony-stimulating factor (GM-CSF), and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and proliferate in response to stimulation with autologous tumor cells.<sup>19,20</sup> Antitumor T cells can be grown to large numbers *in vitro* and transferred adoptively to treat even substantial tumor burdens in both humans and mice.<sup>21</sup> Finally, tumor antigens recognized by autologous human T cells have been identified by the use of molecular cloning techniques.<sup>22,23,24,25 and 26</sup> Taken together, these findings provide nearly incontrovertible evidence that a T-cell immune response can occur against an autologous tumor.

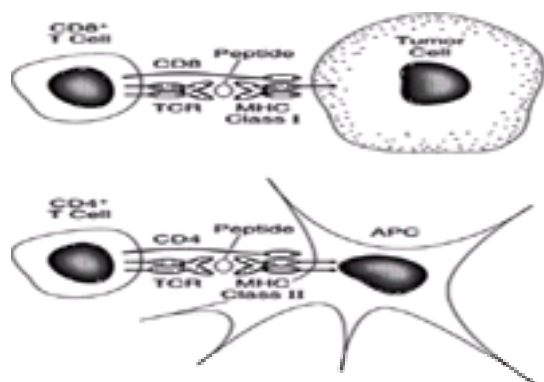

## ANTIGEN PRESENTATION TO T CELLS

The relative importance of how antigens are recognized by T cells (i.e., what T cells “see”) to the biologic therapy of cancer is linked largely to the establishment of new immunotherapies based on T cells. These new therapies have ushered in an entirely new set of challenges having to do with how T cells recognize, or may fail to recognize, tumor antigens.

T-cell responses were found by early investigators to be controlled by the presence of particular genes encoded in the MHC. Polymorphisms at this genetic region were observed to control the ability of an animal to mount a T-cell response. Early attempts to demonstrate direct binding of antigen to T cells failed, while attempts succeeded in the case of B cells. Although a straightforward and still useful model of the recognition of antigen by humoral factors was promulgated before the 1900s, it took nearly another hundred years for a similar event to occur for T cells.

T cells express on their cell surfaces molecules of exquisite sensitivity, very much like the antibody molecules found on the surfaces of B cells. These molecules, called *TCRs*, recognize peptide fragments of antigens, called *epitopes*, that are noncovalently complexed with MHC molecules. The two major types of MHC molecules, class I and class II, are integral membrane glycoproteins that are noncovalently complexed with antigenic peptides. Class I molecules present antigenic peptides to CD8+ lymphocytes; class II molecules perform the same function for CD4+ lymphocytes. CD8+ effector cells sometimes are termed *cytotoxic T lymphocytes* (CTLs), because they can lyse target cells directly through the release of lytic granules as well as through triggering “death” receptors, such as Fas, on target cells. CD4+ T cells, while also capable of cytotoxic activity in some cases, are called *helper T cells*, because they enhance antibody responses by activating B cells, promote other T-cell responses, and activate other important cells in the immune system, such as dendritic cells and macrophages.

A model of how the two major types of T lymphocytes may interact with target cells is depicted in [Figure 4-1](#). A CD8+ T cell is shown interacting directly with a tumor cell, while a CD4+ T cell is shown interacting with an antigen-presenting cell (APC) expressing class II molecules. While class I molecules are found on most tumor cells and somatic cells, class II molecules are found in high concentrations on only a subset of tumor cells and on B-cell, bone marrow–derived phagocytic cells (e.g., macrophages), Langerhans'-dendritic cells, follicular dendritic cells and, in lesser quantities, on other cells including subpopulations of thymocytes, activated peripheral T cells, and certain epithelial cells.

**FIGURE 4-1.** A model for stimulation of CD4+ and CD8+ T-cell antitumor immunity, based on CD8+ T cells interacting with tumor cells and CD4+ T cells interacting with host antigen-presenting cells (APCs). MHC, major histocompatibility complex; TCR, T-cell receptor.

## MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULES AS ANTIGEN RECEPTORS

A molecular understanding of the structure of MHC molecules has made clear their function with respect to antigen recognition by T cells: MHC molecules are *receptors* for peptide antigens.<sup>27,28 and 29</sup> The major locations, or loci, for class I genes are named *A*, *B*, and *C* in the human and *K*, *D*, and *L* in the mouse ([Fig. 4-2](#)). Class II molecules originate from three major subregions in the human, designated *DF*, *DQ*, and *DR*, and two in the mouse designated *I-A* and *I-E*. MHC molecules from these major subregions are codominantly expressed. The extent of MHC polymorphism present in the gene pool usually results in heterozygosity for most individuals at every major class I and class II locus. Because there are three different major class I loci and three different major class II loci in the human, most individuals express six different class I alleles and six different class II alleles. Codominant expression in a single individual of MHC molecules originating from multiple loci enhances that individual's ability to present a variety of antigens.

**FIGURE 4-2.** Highly schematic map of the genomic arrangement of the major histocompatibility complex in humans and mice. For simplicity, class Ib genes and the class III regions are not shown.

MHC class I molecules can also act as inhibitors of lysis by natural killer (NK) cells and at least some T cells, a function described later in this chapter in the section [Natural Killer Cells](#) and in recent reviews.<sup>30,31</sup>

### Structure of Major Histocompatibility Complex Molecules

X-ray crystallographic data have indicated that MHC molecules have peptide-binding domains consisting of a deep groove that runs between two long  $\alpha$  helices found on the outward-facing surface of the MHC molecule.<sup>27,28,32</sup> X-ray crystallographic findings have since been refined and extended to include x-ray images of particular peptides lying in the clefts of MHC molecules in an extended conformation.<sup>33,34,35,36,37,38,39</sup> and <sup>40</sup> An ever-clearer crystallographic picture of the interaction of the TCR with the peptide-MHC complex has become available with the solution of the diffraction pattern of this trimolecular structure.<sup>41,42</sup>

While the general architecture of the peptide-binding grooves of MHC class I and class II molecules are almost identical, critical differences fundamentally change the way peptides are bound. Class I molecules bind shorter peptides of defined lengths (generally 8 to 10 residues), whereas class II molecules bind peptides that appear to be arbitrary in length (often 12 to 20 amino acids, but occasionally longer). In fact, class II molecules often bind a core motif of an antigen that can extend in either direction by different lengths (also referred to as *nested sets* of peptides). The binding cleft of class I molecules is closed at both ends, enabling the molecule to make hydrogen bonds with the bound peptides at both the N-terminal and C-terminal. Class II molecules, on the other hand, have a peptide-binding cleft that is open on both ends. In both the class I and class II molecules, peptides are bound by pockets in the binding site.

The affinity of the TCR for the peptide-MHC complex is far weaker than that of most antibody-antigen interactions, a property consistent with an important role for other antigen-independent T-cell surface receptors acting as cofactors in the triggering process.<sup>43,44</sup> TCR-peptide-MHC complex interactions have low affinities and rapid off-rates, thus allowing for a rapid scanning-type interaction.<sup>45,46</sup>

### Polymorphism of Major Histocompatibility Complex Molecules

Sequence studies indicate that MHC class I and class II molecules are among the most highly polymorphic molecules in the genome. The polymorphism of MHC molecules is concentrated in the peptide-binding grooves.<sup>47,48</sup> Specifically, the polymorphism of MHC molecules is concentrated in the pockets along grooves of MHC molecules where amino acid side chains fit into the molecule. The polymorphisms form the molecular basis for the preference of different MHC alleles for different peptide sequence motifs, and they enable each MHC molecule to bind a different set of peptides. It has been demonstrated that MHC polymorphism causes differences in levels of human resistance to specific infections and ensures that, within a species, a broad ability to bind peptides derived from a pathogenic challenge exists.<sup>49,50</sup>

MHC diversity is, of course, what makes the job of the transplantation surgeon so difficult and must be taken into account by the cancer immunotherapist. For example, tyrosinase, which is a tumor antigen associated with normal melanocytes and with melanoma cells, has an epitope that is presented to lytic CD8+ T lymphocytes in the context of the human leukocyte antigen HLA-A24.<sup>51</sup> Use of this peptide in a patient not expressing this class I molecule is likely to be ineffective, because that particular peptide would be unlikely to bind efficiently to other class I alleles and because the appropriate presenting molecule would not be found in that patient.

## DIFFERENCES BETWEEN MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I AND CLASS II MOLECULES

Although class I and class II molecules are united by their function as receptors for antigenic peptides, the differences in structure and intracellular trafficking are critical. Class I and class II molecules differ structurally, have different genetic organization and tissue distribution, present bound peptides to different T-cell subsets, and elicit different types of immune responses. Class I and class II molecules also differ in their requirements for binding of peptide antigens, and these peptides originate from different sources. Finally, the two types of MHC follow different intracellular routes on their way to the cell surface and noncovalently associate with peptides in different subcellular compartments.

### Recognition of Major Histocompatibility Complex–Antigen Complexes by T-Cell Subsets

There are many interactions involved in T-cell activation, but the specificity of T-cell recognition of a cognate partner cell occurs via the interaction of the TCR with an MHC molecule to which is bound a peptide. The TCR, which is a heterodimer associated on the cell surface with the CD3 complex,<sup>52</sup> is discussed in greater detail later, under Antigen-Specific T-cell Receptors. Although no clear structural or sequence differences between TCRs' detecting class I and detecting class II molecules have been found, a clear difference between the two sets of T cells is found in the ligands for the cell surface markers CD4 and CD8, from which the T-cell sets derive their names. CD8 molecules bind to the  $\alpha_3$  domain of the class I molecules on the target cell,<sup>53,54</sup> and CD4 molecules bind to the  $b_2$  domain of the class II heterodimer on the target cell.<sup>56,57,58</sup> and <sup>59</sup>

Some peptide-MHC complexes, designated *antigenic*, trigger a T-cell response that can consist of proliferation, up-regulation of surface molecules, activation of lytic machinery, secretion of cytokines, or even death by apoptosis. The minimum number of MHC molecules that must be occupied by a particular peptide to activate a very responsive T cell is thought to be extremely low: on the order of 0.03% of the total MHC or fewer than several hundred peptide-MHC complexes.<sup>60,61</sup>

### Sources of Antigens Bound by Major Histocompatibility Complex Class I and Class II Molecules

Antigens complexed with MHC class I and class II molecules originate from two different sources ( [Fig. 4-3](#)). Class I molecules generally present antigens derived from intracellular sources, whereas class II molecules usually present antigens derived from extracellular sources, although clear examples exist that contradict this distinction, especially in “professional” APCs.<sup>62</sup> A more precise understanding of the difference in the sources of antigens can result from an understanding of patterns of intracellular trafficking of these two sets of molecules: Class II molecules intersect endocytosed antigen, whereas class I molecules efficiently bind to intracellular antigens in the endoplasmic reticulum.<sup>63,64</sup> Thus, antigens or antigenic fragments intersecting with the endoplasmic reticulum can be presented by class I molecules; those that intersect with the endosomal subcellular compartment can be presented by class II molecules.

**FIGURE 4-3.** Intracellular trafficking pathways in the presentation of endogenous and exogenous antigen (Ag). CPL, compartment for peptide loading; SRP, signal recognition particle; TAP, transporter associated with antigen processing.

As a result of the differences in the cell biology of MHC molecules, peptides binding to class I molecules are derived mainly from intracellular-cytosolic proteins such as histones and stress proteins, whereas class II peptides are derived primarily from membrane glycoproteins or serum proteins known to enter the acidic vacuolar

compartment in large quantities.<sup>65,66</sup> Naturally processed peptides bound to class I molecules are of a very specific size (8 to 10 amino acids) and are smaller than those bound to class II molecules (12 to 20 amino acids), which are much more variable and often nested.<sup>65,66</sup> These peptides bind to MHC molecules with affinities that can range from the picomolar to micromolar range. Despite a restricted length of peptides presented by MHC class II molecules and the even more restricted length of those presented by class I, a tremendous amount of specificity can still occur. (Note that it is possible to make at least  $5 \times 10^{11}$  different peptides of nine amino acids.)

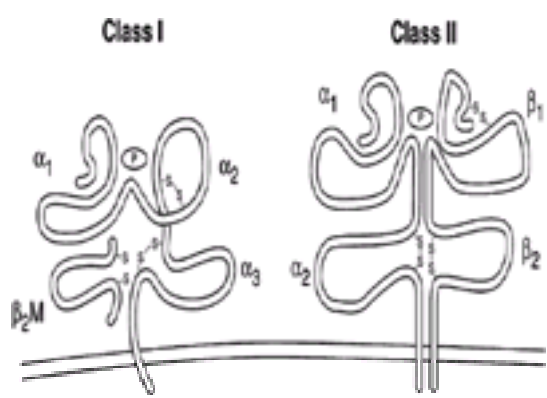

It is now possible to forecast which epitopes within a protein will bind to particular MHC molecules. Allele-specific epitope forecasting has now been done with a large number of human and murine MHC molecules,<sup>67,68,69,70</sup> and <sup>71</sup> which are characterized by strong preferences for particular amino acid side chains at some positions in the bound peptides and a wide tolerance for amino acid side chains at other positions. Although the anchor positions are critically important in the prediction of which peptides will bind to particular MHC molecules, the amino acid side chains at other positions can play a role and cannot be disregarded.<sup>72</sup>

## MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I PATHWAY FOR ANTIGEN PROCESSING

CD8+ T lymphocytes are able to monitor the contents of cells by interacting with class I molecules, presenting a display of peptides carried from the endoplasmic reticulum (ER) to the cell surface.<sup>73,74</sup> and <sup>75</sup> Antigen processing is generally necessary for the expression of class I molecules at the cell surface, because class I  $\alpha$  chains do not efficiently exit the ER in large quantities unless they are fully assembled with peptide and  $\beta_2$ -microglobulin. Furthermore, they need to bind a peptide to be thermodynamically stable. “Empty” class I molecules appear to be unstable at 37°C but somewhat more stable at lower temperatures.<sup>76</sup> Such empty class I molecules are short-lived and subject to proteolysis but nevertheless are expressed at relatively low levels by certain cells, especially those deficient in antigen processing. Because most nucleated cells express stable class I molecules on their cell surfaces, antigen processing is probably a universal characteristic of normal cells. Thus, the molecules involved in the processing of antigen are likely to be expressed ubiquitously as well.

### Structure of Major Histocompatibility Complex Class I Molecules

Class I molecules are heterodimers composed of an extremely polymorphic 45-kD  $\alpha$  chain and  $\beta_2$ -microglobulin. Class I molecules are considered by some to be true heterotrimers, as a peptide eight to ten amino acids long having a molecular weight of approximately 1 kD is required for stability and proper expression. Highly schematic structures of class I and class II molecules are shown in [Figure 4-4](#). A bound peptide is presented by the class I molecule.

**FIGURE 4-4.** Highly schematic diagram of the domain structure of class I and class II.  $\beta_2$ -M,  $\beta_2$ -microglobulin; P, peptide; S, disulfide links.

The  $\alpha$  chains of class I molecules (also called *heavy chains*) are encoded in the genome in an eight-exon form. The first exon encodes a signal peptide or leader sequence that directs insertion of the rest of the nascent class I molecule into the ER during translation. The next three exons encode the three large extracellular domains (see [Fig. 4-4](#)). The  $\alpha_1$  and  $\alpha_2$  domains are directly involved in the binding of peptides. The  $\alpha_3$  domain (exon 4) contains the nonpolymorphic region that is the ligand for the CD8 molecule and shares close homology with the constant region of Igs. Note that  $\beta_2$ -microglobulin also shares structural homology with the Ig constant regions. Exon five encodes a 25–amino acid transmembrane region that forms a hydrophobic  $\alpha$  helix that anchors class I into the cell membrane. A short intracytoplasmic segment (30 amino acids long encoded by exons 6, 7, and 8) is involved in the intracellular trafficking of class I molecules and contains regions that interact with the cytoskeleton as well as residues that can be phosphorylated by cyclic adenosine monophosphate–dependent protein kinase A and pp60 src kinase.

$\beta_2$ -microglobulin is a structural component of the MHC class I molecule presented on the cell surface and plays an indispensable role in the proper folding of the 45-kD class I  $\alpha$  chain. The  $\beta_2$ -microglobulin molecule is noncovalently associated with the  $\alpha$  chain. Its gene is not encoded within the MHC and has minimal polymorphism, even among mammalian species. A number of human cell lines, including melanomas, renal cell cancers, and a cell line named *Daudi*, express virtually no class I on their cell surfaces as a result of absent or mutated  $\beta_2$ -microglobulin.<sup>77,78</sup> Thus, in these cell lines, the class I  $\alpha$  chain molecules do not fold properly, never leave the ER, and are degraded rapidly.  $\beta_2$ -microglobulin-deficient mice have been found to express little, if any, functional class I antigen and have no mature CD8+ T cells.<sup>79</sup>

### Origin and Generation of Peptides: The Proteasome

The task of generating peptide fragments from intracellular proteins for presentation by class I molecules is achieved, in part, by a molecular complex known as the *proteasome*.<sup>80</sup> This bulky complex has a remarkable ring-like appearance when visualized through the electron microscope and is composed of at least 16 subunits. Highly conserved through evolution, the proteasome is thought to be involved in the protein economy of cells. This primitive structure was likely adapted by the eukaryotic immune system to sample the products of cellular proteolysis for display to the immune system by MHC class I.<sup>81</sup>

Two polymorphic proteasome component genes (low-molecular-weight proteins) are encoded in the class II region of the MHC and are designated *LMP-2* and *LMP-7* and appear to affect the peptide sets that are generated by this structure. Like many of the molecules involved in antigen processing and presentation, the expression of *LMP-2* and *LMP-7* is up-regulated by IFN- $\gamma$ .<sup>82,83</sup> and <sup>84</sup> Interestingly, low or absent expression of these two molecules has been found in some cancer cells.<sup>85</sup> Another molecule, called *MECL-1*, or *LMP-10*, is also up-regulated by IFN- $\gamma$  and can replace the proteasome subunit Z.<sup>86</sup>

Other proteasomal subunits that may play a positive role in the processing of some antigens are PA28 and PA700. Although their precise functions are unknown, these subunits may aid in the unfolding or degradation of protein substrates. One model proposes that the proteasome binds to molecules that transport peptides across the ER membrane, but this mechanism remains to be demonstrated. IFN- $\gamma$  changes the proteolytic activity of proteasomes, perhaps to favor the production of peptides capable of binding to MHC class I.<sup>87</sup>

Many cytosolic proteins, the peptide fragments of which eventually find their way onto MHC class I molecules, are first ubiquitinated. Ubiquitin, a protein so named because it seemed to exist everywhere inside the cell at the same time, is attached to proteins that have been targeted for degradation. This attachment is covalent and is mediated by a clustered triad of enzymes called *E1*, *E2*, and *E3*. Ubiquitinated proteins generally are proteolytically degraded by the proteasome.<sup>88</sup>

### Translocation of Peptides by TAP and the Role of Tapasin

Once peptide fragments are generated in the cytosol, they must be transported into the ER, a task largely carried out by another product of the MHC region, the transporter associated with antigen processing, called *TAP*. The genes encoding TAP are located in the MHC class II region in both the human and mouse genomes and are interdigitated with the genes encoding the two LMP components of the proteasome. The TAP heterodimer is an adenosine triphosphate–dependent peptide pump, is a member of the ABC (ATP-binding cassette) superfamily of transmembrane transporters, and is related to the products of the multidrug resistance gene.<sup>89,90,91,92</sup> and <sup>93</sup> TAP transfers peptides from the cytoplasm directly to newly synthesized class I molecules.<sup>94</sup> There is a growing body of evidence for the selectivity

of peptide transport by TAP, although the specificity of the TAP peptide-binding site is more promiscuous in human cells than in mouse cells.

In addition to their role in antigen processing, TAP molecules are involved in the assembly of the class I a chain/b<sub>2</sub>-microglobulin/antigenic peptide trimolecular complex through a molecule called *tapasin*.<sup>95</sup> Tapasin, a 48-kD protein, binds to newly born MHC class I heavy-chain b<sub>2</sub>-microglobulins that have not yet been loaded with peptide, as well as to the TAP heterodimers. Tapasin may facilitate peptide loading of class I molecules in a number of ways. First, it approximates empty class I molecules to the transporters by tethering the two together. Second, tapasin may regulate TAP function by inhibiting TAP's ability to transport peptides in the absence of empty class I molecules in the ER. Third, a part of the tapasin molecule has been hypothesized to bind directly, but with low affinity and with a fast off-rate, to the peptide-binding cleft of the class I heavy chain. This interaction might be similar to the way the peptide-binding grooves of "empty" MHC class II molecules are occupied by a piece of the invariant chain known as *CLIF* [described later in the section [Role of Invariant Chain \(Ii\) in the Folding, Trafficking, and Protection of Class II](#)]. ER-60 is part of the late assembly complexes consisting of MHC class I, tapasin, TAP, calreticulin, and calnexin.

Classical class I molecules assemble in the ER with peptides mostly generated from cytosolic proteins by the proteasome. The activity of the proteasome can be modulated by a variety of accessory protein complexes. A subset of the proteasome b subunits (LMP-2, LMP-7, and MECL-1) and one of the accessory complexes, PA28, are up-regulated by IFN- $\gamma$  and affect the generation of peptides to promote more efficient antigen recognition. The peptides are translocated into the ER by TAP. A transient complex containing a class I heavy-chain b<sub>2</sub>-microglobulin dimer is assembled onto the TAP molecule by successive interactions with the ER chaperones calnexin and calreticulin and a specialized molecule, tapasin. Peptide binding releases the class I b<sub>2</sub>-microglobulin dimer for transport to the cell surface, while lack of binding results in proteasome-mediated degradation. The products of certain nonclassical MHC-linked class I genes bind peptides in a similar way. A homologous set of b<sub>2</sub>-microglobulin-associated membrane glycoproteins, the CD1 molecules, appears to bind lipid-based ligands within the endocytic pathway.

### **Chaperones in the Class I Pathway**

Although the class I pathway generally presents peptides of cytoplasmic origin, exogenous antigens that are chaperoned by a heat-shock protein (HSP) can gain access to the class I processing pathway of certain cells, such as particular subsets of macrophages.<sup>96,97</sup> HSPs derived from tumor cells may be useful in stimulating antitumor CTLs *in vitro*.<sup>98,99</sup> Furthermore, inoculation of purified HSPs derived from tumor cells can induce protective immune responses against subsequent tumor challenge in experimental animal systems.<sup>100</sup>

Chaperone proteins are involved in the folding of nascent or incompletely folded proteins and are thought to aid proteins in gaining their proper conformation. Two important chaperones that help glycoproteins in the ER to fold are calnexin and calreticulin. Immature class I molecules have been shown to associate transiently with an 88-kD protein called *calnexin*.<sup>101</sup> Calnexin (also called *P88* or *IP90*) probably is involved in the folding of class I molecules. Association of class I a chains with b<sub>2</sub>-microglobulin and peptide is likely to cause dissociation of the chaperone molecules.<sup>102</sup> In addition to its possible functions in protein folding, calnexin may be considered a quality-control molecule, because it prevents unfolded, misfolded, or incompletely assembled a chain molecules from exiting the ER.<sup>101,103,104,105,106 and 107</sup> Calnexin plays a similar role for other proteins, among them such immunologically important proteins as MHC class II<sup>108,109 and 110</sup> and the a/b chains of the T-cell receptor, which do not leave the ER until they are fully assembled with the CD3 complex. *Calreticulin*, another ER-resident molecule, is a lectin-like chaperone that may replace calnexin after the MHC class I heavy chain binds with b<sub>2</sub>-microglobulin.<sup>111</sup> Calreticulin clearly differs from calnexin in the way that it associates with class I. Another molecule known to associate with immature Ig molecules, called *BiF*, also may associate with a subset of class I molecules or may associate with class I molecules in some not-yet-understood sequence with calnexin.

### **Role of Interferon- $\gamma$**

There is genetic evidence for the related functions of many of the various molecules described in the class I pathway: TAP and proteasome component molecules appear to be very closely associated with the MHC region encoding class I a chains and class II on chromosome 17 in the mouse or chromosome 6 in the human. Many of these groups of molecules appear to be regulated in concert, with IFN- $\gamma$  as the conductor. Molecules known to be up-regulated by IFN- $\gamma$  include at least two, but probably three, proteasome component and regulatory molecules,<sup>112</sup> the peptide transporters, class I heavy chain, and b<sub>2</sub>-microglobulin. Note also that some HSPs also are inducible with IFN- $\gamma$ .<sup>113</sup> Thus, these groups of molecules appear to share regulatory elements that allow them to be regulated in concert.

### **Nonclassical Major Histocompatibility Complex and Non-Major Histocompatibility Complex–Encoded Class I Molecules**

Nonclassical MHC molecules often are labeled as *MHC class Ib molecules* in the literature. It is now clear that this group of molecules includes members that are not encoded with the MHC region of the genome. As a group, nonclassical MHC molecules generally are expressed at low levels. They are characterized by limited polymorphism, in stark contrast to MHC class I or class II molecules, which are among the most polymorphic genes to be described. Here, we summarize only briefly some examples of nonclassical MHC molecules. A number of excellent reviews of the topic have recently been published.<sup>114,115 and 116</sup>

One important class Ib molecule is designated *HLA-E*. Its homologue in the mouse is likely to be *Qa-1*. These molecules have limited sequence polymorphism and are expressed on many different tissues. An important function appears to be modulation of NK-cell activity through binding with NK cell surface CD94/NKG2A (inhibition) or CD94/NKG2C (activation).<sup>117</sup>

*HLA-G* molecules are expressed by the placenta at the maternal-fetal interface. Mice appear to lack any homologue. Although *HLA-G* is nonpolymorphic, it behaves in many ways like classical class I molecules in that its loading in the ER is TAP-dependent and it binds to b<sub>2</sub>-microglobulin. *HLA-G* binds to peripheral blood myelomonocytic cells.<sup>118</sup> Like *HLA-E*, it may contribute to the inhibition of NK cells.<sup>119</sup>

Two other MHC class Ib molecules warrant mention. The first is the mouse *H2-M3* molecule, which appears to have a specialized capacity to bind to N-formylated peptides. Formylated peptides are characteristic of some peptides derived from microorganisms, as well as from "self" mitochondrial proteins. Finally, *CD1* is a molecule encoded outside the MHC that is capable of interacting with both ab and gd T cells.<sup>120</sup> *CD1* appears to be able to bind and present hydrophobic lipid- and lipoglycan-containing molecules.<sup>121,122</sup> At least two different forms of *CD1* exist—*CD1a* and *CD1b*—which exhibit different intracellular trafficking patterns and some differences in function.<sup>123,124</sup>

## **MAJOR HISTOCOMPATIBILITY COMPLEX CLASS II PATHWAY FOR ANTIGEN PROCESSING**

The ability of a cell to process antigens via the class II pathway (see [Fig. 4-3](#)) is more specialized than the almost ubiquitous ability of nucleated cells to process antigen via the class I pathway. Class II–producing cells include macrophages, dendritic cells, Langerhans cells, and B lymphocytes. These cells not only bear class II heterodimers but also possess the invariant chain monomer, the requisite enzymatic machinery, an important subcellular compartment, and molecules called *HLA-DM*, whose essential function in the class II pathway was discovered more recently. As in the class I system, the interaction of class II–peptide complexes with T cells can now be studied with class II tetramers.<sup>125</sup>

### **Structure and Assembly of Major Histocompatibility Complex Class II Molecules**

The class II molecule is very similar to the class I molecule in its general shape, but it is composed of an a chain of 34 kD and a b chain of 28 kD, both of which are integral membrane glycoproteins (see [Fig. 4-4](#) for a highly schematic representation). a and b chains have transmembrane regions as well as short intracytoplasmic regions. The a<sub>1</sub> and b<sub>1</sub> domains of the class II molecule correspond to the a<sub>1</sub> and a<sub>2</sub> domains of the class I molecule and thus are directly involved in the binding of the presented peptide. The a<sub>2</sub> domain of class II corresponds with the b<sub>2</sub>-microglobulin light chain of class I. Finally, the b<sub>2</sub> domain of class II corresponds with the a<sub>3</sub> domain of class I and is involved in the binding of CD4.

Newly synthesized MHC class II molecules assemble in the ER. Three a/b dimers assemble together with an invariant chain trimer to form a nine-chain structure.<sup>126</sup> Such a conglomeration is thought to stabilize these molecules during their transport through the Golgi apparatus and into the endosomal system (sometimes via the cell surface), where they intersect with peptides in a specialized subcellular compartment called the *compartment for peptide loading (CPL)* by some workers.

### Compartment for Peptide Loading

The peptides ultimately presented by class II are derived from protein molecules that generally are acquired from outside the cell (i.e., exogenous) by endocytic vesicles. These vesicles change in composition as they move away from the periphery of the cell toward the nucleus, become acidified, and acquire high concentrations of proteolytic enzymes. Pharmacologic agents, such as chloroquine, that disrupt intracellular pH gradients inhibit antigen processing. Furthermore, mutant cell lines, defective in endosomal acidification, diminish antigen-processing abilities. In B cells, surface-bound Ig molecules may be involved in the acquisition of antigens for presentation. Protein molecules to be presented by the class II pathway are processed by denaturation and proteolysis to short linear segments, some of which fit into the antigen-binding groove of class II molecules. These peptides play a role in determining the structure of class II heterodimers.

A unique endosome-related subcellular compartment has been identified in specialized APCs that naturally express class II. Class II molecules are loaded with antigen in this specialized compartment known as the CPL.<sup>127,128,129 and 130</sup> Morphologically, CPLs are somewhat heterogeneous in structure. They are spherical or tubular and contain internal membrane vesicles or infoldings, covered with class II a/b. These infoldings presumably increase the surface area for class II and help optimize exposure to potentially antigenic peptides. The invariant chain, Ii, likely targets the class II a/b/Ii complex to the CPL, probably by a dileucine motif in the cytoplasmic tail of the Ii.<sup>127</sup> Because the FcR11-B2 receptor also contains a dileucine motif, such a motif could be implicated in the specific delivery of antigen complexed with antibody to the CPL.

### Role of Invariant Chain (Ii) in the Folding, Trafficking, and Protection of Class II

Class II heterodimers associate with the Ii in the ER soon after synthesis. Dissociation occurs before expression on the cell surface (see Fig. 4-3). The invariant chain (Ii) has a single transmembrane domain and an amino-terminal cytoplasmic tail. It is coded for on human chromosome 5 and mouse chromosome 18, and it therefore is not genetically linked with the MHC. Human Ii has been found in at least four forms: p33, p35, p41, and p43. These variations result from combinations of alternative splicing and alternative points of the initiation of translation; their different functions are incompletely understood.<sup>131</sup>

Ii is known to have at least three important functions. First, it facilitates the folding of class II molecules in a chaperone-like fashion. Second, a specialized portion of the Ii called CLIP binds to and protects the peptide-binding site from binding by peptides before the designated physiologic site, the CPL.<sup>132</sup> Finally, the cytoplasmic tail of Ii contains an endosomal targeting sequence that directs cellular routing of associated class II heterodimers.

### Facilitating Peptide Loading with HLA-DM

Efficient processing of extracellularly derived protein antigens for presentation on class II molecules does not occur in the absence of HLA-DM. The human and the murine (designated *H-2M*) versions of this molecule are heterodimers, the counterparts of which are called *DMA* and *DME* in the human and *H-2DMA* and *H-2DMb* in the mouse.<sup>133</sup>

These molecules are similar in structure to classical MHC class II molecules, but they are functionally distinct. They do not present peptide antigens to CD4+ lymphocytes but instead reside in the CPL. HLA-DM is likely to induce the dissociation of a nested set of Ii-derived peptides (CLIP) from MHC class II a/b dimers and facilitates peptide loading.<sup>134</sup> This is likely to be a direct enzyme-like interaction that is optimized at an acidic pH.

### ANTIGEN PROCESSING AND PRESENTATION IN MALIGNANCY

Most cells in the body express class I peptide complexes, which are the ligands for the TCR on CD8+ T cells. Some tumor cells clearly present antigenic peptides in the context of class I, because specific recognition of tumor cells by cytolytic CD8+ T cells results in their destruction *in vitro* and *in vivo*. Tumor cells that fail to process or present antigen recognizable by T cells may enjoy a selective advantage, because they are not susceptible to antigen-specific T cells.<sup>135</sup>

Tumor cells escape antigen-specific T-cell recognition by a number of mechanisms. For example, some tumor cells derived from epithelium express either greatly reduced or absent levels of class I molecules on their surfaces. These histologies include embryonal carcinomas, choriocarcinomas, cervical carcinomas, mammary carcinomas, small cell carcinomas of the lung, neuroblastomas, some colorectal carcinomas, and some melanomas. Other tumors, including melanoma and renal cell carcinoma, have been shown to lose b<sub>2</sub>-microglobulin.<sup>77,78</sup> Other tumors can down-regulate the expression of particular class I loci,<sup>136</sup> or lose the genes for particular class I chains.<sup>137</sup> Still other tumors, including small cell carcinoma of the lung, can down-regulate the proteasome component molecules LMP-2 and LMP-7 and TAP1 and TAP2.<sup>85</sup>

### SPECIALIZED ANTIGEN-PRESENTING CELLS

How are antigens, and tumor antigens in particular, presented to the immune system *in vivo*? Although most tumor cells express class I molecules and some tumor cells express class II molecules, they generally do not express an important set of products called *costimulatory molecules* (discussed in detail in the next section, [Dendritic Cells](#)), which are believed to be critical for the activation of many T cells resting from prior stimulation and for the activation of all naive T cells. Naive T cells are those that have not been stimulated by antigen outside the thymus. Specialized cells designated as *accessory cells* can help lymphocytes to respond to antigens. These cells include, first and foremost, dendritic cells (DCs), but they also include mononuclear phagocytes (monocytes and macrophages), activated B lymphocytes, and follicular dendritic cells (FDCs). They are distinguished functionally from the vast majority of somatic cells that can present antigens in the context of MHC only for recognition as target cells by effector T cells. Antigen stimulation by "professional" APCs, exemplified by activated DCs, can stimulate responses not only by resting T cells but also by naive T cells.

### DENDRITIC CELLS

DCs were so named because of their distinctive cell shapes. They continually extend and retract processes that are reminiscent of dendrites in neural tissue. These processes presumably increase the DCs' surface area and its ability to sample surrounding tissues. DCs can be differentiated from macrophages by their lack of Fc receptors and their poor endocytic capacity. While macrophages are persistently adherent to plastic *ex vivo*, DCs are transiently adherent. They abundantly express MHC class II molecules as well as a number of costimulatory molecules.<sup>138,139</sup>

DCs are far more potent initiators of T-cell-dependent immune responses than any other APC that has been tested.<sup>140</sup> They have a remarkably high density of both class I and class II molecules on their surfaces,<sup>141</sup> which are loaded with processed antigen acquired in large part from exogenous sources.<sup>142</sup> DCs are of hematopoietic origin, but they lack B, T, and NK markers, and no specific or unique differentiation antigen has been found on their surfaces. They can be derived from mononuclear phagocytes under the influence of immunomodulatory molecules *in vivo*.<sup>143</sup> DCs express large quantities of the costimulatory molecules B7-1/CD80 and B7-2/CD86 as well as other T-cell-activating ligands, including intracellular adhesion molecule-1/CD54 (ICAM-1/CD54). They are likely to play an important role in the activation of antitumor T cells *in vivo*.

DCs are mobile, traveling from the epidermis to the afferent lymphatics as part of a process of maturation. They can be found in peripheral blood or in bone marrow, but in extremely low numbers, and generally are isolated from spleen or blood by a combination of their buoyant density and their adhesive properties. Although dendritic cells are a rare fraction of the total leukocyte population, they can present antigens efficiently for several days after activation. They acquire this antigen through a process called *cross-priming* or *cross-presentation* in which T-cell responses are activated, by DCs, to cellular antigens that originate outside of the DCs.<sup>144,145 and 146</sup> DCs can be activated by a number of stimuli including lipopolysaccharide (LPS), the interaction of CD40 and CD40 ligand, and double-stranded RNA.<sup>147,148 and 149</sup>

### FOLLICULAR DENDRITIC CELLS

FDCs differ from the DCs in many ways. FDCs are likely to be stromal or fibroblast in origin and, unlike DCs, are not from bone marrow stem cells. Although their name may be confusing, suggesting some relationship to DCs, FDCs are, in fact, functionally unrelated to DCs. Their role in the activation of antitumor responses is unclear, but they may have an immunologic role in the activation of B lymphocytes.

## B LYMPHOCYTES

B cells can concentrate antigen using membrane-bound Ig. Activated B cells can also express large quantities of the costimulatory molecules B7-1 and B7-2. Finally, B cells clearly present exogenous antigens to CD4+ T cells via their class II molecules, and this is a mechanism for B-cell stimulation of antigen-specific T-cell help.

## MONOCYTES AND MACROPHAGES

Mononuclear phagocytes consist mainly of macrophages and monocytes. Monocytes are more differentiated and have more endocytic activity than do macrophages. Macrophages are found in virtually all tissues, especially surrounding blood vessels and near epithelial cells. They generally have what is called a *stellar* morphology. Once they are differentiated, monocytes and macrophages do not divide under normal circumstances. Macrophages in different tissues have different morphologies and different functions. For example, liver macrophages (generally designated *Kupffer cells*) are located in the sinusoids. The Kupffer cells are the major cellular system responsible for the clearance of particulate material or microbes from the circulation. Kupffer cells play a central role in the acute-phase response, releasing IL-1, IL-6, and TNF on phagocytosing bacteria and their products. Macrophages in the peritoneum are a heterogeneous group of cells and can be microbicidal and tumoricidal. Alveolar macrophages efficiently remove particulate materials from the alveolar spaces. They also secrete proteases and bactericidal molecules. Macrophages in bone (osteoclasts) are specialized multinucleated giant cells that are involved in bone resorption and turnover.

Immunologically, macrophages participate as APCs. They can express high quantities of adhesion molecules and, importantly, they express on their surfaces the costimulatory molecules in the B7 family. As noted later, macrophages can participate as major effector cells in antitumor responses and in resisting infectious agents. Finally, macrophages can serve to dampen the immune response by secreting inhibitory cytokines such as IL-10; transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1), - $\beta$ 2, and - $\beta$ 3; and an IL-1 receptor antagonist. They also ameliorate the cellular immune response by promoting connective tissue repair via such factors as fibroblast growth factor.

## T-CELL RECOGNITION OF ANTIGENS

Immune activities of T cells commonly are stimulated after they bind to certain types of other cells. The activities are not stimulated simply because of the binding, however. A variety of receptor-ligand interactions occur between the two cell surfaces that initiate T-cell activation. One of these interactions, that between TCRs and MHC-antigen complexes on the opposing cell surface, is critical for normal antigen-specific activation of most T cells.

## ANTIGEN-SPECIFIC T-CELL RECEPTOR

Like other cells, T cells express a wide array of cell surface receptors for different ligands. However, that which is distinctively designated *T-cell receptor* reacts with specific antigens, albeit generally only after proper processing and presentation by MHC on a target cell surface. The TCR consists of two paired proteins that form a transmembrane, nonsecreted heterodimer unique for each clone of T cells and determining the antigen specificity of the TCR. <sup>150</sup> Two types of TCR have been identified, the  $\alpha\beta$  heterodimer and the  $\gamma\delta$  heterodimer. The crystal structures, determined for four TCRs complexed with peptide-MHC class I and for one TCR complexed with peptide-MHC class II, demonstrate the structural basis for a TCR recognizing both peptide and MHC. <sup>151,152</sup> In addition, recently developed, soluble, fluorescent peptide-MHC complexes permit identification of individual T cells with a particular antigen specificity, including human tumor antigens. <sup>153,154 and 155</sup>

### *T-Cell Receptor Genetics*

TCR genetics provide the primary source of TCR diversity and antigen specificity. The  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  genes encode the TCR by rearrangement from their germline configuration, as do Ig heavy- and light-chain antibody genes. Families of TCR variable (V) genes exist for each receptor chain. During T-cell differentiation, one of the V genes rearranges its position among other gene segments by connecting with one of several alternative joining (J) genes, as a result of losing intervening DNA. A diversity (D) gene between the V and J genes is represented in some but not all classes of chains. This rearranged V(D)J segment encodes the variable region of each TCR chain. After combination with a constant (C) gene, generation of RNA, and RNA splicing to remove unused intervening sequences between V(D)J and C regions, the final protein chain is expressed.

The extracellular, amino-terminal portion of the molecule contains the antigen-binding variable segment, whereas the carboxyl-terminal portion contains the constant region. In contrast to antibodies, the constant region of the T-cell receptor does not contain different subregions that relate to differences in function, such as binding complement or binding to receptors on the surfaces of other cells. The major functions of the constant region appear to be to provide membrane attachment for the TCR and to participate in signal transduction.

The overall diversity in each TCR chain is the result of independent selection of any one of the multiple variable V, D, and J segments and of the combinatorial diversity inherent in the large number of permutations among these choices. Different possible  $\alpha\beta$  or  $\gamma\delta$  pairings also contribute to the TCR diversity. Both molecular and serologic probes allow the determination of specific V-, D-, and J-region usage for the antigen receptor chains of a given TCR. Although somatic mutation does not appear to be a source of diversity in TCRs, non-germline-encoded (N) regions at the junctional sites between V-, D-, and J-encoded segments add to overall receptor diversity.

### *T-Cell Receptor Structure*

Through a process of differentiation, a mature receptor-bearing T cell will express either an  $\alpha\beta$  or a  $\gamma\delta$  heterodimeric TCR. Nearly all T cells that have been characterized as recognizing specific antigens in an MHC-restricted fashion express  $\alpha\beta$  receptors. <sup>150</sup> On the cell surface,  $\alpha$  and  $\beta$  chains, each approximately 40 to 45 kD in molecular weight, are disulfide-linked. Each mature T cell expresses only one  $\beta$  chain gene, because productive rearrangement of a TCR  $\beta$  gene prevents subsequent full rearrangements of other  $\beta$  genes (allelic exclusion), with rare exceptions. <sup>156,157</sup> The TCR  $\alpha$  gene is not subject to allelic exclusion, and T cells have the potential to express two different  $\alpha$  chain genes, one from each allele. <sup>158</sup> Most individual T cells, however, appear to be limited to the functional expression of antigen receptors with the same  $\alpha$  chains. <sup>159</sup>

A high frequency of T-cell clones react not only with the foreign antigens that stimulated their response but also with allo-MHC determinants. <sup>160</sup> This dual reactivity may represent cross-reactivity of a single TCR with different antigens, which would maintain the rule of one cell, one receptor. Nevertheless, the possibility of significant numbers of T cells expressing two TCR  $\alpha\beta$  receptors has not been excluded. <sup>161,162</sup>

The second class of T cells are those expressing  $\gamma\delta$  heterodimers in place of  $\alpha\beta$  heterodimers. <sup>150,163,164 and 165</sup> The  $\gamma$  and  $\delta$  chains are also the products of rearranged genes. The family of V-region genes in the germline is smaller than that for  $\alpha$  and  $\beta$  chains; however, additional mechanisms of diversification exist that expand the mature TCR  $\gamma\delta$  repertoire. Antigen processing and presentation commonly are not needed, and the antigen specificity mediated by  $\gamma\delta$  receptors is predominantly MHC-unrestricted. Indeed, many TCR  $\gamma\delta$  receptors may recognize intact proteins in their native configuration, as Igs do, rather than as MHC-restricted peptides. TCR  $\gamma\delta$  receptors are not much involved in most of the classical T-cell responses; however, they appear to serve important roles in the immune system. They can react with a variety of different antigens, particularly certain HSPs and phosphate-containing nonpeptidic bacterial antigens that have been highly conserved during evolution. TCR  $\gamma\delta$  cells are in the epithelia of the skin, lung, female reproductive tract, and intestine, where they may contribute to an early line of host defense.

### *T-Cell Receptor CD3 Complex*

Expression of TCRs at the cell surface and also triggering of T cells after the cross-linking of TCRs through binding with antigen depend on the close but noncovalent association of TCRs with the CD3 complex, which consists of several invariant proteins. <sup>166</sup> Cytoplasmic portions of this complex are critical to TCR-initiated signal transduction, and particular extracellular portions provide serologic markers commonly used to define mature T cells with anti-CD3 antisera.

### *Stimulation of T-Cell Receptors by Superantigens*

Superantigens involve a very different type of interaction between the TCR, MHC, and antigen that results in linking TCR and MHC. <sup>167,168,169 and 170</sup> Superantigens (SAGs) bind in varying degrees to many MHC class II molecules on the target cells and to selected TCR  $\beta$  chain variable (V $\beta$ ) regions on T cells, away from the classic

antigen-binding regions of these molecules. Crystal structures have been determined for the complex of staphylococcal enterotoxin B (SEB), a bacterial superantigen, with TCR and also for SEB with MHC class II.<sup>171,172</sup> T-cell specificity for SAg is determined by whether the T cell expresses the relevant TCR V $\beta$  region. SAg do not require antigen processing and are not MHC-restricted in the classic sense, as they bind to sites on the MHC class II molecule away from the antigen-binding groove. They may be soluble or bound to cells, and they may arise from endogenous cellular genes. SAg studied thus far are primarily viral and bacterial products, including streptococcal pyrogenic toxins and staphylococcal enterotoxins, notably connected with toxic shock syndrome and selected types of food poisoning. SAg also appear to be associated with the human immunodeficiency and rabies viruses. Because of SAg's binding properties, they can interact with a far higher proportion of T cells than do standard T-cell antigens. Both CD4+ and CD8+ T cells, and possibly T cells expressing selected TCR  $\gamma\delta$  receptors, can be stimulated by SAg. Like T-cell responses to standard antigens, the potential results of SAg stimulation include T-cell proliferation, cytokine production, enhanced expression of particular cell surface molecules, cytotoxic activity, and anergy or cell death.

### **Major Histocompatibility Complex–Independent Stimulation of T-Cell Receptors**

Cross-linking of TCR/CD3 complexes with subsequent cluster formation appears to be a basic requirement for antigen-specific signal transduction in T cells.<sup>173</sup> Antibodies against extracellular domains of the TCR/CD3 complex will substitute for the MHC-antigen complex if the antibodies are anchored to a surface, such as to other cells through the Fc portion of the antibody or to an artificial surface such as plastic. If the antibody specificity is against a nonpolymorphic determinant, T cells are nonspecifically stimulated. On the other hand, if the antibody specificity is against a determinant unique to the TCR, then T-cell stimulation is highly specific.

T-cell mitogens, such as concanavalin A, bind to a variety of cell surface glycoproteins and stimulate T cells in a nonspecific fashion. The stimulation may depend on cross-linking of the TCR/CD3 complex by the mitogens.

Some antigens that are not SAg may be recognized by T cells in a fashion that is not MHC-restricted and does not require antigen processing.<sup>163,164,174</sup> Described as being among these antigens are selected polyvalent haptens, myelin basic protein, the heme component of hemoglobin, and underglycosylated mucins produced by particular adenocarcinomas of the breast, pancreas, colon, and ovary. A common feature of these particular antigens is tandem repeats of an epitope, such as a particular amino acid sequence for tumor mucins. One model envisioned for this reactivity is based on an antigenic molecule with a polyvalent epitope that mediates cross-linking of the TCR. These antigens, unlike SAg, may attach through their epitopes to the classic antigen-binding site of the TCR. However, T-cell activation by the MUC1 mucin tumor antigen requires target cell binding to both the TCR and accessory molecules on the T-cell surface.<sup>175</sup>

In contrast to types of ligands that stimulate T cells independent of MHC, at least two particular types of T cells can recognize antigen in the absence of classical MHC, namely those expressing TCR  $\gamma\delta$  receptors and also NKT cells, discussed later in the section [Natural Killer Cells](#).

## **T-CELL MATURATION**

During ontogeny and in T-cell development in mature organisms, precursors of T cells migrate from the bone marrow to the thymus, where most T-cell development occurs.<sup>176,177</sup> A series of important maturation events, which define specific functions of mature T cells, occur in the thymus. Here, among a considerable amount of cell proliferation and cell death, T cells first express antigen specificity, develop MHC restriction for antigen recognition, and express the cell surface CD4 or CD8 molecules that relate closely to whether the T cell will recognize MHC class I– or class II–restricted antigens. It is here that individual T cells are limited to the expression of a single functional TCR specificity. It is also here that the first round of selection occurs against maturing T cells that react against the body's normal tissue antigens.

Much of the current understanding of T-cell maturation is based on models that involve genetic changes related specifically to T-cell function, such as transgenic or knockout mice with added or deleted germline genes, respectively, and natural mutants that affect the immune system.<sup>178,179 and 180</sup> In addition, mouse models involving T-cell activation by SAg have served important roles, because they allow one to monitor the maturation of relatively large numbers of T cells with a known antigen specificity.

## **MARKERS AND PHENOTYPES**

Cell surface markers based on antibody reactivity have been identified that permit associating individual T cells with a particular stage of maturation.<sup>181,182</sup> The markers are cell surface molecules, which present a characteristic identifying *phenotype* of the cell when expressed individually or in a certain combination. For example, the TCR/CD3 complex now is commonly used as a marker for mature T cells. Thy-1 (mouse) and CD2 are expressed rather ubiquitously but not exclusively on T cells. CD4 and CD8 are expressed differently by distinct T-cell subpopulations, and mature T cells generally express one but not both.

## **DEVELOPMENT OF THE T-CELL ANTIGEN REPERTOIRE: ROLE OF THE THYMUS**

The antigen repertoire comprises the antigens that a group of T cells can recognize when the T cells are considered as a whole. The limits of the repertoire of all T cells in the body are set by the combined specificities of TCRs that can be generated. The TCRs that are expressed initially by immature T cells in the thymus represent random specificities that include binding affinities not only for determinants foreign to the host but also for determinants produced by the host's cells, including tumor cells. However, as described later in this section and in [T-Cell Death in the Thymus](#), T cells expressing some specificities are favored, whereas many others are deleted in the thymus.

The TCRs that mediate MHC-restricted recognition of foreign antigens are encoded by germline genes that, with the few exceptions of extrathymic maturation, are first expressed in the thymus. The TCR repertoire that is expressed by mature T cells as a whole in an individual, however, is molded during at least two points in T-cell development. The first point occurs in the thymus. The second occurs with mature T cells that have left the thymus, and it is discussed later in the section [Peripheral T-Cell Tolerance](#).

In mouse models, cells with the general phenotype of Thy-1+CD4–CD8– contain the precursors of the T-cell lineage and are located primarily under the capsule in the outer cortex of the thymus. Here, they proliferate rapidly. At this stage, rearrangement of the structural gene for the TCR  $\beta$  chain occurs, which suppresses further rearrangements of the gene and allows assembly of a TCR  $\beta$  chain/surrogate TCR  $\alpha$  chain/CD3 complex. This primitive TCR/CD3 complex promotes T-cell maturation to the expression of CD4, CD8, a mature TCR  $\alpha$  chain, and cell surface expression of a functional TCR/CD3 complex. The CD4+CD8+ cells are in the thymic cortex, are relatively immature with respect to their functional capacity to respond to a variety of stimuli, and constitute by far the most thymocytes. For the most part, they are destined to die in the thymus.

The CD4+CD8+ double-positive T cells in the thymic cortex undergo selection that results in their deletion or continued maturation ( [Fig. 4-5](#)). *Positive selection* favors the survival of T cells that, outside the thymus (commonly called the *periphery*), will react with foreign antigens presented by the same MHC determinants that are expressed in the thymic environment. Positive selection and termination of TCR  $\alpha$  chain rearrangement follows the interaction of the TCR with MHC-peptide ligands, primarily on the radiation-resistant cortical epithelial cells in the thymus. MHC-bound peptides that promote positive selection are derived primarily from the endogenous pool of normal proteins within the thymus rather than from foreign proteins. Positive selection may depend on an appropriate level of signaling, triggered by the TCR/CD3 complex and determined by the avidity that represents the concentrations of MHC, peptide, TCR, and their affinities. However, the nature of the MHC-peptide ligands driving positive selection in the thymus and their relationship to the MHC-peptide ligands activating T cells in the periphery have not been established; the relationship may include a TCR's cross-reactivity between one or more MHC-restricted self-peptides in the thymus and an MHC-restricted foreign peptide in the periphery.

**FIGURE 4-5.** The fate of T cells maturing in the thymus, based on a model of T-cell receptor (TCR) affinity for the major histocompatibility–antigen complex on antigen-presenting cells. MHC, major histocompatibility complex; NIL, no affinity.

Expression of the CD4 and CD8 molecules, as well as CD45, has an important role in positive selection and T-cell conversion to CD4 or CD8 single-positive cells.<sup>183,184,185,186</sup> and <sup>187</sup> TCR and CD45, combined with either CD4 or CD8, frequently are considered as a unit with respect to early signals from the TCR/CD3 complex and their regulation. The mechanism by which the irrelevant coreceptor, CD4 or CD8, is lost as selected double-positive cells mature into *single-positive* CD8+CD4– or CD8–CD4+ T cells and T-cell lineage commitment is not clear.

#### **Self–Major Histocompatibility Complex Defined in the Thymus**

Under normal developmental circumstances, the MHC type of the T-cell maturation environment is identical to the genotype of the maturing T cell; that is, the MHC that is functionally recognized as self by the T cell is also genotypically self. However, under certain experimental or clinical circumstances, functional self and genotypic self need not be identical. For example, in bone marrow–transplanted patients or experimental animals, hematopoietic stem cells, including the precursors of T cells, can develop in an MHC environment different from that of the stem cells. In this circumstance, T cells are selected that preferentially recognize foreign antigen in association with MHC determinants of the host type, even when these are different from the genotypically self-MHC determinants of bone marrow–derived cells.<sup>188,189</sup> This situation may present important constraints on the ability of hematopoietically derived cells to function effectively in an MHC-restricted fashion.

#### **T-Cell Death in the Thymus**

There appear to be three paths that end in the disappearance of T cells in the thymus (see Fig. 4-5). First, immature T cells die if they fail to express a functional TCR. Second, they die if the TCR fails to react with MHC-antigen complexes. Third, *negative selection* deletes many of the T cells in the thymus that would otherwise be reactive against normal tissues. These T cells—primarily CD4+CD8+ but also single positive cells, depending on the experimental system—are deleted or sometimes rendered unresponsive in a clonal fashion, based on the ability of the TCR to react with MHC-antigen complexes expressed by cells in the thymic stroma. In contrast to ambiguity about the nature of the TCR ligands (MHC-antigen complexes) that induce positive selection, investigators have identified a variety of ligands that can cause negative selection. In mouse models involving SAGs or transgenic animals in which many T cells express a selected self-antigen specificity, the antigens that activate mature T cells can also trigger antigen-specific deletion of immature T cells in the thymus. Both bone marrow–derived and thymic epithelial cells are effective as APCs for negative selection, although the former appear to be more involved *in vivo*. CD4 and CD8 coreceptors appear to contribute to the triggering of negative selection, as does the lymphocyte function–associated antigen-1/intracellular adhesion molecule (LFA-1/ICAM) interaction. Evidence suggests that clonal T-cell deletion in the thymus has a lower activation threshold than that required for the activation of mature peripheral T cells. This balance would reduce the likelihood of mature peripheral T cells that can react against normal tissues.

T cells in the thymus that are not selected for further maturation die by *apoptosis*, a process resulting in programmed cell death.<sup>190,191,192,193</sup> and <sup>194</sup> As many as 99% of thymocytes in young rodents may be affected. The process is associated with engagement of the TCR and, possibly, costimulatory determinants that result in the expression of genes connected with apoptosis. Immature T cells whose TCRs fail to bind to other cells in the thymus appear to be preprogrammed for death by apoptosis. Apoptosis is characterized by cytoplasmic blebbing, shrinkage of the cell (including the nucleus), collapsing of the chromatin into patches, DNA fragmentation, breakup of the nucleus and, finally, fragmentation of the cell. Apoptosis in thymocytes appears to involve the activation of “suicide” genes, among which is an endogenous endonuclease. Early in the process, cells undergoing apoptosis *in vivo* are recognized by particular cell surface changes and are ingested by phagocytes, so that the end-stages of the process are not reached and local tissue injury from the release of inflammatory agents by dying cells is minimized.<sup>195</sup>

The differences in events between positive and negative selection that result in T-cell survival or apoptosis are not clear, but apoptosis may be initiated simply by a strong signal or set of signals delivered to the immature thymic T cells by a combination of the TCRs and other receptors. The possibility also exists that different MHC-positive cells in the thymic stroma, and perhaps differences in their MHC-restricted peptides, may contribute to whether the outcome is positive or negative selection. It appears unlikely that Fas, a cell surface molecule belonging to the family of TNF receptors with cytoplasmic segment “death domains,” which, if triggered, can initiate apoptosis, is required for thymocyte deletion; however, the issue of Fas involvement is controversial. By contrast, products of the Bcl-2–like family of genes can promote cell survival and contribute to the regulation of apoptosis.<sup>196</sup> Their function appears to be important for maintaining thymocyte viability in older animals, but alone their function or lack thereof does not account for positive or negative selection.

#### **Thymic Maturation of gd T Cells**

T cells that express the TCR gd receptors for antigen (T gd) can also arise in the thymus, but they are primarily CD4–CD8–, with a minority being CD4–CD8+. They are the product of a T-cell lineage that shares with T ab cells a common precursor committed to the T-cell lineage.<sup>163,164,197,198</sup> The lineage of T gd cells parts from that of T ab cells early during T-cell maturation in the thymus.<sup>199,200,201</sup> and <sup>202</sup> Studies carried out with mice whose T cells express TCR gd transgenes indicate that positive and negative selection of these cells, too, occurs in the thymus.

#### **T-Cell Development through Extrathymic Pathways**

Extrathymic pathways for T-cell development in the intestinal epithelium have been studied extensively in thymus-deficient mice.<sup>203,204</sup> and <sup>205</sup> Several unusual features of these cells have been identified. T cells expressing either TCR ab or gd that have developed extrathymically in the intestinal epithelium are predominantly CD4– and commonly express an abnormal form of CD8 consisting of aa homodimers rather than the customary ab heterodimers. Also, the use of Vb genes is more restricted than in their thymus-derived counterparts. Selection of at least some developing T cells may also occur in the intestinal epithelium, but this is an unsettled issue. T cells generated in the intestinal epithelium usually do not recirculate to other tissues, which reduces their potential for causing autoimmune reactions. Although their function is not well understood, at least some gd T cells have cytotoxic activity. Recently described NKT cells, described later in the section [Natural Killer Cells](#), also develop through extrathymic pathways.

## **ACTIVATION OF MATURE T CELLS**

### **SIGNAL REQUIREMENTS FOR T-CELL ACTIVATION**

The responses of mature T cells to activation commonly include combinations of cell proliferation, cytokine production and release, cytotoxic activity, and even death. The initiation of antigen-specific T-cell activation requires cross-linking and clustering of the TCR/CD3 complex with an antigenic ligand, which generally consists of an antigenic peptide in association with a self-MHC product on the surface of another cell. The antigen that initiates an immune response does not need to be the same as that which triggers effector cell functions by the differentiated T cells. Thus, a foreign antigen, or perhaps a SAg, may trigger a response by T cells not capable of being triggered by self-antigen; however, the resulting effector T cells expressing the same TCRs may also react with self-antigen, albeit at a lower affinity than with the original stimulating antigen. TCR/CD3 signaling is closely involved with two additional cell surface molecules: CD8 or CD4, and CD45.

## CD8 and CD4 Molecules as Coreceptors

CD8 and CD4, which are cell surface glycoproteins expressed by mutually exclusive subsets of mature T cells, serve as coreceptors for delivering the TCR/CD3 signals.<sup>152,184,185,206,207</sup> Their role as coreceptors is required for most immune responses by naive T cells and by some activated effector T cells. Acting as coreceptors during antigen recognition, CD8 or CD4 binds to nonpolymorphic regions of the same MHC molecule that presents antigen to the TCR, thus joining with a complex of the TCR/CD3. CD8 and CD4 molecules stabilize the TCR/MHC-peptide complex and contribute to both the binding avidity of TCR to the MHC-antigen complex and to the generation of cytoplasmic signals.

## CD45 and T-Cell Activation

CD45, a transmembrane protein tyrosine phosphatase on T cells and other hematopoietic cells, also contributes in a critical fashion to TCR signaling.<sup>208,209 and 210</sup> CD45, generally known as the *leukocyte common antigen*, is expressed as multiple isoforms resulting from alternative splicing of three exons encoded by a single gene. It has an essential role in linking antigen-stimulated TCR/CD3 complexes to their cytoplasmic signaling pathways. Although blocking antibodies have not had a notable effect on T-cell function, T-cell lines lacking CD45 are markedly defective in TCR signaling by MHC-antigen complexes; responsiveness of the cells is restored by introducing normal CD45 genes. In CD45-deficient mice, thymocyte maturation is largely blocked, and responses of the few peripheral T cells to MHC-restricted antigens are defective.

Following activation of normal naive T cells, their expression of CD45 changes to a lower-molecular-weight form. The different isoforms of CD45 that are expressed on naive as compared with activated or memory T cells may contribute to the different triggering responses of these cells.<sup>184</sup>

## T-Cell Receptor Signal Transduction

The cascades of biochemical reactions that transmit the TCR/CD3 activation signals from the cell surface to nuclear DNA have been partially established.<sup>211,212</sup> Phosphorylation of numerous cytoplasmic and membrane proteins is an essential part of the process. Inositol trisphosphate and diacylglycerol, referred to as *second messengers*, are generated by the hydrolysis of phosphatidylinositol(4,5)bisphosphate, which is initiated through several biochemical intermediates by triggering the TCR/CD3 complex. *Second messenger* is a generic term for molecules produced in response to transduction of a signal initiated by an extracellular ligand, which is the first messenger. The signal cascade is commonly referred to as the *phosphatidylinositol (PI) second messenger pathway*. The second messengers are at the beginning of two major intracellular signaling routes. Inositol trisphosphate and diacylglycerol release free calcium from intracellular stores and activate protein kinase C, respectively. The mobilization of calcium and activation of protein kinase C by other means, such as calcium ionophores and phorbol esters, respectively, can also stimulate T-cell division and cytokine production, independent of TCR/CD3 triggering. The two TCR/CD3 signaling routes finally join in a synergistic fashion within the nucleus to initiate gene transcription. TCR/CD3 complexes that have triggered signaling may be internalized, degraded, and replaced. This process permits sequential receptor stimulation by individual MHC-peptide complexes on the target cells, and it improves the opportunity for target cells expressing low densities of antigen to activate T-cell responses.

Some forms of TCR/CD3 triggering may be sufficient to contribute only to partial responses—for example, lymphokine production but not the expression of growth factor receptors or proliferation. Indeed, the type of T-cell response is sensitive even to single amino acid substitutions in the peptide antigen that are sufficiently subtle to preserve TCR/CD3 triggering yet different enough to vary the nature of the TCR/CD3 signal and the T-cell functional response.<sup>213</sup> The ultimate T-cell response depends on the balance of a variety of factors, including the state of differentiation of the responding cell, the nature of the TCR/CD3 signal, and the different modulating signals from its other cell surface receptors, which, in part, reflect the action of cytokines in the environment and the nature of the APC.

## Functional Consequences of T-Cell Receptor Triggering

TCR triggering of T cells commonly induces expression of the high-affinity IL-2 receptor, rouses cells to move from the G<sub>0</sub> resting stage of the cell cycle into the G<sub>1</sub> stage, initiates gene transcription for selected cytokines such as IL-2, and activates effector cell functions of cytotoxic T cells. The IL-2 receptor has a major role in the proliferation of T cells after activation by antigen.<sup>214,215 and 216</sup> The high-affinity cell surface receptor for IL-2 consists of three transmembrane chains—a, b, and g—and is expressed only by activated T cells owing to the lack of a chain expression by resting T cells. The high-affinity receptor promotes T-cell proliferation with relatively low concentrations of IL-2. The b chain, which is expressed constitutively by CD8+ but not by CD4+ T cells, combines with the g chain to form an IL-2 receptor with an intermediate affinity that is approximately 1/100 that of the high-affinity receptor and is expressed on naive T cells. Expression of the b chain is also up-regulated following T-cell activation. Thus, signals from triggered TCRs generally leave naive and many memory T cells poised to generate the T-cell growth factor, IL-2, among other cytokines. The cells also are poised to proliferate after IL-2 binding to and triggering of IL-2 receptors. The result of TCR signaling, however, is not necessarily the staging of an antigen-specific immune response. As described later in the section [Deletion of Mature T Cells](#), it may precipitate cell death by apoptosis.

## Adhesion and Accessory Molecules

Relatively weak interactions between the TCR and antigen can be reinforced. Binding of accessory molecules to ligands on APCs, such as LFA-1 to ICAMs, CD2 to LFA-3, and CD5 to CD72, enhances conjugation of the two cells and thereby raises the likelihood of interactions between the TCR and the MHC-peptide complexes (Fig. 4-6).<sup>217,218</sup>

**FIGURE 4-6.** Some of the cell surface molecules associated with receptor-ligand pairing during T-cell recognition of antigens on antigen-presenting cells (APCs). ICAM, intracellular adhesion molecule; LFA-1, lymphocyte function-associated antigen-1; MHC, major histocompatibility complex; TCR, T-cell receptor.

Molecules that facilitate the binding of a lymphocyte to its target cell have been referred to as *adhesion* molecules. However, an increasing number of these molecules also appear to provide signaling activity after engagement with their ligands, either by enhancing the signal generated by the TCR or by contributing independent stimulatory signals.<sup>182,219,220,221 and 222</sup> CD28, CD2, CD5, LFA-1, CD44, CD69, CD4, and CD8 are examples of cell surface receptors that contribute to the signaling events. Optimal activation of T cells with weak avidity for an antigen is thus dependent on receptor-ligand interactions that promote the binding of T cells to APCs and that contribute to the T-cell-activating signals.

## CD28 SIGNALING IN T-CELL ACTIVATION

Triggering the TCR/CD3 complex is often referred to as the *first signal* for T-cell activation. With naive CD4+ and CD8+ T cells and many memory cells as well, the first signal alone is commonly insufficient for stimulating IL-2 production, proliferation, and differentiation. CD28 molecules on the T-cell surface can provide a critical *second* or *costimulatory signal* by engaging the B7 family of ligands on the APCs, particularly in inflamed sites where APCs are optimally activated.<sup>223,224</sup> Mice that lack CD28 appear unable to generate T-cell responses to certain viruses or to generate T-cell-dependent antibody responses. CD28 is a homodimeric

transmembrane glycoprotein found on the majority of human peripheral T cells and, in the mouse, on almost all T cells in lymphoid organs or the peripheral blood. Activation of T cells enhances the expression of CD28 and also induces the expression of CTLA-4, a structural homologue of CD28 with a lower level of surface expression than CD28 but a far higher avidity for ligands in the B7 family.<sup>225,226 and 227</sup> CD28 and CTLA-4 signals can have opposite effects. Cross-linking CTLA-4 by B7 ligand can inhibit T-cell activation, IL-2 production, and subsequent cell proliferation. Mice lacking CTLA-4 experience severe, generalized T-cell lymphoproliferation and die within several weeks after birth. Consequently, CTLA-4 may provide a mechanism for down-regulating a T-cell response.

### **B7 Family of Ligands**

The B7 family of ligands for CD28 and CTLA-4 has two key members: B7-1 (CD80), originally called *B7* or *BB1*, and B7-2 (CD86), each of which can trigger second signals.<sup>228,229,230 and 231</sup> They are both expressed by APCs: the DCs, monocyte-macrophages, and activated B cells described earlier in the section [Specialized Antigen-Presenting Cells](#). They have also been detected on activated T and NK cells. Encoded by separate genes, B7-1 and B7-2 each react with CD28 and CTLA-4 with similar binding affinities, and they have, in part, overlapping and redundant functions. However, there are significant differences in their rates of enhanced expression on activated cells and in their contributions to the development of autoimmune disease in several animal models.

### **Functional Consequences of the Second Signal**

For naive and many memory T cells, the signaling pathway associated with triggering CD28 completes the pathway for T-cell activation that was initiated by TCR/CD3.<sup>211</sup> Triggering CD28, among other activities, appears to stimulate prolonged IL-2 production by increasing the half-life of its messenger RNA (mRNA) and by increasing the rate of gene transcription.

IL-2, a single 15-kD polypeptide, is the major growth factor for T cells.<sup>232,233 and 234</sup> Although not produced by resting T cells, IL-2 is generated after cell activation, particularly by the Th1 subset of CD4+ helper T cells. Extracellular levels of IL-2 are tightly regulated by the requirement for continuous activation signaling for transcription of its gene, by the controlled half-life of its mRNA, by its serum half-life of minutes, and by the short life span of the activated T cells producing IL-2. IL-2 stimulates both cell proliferation and survival. Activated T cells commonly die without IL-2, as described later in the section [Deletion of Mature T Cells](#).

Mice that are unable to produce IL-2 are only modestly immunodeficient, although they are more prone to autoimmune diseases and die at a young age. The explanation may represent imperfect redundancy among subsets of cytokines. For example, partial compensation for IL-2 may be provided by IL-15, which can stimulate proliferation and differentiation of T cells.<sup>235,236</sup> The second signal also increases the production of other cytokines (e.g., IFN- $\gamma$  and GM-CSF) likely by the same mechanisms as associated with IL-2. In addition, the second signal activates genes whose products, particularly Bcl-xl, protect against apoptosis, as described later in the section [Deletion of Mature T Cells](#).

In some mouse models, CD28/B7 interactions induce sufficiently high IL-2 production by CD8+ cells that CD8+ CTLs can be generated in the absence of CD4+ T-cell help.<sup>237</sup> Indeed, a major function of helper T cells for CD8+ T-cell responses may be to activate APCs and their expression of costimulatory ligands, such as B7, rather than simply to provide such cytokines as IL-2 directly to the responding CD8+ T cells. Thus, TCR engagement initiates the response in an antigen-specific fashion, while the requirement for a second signal tends to restrict the response of naive T cells to APCs that provide both antigen and second signals.<sup>238</sup>

Normal cells that express a TCR-reactive antigen but lack a second signal ligand will generally not activate naive T cells; indeed, these cells may induce anergy by apoptosis, as described later in the section [T-Cell Clonal Anergy](#). Of note, T cells can respond even if the ligands for first and second signals are on separate cells, as might be the case for activating CD8+ CTL precursors, with a first signal stimulated by tumor cells and a second signal by APCs. Having the two signals initiated by the same cell is far more efficient, however.

The stimulation requirements of one T-cell population can differ substantially from those of another. For example, naive CD8+ and CD4+ T cells require both TCR triggering and second signals to proliferate and generate activated effector cells. Activated effector cells, however, do not require second signals to engage and kill target cells or release cytokines.<sup>239,240,241 and 242</sup> The effector cells also do not need to produce IL-2 or to proliferate.

Costimulatory molecules on APCs that can provide critical second signals in the absence of the B7 family have been reported, such as ICAM-1 (the ligand for LFA-1), heat-stable antigen, and selected members of the TNF family.<sup>222,243,244</sup> They apparently are not, however, the usual primary source of second signals, and the T-cell response is commonly partial and suboptimal. Alternative sources of costimulation are most effective when combined with a strong primary signal from the TCR.

## **ENDING THE NORMAL IMMUNE RESPONSE OF ACTIVATED T CELLS**

Eliminating most of the activating antigen generally results in death by apoptosis for the responding lymphocytes, except for those remaining as memory cells.<sup>177,193,245</sup> After antigen clearance, the priorities of the antigen repertoire of a body's T cells return toward their baseline levels, with emphasis represented by memory cells. Studies of this subject, which are at a relatively early stage, indicate that many factors can contribute to the death or suppression of T cells activated in an immune response and that no factor acting alone is generally responsible. Perhaps the foremost factor is that in the absence of antigen, the stimulation for producing supportive cytokines—particularly IL-2—disappears, resulting in death of the activated T cells. Also, antiapoptosis factors in the Bcl-2 family, which raise the threshold for death from IL-2 withdrawal, diminish without the T-cell activation signals. In addition, activated T cells express CTLA-4 at the cell surface, and triggered CTLA-4 can interfere with CD28-induced activation signals, as described earlier in the section [CD28 Signaling in T-cell Activation](#). Activated T cells also express members of the TNF receptor family with death domains, such as Fas, which can trigger apoptosis when cross-linked. Thus, activated T cells are more at risk for apoptotic death than are resting cells. There are other factors too. Antiinflammatory cytokines, TGF- $\beta$  and IL-10 in particular, are produced by activated lymphocytes and macrophages or by tumor cells (TGF- $\beta$ ). These cytokines inhibit T-cell expansion, which contributes to the weakening of a response. Recent studies have identified the liver as the key site where circulating, activated CD8+ T cells are trapped, after which they die by apoptosis.<sup>246</sup> Suppressor T cells may interfere with activated T cells or their generation, as described later in the section [Suppressor T-Cell](#). T-cell responses may also be ended prematurely by mechanisms associated with peripheral T-cell tolerance.

## **PERIPHERAL T-CELL TOLERANCE**

In contrast to immune responses running a normal course, they can be avoided or aborted very early in the face of naive T cells capable of recognizing the antigen of interest. These events contribute to *tolerance*, which can be considered, in the broad sense, as failure of the host to generate a normal T-cell response against the antigen of interest and, consequently, failure of the host to clear away cells expressing the antigen. From the broad view, immunoregulatory factors that contribute to ending a normal T-cell response, discussed in the previous section, may contribute to tolerance too, if they help to abort the response. Of note, mechanisms not addressed here can account for a host's failure to reject cells against which a normal, sustained T-cell response has been generated.

The potential for mature T-cell responses to self-antigens is reduced in the thymus in an antigen-specific fashion by negative selection, a condition referred to as *central tolerance*. However, some T cells leaving the thymus have the potential to react against self-antigens in the periphery. Escape of self-reactive T cells from the thymus is particularly likely for cells that can react in the periphery with tissue-specific antigens unlikely to be presented adequately or imitated in the thymus in a fashion sufficient to induce clonal deletion. The escaped T cells may encounter more potent immunizing conditions in the periphery, which are sufficient to stimulate T-cell activity against MHC/self-peptide complexes on normal host cells that otherwise would be ignored. For example, an inflamed environment occurring naturally or as part of intentional immunization might reach the threshold necessary for triggering otherwise unresponsive, self-reactive T cells by activating APCs and up-regulating cell surface ligands and receptors that promote immune responses. The lack of a reaction between these potential antigen-responsive T cells and relevant antigens that are present in the body has been referred to as a state of *immunologic ignorance* that, when overcome, may result in autoimmunity.

Tolerance among mature T cells can also be induced in the periphery in an antigen-specific fashion by causing cellular anergy, in which the T cells are unresponsive to the antigen, or by deleting the cells.

## **T-CELL CLONAL ANERGY**

In a variety of mouse models, primarily *in vitro* ones, naive T cells and some memory T cells become anergic in an antigen-specific or clonal fashion after TCR triggering (signal 1) in the absence of costimulation (signal 2).<sup>223,247,248</sup> The anergic cells are not deleted; they produce cytokines other than IL-2, albeit at subnormal

levels, and they generate increased amounts of high-affinity IL-2 receptor. They do not, however, produce IL-2 or proliferate, even under optimal conditions for normal activation. The antiproliferative state can develop within a day of antigen exposure and presumably can last as long as the anergic cells are exposed to antigen. The anergy results from a block in IL-2 gene transcription.

CD4<sup>+</sup> Th1 and many CD8<sup>+</sup> naive T cells are susceptible.<sup>249</sup> Anergy appears to be inducible only in cells that secrete IL-2, and it can be reversed in at least some cases with IL-2 or by removing the source of antigen.

The opportunities for delivery of signal 1 alone for antigens associated with autologous cells are numerous. Most nucleated cells express MHC class I with endogenous antigens, but relatively few can also provide signal 2. Signal 1 for antigens complexed with MHC class II may be provided without signal 2 by resting B cells and by selected cell types in areas of inflammation, such as vascular endothelial cells. DCs that express MHC class I–restricted antigens by cross-priming, as discussed earlier in the section [Dendritic Cells](#), but are not well activated may be a common source in draining lymph nodes of tolerance-inducing cells for self-antigens.<sup>250,251</sup> and <sup>252</sup> Whether anergy is a prelude to cell death is an unsettled issue.

Other mechanisms or events that have been associated with a reversible, functional inactivation in various models include down-regulation of expression of the TCR/CD3 complex and CD8<sup>253,254</sup> and exposure to structurally suboptimal ligands.<sup>255</sup> Future studies will determine the extent to which the existing observations of anergy and ways of reversing it can be generalized to both CD4<sup>+</sup> and CD8<sup>+</sup> T cells in various states of activation or differentiation and to *in vivo* situations.

## DELETION OF MATURE T CELLS

After activation, mature peripheral T cells can be deleted by repetitive restimulation with high concentrations of antigen.<sup>256,257,258,259</sup> and <sup>260</sup> Conventional antigens, SAGs, T-cell mitogens, and antibodies against the TCR/CD3 complex have all been associated with the outcome. The process, referred to as *activation-induced cell death* (AICD), can affect Th1 and Th2 CD4<sup>+</sup>, CD8<sup>+</sup>, and TCR gd<sup>+</sup> T cells. In most cases, T-cell deletion is preceded by IL-2 release from the activated cells, rapid proliferation, and enhanced expression of Fas and Fas ligand for several days, followed by an apoptotic death. When activated, proliferating T cells pass through the late G<sub>1</sub> or S phase of the cell cycle, where they appear to be far more susceptible to apoptosis than in the resting stage.

The roles of factors contributing to AICD, such as the strength of the TCR stimulation, the presence of various cytokines, and cosignals delivered by accessory cells, are unsettled. However, the deletion appears to be caused by apoptosis triggered primarily by Fas but also by the receptor for TNF, both of which are up-regulated on activated T cells and subject to triggering by their respective ligands, which are also expressed by activated T cells. Studies of Fas-mediated AICD indicate that apoptosis affects primarily the activated T cells with TCRs bound to antigen at the time that Fas is triggered. Activated T cells from mice with a defect in the Fas gene are less susceptible to AICD than normal T cells.<sup>261</sup> These mice exhibit lymphoproliferative and autoimmune disorders. AICD may also serve a normal physiologic function by limiting the height and duration of a T-cell response. Products of the Bcl-2–like family of genes appear to protect against peripheral T-cell apoptosis, particularly Bcl-xl, which can be induced by costimulation from CD28 and can resist either death associated with IL-2 withdrawal or, in some cases, death from activation of Fas.<sup>193,262,263</sup>

A high and persistent load of antigen can induce clonal deletion of CTLs and result in a state designated as *high-zone tolerance*.<sup>264,265</sup> and <sup>266</sup> High-zone tolerance may develop through clonal anergy, clonal deletion, or both, and it appears particularly relevant to the tumor-bearing situation where high levels of antigen prevail.

Withdrawal of IL-2 can also result in the death of activated T cells.<sup>193,260,267</sup> The mechanism differs significantly from that associated with the triggering of receptors in the TNF receptor family, such as Fas. IL-2 withdrawal and Fas stimulation probably involve two at least partially different apoptosis pathways. For example, apoptosis associated with IL-2 withdrawal is better inhibited by selected members of the Bcl-2 family than apoptosis associated with Fas. Unlike Fas-mediated apoptosis, IL-2 withdrawal may destabilize mitochondria, resulting in leakage of cytochrome c and subsequent initiation of apoptosis. Moreover, apoptosis from IL-2 withdrawal may be prevented by other T-cell growth cytokines, such as IL-4, IL-7, and IL-15.

## STATES OF MATURE T CELLS

### NAIVE, EFFECTOR, AND MEMORY T CELLS

Three populations of T cells—naive T cells, effector T cells, and memory T cells—constitute the antigen repertoire of the pool of mature T cells.<sup>268,269,270</sup> and <sup>271</sup> They differ by their state of activation and by prior exposure to antigen. The T cells commonly referred to as *naive* or *virgin* are immunocompetent T cells that have not encountered antigen in the periphery, such as those that have just emerged from the thymus, the primary lymphoid organ for generating mature T cells from nonfunctional precursors. After activation, these cells may develop specific functions associated with cytotoxic activity or the release of particular cytokines. In this activated state, they are referred to as *effector* cells. After a short period in the activated state, most of the cells die, but some appear to become *memory* cells. The extent of T-cell death depends, in part, on the dose of antigen, with lower doses resulting in less death. Products of the Bcl-2–like family of genes provide a level of protection against Fas-mediated apoptosis of activated mature T cells, and this may contribute to the survival of memory T cells after a T-cell response.

Naive T cells are long-lived and circulate through the blood stream and lymphatics between the *secondary lymphoid organs*, such as lymph nodes, where they may encounter APCs presenting their specific antigens and be activated. The long life span of naive T cells appears to depend on their TCRs interacting with normal cells expressing complexes of MHC/self-peptide; otherwise, the naive cells die by apoptosis.<sup>272,273</sup> The interaction does not trigger cell activation and the generation of effector functions,<sup>273</sup> perhaps because TCR triggering is relatively weak, as with positive selection in the thymus. Naive T cells are uncommon in nonlymphoid tissues. They are primarily resting cells that do not proliferate rapidly without antigen stimulation, which would change them to the activated or effector category. Consequently, little of the antigen repertoire represented by naive T cells is against a particular pathogen, unless a SAG is involved, as discussed earlier in the section [Stimulation of T-Cell Receptors by Superantigens](#). As a whole, naive T cells form the bulk of the body's antigen repertoire and, in response to general T-cell depletion, the body's naive T-cell population commonly will expand back to its baseline numbers.<sup>177</sup>

Effector T cells generally are activated, can proliferate rapidly, act immediately after target cell contact (e.g., cytotoxicity or cytokine release), and are short-lived. Exhibiting homing properties different from those of naive T cells, they are commonly found in nonlymphoid, extravascular tissues.

Memory T cells are characterized by their ability to generate an immune response that is earlier, more intense, and longer-lasting than that of naive cells, after reexposure of the host to the same antigen or a cross-reacting antigen. Unlike effector cells, however, they do not carry out effector cell functions immediately after antigen stimulation, in the context of cytotoxicity or cytokine release. Their presence in both lymphoid and nonlymphoid peripheral tissues, including areas of inflammation, may reflect the homing patterns of different subsets of memory cells.<sup>274</sup> They appear to be descended from naive T cells that have been activated, although the nature of the progenitors has not been settled, such as naive cells versus effector cells. The memory response probably is associated with a higher frequency of precursors to the effector cells and higher levels of cell surface signaling and adhesion molecules on the memory cells.<sup>275,276</sup> T-cell memory appears to involve a chronic proliferation of T cells responding to persisting antigen, at least for relatively short-term memory. In at least some cases, long-term memory may persist in the absence of the immunizing foreign antigen and even cross-reacting foreign or self-antigen.<sup>177</sup> Some of the memory T cells, probably those not encountering foreign antigen, may be in a resting (nonproliferative) state. As discussed earlier in the sections [T-Cell Clonal Anergy](#) and [Deletion of Mature T Cells](#), T cells specifically reactive with the antigen may be deleted or functionally inactivated. In response to general T-cell depletion, the body's memory T cells expand back to their baseline numbers, independent of that for naive T cells and that for B lymphocytes.<sup>177</sup>

### PHENOTYPES OF ANTIGEN-STIMULATED T CELLS

Characteristic cell surface markers have greatly facilitated tracking antigen-activated effector T cells and distinguishing them from naive T cells. The activated mature peripheral T cells express CD45RO, a low-molecular-weight isoform of CD45, and relatively little of the higher-molecular-weight form (CD45RA) associated with naive cells. They may also express a variety of cell surface molecules at higher levels than are found on naive T cells, including CD2, LFA-1, LFA-3, CD27, CD29, CD44, CD69, adhesion molecules in the very late activation antigen (VLA) series that react with extracellular matrix proteins, the IL-2R $\alpha$  chain associated with high-affinity IL-2 receptor activity, and MHC class II molecules. CD44 is commonly used as a marker for memory cells, because of persistent expression by the cells. As the activated cells revert to a resting stage, many of the activation markers are lost. An unsettled issue is how well cell surface markers can distinguish between activated cells and memory cells; consequently, the two types of cells are grouped together here.

## T-CELL MIGRATION

The antigen repertoire of peripheral T cells can be partitioned, to an extent, in the body through the selected migration of T cells out of the circulation. Naive T cells exit the circulation directly into lymphoid tissues through a specialized type of venule designated *high endothelial venules*.<sup>277,288 and 279</sup> The movement of the T cells through the endothelium occurs in several sequential steps that involve progressively tighter binding of the lymphocytes to the endothelial wall and, finally, migration through the endothelium into the extravascular space. Specialized adhesion molecules on naive T cells (e.g., L-selectin), binding to particular mucin-like molecules on the high endothelial venule, provide specificity for the exit site. The process of cell migration into particular tissues and microenvironments is also called *homing*.

Effector and most memory cells do not bear receptors (e.g., L-selectin) associated with migration directly into normal secondary lymphoid tissues. Instead, they migrate to other selected sites, such as the gastrointestinal wall, the skin, and sites of inflammation. Other receptors not expressed by naive cells have been identified (e.g., VLA-4 for inflamed sites and cutaneous lymphocyte antigen for skin) that contribute to the selective exit sites for memory and effector T cells.

Chemotactic cytokines, or *chemokines*, contribute to the exit sites for cells by binding to specific determinants on the endothelial wall, such as macrophage inflammatory protein-1b (MIP-1b), which binds to selected proteoglycans on the endothelium and promotes T-cell adhesion, particularly of CD8+ T cells.<sup>280</sup> Inflammation and associated cytokines also up-regulate lymphocyte-binding ligands expressed by the endothelial cells.

The tissue migration of lymphocytes, and of leukocytes in general, is largely influenced by chemokines.<sup>176,281,283 and 283</sup> These small proteins belong to a family of at least 40 members in humans. On the basis of a cysteine motif, most of the chemokines and their receptors are classified as in the CXC (a) or CC (b) subfamilies. At least 15 cell surface, G protein-coupled receptors for chemokines have been identified. Chemokines in the CXC subfamily act primarily on neutrophils and other selected leukocytes, whereas those in the CC subfamily generally act on a different spectrum of leukocytes and not on neutrophils. Within a subfamily, there is redundancy in receptor-ligand pairing in that most receptors bind more than one chemokine and several chemokines can bind to more than one receptor. A single cell can express different chemokine receptors; thus, cell migration may respond to combinatorial patterns and gradients of chemokines. Cells activated by chemokines may change in other ways, too, such as modulating the expression of cell surface adhesion molecules. Although the conditions have not been resolved under which several types of cells do or do not express particular chemokine receptors, a general pattern is emerging in which chemokine receptor expression, and thus responsiveness to chemokines, may vary with the subtype of cell, such as Th1 versus Th2 T cells, with resting or immature versus activated or mature cells, and with the source of activation. For example, immature DCs express receptors for chemokines commonly produced at sites of inflammation by resident cells and infiltrating leukocytes and, hence, may home to these sites, where they gather antigens, are activated by cytokines associated with inflammation, and appear to alter their expression of receptors to ones associated with chemokines produced constitutively in normal lymphoid tissues, with subsequent homing to these sites. Consequently, the recruitment of particular combinations of cells to selected sites, such as naive CD8+ T cells, CD4+ Th1 helper cells, and APCs, is strongly influenced by an integrated combination of cytokines and chemokines. By regulating lymphocyte migration to particular anatomic sites, chemokines affect not only the activation of lymphocytes by antigens but the development and maturation of normal lymphoid tissues.

## FUNCTIONS OF MATURE T CELLS

T cells carry out direct and final effector functions. They can also regulate the effector functions of distinct cell populations. This multiplicity of functions confers a potentially pivotal role for the T cell in immune responses.

The CD4+ and CD8+ subsets of T cells differ from one another in important functional parameters.<sup>249,284,285</sup> CD4+ T cells frequently express a “helper” phenotype, as measured by their ability to help B-cell responses (antibody secretion) or the responses of other T-cell populations. CD8+ T cells frequently are cytotoxic or are capable of suppressing the immune response of other lymphoid populations. However, these correlations of CD4/8 phenotype with function are by no means absolute.

The bias toward helper function in CD4+ T cells appears to be the indirect consequence of the fact that most helper cells are MHC class II-restricted, and the bias toward cytotoxic function in CD8+ T cells results from the fact that most cytotoxic T cells are MHC class I-restricted. The restrictions are a consequence of CD4 and CD8 molecules binding to conserved determinants expressed by MHC class II and class I molecules, respectively.

The relationship works out well conceptually in that cells other than APCs, expressing antigenic peptides complexed with MHC class I molecules, generally express endogenously produced antigens, such as virus-infected cells and tumor cells that are targets of the host immune response. In contrast, cells expressing antigenic peptides complexed with MHC class II molecules generally have acquired the antigens from exogenous sources, and these cells stimulate the immune response rather than serve as targets of the response.

## HELPER T CELLS

In a variety of immune responses, one T-cell population facilitates or helps the development of effector functions of other T or B lymphocytes. The best-studied example is T-cell help for particular antibody responses by B cells.<sup>286,287 and 288</sup> This function may involve specific signals transmitted by direct interaction of helper T cells and B cells as well as signals delivered by T-cell lymphokines.

The generation of CTLs *in situ* also generally requires help from other T cells.<sup>287,288</sup> The helper T cells, activated on APCs, may provide IL-2 and other cytokines for nearby CTL precursor cells attached to the same APCs. The predominant activity of helper T cells, however, may be to promote progressive self-activation and APC activation through TCR/MHC-peptide coupling and CD40/CD40L coupling between conjugated helper T cells and APCs, followed by the activated APCs instigating the critical first (TCR-triggering) and second (e.g., CD28-triggering) signals for activating attached naive CTL precursors.<sup>289,290 and 291</sup> In addition, the activated APCs may provide important cytokines, such as IL-12, for CTL activation. The latter pathway allows for the stimulation of CTL precursors by APCs activated in the absence of helper T cells, which occurs with some types of microbial infections.

## CD4+ T-CELL SUBSETS

CD4+ helper T cells have been further subdivided into two groups of cells, Th1 and Th2, on the basis of the patterns of cytokines that they secrete after being stimulated.<sup>249,292,293,294,295,296,297 and 298</sup> In contrast to the T-cell receptor, which determines the specificity of the T cell, the secreted cytokines determine the function of the T cell. One group promotes primarily cellular immune responses and the other group humoral immune responses. Thus, in mouse models, Th1 cells secrete primarily IL-2, IFN- $\gamma$ , and TNF- $\beta$  (lymphotoxin), but not IL-4, IL-5, IL-6, or IL-10, and they promote delayed-type hypersensitivity responses, cytotoxic cell responses, and macrophage activation. Responses by Th1 cells promote cellular immune inflammatory reactions and appear to provide the primary host immune defenses against intracellular pathogens. By contrast, Th2 cells secrete IL-4, IL-5, IL-6, and IL-10, but not IL-2 or IFN- $\gamma$ , and they promote B-lymphocyte responses and the synthesis of IgG, IgE, and IgA antibodies. Responses by Th2 cells promote humoral immunity, allergic reactions, and immediate hypersensitivity reactions, which provide defenses against extracellular pathogens. Th1 and Th2 cells appear to represent a later stage of differentiation from Th0 cells, which display an intermediate cytokine profile. Naive T cells generate primarily IL-2 after stimulation, and the pattern of cytokines surrounding these stimulated T cells strongly influences whether a Th1 or Th2 type of response develops.

The responses of the two classes of helper T cells are influenced differently by many factors, including the nature of the antigen and its dose, the type of APC and its membrane-bound costimulatory signals, and various pharmacologic agents. As with humoral and cellular immunity, the responses of the two classes of helper T cells often are regulated in a reciprocal fashion, and here the influence of cytokines is critical. For example, in mouse models, the presence of IFN- $\gamma$  and IL-12 and the absence of IL-4 tend to promote the activation of Th1 cells, whereas IL-4 and IL-10 tend to promote the activation of Th2 cells. Reciprocal roles for individual cytokines have been observed, in that IFN- $\gamma$  can directly inhibit the proliferation of Th2 cells, and IL-10 can inhibit cytokine production by Th1 cells indirectly by inhibiting macrophage activation of the Th1 cells.

Patterns of secreted cytokine profiles have been extended to subgroups of CD8+ cytotoxic cells and to T<sub>gd</sub> cells as well, which are referred to as *type 1 cells* if they secrete Th1-like cytokines (the major subgroup), or as *type 2 cells* if they secrete Th2-like cytokines.<sup>299,300 and 301</sup> Cytotoxic CD8+ T cells in these categories are also referred to as *Tc1* or *Tc2 cells*.

Cytokine patterns themselves have been identified as type 1 or type 2, analogous to those typically produced by Th1 or Th2 mouse cells, to refer to their functions

rather than their cellular source.<sup>302</sup> This frame of reference has been useful when cells other than CD4+ T cells contributed to the cytokine pool, such as NK cells (e.g., IFN-g) and macrophages or B cells (e.g. IL-10).

## SUPPRESSOR T CELLS

T-cell suppression of other T cells can be mediated by a variety of mechanisms.<sup>287,303,304</sup> and <sup>305</sup> Suppressor cell activity has been associated with both CD4+ and CD8+ T cells.

In some instances, suppression appears to be antigen-nonspecific. Possible mechanisms include an effect of cytokines that nonspecifically interfere with proliferation or differentiation of immune cells. For example, CD4+ Th1 and Th2 helper T cells can each release cytokines that nonspecifically suppress the other, promoting "immune deviation" toward a Th1-propelled cellular response or a Th2-propelled humoral response. Alternatively, bystander T cells, activated against other antigens, may consume the cytokines essential for T-cell responses against the antigen of interest. States of increased nonspecific suppression have been observed in several pathologic conditions, including some tumor-bearing hosts.

In other cases, suppression may be highly antigen-specific.<sup>304,306,307</sup> and <sup>308</sup> Suppressor T cells may also act directly on the T cells being suppressed, by exerting veto activity. Veto cells destroy T cells that recognize antigens on the surface of the veto cell.<sup>309,310</sup> and <sup>311</sup> In addition, cytotoxic CD4+ Th1 cells may suppress a response by damaging APCs expressing antigens restricted by MHC class II. Cytotoxic CD8+ T cells may act in a similar fashion, as at least some APCs appear able to process exogenous antigens and present them as MHC class I-restricted, as described earlier in the section [Dendritic Cells](#).

Suppressive influences can exist in any immune response. The absence of a strong immune response does not necessarily reflect the absence of antigen recognition by the immune system but rather may reflect suppression.

## CYTOTOXIC EFFECTOR CELL MECHANISMS

Different host mechanisms for destroying target cells have evolved, resulting in a diverse collection of cytotoxic cells capable of reacting against a wide variety of foreign cells and organisms. A common feature among them, however, is that cytotoxicity is a regulated process. They are generally activated as a result of cell surface ligands on the target cells binding and triggering selected cell surface receptor molecules on the effector cells.

Major sources of cytotoxic effector cells that have been studied extensively are CTLs, NK lymphocytes, and activated macrophages.

## CYTOTOXIC T LYMPHOCYTES

CTLs result from classic T-cell immune responses: (1) The CTL response is initiated by exposure to antigen, (2) generation and regulation of the response depends on a complex MHC-dependent interaction of antigen-processing cells and T cells, (3) the T-cell antigen receptor (TCR) provides MHC-dependent antigen specificity for the interaction between CTLs and target cells, and (4) memory responses commonly follow reexposure to the antigen, resulting in more rapid, longer, and higher-level responses.

CTLs do not have a characteristic morphology. They may appear as small, resting, agranular lymphocytes or as large, blastic, granular cells or as gradations in between.

All CTLs express the TCR/CD3 complex (described earlier in the section [T-Cell Receptor CD3 Complex](#)), which triggers antigen-specific responses. Most CTLs do not express cell surface receptors for Ig (FcR).<sup>312,313</sup> Most CTLs express either CD8 or CD4 molecules (primarily CD8) but rarely both. In mouse models, both CD8+ and CD4+ T cells can mediate tumor rejection.<sup>314</sup> The class of MHC molecule with which the target cell antigen is associated correlates with whether the CTL is CD4+ or CD8+: CD8+ CTLs recognize primarily MHC class I-associated antigens, and CD4+ CTLs recognize primarily MHC class II-associated antigens.

The distinction between T cells with cytotoxic activity and those with helper activity is not absolute. For example, stimulated CD4+ Th1 T cells can be cytotoxic by the Fas ligand pathway described later in this section (probably their most cytotoxic common pathway), by the release of cytotoxic granules, or by the release of a relatively slow-acting cytotoxic product, lymphotoxin.<sup>315</sup> Stimulated CD4+ Th1 T cells also may release cytokines, such as IL-2 and IFN-g, that can promote CTL generation. Moreover, these cells may release GM-CSF after stimulation, which can promote tumor rejection, perhaps through enhancing the development of DCs and their role as APCs.<sup>316</sup> Thus, Th1 or inflammatory CD4+ T cells have the potential to be either helper cells or cytotoxic cells; however, antigen-specific triggering of these cells will be primarily from MHC class II-restricted antigens on the target cells.

Although CTLs use different pathways to destroy target cells, common features are found. The cytolytic reactions generally are triggered by cross-linking of the TCRs on CTLs after contact with target cell antigens expressed at the cell surface. A variety of costimulatory accessory molecules, mentioned earlier in the section [Adhesion and Accessory Molecules](#), may not only facilitate the binding of CTLs to target cells but may contribute to T-cell triggering by the TCRs. Consequently, the activation of only a few TCRs or TCRs with low affinity for MHC-antigen complexes may be capable of triggering T cells with the support of cosignaling molecules. Death of the target cells usually includes apoptosis, with such distinguishing characteristics as membrane blebbing, chromatin condensation, and DNA fragmentation, followed by lysis. In addition, CTLs are not destroyed during the cytolytic reaction; they can recycle to kill more target cells, although their life span is relatively short. CTLs appear to use two significantly different ways of destroying target cells during rapid cytolytic reactions: granule exocytosis and the triggering of target cell receptors by particular TNF-related molecules expressed by the CTLs, such as Fas ligand (FasL/Apo1L/CD95L)<sup>317</sup> and the recently reported TNF-related apoptosis-inducing ligand (TRAIL/Apo2L).<sup>318,319</sup>

With respect to granule exocytosis, specialized granules are secreted into areas of close contact with target cells after triggering of the TCRs. The granules contain two types of proteins that contribute to the destruction of target cells: perforin (cytolysin), which is related to the terminal component of complement and forms pores in the outer membrane of the target cells, and granzymes, a subfamily of serine proteases that are found in lymphocytes and appear to be necessary for apoptosis of the target cells. The serine proteases may enter the target cells through the perforin-generated pores.

Other rapid cytolytic reactions of CTLs with target cells, however, lack features of the granule secretion mechanism and appear to depend on the triggering of receptors for TNF-like molecules on the target cells. A well-characterized example of these receptors is Fas, also referred to as *APO1* or *CD95*, which is expressed on the surface of a wide variety of cell types.<sup>194,320,321,322,323,324</sup> and <sup>325</sup> Cross-linking of Fas molecules commonly triggers apoptosis in cells expressing these molecules. A Fas ligand that is a transmembrane protein belonging to the TNF family has been identified on the surface of activated CTLs, particularly among CD8+ T cells and CD4+ Th1 T cells. The antigen specificity of Fas-mediated cytolysis by CTLs may depend on TCR-mediated stimulation of the CTL for brief expression of the Fas ligand in a functional form at the site of contact with the TCR-triggering target cell.<sup>326,327</sup>

Tests of gene-knockout and gene-reconstitution mouse models have clearly established the importance of granule exocytosis and the Fas-mediated pathways.<sup>326,327,328,329</sup> and <sup>330</sup> Perforin-deficient mice are impaired in their resistance to at least noncytopathic choriomeningitis virus, *Listeria monocytogenes*, and tumors.<sup>331,332</sup> Whereas the granule exocytosis pathway may be used more against pathogens, the Fas-mediated pathway may be more involved with down-regulating immune responses.<sup>191,194,245,260,333,334</sup> Of note, Fas is markedly up-regulated on activated T cells, B cells, and NK cells. However, not all Fas-expressing lymphocytes are susceptible to apoptosis through this pathway; prolonged stimulation for at least a period of days may be needed. Understanding which cells are susceptible to this mode of down-regulation is at an early stage.

At least some T cells express additional receptors that can down-regulate cytotoxic activity through an interaction with MHC class I determinants on target cells.<sup>335,336</sup> Initially found on NK cells, the inhibitory receptors are not related to the antigen-specific TCR. They contribute to the balance between activation and inhibition of T-cell cytotoxic function.

The release of cytotoxic mediators by CTLs is generally antigen-specific and MHC-restricted, because of the TCR-mediated triggering. The cytotoxic activity of the released mediators, however, is not target cell-specific. Only to the extent that their activity is limited to the immediate vicinity of the triggered parent CTLs is cytotoxicity specific for target cells bound to the CTLs. Local activity probably is facilitated by focused effector molecules at the site of target cell contact,

concentration gradients, a short burst of cytotoxic molecules from the parent CTLs, and a short half-life of the mediator.

Several exceptions to the antigen specificity of CTL-mediated lysis of target cells have been described.<sup>317,337,338,339 and 340</sup> For example, the expression of Fas ligand on the CTL surface at sites other than contact with the TCR-triggering target cell may destroy innocent bystander cells that express Fas and are in contact with the CTL. In addition, nonspecificity may result from lymphotoxin/TNF- $\alpha$  - like molecules that are released from CTL on triggering by MHC-restricted antigens but, given an opportunity to accumulate in the intercellular space, are nonspecifically toxic. The TNF-related, apoptosis-inducing ligand, TRAIL, may be an exception, as the soluble form appears to be more toxic for cancer cells than for normal cells; as a result, the soluble form is being evaluated as a possible cancer chemotherapeutic agent.<sup>341</sup>

## **NONSPECIFIC CYTOTOXIC CELLS**

NK cells and activated macrophages are the host's major sources of cell-mediated cytotoxic activity that is not triggered by antigen-specific recognition of foreign cells. They are part of the host's innate or front-line defense mechanisms, because to function they require no antigen-specific adaptation of the host or immunization. Although there is no memory response by these cells, NK cells and macrophages can be activated by T-cell cytokines, such as IFN- $\gamma$ . After cell contact, both types of effector cells can be triggered to kill sensitive target cells by antibody-independent interactions between surface molecules on effector and target cells. The nature of these molecules is at a relatively early stage of identification. By contrast, Ig receptors on NK cells and activated macrophages can trigger antibody-dependent cellular cytotoxicity, if the bound target cells have reacted with appropriate Ig subclasses. Thus, apart from their independent roles in host defense, these cells are also important accessories to cytotoxic immunity. In addition, their production of cytokines and chemokines as part of the early, innate host defense response can strongly influence subsequent adaptive immune responses. For example, activated NK cells may release large amounts of IFN- $\gamma$ , which can promote inflammatory, Th1-type T-cell responses and also enhance the expression of a wide array of cell surface molecules.

### **Natural Killer Cells**

NK cells are a relatively small population of lymphocytes distinct from T and B lymphocytes.<sup>342,343,344 and 345</sup> They generally are large, granular lymphocytes that originate in the bone marrow. NK cells share a common progenitor with T cells, and NK cell precursors have been identified in the thymus; however, they do not require the thymus for maturation, and they probably diverge from the T-cell lineage at an early stage of differentiation.<sup>176</sup>

Several markers are particularly helpful in distinguishing between NK cells and CTLs.<sup>343,346</sup> Human NK cells are primarily TCR/CD3 $^-$ , CD5 $^-$ , CD56 $^+$ , FcR $^+$ . These cell surface features have been used both for physically separating the cells and for functionally distinguishing between NK cell and CTL activity.

Although the picture is far from complete, the basic cytotoxic mechanisms of NK cells and CTLs appear to be similar.<sup>321,346,347,348,349 and 350</sup> Granule exocytosis, perforin, and granzymes have well-established roles in cytotoxicity mediated by NK cells. As with CTLs, the bulk of lytic activity from NK cells depends on perforin.<sup>351,352</sup> Like CTLs, NK cells depend on surface accessory molecules for the initial binding to target cells. Also like CTLs, accessory molecules expressed on NK cells, such as CD2 and CD69, can contribute to effector cell function when bound to ligand. Granule exocytosis is followed by target cell lysis with apoptosis and then detachment of the NK cell.

NK cells, as with CTLs, can also express or secrete molecules related to TNF, such as FasL and TRAIL, and destroy target cells by apoptosis.<sup>353,354 and 355</sup> As in T cells, activation of NK cells increases the expression of these molecules.

Although NK cells are not target cell-specific, they exhibit target cell selectivity by mechanisms independent of antibody and antibody-dependent cellular cytotoxicity.<sup>335,336,342,343 and 344,356,357</sup> For example, they are more toxic for tumor cells and virus-infected cells than for most normal cells. Also, different clones of NK cells show different patterns of cytotoxicity with panels of tumor cells from different sources. Different susceptibilities of target cells to NK cells are, in part, due to families of cell surface receptors that can be expressed by NK cells and that recognize polymorphic MHC class I molecules expressed by target cells.<sup>358,359,360,361,362 and 363</sup> One family of inhibitory receptors, the NK cell complex, is controlled by genes clustered on human chromosome 12 that encode glycoproteins of the C-type lectin superfamily. Another family, designated *killer inhibitory receptors*, is controlled by genes clustered on human chromosome 19 that encode particular glycoproteins in the Ig superfamily. When cross-linked, the receptors can deliver a dominant signal that inhibits triggering of cytotoxic activity and cytokine expression. Function of the different families of inhibitory receptors is related to a component of their intracytoplasmic tails, the immunoreceptor tyrosine-based inhibition motif ( *ITIM* ), which on tyrosine phosphorylation can temporarily inhibit the activation of a variety of cellular activities, such as cytotoxicity and cytokine release.<sup>364</sup> This mechanism appears to explain the tolerance of NK cells for normal cells, as a consequence of the inverse relationship between MHC class I expression and susceptibility to NK-mediated cytotoxicity.<sup>365</sup> Thus, there may be two functionally opposed sets of receptors and ligands associated with triggering cytotoxicity. One set, ill-defined, is not MHC-restricted and triggers cytotoxic activity. The other set, which recognizes an MHC class I ligand, can inhibit cytotoxicity. If tumor cells lose MHC class I expression, they escape CTLs; however, they become more susceptible to a subclass of NK cells.

The distinction between NK cells and NK-like activity is important. For example, CTLs cultured with IL-2 can exhibit NK-like activity, but they are not NK cells. Also, a subset of T cells, *NKT cells*, has recently been described, that expresses some of the cell surface markers usually characteristic of NK cells. NKT cells develop outside the thymus, depend on TCR interaction with MHC class I-like CD1 molecules for development, express a very limited TCR repertoire that reacts particularly with galactosylceramide presented by CD1 molecules, and are CD4 $^-$ CD8 $^-$  or CD4 $^+$ CD8 $^-$ .<sup>366</sup> The TCRs of NKT cells are composed of an invariant TCR- $\alpha$  chain paired preferentially with particular V $\beta$  chains (Va24/V $\beta$ 11 in humans), and they commonly are able to recognize selected lipid or glycolipid antigens or hydrophobic peptide antigens presented by cell surface CD1 molecules. NKT cells mediate NK-like cytotoxicity after triggering of the TCR; however, their role in regulating early responses of NK cells and T cells also appears important because of their ability to release rapidly large amounts of IFN- $\gamma$ , IL-4, or both after activation.

### **Lymphokine-Activated Killer Cells**

Both CTLs and NK cells cultured with relatively high doses of IL-2 show enhanced nonspecific cytotoxic activity, as revealed by their ability to lyse selectively a broad spectrum of fresh autologous, syngeneic, or allogeneic tumor cells that are relatively insensitive to normal NK-mediated cytotoxicity.<sup>367,368 and 369</sup> They are referred to as *lymphokine-activated killer cells*. The greater cytotoxic activity of these cells appears to result, in part, from their activation-enhanced expression of surface molecules that contribute to target cell binding and to triggering cytotoxic activity.

### **Macrophages**

Activated macrophages, as with NK cells and CTL cultured with relatively high doses of IL-2, can be nonspecifically cytotoxic for tumor cells *in vitro*.<sup>314,370,371,372,373,374,375 and 376</sup> IFN- $\gamma$  and bacterial products, such as LPS, are among the most potent sources of macrophage activators. Macrophages can be activated by many additional factors, including tumor cell contact.<sup>314,370,371,372,373,374,375</sup> As with NK cells, the basis for triggering cytotoxicity after contact between activated macrophages and tumor cells has not been established.

Macrophages and monocytes are clearly distinct from CTL and NK cells. In contrast to CTL or NK cells, they may be phagocytic; express CD14, CD36, or CD68; have a relatively abundant cytoplasm lacking large azurophilic granules; and are commonly adherent to culture vessel surfaces *in vitro*. Although they may express CD4, they do not express the TCR, CD3, or CD8.<sup>377</sup>

Mediators of cytotoxicity, triggered by the binding of activated macrophages to tumor cells, include the following products: cytolytic proteases; TNF- $\alpha$  and related factors; IFN- $\alpha$ , $\gamma$ ; IL-1; reactive oxygen intermediates, such as H<sub>2</sub>O<sub>2</sub>; reactive nitrogen intermediates, such as nitric oxide; arginase; thymidine; and lysosomal enzymes.<sup>372,378,379</sup> A serine protease has also been implicated.<sup>373</sup> Many of the cytotoxic mediators may also act on tumor cells that are not in direct contact with macrophages, but most of the cytotoxic effects on bystander cells can be against both normal and tumor cells. Several mechanisms limit bystander effects, including short half-lives of the cytotoxic factors.

Correlations have been established in several animal models between progressive tumor growth *in vivo* and resistance of tumor cells to macrophage cytotoxicity *in vitro*. However, macrophages can also promote growth of some tumors by effects on the tissue stroma, the blood supply, or the tumor cells themselves.<sup>380</sup> The net effect of macrophages on tumors appears to depend on an array of factors that, with naturally occurring host responses, may balance differently for each tumor.

## B CELLS AND HUMORAL IMMUNITY

### IMMUNOGLOBULIN HETEROGENEITY AND CLASSES

B cells are antibody-producing cells, in addition to serving as APCs. Driven by antigen binding to cell surface, membrane-anchored Ig, mature B cells proliferate and differentiate into end-stage plasma cells, which produce and release soluble antibodies into extracellular fluids. Antibodies are commonly referred to as *immunoglobulins*, which are highly heterogeneous but have a common basic monomeric structure consisting of four disulfide-linked polypeptide chains ( Fig. 4-7).<sup>381,382</sup> and <sup>383</sup> The two smaller polypeptides of an antibody molecule are identical, are either kappa (k) or lambda (l), and are referred to as *light chains*. The two larger chains of a monomeric Ig, also identical, are referred to as *heavy chains*. The great structural heterogeneity of antibody molecules that accounts for the body's ability to react with a vast variety of antigens results from variability in parts of the molecule near the N-terminals of the heavy and light chains, where the binding sites for antigens are located. A four-chain antibody structure has two antigen-binding sites, because each antigen-binding site is formed by the N-terminal regions of a heavy- and light-chain pair.

FIGURE 4-7. IgG immunoglobulin molecule with pepsin and papain cleavage sites. SS, disulfide bond.

A second source of structural heterogeneity of antibodies is in the C-terminal portion of the heavy chains. This heterogeneity, which is much less than that associated with antigen-binding activity, accounts for the structural and biologic differences between the five major Ig classes that have been identified in humans: IgG, IgA, IgM, IgD, and IgE. The Ig classes (isotypes) differ from one another with respect to a variety of properties, such as size, carbohydrate content, the concentration in serum, the serum half-life, the portion that is intravascular, and the ability to cross the placenta ( Table 4-2). The circulating Ig classes also are associated with particular biologic activities resulting from interactions of the carboxy-terminal region of the heavy chain with Ig receptors on cells or with other soluble molecules. The biologic activities of selected Ig classes bound to antigen include activating the complement cascade (IgG and IgM); triggering cytotoxic activity by macrophages and particular lymphocytes, such as NK cells (IgG); triggering mast and basophil cells to degranulate (IgE); and promoting phagocytosis of antibody-antigen-complement complexes (IgG and IgM). Entering secretions, such as breast milk and on mucosal surfaces, is characteristic of IgA antibodies, and bound antigen is not a prerequisite.

### MONOCLONAL ANTIBODIES

Normal humoral immune responses by B lymphocytes are polyclonal and, as a result, the antibodies are heterogeneous. By immortalizing and cloning antibody-producing cells, however, large amounts of homogeneous antibody reacting with a single epitope can be generated.<sup>384,385</sup> and <sup>386</sup> Antibody-producing cells, particularly from mice, are commonly immortalized by fusing them with plasma cell tumors that do not produce Ig but nevertheless are capable of supporting antibody synthesis and secretion. The antibody-producing cell contributes the genetic coding for the antibody to the hybridoma brought about by the fusion, and the plasmacytoma provides the ability to replicate indefinitely.

By cloning large numbers of hybridomas and characterizing the antigen specificities of the different monoclonal antibodies, investigators have generated large and renewable quantities of reagents that, as a group, identify an extensive array of biologically important molecules. These include cellular components that stimulate or regulate immune responses, cellular markers that distinguish one class of cell involved with immune responses from another, cellular markers that help to diagnose the nature of a tumor biopsy specimen, and antigens selectively expressed by tumor cells. Monoclonal antibodies are used not only for identifying and purifying molecules or cells but for triggering or blocking activation molecules on cell surfaces and for targeting cytotoxic and diagnostic imaging reagents to tumors *in vivo*. With access to the mRNA coding, mouse monoclonal antibodies have been restructured genetically by recombinant DNA technology to generate new types that may be useful in diagnosing and treating cancer. Examples include humanizing mouse antibodies by introducing human sequences without altering the antigen specificity and reducing the antibody size by coding for variable regions of heavy and light chains connected by a polypeptide spacer.

### B-CELL MATURATION IN THE BONE MARROW

Stem cells develop within the adult bone marrow into B cells expressing surface IgM and IgD Igs in a fashion that does not require interaction with foreign antigens.<sup>387,388,389</sup> and <sup>390</sup> These naive or virgin B cells then circulate to lymphoid organs where, stimulated by antigen and appropriate cosignals, they mature further into cells expressing the other Ig classes.

#### Immunoglobulin Gene Rearrangements as Markers of Maturation Stages

The earliest indication of commitment of a bone marrow stem cell to the B-cell lineage appears to be rearrangement of nonadjacent germline variable V, D, and J genes coding for the variable region of the IgM heavy chain, so that they are next to one another. Successful rearrangement of a V(D)J segment is followed by synthesis of IgM (μ) heavy chains in a fashion similar to that of a T-cell receptor chain, cell surface expression of the μ chain combined with a temporary surrogate light chain, cessation of further rearrangements of H-chain genes, and the start of rearrangements of kappa (k) light-chain genes. Successful Vk-Jk pairing results in k-chain synthesis; matching of k and μ heavy chains and expression of monomeric surface IgM molecules; and termination of the gene rearrangements. With a few nonproductive Vk-Jk alignments—perhaps only two—rearrangement of k-chain genes stops and that of lambda (l) light-chain genes starts, with success resulting in μ heavy chains pairing with l light chains. The life span appears to be short for cells with nonproductive gene rearrangements. The large diversity among antibody molecules reflects, in part, the different functional gene arrangements and chain pairings that are possible. Developing B cells with light chains and μ heavy chains

express surface IgM alone, followed in time by both IgM and IgD, which mark the completion of antigen-independent maturation in the bone marrow.

B-cell tumors and Ig-deficiency disorders often represent arrested stages of normal B-cell development. Characterizing the Ig gene rearrangements in these situations has provided key information about the sequence of events during normal maturation and has helped to identify and classify B-cell tumors.

IgM anchored by transmembrane domains to the cell surface are specific markers for B cells. CD19 and CD20, which are not Igs, are also used for identifying B cells. These cell surface products are expressed by pre-B cells and by mature B cells but not by plasma cells.

In addition to the conventional B-cell lineage, another lineage has been observed in humans and in animal models.<sup>391</sup> Referred to as *B-1 B cells*, in contrast to conventional B-2 B cells, they are bone marrow-derived but differ from the conventional lineage, in part by the general location of mature cells (extra lymphoid sites, such as the peritoneal cavity), cell surface markers (CD5), and the antigen specificity repertoire, which is more restricted, of lower affinity, and of broader specificity than the conventional repertoire. Although not as common as conventional B cells, like Tgd cells they may contribute to early host reactions against particular pathogens.

### **B-Cell Antigen Receptor**

IgM integrated into the cell surface serve as antigen receptors and cell-signaling molecules.<sup>392,393</sup> These Igs appear to be part of a signaling complex, the B-cell antigen receptor, that includes at least two additional noncovalently bound transmembrane invariant polypeptides, Ig- $\alpha$  and Ig- $\beta$ , analogous to the TCR/CD3 complex on T cells. Antigen-specific activation of B cells leads to cell proliferation and differentiation through a process of cell signaling that, like T-cell activation, appears to use multiple tyrosine kinases and the phosphatidylinositol second messengers to turn on DNA transcription factors. Analogous to CD4 and CD8 in T-cell activation, the complex of CD19, CD21, and CD81 has been implicated as a coreceptor for B-cell activation by the binding of CD21 (CR2) to fragments of complement CR3 associated with the antigen.

### **Regulation of B-Cell Maturation in the Bone Marrow**

The maturation of B cells is sensitive to a variety of factors in the bone marrow environment, including stromal cells that provide supportive cytokines (e.g., IL-7), chemokines (SDF-1), and direct cell interactions.<sup>388,389,393,394</sup>

Cell surface IgM on developing B cells may have an important role in signaling, similar to the T-cell receptor on thymocytes. B-cell development is arrested in animals genetically unable to express cell surface IgM, which may serve as a source of positive signals for development as a result of relatively low-affinity interactions with self-antigens. However, activation of immature B cells by cross-linking surface IgM molecules with either antigen or anti-IgM antibodies can result in cell deletion, likely by apoptosis, rather than proliferation and differentiation. Fas-dependent mechanisms appear to be associated with the apoptosis. For antigen-mediated deletion of immature B cells, relatively high-affinity binding to the surface IgM may be needed. A pause in cell maturation appears to precede deletion. During this period, a portion of the autoreactive B cells rearrange their light-chain genes by a process referred to as *receptor editing*, and cells with successful rearrangements escape negative selection by expressing new antigen specificities that are not autoreactive.<sup>395</sup>

### **One Antibody Specificity per Cell**

As a consequence of limiting successful gene rearrangements, each B cell generally expresses the heavy chain of only one chromosome, the light chain of only one chromosome (allelic exclusion) and, moreover, only one class of light chain (k or l, isotype exclusion).<sup>396</sup> Hence, each B cell generally produces only one antibody specificity.<sup>397</sup> For individual B cells expressing both IgM and IgD molecules, the two classes of antibodies have the same heavy-chain variable region and the same light chains, probably as a result of differential splicing of a single primary RNA transcript that includes the rearranged variable region and both  $\mu$  and d constant region genes. Hence, they have the same basic antibody specificity for antigen and preserve the general observation of one specificity per cell. As with T cells, antigen specificity is established before a mature but naive B cell encounters foreign antigen. These B cells, considered as a whole, comprise a host's primary B-cell repertoire. The primary repertoire represents antibodies of lower affinity and broader specificity than what follows with further antigen-driven maturation.

## **B-CELL MATURATION IN LYMPHOID ORGANS**

Mature but naive B cells migrate from the primary lymphoid organ where they are produced—the bone marrow—to secondary lymphoid organs throughout the body, where further maturation is induced by stimulation with antigens and appropriate cosignals. Successfully stimulated B cells differentiate into antibody-secreting plasma cells or into memory cells. Unstimulated cells appear to die by apoptosis after a relatively short life span.

### **T-Cell-Dependent Antibody Responses**

B-cell responses to protein antigens commonly depend on helper (CD4+) T cells.<sup>392,398,399,340,341 and 402</sup> T-cell-dependent activation of naive B cells starts with antigen binding to Ig cell surface receptors. Antigen processing follows with presentation of MHC class II-restricted peptides. In T-cell-rich areas of lymphoid organs, the B cells act as APCs to helper T cells, with receptors capable of binding to the MHC-restricted peptide. Successful T-cell/B-cell interactions may require previously activated helper T cells. The cognate T-cell/B-cell interaction results in mutually rising levels of activation, including up-regulation of the cell surface B7 family of costimulatory molecules on the B cells. Engagement of the CD40 receptor on B cells by a CD40 ligand (CD40L) on activated helper T cells leads to B-cell activation, enhanced by exposure to T-cell-derived IL-4 and other cytokines and additional B-cell/T-cell receptor-ligand interactions. Establishing germinal centers that include FDCs and helper T cells, the activated B cells undergo class switching, antibody affinity maturation and, finally, differentiation into antibody-secreting plasma cells or memory B cells. The B-cell response to an antigen not previously encountered is, in the early stage, primarily by activated naive cells producing IgM antibodies of relatively low affinity.

### **Class Switching**

Ig class (isotope) switching occurs, in which cells expressing IgM and IgD receptors at the surface differentiate, essentially irreversibly, into cells expressing IgG, IgA, or IgE receptors.<sup>403,404</sup> Antibody molecules resulting from a class switch express a new isotype and new associated biologic functions; however, the antigen specificity remains intact, because the light chains and the variable region of the heavy chain do not change. The switching is controlled by a combination of factors, including B-cell-activating agents (e.g., antigens), contact with helper T cells, and particular cytokines (e.g., IL-4, IFN- $\gamma$ , and TGF- $\beta$ ). For example, the switch to IgE by B cells previously activated by antigen and T-cell contact is promoted by IL-4 but inhibited by IFN- $\gamma$ . Class switching involves DNA recombination events between switch regions associated with each heavy-chain constant region. As a result, the V(D)J rearrangement, coding for the variable region of the heavy chain, comes into close approximation to a new constant region gene, probably because of intervening DNA forming a loop and being deleted (e.g., as a circular episome).

### **Changes in Antibody Affinity for Antigen**

Somatic hypermutation in the variable region genes for heavy and light chains of dividing B cells in the germinal centers of secondary lymphoid organs increases the antigen repertoire and the range of antibody-binding affinities for each antigen.<sup>405,406 and 407</sup> As a result, B cells expressing high-affinity antibodies preferentially expand in the face of falling levels of antigen associated with the end of the response. If the response is prolonged, such as after immunization with an adjuvant, class switching and affinity maturation may occur later during the initial (primary) response to the antigen.

### **Memory**

Most B cells and plasma cells associated with a primary (IgM) antibody response disappear at the end of the response, which is associated with removal of the antigen and Fas-mediated apoptosis. However, some B cells survive responses to T-dependent antigens as memory cells.<sup>271,392</sup> Memory B cells express surface Ig molecules other than IgM and develop through a T-cell-dependent process. They appear not to be derived from B cells that have generated a primary (IgM) antibody response but rather from a separate differentiation pathway. Expression of Bcl-2 genes in memory cells may protect against apoptosis. Memory cells are not restricted to the site of antigen interaction; they contribute to the pool of recirculating lymphocytes. Long-term memory cells may not need to divide to survive for years. After reexposure to antigen, activated memory cells generate a more rapid response than the primary one. Moreover, the secondary (anamnestic) response is more

intense, lasts longer, and exhibits class switching away from IgM antibodies and increased antibody affinity for the antigen.

### **T-Cell–Independent Antibody Responses**

B-cell responses to some antigens, particularly various bacterial products, occur in the absence of MHC class II–restricted T-cell help. These responses are referred to as *T-cell–independent*.<sup>408</sup> They include antigen-specific responses against low doses of haptened B-cell mitogens (e.g., trinitrophenyl (TNP)-LPS), which can occur in the absence of accessory cells. They also include responses against large nonprotein molecules with repeating, appropriately spaced copies of an antigenic epitope, such as particular bacterial polysaccharides. The multivalent antigens cross-link the B-cell surface Igs capable of binding the epitopes, resulting in a signal that, combined with exposure to particular cytokines (e.g. IL-5), leads to B-cell activation and antibody secretion, particularly IgM. Isotype switching, affinity maturation, and memory do not occur with these responses as they do with T-cell–dependent responses.

### **Mature B-Cell Tolerance**

As with T cells, mature B cells may show tolerance for particular antigens, through deletion, anergy, or ignorance.<sup>409,410,411</sup> and <sup>412</sup> Mature B cells specific for T-dependent antigens are subject to deletion after binding of autoantigen in the absence of successful signaling (e.g., the CD40 ligand) from helper T cells. Apoptosis triggered by Fas on susceptible cells may be involved. B cells can also become unresponsive (anergic) to soluble antigens, probably at a lower antigen concentration or affinity than with deletion, as a result of a failure in signaling from the surface Ig. The life span of anergic B cells is relatively short; hence, the anergy blends into cell deletion. The anergic state may be offset by stimulating the cell surface CD40 molecule and adding IL-4 or by transferring the cells to an antigen-free environment. In addition, B-cell responses that depend on T-cell help can fail as a result of T-cell tolerance. Also, autoreactive B cells may be competitively blocked by other antigen-activated B cells from entering the limited space within the lymphoid follicles of secondary lymphoid organs, where conditions favor optimal stimulation, proliferation, and differentiation. Finally, B cells may simply ignore antigens because of insufficient concentrations or avidity.

## **SUMMARY**

The immune system has evolved as a highly complex and adaptive mechanism for distinguishing between nonself and self and for neutralizing or clearing nonself from the host. Extracellular pathogens are attacked primarily by humoral immune responses, which depend on soluble antibodies produced by B lymphocytes for antigen recognition and for recruitment of effector arms, such as phagocytes and the complement system. Foreign cells, including host cells bearing intracellular pathogens, are recognized and destroyed primarily by cellular immune responses, which depend on the TCR for specific recognition of cell surface antigens and for triggering T-cell activities that kill the foreign cells either directly or through recruitment of other host cells, such as macrophages.

T cells that directly kill foreign cells are commonly CD8+ and generally recognize a cell surface complex of MHC class I molecules and foreign peptides, derived primarily from intracellular proteins processed in the foreign cells through a particular cytoplasmic pathway. Foreign proteins that are shed and picked up by the host's normal APCs, such as macrophages and DCs, are processed mainly by a different cytoplasmic pathway for cell surface presentation if they are expressed as a peptide complex with MHC class II molecules. The peptides bound to MHC class II molecules on APCs are recognized primarily by CD4+ T cells that are not directly cytotoxic but rather function primarily to help immune responses. In this fashion, directly cytotoxic T cells focus on the foreign cells rather than on normal host cells.

Through somatic shuffling of gene components, millions of different gene combinations are efficiently generated by each host to produce antibodies and TCRs that, taken as a whole for the host, can recognize millions of different antigens. Somatic mutations in antibody genes expand the range even further. Generally, each cell in the B-cell lineage expresses only one antibody specificity, and each T cell expresses only one antigen receptor specificity. As a consequence, the immune system can regulate the responses against each antigen by promoting or limiting the expansion and activation of cells that react specifically with the antigen. After immunization, a select portion of lymphocytes may persist as a pool of antigen-specific memory cells, which generate relatively quickly a more intense and longer immune response after reexposure of the host to the antigen.

Stimulating T lymphocytes in an antigen-specific fashion commonly requires two cell surface signals. The first signal selects the cell to respond and provides specificity as a result of triggering the antigen-specific receptor (TCR) on the cell surface. The second is an essential (but by itself insufficient) costimulatory signal from APCs, which adds stringency and reduces the likelihood of careless responses. A first signal without a second signal commonly results in anergy or death. The immune response is promoted or limited by regulatory cells through their secreted cytokines and cell surface ligands, which, as a group, form a network of overlapping activities that reduce the likelihood of general failure of an immune response or of an immune response getting out of hand.

Although far from perfect, immune responses avoid activity against self-antigens generally as a result of processes that remove or inactivate self-reactive cells during the early maturation or adult life of T cells and B cells. Because autologous human tumor antigens recognized by the host's T cells commonly involve unaltered self-proteins, the inactive T cells with potential antitumor activity are of particular interest to tumor immunologists.

## INTRODUCTION

Cytogenetic testing is one of the fastest-growing areas of testing in oncology. In most cytogenetic laboratories, cancer cases have come to constitute more than 50% of cytogenetic testing done. It is difficult to estimate the total testing being done. A recent survey by the Association of Genetic Technologists reported that more than 95,000 cancer studies were performed in the United States in 1998 (reported by 202 responding laboratories from 243 laboratories surveyed). Because large commercial laboratories did not report their numbers, one would estimate that the total number of such tests in the United States is close to 200,000 per year. This number is, however, rapidly rising as clinicians are becoming aware of the prognostic and diagnostic value of chromosome studies. In this chapter, we do not review the molecular cytogenetic knowledge in particular diseases nor discuss the biological effect of cancer chromosomal abnormalities (e.g., oncogene activation or tumor suppressor genes), because these are covered in detail in separate chapters. We do, however, provide an overview of basic cancer cytogenetics covering terminology, chromosome structure, mechanisms of formation of chromosomal abnormalities, and new technical developments in the field, and cover some genetic topics not covered in other chapters. The continuous advances in techniques of molecular cytogenetics in the last decade are emphasized.

## HISTORY OF CANCER CYTOGENETICS

Boveri<sup>1</sup> established the modern paradigm that mutations in somatic cells cause the uncontrolled cell proliferation called *cancer*. The modern era of human cytogenetics confirmed this view. This era was ushered in with the simultaneous publications by Tjio and Levan<sup>2</sup> of good-quality, unbanded human karyotypes showing 46 chromosomes. Technical improvements were the key to the development of clinical cytogenetics. Within a few years (1956 to 1960), researchers identified specific chromosomal abnormalities associated with congenital abnormalities (e.g., Down, Turner's, and Klinefelter's syndromes) and with cancer. The opening salvo in cancer cytogenetics was the demonstration of the Philadelphia chromosome as associated with chronic myelogenous leukemia (CML).<sup>3</sup> The development of banding techniques in 1969 and 1970 allowed further characterization of this aberration as a balanced translocation involving chromosomes 9 and 22.<sup>4</sup> In the last three decades, the knowledge of human cancer cytogenetics has expanded significantly with the addition of new molecular methodologies, such as *in situ* hybridization (discussed later in [Fluorescence \*In Situ\* Hybridization](#)). The field now is best described as *molecular cytogenetics*.

## CHROMOSOME STRUCTURE AND FUNCTION

Each normal human somatic cell nucleus has 46 chromosomes, 23 chromosomes being maternal and the other 23 being paternal in origin. This diploid chromosome number is reduced to 23 (haploid) during meiosis, a specialized nuclear division during gametogenesis in the ovaries and testis. At conception, haploid cells from each parent combine to form a new diploid cell (zygote), which then divides via mitosis (somatic nuclear division), ultimately creating the fetus. Errors in mitosis or meiosis can lead to pathogenetic changes (discussed later in [Numeric Abnormalities](#)). Genetic instructions are encoded in DNA. DNA replicates during the S phase of the cell cycle and condenses during the prophase of mitosis (somatogenesis) and meiosis (gametogenesis). During metaphase, the characteristic chromosome structures can be observed: Each chromosome represents two chromatids joined at an area of constriction known as the *centromere*.

## LOWER-ORDER CHROMATIN STRUCTURE

The human genome consists of approximately  $6.8 \times 10^9$  base pairs (bp) of DNA in each diploid cell. If stretched end to end, this length of DNA would span 2 meters. In a normal diploid human cell, this DNA is packaged into 44 autosomes and the two sex chromosomes in a compact nucleus. The first level of packaging involves a wrapping of 200 bp in two turns around a histone core, resulting in the complexes called *nucleosomes* with a diameter of 10 nm. This basic DNA fiber then is further condensed in a 30-nm-diameter spiral called a *solenoid fiber*. The solenoid in turn forms larger fibers that are visible with the light microscope as chromatin fibers. Chromatin loops of 60 to 90 kb are anchored at scaffold attachment regions. These loops also appear to represent functional replication domains called *replicons*.

## HIGHER-ORDER CHROMATIN STRUCTURE

The development of various banding techniques in the period from 1969 to 1971 revealed that various chromosomal regions respond differently to biochemical and physical treatments. This suggested that there is a higher-order structure for human chromosomes. One of the first recognized divisions of chromatin is into the categories of euchromatin and heterochromatin. Heterochromatin was the material that stained dark (heteropyknotic) with various staining techniques, giving rise to chromocenters in interphase. We now know that this dark staining is a result of the more condensed DNA structure in these regions picking up more DNA dyes.

There are two types of heterochromatin. *Constitutive heterochromatin* is chromatin that is constitutionally condensed in all cells and cell types and is composed of highly repeated sequences that can be detected in cytogenetic preparations using the technique of C-banding. In humans, constitutive heterochromatin is found at the centromeric regions of all chromosomes as well as in the pericentromeric areas of chromosomes 1, 9, and 16 and in the distal long arm of the Y chromosome. *Facultative heterochromatin* can switch from condensed to decondensed and vice versa. An example of the latter type is the inactivation of the X chromosome in female cells for gene dosage compensation. Meiotic pairing has been shown to require heterochromatin homology and to be sensitive to repeat numbers in both male and female *Drosophila*.<sup>5</sup> Banding is produced along the chromosomal length of euchromatin because of both structural and functional differences in light and dark

G-bands ([Table 5-1](#)).

	R-bands (Light G-bands)	G-bands (Dark R-bands)
Quiescence	Full	High
Heteroploidy in prokaryotes	Negative	More condensed
Replication in S phase	Early	Late
Minute condensation (in metaphase)	Fast	Slow
Chiasmata and break frequency	High	Low
DNA base composition	GC-rich	AT-rich
Repeats	LINE	LINE
	Alu (humans)	L1
Gene regulation	EL, R2 in mouse	—
	CpG islands	TATA boxes
Common genes	House-keeping + some TS	TS

LI, a mouse long interspersed nuclear element; LINE, long interspersed nuclear element; SINE, short interspersed nuclear element; TS, tumor specific.

**TABLE 5-1.** Functional Significance of Chromosomal Banding Patterns

## TELOMERES AND TELOMERASE

A double-strand break in DNA is susceptible to recombination and fusion and also triggers cell-cycle arrest mediated by p53. Further, DNA replication, as it is now understood, would result in shortening of the ends of replicating linear DNA owing to the mechanisms of function of the DNA replication proteins. Thus, there is an obvious need for telomeres to be unique. Examination of human cells as well as cells from other vertebrates showed that the ends of chromosomes are capped by a simple repeat of six nucleotides (TTAGGG). The telomere sequence is synthesized by a specialized DNA polymerase called *telomerase* (reviewed in ref. [6](#)). The telomerase function includes an enzymatic protein component as well as an RNA component acting as a primer. Telomerase is responsible for programmed end healing *in vivo* after breaks and in maintaining telomere length. The telomeres further bind other specific proteins that appear to function in protecting the ends of the chromosomes from recombination, nuclease attack, activation of cell-cycle checkpoints, and end-to-end fusions.

Hayflick and Moorehead<sup>7</sup> recognized that fibroblast cells grown in culture have limited replicative potential (50 to 100 cell divisions). This Hayflick phenomenon is now understood as explained by age-related deterioration of telomeres.<sup>8</sup> In the absence of telomerase, the ends of the chromosomes would shorten gradually (by 25 to 200 bp in each replication) owing to the end-replication problem. It is believed that in normal cells, this deterioration of telomeres can eventually lead to cell-cycle arrest and, thus, cellular senescence. The reverse is also true; it was shown that telomerase reactivation is important in immortalization of cell lines and in cancer development and metastasis.<sup>9,10</sup> The technique developed by Kim et al.,<sup>9</sup> called *telomeric repeat amplification protocol*, is used, with several available commercial and other modifications, to detect telomerase activity in cell extracts.

It is now recognized that telomerase activity is found in the majority of primary human tumors.<sup>11</sup> There is the potential for development of novel cancer therapies by regulating telomerase or proteins that in turn regulate telomerase levels in cancer cells. Prognostic value for examining telomerase activity in certain cancers is being discussed. An example of this is a significantly worse prognosis in meningiomas with telomerase activity versus those without it.<sup>12</sup> One complicating factor is that there are other pathways for developing “immortality” besides telomere maintenance or for maintaining telomeres without detectable telomerase activity (e.g., involving recombination). In fact, some human cancer cells even at metastasis have decreased telomeres and are susceptible to end-to-end attachments in metaphase. This phenomenon was recognized very early in human cytogenetics as “sticky” chromosomal ends. This reduction in telomere length is usually attributed to the increased cell division (most cancers start from a single cell with increased proliferative capacity). Further, genetically engineered mice lacking telomerase RNA lose their telomeres but are still capable of developing tumors.<sup>13</sup>

Some human premature aging syndromes result from decreased replicative capacity of the cells. In the example of Hutchison-Gilford progeria, telomeres are markedly reduced, resulting in decreased replicative capacity. Similar findings are reported in Down syndrome, which predisposes to premature senescence of the immune system as well as predisposition to early Alzheimer's disease.<sup>14</sup> Other nuclear and mitochondrial genes seem to influence aging. For example, Werner and Bloom syndromes are characterized by mutations in DNA helicases.<sup>15</sup>

## CENTROMERES

The centromeric DNA is vital to the attachment of specialized proteins to form a functioning structure called the *kinetochore*. Kinetochores are responsible for the segregation of the chromatids to the opposite poles of the dividing nucleus during anaphase of mitosis and the segregation of the homologous chromosomes during anaphase of the first meiotic division. The centromere provides a useful landmark along the chromosome axis, dividing each chromosome into two segments or arms: a short arm (known as the *p arm* from the French *petit*) and a long arm (the *q arm*, named after the next letter in the alphabet). By convention, chromosomes are identified by their centromeres. Thus, a derivative chromosome, mostly chromosome 3 material but only one centromere of chromosome 21, is a derivative chromosome 21. Human chromosomes are normally monocentric. Cancer cells occasionally have dicentric and even polycentric chromosomes. Chromosomes are classified by their centromere positions and size into seven groups, A through G ([Fig. 5-1](#)). Metacentric chromosomes have equal or almost equal arms (centromere at or almost at the middle of the chromosome). Acrocentrics (chromosomes 13, 14, 15, 20, 21) have a very tiny short arm carrying a satellite of repeat sequences and the nucleolar organizer region and the DNA coding for recombinant RNA (rRNA). A *submetacentric* is a chromosome wherein the short arm is less than one-half the length of the long arm. Centromeres can be detected using antikinetochore antibodies (e.g., from serum of patients with combined calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) as well as using alpha satellite DNA probes.

**FIGURE 5-1.** Chromosome numbering and nomenclature. The figure illustrates a normal male karyotype. Chromosomes are numbered according to size and centromere position (left panel). Chromosomes are classified into groups based on size and centromere position and, within groups, by banding patterns. Groups A (1–3), B (4,5), C (6–12, X), D (13–15), E (16–18), F (19–20), G (21, 22, Y). Examples of a metacentric, a submetacentric, and an acrocentric chromosome (right panel).

## CYTOGENETIC METHODS

### SPECIMEN REQUIREMENTS

Most cancer cytogenetic testing involves bone marrow for hematologic malignancies. However, solid-tumor cytogenetics is likely to be the next area of increased clinical relevance, especially with the new techniques of molecular cytogenetics. For hematologic malignancies, a bone marrow aspirate is the preferred sample,

although success can also be achieved in some difficult cases using core biopsies. Peripheral blood samples can be submitted if there are circulating blast cells. A lymph node biopsy may also be used in cases with lymph node involvement. Technologies have developed such that even fine-needle aspirates can be tested for cytogenetic abnormalities. Other types of specimens can be studied, including infiltrates, pleural effusion, spinal fluid, and basically any tissue that may contain dividing cancer cells.

It is important to provide clinical information on specimens submitted for testing. This helps to select appropriate culture and analysis procedures and, in some cases, to suggest additional tests. Examples include (1) the need to stimulate cultures with B-cell mitogens (e.g., Epstein-Barr virus, lipopolysaccharide, or 12-O-tetradecanoyl-phorbol-13-acetate) in B-cell malignancies; (2) the importance of longer culture time in some myeloid disorders [e.g., for detection of t(15;17) in acute myelogenous leukemia (AML) M3]; and (3) offering fluorescence *in situ* hybridization (FISH) tests in cases of certain translocations should the routine cytogenetics prove negative [e.g., inv(16) in M4e or t(9;22) in CML]. It is recommended that cytogenetic studies be performed at diagnosis and for follow-up of cancer progression. Occasionally, failure to obtain results can be due to the fact that a patient is under treatment (treatments are intended to block cell division). Because the study requires viable cells, specimen handling is important in cytogenetics. Drawing of a bone marrow or a blood sample should be performed using heparinized (sodium heparin) and sterile collection tools and containers. For bone marrow aspirates, volumes can be from 0.25 to 1.0 mL; for blood, 3 to 5 mL is adequate. However, small specimens can also be processed; the best approach is to check with the laboratory.

## BANDING TECHNIQUES (CLASSIC CYTOGENETICS)

Chromosome analysis requires examining cells in the process of mitosis in which the chromosome structure is most clearly defined (most commonly cells in late prophase or early metaphase). Spontaneously dividing tissues, such as occur in hematopoiesis or in cancer, would be expected to provide mitotic cells for analysis even in a direct harvest of the material submitted. In practice, the quality of such preparations is suboptimal, and cell culture may be required in some cases. The time required for culture and analysis varies, depending on the tissue sampled and specific testing requested. Average turnaround time for studies can be as short as 2 to 3 days for bone marrow, 4 to 7 days for blood, and up to 3 weeks for some solid-tissue biopsies. Chromosomes are prepared on glass slides and are treated by digestion (e.g., with trypsin) and then stained to produce a banding pattern. The most commonly used staining techniques are G-banding and R-banding, which produce characteristic staining or banding patterns for each human chromosome. These techniques, in combination with the physical chromosomal structure, allow for the identification of individual chromosomes.

## FLUORESCENCE *IN SITU* HYBRIDIZATION

Mammalian DNA is a double-stranded helix with a phosphate and sugar backbone and hydrogen bonds linking the nucleotides cytosine (C) to guanine (G) and adenine (A) to thymine (T). Under appropriate conditions, the double-stranded DNA can be resolved to single strands, and the complementary single-stranded DNA can be reannealed to a double-stranded helix. The property of DNA strand complementarity is used in various molecular methods involving DNA hybridization. By merging the nucleic acid hybridization onto metaphase chromosome spreads, FISH has established a solid technical foundation for the field of molecular cytogenetics. The principle of FISH is the hybridization of a DNA probe with incorporated reporter molecule to its complementary chromosomal locus, followed by detection of the hapten using fluorescent microscopy, usually with computer-assisted imaging analysis. A routine FISH protocol involves multistep procedures. The reporter molecule can be a protein, such as biotin or digoxigenin, or a fluorescent molecule, such as rhodamine or fluorosiothiocyanate. Incorporation of the reporter molecule in the probe is performed using nick translation or primer extension with labeled nucleotides. The labeled DNA probe and targeted specimen are treated to denature double-stranded DNA to single strands and then are allowed to hybridize for 2 to 24 hours (depending on specimen and probe).

FISH analysis extends routine cytogenetic banding methods by resolving ambiguous diagnosis and providing a new tool to diagnose submicroscopic abnormalities. FISH is a relatively simple, fast, and reliable procedure. Depending on the sequence complexity of labeled DNA probe and the content of tested specimen, FISH has variable signal sensitivity and spatial resolution. Hybridization probes range from very small DNA fragments (500 bp) to large yeast artificial chromosomes or bacterial artificial chromosomes. The spatial resolution measured by the closest separable signals could range from 5 Mbp on metaphase chromosomes to 100 Kbp on interphase chromatin. The most important features of FISH techniques are its applicability to different specimens and its use for simultaneous detection of several targets using multiple probes. Specimens that can be used for FISH include peripheral blood cells, cultured cell lines, bone marrow cells, paraffin-embedded tissue sections, and frozen tissues. Specific applications of FISH include:

1. Delineation of chromosomal numeric abnormalities. For example, interphase FISH has been used for detection of trisomy 8 in myeloid disorders, trisomy 7 in prostate cancer,<sup>16</sup> and trisomy 12 in chronic lymphocytic leukemia,<sup>17,18</sup> and ovarian cancers.<sup>19</sup>
2. Detection of specific translocations, such as those involving immunoglobulin genes in lymphomas, and other translocation seen in leukemias ( Fig. 5-2)
3. Determining degree of engraftment after sex-mismatched bone marrow and cord blood transplantations (see Fig. 5-2D)
4. Determining the origin of specific translocations and marker chromosomes using paint probes in cases where G-banding cannot identify the origin (see Fig. 5-2F;)
5. Revealing cases with gene amplification (e.g., see Fig. 5-2E).

**FIGURE 5-2.** Examples of application of molecular cytogenetics. **A:** Fluorescence *in situ* hybridization (FISH) using probes for ETV6 gene at 12p13 (green) and CBFA2 (AML1) gene at 21q22 (red). These are useful probes for the detection of the t(12;21), a very common translocation in childhood acute lymphocytic leukemia. **B:** FISH using probes for BCR at 22q11.2 (green) and ABL at 9q34 in a case of chronic myelogenous leukemia. Arrow shows the Philadelphia chromosome with fused signals. **C:** Using same probes as in **B**, showing the ability to detect a fusion in the interphase nucleus on the right (arrow). **D:** Use of repetitive probes for X (red) and Y (green) in sex-mismatched bone marrow transplant. **E:** Illustration of FISH use in gene amplification using a probe for c-myc on 8q24. The probe labels the distal 8q in this case (arrow) plus an amplified area on the homologous 8q (between arrows). **F:** Use of FISH to identify two marker chromosomes (arrows) as derived from chromosome 15 (probes for 15p in green and proximal 15q in red). **G:** Comparative genomic hybridization profile of two chromosomes (19 and 20) from a case of melanoma showing amplification of the distal end of 20q. FISH using BTAK(STK1 5), a gene that hybridizes to 20q and is amplified in a number of cancers showing normal signal on metaphases from normal blood cells.

## MULTICOLOR FISH AND SPECTRAL KARYOTYPING

In the last few years, new development of FISH allowed for detection of different chromosomes using probes combinatorially labeled with several fluorescent dyes. One method of analysis of this is to image each fluorophore separately and then to allow a computer to translate the different color combinations to values or ratios that are then pseudocolored, resulting in a karyotype with 24 colors for each of the human chromosomes (1 through 22, X, and Y). This multicolor FISH technique can be used to identify derivative and marker chromosomes. A similar technique, named *spectral karyotyping*, also was introduced by using a combination of epifluorescence microscopy, CCD (cooled-coupled device) imaging, and Fourier spectroscopic measurement.<sup>20,21</sup> Multicolor FISH and spectral karyotyping cannot detect intrachromosomal anomalies, such as inversions, still require metaphases from the test specimen of good quality, and are limited in resolution to abnormalities involving one or more bands at a 450-band level.

## PRIMED *IN SITU* LABELING

of mitosis and the second meiotic division, chromatids separate (disjoin) and migrate to the opposite poles of the cell. A failure of separation in either of these situations is termed *nondisjunction*. Rather than both daughter cells receiving the expected number of chromosomes, there will be gain of material in one daughter nucleus and loss of genetic material in the other daughter nucleus. For human autosomes, the normal situation is *disomy* (two copies of each chromosome). Thus, *trisomy* refers to having an extra chromosome and *monosomy* to having a missing chromosome.

Another mechanism for producing a chromosome abnormality is anaphase lag, wherein a chromosome lags at anaphase and fails to be included in daughter nuclei and so is lost. This can result only in monosomy. Trisomies and monosomies are common in human cancers. Polyploidy occurs when cells have more than the normal two sets of chromosomes (diploidy). Thus, a triploid cell will have three sets of chromosomes (modal number of chromosomes, 69) and a tetraploid cell four sets (modal number of chromosomes, 92). Polyploidy is noted in both hematologic malignancies and solid tumors and usually is seen duplicating a set of chromosomes that already have abnormal chromosomes (structural or numeric).

Our understanding of the impact of numeric abnormalities on development and progression of cancer has actually lagged behind that of structural abnormalities. For monosomy, speculation about loss of tumor suppressor genes on these chromosomes abound but, for the most common monosomies (e.g., monosomy 7 in myeloid disorders), no confirmed tumor suppressor genes have yet been cloned that are proven to be directly related to these monosomies. Trisomies are even more problematic, as it is difficult to show that specific genes on the extra chromosome are responsible for cell proliferation because of a dosage effect (three vs. two copies of the gene). Recently, it was demonstrated that the extra chromosome 7 in papillary renal carcinomas with trisomy 7 includes the mutant MET allele.<sup>31</sup> This indicates that one mechanism for the effect of a trisomy is duplication of mutant oncogenes. Other involved mechanisms include gene interactions, imprinting, or position effects.<sup>32,33</sup>

## STRUCTURAL ABNORMALITIES

Numeric chromosomal abnormalities entail loss or gain of whole chromosomes. By contrast, structural abnormalities involve changes in part of one or more chromosomes. By definition, structural chromosomal aberrations require one or more breaks in the DNA sequence. Structural chromosomal rearrangements are expected to be deleterious. Thus, it is not surprising that strong selective forces in evolution resulted in numerous mechanisms to reduce the rate of chromosomal aberrations, including numerous pathways of DNA repair or cell-cycle arrest after DNA breaks (e.g., p53-mediated cell-cycle arrest in response to double-stranded DNA breaks); protective nuclear architecture with chromosome domains; increased nuclear size in the gametocytes; and asynchrony of DNA replication. Despite these mechanisms, a high incidence of chromosomal abnormalities clearly escapes this negative selection, resulting in an estimated 1% of newborns with constitutional chromosomal abnormalities and, of course, the many chromosomal abnormalities seen in cancer.<sup>32,33</sup>

While DNA breaks can occur in any sequence, there are clear preferential sites for DNA rearrangements. Several studies on recurrent cancer translocations are particularly illustrative of possible mechanisms for the origin of these abnormalities. In lymphoid neoplasms, it is now well established that many translocations in the immunoglobulin family of genes (immunoglobulin heavy-chain and light-chain genes, T-cell receptor genes, etc.) occur during the genomic DNA rearrangements normally seen in those cells. This occurs because of errors involving transposition during attempted normal recombination of these genes.<sup>34,35</sup> In other structural abnormalities, a role for repeat sequences at the junction points is implicated. There is experimental evidence of the role of interchromosomal recombination using repeat sequences after double-strand break repair.<sup>36</sup> Studies on the breakpoints involved in simple and complex t(9;22) showed Alu repeats preferentially localized near the breakpoints.<sup>37</sup> Deininger and Batzer<sup>38</sup> reviewed many other cases of involvement of Alu repeats in both constitutional and somatic genomic rearrangements. This, combined with the observation of proximity of these genes during certain stages of the cell cycle and differentiation of hematopoietic cells, suggests a possible mechanism for their formation by illegitimate pairing and exchange.<sup>39</sup>

The mechanisms by which structural chromosomal rearrangements exert an effect on the phenotype are varied. Clearly, balanced translocations in cancer lead to fusion products or gene regulation changes (e.g., overexpression of certain genes) that have a direct impact on cellular proliferation, escape from cell-cycle arrest, or apoptosis. In the case of deletions, duplications, trisomies, and monosomies, a gene dosage effect can also be involved. However, gene regulation at the translocation breakpoint or dosage effects probably do not explain all cases. Accumulated data suggest that structural chromosomal abnormalities can impact gene expression not only of the affected chromosomes but of nearby chromosomal regions. In cancer, the acquisition of "suites" of particular chromosomal rearrangements in cancers after the presumed initial cancer genetic change may be explained by nuclear position effects.<sup>32</sup> Another example is cited for the repeated establishment of isochromosome 17q in certain cancers.<sup>40</sup> However, gene alterations at or near the breakpoints clearly explain the effects of the majority of translocations in cancer cytogenetics. This still provides a veritable gold mine for positional cloning of new cancer related genes.

### Reciprocal Translocations

A common type of structural chromosome change is the reciprocal translocation. This involves breakage of two chromosomes, a reciprocal exchange, and resealing of the broken ends (Fig. 5-4D). Considering the size of the genome and the small percentage of the DNA that is coding, most random breaks resulting in balanced translocations would not produce a phenotypic effect because no genetic material is lost or gained in the process and no genes are disrupted. A clinically significant abnormality may result when a translocation causes disruption or activation of genes or has a long-range effect on other genes. Although phenotypically normal themselves, carriers of constitutional reciprocal translocations are at increased risk of producing chromosomally unbalanced offspring. Somatic (acquired) translocations in cancer usually result in fusion gene products or in activation of an oncogene function or in both (discussed in Chapter 45.1 and Chapter 46.1).

**FIGURE 5-4.** Some structural chromosomal abnormalities seen in cancer cytogenetics; compare with normal banding pattern in Figure 5-1. **A:** Deletion of the short arm of 17. **B:** Paracentric inversion of the long arm of chromosome 3. **C:** Dicentric chromosome with centromeres from chromosomes 7 and 11 (breakpoints on the short arm). **D:** Common reciprocal translocation of 8q and 21q noted in acute myelogenous leukemia M2.

A few examples here are worth commenting on. The t(14;18)(q32;q21) is found in a majority of lymphomas with follicular center cell morphology and in one-third of diffuse large cell lymphoma. The translocation is associated with overexpression of BCL2 gene at 18q21. The BCL-2 protein is localized in mitochondria, the endoplasmic reticulum, and the nuclear envelope and is involved in cell-cycle regulation. Various rearrangements involving 11q23 occur in acute lymphocytic leukemia (ALL) and a subset of cases with AML. The disrupted gene is the MLL gene at 11q23 with more than 30 different partner genes involved (hence, MLL is called a *promiscuous oncogene*). The t(11;22)(q24;q12) is found in more than 90% of cases of Ewing's sarcoma and can be very diagnostic. FISH can be used to detect all these translocations using dual color probes (see Fig. 5-2).

### Robertsonian Translocations

Robertsonian translocations specifically involve breakage at or near the centromeres of two acrocentric chromosomes with the long arms joining to form a novel metacentric or submetacentric chromosome. Because the short arms of these acrocentric chromosomes carry only ribosomal genes, these translocations can reduce the chromosome number without causing a phenotypic abnormality. While these are the most common constitutional translocations, they are very rare as somatic mutations in cancer. When they have been noted in cancer, they seem to exert an effect by being unbalanced translocations resulting in trisomies for the long arms of

the acrocentric chromosomes.

### Deletions

Deletions are common in cancer cells. At the G-band level, these may appear as terminal deletions (i.e., one breakpoint with loss of material distal to the breakpoint; [Fig. 5-4A](#)). However, most, if not all, are likely not true terminal deletions, and there is no proof that terminal deletions exist in cancer, probably because of cell-cycle arrest due to failure to correct breaks. There are very rare examples of telomere regeneration. The single confirmed recapping by telomeres of a terminally deleted chromosome is the reported chromosome 16 deletion noted in rare cases of patients with mental retardation and hemoglobin abnormalities. Deletions designated as *terminal*, on the basis of G-band examination, are either interstitial deletions or cryptic unbalanced translocations. For example, a molecular study of melanoma cell lines with identified "terminal deletions" <sup>41</sup> showed that there is subtelomeric material from other chromosomes located at the ends of these shortened chromosomes. A specialized deletion that occurs on both ends of the chromosome with joining of the two ends results in ring chromosomes.

### Duplication

An intrachromosomal duplication requires at least two breakpoints with the segment between them duplicated either head to tail (direct duplication) or head to head (inverted duplication). One of the most common duplications seen in hematologic malignancies is the duplication of the long arm of chromosome 1 (breakpoints at q12-q21 and q31-q44). This duplication is especially noted in lymphoid malignancies (ALL and lymphomas), usually as a secondary abnormality with poor prognosis.

### Inversions

An inversion is an alteration in a chromosomal segment involving two breaks, with reintegration of the segment in the chromosome in reverse orientation. When the two breakpoints occur on one side of the centromere, this is termed *paracentric inversion*. A good example is the paracentric inversion of the long arm of chromosome 3 seen in AML ([Fig. 5-4B](#)). If the two breaks surround the centromere (pericentric inversion), a change in arm ratio of the chromosome may occur. The pericentric inversion of chromosome 16 seen in acute myelomonocytic leukemia with abnormal eosinophils (M4eo) is a good example. The result of the inversion is a fusion between the myosin heavy-chain gene (MYH11) on 16p13 and the core-binding factor  $\beta$ , a transcription factor at 16q22. In a subset of patients with inv(16), the breakpoints also appear to cause loss of a gene for a multidrug resistance protein. <sup>42</sup> Because this inversion is rather difficult to see in suboptimal chromosome preparations, FISH is an ideal tool for detecting this inversion. While noted in a number of FAB classes, most cases of inv(16) are classified as M4eo and carry a favorable prognosis. In those patients, trisomy 8, trisomy 22, and deletion of chromosome 7 may also occur.

### Isochromosomes and Dicentric Chromosomes

An isochromosome is derived by breaks in one arm of a chromosome followed by rearrangement of the chromatids to produce duplications of the other arm of the chromosome. These are usually dicentric chromosomes, with the net effect being a loss of material from one arm and duplication of the other arm. A classic example is the common observation of isochromosome 17q seen in myeloid and lymphoid malignancies as well as in adenocarcinomas (different organs) and neuroectodermal tumors. In all these cases, the presence of i(17)(q10) carries a poor prognosis. An i(1)(q10) is noted in adenocarcinomas (breast, kidney, intestine, uterus) and less so in hematologic malignancies. A variation is the break involving two nonhomologous chromosomes forming a dicentric chromosome ([Fig. 5-4C](#)).

### Gene Amplification

Molecular genetic methods allowed for rigorous study of variations in gene copy number in mammalian cells. This allowed for the understanding of the earlier cytogenetic observation of "double minutes" (DMs) and of homogeneously staining regions (HSRs) in cancer cells and drug-resistant cell lines. HSRs and other forms of chromosomal DNA amplification are notable as unusually banded regions on the chromosomes. DMs are extrachromosomal, acentric (lacking centromeres), circular DNA molecules (lacking telomeres) and can be variable in size. Generally, DMs are less stable than HSRs in culture, which is expected, as DMs lack centromeres and would not segregate properly to daughter nuclei in mitosis. Gene amplification is noted in many biological phenomena, including amplification of insecticide detoxification genes in insects, induced amplification of certain genes in cultured cells (used to produce certain proteins industrially), amplification of developmental genes in *Xenopus* and other organisms, amplification of drug resistance genes, and amplification of certain oncogenes in cancer.

It is the latter topic that is of interest here. A duplication of a chromosome or a chromosome region is not considered here under amplification (e.g., CML patients can have two or three Philadelphia chromosomes harboring the fusion *abl-bcr* gene). An example of gene amplification in cancer drug resistance is dihydrofolate reductase amplification in methotrexate resistance. Another interesting example is the amplification of the P glycoprotein gene (chromosome 7) in multidrug resistance, causing failure of cancer chemotherapy. <sup>43</sup> Researchers have identified many genes amplified in cancer. Following are a few examples (a complete listing and discussion being beyond the scope of this chapter):

- c-myc (8q24) amplification in small cell lung carcinoma (SCLC)
- N-myc (2p23-24) amplification in neuroblastoma (advanced stages), SCLC
- Cholinesterases (3q26) in ovarian carcinoma
- HER-2/neu (C-erbB-2, 17q11.2) in breast carcinoma
- Cellular apoptosis susceptibility at 20q13 in breast cancer
- Epidermal growth factor receptor (7p12.1-12.3) in glioma and non-SCLC
- PRAD1/cyclin D1, bcl-1, HST-1, INT-2 (11q13) in breast, non-SCLC, head and neck, and other cancers
- MDM2 (12q13-14) in neuroblastoma, sarcoma, glioma
- Primase 1 (12q13) in osteosarcoma.

## CAUTIONS TO EXERCISE IN INTERPRETING CHROMOSOMAL ABNORMALITIES SEEN IN CANCER STUDIES

### FAILURE TO DETECT A CHROMOSOME ABNORMALITY BY ROUTINE G-BANDING

In examining a sample from a presumed malignant tissue, one must always remember that normal cells are found mixed with the malignant cells and, thus, can significantly complicate the analysis. A report of 20 normal metaphases should be read with caution, as these metaphases could be those of a cancer that happens to be diploid and to lack visible structural abnormalities or of normal surrounding cells. In some malignancies, normal cells in the submitted sample can give much better chromosome morphology than abnormal cells. This is especially true in acute lymphoblastic leukemia. Experienced cytogenetic technologists learn to analyze fuzzy, poor metaphases and quickly to identify these abnormalities, even in poor cells. Further, there are expected variations between laboratories owing to different referral bases. Physicians differ in their referral patterns, and individual referral may vary, depending on such factors as the patient-specific situation, stage of the disease, and even financial considerations. As more data accumulate, there are now more clear indications for cytogenetic studies that should decrease (but not eliminate) variation in the rate of detection of chromosomal abnormalities by different laboratories.

Failure to note the aberration in routine analysis may also occur because the abnormality involves a small amount of chromosomal material or produces little change in perceived banding patterns. The t(15;17)(q22;q22) in AML M3 and inv(16)(p13q22) seen in AML M4eo are not easily noted in short or poorly banded chromosomes. A more interesting example is the complete failure of detection of t(12;21) by banding methods because the exchange is between segments of these chromosomes that stain similarly (light) by G-banding. The translocation resulting in a fusion of the ETV6 (TEL) gene at 12p13 and the CBFA2 (AML1) gene at 21q22 is variably reported in 16% to 36% of cases of childhood ALL. This t(12;21)(p13;q22) is reported to be associated with B-cell precursor ALL, with presumed favorable prognosis. FISH using probes for ETV6 and CBFA2 is the method of choice for identifying this translocation (see [Fig. 5-2A](#)).

### CONSTITUTIONAL CHROMOSOMAL ABNORMALITIES

Some chromosomal abnormalities are present at birth and are not related to neoplasia. These include balanced translocations, Robertsonian translocations, inversions, and insertions that are found at some level in normal-appearing individuals (but in most cases affecting their reproductive success or resulting in the birth of children with congenital abnormalities or both). Other constitutional abnormalities can be associated with an abnormal phenotype, and some predispose to cancer development (e.g., Down, Klinefelter's, and chromosome breakage syndromes). Of course, these abnormalities usually are found in all cells in a person and are not limited to a particular tissue type. Thus, when we find such abnormalities in all examined cells, we are suspicious of a potential constitutional translocation. Obvious exceptions to this assumption are translocations classically noted in certain cancers, such as t(9;22) in CML, in which all examined cells may have the translocation,

but it is not a constitutional translocation. To distinguish between a constitutional translocation and a novel translocation found in all sampled cells, a cytogeneticist may request a constitutional chromosome study. The simplest is to get a peripheral blood sample cultured for 48 to 96 hours using B- or T-cell stimulants (mitogens) to ensure adequate numbers of actively dividing cells for analysis. Chromosome studies may also be performed using other cells, such as skin fibroblasts.

## FRAGILE SITES

Cytogeneticists regularly observe breaks in preparations of human chromosomes. Fragile sites are visible cytogenetically as breaks at consistent sites in the genome. Some of these sites are induced by certain chemicals (e.g., aphidicolin, methotrexate). The sites, which now number more than 100, are heterogeneous in their method of induction (some are constitutively expressed and are not induced) and in their location and the sequences involved. Some are associated with integration sites for oncogenic viruses. Some occur in or near tumor suppressor genes and may be associated with the chromosomal events leading to loss of those genes. The best example of the latter phenomenon is the aphidicolin-induced fragile site at 3p14.2 (FRA3B), which occurs within the tumor suppressor gene FHIT involved in numerous cancers, including the translocation t(3;8)(p14.2;q24) seen in clear cell renal carcinoma.<sup>44</sup> Much more work needs to be done to resolve the relationship between other fragile sites and chromosome translocations and aberrations seen in cancer. When fragile sites are found in one or a few examined metaphases, this is noted in the workup. Such findings may fall into one of three categories: (1) rare events in normal individuals noted as chromatid and chromosome breaks (not clinically significant), (2) breaks at the same site in multiple untreated cells, considered constitutional fragile sites (their relevance to the cancer being unknown now), or (3) multiple breaks in many cells at different sites, possibly suggesting one of the chromosome breakage syndromes (e.g., ataxia-telangiectasia or xeroderma pigmentosum) or other pathologic mechanisms.

## SATELLITE ASSOCIATIONS

The human karyotype normally includes five pairs of acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22). On average, seven to eight of the short arms of these chromosomes carry satellites and a satellite stalk with the nucleolar organizer region. Satellite associations can be seen persisting through metaphase as remnants of the nucleolar associations. These are normal findings. Speculations in the literature that this predisposes to Robertsonian translocations have not been confirmed. Robertsonian translocations are common in animals that lack nucleolar organizer regions or satellites on the short arms of involved chromosomes.

## PROBLEMS WITH SOLID TUMORS

A biopsy of a solid tumor usually contains a number of tissue types (e.g., blood vessels, epithelial cells, fibroblast) in addition to the tumor cells. Further, tumor cell growth is usually not very good, and normal cells can grow faster than tumor cells *in vitro*. Various technical tricks can be used to obtain decent results from such specimens, including selecting appropriate media (avoiding media that stimulate growth of normal fibroblasts), treating primary cultures with trypsin to remove fibroblasts, and culturing at lower density. Recent molecular cytogenetic methods can obviate the need for cell culture in assaying for specific chromosomal abnormalities.

## CLONAL EVOLUTION AND CHROMOSOME EVOLUTION

Early studies using X-inactivation as a marker for clonality in female cells suggested that most, if not all, cancers originate clonally. Later chromosome studies confirmed the clonal origin of cancer cells with specific chromosomal abnormalities. However, there are published cases of apparently independent clones with distinct chromosomal abnormalities (occurring in approximately 1% of cases of leukemias and lymphomas). The generally accepted explanation for most of these cases is that a unifying submicroscopic event occurred, with further genetic alterations appearing as unique events (i.e., they are an evolution of the original clone). True multiclonal cancers are indeed rare. In testing, we usually examine a minimum of 20 metaphases in an attempt to locate a clone with a chromosomal abnormality. According to the ISCN (1995),<sup>30</sup> a clone is recognized if three or more cells have the same missing chromosome or two or more cells exhibit the same additional chromosome or structural abnormality. The reason for the difference in number of cells needed to define a clone with a missing chromosome (monosomy) versus one with trisomy relates to the possibility in cytogenetic preparation of overspreading of chromosomes and, hence, artifactual "missing" chromosomes. If one of the first 20 cells showed a particular aberration likely related to the cancer, a count of additional cells can be initiated or molecular cytogenetic methods used to confirm the presence of a clone. In any case, once a clone is identified, this can provide a baseline for diagnosis, prognosis, and follow-up study of relapse.

Many cancers are seen with only simple aberrations, such as the t(9;22) in CML. Early cytogenetic studies, however, still showed significant complex karyotypes in many cancers, suggesting that these early events can progress to more complex karyotypes. The stepwise progression of cancer by acquiring additional abnormalities is now well established for a number of cancers. A good example of this is colorectal carcinoma, which involves a successive series of genetic alterations. One must caution, though, that simplistic multistage scenarios usually are not the common pattern seen. For many solid tumors, chromosome instability results in massive karyotypic changes that appear totally unrelated to selective advantage. One possible explanation is that a genetic event resulting in cancer or predisposition to cancer removes a cell-cycle checkpoint involved in preventing damaged cells from dividing. An example is that cells missing p53 can accumulate chromosomal abnormalities because of the absence of p53-mediated cell-cycle arrest after double-stranded DNA breaks.

## CONSTITUTIONAL CHROMOSOMAL ABNORMALITIES PREDISPOSING TO CANCER DEVELOPMENT

We do not review here hereditary cancer syndromes due to gene mutation (e.g., hereditary breast cancer and Li-Fraumeni syndrome). We are more interested in syndromes with microscopically visible chromosomal abnormalities that predispose to cancer. A partial listing of the latter conditions is shown in [Table 5-3](#). Many of these syndromes are detailed and continuously updated on the Web via *Online Mendelian Inheritance in Man* (<http://www3.ncbi.nlm.nih.gov/Omim/>). Specific information about cancer risks for certain syndromes are available at <http://www.infobiogen.fr/services/chromcancer/Kprones/Kproneliste.html>. Both Bloom syndrome and Werner syndrome genes have been cloned and found to code for putative helices on chromosomes 15 and 8, respectively. Because, in both of these conditions, chromosome breakage is increased, it is suspected that the absence of these helices increases the probability of illegitimate recombination.

Chromosomal Abnormality	Associated Cancer
Down syndrome (trisomy 21)	Leukemia, solid tumors
Klinefelter syndrome (47,XXY)	Leukemia, prostate cancer
Turner syndrome (45,X)	Leukemia, thyroid cancer
Y chromosome deletion (45,X,-Y)	Leukemia, testicular cancer
Philadelphia chromosome (t(9;22))	Chronic myeloid leukemia
Robertsonian translocation (14;21)	Leukemia
Chromosomal instability	Various solid tumors

TABLE 5-3. Constitutional Chromosomal Abnormalities Predisposing to Cancer Development

## DATA MINING IN CANCER CYTOGENETICS

The proliferation of information in the rapidly growing cancer cytogenetics field has been a great asset to both clinicians and researchers. Fortunately, the development of information technology has made it easier to keep abreast of the rapid developments in this field. There are commercial or semicommercial databases for cancer cytogenetics. An example is the software called *Cancer Cytogenetics Lookup* published by Gilbert B. Coté. Further, the large text by Mitelman, titled *Catalogue of Chromosome Aberration in Cancer*,<sup>45</sup> is also available as a compact disk (John Wiley & Sons). However, the proliferation of free Internet resources with online direct access to continuously updated data has mushroomed. [Table 5-4](#) lists some specialized Web pages of interest. Of course, there are many other resources to the student of cancer cytogenetics, including subscribing to bibliographic updates (e.g., *Current Contents*, now available on the Web), running search engines for Web pages (e.g., Yahoo, Infoseek, Excite, etc.), and local and national library search engines (e.g., Medline).

**TABLE 5-4.** Web Sites of Interest in Cancer Genetics and Cytogenetics

There are also specialized list servers that help to facilitate communications between researchers and clinicians. For example, one could get onto the Molecular Genetics list serve at <http://www.hum-molgen.de> and be able to ask and answer questions for various areas of molecular genetics.

## GLOSSARY

**acrocentric:** of chromosome whose centromere is very close to one end

**amplicon:** a unit of gene amplification, usually containing a large segment of DNA containing many genes

**amplification:** an increase in the number of copies of a particular DNA sequence

**aneuploidy:** meaning “not euploid,” having missing or additional chromosomes or chromosome material

**centromeres (from *ken*trion = center, *meros* = part):** the site of attachment of chromosomes to the mitotic or meiotic spindle; considered by some to be the kinetochore (the functional centromere) and that centromere should refer only to repetitive DNA sequences (in humans, alphoid repeats) that attract centromere proteins

**chromatid:** one of the two visibly distinct longitudinal parts of a replicated chromosome seen in late prophase and in metaphase; after separation, becomes a daughter chromosome

**chromosome:** a nuclear subunit that includes linked genes as well as a centromere structure (found in eukaryotes)

**diploidy:** having the normal two homologous sets of chromosomes

**disjunction:** the separation of daughter chromosomes (chromatids) or of homologous chromosomes (in meiosis I)

**haploid:** having one set of chromosomes (present in gametes)

**kinetochore:** a specialized structure at the centromere that functions to elongate or digest microtubules to allow disjunction in meiosis and mitosis; a functioning centromere produces the primary constriction of a chromosome

**metacentric:** of chromosome, the centromere of which is roughly in a median position

**monosomic:** a condition in which one chromosome is missing; thus, in humans, having 45 chromosomes ( $2n - 1$ )

**polyploidy:** having one or more extra sets of chromosomes (triploidy, tetraploidy, etc.)

**telomerase (telomere terminal transferase):** a specialized ribonucleoprotein that uses its RNA component as a template to synthesize telomeric repeats

**telomeres:** repeated DNA sequences (TTAGGG in vertebrates) found at the ends of linear chromosomes; provide protection of the end from degradation and attract proteins that prevent the ends from recombination and from triggering cell-cycle checkpoints

**TRAP(Telomeric Repeat Amplification Protocol):** a technique using polymerase chain reaction to measure telomerase activity in cell extracts; developed by Kim et al.<sup>9</sup> and now having numerous available modifications

**trisomy:** a condition in which there is one extra chromosome; thus, in humans, having 47 chromosomes ( $2n + 1$ )

## INTRODUCTION

A cell's ability to produce exact replicas of itself is an essential component of life. This process must be performed with great fidelity in order for whole organisms and species to propagate. The molecular machinery used to control the cell division cycle and replicate is highly organized and well conserved through evolution. Although we are only beginning to unravel the mechanisms in this process, it is clear that multiple extracellular and intracellular signals must be integrated in order to accomplish this complex task.

Although evolution and cellular differentiation may rely on some subtle genetic or epigenetic changes in a given cell, these changes must occur in an orderly and controlled fashion to prevent disastrous outcomes. Gross lack of fidelity in the cellular reproduction process leads to genetic instability, which appears to significantly contribute to the development of malignancy. In order to understand how cancers start and to devise optimal strategies to eliminate cancer cells, we must be able to identify the molecular distinctions between normal cells and tumor cells. Aberrations of normal cell-cycle control reflect some of the molecular alterations that are characteristic of cancer cells.

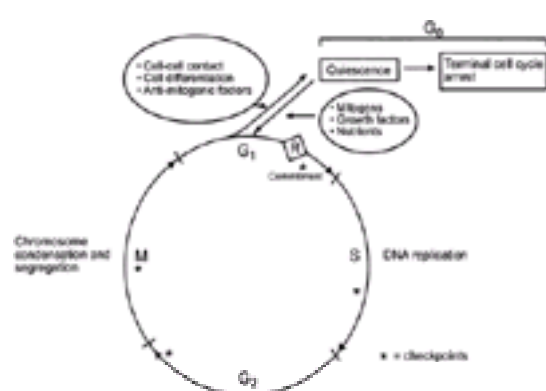

In this chapter, we review (1) the present understanding of mechanisms by which a normal cell controls the ordered progression through its cell cycle, (2) how regulatory mechanisms are integrated with extracellular signals, and (3) how a normal cell monitors its own progress through several *checkpoints* in the cell division cycle. We emphasize how these normal processes may go awry in cancer cells. Finally, we discuss the potential implications of this knowledge for our understanding of cancer biology and the development of novel therapeutic strategies.

## MECHANICS OF THE CELL DIVISION CYCLE

### BRIEF OVERVIEW

#### Cell-Cycle Phases

In any proliferating mammalian cell, the replication of the entire genome and the division of the cell into genetically identical daughter cells can be broken down into four distinct cell-cycle phases ([Fig. 6-1](#)). In the first phase, known as G<sub>1</sub> (for *gap 1*), the cell undergoes biochemical changes to prepare for entry into S phase in which new DNA is synthesized. As discussed later, in section [G<sub>1</sub> to S Transition](#), a number of these biochemical events are now known; however, cellular factors that drive these changes, such as cell size, protein content, or nutrient environment, are still poorly understood for mammalian cells. In S phase, the cell generates a complete copy of its genetic material and then proceeds into a second preparatory phase, known as G<sub>2</sub> (for *gap 2*), before entry into mitosis (M phase). In M phase, the replicated DNA is carefully condensed into compact chromosomes that are precisely segregated so that two daughter cells each receive a full complement of the genetic material. Following mitosis, a proliferating cell directly reenters G<sub>1</sub> phase as it prepares for further replication.

**FIGURE 6-1.** Schematic representation of cell-cycle phases. Mitogenic growth factors can drive a quiescent cell from G<sub>0</sub> into the cell cycle. Once the cell cycle passes beyond the restriction point (R), mitogens are no longer required for progression into and through S phase. The DNA is replicated in S phase and the chromosomes are condensed and segregated in mitosis. In early G<sub>1</sub> phase, certain signals can drive a cell to exit the cell cycle and enter a quiescent phase. Other signals such as cellular differentiation can make this irreversible. Cell-cycle checkpoints (denoted by asterisks and discussed in the text) in G<sub>1</sub>, S, G<sub>2</sub>, and M have been identified.

Because of the complexity and irreversibility of cellular replication, eukaryotic cells have evolved several checkpoints, which are biochemically defined points in the cell cycle that can be activated to prevent the transition across certain cell-cycle phases<sup>1,2</sup> (see [Fig. 6-1](#)). In this way, a normal cell can ensure that DNA synthesis is not initiated or is not continued under adverse conditions, and that chromosomes do not condense and segregate into daughter cells until the entire genome has been accurately replicated and prepared for mitosis. Loss of these checkpoints, which would have disastrous implications by leading to a variety of genetic abnormalities, is commonplace in cancer cells.

As depicted in [Figure 6-1](#), any proliferating cell has an additional option, which is the entry into a quiescent state known as G<sub>0</sub>. Entry into G<sub>0</sub> phase from G<sub>1</sub> is an important decision in cellular development (such as in lymphocyte or skeletal muscle cell maturation). *In vitro*, it is largely governed by the presence or absence of growth factors or nutrients that allow the procession through G<sub>1</sub> into S phase. If these growth factors are adequate, the cell traverses a point in G<sub>1</sub> phase after which the growth factors are not required. This point or transition is known as the restriction point (see [Fig. 6-1](#)).<sup>3</sup> If cellular environmental conditions are not right for a cell to proceed across the restriction point, it enters G<sub>0</sub> phase. Importantly, entry into G<sub>0</sub> may be reversible or it may be irreversible, such as during skeletal muscle or neuronal differentiation. Although the restriction point was described over 20 years ago, the precise biochemical events that define it are still not known.<sup>4</sup>

## Regulatory Mechanisms

As described in further detail later in this chapter, research has characterized many of the molecular and biochemical events that control the transition across different cell-cycle phases and into or out of a quiescent phase. Two common regulatory themes have emerged. First, many of the key regulatory proteins are controlled by posttranslational modifications in a cell-cycle–dependent manner. Perhaps the best known example of this is the hyperphosphorylation of the retinoblastoma gene product, RB, which renders it inactive as a cell crosses the restriction point.<sup>5,6</sup> The hyperphosphorylation of RB and many other components of the cell-cycle machinery is mediated by heterodimeric complexes of regulatory proteins known as cyclins and their catalytically active partners known as cyclin-dependent kinases (cdks).<sup>5</sup> Regulation of cyclin/cdk activity is central to all phases of the mammalian cell cycle.

A second important theme that has emerged is that many of the posttranslational modifications of cell-cycle proteins alter their stability and increase their proteolytic degradation.<sup>7,8</sup> Because protein degradation is irreversible, it seems to be a natural mechanism to ensure that the cell cycle progresses in only one direction. This regulatory mechanism is important in every cell-cycle phase and has been conserved in many eukaryotic organisms.

As one might expect, because cancer cells have fundamental abnormalities in cell-cycle control, it is not surprising that they have been found to have abnormalities in many of the components that control each of the cell-cycle phases. These abnormalities are described in greater detail as specific phases of the cell cycle are discussed.

### G<sub>1</sub> TO S TRANSITION

In a proliferating cell, molecular events in G<sub>1</sub> phase prepare the cell for the synthesis of new DNA. In different types of mammalian cells grown in culture, there can be great variations in the length of this phase, which may be very short or last for many hours. The length of the G<sub>1</sub> phase is somewhat dependent on extracellular signals (such as nutrients or growth factors in the environment) and may be coupled to a cell's growth in size.<sup>9</sup> Although much is known about events that lead up to the exit from G<sub>1</sub> into S phase, how the length of G<sub>1</sub> is determined for an individual cell is not clear.

Not only is the length of the G<sub>1</sub> phase of the cell cycle variable, but whether a cell completely traverses this phase at all seems to be an active *decision*. As noted previously, when a cell does not traverse G<sub>1</sub>, it enters a quiescent phase known as G<sub>0</sub>. *In vivo*, there are many examples of different types of mammalian cells, such as epithelial cells or lymphocytes, which are normally arrested in a quiescent phase but may be induced to reenter a proliferative phase by certain physiologic stimuli such as mitogenic growth factors (see Fig. 6-1). This arrest and reentry into the cell cycle can be largely recapitulated in cell culture systems for normal cells. However, the ability to arrest in G<sub>0</sub> phase of the cell cycle (e.g., because of contact with other cells or lack of external mitogenic growth factors) is fundamentally abnormal in cancer cells.

In addition to entry into a *reversible* G<sub>0</sub> state, under some conditions the entry into such a state can be irreversible (see Fig. 6-1). This occurs during the terminal differentiation of cells such as skeletal muscle or neurons and during cellular senescence, which is largely an *in vitro* phenomenon that may be analogous to cellular aging.<sup>10,11</sup> The molecular mechanisms by which this *irreversible* arrest occurs and is maintained are only now becoming clear in certain settings, such as in skeletal muscle cells, which require the retinoblastoma gene product RB for irreversible cell-cycle arrest.<sup>12,13</sup>

*In vitro*, it is clear that the complete transit across G<sub>1</sub> phase is governed by the presence of extracellular growth factors that push a cell past the restriction point.<sup>3</sup> This point is functionally defined as a time in late G<sub>1</sub> phase beyond which growth factors are not required for initiation and completion of DNA synthesis and mitosis. Without adequate growth factors, the cell enters a reversible G<sub>0</sub> arrest described previously. Biochemical events that are concurrent with passage through this restriction point include the hyperphosphorylation of RB, the functional activation of a cellular transcription factor known as E2F-1, the accumulation of a certain threshold level of cyclin/cdk activity, and the loss of key cyclin-dependent kinase inhibitors.<sup>5,14</sup> However, whether or not this point can actually be attributed to any single event in mammalian cells is formally unknown.

Of these possible biochemical events that may form the restriction point, most work has focused on the role of the retinoblastoma gene product RB. Disruption of the RB gene was first found in retinoblastoma tissue<sup>15</sup> and subsequently in tumors from patients with sporadic forms of cancer.<sup>16,17</sup> The first clues to RB function came when it was found that its forced expression caused cells to arrest in G<sub>1</sub> phase.<sup>18</sup> Naturally occurring mutations in the RB gene rendered the protein unable to stop cell proliferation.<sup>19</sup> Hence, RB was the first tumor suppressor identified that directly functioned to block cell proliferation.

Further insight into how RB itself was regulated came from studying how it was altered during the cell cycle. Numerous studies have now proven that RB becomes progressively hyperphosphorylated as cells pass from G<sub>1</sub> into S phase.<sup>20,21</sup> This correlation suggested that hyperphosphorylation inactivated RB and allowed cell-cycle progression into S phase. Although this inactivation may be important, it is probably not the sole basis for the restriction point because cells that lack the RB gene still retain certain aspects of restriction point control.<sup>22</sup>

One logical extension of these studies was to determine the mechanism by which RB prevented S phase entry and how RB hyperphosphorylation blocked this function. Insight into this has come from a large body of work focused on identifying cellular proteins that interact with RB. There have been over 20 such proteins identified using a variety of assays.<sup>23</sup> One of the proteins identified, the transcription factor E2F-1, is central to how RB prevents cell proliferation.<sup>24,25</sup>

E2F-1 was the founding member of what is now known to be a family of at least six related transcription factors, which seem to have specific, nonoverlapping functions *in vivo*.<sup>24</sup> Most is known about E2F-1, which may be particularly important for regulating the G<sub>1</sub> to S transition. As a transcription factor E2F-1 activates the expression of a variety of genes, many of which encode either transcription factors that are induced as cells enter S phase or proteins that are involved in DNA synthesis, such as dihydrofolate reductase.<sup>24</sup> In fact, E2F-1–mediated activation of these genes is so critical that the forced expression of E2F-1 alone is sufficient to drive some cells from quiescence into S phase.<sup>26</sup> A number of studies have also shown that when RB physically interacts with E2F-1, it blocks E2F-1–mediated activation of these genes.<sup>27,28</sup> Hence, it has been proposed that the RB suppresses tumor formation by repressing genes normally induced by E2F-1 and the loss of RB would be expected to disrupt this active repressor complex (Fig. 6-2). How RB and E2F-1 form an active repressor complex is not known, but there are provocative data that this complex may alter chromatin structure by modulating histone deacetylase activity.<sup>29,30</sup> Despite these studies, the importance of histone deacetylase as a mediator of RB tumor suppression is not yet known.

**FIGURE 6-2.** Schematic model for the control of E2F-dependent genes and S-phase entry by RB. **A:** When active, RB can form a complex with the transcription factor E2F. The localization of RB to this complex by E2F can suppress the transactivation function of E2F as well as other transcription factors that may be colocalized. Other proteins (?) have been suggested to be in such a transcription repressor complex such as histone deacetylase-1.<sup>29,30</sup> This complex represses the expression of genes required for S-phase entry. **B:** When RB is inactivated (by phosphorylation of the protein or by mutation of the gene) the repressor complex presumably does not form and genes required for S phase are expressed.

Given the proposed model that hypophosphorylated RB and E2F-1 form an active repressor complex that is disrupted by RB hyperphosphorylation, it is important to understand the mechanisms driving RB hyperphosphorylation. The first insight into this came with the discovery of a class of genes known as cyclins in yeast cells. These cyclins are expressed in a cell-cycle-dependent manner and are required for the transition from G<sub>1</sub> into S phase in yeast.<sup>5</sup> It was later discovered that mammalian cells also had cyclins, which were expressed in a cell-cycle-dependent manner and were functionally similar to yeast cyclins. Mammalian cyclins are actually a family of related genes that includes D-type cyclins (D1, D2, and D3) and cyclin E, which are expressed maximally as cells progress from G<sub>1</sub> into S phase, and cyclin A, and B-type cyclins, which are expressed in other phases of the cell cycle<sup>5,14,31</sup> (Fig. 6-3). Like the yeast cyclins, mammalian cyclins form complexes with a catalytic partner, known as a cdk. There are at least seven mammalian cdk that function in distinct phases of the cell cycle (see Fig. 6-3) and have different biochemical properties including different cyclin partners, potential substrates, and link to human cancer.<sup>14,31</sup> Elegant study of the crystal structure of cyclin A and cdk2 demonstrated that the binding of the cyclin to the cdk physically alters the structure of the cdk and activates the enzyme.<sup>32</sup> In addition to this, cyclin binding may provide substrate specificity to the cdk.

**FIGURE 6-3.** Schematic representation of changes in cyclins and cdk through the cell cycle. Synthesis of D-type cyclins are stimulated by growth factor signals in the G<sub>1</sub> phase of the cycle and associate primarily with cdk4 and 6. Cyclin E is synthesized later in G<sub>1</sub> and associates with cdk2. Cyclin A is synthesized late in G<sub>1</sub>, throughout S phase, and into early G<sub>2</sub> and associates with cdk2 in early S phase and cdc2 in late S phase and early G<sub>2</sub>. Cyclin B is synthesized late in G<sub>2</sub> and M phase and associates with cdk1 (also known as *cdc2*). The loss of cyclin B/cdk1 activity at the end of M phase is required for reentry into the next G<sub>1</sub> phase.

With respect to the G<sub>1</sub> to S phase control, the key function of cyclins and cdk is to phosphorylate the RB protein.<sup>33,34</sup> The phosphorylation of certain serine or threonine residues in RB reverses the cell-cycle arrest by disrupting the RB-E2F-1 complex.<sup>35</sup> In this process, D-type cyclin/cdk complexes are activated earlier than cyclin E/cdk2, and both cyclins are required for the efficient phosphorylation of RB and entry into S phase (see Fig. 6-3).<sup>36</sup> The significance of potential differences in RB phosphorylation mediated by different cyclin/cdk complexes is not known.

It is relevant to emphasize that many aspects of cyclin/cdk biology are unresolved. First, although RB clearly is a target for cyclin/cdk complexes, whether it is the most important substrate for regulating entry into S phase is not known. Other possible substrates include RB-related proteins p107 and p130<sup>37,38</sup> that seem to have partially redundant roles with RB in cell-cycle control, components of the DNA synthesis machinery (discussed later in [S Phase](#)), and even E2F-1 itself.<sup>39</sup> Second, it is not obvious why mammalian cells should require so many different cyclins/ckds to phosphorylate RB. This is especially true when one considers, for example, that cyclin E seems to be able to accomplish everything that cyclin D1 can do in an elegant *knockout/knockin* experiment in mice.<sup>40</sup> It seems likely that as more is understood about possible *in vivo* targets for different cyclin/cdk complexes, the purpose of such a large family of cyclins will also become clearer.

Because cyclin/cdk activity is so important for regulating the G<sub>1</sub>-to S-phase transition, their activity can be regulated at numerous levels. At present, it appears that cyclin/cdk activity can be controlled by at least six different mechanisms (Fig. 6-4).<sup>14,41</sup> The first level of regulation is that different cyclins are synthesized at discrete stages of the cell cycle. In this regard, the expression of D-type cyclins is closely coupled to the presence or absence of mitogenic growth factors and may be viewed as growth factor sensors.<sup>42</sup> Second, in addition to the regulation of cyclin synthesis, there is active regulation of cyclin degradation. In yeast cells in G<sub>1</sub>, this is mediated by a cellular activity known as the SCF (for Skp-1, cullin, and F-box).<sup>43</sup> A similar complex has been identified in mammalian cells as well. This *machine*, which is analogous to the anaphase promoting complex (APC), that regulates mitosis, targets certain cell-cycle proteins for degradation by the ubiquitin-proteasome system. Third, in addition to the regulation of cyclin protein levels, cyclin activity is regulated by the requirement for complex formation with a cdk as discussed previously. Fourth, the cyclin/cdk complex must be activated by a cdk-activating kinase, which phosphorylates a conserved threonine residue on the cdk.<sup>44</sup> Fifth, additional amino acid residues in the cdk must be dephosphorylated. This is accomplished by both inhibiting certain kinases (known as Wee1/Myt1) and activating certain phosphatases (known as cdc25 A, B, and C).<sup>41</sup> Finally, cyclin/cdk activity is controlled by further protein-protein interactions between cdk or cyclin/cdk complexes and other proteins known as cyclin/cdk inhibitors (CKIs). Once fully activated, cyclin/cdk complexes phosphorylate a variety of substrates that are involved in both the G<sub>1</sub> to S transition as well as the G<sub>2</sub> to M transition.

**FIGURE 6-4.** Multiple levels of regulation of cyclin/cdk activity. The activity of cdk can be regulated by at least six different mechanisms: (1) and (2) cyclins are synthesized and degraded at specific stages of the cycle; (3) cdk must associate with cyclins in order to be active; p21-related and p16-related CKIs can positively and negatively influence this step, respectively; (4) cdk complexed with cyclins must be activated by a cdk-activating kinase; (5) cdk activity is further controlled by inhibitory phosphorylation at threonine 14 and tyrosine 15, which can be removed (and thereby activate the cyclin/cdk) by cdc25 phosphatases; and (6) p21-related CKIs can further inhibit cyclin/cdk activity by direct complex formation with the cyclin/cdk. The activated cyclin/cdk complex phosphorylates a variety of substrates to facilitate both the G<sub>1</sub> to S phase and the G<sub>2</sub> to M phase transition.

CKIs have grown in importance and in number since they were first described. Thus far, two groups of CKIs have been identified (Table 6-1). One group includes p21<sup>WAF1/CIP1</sup>, p27<sup>KIP1</sup>, and p57<sup>KIP2</sup>, which appear to be *universal* inhibitors of cyclin/cdk activity that function by forming a complex with the cyclin/cdk.<sup>45,46,47,48,49</sup> and <sup>50</sup> A second group includes p16<sup>INK4e</sup>, p15<sup>INK4b</sup>, p18<sup>INK4c</sup>, and p19<sup>INK4d</sup>.<sup>51,52,53</sup> and <sup>54</sup> These four specifically inhibit cyclin D-associated cdk4 and cdk6 (hence, the name *inhibitors of cdk4*). As was said of cyclins and cdk, why there should be such a large number of CKIs is an interesting question. To be sure, there are clear biologic differences between these two families. First of all, although p16<sup>INK4e</sup> clearly functions as a tumor suppressor in humans, the full role of other CKIs in human cancer is not yet clear.<sup>55</sup> There are also biochemical differences among different CKIs. For example, p21-like CKIs bind to the cyclin/cdk complex, whereas p16-like CKIs bind to the cdk4 or cdk6 subunit to prevent cyclin D/cdk complex formation<sup>14</sup> (see Fig. 6-4). Intriguingly, p21-related CKIs may function in some capacity as activators of cyclin/ckds.<sup>56</sup> This is based on the observation that p21-like CKIs can bind to cyclin/ckds at greater than 1:1 stoichiometry. The activity of the cyclin/cdk complex is

only inhibited at high ratios of p21-like CKI to cyclin/cdk.<sup>57,58</sup> Finally, different CKIs can be regulated in distinct ways. For example, p21<sup>WAF1/CIP1</sup> was identified because the p53 tumor suppressor gene can induce its expression.<sup>46</sup> As such, it was an obvious candidate effector for p53-mediated cell-cycle arrest after genotoxic stress such as gamma irradiation<sup>59,60</sup> (see [Cell-Cycle Checkpoints](#), later in this chapter). Similarly, both p27<sup>KIP1</sup> and p15<sup>INK4b</sup> can be modulated by transforming growth factor- $\beta$ , and hence may be functional effectors of the antimitogenic effects of transforming growth factor- $\beta$ .<sup>52,61</sup> It is likely that further understanding of the biochemical differences between different CKIs and *in vivo* studies of their function will help clarify their relevance to human cancer.

**TABLE 6-1.** Classes of Cyclin-Dependent Kinase (cdk) Inhibitors

In summary, mammalian cells have developed an elegant system in which several layers of regulators control the *decision* to traverse G<sub>1</sub> phase and enter S phase ([Fig. 6-5](#)). RB and possibly other RB-related proteins function by actively repressing E2F-1–dependent genes at the working end of this biochemical and genetic pathway. The ability of RB to form a repressor complex with E2F-1 is regulated by multiple members of cyclin/cdk family. Of these, D-type cyclins may be particularly important as an intranuclear *sensor* of extracellular growth factors. The activity of cyclin/cdk complexes is regulated by multiple mechanisms to coordinate the decision to enter S phase with extracellular cues. These mechanisms include positive and negative influences by members of two families of CKIs that respond to both extracellular and intracellular signals. At some critical point that seems to be defined by the activation of a threshold level of cyclin/cdk activity, the RB-E2F repressor activity is turned off and the cell makes the commitment to enter S phase.

**FIGURE 6-5.** Schematic diagram showing several layers governing the regulation of G<sub>1</sub>-to-S-phase transition. At present, the event most closely correlated with the transition across the restriction point seems to be the phosphorylation of RB, which disrupts the RB/E2F-1 repressor complex. This leads to the induction of E2F-1–dependent genes and commitment to enter and progress through S phase. The function of RB in this complex is controlled by a number of cyclin/cdk (cyclin-dependent kinases) complexes that are active in G<sub>1</sub> phase. These cyclin/cdk complexes are, in turn, largely negatively regulated by a number of cyclin/cdk inhibitors (CKIs). The activity of both cyclin/cdk complexes and CKIs are lastly regulated by a number of extracellular signals (such as mitogenic or antimitogenic factors) and intracellular signals (such as DNA damage or differentiation factors).

Despite this detailed working model, important questions remain. For example, clarifying the molecular basis for the restriction point will be an important advance in the basic understanding of cell-cycle control. Determining the importance of different regulatory proteins in different types of human cancer will also be important. Finally, understanding how RB and E2F actually function as an active repressor may open up new therapeutic avenues based on better understanding of the working end of this pathway.

## S Phase

The task of generating an exact copy of more than 3 billion base pairs of DNA in the human genome is quite daunting. As is described here, mammalian cells have had to surmount a number of mechanistic difficulties to accomplish this. The importance of the machinery that accomplishes this task is clear because many of the components have been highly conserved from bacteria to humans. What is perhaps an even more important task, though, is how to regulate this DNA synthesis machinery. Each of these 3 billion base pairs must be copied one time, and only one time, during each cell division cycle. Except in rare circumstances in certain organisms or certain developmental states, the synthesis of DNA more or less than one time per cell cycle would be devastating. Since the last writing of this chapter, much insight has been gained into how DNA synthesis is regulated.

It is now known that DNA synthesis begins at defined sequences in the genome of most organisms. These *origins of replication* contain specific DNA sequences, which have been referred to as *autonomously replicating sequences* or *replicator* elements.<sup>62</sup> A technique known as DNA footprinting was used to evaluate proteins that were bound to these DNA elements at different phases of the cell cycle. These studies have shown that there are two different footprint patterns on replicator elements at different phases of the cell cycle, and a change in this pattern occurs as DNA synthesis begins. The multiple proteins that form a DNA-binding complex to generate these footprints are known as the origin of replication complex (ORC).<sup>63</sup> Based on the timing of the two observed ORC footprints, it is thought that these represent a prereplication ORC (pre-RC) and a postreplication ORC (post-RC).<sup>64</sup> The pre-RC is assembled and competent to begin replication in G<sub>1</sub> phase but is held in check by some mechanism to prevent the formal initiation of DNA synthesis (i.e., the conversion of a pre-RC to a post-RC) until S phase. The post-RC represents a complex that is competent to carry out DNA synthesis from the origin of replication to which it is bound.

The molecular components of a pre-RC and post-RC have been studied using biochemical and genetic approaches in different types of eukaryotic cells. There are a large number of proteins of different classes that form these pre-RCs and post-RCs. Some of these proteins, such as ORC proteins 1 through 6 and MCM proteins 2 through 7, have been identified and are beginning to be biochemically characterized.<sup>64</sup> However, mechanistic details for how ORCs function are largely unknown.

In addition to identifying the individual components of the pre-RC and post-RC, work has focused on understanding how a pre-RC is converted to a post-RC and how this is directly linked with DNA synthesis. The changes in footprint pattern as a pre-RC becomes a post-RC coincide with the loss or gain of different molecular components of this complex. Because of the importance of cyclin/cdk activation at the G<sub>1</sub> to S transition, it is likely that cyclin/cdk complexes will be shown to phosphorylate particular substrates that directly affect the pre-RC and post-RC complexes. For example, there is some evidence that MCM proteins, which are components of the ORC, are phosphorylated at the transition to S phase.<sup>65</sup> The phosphorylation of at least one of these (MCM4) can be mediated by a cyclin/cdk.<sup>66</sup> Such a posttranslational modification may be involved in changing a pre-RC to a post-RC and actually driving the formal initiation of DNA synthesis.

The regulation of pre-RC and post-RC is also probably coupled to the mechanism by which a cell prevents *re-replication* of DNA in S phase. The cell cycle can be generally divided into two states: an assembly state and a replication state.<sup>64</sup> The former state allows the assembly of pre-RCs at replicator elements but prevents the formal initiation of DNA synthesis until other critical factors are supplied (such as G<sub>1</sub>/S cyclin/cdk activity) ([Fig. 6-6](#)). The latter state allows DNA synthesis from

preassembled ORCs but does not allow assembly of *new* pre-RCs. The loss of cyclin/cdk activity at the end of mitosis is one factor that probably allows the reformation of the pre-RCs. There may also be other factors, such as *licensing factor*,<sup>67</sup> which seems to be supplied to a cell only *after* completion of mitosis to prevent rereplication of DNA (see Fig. 6-6). As more is learned about the existence of states that are competent and not competent for new DNA synthesis, many more regulatory details will be elucidated.

**FIGURE 6-6.** Schematic model of how the ability to synthesize new DNA may be regulated. After mitosis is complete, a cell becomes competent to initiate new DNA synthesis. This competency correlates with the presence of a prereplication complex (pre-RC) bound to DNA replicator elements. At the formal initiation of DNA synthesis (replication fork initiation), which is driven by certain poorly defined events (activating factors), the pre-RC complex changes to a post-RC complex while DNA is synthesized. This post-RC complex is unable to bind to new DNA replicator elements and, hence, DNA can only be synthesized one time per cell cycle. The transition from a post-RC back to a pre-RC, on completion of the next mitotic phase, is negatively and positively regulated by cyclin B/cdk1 and a poorly defined licensing factor (see text for details).

In addition to the task of allowing DNA synthesis only one time during the cell cycle, the cell faces the task of ensuring that newly synthesized DNA is *accurately* copied. The enzymes that accomplish this are called DNA polymerases, three of which are known to be involved in DNA replication (as opposed to repair) in eukaryotic cells (DNA polymerases  $\alpha$ ,  $\delta$ , and  $\epsilon$ ). The double-stranded nature of genomic DNA provides a mechanism to ensure accuracy because each existing strand serves as a template for a new strand. Although the DNA polymerases copy it with high fidelity, they are not perfect. Approximately one incorrect nucleotide is incorporated for every  $10^5$  to  $10^6$  correct nucleotides. At this rate, 1000 to 10,000 mutations would be generated with each cell division. In order to prevent this, the DNA polymerases are endowed with *proofreading* functions that allow misincorporated nucleotides to be detected and removed by 3' to 5' exonuclease activity of the DNA polymerase. This process reduces the error rate by approximately 1000-fold.<sup>68</sup> In addition to the repair activity that is closely coupled to DNA synthesis, other repair processes detect and replace mismatched DNA bases or other DNA abnormalities to further limit errors associated with DNA replication. Inefficiencies in DNA repair machinery appear to be important in the development of some forms of cancer, such as certain forms of hereditary colon cancer that are linked to abnormalities in DNA mismatch repair enzymes.<sup>69</sup>

In addition to the problem of accuracy, the cell faces a problem due to the sheer magnitude of the task of copying all 3 billion base pairs. A single replication fork traveling at approximately 3000 bases per minute would require approximately 1 month to replicate just one of the 46 human chromosomes.<sup>70</sup> As described previously, the cell addresses this problem by initiating DNA replication at multiple origins of replications. Interestingly, these multiple origins appear to fire in an ordered fashion.<sup>64</sup> The mechanisms by which origins fire early or late in S phase are not understood.

After any individual ORC is activated to begin DNA synthesis, how the polymerase generates an elongating strand of newly synthesized DNA is another mechanistic hurdle. Because DNA is a double-stranded helix, it must be unwound and both strands of the DNA must be copied simultaneously. The synthetic process is started from an RNA primer on each of these strands and makes the new strand in the 5' to 3' direction (Fig. 6-7). Because the double-stranded DNA is arranged in an antiparallel fashion, one new strand is synthesized continuously (*leading strand*) and the other discontinuously (*lagging strand*). As described for the ORCs, much work has focused on identifying the proteins that are required for DNA synthesis at the replication forks of eukaryotic cells. These include PCNA, RPA, RFC, DNA polymerases, DNA primase, and RNaseH.<sup>71</sup> Some of the mechanics of the process are now understood, such as PCNA forming a molecular *sliding clamp* to hold the polymerase on the DNA.<sup>72</sup> After the DNA polymerase complex has proceeded along the length of a strand of DNA to the next replicon, the RNA primer is replaced by DNA and a DNA ligase closes the gap between the two newly synthesized stretches of DNA. With this, DNA synthesis is essentially complete.

**FIGURE 6-7.** The end-replication problem and role of telomerase in circumventing it. The end of a DNA molecule is replicated on one strand by continuous replication proceeding to the end of the molecule, whereas the other strand is replicated discontinuously using RNA primers and Okazaki fragments. Removal of the RNA primer and Okazaki fragment ligation leaves a region at the 3' end of one nascent DNA strand unreplicated (box). If there were no mechanism to fill the gap, the chromosome end would get shorter with each round of replication. Telomerase solves this problem by binding to the telomere at the 3' end of the nascent DNA strand and extending this end. This provides an elongated template for the DNA polymerase to use, which allows the entire original genomic DNA sequence to be completely replicated. (Adapted from ref. 74, with permission.)

One final hurdle, though, for a cell to *completely* copy the entire genome involves the synthesis of new DNA at the end of each chromosome. Because DNA polymerases require an RNA primer to begin this process and because they only assemble a new strand in the 5' to 3' direction, each linear chromosome would fail to copy DNA at the very 3' end of each chromosome with every round of replication (see Fig. 6-7).<sup>73</sup> This would be deleterious because numerous rounds of DNA replication would result in a large amount of DNA being lost from the chromosome ends.

It appears that eukaryotic cells deal with this *end-replication* problem by the use of specialized structures called *telomeres*, which are simple tandemly repeated sequences at the end of each chromosome (see Fig. 6-7). These repeated DNA sequences are recognized by telomerase, a holoenzyme containing a reverse transcriptase (polymerase) and an RNA component that is complementary to the repeated DNA sequences of a telomere. The reverse transcriptase extends the 3' end of the chromosomal DNA by *reading* the RNA component as a template<sup>73,74</sup> (see Fig. 6-7). In this way, telomerase prevents the loss of this 3' end of the DNA to defeat the end-replication problem.

In addition to providing a mechanism to complete the DNA synthesis task, telomerase activity is particularly important for cancer biology because it confers unlimited cell proliferation capacity,<sup>73,74</sup> which is a hallmark of a malignant cancer cell. There is good experimental evidence that most telomerase-deficient cells can only replicate a finite number of times until the telomeric ends of the chromosomes become shortened to a critical point that arrests further cell proliferation.<sup>73</sup> Because most normal cells in the body do not have telomerase activity, it has been suggested that the loss of telomeric DNA may be the basis for cellular aging. On the other hand, tumor cells appear to be immortalized by virtue of the increased telomerase activity.<sup>75</sup> Because increased telomerase activity is relatively specific to cancer cells in a human body, the pharmacologic inhibition of telomerase may, indeed, be a new therapy for cancer that is directly based on better understanding of the DNA

synthesis process.

## M-PHASE ENTRY AND EXIT

Once the cell has copied the entire genome, it enters a second gap phase, known as  $G_2$ , to prepare for entry into mitosis, the phase in which the duplicated genome is segregated to two daughter cells. The successful completion of mitosis may be considered the most crucial phase in the cell cycle because errors in this process are irreversible and lead to dramatic alterations in the genetic material such as the loss or gain of entire chromosomes. Much insight has been gained into the regulation of this process since the last writing of this chapter and can be found in excellent, detailed reviews.<sup>8,76,77</sup> Three main features of this regulation are presented here. Because of its complexity, it is helpful to consider mitosis in several distinct phases (Fig. 6-8A). In the first place, the actual entry into mitosis is carefully controlled to prevent the segregation of chromosomes that have not completed DNA synthesis. Second, there are many structural changes that occur in a cell during mitosis such as chromosomal condensation, centrosome migration, microtubule polymerization, spindle assembly, nuclear membrane dissolution, microtubule and kinetochore attachment, alignment of all chromosomes on a plane between the centrosomes, and the separation of sister chromatids (see Fig. 6-8A). The actual separation of sister chromatids, a process that constitutes the metaphase to anaphase transition, represents an important checkpoint for a cell because chromatid separation is not easily reversed. Finally, after anaphase is complete, the chromosomes lose their highly condensed structure, the nuclear envelope reforms, and the cell undergoes cytoplasmic division (cytokinesis) to complete the cell cycle. At this stage, the cell must formally exit mitosis to reset itself for the next cell division cycle. Most of what is known about mitotic control in mammalian cells relates to how the entry into mitosis, the metaphase to anaphase transition, and the exit from mitosis are governed.

**FIGURE 6-8.** Schematic diagram of  $G_2$ - to M-phase regulation. **A:** The large number of complex structural changes that occur during M phase generally seem to be regulated at three key transition points: the formal entry into mitosis, the metaphase to anaphase transition, and the formal exit from mitosis. **B:** Regulation of the transition across M phase involves multiple events. First, the accumulation of maturation- (or mitosis) promoting factor (MPF) (cyclin B/cdk1) to a critical level seems to mark the formal beginning of M phase. The accumulation of cyclin B is governed by decreased anaphase promoting complex/cyclosome (APC/C) activity, and a number of other cyclin/cdk (cyclin-dependent kinase) activating steps (see Fig. 6-4). Once activated cyclin B/cdk1 phosphorylates a number of targets, including cdc25 phosphatase, which positively feeds back to activate more cyclin B/cdk1. Cyclin B/cdk1 also seems to activate polo-like kinases (PLKs), which are kinases physically localized to (and hence may regulate) certain key mitotic structures such as kinetochores and spindle pole bodies. Finally, PLKs can activate APC/C again during M phase, which leads to the degradation of proteins that may be directly involved in the separation of sister chromatids (metaphase to anaphase transition). APC/C activation also causes the degradation of cyclin B, which both ends the mitotic phase and facilitates the reformation of the pre-RC to set the stage for the next cell-cycle phase (see Fig. 6-6).

The first regulatory mechanism for mitosis involved the maturation- (or mitosis) promoting factor (MPF), which was identified as a cytoplasmic activity in metaphase-blocked *Xenopus* oocytes that could drive other cells into mitosis.<sup>78</sup> MPF was characterized as a complex of cyclin B and cdk1 (also known as cdc2) (Fig. 6-8B).<sup>79</sup> Many studies have demonstrated that the activation of cyclin B/cdk1 is the most crucial step governing whether a cell enters mitosis.<sup>77</sup> Because of this central role, cyclin B/cdk1 is regulated at many levels, including some that are different from the  $G_1/S$  cyclin/cdks discussed previously. First, the levels of cyclin B protein are increased during late S and  $G_2$  phase by both increased synthesis and decreased destruction. Second, newly synthesized cyclin B binds to unphosphorylated cdk1, which becomes activated by phosphorylation at threonine 161 by cdk-activating kinase. Approximately concurrent with this, the cytoplasmic cyclin B/cdk1 complexes must be relocalized to the nucleus by an as yet unclear mechanism.<sup>80</sup> In addition, the competing kinases (Wee1/Mik1/Myt1) and phosphatases (cdc25 B and C), which govern the phosphorylation of threonine 14 and tyrosine 15 on cdk1, must allow dephosphorylation of these residues to activate the cyclin/kinase activity (see Fig. 6-8B).<sup>77</sup> Once activated, a positive feedback loop between cyclin B/cdk1 and cdc25C exists to allow further activation of B/cdk1, which drives the initiation of mitosis by phosphorylating specific nuclear proteins.<sup>77</sup> The identification of the specific proteins that are phosphorylated by cyclin B/cdk1 to drive the initiation of mitosis will be important for our understanding of this phase of the cell cycle. Because the cdc25 phosphatase plays a key role in the initial activation of cyclin B/cdk1, it is not surprising that it also has an important role in a checkpoint pathway that can be activated to prevent the entry into mitosis in response to genotoxic stress (see section [G<sub>2</sub>- to M-Phase Checkpoint](#), later in this chapter).

A second important regulatory mechanism may help link biochemical changes such as phosphorylation of specific proteins with structural changes such as spindle body assembly. This mechanism involves a family of kinases known as polo-like kinases (PLKs) after polo kinase, the first of this family identified in *Drosophila*.<sup>76</sup> Like cdks, PLKs represent a family of kinases conserved from yeast to humans. Although they may have functions at several stages of the cell cycle, the best-characterized roles are during mitosis.<sup>76</sup> In the first place, they indirectly activate cyclin B/cdk1 by phosphorylating and activating cdc25. Whether PLKs are initial activators of cyclin B/cdk1 or play a role in the positive feedback loop for B/cdk1 activation is not known. Second, at different stages of mitosis PLKs are localized to spindle pole bodies, kinetochores, and the spindle midzone, which suggests that they may play a role in spindle apparatus assembly, sister chromatid pairing and separation, and even cytokinesis. Because cyclin B/cdk1 may activate them, PLKs could directly link the biochemical activity of MPF with structural changes that occur during mitosis. However, the mechanistic details of this are far from understood. Finally, PLKs may also activate the APC/cyclosome (APC/C), which has roles in both the metaphase to anaphase transition as well as the formal exit from mitosis.

Finally, it has become clear that regulated destruction of certain proteins is a central force driving entry into, transition through, and exit from mitosis. At the heart of this is a large complex of proteins known as the APC/C. As with PLKs, the importance of the APC/C is indicated by the fact that it has been conserved in evolution from yeast to humans.<sup>81</sup> It functions by marking particular proteins with a ubiquitin molecule that leads to the destruction of the ubiquitinated protein by the 26S proteasome degradation machine. Numerous studies have shown that the down-regulation of APC/C activity contributes to the accumulation of cyclin B, which is required for a cell to enter into mitosis (see Fig. 6-8B).<sup>82</sup> In addition, the APC/C contributes to the destruction of the *glue* that holds sister chromatids together; hence, it drives the metaphase to anaphase transition.<sup>82</sup> Finally, activation of the APC/C eventually guides the destruction of cyclin B protein to mark the end of mitosis.<sup>82</sup> Importantly, by destroying all mitotic cyclin/cdk activity, the APC/C also allows the entry into the next  $G_1$  phase by allowing the formation of new pre-RC (see Fig. 6-6). Moreover, the APC/C remains active to prevent the reaccumulation of cyclin B until the next mitotic entry is scheduled.

## CONTROL OF THE CELL DIVISION CYCLE

Obviously, the cell does not use the complex DNA synthesis and cell division machinery in a vacuum. It must continuously integrate extracellular signals from the environment as well as intracellular signals regarding the status of the genome. These signals contribute to the control of cell division and also constitute formal checkpoints that may be activated in times of cellular stress. How a cell accomplishes the integration of extracellular signals and the mechanisms by which it checks its progress through cell division are reviewed in this section.

### EXTRACELLULAR SIGNALS

Nutrient status, cell-cell contact, and extracellular peptides can all influence intracellular events. The significant question that arises is how do these extracellular factors communicate with the intracellular machinery to influence cell-cycle progression? For example, growth factors cause cells in the resting or  $G_0$  phase of the cell cycle to enter and proceed through the cycle. Continued growth factor exposure is required for progression through  $G_1$  until the cell reaches the restriction point (see Fig. 6-3), after which time the cell proceeds through the rest of the cell cycle. How does the presence of an extracellular polypeptide, such as a growth factor,

influence the cell cycle in this way? Much progress has been made in understanding the exact details of the many events that occur after any single growth factor stimulates a cell to proliferate. Unfortunately, these events are so complex that it would be impossible to provide adequate detail in this chapter. Therefore, we address general themes that have emerged more recently.

Many growth factors (or cytokines) are soluble proteins that mediate cellular communication. In general, these growth factors bind to specific receptors on the surface of cells and initiate a cascade of biochemical signals that influence intracellular events. Typically, one of the first events is the phosphorylation of the receptor or a protein associated with the receptor.<sup>83</sup> Some cyto-kine receptors contain intrinsic tyrosine kinase domains, whereas other cytokine receptors have no intrinsic kinase function but are capable of recruiting and activating nonreceptor tyrosine kinases, which can transduce signals *downstream* to other proteins. A common end point for this cascade is the change in activity of certain transcription factors leading to the induction or repression of specific genes involved in cell proliferation, cell differentiation, or cell survival (Fig. 6-9). Examples of such signaling pathways include the activation of the RAS-RAF-MAP kinase pathway in response to epidermal growth factor signaling,<sup>83,84</sup> and<sup>85</sup> or the activation of the Janus kinase (Jak) family that then activates the STAT family of transcriptional regulators in response to interleukin signaling.<sup>86,87</sup> and<sup>88</sup> With the role that growth factor receptors and signal transduction components have in mediating the cellular decision to proliferate by driving the G<sub>1</sub> to S transition, it is not surprising that many of these components have been found to be abnormal in human cancers. The HER2/neu epidermal growth factor-like growth factor receptor is an elegant example of both the identification of important components of this pathway and how such knowledge has been translated into a novel therapeutic approach that is specifically designed to disrupt this pathway using anti-HER2/neu antibodies.<sup>89</sup>

**FIGURE 6-9.** Schematic illustration of two pathways that transduce extracellular signals to control intracellular and intranuclear events. Epidermal growth factor is illustrated as an example of a growth factor that binds to its receptor and initiates a cascade of events, beginning with the autophosphorylation of the receptor itself. An adaptor protein (Grb2) binds to the phosphorylated receptor, which then binds to the guanine nucleotide releasing factor (Sos). This complex activates ras by exchanging guanosine diphosphate for guanosine triphosphate. The guanosine triphosphate-bound active form of ras binds to and activates the serine/threonine kinase raf. Raf phosphorylates and activates mitogen-activated protein-kinase kinase (MAPKK), which in turn phosphorylates and activates mitogen-activated protein kinase (MAPK). The targets phosphorylated by MAPK appear to be both cytoplasmic and nuclear proteins, at least some of which can activate transcription of certain gene products involved in cell proliferation. The Jak/STAT pathway is illustrated as being initiated by interferon (IFN) binding to its receptor (IFNR), which leads to activation of members of the Jak family of nonreceptor tyrosine kinases. These kinases then phosphorylate members of the STAT family of transcription factors on tyrosine residues, which translocate to the nucleus, bind specific DNA sequences, and promote transcription. There may be significant cross-talk between signaling pathways. In this example, this is illustrated by (1) the activation of the Jak pathway by certain peptide growth factors ( *dashed arrow*) and (2) the phosphorylation of serine residues on STAT proteins by MAP kinase.

It must be emphasized that these are only two of a large number of pathways that have been identified. Moreover, these apparently linear pathways are not linear at all, as there is much cross-talk between different components of a pathway, which suggests that the cellular responses to any single factor may depend on the balance of signals from different growth factor pathways.<sup>90</sup>

Despite the complexity of these mitogenic signaling pathways, there is the suggestion that most converge on a common intranuclear event. It has been observed that most, if not all, mitogenic growth factors at some point lead to increased expression of certain D-type cyclins.<sup>5</sup> As noted previously, this is an essential component of the ultimate activation of cyclin D/cdk activity (see Fig. 6-4). However, the induction of cyclin D protein is not sufficient to drive the entire decision for a cell to proliferate. Therefore, it must be integrated with other biochemical events in the nucleus. This observation provides a framework to think about how signaling of cells at the cell membrane by extracellular growth factors can affect the machinery that directly drives cell proliferation across the G<sub>1</sub> to S boundary. As more is learned about mitogenic signal transduction pathways, the knowledge of how growth factors influence the cell-cycle machinery should lead to novel therapeutic strategies to treat cancer.

## CELL-CYCLE CHECKPOINTS

The events of the cell cycle appear to be highly ordered into dependent pathways so that the initiation of any event in the cell cycle is dependent on the completion of earlier events. For example, mitosis is dependent on completion of DNA synthesis, chromatid separation is dependent on kinetochore assembly and chromosome alignment, and DNA replication during S phase is *licensed* by the cell having completed a prior mitosis. The control mechanisms that enforce this ordered dependency are called cell-cycle checkpoints.<sup>1,2</sup> It is important to emphasize that a variety of signals, from both extracellular as well as intracellular events, can activate these checkpoints to prevent cell-cycle progression. For example, nutrient deprivation, temperature changes and other forms of environmental stress, nucleotide depletion, or damage to the DNA all can inhibit cell-cycle progression by invoking these cell-cycle checkpoint controls.

It is now clear that cell-cycle checkpoints are actively regulated by components of the cell-cycle machinery. For example, cell-cycle arrest following DNA damage is not simply a by-product of the structural damage to the DNA. Moreover, mutations in the genes that control these checkpoints can disrupt the arrest signals and allow continued cell-cycle progression when it may be inappropriate. Such mutations could result in altered responses to environmental or therapeutic DNA-damaging agents, such as increased or decreased cell death, increased mutation rate, and genetic instability. It is not surprising, then, that mutations in cell-cycle checkpoint genes are now thought to both significantly contribute to cancer development and affect the responses of tumor cells to chemotherapy and radiation therapy.<sup>91</sup>

Damage to the DNA by ionizing radiation is the one stimulus for cell-cycle checkpoint activation that has been the most intensively studied. When nuclear DNA has been damaged by either intrinsic or extrinsic processes, normal cells cease progressing through the cell cycle at one of several points: either before entry into S phase, within S phase, or before entry into mitosis (see Fig. 6-1). Presumably, arrest at these particular points in the cell cycle would limit the propagation of genetic mutations to daughter cells by allowing for DNA repair, and it may also prevent cell death. We briefly review what is known about each of these DNA damage checkpoints as well as two additional checkpoints that are not directly activated by DNA damage but may still be relevant to cancer development.

### G<sub>1</sub>- to S-Phase Checkpoint

The tumor suppressor gene, p53, appears to be a critical component of the signaling pathway that arrests cells in G<sub>1</sub> after DNA damage (Fig. 6-10). It is mutated in a large proportion of human cancers and the Li-Fraumeni familial cancer syndrome is caused by germline mutations in the p53 gene,<sup>92,93</sup> which supports the importance of p53 function in cancer prevention. There are two potential mechanisms by which the loss of the p53-mediated G<sub>1</sub> to S checkpoint could lead to increased cancer susceptibility. First, DNA damage is known to increase p53 protein level and activity, which secondarily increases the level of the p21<sup>WAF1/CIP1</sup> CKI. Increased p21<sup>WAF1/CIP1</sup> inhibits the activity of cyclin/cdk complexes that drive the G<sub>1</sub>- to S-phase transition by preventing the hyperphosphorylation of RB (see Fig. 6-10). In cells that lack p21<sup>WAF1/CIP1</sup>, the G<sub>1</sub> to S arrest after DNA damage is defective.<sup>94</sup> In addition to being critical for G<sub>1</sub> to S arrest, p53 also can drive programmed cell death or apoptosis in certain cells in response to DNA damage.<sup>94,95</sup> What governs whether p53 causes cell-cycle arrest or programmed cell death is not well understood. Nonetheless, it is clear that the loss of p53 can result in inappropriate cellular response to DNA damage by two mechanisms: allowing damaged DNA to be replicated and allowing the survival of cells that normally would undergo programmed cell death (see Fig. 6-10). In this regard, it is easy to understand how p53 mutations would be critical to cancer development. In addition, the loss of p53-mediated apoptosis in response to therapies that cause DNA damage could have a significant effect on tumor response. Two new genes, p73 and p63, have been identified as relatives of p53.<sup>96,97</sup> The full importance of these p53-related genes in human cancer and the

G<sub>1</sub> to S checkpoint will require further study.

**FIGURE 6-10.** Schematic diagram of several cell-cycle checkpoints in mammalian cells. Ionizing radiation causes DNA damage in the form of strand breaks. This activates several signal transduction pathways, depending on the phase of the cell cycle. For cells in G<sub>1</sub>, DNA damage leads to increased p53 protein, which is dependent on signaling through ATM. Increased p53 protein levels lead to transcriptional activation of certain genes, such as gadd45, mdm2, p21, cyclin G, and Bax, which causes either cell-cycle arrest by induction of p21<sup>WAF1/CIP1</sup> or apoptosis. For cells in S phase, DNA damage arrests further DNA synthesis in an ATM-dependent and an nbs1-dependent manner.<sup>150</sup> In cells in G<sub>2</sub> and M phase, DNA damage leads to the activation of proteins such as chk1 and chk2, which can phosphorylate cdc25 phosphatase. Phosphorylated cdc25 is then bound by, and hence inactivated by, 14-3-3 proteins, which therefore prevents the activation of cyclin B/cdk1 (MPF). The role of ATM and potentially other proteins in this checkpoint are not yet known. It is important to emphasize that the cell-cycle checkpoints differ in response to different types of DNA damage, such as that induced by gamma irradiation versus various genotoxic drugs or ultraviolet irradiation.

### S-Phase Checkpoint

The molecular controls of S-phase arrest after DNA damage in mammalian cells are less well understood, but a number of yeast genes, such as MEC1, MEC2, and HUS1, have been identified that control the S-phase checkpoint.<sup>98</sup> Although clear mammalian counterparts to these genes are just now being identified, the ATM gene, which is *mutated in ataxia-telangiectasia* and is related to MEC1, seems to be particularly important for the S-phase checkpoint. The first insight into this came from the study of patients with ataxia-telangiectasia, who are cancer prone, and from study of these patients' cells, which are defective in all three DNA damage-induced checkpoints, including the S-phase checkpoint.<sup>99</sup> The ATM gene product is a nuclear and cytoplasmic protein kinase that can phosphorylate certain proteins that are known to be involved in DNA damage checkpoints and DNA repair, such as p53.<sup>100</sup> Although studies of ATM-related genes in yeast have suggested potential biochemical and genetic mechanisms,<sup>2</sup> how ATM regulates the S-phase checkpoint is not yet known (see [Fig. 6-10](#)).

### G<sub>2</sub>- to M-Phase Checkpoint

The DNA damage-induced arrest of cells in the G<sub>2</sub> phase of the cell cycle is prominent in most mammalian cell types and has been intensively studied by radiobiologists for years because of an apparent link between G<sub>2</sub> arrest and radiosensitivity.<sup>101</sup> In yeast, the RAD9, RAD17, RAD24, MEC1, MEC2, and MEC3 genes all appear to be involved in signaling the cell to arrest in G<sub>2</sub> after DNA damage,<sup>91</sup> and mutations in these genes lead to increased genetic instability and increased radiosensitivity. Work clarifying many details of this pathway in mammalian cells indicates that it controls the activation of cyclin B/cdk1, which is particularly important for regulating entry into mitosis (see [Fig. 6-8](#)). Briefly, in yeast it has been shown that DNA damage activates a kinase known as chk1, which can phosphorylate cdc25, the phosphatase that is critical for activating cyclin B/cdk1 at entry into mitosis. Phosphorylated cdc25 can be bound and, hence, inactivated by 14-3-3 proteins (see [Fig. 6-10](#)).<sup>102</sup> Similar themes are emerging from study of mammalian cells. ATM also appears to have a role in this pathway; however, the molecular details are not yet known.

### Mitotic Spindle Checkpoint

In addition to the DNA damage-induced checkpoint to prevent entry into mitosis, there is another mitotic checkpoint that involves the mitotic spindle apparatus. This checkpoint functions to prevent the metaphase to anaphase transition until all sister chromatid pairs are aligned and attached to the mitotic spindle apparatus (see [M-Phase Entry and Exit](#), earlier in this chapter) (see [Fig. 6-8](#)). Abnormalities in this checkpoint can lead to gross changes in chromosome number, which is a common occurrence in cancer cells. Several yeast genes (MAD1, MAD2, MAD3, BUB1, BUB2, and BUB3) have been found that control mitotic arrests when the microtubule apparatus is poisoned,<sup>91</sup> but mammalian counterparts have not been identified. Interestingly, p53 has been implicated in a spindle checkpoint in mouse cells,<sup>103</sup> which again demonstrates its importance in numerous aspects of cancer cell biology.

### Cellular Senescence

Finally, it has been suggested that cellular senescence also represents a type of cell-cycle checkpoint that is activated when chromosomal telomeres become shortened to a critical point.<sup>104</sup> It is thought that critically shortened telomeres may cause DNA strand abnormalities to activate one or more cell-cycle arrest signals and prevent further cell proliferation (hence, senescence). This could be significant for tumorigenesis because tumor cells may have defective checkpoint-signaling pathways. Thus, in addition to expressing telomerase activity (see [S Phase](#), earlier in this chapter), the loss of a growth inhibitory checkpoint signal to induce senescence could also contribute to the development of cellular immortality in tumor cells.

## IMPLICATIONS FOR CANCER

### CANCER DEVELOPMENT

Cancer cells exhibit a diverse set of phenotypic abnormalities, including loss of differentiation, increased motility or invasiveness, and decreased drug sensitivity. However, one phenotypic abnormality that is virtually pathognomonic of all cancer cells is dysregulation of cell-cycle control. A common misconception is that cancer cells replicate faster than normal cells. Rather, the growth abnormality in cancer cells appears to result from two factors: (1) lack of appropriate control responses to the signals that normally cause the cell to stop going through the cell cycle, and (2) lack of a cellular death program in response to appropriate stimuli or stresses. The transformation of a normal cell to a tumor cell appears to be dependent on mutations in gene products important in integrating extracellular and intracellular signals to the cell cycle and cell death machinery and on those gene products involved in directly controlling cell-cycle progression. Loss of either type of function would lead to loss of regulatory cell growth signals.

An evolution has occurred over the past 25 years in our thinking about the nature of the growth abnormalities present in cancer cells. The discovery of oncogenes in the 1970s and their overexpression or increased activity in tumor cells led to the suggestion that the abnormality in tumor cells was the presence of too much of a signal that pushed the cell through the cell cycle. The discovery of tumor suppressor genes in the 1980s added to this model by suggesting that the growth abnormalities of tumor cells resulted from a combination of too few of the cell-cycle *brakes* (tumor suppressors) and too many of the cell-cycle *accelerators* (oncogenes).

This model has been even further revised in the past several years with the recognition of the importance of cell death controls in maintaining appropriate numbers of cells in a given tissue. Changes in tissue cell number are dictated by the number of new cells generated by cellular proliferation and the number of cells lost to the tissue by cell death ([Fig. 6-11](#)). The number of proliferating cells is controlled by a combination of the gene products driving the cell through the cycle (can be considered oncogenes in a simplified model) and the gene products that inhibit cell-cycle progression (considered tumor suppressor genes in a simplified model). In a simplified model, the number of cells dying in a tissue is a function of the relative activities of the gene products that block programmed cell death (antiapoptosis genes) and the gene products that enhance programmed cell death (apoptosis-enhancing genes). Thus, tumors may develop and malignant cells may continue to increase their numbers by acquiring mutations in genes that result in combinations of increased drive through the cell cycle (increased *oncogene* activity), decreased

inhibition of cell-cycle progression (loss of *tumor suppressor* genes), increased antiapoptosis signals (e.g., overexpressed BCL2) and decreased proapoptosis signals (e.g., decreased BAX or mutated p53). Cell differentiation is also probably associated with slowing or stopping cell proliferation, and some abnormal gene products in malignancies that drive proliferation also appear to inhibit differentiation.

**FIGURE 6-11.** The steady-state number of cells in a tissue is a function of the relative amount of cell proliferation and cell death. Cell proliferation is influenced by the balance of positive effects of oncogenes and negative effects of tumor suppressor genes. Cell death is influenced by the balance of positive and negative effects of proapoptotic and antiapoptotic gene products. Simplistically, cell number may be increased by increased activity of oncogenes or antiapoptotic genes or by decreased activity of tumor suppressor genes or proapoptotic genes.

### Oncogenes

One formal definition for an oncogene is that the oncogene product contributes to malignant transformation either *in vitro* or *in vivo*. The concept used previously that oncogenes are gene products that enhance cell-cycle progression is not always true, but is useful for the discussion here. Oncogenic mutations in tumor cells will not be discussed in great detail here. However, it is clear that many of the genes that have been classified as oncogenes are positive growth signals. They can fall into categories of abnormally activated growth factors (e.g., c-SIS), growth factor receptors (e.g., HER2/neu and c-FMS), intracellular signaling molecules (e.g., c-SRC, RAS, and c-RAF), and nuclear transcription factors (e.g., c-MYC). Such signaling pathways were discussed previously as influencing the actual cell-cycle machinery, and it is easy to envision how activating mutations in any of these genes could lead to enhanced signals that inappropriately keep the cell going through the cell cycle. Positive signals directly involved in the cell-cycle machinery have been linked to oncogenesis by the observations of abnormally high levels of cyclin expression in certain tumor cells.<sup>105</sup> In addition, the cdk-activating cdc25 phosphatases have been demonstrated to have cooperative oncogenic activity in soft agar and nude mouse tumor assays and appear to be overexpressed in a significant percentage of primary human breast carcinomas.<sup>106</sup>

### Tumor Suppressor Genes

The existence of tumor suppressor genes, predicted in the 1970s by the elegant epidemiologic studies of Knudson<sup>107</sup> and by subsequent cell fusion studies,<sup>108</sup> finally became a reality with the discovery of the retinoblastoma (RB) gene and later the role of the p53 gene in the 1980s.<sup>109</sup> Although a number of tumor suppressor genes have been identified to date (including APC, BRCA1, BRCA2, NF1 and NF2, WT1, and VHL), RB and p53 are unusual tumor suppressor genes in that they directly influence the cell-cycle machinery. As discussed previously, RB expression inhibits cell-cycle progression by binding to E2F-1 and blocking transcription of genes necessary for entry into S phase. p53 inhibits cell-cycle progression by inducing the transcriptional activation of the CKI, p21<sup>WAF1/CIP1</sup>, which in turn inhibits activation of the cdk such that it cannot phosphorylate substrates such as RB.

As discussed previously, p53 participates in a cell-cycle checkpoint signal transduction pathway that causes either a G<sub>1</sub> arrest or apoptotic cell death after DNA damage. Loss of p53 function during tumorigenesis thus can result in both inappropriate progression through the cell cycle after DNA damage and survival of a cell that might otherwise have been destined to die. It is easy to conceive how this would cause both increased genetic instability and decreased apoptosis and contribute to malignant transformation. Additionally, roles for p53 in controlling certain aspects of the progression from the G<sub>2</sub> phase of the cell through mitosis and chromosome segregation have been suggested.<sup>110,111</sup> Thus, it is not surprising that p53 is the most commonly mutated gene in human cancers identified to date, with at least 50% of tumors having abnormal p53 genes.<sup>92</sup> Some tumors also develop other mechanisms of inactivating p53 function by overexpression of the p53-binding protein, mdm2,<sup>112</sup> or by infection with high-risk human papilloma tumor virus (HPV) and expression of the HPV E6 protein, which binds to p53 and enhances its degradation.<sup>113</sup> Inactivation of p53 by overexpression of mdm2 appears to occur primarily in sarcomas and inactivation by HPV infection in cervical carcinomas.<sup>112,114</sup> Thus, many tumors appear to inactivate p53 function by these mechanisms, rather than by mutation of the p53 gene itself, but the end result is the same since p53 function and certain aspects of cell-cycle control are abrogated.

The RB gene is mutated in a number of different tumor types, but others may have mutations elsewhere in the cell-cycle pathways that use RB. For example, cyclin D/cdk4 complexes phosphorylate RB and it appears that p15<sup>INK4b</sup> and p16<sup>INK4e</sup>, which are inhibitors of cyclin D/cdk4, are mutated in a variety of tumor types. In contrast, the p21<sup>WAF1/CIP1</sup> and p27<sup>KIP1</sup> cdk inhibitors are rarely mutated.<sup>115</sup> In principle, any cdk inhibitor might act as a tumor suppressor protein.<sup>14</sup> Loss of RB pathway function could certainly lead to loss of normal inhibitory controls of cell-cycle progression. However, some data also suggest that loss of RB function alone enhances apoptosis tendencies of cells, so by itself might not result in tumor development.<sup>116,117,118</sup> and <sup>119</sup> It has been suggested<sup>119</sup> that loss of RB function, leading to enhanced cell proliferation, coupled with genetic changes that cause loss of apoptosis signals, would be an efficient combination for enhancing malignant transformation (see [Apoptosis: Another Step in the Cell Cycle That Goes Awry in Tumor Cells?](#), later in this chapter).

Characterization of the tumor suppressor locus coding for the cyclin kinase inhibitor p16<sup>INK4e</sup> revealed a novel tumor suppressor gene and a genomic organization that is unprecedented in mammalian cells and affects both the RB and p53 pathways.<sup>120</sup> The p19<sup>ARF</sup> gene was found as an alternatively spliced gene encoded within the genetic locus that codes for p16<sup>INK4e</sup>. Interestingly, the p19<sup>ARF</sup> gene product induces a growth arrest that is dependent on the p53 protein.<sup>121,122</sup> Thus, this single genetic locus codes for two proteins, one of which (p16<sup>INK4a</sup>) inhibits proliferation via the RB pathway by inhibiting activation of cyclin-dependent kinases and a second protein (p19<sup>ARF</sup>) that inhibits proliferation via activation of p53 ( [Fig. 6-12](#) ).<sup>122</sup> The mechanism by which p19<sup>ARF</sup> affects p53 protein levels has been shown to be via binding to the mdm2 protein and sequestering mdm2 in the nucleolus.<sup>122,123,124,125,126</sup> and <sup>127</sup> The sequestration of mdm2 results in increased p53 protein levels because mdm2 normally binds to p53 and enhances its proteolytic degradation. This p19<sup>ARF</sup>-mediated increased level of p53 protein results in growth arrest of a cell.

**FIGURE 6-12.** Schematic diagram depicting the cell-cycle checkpoints mediated by the p16<sup>INK4e</sup>/p19<sup>ARF</sup> genetic locus. Mitogenic signals that activate cyclin D/cdk4 to lead to cell proliferation can be blocked by p16<sup>INK4e</sup>. In certain cellular contexts, mitogenic signals that would normally drive cell proliferation can instead activate the p19<sup>ARF</sup> pathway. Activated p19<sup>ARF</sup> indirectly activates p53 by a mechanism that involves mdm2. Activated p53 may lead to cell-cycle arrest or apoptosis as noted in Figure 6-10. In this way, p19<sup>ARF</sup> can act as a checkpoint to “sense” what may be inappropriate oncogenic cell proliferation signals. Of note, the DNA damage response

checkpoint, which also involves p53, is independent of p19<sup>ARF</sup>. (Adapted from ref. 122, with permission.)

The genetic locus coding for these two genes is on chromosome 9p in human cells and is a common area of mutation in human tumors.<sup>128</sup> Intriguingly, oncogene activation is one cellular stimulus that has been shown to activate p19<sup>ARF</sup> and initiate this p53-mediated growth arrest.<sup>129,130</sup> If this pathway were not inactivated during tumor formation, activation of an oncogene would simply cause a p53-mediated growth arrest or apoptosis. Thus, tumor cells can bypass this normal cellular response to oncogene activation by mutating either p19<sup>ARF</sup> or p53 (see Fig. 6-12). Furthermore, since this same locus also codes for a gene product that limits cellular proliferation by inhibiting the RB pathway, deletion of this locus would eliminate two gene products that limit cellular proliferation through two different critical pathways. Thus, it is not at all surprising that this locus is so commonly mutated in human tumors.

### Apoptosis: Another Step in the Cell Cycle That Goes Awry in Tumor Cells?

Apoptosis is a mode of cellular death that is an energy-dependent, programmed event (hence the name *programmed cell death*) that occurs in response to certain stimuli. There are characteristic morphologic (nuclear condensation and fragmentation, cell shrinkage, and relative sparing of the cellular membrane and internal organelles) and biochemical (DNA fragmentation and selected proteolysis) events that occur during apoptotic cell death.<sup>131</sup> In addition, a variety of stimuli, such as irradiation or chemotherapy, viral infection, growth factor or hormone withdrawal, and cytotoxic lymphocyte killing, can initiate this death program. Obviously, some of these stimuli are cell-type specific. Apoptosis is also a critical event in normal development and in normal tissue homeostasis, clearly playing a role, for example, in nervous system development and in lymphocyte selection processes in the immune system.

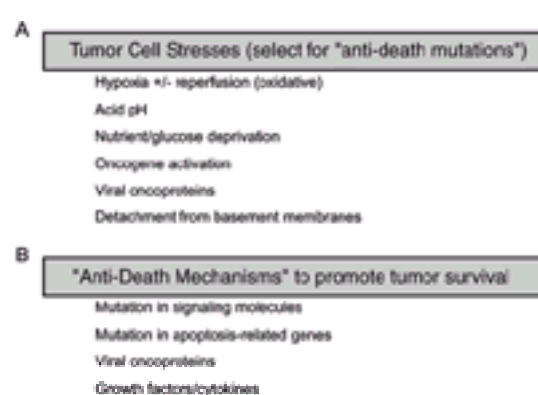

Some of the gene products that control the cell cycle also appear to influence apoptosis tendencies (e.g., c-myc, p53, RB). It has been suggested that apoptosis occurs when *conflicting* cell-cycle signals are simultaneously active in the cell or when survival signals coming from extracellular peptides are blocked. Some models also conceive of apoptosis as an integral part of the cell cycle, with apoptotic death being viewed as a type of permanent exit from the cycle, just as the G<sub>0</sub> quiescent phase is an exit from the cycle. It has also been suggested that apoptotic death is the natural *default* outcome for cycling cells unless a survival factor (hormone or growth factor) is present to keep the cell alive as it progresses through the cycle. Since responses to current antineoplastic therapies (chemotherapy and radiation therapy) are also likely to be affected by the apoptosis tendencies of cells, this process has obvious therapeutic implications.

It appears that a decrease in apoptosis tendencies is a key step in tumor development ( Fig. 6-13). Experimental tumorigenesis systems using DNA tumor virus models and transgenic animal models led to the suggestion that an initial mutation in a cell may occur in a gene that increases cellular proliferation. Examples of such mutations include loss of function of RB or overexpression of c-MYC. However, these genetic changes, which increase proliferation, also appear to lead to increased apoptotic cell death, thus leading to no net increase in absolute cell number in the tumor.<sup>132</sup> However, if one cell in this proliferating (and apoptotic-prone) population then developed a mutation that abrogated the cell death response, then it is easy to envision how this would lead to a significant increase in cell number in the population. Dysfunction of p53 or overexpression of BCL2 are examples of genetic changes that could inhibit the death response initiated by c-MYC overexpression or RB mutation. Subsequent genetic changes in these cells could then contribute to other phenotypic changes associated with tumors, such as invasiveness and metastasis.

**FIGURE 6-13.** Model of multistep tumor progression incorporating current concepts of genetic changes occurring during tumorigenesis. Genetic changes such as loss of RB function or overexpressed c-MYC may lead to increased cell proliferation. However, these changes also lead to increased apoptosis ( *black ovals*) and thus there is no significant net increase in cell number. The viral gene products, E1A from adenovirus, T antigen from SV40, and E7 from human papilloma virus, appear to have similar effects on the cell by virtue of binding to RB. Subsequent genetic changes that decrease apoptosis (such as loss of p19<sup>ARF</sup> or p53 or overexpression of bcl-2) would then lead to increases in total cell number. Viral gene products, such as adenovirus E1b, SV40 large T antigen, and human papilloma virus E6, appear to accomplish this by binding to p53 protein. Additional genetic changes further contribute to the malignant cell phenotype by enhancing local invasiveness and metastasis. Although the order of the genetic events may vary in different settings, the concept that both increased proliferation signals and decreased cell death signals contribute to tumorigenesis probably applies to most tumor types. (Concept adapted from ref. 119, with permission.)

In addition to oncogenic genetic changes providing a selection pressure for loss of apoptotic signals during tumor development, the harsh microenvironment surrounding the tumor mass can similarly favor cellular alterations that oppose death pathways. As the number of cells in a tumor mass grows, significant cellular stresses ensue. For example, the tumor mass is exposed to periods of hypoxia as well as oxidative stress during reperfusion. In addition, suboptimal blood supplies to tumor masses result in periods of time in which the tumor is exposed to acid pH and deprivation of nutrients and glucose. Growth of the tumor mass also results in cellular detachment from normal tissue basement membranes. All of these microenvironmental situations might typically kill the exposed cells. In order for a tumor mass to grow beyond a certain size, it must develop mechanisms to survive in this harsh microenvironment. Similar to the mechanisms a developing tumor uses to survive the oncogenic stresses discussed previously, mutations in death-signaling pathway would allow the developing tumor to survive these microenvironmental stresses. Thus, mutations in survival- signaling molecules or gene products involved the apoptosis machinery, and alterations in growth factor or cytokine exposure favor continued development of a tumor mass (Fig. 6-14).

**FIGURE 6-14.** Mutations involved in tumor progression allow tumor cells to survive harsh microenvironmental stresses. Tumor cell stresses **(A)** would lead to cell death in normal cells. Tumor cells acquire a number of genetic changes **(B)** that allow the malignant cells to survive these harsh conditions. For any given tumor type, the exact nature of these genetic changes may not be known. Little is known about the sequence of these genetic changes during tumor development *in vivo*.

Significant insights have been gained into the molecular steps involved in cell death-signaling pathways. These insights began with the molecular characterization of

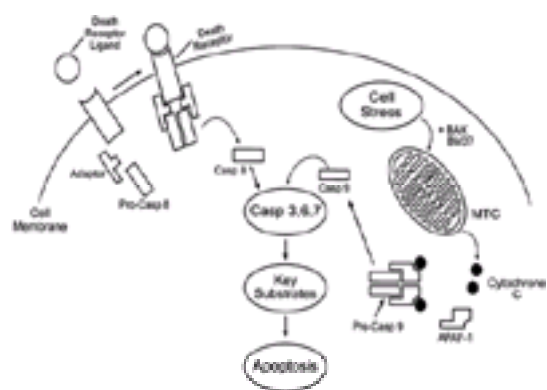

the t(14;18) chromosomal translocation commonly seen in follicular lymphomas resulting in identification of the antiapoptotic gene BCL2.<sup>133</sup> The concept developed in the follicular lymphoma model was that the abnormal lymphoid cells grow initially because of loss of cell death tendencies due to BCL2 overexpression caused by the translocation of the BCL2 gene from chromosome 18 to the actively transcribed immunoglobulin gene on chromosome 14 in B-lymphoid cells. At this point, such lymphomas are rather indolent, but are difficult to cure with chemotherapy. However, at some later stage, they develop other genetic changes and become more aggressive. We now know of a family of related gene products that interact with each other to influence apoptotic tendencies. Korsmeyer and colleagues developed a model in which the bcl-2-like protein, bax, can drive the cell toward apoptosis when it forms complexes with itself<sup>134,135</sup> (Fig. 6-15). When bcl-2 protein is expressed at high levels in cells, it forms complexes with bax, preventing bax homodimerization and inhibiting cell death. Other antiapoptotic proteins with homologies to bcl-2 and bax, such as bcl-x<sub>L</sub> and mcl-1, have also been identified.<sup>136,137</sup> The list of antiapoptotic and proapoptotic gene products continues to grow and it appears that some of this apparent redundancy of proteins results from tissue-specific expression and use of the different proteins in different signaling pathways.

**FIGURE 6-15.** Overexpression of Bcl-2 inhibits apoptotic cell death following many different stimuli. The current model of how Bcl-2 accomplishes this is based on the observation that Bcl-2 protein binds to BAX protein. It has been proposed that BAX protein binds to itself and drives the cell toward apoptosis. Bcl-2 can bind to BAX and prevent BAX homodimerization. A number of different proteins similar to Bcl-2 and BAX have been identified, some of which are proapoptotic (listed as BAX-like) and some of which are antiapoptotic (listed as Bcl-2-like). The use of these different proapoptotic and antiapoptotic proteins may be cell-type specific. [Model based on the work of Korsmeyer and colleagues (ref. 134), with permission.]

Critical details in death-signaling pathways have been elucidated in recent years and incorporate much of what had been known about the bcl-2 family and survival-signaling pathways. One major insight was the identification of a family of specific proteases, now referred to as *caspases*, which are critical for apoptosis signaling.<sup>138</sup> Current models suggest that apoptosis is dependent on a series of highly regulated proteolytic cleavages that result in selected activation or inactivation of certain molecules and eventually result in the highly ordered internal destruction of the cell ( Fig. 6-16). The release of cytochrome C from the mitochondria and association of cytochrome C with the apaf-1 protein and caspase 3, is a critical step in death induced by genotoxic damage, as would be induced by many chemotherapeutic agents.<sup>138,139</sup> Predictably, growth factors, such as interleukin-3, which provide survival signals to cells, appear to act via modulation of one or more steps in these pathways.<sup>140,141</sup> One particularly interesting mechanism along these lines is the interleukin-3-induced phosphorylation of the *pro*apoptotic protein, BAD, which causes the release of the *anti*apoptotic protein, bcl-x<sub>L</sub>, promoting cell survival.<sup>142</sup>

**FIGURE 6-16.** Schematic diagram depicting mechanisms for activation of caspases that lead to apoptosis in mammalian cells. One pathway that can be activated by a variety of cellular stresses (see text for details) involves the release of cytochrome C from mitochondria (MTC). Cytochrome C and apaf-1 activate procaspase 9, which subsequently activates a series of effector caspases (Casp 3, 6, 7), which mediate proteolytic destruction of cellular proteins resulting in apoptosis. A second apoptotic pathway can be activated by extracellular signaling molecules. Receptor activation leads to activation of procaspase 8, followed by activation of effector caspases. This latter pathway may be independent of mitochondrial activities. (Adapted from Green DR. Apoptotic pathways: the roads to ruin. *Cell* 1998;94:695, with permission.)

It is now clear that a group of extracellular molecules can also act as death-inducing signals by interaction with selected cell surface receptors (called *death receptors*) to initiate cellular suicide via activation of a different caspase-dependent pathway, one that may not involve mitochondria (see Fig. 6-16).<sup>135,143</sup> Fas ligand and Fas receptor are examples of an extracellular molecule and death receptor that initiate programmed cell death in this way, and this pathway appears to be particularly important in the regulation of cell death in lymphoid cells. Tumor necrosis factor and the TRAIL family<sup>143</sup> are additional examples of cytokines that act via this type of pathway. As discussed previously, alterations in these death-signaling pathways can contribute to tumor development by keeping the tumor cells alive in the face of genetic changes or microenvironmental stresses that would normally result in cell death. The potential impact of loss of these death-signaling pathways on tumor responses to therapy is obvious.

## CANCER THERAPY

A major limiting factor for cancer cures at this time is the toxicity of chemotherapy and radiation therapy to normal tissues. The doses of current antineoplastic agents that would be required to kill resistant tumors would also lead to patient mortality. The selection pressures for loss of apoptotic pathways during tumor development would only make this selective killing of tumor cells with cytotoxic agents more difficult. The more we understand about the molecular and cellular differences between tumor cells and normal cells, the more likely we are to be able to achieve this selectivity by identifying specific targets within tumor cells.

Since alteration in cell-cycle control is one hallmark difference between normal and cancer cells, it is reasonable to consider cell-cycle targets to achieve this desired specificity. Unfortunately, these same cell-cycle alterations may also contribute to making tumor cells more resistant to cytotoxic therapies. For example, genetic instability is a common feature of tumor cells and presumably contributes to the large number of mutations that occur during tumorigenesis. Such genetic instability, arising from mutations in cell-cycle checkpoint or DNA repair genes, could also give the tumor cell an advantage by creating the capability for it to mutate to find ways to become resistant to therapeutic agents. Two ways to address this are to find ways to limit instability or to find ways to kill the cells quickly so that they do not have time to become resistant. Although it is not clear how one might go about reducing genetic instability, taking advantage of new insights into apoptotic signaling pathways could allow us to more effectively induce rapid apoptosis and achieve this second goal.

It has been suggested that we could take advantage of altered cell-cycle checkpoints in tumor cells to make chemotherapy and radiotherapy given in a particular sequence more specifically toxic for tumor cells.<sup>91</sup> For example, although loss of the G<sub>1</sub> checkpoint in tumor cells by itself does not make tumor cells more sensitive to irradiation, selective combinations of therapies could theoretically selectively kill the tumor cells that continued to progress through the cell cycle after treatment with the first cytotoxic agent while the normal cells that arrested are relatively protected. Another scenario arises from the observations that yeast that are defective in the G<sub>2</sub> checkpoint are more sensitive to irradiation<sup>1</sup> and that abrogation of the G<sub>2</sub> checkpoint in mammalian cells (e.g., by caffeine) makes the cells more sensitive to

DNA-damaging agents. It has been suggested that tumor cells, particularly those tumor cells that have lost the G<sub>1</sub> checkpoint because of mutations in p53, may be particularly sensitive to inhibition of the G<sub>2</sub> checkpoint.<sup>144,145 and 146</sup>

Telomerase provides another potential cell-cycle-related, tumor-specific target. As discussed previously, telomerase activity is expressed in embryonic tissues and is usually turned off in differentiated somatic cells, but appears to be reexpressed in tumor cells, giving them unlimited replication potential.<sup>75</sup> Thus, since telomerase is a relatively tumor-specific gene product and since inhibition of its activity would theoretically lead to eventual cessation of cellular replication, telomerase is an attractive potential novel target for antineoplastic therapies. Potential problems with this as a target are the potential toxicity to stem cells in the gastrointestinal tract or bone marrow and the question of how long it would be necessary to inhibit its activity before the tumor cell stopped growing. It is possible that the latter problem may be circumvented by using telomerase inhibitors in combination with other cytotoxic agents.

Perhaps the most direct way to make tumor cells more sensitive to current therapies is to enhance the apoptosis tendencies of the tumor cells either directly or in conjunction with exposure of the cells to chemotherapy and radiotherapy. It can be argued that the inherent rapid apoptosis tendencies of tumors dictate our observed response rates with current therapies. The tumors in which we have reasonable cure rates (e.g., lymphoid malignancies, germ cell tumors) probably derive from tissues that have greater tendencies to undergo DNA damage-induced apoptosis than the tissues that give rise to relatively resistant tumors (e.g., carcinomas of colon, pancreas, breast). As we continue to elucidate the steps controlling apoptosis responses, then our opportunities to biochemically modulate these responses are enhanced such that a rapid apoptosis response may be initiated on exposure of a resistant carcinoma cell to chemotherapy and radiation therapy. Specificity could also theoretically be achieved by appropriate use of death receptor-ligand interactions or use of cell-type specific survival factors.<sup>147</sup> For example, at least in certain settings, the TRAIL ligand appears to selectively induce a death-signaling pathway in tumor cells.<sup>143,148,149</sup> If this holds up in clinical settings, this particular death-receptor pathway may provide a novel approach to enhance therapeutic index.

Advances have shed much light on the molecular controls of cell-cycle progression and cell death. These insights also suggest specific molecular differences between normal cells and tumor cells that appear to be critical for cellular transformation and provide potential tumor-specific targets for improving antineoplastic therapies. Continued investigations into these molecular processes may eventually provide the answers we need to prevent or better treat malignant processes.

## APOPTOSIS

Multicellular organisms have developed a highly organized and carefully regulated mechanism of cell suicide to craft the development of multiple lineages and to maintain cellular homeostasis. Normal development and morphogenesis proceed by the production of excess cells, which are then removed by a genetically programmed, evolutionarily conserved process. This same program of cell death is used by the organism to remove damaged cells, including virally infected cells.

Programmed cell death may have first been recognized in the developing neuronal system of the toad by Vogt.<sup>1</sup> Kerr and colleagues described cell deaths with distinct ultrastructural features, including plasma membrane blebbing, volume contraction, nuclear condensation, and endonucleolytic cleavage of DNA. They noted that these features were consistent with an active, regulated process and coined the term *apoptosis* from the Greek word used to describe “dropping off” or “falling off” of petals from flowers or leaves from trees.<sup>2,3</sup>

Studies of chromosomal translocations in human lymphoid malignancies yielded the *BCL-2* gene, the first component of the cell death pathway to be identified. The most common chromosomal translocation found in these malignancies is the t(14;18):(q32;q21) harbored by 85% of follicular and 20% of diffuse B-cell lymphomas.<sup>4,5</sup> The breakpoint proved to be the result of aberrant immunoglobulin heavy-chain gene rearrangements,<sup>6,7</sup> and<sup>8</sup> in which *BCL-2* was introduced from chromosome 18.<sup>9</sup> The consequence of this rearrangement is to place *BCL-2* under the transcriptional control of the immunoglobulin (Ig) heavy-chain locus. B cells harboring this translocation express inappropriately elevated levels of BCL-2 protein.<sup>10</sup>

Clues to the biologic consequence of BCL-2 overexpression reside in the natural history of follicular lymphoma.<sup>11</sup> The disease usually follows an indolent course, with symptoms that wax and wane over years. Transformation to a high-grade lymphoma with diffuse mixed or diffuse large cell morphology often occurs within the first decade.<sup>11</sup> When a *BCL-2-Ig* minigene that recapitulated the t(14;18) breakpoint was inserted into the germline of a mouse, follicular hyperplasia resulted (Fig. 7-1). This polyclonal expansion of small resting B cells was principally in G<sub>0</sub>,G<sub>1</sub> phase of the cell cycle.<sup>12,13</sup> Over time, these mice progress to diffuse, large cell immunoblastic lymphoma. Long latency followed by progression to high-grade malignancy is essentially diagnostic for the acquisition of second genetic abnormalities. Indeed, approximately one-half of the high-grade tumors have acquired an additional translocation, placing *c-myc* under the control of the Ig heavy-chain locus, thus combining an inherent survival advantage (*Bcl-2*) with a gene that promotes proliferation (*c-myc*).<sup>14</sup> Further evidence for the potent synergy of such a combination emerged when *Bcl-2* transgenic mice were mated to *myc* transgenic mice, resulting in the rapid appearance of an undifferentiated hematolymphoid leukemia.<sup>15,16</sup> The oncogenic potential of BCL-2 is not restricted to the B-cell lineage; overexpression in T cells results in peripheral T-cell lymphomas.<sup>17,18</sup>

**FIGURE 7-1.** *Bcl-2-Ig* transgenic mice. The *Bcl-2-Ig* minigene recapitulates the t(14;18) chromosomal translocation of follicular B-cell lymphoma. Gain of function *Bcl-2* leads to B-cell expansion and an enlarged white pulp in the transgenic spleen (left) versus control spleen (right). B cells accumulate due to extended cell survival (graph).<sup>12</sup>

Tumorigenesis reflects the accumulation of excess cells, which formally results from increased cell proliferation and decreased cell death.<sup>19,20</sup> The first oncogenes to be discovered were genes involved in signal transduction or regulation of transcription. Gain of function mutations in these genes results in oncogenesis by increased proliferation. A second class of oncogenes was subsequently identified whose normal function is to inhibit growth and proliferation. It is often loss of function mutations in this class of genes that results in tumors. *BCL-2* represents the cardinal member of a third class of oncogenes, which regulate cell death, resulting in resistance to apoptosis that enables the accumulation of additional genetic aberrations.<sup>12,13,14,15</sup> and <sup>16,20</sup>

## GENETICS OF CELL DEATH

A genetic program of developmental cell death emerged from the study of the nematode *Caenorhabditis elegans*. These worms are particularly well suited to the study of cell fates because they are transparent, allowing visualization of individual cells. During the development of the *C. elegans* hermaphrodite, 1090 cells are generated, and 131 of these cells undergo programmed cell death.<sup>21,22</sup> Genes have been identified that reside in a common, core pathway responsible for the regulation of all 131 cell deaths. Moreover, lineage-specific genes that reside in private pathways more upstream are responsible for initiating the cell deaths. Furthermore, two complementary sets of genes have been identified that control the phagocytosis of cell corpses. Functional mammalian counterparts to many of these genes have been identified (Fig. 7-2), indicating that the basic tenets of apoptosis are conserved from nematodes to humans.

**FIGURE 7-2.** The genetic pathway regulating cell death in the nematode *Caenorhabditis elegans* has been well characterized and has been conserved in evolution from worms to mammals. Cell death in the nematode transpires by a mechanism in which death is executed by a single protease (CED-3), whose activity is regulated by a single activator (CED-4) and inhibitor (CED-9).<sup>28</sup> Mammalian counterparts for the *C. elegans* genes are indicated in parentheses.

The *ced-9* (for cell death abnormal) gene confers resistance to cell death. Loss of function mutations of *ced-9* result in massive cell death leading to death of the worm.<sup>23</sup> Conversely, overexpression of *ced-9* inhibits cell death. Thus, *ced-9* is both a structural and functional homologue of *Bcl-2*.<sup>24,25</sup>

Three additional genes required for apoptosis have been identified, *egl-1* (egg-laying abnormal), *ced-3*, and *ced-4*. Loss of function mutations in either *ced-3* or *ced-4* can rescue cells from death.<sup>22</sup> *Egl-1* functions as an upstream, negative regulator of the *BCL-2* homologue *ced-9*.<sup>26</sup> Whereas the killing activity of *ced-4* requires functional *ced-3*, the killing activity of *ced-3* is independent of active *ced-4*.<sup>27</sup> *Ced-4* thus appears to function upstream of *ced-3* in this genetic pathway. An overall genetic pathway consistent with all the observations would be *egl-1* @ *ced-9* @ *ced-4* @ *ced-3*.

*Ced-3* encodes a cysteine protease homologous to the mammalian interleukin 1 beta-converting enzyme (ICE), or caspase 1, required for the proteolytic activation of pro-interleukin-1b.<sup>28,29</sup> and<sup>30</sup> Transient expression of either CED-3 or ICE induces apoptosis in mammalian cells, suggesting that this family of proteases plays a critical role in programmed cell death.<sup>31</sup> The mechanism by which cell death in the nematode transpires is remarkably simple: Death is executed by a protease (CED-3) whose activity is regulated by an activator (CED-4) and an inhibitor (CED-9).<sup>32</sup> Mammalian counterparts for each of the members of the *C. elegans* apoptotic pathway exist (see Fig. 7-2).

## DEATH RECEPTORS

In mammals, the initiation of programmed cell death occurs through interaction of death ligands such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), Fas, or TNF-related apoptosis-inducing ligand (TRAIL), with their respective receptors followed by aggregation of these receptors.<sup>33</sup> Recruitment of adaptor proteins, such as Fas-associated death domain (DD) protein (FADD), TNF receptor-associated DD protein (TRADD), and receptor interacting protein (RIP), to a plasma membrane complex ensues through interactions between yet a third domain, the death domain (DD), present on both the receptor and adaptor proteins.<sup>34,35,36</sup> and<sup>37</sup> Recruitment of the initiator caspase 8 (also called Fas-associated death domain-like interleukin 1 beta-converting enzyme [FLICE]) through interaction of its death effector domain (DED), results in its subsequent activation, evidently by self-proteolytic cleavage ( Fig. 7-3). Caspase recruitment can be inhibited by proteins such as FLICE-inhibitory protein (FLIP) whose DED interacts with and ties up adaptor proteins.<sup>38</sup>

**FIGURE 7-3.** Cell fate after activation of tumor necrosis factor (TNF) family receptors (TNFR) is determined by the balance between cell survival and cell death signals. Signals through Fas-associated death domain (DD) protein (FADD) result in recruitment and activation of the initiator caspase 8 followed by activation of downstream effector caspases, ultimately resulting in cell death. Signals through TNF receptor-associated DD protein (TRADD) result in recruitment of receptor interacting protein (Rip), followed by nuclear factor  $\kappa$ B (NF $\kappa$ B) activation and transcription of genes involved in cell survival. The balance between these two opposing pathways determines the ultimate fate of the cell.

In addition to transducing a death signal through caspase activation, engagement of the TNF- $\alpha$  receptor results in a survival signal through nuclear factor  $\kappa$ B (NF $\kappa$ B).<sup>39,40,41</sup> and<sup>42</sup> An additional survival signal appears to be mediated by TNF-induced activation of stress-activated protein kinase/c-JUN amino-terminal kinase.<sup>43,44</sup> It is the balance between these opposing signals that ultimately determines whether a cell lives or dies ( Fig. 7-4). Accordingly, mice deficient in the RelA subunit of NF $\kappa$ B die between embryonic days 15 and 16 of massive liver apoptosis.<sup>45</sup> Mice deficient in the upstream DD kinase RIP survive this critical stage of development, but die between days 1 and 3 with apoptosis of the thymus and adipose tissue.<sup>46</sup> T-cell death mediated by TNF receptor-2 requires RIP; induction of RIP during T-cell activation promotes a change in TNF receptor-2 signaling from NF $\kappa$ B activation to apoptosis, suggesting a role for this kinase in the switch from survival to apoptosis in some situations.<sup>47</sup>

**FIGURE 7-4.** Model of the mammalian cell death pathway. Left: A major checkpoint in this pathway is the ratio of proapoptotic (BAX) to antiapoptotic (BCL-2) members. Downstream of this checkpoint are two major execution programs: mitochondrial dysfunction and caspase activation. Mitochondrial dysfunction is manifested as altered mitochondrial transmembrane potential ( $\Delta\psi$ ); disturbed mitochondrial physiology, including ROS production; and, at times, mitochondrial swelling. Cytochrome *c* is released from the mitochondrial membrane space to complex with Apaf-1 and activate caspase 9. Caspase activation may occur following a mitochondrial loop with Apaf-1/cytochrome *c* or directly in cells in which caspase 8 activates effector caspase 3. Caspases are activated by two cleavage events between the prodomain and the large subunit, and subsequently between the large and small subunits. The active caspase consists of a complex with two large and two small subunits. These activated caspases cleave death substrates, such as poly (ADP-ribose) polymerase (PARP) and laminin, culminating in cell death. Right:

Activation of a Fas/TNF- $\alpha$ -family cell surface receptor leads to recruitment and activation of caspase 8, which in turn cleaves cytosolic p22 BID. After cleavage, truncated BID (tBID) translocates to the mitochondria, resulting in the release of cytochrome *c*.

Evidence that NF $\kappa$ B plays a role in cellular transformation arises from both human and animal tumors.<sup>48</sup> T-cell-specific expression of the avian retroviral oncogene *v-rel* gives rise to T-cell leukemias in transgenic mice. Direct alterations of the NF $\kappa$ B2 locus have been reported in T-cell lymphomas.

Other death stimuli, including DNA-damaging agents and staurosporine, trigger the release of cytochrome *c* from the mitochondrial intermembrane space, resulting in the formation of a caspase 3 activating complex, termed the *apoptosome*. The requisite members of the apoptosome include cytochrome *c*, deoxyadenosine triphosphate (dATP), Apaf-1 (a mammalian homologue of CED-4), and caspase 9.<sup>49,50</sup> and<sup>51</sup> In the presence of cytochrome *c* and dATP, Apaf-1 oligomerizes together with procaspase 9 via caspase activation and recruitment domains (CARD).<sup>52</sup> Procaspase 9 is subsequently activated by proteolysis and, in turn, activates caspase 3.<sup>53</sup> Activated effector caspases carry out their role in cell death through the proteolytic cleavage of antiapoptotic proteins and repair proteins, as well as through the degradation of cell structures such as the nuclear lamina.<sup>54</sup>

## CASPASES

Caspase 1 is the prototype of a large family of proteases whose members function in inflammation or apoptosis.<sup>54</sup> Caspases are expressed as inactive proenzymes and are activated by proteolytic cleavage after a death stimulus. Members of the caspase family possess a common structural motif consisting of three domains: an amino-terminal domain, a large subunit, and a small subunit. Caspase cleavage consensus sites separate each domain. After cleavage, the large and small subunits associate to form a heterodimer. Crystallographic analyses of both caspase 1 and caspase 3 show association of two heterodimers to form a tetramer. Both the large and small subunits contribute residues important for substrate binding and specificity. The two catalytic sites of the tetramer appear to function independently.<sup>55,56</sup> and<sup>57</sup>

Caspases are cysteine proteases that cleave substrates after an aspartate residue. Substrate specificity of individual caspases is determined by the size of the substrate binding pocket, which dictates the preferred amino acids immediately amino-terminal to this aspartate residue.<sup>55,56,57,58</sup> and<sup>59</sup> In the case of caspase 1, a relatively large pocket is consistent with the preference for bulky, hydrophobic residues, whereas the smaller pocket of caspase 3 is consistent with the preference for less bulky residues such as aspartate.

Caspases function in both initiation of apoptosis in response to proapoptotic signals and in the subsequent effector pathway to disassemble the cell. On this basis, they can be separated into initiator caspases, which link death signals to the cellular death program, and effector caspases, which carry out a coordinated program of proteolysis resulting in the destruction of critical cell structures involved in homeostasis and repair.

Caspase prodomains play a key role in specifically transducing death signals to result in caspase activation. Within these prodomains, two distinct structural domains have been identified that mediate specific protein-protein interactions: DED and CARD. DEDs are found in initiator caspases, such as caspase 8 and caspase 10. These domains mediate caspase targeting to death receptors via interaction with DEDs on adaptor proteins such as FADD/MORT1.<sup>34,60,61,62,63</sup> and<sup>64</sup> Activation of upstream caspases initiates a proteolytic cascade that allows rapid transmission and exponential amplification of a death stimulus. Effector caspases such as caspase 3 are activated, culminating in destruction of the cell by apoptosis. Depending on the death signal and the cell type involved, this process appears to proceed through a pathway of mitochondrial dysfunction and the release of cytochrome *c* or, alternatively, a mitochondrial-independent pathway.<sup>65</sup>

## THE Bcl-2 FAMILY

The Bcl-2 family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway (see Fig. 7-4),<sup>66</sup> providing a pivotal decisional checkpoint in the fate of a cell after a death stimulus. At least two effector pathways exist downstream for the execution of apoptosis, the caspase pathway and mitochondrial dysfunction. Mitochondrial dysfunction manifests as altered mitochondrial transmembrane potential ( $\Delta\psi$ ); release of proteins from the mitochondrial intermembrane space, including cytochrome *c*, that triggers the activation of Apaf-1 and caspases; and the production of reactive oxygen species. Thus, the effector caspases may be activated directly following engagement of a surface death receptor or downstream of a mitochondrial amplification loop.

Both pro- and antiapoptotic family members have been identified (Fig. 7-5). Members of the family possess up to four conserved helical domains, designated *BH1*, *BH2*, *BH3*, and *BH4*.<sup>67,68</sup> and<sup>69</sup> Mutagenesis studies of BCL-2 indicate that the conserved domains are necessary for the interaction with proapoptotic proteins such as BAX and for the inhibition of cell death.<sup>70</sup> The proapoptotic and apoptotic family members may also have independent activities.<sup>71,72</sup> An intact amphipathic helical BH3 domain is required for the proapoptotic proteins BAX or BAK to initiate apoptosis.<sup>73,74</sup> BAX and BAK are more highly conserved prodeath members of the BCL-2 family bearing BH1, BH2, and BH3 domains. A subset of proapoptotic Bcl-2 family members possess sequence homology only within the BH3 domain, further emphasizing the concept that this region forms a critical DD. The recognition that the upstream proapoptotic molecule in *C. elegans*, EGL-1, was also a “BH3 only” protein supports the role of these proteins at the intersection with the core apoptotic pathway.<sup>75</sup>

**FIGURE 7-5.** Summary of antiapoptotic and proapoptotic BCL-2 members. BCL-2 homology regions (BH1 to BH4) are denoted, as is the carboxy-terminal hydrophobic (TM) domain. (From ref. 66, with permission.)

The three-dimensional structures for both an antiapoptotic molecule, BCL-X<sub>L</sub>, and the proapoptotic molecule BID have been determined.<sup>76,77</sup> and<sup>78</sup> The Bcl-X<sub>L</sub> a helical structure includes two central hydrophobic cores sandwiched by two amphipathic helices similar to the membrane translocation domain of the bacterial toxin diphtheria toxin fragment B and the colicins. In fact, electrophysiologic studies have shown that BAX and BCL-2 are capable of forming ion channels in artificial membranes.<sup>79</sup> In their closed, monomeric forms, the helices comprising domains BH1 to BH3 of the full family members are juxtaposed to form a hydrophobic pocket; this pocket receives the hydrophobic face of a BH3 amphipathic helix to form hetero- or homodimers.<sup>80,81</sup>

As predicted from their structure, antiapoptotic molecules are principally integral membrane proteins found in the outer mitochondrial membrane, endoplasmic reticulum, or outer nuclear membrane.<sup>82,83,84</sup> and<sup>85</sup> In contrast, many of the proapoptotic molecules, especially the “BH3 domain only” subset are localized to the cytosol or cytoskeleton and undergo posttranslational modification after a death signal, which allows them to target and integrate into the mitochondrial membrane.<sup>86,87,88</sup> and<sup>89</sup> These modifications in response to death stimuli suggest that these BH3-only molecules are candidates for an upstream link between the BCL-2 checkpoint and proximal signal transduction (Fig. 7-6).

**FIGURE 7-6.** Model of apoptotic and survival signaling pathways involving the BCL-2 members. Left: Activation of tumor necrosis factor (TNF)/Fas cell surface receptor leads to activation of caspase 8. Caspase 8 cleaves cytosolic p22 BID, generating a p15 carboxy-terminal fragment that translocates to the mitochondria, resulting in the release of cytochrome *c*. Released cytochrome *c* activates Apaf-1, which in turn activates a downstream caspase program. Right: A death stimulus interleukin-3 (IL-3) deprivation induces the translocation of BAX to the mitochondria, where it is an integral membrane homo-oligomerized complex. Center: Activation of the insulin-like growth factor (IGF), nerve growth factor (NGF), or interleukin-3 (IL-3) receptors stimulates phosphoinositide 3 kinase (PI3-K) and Akt, resulting in the phosphorylation of BAD at serine 136. Survival factors, such as IL-3, also activate the mitochondrial-based cyclic adenosine monophosphate–dependent protein kinase (PKA) holoenzyme, resulting in the phosphorylation of BAD at serine 112. Phosphorylated BAD is inactive, sequestered to the cytosol by the phosphoserine-binding protein 14-3-3. Dym, mitochondrial transmembrane potential.

In support of this thesis, the BH3-only protein BAD is modified by phosphorylation on two serine residues in the presence of the survival factor interleukin-3 (IL-3).<sup>90</sup> In its phosphorylated form, BAD is inactive, bound, and sequestered by a cytosolic molecule, 14-3-3. On exposure to a death stimulus, such as IL-3 deprivation, BAD is dephosphorylated, resulting in the interaction of the BH3 domain of active BAD with the hydrophobic pocket of BCL-X<sub>L</sub> at the mitochondrial membrane.<sup>91</sup>

Distinct kinases appear to be responsible for the phosphorylation of the two serine sites in BAD. The phosphoinositide 3 kinase pathway regulates the phosphorylation of serine 136 in BAD. AKT, a serine/threonine survival signaling kinase in that pathway, can phosphorylate BAD serine 136.<sup>92,93,94</sup> and<sup>95</sup> AKT can also phosphorylate and inactivate the proapoptotic transcription factor FKHRL1 and caspase 9.<sup>94,95</sup> The phosphorylation and inactivation of serine 112 is mediated at the mitochondrial membrane by cyclic adenosine monophosphate–dependent protein kinase that is tethered to this locale by a mitochondrial-based A kinase anchoring protein (AKAP).<sup>96</sup> Thus, a single proapoptotic molecule BAD has multiple signal transduction pathways that converge to inactivate it. This example indicates how complex the regulation of this pathway is and offers additional steps for therapeutic intervention.

Another BH3-only protein, BID, connects the death signal through TNF- $\alpha$  or Fas to the downstream death effectors. BID exists in the cytoplasm as an inactive 22-kD protein. After TNF- $\alpha$  or Fas signals, BID is cleaved in an unstructured loop by caspase8 to generate an active 15-kD fragment, truncated BID (tBID) which translocates and inserts into the mitochondrial membrane.<sup>97,98,99</sup> and<sup>100</sup> Cleavage eliminates the amino-terminal inhibitory  $\alpha_1$  helix, exposing the hydrophobic face of the BH3 domain as well as two central hydrophobic cores. Once integrated into the mitochondrial membrane, p15 BID results in the release of cytochrome *c*. The presence of BCL-2 or BCL-X<sub>L</sub> ties up tBID, often preventing the release of cytochrome *c*.

The proapoptotic full family members BAX and BAK also demonstrate inactive and active conformations. Inactive BAX exists as a monomer in the cytosol, which translocates to the mitochondrial membrane where it resides as an active homo-oligomerized integral membrane protein. The translocation and oligomerization steps that activate BAX are, interestingly, blocked in cells protected by BCL-2.

## Bcl-2 FAMILY MEMBERS PLAY CRITICAL ROLES IN TISSUE HOMEOSTASIS

The most stringent test for the role of a gene in normal development and homeostasis is an animal in which the gene of interest has been disrupted. Newborn *Bcl-2* knockout mice are viable, but the majority die within a few weeks of birth.<sup>101,102</sup> and<sup>103</sup> The surviving mice develop renal failure due to severe polycystic kidney disease. BCL-2 functions in the normal fetal kidney to maintain cell survival during inductive epithelial-mesenchymal interactions. At 5 to 6 weeks, the animals turn gray because of apoptosis of melanocytes. The hematopoietic system is initially normal, but thymus and spleen subsequently undergo massive involution due to apoptosis, reflecting a failure to maintain homeostasis in both B and T cells. Mice lacking *Bcl-X<sub>L</sub>* are unable to complete normal development, with embryos dying of erythroid and neuronal apoptosis.<sup>104,105</sup> It thus appears that different antiapoptotic family members predominate in a tissue- and developmental-specific manner.

Loss of the proapoptotic gene *Bax* results in hyperplasia of thymocytes and B cells and accumulation of atrophic granulosa cells and excess primordial follicles that fail to undergo apoptosis.<sup>106</sup> The male mice are infertile because of failure of normal postnatal death of spermatogonia. This leads to a markedly disorganized seminiferous tubule and failure to successfully complete meiosis. Increased cell numbers are present in *Bax*-deficient neurons, indicating that cells that normally would have died during embryonic development because of inadequate innervation are saved in the absence of *Bax*.<sup>107</sup>

Mice without BID successfully complete embryonic development and appear grossly normal. However, the mice are resistant to Fas-induced hepatocellular apoptosis, indicating a critical role for a BID-dependent mitochondrial amplification loop in this Fas-signaled death.<sup>108</sup>

## ROLE OF MITOCHONDRIA

The mitochondrial dysfunction that occurs in cell death manifests as an initial hyperpolarization, followed by a loss of Dym; the release of proteins from the mitochondrial intermembrane space, such as cytochrome *c*; and altered mitochondrial physiology, including the production of reactive oxygen species. Prior studies of necrotic death and late stages of apoptotic cell death have noted mitochondrial swelling attributed to the opening of a mitochondrial permeability transition pore that allows the passage of solutes and dissipation of the transmembrane gradient. The localization of antiapoptotic molecules, such as *BCL-2* and *BCI<sub>X<sub>L</sub></sub>*, as well as the translocation of proapoptotic BAX and tBID to the mitochondrial membrane, emphasizes the importance of mitochondrial dysfunction in the action of these molecules. The specific mechanisms by which these proteins elicit their mitochondrial effects is an area of intense interest.

The importance of the mitochondria in the execution of apoptosis varies depending on both cell type and death stimulus. In certain cell types, activation of the TNF/Fas death receptor activates robust quantities of caspase 8 and subsequent effector caspase 3 with no requisite role for mitochondria, whereas other cells such as liver require the mitochondrial amplification loop to die. Other death stimuli, such as growth factor deprivation, may proceed in the absence of caspases and depend heavily on mitochondrial dysfunction.<sup>109,110</sup> and<sup>111</sup>

## CELL PROLIFERATION AND APOPTOSIS

Apoptosis represents a brake on cellular expansion, countering abnormal cell proliferation. Substantial evidence exists for cross-talk between proliferation and apoptosis pathways.<sup>112</sup> The oncoproteins *c-Myc* and adenovirus E1A, both potent inducers of proliferation, also have been shown to possess proapoptotic properties.<sup>113,114,115</sup> and<sup>116</sup> The mitogenic and apoptotic properties of both *c-Myc* and adenovirus E1A are genetically inseparable.<sup>113,117,118</sup> E1A induces proliferation and apoptosis by interacting with either the retinoblastoma protein (Rb), a regulator of cell-cycle progression, or the transcriptional corepressor p300.<sup>119,120,121,122</sup> and<sup>123</sup> *c-Myc* appears to promote apoptosis by multiple pathways.<sup>112</sup>

Rb itself also provides a link between cell proliferation and apoptosis. Rb functions as a cell-cycle checkpoint between G<sub>1</sub> and S phase and mediates its effect through interaction with a family of transcription factors that control the expression of genes required for cell-cycle progression, the E2F proteins.<sup>124,125</sup> and<sup>126</sup> Complexes containing both E2Fs and Rb have been shown to bind to target DNA sequences in a number of promoters and actively repress transcription.<sup>127,128,129</sup> and<sup>130</sup> Entry into S phase induced by ectopic expression of E2F or mutagenesis, which abolishes interaction with Rb, results in increased apoptosis.<sup>131,132</sup> and<sup>133</sup> Mice in which the Rb gene has been knocked out by homologous recombination die at embryonic day 12 to 13 and exhibit both proliferation and apoptosis of liver, central nervous system,

lens, and skeletal muscle.<sup>134,135</sup> E2F-1 knockout mice develop a broad spectrum of tumors, including lymphomas, and display decreased apoptosis in double-positive thymocytes, further establishing the link between cell proliferation, apoptosis, and tumorigenesis.<sup>136,137</sup>

Oncogenes have been shown to sensitize cells to a wide variety of stimuli, including DNA damage, hypoxia, death receptors such as TNF- $\alpha$  and Fas, and growth factor withdrawal.<sup>113,138,139,140,141,142,143</sup> and <sup>144</sup> It appears that the cellular machinery directing cell proliferation and apoptosis is coupled, suggesting that the decision of a cell to undergo apoptosis or proliferation may be determined by the balance between growth and survival signals.<sup>145</sup>

One potential link between these two processes is the p53 tumor suppressor. Loss of p53 has been observed in numerous tumor types, and p53 function is abrogated in a large percentage of tumors.<sup>146,147</sup> p53 expression is induced in response to a variety of cellular stresses, including DNA damage, hypoxia, and oncogene activation, resulting in cell-cycle arrest or apoptosis. Mice deficient for p53 are developmentally normal, but 75% develop spontaneous tumors by 6 months of age.<sup>148</sup> Germline mutation of p53 in humans results in Li-Fraumeni syndrome, and more than 50% of these individuals develop tumors by 30 years of age.<sup>149</sup>

The majority of p53 mutations in human tumors cluster within the DNA-binding domain, suggesting that p53 exerts its tumor suppressor effects through transcriptional regulation of target genes.<sup>150</sup> The mechanism by which p53 exerts its apoptotic effect appears to be multifactorial. p53 is able to induce the expression of *BAX* and *FAS*, as well as another member of the TNF family of death receptors, DR5.<sup>151,152,153</sup> and <sup>154</sup> In addition, p53 inhibits the expression of *BCL-2*, and *BCL-2* can inhibit p53-induced apoptosis in select settings.<sup>155,156,157</sup> and <sup>158</sup> p53 also appears to induce apoptosis by post-translational mechanisms.<sup>159,160</sup>

## POSSIBILITIES FOR THERAPEUTIC INTERVENTION

Given the ability to induce apoptosis in lymphoid cells and many types of tumor cells, the death receptors are attractive targets for therapeutic intervention in cancer. However, infusion of TNF- $\alpha$  causes a lethal inflammatory response resembling septic shock, which results from proinflammatory activation of macrophages and endothelial cells,<sup>161,162</sup> and infusion of agonistic anti-Fas antibody causes lethal hepatic apoptosis. The related death ligand TRAIL (APO2L) appears to possess the ability to induce apoptosis in a wide variety of tumor cell lines. *In vivo* administration of a leucine zipper form of TRAIL in which the molecule is stabilized as a trimer suppresses the growth of a mammary adenocarcinoma cell line in SCID (severe combined immunodeficiency) mice.<sup>163</sup> Normal cells treated *in vitro* with TRAIL showed no decreased viability. Similarly, recombinant TRAIL administered shortly after tumor xenograft injection markedly reduces tumor incidence. In addition, treatment of mice bearing solid tumors resulted in tumor cell apoptosis as well as improved survival. A synergistic effect was obtained with TRAIL and 5-fluorouracil or irinotecan (CPT-11). Encouragingly, intravenous injections of TRAIL into nonhuman primates did not result in toxicity to tissues or organs.

The *BCL-2* gene provides another promising target for therapeutic intervention, particularly in the therapy of low-grade lymphoma in which *BCL-2* overexpression plays an important role.<sup>164</sup> The strategy of antisense oligonucleotide therapy has been used to "silence" *BCL-2* expression. Antisense oligonucleotides are short stretches of DNA, approximately 16 to 20 bases in length. The oligonucleotides are internalized by cells through a saturable endocytosis pathway. On injection into a host, expression of a specific gene can be blocked by hybridization with the target messenger RNA through Watson-Crick base pairing. The result is either degradation of the RNA-DNA complex by RNase H or block in translation of the RNA.

An 18-base-pair antisense oligonucleotide, G3139 (Genta, San Diego, CA), was designed against *Bcl-2* for the treatment of follicular lymphoma.<sup>165</sup> Initial studies in a t(14;18) murine xenograft lymphoma model were encouraging, with absence of disease by polymerase chain reaction in 10 of 12 animals tested. A phase I clinical trial of G3139 has been completed on patients with relapsed B-cell non-Hodgkin's lymphoma with evidence of *BCL-2* overexpression by immunohistochemistry of lymph node biopsy.<sup>166</sup> The main toxicity was reversible thrombocytopenia. Of the 20 evaluable patients (N = 21), one complete response was achieved in a patient with stage IV follicular lymphoma. Two patients had partial responses, eight patients had stable disease, and nine patients progressed. Current phase II studies are under way to investigate the role of G3139 in combination with conventional chemotherapy.

*BCL-2* also has been shown to play a role in solid tumors. In prostate cancer, *Bcl-2* overexpression confers both chemoresistance and resistance to apoptotic cell death after androgen withdrawal.<sup>167,168,169,170,171</sup> and <sup>172</sup> In an androgen-dependent tumor model, *in vitro* treatment of tumor cells with antisense *BCL-2* enhances cytotoxicity of paclitaxel.<sup>167</sup> *In vivo* administration of antisense *BCL-2* oligonucleotides in combination with paclitaxel to animals with established tumors results in inhibition of tumor growth. In addition, treatment in combination with paclitaxel after castration results in a significant delay in tumor recurrence. *BCL-2* is also highly expressed in malignant melanoma.<sup>173,174</sup> In a preclinical xenograft model, *BCL-2* antisense oligonucleotides significantly sensitized the tumor cell response to subsequent dacarbazine.<sup>175</sup> It thus appears that *BCL-2* antisense therapy may have a potential role in combination with other chemotherapeutic drugs as a chemosensitizing agent.

## CONCLUSIONS

Apoptosis is an evolutionarily conserved, highly regulated mechanism for maintaining homeostasis in multicellular organisms. Numerous signals are capable of modulating cell death. After a death stimulus, the signal is propagated and amplified through the activation by proteolytic cleavage of caspases, culminating in the ordered disassembly of the cell. The process may transpire through a mitochondrial-dependent or -independent pathway, depending on the death signal and cell type involved. The *Bcl-2* family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway, providing a pivotal checkpoint in the fate of a cell after a death stimulus. The proapoptotic molecules BID, BAD, and BAX undergo modification and intracellular translocation on receipt of a death stimulus, connecting distinct upstream signal transduction pathways with the common, core apoptotic pathway. The distribution of inactive conformers of the BH3-only members suggests that they may function as sentinels for recognizing cellular damage.<sup>66</sup> BIM would monitor microtubule function, BID would amplify minimal caspase 8 activation, and BAD would patrol for metabolic stress after loss of critical survival factors. This model would explain how seemingly diverse cellular injuries converge on a final common pathway of cell death.

Finally, the cellular pathway to apoptosis appears to communicate with the pathway for cell proliferation.<sup>112</sup> As a result, activation of cell proliferation by oncogenes also results in sensitization to apoptosis. Reciprocally, the expression of antiapoptotic molecules often retards cell-cycle progression.<sup>176</sup> This interconnection provides a means for limiting the threatening expansion of cells with a lesion in either pathway. These observations fit the evidence that defects are required in both proliferation and cell death pathways, as single defects tend to be self-correcting in their net effect on cell number. The molecules mediating apoptotic pathways provide an exciting opportunity for rational design of new therapeutic agents to specifically promote apoptosis of cancer cells.

## INTRODUCTION

Metastasis is the spread of cancer cells from a primary tumor to vital organs and distant sites in the cancer patient's body. Metastatic disease is the hallmark of malignant cancer. The formation of tumor metastasis is the major cause of treatment failure in cancer patients and is a principal contributing factor to cancer morbidity and mortality. Metastatic disease has significant biologic and prognostic impact on cancer diagnosis and treatment.

The formation of metastatic foci is a continuous process that can begin early in the growth of the primary tumor and increases in frequency with tumor duration and tumor burden. Metastases may also disseminate to form new metastatic lesions in other organs (metastases will metastasize). The variation in size, age, dispersed anatomic location, and heterogeneous composition of metastases makes complete eradication of metastatic disease by currently available therapeutic strategies extremely difficult. The patient with metastatic disease succumbs to organ failure secondary to anatomic compromise caused by multiple metastases or to complications associated with systemic therapy directed against the metastatic disease. The design of more effective therapies to treat metastatic cancer requires better understanding of the molecular events and cellular processes that are involved in the process of metastasis formation.

## THE METASTATIC CASCADE

It is well established, from both clinical observations and mechanistic studies, that metastasis formation is an inefficient process. Studies have demonstrated that late events in metastasis formation are largely responsible for the inefficiency of this process. Large numbers of tumor cells and tumor cell clumps are shed into the vascular drainage system of a primary tumor.<sup>1,2</sup> It has been demonstrated experimentally that, after intravenous injection of highly metastatic tumor cells, only approximately 0.01% of these cells form tumor foci. The number of circulating tumor cells and tumor emboli correlate with the size and age of the primary tumor (i.e., larger tumors shed more tumor cells and emboli). However, the number of circulating tumor cells does not correlate with the clinical outcome of metastases.

The inefficiency of tumor cells in completing the metastatic cascade is the result of the fact that successful formation of metastatic foci consists of several highly complex and interdependent steps. Each step is rate limiting in that failure to complete any of these events completely disrupts metastasis formation. The steps involved in metastasis formation are thought to be similar in all tumors and are characterized as follows ( [Fig. 8-1](#)):

**FIGURE 8-1.** The pathogenesis of cancer metastasis. To produce metastases, tumor cells must detach from the primary tumor, invade the extracellular membrane and enter the circulation, survive in the circulation to arrest in the capillary bed, adhere to subendothelial basement membrane, gain entrance into the organ parenchyma, respond to paracrine growth factors, proliferate and induce angiogenesis, and evade host defenses. The pathogenesis of metastasis is therefore complex and consists of multiple sequential, selective, and interdependent steps whose outcome depends on the interaction of tumor cells with homeostatic factors.

1. **Oncogenesis (tumorigenesis).** After the initial neoplastic transformation, the tumor cells undergo progressive proliferation that is accompanied by further genetic changes and development of a heterogeneous tumor cell population with varying degrees of metastatic potential. The initial growth of the primary tumor is supported by the surrounding tissue microenvironment, which eventually becomes rate limiting for further growth.
2. **Angiogenic switch.** As the tumor grows and central tumor cells become hypoxic, the tumor initiates recruitment of its own blood supply. This process is called the *angiogenic switch* and involves the secretion of various angiogenic factors and the removal or suppression of angiogenesis inhibitors. Vasculature of the tumor is also associated with a dramatic increase in the metastatic potential of these tumors. Studies demonstrate that some tumors and metastases arising in vascularized tissues may first co-opt existing vasculature before initiating recruitment of new vessels.
3. **Clonal dominance and invasive phenotype.** Continued genetic alterations in the tumor cell population results in selection of tumor cell clones with distinct growth advantage and acquisition of an invasive phenotype. Invasive tumor cells down-regulate cell-cell adhesion, alter their attachment to the extracellular matrix (ECM) by changing integrin expression profiles, and proteolytically alter the matrix. Collectively, these changes result in enhanced cell motility and the ability of these invasive cells to separate from the primary tumor mass. These cells can detach from the primary tumor and create defects in the ECM that define tissue boundaries, such as basement membranes, thus accomplishing stromal invasion. Furthermore, the poorly formed tumor vasculature that forms in response to the angiogenic switch in phenotype of the primary tumor, as well as thin walled lymphatic channels in the surrounding stroma, are readily penetrated by these invasive tumor cells and offer ready conduits to the systemic circulation. Endothelial cells responding to the angiogenic stimulus produced by the primary tumor also express an invasive phenotype.
4. **Survival in the circulation.** Once the tumor cells and tumor cell clumps (emboli) have reached the vascular or lymphatic compartments, they must survive a variety of hemodynamic and immunologic challenges. Little is known about how these factors may impact on the inefficiency of the metastatic process in human cancers.
5. **Tumor cell arrest.** After survival in the circulation, tumor cells must arrest in distant organs or lymph nodes. This arrest may occur by size trapping on the inflow side of the microcirculation, or by adherence of tumor cells through specific interactions with capillary or lymphatic endothelial cells, or by binding to exposed basement membrane.
6. **Extravasation and growth at the secondary site.** In most cases, arrested tumor cells extravasate before proliferating. Studies suggest that extravasation of tumor cells is not dependent on protease activity and is independent of metastatic potential. After exiting the vascular or lymphatic compartments, metastatic tumor cells may proliferate in response to paracrine growth factors or become dormant. After extravasation, tumor cells migrate to a local environment more favorable

for their continued growth. Findings using *in vivo* videomicroscopy demonstrate that the poor growth of tumor cells after extravasation from the circulation is a major factor contributing to the inefficiency of the metastatic process.

7. Angiogenesis in metastatic foci. Finally, continued growth of the metastatic foci is also dependent on angiogenesis. The development of this neovascular network at the metastatic site enhances the metastatic potential of these cells just as it does for the primary tumor.
8. Evasion of immune response. Metastatic foci of tumor cells must evade eradication by immune responses that may be either nonspecific or targeted directly against the tumor cells.

As might be expected from the highly complex nature of metastasis formation, no single gene product is responsible for metastasis formation. Successful completion of many of the steps of the metastatic cascade is the result of both the acquisition of positive effectors as well as the loss of negative regulators. Unrestrained growth is not sufficient to result in tumor invasion and metastasis. Tumor invasion is not a passive process secondary to tumor growth, and it may require additional genetic changes other than those associated with the tumorigenic phenotype. Tumorigenicity and metastatic competence have some overlapping features but are clearly under separate genetic control. Research on tumor cells has identified gene products that can facilitate completion of each of the steps outlined above. These are the molecular effectors of tumor invasion and metastasis. In many cases, research also has identified gene products that function to block successful completion of each of the steps in the metastatic cascade. The idea that there is loss of negative effectors, as well as positive phenotypic changes, associated with malignant progression and metastasis formation is now well established. In this chapter, some of the steps in the metastatic cascade are examined with the aim of identifying both the molecular mechanisms and the effector and suppressor genes that may become a target for new and effective cancer therapies. Immune modulation of cancer is discussed elsewhere (see [Chapter 4](#)), as is the process of tumor-associated angiogenesis (see [Chapter 9](#)). In addition, the angiogenic response at the metastatic foci is conceptually the same as in the primary tumor; therefore, the discussion of these points is limited here.

## ONCOGENESIS: METASTASIS AND TUMORIGENESIS ARE UNDER SEPARATE GENETIC CONTROL

Many tumors progress through distinct stages that can be identified by histopathologic examination. Pathologists use the identification of these distinct phases to diagnose and classify tumors into different prognostic categories (e.g., normal tissue, hyperplasia, dysplasia, carcinoma *in situ*, and frankly invasive carcinoma). Genetic analysis of these different stages of tumor progression resulted in the multistep theory of tumorigenesis, which involves activation of oncogenes, inactivation of tumor suppressor genes, and identification of a host of tumor-associated molecules (cancer markers). The progressive alteration in cellular oncogenes and inactivation of tumor suppressor genes that results in uncontrolled growth and loss of contact-dependent cell growth has been well documented in many tumor types, and it is the subject of separate chapters in this text (see [Chapter 1](#) and [Chapter 2](#)). It also has been demonstrated that transfection of certain of these oncogenes into the correct recipient cell can result in acquisition of invasive and metastatic phenotype. Thorgeirsson et al.<sup>3</sup> were first to demonstrate that transfection of activated Ras oncogene sequences into fetal mouse fibroblasts result in acquisition of a metastatic phenotype when these cells are implanted in the nude mouse. This finding has been confirmed in both fibroblast and epithelial cells of human and rodent origin when transfected with Ras. Similar findings, but with lower efficiency, have been observed with several other oncogenes (Mos, Raf, Src, Fes, and Fms) when transfected into an *appropriate* recipient cell.

At first, these results might suggest that the metastatic phenotype might arise from genetic alterations associated with the acquisition of tumorigenicity. However, cells can be transformed by oncogene transfection, but not all cells acquire a metastatic phenotype after oncogene transfection.<sup>4</sup> In addition, the adenovirus 2E1A gene was shown to suppress Ras induction of the metastatic phenotype without alteration in tumorigenicity or inhibition of soft agar colony formation.<sup>5</sup> These findings demonstrate that a clear separation exists between the genetic changes that drive tumorigenicity and the metastatic phenotype. These findings can be explained by the fact that invasion and metastasis require activation of additional effector genes or suppression of local inhibitors over and above those required for uncontrolled growth alone. The failure to induce metastatic competence by Ras in some cell systems is explained by a deficiency or suppression of these effector molecules in these cell types. These metastasis effector genes or gene products may be downstream of Ras or totally independent pathways that are involved in cell attachment or regulation of protease activity. In studies in which Ras effectively confers a metastatic phenotype, the metastasis effector genes are activated and suppressor genes are inactivated before Ras transfection, and the addition of Ras oncogene allows completion of the metastatic cascade. This finding is demonstrated by the observation that Ras plus E1A reverses the metastatic potential and metalloproteinase expression observed in rat embryo cell lines.<sup>5,6</sup> Candidate effector genes include those associated with cellular adhesion to ECM components, as well as proteases, motility factors, angiogenic factors, and growth regulation. Candidate suppressor genes would include genes associated with enhanced cell-cell attachment; phosphatase activities that regulate focal adhesion assembly; angiogenesis inhibitors; protease inhibitors; and factors that suppress cell migration, invasion, and growth.

## ANGIOGENESIS: BALANCE OF POSITIVE AND NEGATIVE EFFECTORS

Classic studies by Folkman and colleagues in the 1970s demonstrated that continued growth of tumors requires persistent new blood vessel growth and that inhibition of this angiogenic response results in tumor dormancy.<sup>7,8</sup> These studies suggested that tumor cells release soluble factors that induce the angiogenic response (i.e., angiogenic factors). This process is now referred to as the *angiogenic switch*—that is, the switch from a nonangiogenic to an angiogenic phenotype.<sup>9</sup>

It has been experimentally demonstrated that shedding of malignant cells into the venous drainage is commensurate with the initiation of a tumor angiogenic response and is quantitatively related to the surface area of new tumor vessel.<sup>10</sup> This process may be facilitated by the immature nature of newly formed tumor vessels. Weidner and colleagues have reported the correlation of angiogenic response with the frequency of metastasis, disease recurrence, and reduced survival in a number of different human tumors.<sup>11,12 and 13</sup>

Some reports challenge the presumption that most tumors and metastases originate as small, avascular tumor cell clumps that must recruit new vessels for continued growth. Studies find that tumors arising or metastasizing into vascularized tissues may initially co-opt existing blood vessels.<sup>14</sup> Subsequently, there is regression of the co-opted vessels and increased production of angiogenic factors by the tumor cells that recruit a neoangiogenic response.

Researchers have begun to identify angiogenesis inhibitors that either must be modified or removed during the tumor-induced angiogenic response. Examples of these inhibitors include platelet factor-4, interferon- $\alpha$ , thrombospondin, and protease inhibitors [tissue inhibitors of metalloproteinases (TIMPs)]. The list of inhibitors of angiogenesis continues to grow with the identification of pigment epithelium-derived factor.<sup>15</sup> Inhibitors of angiogenesis can work at many levels by blocking endothelial cell growth, cell attachment, or migration.

A novel direction in angiogenesis inhibitors is the identification of cryptic inhibitors that are revealed by proteolytic modification of ECM components. This finding suggests a class of angiogenesis inhibitors that are contained within other proteins that are not antiangiogenic and must undergo proteolytic processing to uncover the antiangiogenic activity. Examples of these types of inhibitors include a 29-kD fragment of fibronectin<sup>9</sup>; the 16-kD fragment of prolactin; angiostatin released from plasminogen<sup>16,17</sup>; and endostatin, a C-terminal fragment of collagen XVIII.<sup>18</sup> The newest member of this group is the cleaved conformation of the serpin antithrombin.<sup>19</sup> Thus, local regulation of angiogenesis can be achieved by proteolytic release of cryptic angiogenesis inhibitors.

In a study by Bergers et al.,<sup>20</sup> the RIP1-Tag2 model of pancreatic islet  $\beta$ -cell tumors has been useful in examining the effects of angiogenesis inhibitors on multistage carcinogenesis in mice. The findings of this study demonstrate that antiangiogenic drugs can be targeted to selective stages of cancer progression and that combination of agents with different mechanisms of action should be used at different stages of tumor development.

Tumor angiogenesis is the result of a tightly regulated process and a delicate balance of both pro- and antiangiogenic factors. The process of endothelial cell invasion and formation of new blood vessels has many functional similarities to the process of tumor cell invasion.<sup>21</sup> Understanding the mechanisms of cell invasion may allow identification of new strategies to disrupt the invasive process. In addition to therapeutic use of antiangiogenic agents, it should be possible to target molecules that are involved in the process of cellular invasion that is required for both angiogenesis and tumor metastasis.

## TUMOR HETEROGENEITY AND CLONAL DOMINANCE

It is now well recognized that most neoplasms consist of several tumor cell populations that vary widely in several important biologic characteristics. These characteristics include growth rates, karyotype, production of growth factors and stimulators of angiogenesis, hormone production, receptor content, and susceptibility to damage by cytotoxic agents, immune response, and hypoxia. Fidler et al.<sup>22,23 and 24</sup> first demonstrated the concept of heterogeneity of primary neoplasms in 1977. This concept is important because it suggested that not all tumor cells in the primary tumor population share the same propensity to form metastases and that formation of metastatic foci selects for an aggressive subpopulation of tumor cells out of the primary tumor. It was logical to assume that the size of the aggressive subpopulation in the primary tumor would reflect the propensity of that tumor to metastasize. This assumption would be of prognostic significance if a clinical assay of the primary tumor were able to detect and determine the presence of the highly aggressive subpopulation. However, evidence of a significant difference between the

average metastatic propensity of cells comprising a primary tumor compared with those from an established metastasis was not forthcoming. This discrepancy was examined experimentally by Kerbel et al.<sup>25,26</sup> and <sup>27</sup> by using genetic markers to tag different subpopulations in the primary tumor. This work demonstrated that the metastatic subpopulation dominates the primary tumor mass early in its development. This dominance arises secondary to a selective growth advantage in the metastatic cells responding to local growth factors. Thus, the measurement of the average level of a molecular marker associated with metastatic propensity in the primary tumor reflects the likelihood of that tumor to form metastases. This finding has subsequently been confirmed in clinical studies by demonstration that the average level of a specific marker or oncogene measured within the primary tumor can be correlated with clinical evidence of metastasis or recurrence.

## DEFINING THE INVASIVE PHENOTYPE

During the transition from benign to invasive carcinoma, extensive changes occur in the quantity, organization, and distribution of subepithelial basement membrane. The hallmark of invasive carcinoma is disruption of the epithelial basement membrane and the presence of cancer cells in the stromal compartment.<sup>21,28</sup> Benign proliferative disorders, such as fibrocystic disease, sclerosing adenosis, intraductal hyperplasia, intraductal papilloma, and fibroadenoma, are all characterized by disorganization of the normal epithelial architecture. But no matter how extensive this disorganization may become, these benign lesions are always characterized by a continuous basement membrane that separates the neoplastic epithelium from the stroma.<sup>21,28</sup>

In contrast, invasive carcinoma is characterized by a loss of basement membrane around the invasive tumor cells in the stroma. Once the basement membrane barrier is compromised, it is impossible to determine the quantity or location of tumor cells that may have escaped from the primary tumor. Thus, local invasion is paramount to malignant conversion.

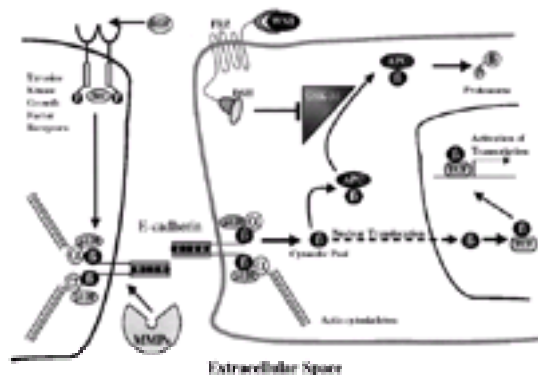

The ability to cross basement membrane barriers is not unique to malignant carcinoma cells. During an inflammatory response, nonneoplastic immune cells regularly cross the subendothelial basement membranes, as do endothelial cells during the angiogenic response. Trophoblasts invade the endometrial stroma and blood vessels to establish contact with the maternal circulation during development of the hemochorial placenta. However, these normal cell types respond to additional signals that result in differentiation and subsequent loss of their invasive phenotype. Indeed, both normal and tumor cell invasion share functional similarities. In tumor cell invasion, however, it is the lack of response to negative signals or regulators and the continued invasion with ongoing tumor cell growth that is unique to cancer metastasis.<sup>21,28</sup>

Tumor cell interaction with the basement membrane is defined as the critical event of tumor invasion that signals the initiation of the metastatic cascade.<sup>21,28</sup> Basement membranes are composed of a dense meshwork of type IV collagen, laminin, and heparin sulfate proteoglycans that is interspersed with entactin and other minor components. Basement membranes do not contain pores that would allow passive tumor cell migration. Early studies on defining the invasive phenotype on malignant tumor cells focused on the interaction of tumor cells with the epithelial basement membrane. These studies defined the three-step hypothesis of tumor cell invasion: tumor cell attachment to the basement membrane, creation of proteolytic defects in the basement membrane, and migration of tumor cells through these defects.<sup>21,28</sup> It is now recognized that these three steps describe tumor cell interaction with all types of ECM and not just basement membrane. Furthermore, nonneoplastic invasive cells, such as trophoblasts, endothelial cells, and inflammatory cells, all use mechanisms for invasion that are functionally similar to tumor cells. The difference between these normal invasive processes and the pathologic nature of tumor cell invasion is therefore one of regulation. An understanding of the factors that control cellular processes essential to the invasive phenotype should allow identification of novel targets for therapeutic intervention to prevent and treat both angiogenesis and metastasis formation.

## CELL-CELL ADHESION SUPPRESSES OR FACILITATES METASTASIS FORMATION

The initial events in cellular invasion are changes in cell adhesion. These changes consist of alteration in both cell-cell adhesion and interactions with the ECM. A variety of cell surface receptors that mediate these interactions have been characterized, including the cadherins, integrins, immunoglobulin superfamily, and CD44. Tumor cells must decrease cell and matrix adhesive interactions to escape from the primary tumor. At later stages in the metastatic cascade, however, tumor cells may need to increase adhesive interactions with cells and ECM, such as during arrest and extravasation at a distant site. The apparent contribution of each class of cell adhesion molecules to invasive behavior will in some way be dependent on the tumor cell population and model system used to study these interactions. We review the contribution of changes in cell-cell adhesion to tumor progression before considering alterations in association with the ECM.

The majority of human cancers arise in epithelial cells. Several types of junctional structures, such as desmosomes, tight junctions, and adherens-type junctions tightly interconnect normal epithelial cells. The formation and maintenance of these contacts require  $\text{Ca}^{2+}$ -dependent homophilic interactions mediated by the cell-adhesion molecules known as *cadherins* (Fig. 8-2). Cadherins are a superfamily of single-pass transmembrane glycoproteins that mediate  $\text{Ca}^{2+}$ -dependent cell-cell adhesion. The cadherin superfamily now consists of five subfamilies: the classic type I and type II cadherins, desmosomal cadherins, protocadherins, and cadherin-related proteins.<sup>29,30</sup> The classic cadherin, epithelial cadherin (or E-cadherin), mediates homotypic cell adhesion in epithelial cells. E-cadherin is a transmembrane glycoprotein that has five extracellular homologous domains (ectodomains), a single membrane-spanning region, and a cytosolic domain. E-cadherin is physically anchored to the actin cytoskeleton by cytoplasmic proteins termed *catenins*.  $\beta$ -Catenin is also a major component of the WNT signaling pathway.

**FIGURE 8-2.** Disruption of cell-cell adhesion concomitant with tumor progression. E-cadherin is a homotypic cell adhesion molecule containing five homologous, extracellular domains (ectodomains) that bind divalent calcium ions. Calcium binding promotes homophilic cell-cell E-cadherin complexes found in such structures as desmosomes, tight junctions, and adherens-type junctions. The cytoplasmic tail of E-cadherin involved in cell-cell adhesion interacts with  $\beta$ -catenin,  $\alpha$ -catenin, and  $\text{p120}^{\text{CAS}}$  ( $\text{p120}$ ). Loss of E-cadherin function, by germline mutation, promoter hypermethylation, or destruction of the ectodomains by matrix metalloproteinase (MMP) activity, results in an increase in free cytosolic  $\beta$ -catenin levels. Increased cytoplasmic  $\beta$ -catenin can be directed to the proteasome complex by glycogen-synthetase kinase 3b (GSK3b) phosphorylation and subsequent interaction with the adenomatous polyposis coli (APC) gene product. The frizzled (FRZ)-dishevelled (DSH) pathway for WNT signaling can down-regulate the activity of GSK3b. Activation of the WNT signaling pathway or loss of APC function facilitate the increase in cytosolic  $\beta$ -catenin levels, which are associated with loss of E-cadherin function, or mutations of the  $\beta$ -catenin gene, which result in reduced association with E-cadherin cytoplasmic domain. Translocation of  $\beta$ -catenin to the nucleus results in gene expression associated with cell transformation and tumor growth (i.e., c-Myc, cyclin D1). It is noteworthy that this cascade of cellular transformation can be initiated by expression of an extracellular protease that culminates in enhanced chromosomal instability.<sup>35</sup> EGF, epidermal growth factor; P, phosphorylated amino acid residue(s); TCF, tissue coding factor.

Any disruption of the intracellular E-cadherin–catenin complex results in loss of cell adhesion. This would include changes in E-cadherin expression or function, as well as genes other than E-cadherin that are required for complex formation and function. Abundant evidence indicates that E-cadherin function is frequently lost during progression of many human cancers, including those arising in the breast, prostate, esophagus, stomach, colon, skin, kidney, lung, and liver.<sup>31,32</sup> This loss of E-cadherin function arises via several different mechanisms. In familial gastric carcinomas, germline mutations in the E-cadherin gene predispose individuals to develop malignant cancer. Mutations in  $\beta$ -catenin are found in many primary tumors, including prostatic cancer, melanoma, and gastric and colon cancer. Another mechanism disrupting E-cadherin function during tumor progression is hypermethylation of the E-cadherin promoter, resulting in decreased gene expression. This has been found to be a major mechanism in papillary thyroid cancer in that 83% of cases of this disease demonstrated hypermethylation of the E-cadherin promoter.<sup>33</sup> Yet another mechanism to alter E-cadherin function is proteolytic modification. Lochter et al.<sup>34</sup> have reported that E-cadherin function can be disrupted by degradation of E-cadherin's extracellular domains by stromelysin-1, a member of the matrix metalloproteinase (MMP) family that has been closely linked with tumor progression.

Constitutive expression of active stromelysin in mammary epithelial cells results in cleavage of E-cadherin and progressive phenotypic changes *in vitro*, including loss of catenins from cell-cell contacts, down-regulation of cytokeratins, and up-regulation of vimentin and MMP-9. These changes result in a stable epithelial to mesenchymal transition of cellular phenotype. *In vivo* stromelysin expression promotes mammary carcinogenesis that includes stereotyped genomic changes distinct from those seen in other mouse breast cancer models.<sup>35</sup> It has been reported that loss of H-cadherin expression occurs during the progression of breast cancer,<sup>36</sup> but little is known about the function of other cadherin family members during tumor progression. In summary, a decrease in cell-cell adhesion is associated with malignant conversion. Forced expression of E-cadherin in tumor cell lines results in reversion from an invasive to a benign tumor cell phenotype.<sup>31,32</sup>

In normal cells, b-catenin is sequestered in the intracellular adhesion complex with the cytoplasmic domain of E-cadherin, a-catenin, g-catenin, and p120<sup>CAS</sup> (Crk-associated substrate). Loss of cell-cell adhesion results in disruption of the adhesion complex and free b-catenin. Free b-catenin is bound by the adenomatous polyposis coli (APC) gene product and is rapidly phosphorylated by glycogen-synthetase kinase 3b (GSK3b). Phosphorylated b-catenin is subsequently degraded in the ubiquitin proteasome pathway. In many colon cancer cells, the tumor suppressor gene APC is nonfunctional. This lack of function can lead to accumulation of high levels of cytoplasmic b-catenin that can subsequently be translocated to the nucleus. The WNT-1 protooncogene-initiated signaling pathway, which includes the frizzled (FRZ) and disheveled (DSH) gene products, can block activity of GSK3b, which can also result in accumulation of b-catenin. In the nucleus, free nonphosphorylated b-catenin can bind to members of the TCF (tissue-coding factor)/LEF-1 (lymphoid enhancer-binding factor 1) family of transcription factors. It has been demonstrated that, after inactivation of APC function, the increase in available b-catenin enters the nucleus, complexes with transcription factor Tcf-4, and up-regulates c-Myc expression.<sup>37</sup> It also has been shown that b-catenin activates transcription from the cyclin D1 promoter and contributes to neoplastic transformation by causing accumulation of cyclin D1.<sup>38</sup> These findings link changes in cell-cell adhesion with intracellular signaling, oncogene expression, and tumor cell growth. Thus, loss of cadherin-mediated cell-cell adhesion is an important event that has many far-reaching consequences for acquisition of the invasive phenotype and tumor progression.

Other types of cell-cell adhesive interactions can actually facilitate metastasis formation. These may be particularly important during tumor cell arrest and extravasation. These molecules include members of the immunoglobulin superfamily, such as nerve cell adhesion molecule and vascular cell adhesion molecule-1.<sup>39,40,41,42 and 43</sup> The immunoglobulin superfamily has a wide variety of members involved in cellular immunity and signal transduction, as well as cell adhesion. Members of the superfamily share the immunoglobulin homology unit that consists of 70 to 110 amino acid residues organized into seven to nine b-sheet structures. The diversity of superfamily members precludes generalization about their role in tumor cell invasion and metastasis. However, the role of one family member seems straightforward. Vascular cell adhesion molecule-1 is an endothelial cell, cytokine-inducible, counter-receptor for VLA-4 (very late antigen-4) integrin, also known as  $\alpha_4\beta_1$  integrin receptor. The role of integrin receptors is discussed separately (see [Role of Integrins in Tumor Invasion](#), later in this chapter). Normally, VLA-4 is expressed on leukocytes and functions in mediating leukocyte attachment to endothelial cells. VLA-4 is also found on tumor cells in malignant melanoma<sup>44</sup> and metastatic sarcoma but not in adenocarcinomas.<sup>45</sup> It is thought that expression of VLA-4 may facilitate interaction of circulating tumor cells with endothelium before tumor cell extravasation. This was demonstrated by intravenous injection of human melanoma cells into nude mice pretreated with VLA-4-inducing cytokines, which resulted in an enhanced number of lung metastases formed compared with no cytokine pretreatment of the mice.<sup>46</sup> Cell-cell adhesive interactions can either suppress or facilitate metastasis formation. Either role is dependent on the specific context and molecular mechanisms of cell-cell interaction.

## CELL-EXTRACELLULAR MATRIX INTERACTIONS IN TUMOR PROGRESSION

As already discussed, the interaction of the tumor cell with the ECM, in particular the basement membrane, defines the invasive phenotype, and tumor invasion is paramount to metastasis. It is now recognized that the ECM exerts a profound influence on cell behavior and that cells direct the assembly and disassembly of the matrix. This concept is known as *dynamic reciprocity* and also applies to the interaction of malignant tumor cells with the ECM. During the process of metastasis formation, malignant tumor cells must interact with a variety of different types of ECM. These types include the subepithelial basement membrane of the tissue of origin, stromal elements of the tissue of origin, subendothelial basement membranes during extravasation, and the stromal and basement membranes of the organ(s) at the site of metastasis growth. Attachment of nonneoplastic cells to the ECM is prerequisite for cell survival. A fundamental difference for neoplastic cells is the loss of anchorage requirement for cell survival and growth. The anchorage-independent growth of tumor cells may result from an uncoupling of cell survival signals transduced from the ECM by attachment, coupled with activation of cell-cycle progression that is associated with neoplastic transformation. Tumor cell interactions with the ECM have profound implications for both cell-cycle regulation and migration.

### ROLE OF CD44 IN TUMOR INVASION

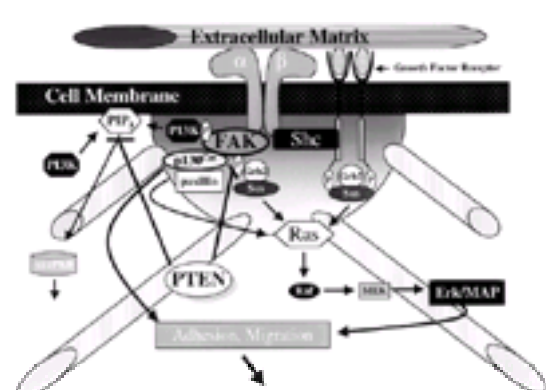

CD44 is a transmembrane glycoprotein with a large ectodomain and single cytoplasmic domain. CD44 is involved in cell adhesion to hyaluronan (HA). The gene encoding CD44 is on the short arm of human chromosome 11<sup>47</sup> and contains both constant and variable exons.<sup>48</sup> As a result of this gene structure, a number of differentially spliced isoforms of CD44 can be generated. The isoform containing no variant exon sequences is referred to as *standard CD44*. A total of nine variant regions (v2 to v10) can encode protein sequences. Alternatively spliced messenger RNA variants of CD44 (CD44v) can contain one or more variant coding regions. More than 30 different splice variants have been detected by polymerase chain reaction analysis.<sup>49</sup> In addition to these variants, cell type-specific differences in glycosylation of the core protein also exist. The pattern of glycosylation and presence of variant exons influence the ability of CD44 to function in HA binding.<sup>50</sup>

Several lines of evidence suggest that CD44 expression plays a role in metastasis formation. Clinical correlation studies demonstrate that a variety of different types of cancer that express high cell surface levels of CD44 have a poorer clinical outcome when compared with tumors that have low CD44 surface expression.<sup>51,52 and 53</sup> Forced expression of CD44v4 to v7 confers metastatic ability to a nonmetastasizing rat pancreatic carcinoma cell line.<sup>54</sup> Metastasis formation could be blocked using antivariant antibodies.<sup>55</sup> However, the exact role of CD44v in metastasis formation remains elusive.

In some tumors, CD44-associated increases in tumor growth and metastatic potential correlate with CD44-mediated cell attachment to HA.<sup>56,57 and 58</sup> CD44 also functions in HA uptake and degradation that is also correlated with tumor cell behavior.<sup>56,59,60</sup> It also has been demonstrated that CD44 aggregation on the cell surface creates a binding site for the active MMP-9.<sup>61</sup> It is postulated that bound MMP-9 may liberate ECM-bound HA and facilitates tumor cell HA uptake and degradation. These findings link cell adhesion and ECM turnover. In addition, they suggest that CD44 may function at different stages of tumor cell invasion and metastasis and that the specific CD44 role may depend on the specific stage of metastasis formation that is examined.

### ROLE OF INTEGRINS IN TUMOR INVASION

Integrins are heterodimeric transmembrane proteins that are formed by the noncovalent association of  $\alpha$  and  $\beta$  subunits.<sup>61,62,63 and 64</sup> Considerable redundancy within cell-ECM interaction mediated by integrins exist, because most integrins bind to several individual matrix proteins, and ECM components, such as laminin, fibronectin, vitronectin, and collagens, bind to several different integrin receptors. This fact suggests that integrins are capable of providing the cell with detailed information about the surrounding ECM environment, which is then integrated at the cellular level to generate a cellular response ( [Fig. 8-3](#)). It is now well established that integrins can signal across the cell membrane in both directions.<sup>65,66 and 67</sup> Binding of ECM ligands to integrins is known to initiate signal transduction pathways that can result in cell proliferation, differentiation, migration, or cell death (apoptosis, anoikis). This is referred to as *outside-in signaling*. It is also known that intracellular events can modulate the binding activity of integrins for their ligands in the ECM, which is referred to as *inside-out signaling*. Both integrin clustering and ligand occupancy are crucial for the initiation of intracellular integrin-mediated signal pathways.<sup>68</sup>

**FIGURE 8-3.** Role of integrins in tumor cell invasion and metastasis: integration of kinase and phosphatase activities. Binding of extracellular matrix components to

integrin receptors initiates an intracellular signaling cascade that results in formation of a focal adhesion complex consisting of cytoskeletal and signal transduction molecules. Ligand binding to the integrin receptor results in integrin clustering and association of signal transduction molecules. Integrin receptor clustering induces autophosphorylation of focal adhesion kinase (FAK) on tyrosine 397. Subsequently, a Src homology 2 (SH2)-containing (Shc) adapter protein of the Src kinase family that binds to specific phosphotyrosine residues (Y397) on FAK is recruited to the integrin-FAK complex. Recruitment of additional proteins, such as  $\alpha$ -actinin, talin, and paxillin, to this complex connects the focal adhesion complex to the filamentous actin cytoskeleton. Interaction of Shc with FAK results in additional sites of phosphorylation on the FAK molecule and subsequent recruitment of additional SH2 adapter proteins, such as Grb2 and the nucleotide exchange factor Sos. These interactions lead to activation of the mitogen activated protein (MAP) pathway, which stimulates tumor cell growth, adhesion, and migration. Similarly, receptors for growth factors can transiently associate with the focal adhesion complex to synergistically activate the MAP kinase pathway. FAK activation also acts upstream of the Akt/protein kinase B (PKB) signaling pathway, which promotes cell survival. Association of the p85 subunit of phosphatidylinositol-3 kinase (PI3K) with tyrosine 397 in FAK mediates this effect. The rapid elevation of the phosphatidylinositol(3,4,5)triphosphate ( $PIP_3$ ) lipid product of PI3K activity stimulates the Akt/PKB pathway, leading to enhanced cell survival. Crk-associated substrate (p130<sup>CAS</sup>) is another SH2- and SH3-containing signal transduction that associates with FAK on integrin binding to the extracellular matrix. Interaction of p130<sup>CAS</sup> with FAK is mediated by a proline-rich region on FAK (residues 712–178) that interacts with the SH3 domain of p130<sup>CAS</sup>. Activation of p130<sup>CAS</sup> promotes cell migration and invasion that is associated with enhanced metastatic behavior. The tumor suppressor gene PTEN inhibits cell adhesion, migration, and invasion. This inhibition is mediated by direct PTEN dephosphorylation of FAK and Shc, leading to negative regulation of the p130<sup>CAS</sup> pathway, which affects cell attachment, migration, and invasion. Down-regulation of the MAP kinase pathway by PTEN dephosphorylation of FAK and Shc negatively affects cell growth in addition to attachment and migration. PTEN is also known to directly dephosphorylate  $PIP_3$  and negatively regulate the downstream Akt/PKB cell survival pathway. PTEN may also disrupt this pathway indirectly by dephosphorylation of FAK, which alters P13K activation. Thus, integrin-mediated regulation of cell growth, adhesion, migration, and invasion is a complex network of signal transduction cascades that have both positive (kinase) and negative (phosphatase) regulatory elements. EGF, epidermal growth factor; Erk, extracellular signal-regulated kinase; MEK, MAP kinase or ERK kinase; P, phosphorylated amino acid residual(s).

Integrin-mediated signal transduction involves both direct activation of signaling pathways and collaborative signaling (also referred to as *cooperative signaling*), in which integrins modulate signaling events initiated through receptor tyrosine kinases.<sup>67,69</sup> The *cis* association of integrins with other receptors on the same cell surface results in formation of multireceptor complexes. There is little evidence that these multireceptor complexes signal through exclusive, integrin-specific pathways, but instead they cooperate with the other receptors to influence a variety of signaling pathways. Direct integrin signaling starts after engagement of the integrin with their ECM ligands, lateral clustering of the integrin receptors, and interaction of the integrin cytoplasmic domain to form complexes with proteins that link to the cytoskeleton. This results in organization of cell structures known as *focal adhesions*.

Autophosphorylation of the focal adhesion kinase (FAK) was among the first integrin-mediated signaling events to be identified. This autophosphorylation event on tyrosine 397 results in recruitment of Src-family protein kinases that in turn results in phosphorylation of additional tyrosine residues on FAK. Phosphorylation of FAK can result in activation of the extracellular signal-regulated kinase (ERK)/mitogen-activated protein (MAP) kinase pathway. Activation of the MAP kinase pathway has been linked to induction of cell migration.<sup>70</sup> The activation of MAP kinase can be mediated by Grb-2 recruitment to FAK that then binds Sos, a guanine nucleotide exchange factor for Ras.<sup>67,71</sup> Alternatively, activation of the MAP kinase pathway can result from FAK phosphorylation of paxillin and the Crk-associated substrate (p130<sup>CAS</sup>) that leads to binding of link proteins, such as Nck.<sup>72</sup> In addition, phosphorylation of FAK at tyrosine 397 creates a binding site for the regulatory subunit of phosphoinositol-3 kinase and triggers activation of this signal pathway.<sup>73</sup>

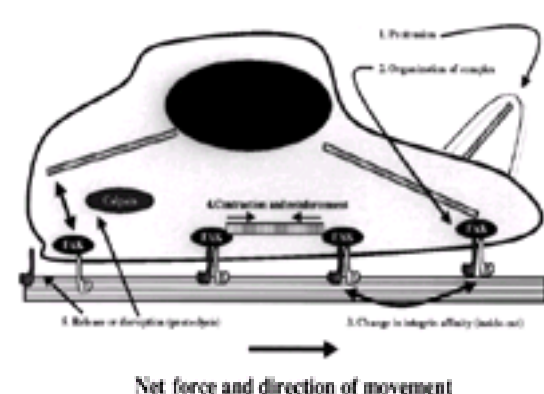

The knowledge that FAK is tyrosine phosphorylated on integrin activation suggests that focal adhesion-associated protein tyrosine phosphatases (PTP) could modulate FAK function. Several PTPs that interact with components of the focal adhesion complex have been identified. These are PTP-a and PTP-PEST [protein tyrosine phosphatase rich in proline (P), glutamic acid (E), serine (S), and threonine (T)], which negatively regulate Src and paxillin, respectively.<sup>74,75</sup> It has been shown that, in PTP-PEST-deficient cells, a defect in cell motility correlates with an increase in the size and number of focal adhesions.<sup>76</sup> This defect appears to be due in part to the constitutive increase in tyrosine phosphorylation of paxillin, as well as p130<sup>CAS</sup> and FAK.

A PTP that interacts directly with FAK is referred to as *PTEN*.<sup>77</sup> PTEN was identified as a tumor suppressor gene on human chromosome 10q23, which is frequently mutated or deleted in a wide variety of human cancers, including gliomas and prostate, breast, lung, bladder, endometrial, kidney, and oropharyngeal cancers.<sup>71</sup> The gene encodes both a phosphatase domain and also has extensive sequence homology to the cytoskeletal protein tensin. PTEN functions as a dual-specificity phosphatase in that not only is it a PTP but it also dephosphorylates the lipid phosphoinositol(3,4,5)triphosphate ( $PIP_3$ ). The current view is that both phosphatase activities function as tumor suppressor activities. The lipid phosphatase activity regulates levels of  $PIP_3$ , which in turn regulates activation of the protein kinase B pathway that is protective against programmed cell death (apoptosis, anoikis). As a PTP, PTEN regulates the phosphorylation status of FAK and Shc that in turn regulate cell adhesion, migration, cytoskeletal organization, and MAP kinase activation. To summarize, loss of PTEN function results in alterations in integrin-mediated signaling via FAK and  $PIP_3$  pathways, which results in achievement of an invasive phenotype.<sup>71</sup> The protein kinase activity just described functions to promote cell invasion. This process is countered by the PTP activities, which act as tumor suppressors.

The roles of specific integrins in tumor progression and metastasis formation are dichotomous. The decreased expression of some integrins is associated with cellular transformation and tumorigenesis. These include  $\alpha_5\beta_1$  and  $\alpha_2\beta_1$  integrins. HT29 colon carcinoma cells lacking  $\alpha_5\beta_1$  expression are either significantly less tumorigenic or completely nontumorigenic when forced to express  $\alpha_5$ .<sup>78</sup> Loss of  $\alpha_2\beta_1$  expression in breast epithelial cells correlates with the transformed phenotype, and reexpression of this integrin abrogates the malignant phenotype.<sup>79</sup> On the other hand, expression of some integrins directly correlates with tumorigenicity and tumor progression. For example, the  $\alpha_v\beta_3$  integrin is expressed in metastatic melanoma but not in benign melanocytic lesions.<sup>80,81</sup> Antibodies against  $\alpha_v$  integrins blocked growth of human melanoma xenografts in nude mice.<sup>82</sup> Integrin  $\alpha_6$  expression is increased in oropharyngeal and bladder cancers and in lung tumors.<sup>46,83,84,85,86</sup> and <sup>87</sup> Tumor progression is associated with expression of  $\alpha_3\beta_1$  in 82% of tumors. The molecular events associated with enhanced integrin expression and tumor progression are not well defined. Clearly, in nontransformed cells, integrins are implicated in growth regulation. But tumor cell growth is anchorage-independent. This observation suggests that the role of integrins in tumor invasion and metastasis may only be secondarily related to growth control. Integrins are also directly involved in cell migration.

## CELLULAR MIGRATION: NEW INSIGHTS

Cell migration requires transmission of propulsive force from the ECM to the cytoskeleton of the migrating tumor or endothelial cell ( Fig. 8-4). Repetitive assembly of cytoskeletal elements to form membrane ruffles, lamellipodia, filopodia, and pseudopodia accomplishes cell movement.<sup>88,89</sup> Lamellipodia are broad, flat, sheet-like structures in comparison to filopodia, which are thin, cylindrical projections. Cell movement begins with protrusion of a filopod or lamellipod. These are formed by polymerization of actin to form elongated central filaments in the filopod and a broader cross-weave mesh in the lamellipod.<sup>90</sup> At the leading edge of the protruding structures, integrins concentrate in specific regions, and after ligation with ECM, ligands form focal adhesions. These focal adhesions are anchored to the actin filaments.

**FIGURE 8-4.** Cellular migration. Cell migration requires transmission of force from the extracellular matrix to the cytoskeleton. This is accomplished in distinct steps, several of which are illustrated. First, there is protrusion of a cellular projection (filopodia or lamellipodia), which is mediated by actin polymerization. The second step

involves organization of the focal adhesion complex and connection with the actin cytoskeleton. This is accomplished via mechanisms described in Figure 8-3. Evidence suggests that if the integrin component of these complexes is not activated, these complexes are continually recycled across the cell surface without cell movement. Step 3 entails engagement of the integrin with the extracellular matrix, which is mediated by a change in integrin affinity. Traction force is generated and transmitted by the contraction and reinforcement of the actin cytoskeleton. The final step in cell locomotion is the release or disruption of the focal adhesion complex at the trailing edge of the migrating cell. Step 5 is accomplished by release of components of the integrin complex or via proteolytic disruption of focal adhesion kinase connections with the filamentous actin cytoskeleton.

Microinjection studies have shown that integrin association with the Rho family of guanosine triphosphate (GTP)ases is critical for organization and assembly of the actin cytoskeleton. It has been demonstrated that a hierarchical cascade exists among these GTPases that controls formation of specific cytoskeletal structures. Cdc42 and Rac control formation of filopodia and lamellipodia, respectively, whereas Rho controls stress fiber formation and focal adhesions.<sup>91</sup>

The integrin connection to the ECM provides adhesive traction, and contraction of the actin filaments results in forward propulsion of the cell body. As the cell moves, new projections occur at the leading edge and are anchored with new focal adhesions. As the cell moves forward, the focal adhesions appear to move in a retrograde fashion on the cell surface. This apparent movement of the focal adhesions has been observed using fluorescent-tagged beads coated with integrin substrates or antiintegrin antibodies.<sup>92,93</sup> and <sup>94</sup> These coated beads can also be used to actually measure the integrin-cytoskeletal traction forces generated, which has led to the demonstration that the strength of the integrin-cytoskeletal interaction can be modulated by the rigidity of the extracellular substrate. When cells are on a rigid substrate, more restraining force is exerted to prevent movement of the focal adhesion. Cells can detect this change in the substrate, and they respond by increasing the force generated by cytoskeletal linkage to the focal adhesion so that the cell pulls harder. This is referred to as *reinforcement of the integrin-cytoskeletal attachments*. Data suggest that Src kinases may be selectively involved in regulating this reinforcement.<sup>94</sup> Researchers have shown that beads binding to the fibronectin receptor in fibroblast containing either wild-type or Src-deficient cells show similar reinforcement of the fibronectin-receptor-actin cytoskeletal linkage. In contrast, when they use vitronectin, there is little reinforcement of the vitronectin receptor in wild-type Src-expressing cells, but a strong reinforcement in the Src-deficient fibroblasts. These authors also show selective association of kinase-defective Src-green fluorescent protein fusion with the  $\alpha_5$  integrin subunit of the vitronectin receptor, but not with the fibronectin receptor. Possible interpretations of these results are that either Src is normally a selective inhibitor of reinforcement of force generation through the vitronectin receptor or that Src promotes the turnover of links between cytoskeletal and integrin components of the focal adhesion complex.

Investigators have used a  $\beta_1$  integrin-green fluorescent protein chimera to follow focal adhesion cycling over the cell surface.<sup>95</sup> These experiments demonstrate that, in stationary cells, focal adhesions were highly motile and moved in a linear fashion to the cell center. In motile cells, the focal adhesions remained stationary and only moved at the trailing edge of the cell. These authors postulate a cellular "clutch-like mechanism" in which alteration in integrin affinity is seen in response to migratory stimulus. Regulation of integrin-ligand interactions by inside-out signaling helps determine the nature of cellular responses to the ECM, such as whether a cell becomes migratory or remains stationary.<sup>96</sup>

The last step in integrin-mediated cell migration is the release of the ECM integrin-cytoskeletal attachments at the trailing edge of the cell.<sup>88</sup> Two mechanisms have been identified in this detachment. The first involves the release of the integrins from the cell surface such that it is left on the substratum. Integrin release from the cell membrane has been observed in fibroblast migration<sup>97</sup> and by tumor cell lines *in vitro*.<sup>98</sup> A second mechanism that mediates release of the trailing edge of the cell is destabilization of cytoskeletal linkages intracellularly by either proteolytic activity or phosphatase activity. Calpain is a  $Ca^{2+}$ -dependent protease that localizes to focal adhesions and regulates retraction in Chinese hamster ovary cells migrating on fibronectin by destabilizing cytoskeletal linkages.<sup>99</sup>

Cell motility is a critical component of the invasive phenotype. Understanding the molecular mechanisms that confer tumor cell motility should allow identification of novel targets for disrupting this process and preventing tumor dissemination. Tumor cell motility can be correlated with metastatic behavior. When parameters such as pseudopod extension, membrane ruffling, or vectorial translation are measured, a quantitative increase in highly invasive and metastatic tumor cells is seen when compared with nonmetastatic counterparts. A variety of stimuli have been shown to stimulate tumor cell motility *in vitro*, including host-derived factors, growth factors, and tumor-secreted factors that function in an autocrine fashion to stimulate tumor cell motility. Autocrine motility factor is a 60-kD glycoprotein produced by human melanoma cells that stimulates tumor cell migration. Autocrine motility factor has been identified as neuroleukin/phosphohexose isomerase.<sup>100,101</sup> Autotaxin (ATX) is a 125-kD glycoprotein that elicits chemotactic and chemokinetic responses at picomolar to nanomolar concentrations in human melanoma cells. ATX contains a peptide sequence identified as the catalytic site in type I alkaline phosphodiesterases (PDEs), and it possesses 5-nucleotide PDE [EC 3.1.4.1 (Enzyme Commission designation for this enzymatic activity)] activity.<sup>102,103</sup> and <sup>104</sup> ATX binds adenosine triphosphate (ATP) and is phosphorylated only on threonine. Thr210 at the PDE active site of ATX is required for phosphorylation, 5-nucleotide PDE, and motility-stimulating activities. ATX also has adenosine-5-triphosphatase (ATPase) and ATP pyrophosphatase activities. ATX catalyzes the hydrolysis of GTP to guanosine diphosphate and guanosine monophosphate, of either adenosine monophosphate or inorganic pyrophosphate to inorganic phosphate, and the hydrolysis of nicotinamide adenine dinucleotide to adenosine monophosphate, and each of these substrates can serve as a phosphate donor in the phosphorylation of ATX. ATX possesses no detectable protein kinase activity toward histone, myelin basic protein, or casein. These results have led to the proposal that ATX is capable of at least two alternative reaction mechanisms—threonine (T-type) ATPase and 5-nucleotide PDE/ATP pyrophosphatase—with a common site (Thr210) for the formation of covalently bound reaction intermediates, threonine phosphate and threonine adenylate, respectively.<sup>103</sup>

## PROTEASES IN TUMOR CELL INVASION

As has been noted, matrix proteolysis has been recognized as a key part of the mechanism of tumor cell invasion. Tumor cells must be able to move through connective tissue barriers, such as the basement membrane, to spread from their site of origin. Although a variety of proteases have been implicated in this process, the family of proteases that has received the most attention has been the matrixins or MMPs. Matrixins and their specific inhibitors, the TIMPs, play important roles in normal physiology, because the ECM is a dynamic matrix of structural proteins, growth factors, and latent enzymes that is constantly being remodeled. Approximately 20 matrixins and four TIMPs have been characterized in humans and other animals.<sup>105,106</sup> The matrixins share a common domain structure (Fig. 8-5), although not all domains are represented in all family members. All of the enzymes have a signal peptide sequence; a propeptide domain (prodomain); a catalytic domain, which includes a highly conserved binding site for the catalytic zinc ion; and a hemopexin-like domain. Two family members, MMP-2 and MMP-9, have a gelatin binding domain containing three fibronectin type II repeats inserted into the catalytic domain just on the amino side of the active site sequence. Five family members have a carboxy-terminal transmembrane domain after the hemopexin domain. This subgroup is also known as the *membrane-type MMPs*. They reside on the cell surface, in contrast to the other family members, which are all secreted as proenzymes into the extracellular milieu. The TIMPs also share a high level of homology, including 12 absolutely conserved cysteine residues that are all involved in intramolecular disulfide bonds. TIMPs are divided into two domains by the disulfide-bonding pattern. An amino-terminal domain contains the inhibitory site, and a carboxy-terminal domain has other binding interactions. Because most of the MMP enzymes are secreted in their proenzyme forms, activation is a key regulatory step. Many of the matrixins are activated by an initial protease cleavage within the prodomain by another matrixin or by a serine protease, such as plasmin or urokinase-type plasminogen activator. This cleavage destabilizes the bond between a conserved prodomain cysteine sulfhydryl group and the catalytic zinc in the active site. The bond breaks and the prodomain is released, which frees the active site for catalysis. Unlike the other family members, which are typically activated outside the cell, MMP-13 and the membrane-type MMP subgroup are activated intracellularly by a furin-dependent cleavage of a conserved RXKR sequence that lies between the prodomain and the catalytic domain. The activation mechanisms have been the subject of a review by Murphy et al.<sup>107</sup>

**FIGURE 8-5.** Simplified schematic domain structure of the matrixin family members. Most matrixins have the same basic domain structure, consisting of signal, pro, catalytic, hinge, and hemopexin-like domains. Matrix metalloproteinase 7 (MMP-7) lacks the hemopexin-like domain, and the gelatinases and membrane-type (MT) matrixins have additional domains. The arrow indicates the location of the furin RXKR cleavage site of MMP-11 and the MT matrixins. The length of each segment is roughly proportional to the number of amino acids that comprise the domain.

An early indication of the importance of matrixins in tumor biology was the characterization in 1980 of a MMP secreted from a melanoma cell line that was able to degrade basement membrane collagen.<sup>108,109</sup> This finding was followed by numerous studies showing that secretion of matrixins enhanced tumor cell invasion in experimental model systems and that inhibition of protease activity by TIMPs or by synthetic metalloproteinase inhibitors impeded invasion. For example, the invasion of HT-1080 fibrosarcoma cells through Matrigel (a reconstituted basement membrane) is enhanced by addition of activated MMP-2 and inhibited by the addition of TIMP-2 or by zinc chelators.<sup>110</sup> *In vitro* evidence has been supported by the results of *in vivo* experiments using transfected cell lines. For example, when MYU3L bladder carcinoma cells are transfected with *mmp-2*, they have enhanced metastatic potential, whereas transfecting the highly metastatic LMC19 cell line with *timp-2* reduces its metastatic potential.<sup>111,112</sup> Mice genetically engineered to overexpress MMP-3 in breast epithelial cells develop spontaneous breast carcinomas, possibly through the effects of MMP-3 on the E-cadherin/b-catenin system.<sup>35</sup>

Although these experiments and many others like them have demonstrated the key role of matrixin-initiated degradation in tumor invasion and metastasis, the role of these enzymes in this process is more complicated than an “degradation equals invasion” paradigm would suggest. Uninhibited matrix degradation would lead to complete dissolution of matrix proteins and would prevent tumor cells from being able to form attachments to each other or to matrix proteins, which is a necessary part of the tumor invasion mechanism. Thus, there is an implied balance between active proteases and inhibitors that results in an optimal invasive phenotype. As a demonstration of this principle, when A2058 melanoma cells are transfected with either sense or antisense *timp-2*, the invasive potential is decreased. Increasing TIMP-2 expression in this cell line enhances cell attachment and decreases motility, whereas decreasing expression decreases both cell attachment and motility. Thus, although protease action in tumor cell invasion is abnormal, it cannot be totally unregulated.

Matrixins have been shown to have effects other than removal of structural barriers to invasion. As noted above, some matrixins act on other proteins to reveal hidden activity. MMP-2 specifically degrades the g2 chain of laminin-5, a structural protein in basement membrane, to reveal a site on the a3 chain that has chemotactic properties.<sup>113</sup> The physiologic role of this fragment may be to act as a wound-related chemoattractant; in tumors, however, this peptide may attract tumor cells to breaks in the basement membrane. In an analogous situation, MMPs have been shown to degrade plasminogen into angiostatin, the angiogenesis inhibitor.<sup>114,115</sup>

Research has focused on the interaction between cell surface adhesion molecules and the matrixin family. One obvious interaction is the simple degradation of cell surface adhesion molecules. For example, MMP-3 degrades E-cadherin on mammary epithelial cells, inducing an increased expression of vimentin and decreased expression of keratin.<sup>34</sup> The cell-matrix adhesion molecule CD44 is also cleaved by matrixins, permitting detachment from the matrix.<sup>116</sup> Decreased cell-cell or cell-matrix adhesion can be a proinvasive phenotype. However, beyond mere degradation of adhesion molecules, cells may control the scope of degradative activity by binding the soluble matrixins with cell surface adhesion molecules, thus limiting degradation to a zone in the immediate vicinity of the cell. On endothelial cells, the integrin  $\alpha_v\beta_3$  binds MMP-2 through the matrixin's hemopexin domain in response to angiogenic stimuli.<sup>117,118</sup> Similarly, CD44 has been shown to bind MMP-9 to the surface of breast carcinoma and melanoma cells.<sup>6c</sup> Interestingly, stimulation of melanoma cells by antibodies to CD44 increased expression of MMP-2,<sup>119</sup> suggesting that binding of matrixins to cell surface receptors might not only provide a mechanism for localizing protease activity but also may serve as an autocrine-stimulating loop mechanism for increased expression of matrixins.

## INTRAVASATION, EXTRAVASATION, AND ORTHOTOPIC EFFECT

The mechanisms of tumor cell intravasation have not been investigated as intensively as the other events in the metastatic cascade. This is due in part to the lack of suitable model systems. A clear role for protease activity in tumor cell intravasation has been demonstrated using the chick chorioallantoic membrane system.<sup>120</sup> In this model, human tumor cells are placed directly onto a chorioallantoic membrane in which the epithelium and basement membrane have been disrupted, allowing tumor cells direct access to the underlying connective tissue that is highly vascularized. Tumor cell intravasation is then quantitated by using polymerase chain reaction amplification of human-specific Alu genomic DNA sequences of tumor cells present in the chorioallantoic membrane on the other side of the chick embryo from the initial tumor cell inoculation. These experiments demonstrate that MMPs, as well as urokinase-type plasminogen activator and the urokinase-type plasminogen activator receptor, are involved in tumor cell intravasation.

Researchers<sup>121,122</sup> have used intravital videomicroscopy to study the events and mechanisms involved in tumor cell extravasation from the circulation. The results of these studies have profoundly changed our thinking about the metastatic process. It appears that a large number (80%) of circulating tumor cells remain viable in the circulation and extravasate up to 3 days after their introduction into the circulation. Surprisingly, both metastatic and nonmetastatic cells extravasate, and this process is not protease-dependent. However, only a small subset of cells (1 in 40) grow to form micrometastases, and even fewer (1 in 100) continue to grow, forming macroscopic tumors. Almost 40% of injected tumor cells remained as dormant solitary cancer cells. These findings suggest that the control of postextravasation growth of individual cancer cells is a dominant effect in metastatic inefficiency. More recent data suggest that the local environment of the target organ may profoundly influence the growth potential of extravasated tumor cells. The importance of tissue microenvironment (host) on growth of the primary tumor is well known and is referred to as *orthotopic effect*.<sup>123</sup>

Xenografts of human metastatic tumor cells in nude or SCID (severe combined immunodeficiency) mice infrequently recapitulate the behavior of the parent tumor to show a spontaneously metastatic phenotype. When injected intravenously, however, many of these same human tumor cells are capable of experimental metastasis formation in what are known as *lung colonization assays*. In pioneering experiments,<sup>124,125 and 126</sup> it has been demonstrated that this effect is due in part to important tumor-host interactions that are not usually provided by models using subcutaneous injection of tumor xenografts. Using orthotopic implantation of tumor xenografts, these investigators have demonstrated that the host microenvironment has a profound influence on a number of tumor cell parameters,<sup>127</sup> including tumor growth, invasive behavior,<sup>126</sup> response to chemotherapeutic agents,<sup>128,129</sup> growth factor and cytokine production,<sup>130,131</sup> and protease profiles for both urokinase and metalloproteinases.<sup>132,133 and 134</sup> An important host contribution to tumor progression is the frequent association of MMP production by stimulated stromal fibroblasts adjacent to invading tumor cells.<sup>135</sup>

During the 1990s, tremendous progress has been made in understanding the process of tumor cell invasion and metastasis formation, which is being revealed as a complex cascade of both promoting agents and suppressors. Loss of function (suppressor inactivation) may occur not only in the tumor cell but also in the host. Such tumor cell-host interactions are complex and difficult to examine in a controlled fashion. However, understanding these complexities is the future of research on cancer metastasis and tumor dissemination. The goal of this research will be the development of new strategies for eradication of established metastases and prevention of new metastatic growth.

## INTRODUCTION

One crucial step for the continuous growth of tumors and the development of metastasis is the induction of vasculature (i.e., angiogenesis).<sup>1,2</sup> A tumor mass that is less than 0.5 mm in diameter can receive oxygen and nutrients by diffusion, but any increase in tumor mass beyond 0.5 mm requires the proliferation and morphogenesis of vascular endothelial cells.<sup>2</sup> The process of angiogenesis consists of multiple, sequential, and interdependent steps. It begins with local degradation of the basement membrane surrounding capillaries, which is followed by invasion of the surrounding stroma by the underlying endothelial cells in the direction of the angiogenic stimulus. Endothelial cell migration is accompanied by the proliferation of endothelial cells and their organization into three-dimensional structures that join with other similar structures to form a network of new blood vessels (Fig. 9-1).<sup>4</sup>

**FIGURE 9-1.** The angiogenic process. The process of angiogenesis is a series of linked and sequential steps that ultimately lead to the development of a neovascular blood supply to the tumor mass. Different steps in the angiogenic process may be occurring in different parts of the tumor at the same time. Tumor cells or host cells (infiltrating immune cells or adjacent normal tissue) secrete angiogenic growth factors, which then bind to specific receptors on endothelial cells. This ligand-receptor interaction leads to endothelial cell proliferation, migration, invasion and, eventually, capillary tube formation. Factors also affect endothelial cell survival under adverse conditions that occur in tumors. The proangiogenic process is balanced by the activity of antiangiogenic molecules that are necessary for homeostatic processes. When the activity of the proangiogenic molecules exceeds the activity of the antiangiogenic molecules, new blood vessel formation occurs. Proangiogenic factors may be constitutively expressed, but their expression may be increased by certain stimuli, such as hypoxia, low pH, cytokines, growth factors, tumor size, activated oncogenes, signal transduction pathways, or loss of tumor suppressor gene function.

## NEOPLASTIC ANGIOGENESIS: THE BALANCE OF PROANGIOGENIC AND ANTIANGIOGENIC MOLECULES

The onset of angiogenesis involves an alteration in the balance between proangiogenic and antiangiogenic molecules.<sup>1,5</sup> These molecules may mediate multiple steps in the process of angiogenesis and also may affect the function of diverse cell types not involved in angiogenesis. A more refined definition of an angiogenic factor is a factor that selectively alters the characteristics of endothelial cells and associated perivascular structures (i.e., pericytes, vascular smooth muscle cells) but does not affect the function of other cell types. [Table 9-1](#) lists most of the proangiogenic and antiangiogenic factors that have been well characterized to date.

Factor	Source	Effect	Reference
Angiogenic factors			
Angiogenic factor 1	Endothelial cells	Stimulates endothelial cell proliferation and migration	1

**TABLE 9-1.** Proangiogenic Growth Factors

Vascular endothelial growth factor–vascular permeability factor (VEGF/VPF) was initially detected as a factor secreted by tumor cells into tissue culture medium or ascites fluid *in vivo*.<sup>6</sup> The factor was identified as a heparin-binding protein of molecular weight 34 to 42 kD and was termed VPF. It was later demonstrated that VPF also stimulated endothelial cell division.<sup>7</sup> Independently, several groups isolated a secreted protein that had selective mitogenic activity for cultured endothelial cells, which they called VEGF.<sup>8,9</sup> On the basis of amino acid and complementary DNA sequence analysis, it is now known that VEGF and VPF are the same protein,<sup>10</sup> and VEGF is the term more commonly used to describe this angiogenic factor.

VEGF is a homodimeric heparin-binding glycoprotein that exists in at least four isoforms due to alternative splicing of the primary messenger RNA (mRNA) transcript. The isoforms are designated VEGF<sub>121</sub>, VEGF<sub>165</sub>, VEGF<sub>189</sub>, and VEGF<sub>205</sub>, according to the number of amino acids that each protein contains.<sup>10</sup> The vascular permeability induced by VEGF is 50,000 times that induced by histamine, the standard for induction of permeability.<sup>11</sup> Induction of permeability by VEGF allows for the

diffusion of proteins into the interstitium on which endothelial cells migrate.

The receptors for VEGF are expressed almost exclusively on endothelial cells. Rarely, expression of the various VEGF receptors has been demonstrated on cells of neural origin, Kaposi's sarcoma cells, hematopoietic precursor cells, and other rare tumor cell types.<sup>12,13</sup> Three VEGF/VPF receptors have been identified. The fms-like tyrosine kinase (Flt-1) and fetal liver kinase 1/kinase insert domain-containing receptor (Flk-1/KDR) are high-affinity VEGF/VPF receptors with an extracellular domain containing seven immunoglobulin-like domains and a split tyrosine kinase intracellular domain.<sup>8</sup> Flk-1 has 85% homology with the human homologue, KDR. Both Flt-1 and Flk-1/KDR have been shown to be important regulatory systems for vasculogenesis and physiologic angiogenesis.<sup>14</sup> However, the interaction of VEGF/VPF with Flk-1/KDR is believed to be the more important interaction for tumor angiogenesis, as it is essential for induction of the full spectrum of VEGF/VPF functions.<sup>8</sup> In fact, many compounds and molecules developed to block VEGF/VPF activities mediated by Flk-1/KDR have been shown to have antiangiogenic activity in animal models.<sup>14</sup> Most recently, VEGFR-3 (Flt-4) has been shown to be the receptor for VEGF-C, which is most likely involved with lymph angiogenesis.<sup>14</sup>

There are at least four other members of the VEGF family. The above-referenced VEGF is referred to as *VEGF-A*. *VEGF-E* most likely plays an important role in vasculogenesis but may have other functions such as activation of invasive enzymes on endothelial cells.<sup>14,15</sup> *VEGF-C* is most commonly associated with lymph angiogenesis but, more recently, its expression has been associated with tumor angiogenesis in several systems.<sup>16,17,18</sup> and <sup>19</sup> *VEGF-C* also binds preferentially to the VEGFR-3. The role of *VEGF-D* is less well defined, but this protein may bind to VEGFR-2 and VEGFR-3 and may induce *in vivo* angiogenesis.<sup>20,21</sup> Little is known about *VEGF-E*, except that it binds to VEGFR-2 and can induce endothelial cell mitosis and angiogenesis.<sup>22,23</sup>

Another family of endothelial cell-specific molecules is the angiopoietin (Ang) family. At present, its members are designated *angiopoietins 1 through 4*. The best characterized of these factors are Ang-1 and Ang-2. Ang-1 and -2 bind to the specific tyrosine kinase receptor Tie-2 on endothelial cells. Ang-1 acts as an agonist and is involved in endothelial cell differentiation and stabilization.<sup>24</sup> In contrast, Ang-2 binds to Tie-2 and blocks the binding of Ang-1 to this receptor.<sup>25</sup> This blockade leads to endothelial cell destabilization and vascular regression.<sup>26</sup> Although the receptor Tie-1 has been identified on endothelial cells, its ligand remains to be identified.

An insightful method for studying the function of various angiogenesis-related molecules is to develop knockout mice for the gene under question. Homozygous knockout of the genes for VEGF or any of the VEGF receptors lead to embryonic death in mice (reviewed in Gale and Yancopoulos<sup>27</sup>). Study of these embryos at the time of death reveals defective vascular development. Similarly, knockout of the genes for Ang-1, Ang-2, Tie-1, and Tie-2 also lead to embryonic lethality and defective vascular development in mice.<sup>28,29</sup> Thus, these factors that are being controlled in such mice are critical for vasculogenesis and likely play an essential role in tumor angiogenesis as well.

Numerous nonspecific angiogenic molecules affect not only the growth of endothelial cells but also the growth of other cell types. These factors include the fibroblast growth factors (FGF), acidic and basic; transforming growth factor- $\alpha$  (TGF- $\alpha$ ); and epidermal growth factor (EGF); platelet-derived growth factor (PDGF); platelet-derived endothelial cell growth factor (PD-ECGF); angiogenin; and the CXC chemokines interleukin-8 (IL-8), macrophage inflammatory protein-1 (MIP), platelet factor-4 (PF-4), and growth-related oncogene- $\alpha$  (GRO- $\alpha$ ).<sup>30</sup>

The process of angiogenesis is dynamic and complex. In fact, the development of a neovascular blood supply is a series of interlinked processes that eventually leads to new blood vessel formation. Studies have demonstrated that different operations in the overall process of angiogenesis may be regulated by different angiogenic factors.<sup>31</sup> For example, basic FGF (bFGF) is the most potent mitogen for endothelial cells, followed by VEGF and PD-ECGF. VEGF and bFGF are also the most potent survival factors for endothelial cells. However, bFGF is the angiogenic factor most associated with increasing activity of degradative enzymes. Hepatocyte growth factor enhances endothelial cell motility more than any other angiogenic factor studied. The more recent recognition of Ang-1 and -2 and their role in endothelial cell stabilization suggests that these molecules are also important in endothelial cell survival.<sup>26</sup>

## LYMPHOID CELL-MEDIATED ANGIOGENESIS

Angiogenesis is essential to homeostasis, and its regulation by lymphoid cells, such as T lymphocytes, macrophages, and mast cells, is well recognized.<sup>32,33,34</sup> and <sup>35</sup> A local inflammatory reaction consisting of T lymphocytes and macrophages often is associated with invasive cutaneous melanoma, and an intense inflammatory reaction often is associated with an increased risk of metastasis, suggesting that angiogenesis induced by inflammation may contribute to melanoma progression and metastasis.<sup>35</sup>

Immunologic mechanisms involved in physiologic angiogenesis are activated subsequent to wound healing.<sup>33</sup> Systemic chemotherapy has been shown to retard the process of wound healing, possibly by decreasing the immune response; whether this is mediated by inhibition of angiogenesis is unclear.<sup>36</sup> We have investigated the role of tumor vascularization and its effect on tumor growth in immunosuppressed mice. The growth of weakly immunogenic B16 melanoma was retarded in myelosuppressed mice as compared with control mice.<sup>35</sup> Further evidence implicating myelosuppression in the retardation of tumor growth and vascularity was obtained from doxorubicin-pretreated animals injected with normal spleen cells 1 day before tumor challenge. Tumor growth in these mice was comparable to that in control mice.<sup>35</sup> Similar results were obtained in athymic mice, suggesting that the tumor vascularization observed in doxorubicin-treated mice reconstituted with normal splenocytes was not mediated solely by T lymphocytes. Because reconstitution with spleen cells enhanced vascularization of the B16 tumors, the results suggest that myelosuppressive chemotherapeutic drugs (e.g., doxorubicin) can inhibit host-mediated vascularization and support the concept that developing tumors can usurp homeostatic mechanisms to their advantage.<sup>37</sup>

The role of infiltrating cells in the angiogenesis of human colon cancer has been reported.<sup>38</sup> High expression of PD-ECGF was found in infiltrating cells, mostly macrophages and lymphocytes, though very little PD-ECGF was expressed in the cancer epithelium. The intensity of staining for PD-ECGF in infiltrating cells correlated with vessel counts, suggesting the involvement of these cells in the angiogenesis of human colon cancer.

Macrophages have been recognized for a number of years as important angiogenesis effector cells.<sup>32,33</sup> They may influence new capillary growth by several different mechanisms. First, macrophages produce factors that act directly to influence angiogenesis-linked endothelial cell functions. *In vitro* studies have shown that macrophages produce in excess of 20 molecules that reportedly influence endothelial cell proliferation, migration, and differentiation *in vitro*<sup>32</sup> and that are potentially angiogenic *in vivo*. A second mechanism by which macrophages might modulate angiogenesis is by modifying the extracellular matrix (ECM). The composition of the ECM has been shown to influence endothelial cell shape and morphology dramatically and may profoundly influence new capillary growth.<sup>39</sup> Macrophages can influence the composition of the ECM either through the direct production of ECM components or through the production of proteases, which effectively alter the structure and composition of the ECM.<sup>33</sup> A third mechanism is by producing substances that suppress angiogenesis. Macrophages have been shown to express the angiogenesis inhibitor thrombospondin-1 (TSP-1) when treated with the chemopreventive agent retinoic acid.<sup>39,40</sup> and <sup>41</sup>

The generation of angiostatin by subcutaneous Lewis lung carcinoma<sup>42</sup> requires the presence of macrophages and is directly correlated with their metalloelastase activity.<sup>43</sup> For example, the addition of plasminogen to Lewis lung carcinoma (3LL) cells cultured *in vitro* did not result in generation of angiostatin, whereas the addition of plasminogen to cocultures of macrophages and 3LL cells did. Elastase activity in macrophages was up-regulated by the cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF). GM-CSF secreted by Lewis lung carcinoma cells significantly enhanced the production of elastase by macrophages and, hence, the generation of angiostatin from plasminogen.<sup>43</sup> These data suggest that elastase released from tumor-infiltrating macrophages is responsible for the angiostatin production in this tumor model and for the angiogenesis-inhibiting role of macrophages.

## REGULATION OF ANGIOGENIC FACTOR EXPRESSION IN TUMORS

Tumor cells may constitutively overexpress angiogenic factors, or they may respond to external stimuli. The most potent external stimulus of angiogenic factor expression is hypoxia.<sup>44,45</sup> Hypoxia is a consequence of tissue that is poorly perfused, and teleologically represents the appropriate response of a cell trying to survive. Hypoxia typically increases angiogenic factor expression by inducing signal cascade pathways that eventually lead to an increase in transcription of VEGF as well as stabilization of the mRNA transcript. The expression of other angiogenic factors such as angiogenin, PD-ECGF, and IL-8 may also be induced by hypoxia.<sup>46,47</sup> and <sup>48</sup> Other microenvironmental factors that increase the angiogenic response include various cytokines and growth factors. The cytokines, insulin growth factor-1, insulin growth factor-2, EGF, hepatocyte growth factor, IL-1, and PDGF have all been shown to up-regulate VEGF.<sup>49,50</sup> and <sup>51</sup> Thus, antiangiogenic therapy may involve down-regulation of upstream targets of the angiogenic factors rather than targeting of angiogenic factors themselves.<sup>52,53</sup> Furthermore, protein products of tumor

suppressor genes such as the von Hippel-Lindau (*VHL*) or *p53* gene also regulate angiogenesis. <sup>54,55</sup>

## ENDOGENOUS INHIBITORS OF ANGIOGENESIS

A large, growing, and structurally diverse family of endogenous protein inhibitors of angiogenesis has been discovered (e.g., TSP-1 <sup>56,57</sup>; the interferons IFN- $\alpha$ , - $\beta$ , and - $\gamma$  <sup>58,59</sup>; the 16-kD fragment of prolactin <sup>60</sup>; angiostatin <sup>42</sup>; endostatin <sup>61</sup>; VEGF or vascular endothelial cell growth inhibitor <sup>62</sup>; vasostatin <sup>63</sup>; METH-1 and METH-2 <sup>64</sup>; and cleavage products of platelet factor 4 <sup>65</sup> or antithrombin III, <sup>66</sup> among many others (Table 9-2). Some of these are internal fragments of various proteins that normally lack any antiangiogenic activity <sup>67</sup>; for example, the active component of angiostatin comprises one or more fragments of plasminogen, <sup>42</sup> and endostatin is a fragment of type XVIII collagen. <sup>61</sup>

Name	Description	Study
Thrombospondin-1 and heparan sulfate	Large, multimeric (200 kD) extracellular matrix proteins	Shen et al. <sup>68</sup>
Angiostatin	16-kD fragment of plasminogen containing active heparin-binding 1-7 or smaller heparin-3 fragments	O'Reilly et al. <sup>42</sup>
Endostatin	18-kD cleavage fragment of type XVIII collagen	O'Reilly et al. <sup>61</sup>
Proteinase	16-kD proteolytic fragment of type XVIII collagen	Shen et al. <sup>68</sup>
Factorial endothelial growth factor inhibitor	Chondroitin sulfate proteoglycan with RGD-binding to vascular endothelial cells	Shen et al. <sup>68</sup>
Fragment of platelet factor 4	Structural fragment of platelet factor 4	Chen et al. <sup>65</sup>
Retinoid of platelet factor 4	16-kD fragment of platelet factor 4	Chen et al. <sup>65</sup>
Factorial	16-kD fragment of platelet factor 4	Shen et al. <sup>68</sup>
Factorial-related protein	Protein related to the platelet factor 4	Shen et al. <sup>68</sup>
SPARC (secreted phosphocoryin)	Fragment of secreted protein, acidic and rich in serine	Shen et al. <sup>68</sup>
Secreted phosphocoryin	Structural fragment of protein, containing an RGD sequence	Shen et al. <sup>68</sup>
Factorial	Structural fragment of protein, non-heparin-binding angiogenic factor	Shen et al. <sup>68</sup>
METH-1 and METH-2	Protein containing heparin-binding and thrombospondin-binding, and fibronectin-binding RGD sequence	Shen et al. <sup>68</sup>
Angiostatin	16-kD fragment of plasminogen	Shen et al. <sup>68</sup>
Endostatin	18-kD fragment of type XVIII collagen	O'Reilly et al. <sup>61</sup>
Factorial-related protein	Fragment of platelet factor 4	Shen et al. <sup>68</sup>

TABLE 9-2. Some Endogenous Inhibitors of Angiogenesis

It is now thought that the tumor angiogenic switch is triggered as a result of a shift in the balance of stimulators to inhibitors. <sup>5</sup> When the ratio is low, tumor angiogenesis is blocked or modest in magnitude; in contrast, when the ratio is high, the angiogenic switch is turned to the on position. <sup>5</sup> Of considerable interest is the finding by Dameron et al. <sup>56</sup> that loss of wild-type *p53* gene function resulted in a loss of TSP expression. Not only did this finding establish a possible critical link between the genetic basis of cancer and tumor angiogenesis; it also opened up the now flourishing field of endogenous angiogenesis inhibitors. Furthermore, it is now increasingly recognized that oncogenes, such as mutant ras or src, may also contribute to tumor angiogenesis by influencing (i.e., enhancing) the production of proangiogenic molecules such as VEGF. <sup>52,68,69</sup> Such effects were slow to be uncovered in the oncogene and tumor suppressor gene fields, given the predominant use of pure tumor cell culture systems to study the function of cancer-causing genetic alterations.

## CLINICAL UTILITY OF ANGIOGENESIS

### THE PROGNOSTIC SIGNIFICANCE OF TUMOR ANGIOGENESIS

With few exceptions, benign neoplasms are sparsely vascularized and tend to grow slowly, whereas malignant neoplasms are highly vascular and fast-growing. <sup>1,2,4</sup> The increase in vasculature also increases the probability that tumor cells will enter the circulation and possibly give rise to metastases. <sup>3</sup> Immunohistochemical staining of breast cancer sections with antibodies against factor VIII, a protein expressed predominantly on the surface of endothelial cells, allowed Weidner et al. <sup>70</sup> to determine the density of the microvasculature. The number of microvessels in microscopic fields selected from the most vascular areas ("hot spots") of the sections correlated directly with metastasis and inversely with survival.

Most recent studies have concluded that increased microvessel density in the areas of most intense neovascularization is a significant and independent prognostic indicator in early-stage breast cancer. <sup>70,71,72,73,74,75,76,77,78,79</sup> and <sup>80</sup> Studies of other neoplasms such as prostate cancer, melanoma, ovarian carcinoma, gastric carcinoma, and colon carcinoma also support the conclusion that the angiogenesis index is a useful prognostic factor. <sup>81,82,83,84,85</sup> and <sup>86</sup> However, the expectation that an angiogenesis index can identify all patients with occult metastatic disease or those with probable distant metastases may be unrealistic for several reasons. <sup>1,87</sup> First, human tumors are heterogeneous and consist of subpopulations of cells having different biologic properties. <sup>88,89,90,91</sup> and <sup>92</sup> Heterogeneity of angiogenic molecule expression has recently been documented in human renal carcinomas and human colon. <sup>93,94</sup> Second, the process of cancer metastasis is sequential and selective, consisting of a series of interlinked but independent steps. <sup>89,92</sup> To produce clinically relevant metastases, tumor cells must complete all the steps in this process. Tumor cells that can induce intense angiogenesis but cannot survive in the circulation or proliferate in distant organs will not produce metastases. <sup>89,92</sup> Like all other steps in the metastatic cascade, angiogenesis is necessary but not sufficient for the pathogenesis of a metastasis. Third, although not all large angiogenic tumors metastasize, inhibition of angiogenesis prevents the growth of tumor cells at both the primary and secondary sites and thus can prevent the development of clinically relevant metastases. <sup>42,61,67</sup>

To study angiogenesis in tumor specimens using current technology, it is necessary to obtain tissue for histologic evaluation. The criterion standard for evaluation of human tumor specimens is to highlight the tumor endothelium with antibodies that differentiate endothelial cells from other cells within the tumor. <sup>95</sup> The first such antibody used was factor VIII-RA (FVIII-RA), and this is still the antibody used in many studies reported in the literature. Other endothelial cell-specific antibodies that are used in the study of angiogenesis include CD31/PECAM, CD34, CD36, TEC-11, and ulex europaeus (UEA). Currently, the antibodies most commonly used in the study of angiogenesis are FVIII-RA, CD31, and CD34 antibodies. Once histologic preparation of a slide is complete, it is necessary to quantify the level of angiogenesis within the tumor. It is essential that an investigator examine angiogenesis systematically. For example, investigators may choose the five most vascularized areas in a tumor by scanning at low power and then count vessels in these areas under higher magnification. In certain tumors, such as colon cancer and gastric cancer, it is necessary to define the location at which tumor counts are obtained, as counts made close to the invading edge of the tumor may be significantly different from counts made further away from the invading edge. <sup>82,83</sup> The number of blood vessels in individual tumor specimens can be quantified either as the number in a single high-power field or as the average number in several high-power fields.

In addition to counting blood vessels in a high-power field, it also is possible to grade the degree of vasculature on a scale of 0 to 3+, with 3+ being the most vascular. Obviously, this approach is subjective and prone to problems of reproducibility. Another method of analyzing tumor angiogenesis involves highlighting the vessels with an endothelial cell-specific antibody and, with the aid of computer imaging analysis, determining the area within a high-power field that is occupied by positively stained cells. Access to imaging systems and computer software is necessary for this technique. A third method for quantifying the degree of angiogenesis is to count the number of branch points in vessels within a tumor. Finally, a very common method employed in Europe is the Chalkley-Grid method. <sup>96</sup> In this methodology, an eyepiece marked with overlapping crossbars is used to visualize the high-power field of a tumor stained with an endothelial cell-specific antibody. The areas where an endothelial cell intersects a crossbar are counted, and the total sum in a high-power field of these counts is equal to the Chalkley score.

The recognition that tumors with a high angiogenic index may be associated with subsequent metastasis suggests that these patients may be the ones most likely to benefit from adjuvant therapy. In a study evaluating the prognostic role of angiogenesis in late-stage lung carcinoma, adjuvant therapy improved survival in patients with a high vessel count but not in patients with a low vessel count. <sup>97</sup> However, the observation that patients with highly angiogenic tumors benefit from adjuvant therapy is not universal. In several studies of node-positive breast cancer patients treated with adjuvant chemotherapy or hormonal therapy, those whose tumors had a high microvessel density were found to have a worse prognosis than those whose tumors had a low microvessel density, despite adjuvant chemotherapy. <sup>98,99</sup> In fact, one recent study suggested that patients with a low VEGF expression have a more favorable outcome secondary to adjuvant therapy. <sup>100</sup> Tumors with a high angiogenic index may represent a biologically more aggressive variant of the disease, against which conventional adjuvant therapies are ineffective. Perhaps antiangiogenic therapy is indicated in these patients. Obviously, well-controlled clinical trials should be designed to determine the efficacy of antiangiogenic therapy as an adjunct in the treatment of patients with highly vascularized solid malignancies.

## OVERVIEW OF ANTIANGIOGENIC STRATEGIES

Antiangiogenic agents currently used in the clinic can be categorized into several broad classes based on the biologic activity of the compounds used. The first class of compounds, metalloproteinase inhibitors, blocks degradation of the basement membrane. Most of the studies on these agents reported to date have been phase I studies in which major toxicity was associated with musculoskeletal and joint pain owing to defects in collagen remodeling.

A second class of antiangiogenic agents includes those designed to inhibit endothelial cell function. These include TNP-470, thalidomide, squalamine, combretastatin A-4 prodrug, and endostatin. Less is known about the biologic effects of these drugs as compared to the first class, and most of these drugs are currently in phase I or phase II trials. How these drugs exert their antiangiogenic activities in *in vivo* models is not fully elucidated at this time; perhaps well-designed clinical trials will shed some light on their mechanisms of action.

A third class of antiangiogenic agents specifically targets an angiogenic factor or factors. These agents include tyrosine kinase inhibitors of the receptors of such factors as VEGF, bFGF, and PDGF. In addition, antibodies directed against these receptors or the factors themselves are either in clinical trials or in the process of being developed for clinical trials. In preclinical trials in animal models, most of these agents inhibited tumor growth, but very few have caused tumor regression. This suggests that tumor regression, which is the typical end point for successful cytotoxic chemotherapy, may not be appropriate for antiangiogenic therapies. Thus, it is necessary to redefine the end points for biologic therapy.

Because endothelial cell survival has recently been recognized as an important characteristic of the development of a neovascular blood supply, drugs that target survival factors are beginning to be introduced into clinical trials. These drugs include antagonists to integrins that are present on the endothelial cell surface. In addition, as VEGF currently is thought of as both a survival factor for endothelial cells and an angiogenic factor, anti-VEGF therapy may affect the survival of tumor endothelial cells.

## TUMOR ENDOTHELIUM (“ACTIVATED ENDOTHELIUM”) AS DISTINCT FROM NORMAL ENDOTHELIUM

The discovery of VEGF receptors and their up-regulation in newly formed blood vessels highlights the fact that there can indeed be major phenotypic differences between mature, quiescent vessels and their newly formed counterparts. Such differences are essential to avoid unwanted toxicity to normal vessels when using antiangiogenic drugs while still achieving a sufficient therapeutic index. A number of such differences in the phenotypes of endothelial cells in normal versus malignant tissues are now known and include a significant elevation of expression of the integrins avb3 and avb5.<sup>101,102</sup> In breast cancer, it has been demonstrated that antibodies to avb3 preferentially stain the tumor vasculature but not the normal vasculature, suggesting that avb3 is a marker for activated endothelium.<sup>103</sup>

An important issue in antiangiogenic strategies is the fact that tumor endothelium at different sites and within different tumors may be phenotypically distinct. Tumor endothelium is heterogeneous in terms of the ability to bind specific peptide sequences.<sup>104</sup> Other markers that are up-regulated in activated endothelial cells include adhesion molecules such as E-selectin,<sup>105</sup> endoglin,<sup>106</sup> glycoproteins such as prostate-specific membrane antigen,<sup>107</sup> the ED-B domain of fibronectin,<sup>108</sup> and various proteases.<sup>109</sup> Many of these unique characteristics of the tumor endothelium can be exploited not only as potential therapeutic targets but also for detection of cancer by various clinical imaging techniques.<sup>108</sup>

## ANTIANGIOGENIC ACTIVITY OF INTERFERON

The IFN family consists of three major glycoproteins that exhibit species specificity: leukocyte-derived IFN- $\alpha$ , fibroblast-derived IFN- $\beta$ , and immune cell-produced IFN- $\gamma$ . Although IFN- $\alpha$  and IFN- $\beta$  share a common receptor (the type I IFN receptor) and induce a similar pattern of cellular responses, certain cellular reactions can be stimulated only by IFN- $\beta$ , probably by the phosphorylation of a receptor-associated protein that is uniquely responsive to IFN- $\beta$ .<sup>110</sup> In addition to their well-recognized activity as antiviral agents, IFNs regulate multiple biologic activities such as cell growth,<sup>111</sup> differentiation,<sup>112</sup> oncogene expression,<sup>113</sup> host immunity,<sup>114</sup> and tumorigenicity.<sup>115,116</sup> and <sup>117</sup> IFNs can also inhibit a number of steps in the angiogenic process. IFN has antiproliferative properties, especially on tumor cells,<sup>118,119</sup> an effect that has been demonstrated also on endothelial cells *in vitro*. IFN- $\alpha$  can inhibit FGF-induced endothelial proliferation<sup>120</sup>; IFN- $\gamma$  also can inhibit endothelial proliferation.<sup>121</sup> IFN- $\alpha$  and IFN- $\gamma$  have been shown to be cytostatic to human dermal microvascular endothelial cells<sup>122</sup> and human capillary endothelial cells.<sup>123</sup>

Systemic therapy using recombinant IFNs produces antiangiogenic effects in vascular tumors, including life-threatening infantile hemangioma,<sup>59,124,125</sup> Kaposi's sarcoma,<sup>126</sup> giant cell tumor of the mandible,<sup>127</sup> and bladder carcinoma.<sup>128</sup> These tumors have also been documented as producing the high levels of bFGF often detectable in the urine or serum of these patients.<sup>129,130</sup> IFN- $\alpha$  and IFN- $\beta$ , but not IFN- $\gamma$ , down-regulate the expression of bFGF mRNA and protein in human carcinoma cells.<sup>58</sup> Indeed, systemic administration of human IFN- $\alpha$  decreased the *in vivo* expression of bFGF, decreased blood vessel density, and inhibited tumor growth of a human bladder carcinoma implanted orthotopically in nude mice.<sup>131</sup>

## ANTIANGIOGENIC THERAPY: ISSUES AND EXPECTATIONS

The understanding that angiogenesis is essential for tumor growth and metastasis formation has led to a large effort to discover effective antiangiogenic compounds. It must be understood that angiogenesis occurs not only in pathologic processes but also in homeostasis. Physiologic angiogenesis is important in reproduction, wound healing, menses, and vascular diseases such as coronary artery and peripheral vascular diseases. Thus, as always, a balance must be maintained between limiting angiogenesis to the tumor and causing significant toxicity to the host.

In addition to the potential toxicity, another issue in antiangiogenic therapy is the chronic nature of this therapy. Because antiangiogenic therapy is designed to inhibit the development of new blood vessels, the end points for success or failure must be redefined. For example, a desired response to standard chemotherapy is one that decreases the cross-sectional area of a tumor by 50% within a few months. However, antiangiogenic therapy is likely to produce stable disease, which early on may be considered a failure. Thus, in evaluating antiangiogenic therapy in the clinic or the laboratory, different criteria for effectiveness must be outlined.

Because antiangiogenic therapy may not decrease tumor growth, it is likely that this therapy will need to be delivered on a chronic basis. Hence, the agent must be easily delivered (i.e., oral) and have few long-term side effects. One must also consider that the effect of antiangiogenic therapy may require a longer interval between evaluations than does chemotherapy, as the stability of disease may be difficult to determine at short intervals.

There have, of course, been reports of complete regression of tumors in experimental models of angiogenesis.<sup>61,132</sup> However, these reports are few, and the vast majority of studies in this field have demonstrated that antiangiogenic therapy leads to an inhibition of tumor growth.<sup>133,134</sup> Thus, it is critical that the reader be able to interpret experimental studies appropriately and avoid creating unrealistic expectations. For example, the sites of tumor injection must be considered when experimental antiangiogenic studies are being conducted. It is clear that endothelia from different organs are phenotypically distinct<sup>104</sup> and that therapy effective at one site may be ineffective at another site. In addition, the growth and patterns of metastases depend on the site of injection.<sup>135</sup> Thus, the most relevant model for evaluating antiangiogenic therapy is an orthotopic model in which the tumor is growing in the appropriate host environment. Moreover, in designing experiments or reading the literature, it is important to determine whether antiangiogenic therapy is being designed as (1) a chemopreventive agent (delivered prior to or at the time of tumor inoculation), (2) adjuvant therapy (delivered when the tumor is at a relatively small volume, such as shortly after tumor injection), or (3) a therapeutic modality (delivered to animals with established tumors).

In evaluating responses to antiangiogenic therapy, one must define the end points prior to initiation of the study. Typically, tumor size or mass is determined at initiation of therapy and at termination of the study. As a surrogate means of assessing drug activity, biopsies of accessible tumors can be obtained for immunohistochemical staining to determine vessel counts, tumor cell proliferation and apoptotic rates, and endothelial cell proliferation and apoptotic rates. More important, survival studies may better assess the effectiveness of antiangiogenic therapy.

Preclinical data suggest that the efficacy of a conventional cytotoxic drug can be improved by combination with an angiogenesis inhibitor.<sup>136</sup> Indeed, a number of antiangiogenic clinical trials currently in progress have been designed to compare the effects of a particular cytotoxic agent alone with the effects of the same agent in combination with an angiogenesis inhibitor. Clearly, the success of Herceptin in improving the effects of cytotoxic chemotherapy in a proportion of advanced-stage breast cancer patients has enhanced the credibility of this strategy of evaluating cytostatic drugs.<sup>137</sup> This could allow conventional end points, such as tumor shrinkage and prolonged survival of very sick patients, to be used, albeit indirectly, as a convenient means of more rapidly assessing the merit of antiangiogenic

drugs.

Another possible approach to effect tumor vascular growth could be the increased use of improved antivascular targeting strategies that can cause acute tumor regression, as shown in various preclinical models. For example, certain tubulin-binding agents,<sup>138</sup> such as combretastatin A-4, can cause such an effect,<sup>139,140</sup> as can antibodies that target tissue factor to newly formed blood vessels, thus causing an intravascular thrombogenic response in such vessels.<sup>141</sup> These drugs kill endothelial cells of newly formed blood vessels by different mechanisms<sup>139</sup> that result in vascular collapse and the subsequent death of much larger numbers of tumor cells. Clearly, the problem here will be to develop drugs that have this ability to cause such a dramatic tumor infarction<sup>141</sup> without major, perhaps even life-threatening, toxic side effects. In this regard, a potentially significant development in the near future could be the use of genomics-based technologies to uncover a large number of highly (or even totally) specific molecular markers for the activated endothelial cells of newly formed blood vessels. This could make antibody-based therapeutics safer and more effective.

Cytostatic antiangiogenic agents have the desired biologic (i.e., antiangiogenic) effect *in vivo*. In experimental animal models, tumors can be resected and analyzed for such changes as the extent of vascularization, vascular structure, and endothelial cell viability or apoptosis as well as for markers of angiogenic activity (e.g., expression of VEGF, bFGF, IL-8). Performing serial biopsies of metastatic tumors will not be practical; thus, reliable surrogate markers of tumor angiogenesis found in serum or urine may be necessary. At present, few, if any such markers (at least of a reliable nature) exist. The use of noninvasive medical imaging strategies (e.g., magnetic resonance imaging, Doppler ultrasound) to monitor changes in tumor blood flow, vascular structure, and permeability may be helpful, and considerable research efforts to determine their efficacy are under way.<sup>142,143,144 and 145</sup>

Toxic effects associated with chronic antiangiogenic therapy may not show up in short-term early-phase clinical trials or in animal models but, rather, only after very protracted courses of therapy. The development of spastic diplegia in some infants or children who had been treated previously and successfully over 1 year with antiangiogenic (IFN- $\alpha$ -2-B) therapy for their life-threatening hemangiomas<sup>146</sup> is an example of such delayed toxic side effects. This undoubtedly will increase the need for targeting tumor blood vessels. The growing interrelationship between the clotting and fibrinolytic pathways and angiogenesis<sup>66</sup> raises the possibility of inciting bleeding and coagulation disorders in patients who receive certain antiangiogenic drugs, as well as the possibility of causing or exacerbating existing cardiovascular defects in older patients. In addition, there is the obvious concern about affecting physiologic forms of angiogenesis in various situations. Thus, wound healing may be adversely affected in a cancer patient who is receiving antiangiogenic drugs, as reproductive angiogenesis would be (e.g., corpus luteum development in adult women and development of the vasculature in embryos). Growth in neonates may also be compromised by angiogenesis inhibitor therapies.<sup>147</sup> However, given the unique structural features of the tumor vasculature, some angiogenesis inhibitors may selectively block tumor angiogenesis without actually affecting other physiologic forms of angiogenesis. This possibility could turn out to be an important factor in selecting the optimal angiogenesis inhibitors for clinical development and their use in cancer patients.

## ANTIANGIOGENIC THERAPY AS A COMPONENT OF OTHER ANTINEOPLASTIC REGIMENS

The combination of an antiangiogenic drug (or drugs), such as TNP-470, with a conventional cytotoxic agent, such as cisplatin, paclitaxel, or cyclophosphamide, can significantly improve the antitumor efficacy of the cytotoxic drug.<sup>136</sup> These effects of combination therapy, which have also been observed for the combination of radiation therapy and angiogenesis inhibitors,<sup>148</sup> could play a significant role in the clinical evaluation and effects of angiogenesis inhibitors.

A more rational, yet futuristic, approach to the treatment of patients with malignancies is to determine the molecular alterations that lead to the various processes involved in tumor growth. Angiogenesis is but one component of the process of tumor growth and metastasis, and overexpression of other genes involved in protection from apoptosis, cell proliferation, and cell invasion (i.e., an individual tumor's malignant fingerprint) must be examined. With the rapid development of gene chip technology, it may be possible in the future to determine the malignant fingerprint of individual tumors and to develop therapies that specifically target the molecular phenotype of an individual tumor. Antiangiogenic therapy may therefore be one component of diverse biologic therapy delivered in combination with anti-growth factor therapy or with agents that induce apoptosis in tumor cells and tumor vessel endothelial cells.

## CONCLUSIONS

Angiogenesis is a dynamic process essential for the growth of primary and metastatic malignancies as well as hematopoietic cancers. Understanding of the basic principles of the biology of angiogenesis has led to the development of new prognostic factors, tumor markers, imaging techniques, and therapeutic modalities. The challenge lies in integrating this knowledge into the care of patients with malignant diseases of all types and stages. An understanding of the basic biology of angiogenesis and tumor biology ultimately will lead to the rational implementation of new paradigms for the treatment of patients with cancer.

A comprehensive review of current antiangiogenic clinical trials is not feasible, as this area of clinical research is in constant evolution. However, the U.S. National Cancer Institute maintains an up-to-date Web site at which information on clinical trials can be accessed: <http://cancertrials.nci.nih.gov/news/angio/table.html>. In addition, an overview of antiangiogenesis can be found at <http://cancertrials.nci.nih.gov/news/angio/index.html>.

## INTRODUCTION

RNA viruses, particularly retroviruses, have been studied as important causes of human cancer and as tools for understanding both viral and nonviral oncogenesis at the molecular level. The retrovirus human T-cell leukemia virus type I (HTLV-I) is the causative agent of adult T-cell leukemia (ATL). Two other RNA viruses, human immunodeficiency virus (HIV) and hepatitis C virus (HCV), are strongly associated with human malignancies. In addition, the discovery and characterization of oncogenes and the subsequent elucidation of protooncogene functions have been closely intertwined with the study of retroviruses.

Retroviruses have been classified on the basis of pathogenic roles into Oncovirinae (tumor viruses), Lentivirinae (genetically complex agents, including HIV), and Spumavirinae (foamy viruses, not known to be associated with human disease). Other classifications based on particle morphology (virus types A–D) and genetic relatedness<sup>1,2</sup> also are used. To illustrate different molecular mechanisms of oncogenesis, this discussion is principally concerned with the Oncovirinae, including the mammalian type C tumor viruses, the avian leukemia/sarcoma viruses, and HTLV-I and -II. The roles played by HIV in the various malignancies associated with acquired immunodeficiency syndrome (AIDS) and by HCV (a flavivirus) in hepatocellular carcinoma (HCC) also are discussed. In all examples, although these virus infections may play key initiating or contributory roles to carcinogenesis, additional, sequential alteration of cellular DNA is generally required to yield the fully malignant phenotype.<sup>3</sup>

## RETROVIRAL GENETICS: SELECTIVE ACCESS TO THE GROWTH CONTROL GENES OF THE CELL

Special features of their replication cycle have made retroviruses useful for investigating the molecular basis of neoplasia. Retroviruses are unique among animal viruses in having an RNA genome that replicates through a DNA intermediate. The virally encoded reverse transcriptase converts the single-stranded RNA genome into a double-stranded DNA copy; a subsequent reaction catalyzed by the retroviral integrase covalently and irreversibly integrates this DNA molecule into a host chromosome where it resides as a provirus. This process can result in mutagenesis, translocation, or altered regulation of any locus in the genome.<sup>4,5</sup>

An integrated provirus resembles other multiexon cellular genes in that it is duplicated along with the cell's genome, passed on to daughter cells during mitosis, and subsequently transcribed into full-length and spliced RNAs [messenger RNAs (mRNAs)]. The ends of the provirus are made up of identical genetic control regions called *long terminal repeats* (LTRs), which are composed of U3 (unique 3' region), R (repeat), and U5 (unique 5' region). The promoter and enhancer functions necessary for RNA polymerase II to initiate viral mRNA transcription reside within the LTR, primarily in U3. Transcription initiates just downstream of the TATA box at the 5' U3/R junction and proceeds through to the polyadenylation (polyA) signal usually located in the R region of the 3' LTR ( [Fig. 10.1-1](#)).

**FIGURE 10.1-1.** Retrovirus genome organization. General genome structure of a typical replication-competent oncoretrovirus. The structure of the double-stranded DNA copy (provirus) is shown below that of the genomic RNA. In the provirus, *gag* (encoding viral core proteins), *pol* (viral replication enzymes), and *env* (viral envelope glycoproteins) genes are flanked on each end by the long terminal repeats (LTR). The viral promoter is located in the 5' U3 region, with transcription termination and poly A signals located in the 3' LTR. The arrow indicates point and direction of transcription initiation. R, repeat.

The locations of transcription initiation and termination result in virion (genomic) RNA that carries the viral promoter (U3 element) downstream of the genes to be transcribed (in contrast to the structure of the provirus). Because a genomic transcript possesses neither an upstream U3 nor a downstream U5, the essential rearrangements that occur during the RNA template strand switching of reverse transcription are establishment of a 5' promoter and of integration-competent termini. The retention of a duplicate U3 promoter element in the 3' LTR of the provirus, though generally not active, has implications for retroviral oncogenesis.

Retrovirus virions normally encapsidate a dimer of identical plus-sense RNA genomes, both of which are used as templates during reverse transcription. However, it is possible for nonidentical transcripts (heterodimers) to be packaged together. Studies with dual selectable markers show that each infectious virion, even if heterozygous, produces only one provirus. Heterodimer packaging plays an important role in the creation of oncogenic retroviruses because, after recombination and reverse transcription, it can result in the creation of novel proviruses. Even when identical RNAs are packaged, aberrant strand transfers during reverse transcription result in high rates of genetic recombination and rearrangement, including sequence deletions, duplications, and inversions.<sup>1,5,6,7</sup> and <sup>8</sup> Recombination can occur between two viruses infecting the same cell or, less commonly, between viral and cellular sequences.

## MECHANISMS OF RETROVIRAL ONCOGENESIS

In the case of acutely transforming retroviruses such as Rous sarcoma virus (RSV), virtually all infected cells are swiftly transformed, whereas for other retroviruses, transformation is an unusual and much delayed outcome that often depends on the cell's accrual of additional alteration of its DNA. The latter group includes agents such as HTLV-I and avian leukosis virus (ALV). Most transforming retroviruses are not cytopathic. Reverse transcription and integration of the viral genome into that

of the cell favor the three major mechanisms by which retroviruses may participate in the malignant transformation process ( Fig. 10.1-2):

**FIGURE 10.1-2.** Three types of oncogenic retroviruses. **A:** Acutely transforming retroviruses. Rous sarcoma virus (RSV) and simian sarcoma virus (SSV), retroviruses that contain oncogenes, are shown. RSV is unique in that the oncogene, *v-src*, has been added to the viral genome without concomitant loss of replicative genes. SSV, an example of the more common oncogene-containing retroviruses, is not replication-competent; the recombination that led to *v-sis* insertion resulted in deletion of some viral sequences. **B:** Slowly transforming retroviruses. In the upper example, a provirus has integrated upstream of a cellular protooncogene. The viral promoters may alter protooncogene expression directly [via read-through transcription originating from the 5' long terminal repeat (LTR) or from transcripts aberrantly originating in the 3' LTR] or indirectly via the effect of viral enhancers increasing transcription from cellular promoters (the viral enhancer can also affect expression of cellular genes 5' to, and in the opposite orientation of, the site of provirus integration). In the lower example, insertional mutagenesis is illustrated. This may lead to inactivation of a tumor suppressor or to production of a mutant cellular protein that could lead to oncogenesis. In both cases, aberrant splicing could lead to production of chimeric viral-cellular proteins. Arrows indicate points of initiation and direction of transcription. **C:** *Trans*-acting retroviruses. In addition to *gag*, *pol*, and *env*, human T-cell leukemia virus type I (HTLV-I) encodes viral regulatory proteins. Tax is implicated in the genesis of adult T-cell leukemia through its interactions with cellular transcription factors, resulting in alteration of expression of many growth-related genes.

1. Acutely transforming retroviruses (e.g., RSV) incorporate and exert control over cellular growth-related genes (protooncogene capture) and subsequently transfer these deregulated genes into new cells.
2. Slowly transforming viruses (e.g., ALV) alter cellular gene expression by chance insertion of *cis*-acting viral regulatory sequences adjacent to these genes (insertional mutagenesis).
3. *Trans*-acting retroviruses (e.g., HTLV-I) alter cellular gene expression and function through viral regulatory protein(s) that act in *trans*.

### ACUTELY TRANSFORMING (TRANSDUCING) RETROVIRUSES AND GENE CAPTURE

Acutely transforming retroviruses provided evidence for viral oncogenesis even before the existence of viruses was recognized. A porcelain filtrate of tumor lysates prepared from chicken sarcomas was shown to cause sarcomas when injected into animals. The causative agent, RSV, is a prototype of the acutely transforming (transducing) retroviruses. It is the only replication-competent oncogene-carrying retrovirus; since oncogene insertions usually supplant essential viral sequences, all other known acutely transforming retroviruses are defective for replication and require a helper virus to supply one or more viral proteins in *trans*. RSV contains the full complement of replicative genes in addition to a transforming gene.

It was not until the 1940s that the first mammalian retrovirus, mouse mammary tumor virus, was isolated; later, a murine leukemia virus was isolated from neonatal mice. Investigation of the actual physical nature of these agents awaited the advent of cell culture, elucidation of the genetic code, and the framework of the "central dogma" (i.e., genetic information flow proceeds unidirectionally from DNA to RNA to protein). The term *retrovirus* was coined when Temin and Mizutani<sup>9</sup> and Baltimore<sup>10</sup> overturned this dogma with their co-discovery of reverse transcriptase in 1970.

RSV mutants defective only for transformation but not for replication were isolated. The mutants were either conditional (temperature-sensitive) or nonconditional. The latter had genomes roughly 20% shorter in length than the oncogenic strain of RSV.<sup>11</sup> Molecular hybridization experiments revealed that the missing "oncogenic" sequences hybridized not only to DNA from infected chicken cells but also to normal chicken, human, and even invertebrate DNA.<sup>11</sup> The inference was that the sequence (*v-src*) was not a native viral gene but rather an altered version of a normal cellular homologue (*c-src*) that had been captured by RSV at some unknown point in evolution. Such cellular genes are designated protooncogenes (or *c-oncs*). All retroviral *v-oncs* are dispensable for viral replication, and in all cases homology exists to cellular genes conserved over long evolutionary distances.

The genetic mechanism whereby retroviruses captured and transduced oncogenes remained surprisingly ambiguous for more than a decade after the characterization of RSV and other transforming retroviruses. Two prevailing models postulate that recombination, generally illegitimate (nonhomologous), occurs after a retrovirus integrates in the vicinity of a protooncogene. Both models require co-packaging into one virion of an abnormal viral transcript containing cellular sequences with that of another viral genome. They differ in the level at which the initial rearrangement takes place. The first model proposes two different events, with the first being a presumably rare deletion of the 3' portion of an integrated provirus. The key feature is that deletion of the 3' LTR brings internal retroviral sequences in contiguity with a downstream protooncogene. The hybrid transcript initiated in the 5' LTR is then processed (e.g., by splicing) and packaged into virions along with a wild-type genome from another provirus infecting the same cell. After infection of another cell, illegitimate recombination during reverse transcription then provides the oncogene-containing molecule with a 3' LTR that supports integration and, in some cases, subsequent replication. In the second model, no deletion of chromosomal DNA is required.<sup>12</sup> Transduction of sequences downstream of the provirus is instead accomplished at the posttranscriptional level by packaging of RNA transcripts generated when RNA polymerase II terminates inefficiently at the retroviral polyadenylation signal in the R repeat. The model postulates co-packaging of such read-through transcripts, followed by illegitimate recombination during reverse transcription. Direct evidence has been obtained for such a mechanism by placing a selectable drug marker transcriptional unit downstream of Rous-associated virus, with and without mutations of the viral polyadenylation signal.<sup>12</sup>

Increased mutation is another dramatic consequence that arises from the transfer of cellular sequences from the host genome into the genome of retroviruses. The point mutation rates of RNA viruses ( $10^{-3}$  to  $10^{-5}$  per nucleotide per replication cycle) are roughly 1 million-fold in excess of cellular DNA.<sup>13</sup> Like all RNA-dependent polymerases so far studied, reverse transcriptase lacks efficient capability to proofread misincorporated bases.<sup>14</sup> One retroviral *v-onc* (*v-mos*) has been experimentally documented to evolve at a rate  $10^6$ -fold higher than its cellular homologue.<sup>15</sup> It is not surprising, then, that *v-oncs* frequently contain point mutations in addition to other genetic changes compared to their protooncogene homologues. Such mutations are necessary preludes to cancer, because mere overexpression of only a few protooncogenes can transform cells; most require genetic alteration for their oncogenic properties. Overexpressed *c-src*, for example, does not transform.<sup>16</sup>

### SLOWLY TRANSFORMING (CIS-ACTIVATING) RETROVIRUSES: INSERTIONAL MUTAGENESIS

Genomic insertion of a provirus can itself be tumorigenic by leading to aberrant activity of adjacent cellular genes (see Fig. 10.1-2). This second mechanism by which retroviruses activate the latent oncogenic potential of protooncogenes is the more common transforming process in nature. Retroviruses that act in this manner, such as avian leukosis virus (ALV), have been termed *chronic*, or *slow-acting tumor viruses*. They do not transform cells in tissue culture. *In vivo*, long latency periods between infection and tumorigenesis are typical, whereas acutely transforming retroviruses reliably transform cultured cells and cause tumors with high probability shortly after infection. Also in contrast to acutely transforming retroviruses, the tumors are monoclonal for the site of insertion. In general, slowly transforming viruses require a second mutagenic event for their transforming properties to become apparent.

In B-cell lymphomas associated with ALV, tumors arising from independent transformation events invariably have ALV proviruses clonally integrated in the vicinity of the *c-myc* gene.<sup>17</sup> These tumors illustrate two general ways in which insertional mutagenesis may operate: promoter insertion and enhancer insertion. In the former, the ALV provirus integrates upstream of, and in the same orientation as, *c-myc*. 3' LTR-promoted *c-myc* transcripts are produced at up to 100-fold higher than normal levels (the transcripts, however, encode a normal *c-myc* protein). Enhancer insertion, however, can occur if the provirus inserts downstream of *c-myc*, or upstream but in opposite orientation to the gene. In this scenario, enhancer elements within the LTR may abnormally increase gene expression. These two roles of retroviruses in studies of *myc*-gene capture and insertional mutagenesis—elegantly confirm the protooncogene hypothesis: The gene was first identified as a protooncogene not

from insertional mutagenesis studies, but from its mutant v-onc homologue in a transforming retrovirus.<sup>2,4</sup>

A related transforming mechanism occurs when insertion of a retrovirus occurs within the c-onc itself or if the 5' LTR-promoted read-through RNAs result in downstream protooncogene transcription.<sup>18</sup> In either case, viral-protooncogene hybrid spliced transcripts encoding novel proteins with transforming potential can then be produced.

## TRANS-ACTIVATING RETROVIRUSES

A third mechanism of transformation involves a *trans*-acting viral protein that regulates the expression or function of cellular growth and differentiation genes. This mechanism is exemplified by HTLV-I, the first and only human retrovirus known to directly cause human cancer.

## HUMAN T-CELL LEUKEMIA VIRUS TYPE I

### HISTORY AND EPIDEMIOLOGY

Today, the concept of a pathogenic human retrovirus has become familiar. However, even in the mid-1970s, although retroviruses had been readily isolated from many species, no human counterparts had been found despite intensive attempts. Soon, however, several technologic advances, combined with epidemiologic insights, began to change the picture.<sup>19,20</sup>

In 1978, a type C-like retrovirus now called *HTLV-I* was isolated from a CD4+ T-lymphoblastoid cell line established from a patient with a cutaneous T-cell lymphoma,<sup>21</sup> most probably adult T-cell leukemia (ATL). An aggressive malignancy of T cells bearing the CD4 marker, ATL had been characterized as a clinicopathologic entity only in the preceding three years.<sup>22,23</sup> The disease was then believed confined to the southern islands of Japan, where, in contrast to most of the world, it predominates over mature B-cell leukemia/lymphoma. The geographic clustering suggested an infectious etiology, and serologic testing of Japanese ATL patients with antigens prepared from the newly discovered HTLV-I revealed nearly 100% seropositivity.<sup>24,25</sup> Other epidemiologic clusters consistent with an etiologic role for endemic HTLV-I infection have since been documented, most notably in the Caribbean basin, the southeastern United States, northeastern South America, Central Africa, and Papua New Guinea. Moreover, transmission of HTLV-I by blood transfusion (but, unlike HIV, not cell-free blood products), needle sharing, breast feeding, and from male to female (rarely the reverse) by sexual intercourse has been well documented.

In addition to seroepidemiologic studies of patients and their close contacts, several lines of evidence support a direct causal role for HTLV-I in ATL. The virus can be isolated reproducibly from ATL patients. Leukemic cells invariably contain an HTLV-I provirus, whereas other cells from these patients do not. Infected individuals born in an endemic region carry their risk of developing ATL with them if they move elsewhere, suggesting that risk is not dependent on environmental cofactors peculiar to endemic areas. Infection clearly precedes transformation, because the tumor cells carry monoclonal or oligoclonal insertions of HTLV-I DNA and have a single T-cell antigen receptor- $\beta$  gene rearrangement.<sup>26,27</sup> This monoclonality also provides additional evidence that transformation is a rare sequel to infection.

Primary T cells infected with HTLV-I do not senesce after a month in culture, as normal T cells do, but become immortalized, acquiring the ability to divide continually in the presence of interleukin-2 (IL-2). Continued culture of immortalized cells eventually can result in selection of a transformed, IL-2-independent clone of cells. There is evidence that, in addition to CD4+ T cells (the phenotype of the majority of ATLS), HTLV-I can also infect and transform CD8+ T cells, as well as immature CD4- CD8- T-cell precursors in bone marrow.<sup>28</sup>

### THE VIRAL REPLICATION CYCLE AND ITS IMPLICATIONS FOR VIRAL SPREAD AND EVOLUTION

Although HTLV-I shares many features with the type C viruses, it is considerably more complex genetically and biologically. In addition to *gag*, *pol*, and *env*, the virus genome contains several additional open reading frames (see Fig. 10.1-2). Of these, the two best characterized genes code the *trans*-regulating proteins Tax and Rex. Both proteins are expressed early in the viral replication cycle and are important for expression of viral genes; as such, they are analogous to the HIV proteins Tat and Rev.<sup>29,30,31</sup> and <sup>32</sup> Rex and Rev, through an interaction with a human nuclear export receptor, CRM-1,<sup>33,34</sup> act as adaptors for the nuclear export of unspliced retroviral mRNA. Additional cellular proteins interfacing with the splicing/export pathways are also involved in mediating Rev/Rex function.<sup>35</sup> Tax is a nuclear protein that activates transcription from the HTLV-I LTR *in trans* by associating with a number of cellular transcription factors.<sup>36,37</sup> and <sup>38</sup> A 21-base-pair repeat sequence within the HTLV-I U3 is necessary for Tax activity and confers Tax inducibility to heterologous genes placed downstream.<sup>39,40</sup>

Little, if any, HTLV-I replication or gene expression is detectable *in vivo* by analyzing primary leukemic cells from humans<sup>41,42</sup>; significant viremia is not detected. The molecular mechanisms that maintain viral latency *in vivo* are unclear. The *in vivo* latency and low levels of viremia in HTLV patients has important implications both for virus spread and evolution. Unlike HIV, there is remarkably little genetic variability among HTLV-I isolates,<sup>43</sup> with 97% to 99% sequence identity among strains derived from Japanese patients and generally 96% to 99% identity across widely diverse geographic regions.<sup>41</sup> Again, unlike HIV, cell-free transmission rarely occurs, either in cell culture or *in vivo*. This property is one factor in the less efficient, endemic transmission of HTLV-I compared to the epidemic spread of HIV-1, even though the same routes of infection appear to be operative.

When a cytopathic virus such as HIV rapidly destroys its host cell, continuous viral spread is imperative. The alternative adopted by HTLV-I is to keep virion burden low but promote gradually accelerating amplification of cells harboring transcriptionally quiescent proviral DNA over the course of the host organism's lifetime. Because infection is by cell transfer, spread in the population is thereby promoted and only in some cases does the process ultimately give rise to frank leukemia.

### MODELS FOR HTLV-I LEUKEMOGENESIS

The most common outcome of HTLV-I infection is an asymptomatic carrier state; HTLV-I carriers have an estimated lifetime risk of developing ATL of approximately 5%.<sup>44</sup> Therefore, factors other than simple viral infection must be necessary for leukemogenesis. Despite the mono- or oligoclonality of HTLV-I proviral insertions in ATL tumors, the sites of proviral insertion are random from patient to patient, indicating that *cis*-acting insertional mutagenesis does not play a role in tumorigenesis. Nor does the virus appear to encode a host-derived oncogene: No homologies between human cellular genes and nonstructural HTLV-I genes have been observed. A third genetic mechanism for tumorigenesis, which appears to be a multistep process, is thus implicated, with the Tax protein being central to transformation.

Tax promotes viral gene expression by indirectly activating the viral promoter in the LTR via interaction with cellular transcription proteins. However, the interaction of Tax with various transcription factors also transactivates numerous cellular gene promoters. A molecular basis for the pleiotropism of Tax was shown to reside in its interaction with the conserved basic regions of varied basic region-leucine zipper DNA-binding domains within such factors, thus altering both affinity and selectivity of the factors for varied cellular promoters.<sup>45,46</sup> The numerous cellular transcription pathways activated by Tax in this way include activating transcription factor/cyclic AMP-responsive element binding protein(ATF/CREB), nuclear factor (NF)- $\kappa$ B/c-Rel, and serum response factor.<sup>47,48</sup> Tax is able to bind directly to the TATA-binding protein, a component of the transcriptional complex, and to p300 and CREB-binding protein, both of which are transcriptional coactivators.<sup>49</sup>

Among the cellular genes transactivated by Tax, the most relevant are the IL-2 and IL-2 receptor (IL-2R) genes.<sup>36,50,51</sup> and <sup>52</sup> Unlike normal resting T cells, ATL cells and T cells transformed *in vitro* by HTLV-I constitutively express the  $\alpha$  chain of the IL-2 receptor at high levels that cannot be down-regulated. In this way, an autocrine loop might arise, stimulating continuous proliferation of infected cells. The autocrine mechanism is not sufficient to explain leukemogenesis, however. For example, in contrast to the invariable expression of IL-2R, not all HTLV-I immortalized cells express IL-2.<sup>53</sup> Possible interactions between another HTLV-I protein (p12I) and the gamma subunit of IL-2R may contribute to the ligand-independent activation of this receptor,<sup>54</sup> resulting in stimulation and expansion of the pool of infected cells at risk for further genetic alteration.

In regard to the latter process, Tax also has been shown to down-regulate expression of a cellular DNA repair enzyme, beta-DNA polymerase,<sup>55</sup> a potentially straightforward link to accelerated accumulation of mutation. In addition, expression of a large number of genes involved in cell proliferation is transactivated by Tax. These include granulocyte-macrophage colony-stimulating factor (GM-CSF), the protooncogenes *c-fos* and *c-sis*, HLA class I molecules,<sup>56</sup> vimentin, and tumor necrosis factor.<sup>19,20,41,42</sup>

The IL-2 independence of HTLV-I-infected T cells involves a cell signaling pathway in which receptor-associated protein kinases in the Janus kinase (Jak) family

phosphorylate cytoplasmic transcription factors called *STATS* (for signal transducers and activators of transcription).<sup>57</sup> After phosphorylation, *STATS* translocate to the cell nucleus and bind to specific DNA elements to modulate transcription. The Jak-*STAT* pathway is triggered by IL-2 in normal T cells; however, transition to IL-2 independence after HTLV-I infection was associated with constitutive activation of the pathway.<sup>58,59</sup>

Tax also has been shown to interact with and presumably inactivate a number of cell-cycle-related proteins, including the cyclin-dependent kinase (cdk) inhibitor p16<sup>INK4A</sup> and the cell-cycle checkpoint protein MAD1.<sup>47,60,61</sup> Tax activates the promoter of p21<sup>waf1/cip1</sup>, also a cdk inhibitor, and through the activation of the ATF/CREB pathway, suppresses the activity of p53, which can prevent p53-induced apoptosis.<sup>47,54,60</sup> It also has been suggested that constitutive action of the IL-2 receptor pathway allows cells, through an unknown mechanism, to avoid apoptosis.<sup>62</sup>

In summary, although the exact steps in HTLV-I-induced leukemogenesis are unclear, Tax seems to play a critical role by direct interaction with cellular proteins involved in transcription, cell-cycle regulation, cell proliferation, and apoptosis. Whatever the role of the virus, however, it seems that a second mutational event is necessary for the transition from cell immortalization to monoclonality and acute ATL. Immortalization and propagation of cells probably allows alterations in the cell cycle and apoptosis pathways to accumulate, allowing a transformed clone to emerge.

### CLINICAL FEATURES OF HTLV-I DISEASE

The clinical presentation, differential diagnosis, and treatment of ATL are discussed elsewhere in this volume, but are described briefly here.<sup>44</sup> In acute ATL, the tumor aggressively infiltrates multiple organs, commonly involving lymph nodes, liver, spleen, skin, and lung. Median survival is measured in months. The age of onset averages 58 years (range, 24 to 85 years), with a male to female ratio of 1.4:1. Either a leukemic or a non-Hodgkin's T-cell lymphoma presentation may predominate. ATL has been classified into four stages: acute, chronic, smoldering, and lymphomatous.<sup>63</sup> Hypercalcemia is commonly seen in the acute and lymphomatous types; death is often the result of opportunistic infection.

The differential diagnosis includes mycosis fungoides, Sézary syndrome, Hodgkin's disease, and T-cell chronic lymphocytic leukemia. HTLV-I seropositivity, negative terminal deoxynucleotidyl transferase (TdT) staining, and CD4 positivity are characteristic of ATL. Detection of a mono- or oligoclonally integrated HTLV-I provirus makes the diagnosis definitive.

In addition to ATL, HTLV-I is also associated with tropical spastic paraparesis/HTLV-associated myelopathy (TSP/HAM), a chronic progressive neurologic disorder.<sup>44</sup>

### HUMAN T-CELL LEUKEMIA VIRUS TYPE II

HTLV-II is closely related to HTLV-I, sharing the same overall genetic organization and 70% homology at the amino acid level. Although it also infects and transforms T cells *in vitro*, HTLV-II is preferentially tropic *in vitro* for the CD8+ subset.<sup>64</sup> The virus was isolated in 1982 from a patient with atypical T-cell variant hairy cell leukemia and subsequently from two other individuals.<sup>65</sup> Other disease associations have been reported; however, convincing epidemiologic data for an etiologic role for HTLV-II in human disease are lacking. Most patients with either T- or B-cell hairy cell leukemia are not HTLV-II infected, and so far no disease has a demonstrated increased incidence in HTLV-II-infected populations. In contrast to HTLV-I, HTLV-II is able to transform T cells in a manner not dependent on activation of the Jak/*STAT* pathway,<sup>66</sup> although the exact mechanism of cell transformation by HTLV-II remains unknown.

HTLV-II is transmitted by the same routes as HTLV-I. Like HTLV-I, and unlike HIV, the genome of HTLV-II is quite stable. Again, this is postulated to be due largely to the latent infection and expansion of infected cells within a person and to transmission being mainly via infected cells, as opposed to free virus.<sup>67</sup> HTLV-II is recognized to be endemic in African pygmies and in many indigenous New World populations, including the Navajo, Pueblo, and Seminole Indians in North America, the Guyami Indians in Panama, and various quite widely separated and remote tribes in South America.<sup>68</sup>

### HUMAN IMMUNODEFICIENCY VIRUS

Although the annual incidence of HIV infection in the United States declined in the late 1990s, HIV disease remains a formidable global health problem. New infections continue at a significant rate, particularly in parts of the world such as Southeast Asia. In addition, a large number of asymptomatic HIV-infected persons are expected to develop AIDS. Newer pharmacologic therapies have slowed the rate of progression to AIDS, but do not eradicate infection.<sup>69,70</sup> Treatment failures due to noncompliance or drug resistance are common, the drugs themselves have a number of potentially serious side effects, and the cost of lifelong therapy can be prohibitive, particularly in underdeveloped countries.

HIV-1 and HIV-2 are members of the lentivirus subfamily of retroviruses. It is now known that both viruses became human pathogens after zoonotic (cross-species) transmission to humans from primate reservoirs. Sooty mangabeys (*Cercocebus atys*) are the reservoir of simian immunodeficiency virus strain sm (SIVsm) and the probable ancestor of HIV-2.<sup>71</sup> A subspecies of common chimpanzee (*Pan troglodytes troglodytes*) inhabiting west equatorial Africa is the reservoir of SIVcpz and the source of at least three independent transmissions of this virus to humans, resulting in the evolution of HIV-1 groups M, N, and O.<sup>72</sup> The hunting and preparation of chimpanzees for food, a common practice in equatorial Africa, provides the most likely mechanism by which the zoonotic infections occurred. Although HIV-2 can also cause AIDS in humans and monkeys, the majority of AIDS cases worldwide are the result of HIV-1 infection. Therefore, this discussion focuses on HIV-1 disease.

As with HTLV-I, the HIV genome and replication cycle are complex (Fig. 10.1-3). In sharp contrast to HTLV-I, however, HIV replicates actively after initial infection, which results in high levels of viremia.<sup>73,74</sup> and <sup>75</sup> This high rate of replication, in concert with a high mutation rate, results in the extreme genetic variability that has been documented for HIV-1. This variability occurs both within individual patients, among patients, and between definable geographic subtypes.<sup>13,74</sup> HIV, unlike HTLV-I, is highly cytopathic for CD4+ T cells.

**FIGURE 10.1-3.** Human immunodeficiency virus (HIV) genome. Overall, the genomic organization of HIV is the same as for the simpler retroviruses, with *gag*, *pol*, and *env* genes flanked on each end by long terminal repeats (LTR). HIV also encodes other proteins involved in the viral replication cycle.

HIV encodes two *trans*-acting proteins, Tat and Rev, that are analogous in function to the HTLV proteins Tax and Rex.<sup>76</sup> Like HTLV-I Tax, HIV Tat is necessary for efficient expression from the viral promoter in the 5' LTR. At a molecular level, however, Tat and Tax act through different mechanisms. Instead of interacting indirectly with a region of the proviral LTR via interactions with cellular transcription factors, Tat interacts directly with a 5' region of HIV RNA known as the *trans*-activating region (TAR) and promotes processive transcription through further interactions with cellular factors that modify RNA polymerase II function.

In contrast, HTLV Rex and HIV Rev use similar mechanisms to promote expression of viral structural and enzymatic proteins. Rex and Rev bind to their respective RNA response elements, *rxre* and *rre*, to mediate the export of full length and singly spliced viral transcripts from the nucleus to the cytoplasm. In addition to Tat and Rev, HIV encodes a number of accessory proteins not found in other retroviruses.<sup>76</sup> These include Vif, Vpr, and Nef, the functions of which are not yet fully

elucidated. The protein Vpr contributes to the ability of HIV to infect nondividing cells, a property unique to lentiviruses.

The immunodeficiency resulting from HIV infection can contribute to tumor development and patient prognosis. There is, however, little evidence that HIV is directly oncogenic.<sup>77</sup> Although HIV infection may contribute to the pathogenesis or complicate the treatment of neoplastic diseases, no viral protein has been shown to be directly transforming. Transduction of cellular oncogenes has not been observed. Despite rare reports of insertional mutagenesis resulting in T-cell lymphoma,<sup>78</sup> this disease does not occur disproportionately in HIV infection.

In HIV infected persons, non-Hodgkin's lymphoma, Kaposi's sarcoma (KS), Hodgkin's disease, and cervical cancer are all AIDS-defining illnesses. Many of the neoplasms common to AIDS patients are associated with infection by DNA viruses. These include human herpes virus-8 (HHV-8), Epstein-Barr virus (EBV), and human papillomavirus.<sup>79</sup> These viruses and their associations with oncogenesis are discussed in detail elsewhere in this volume, but are mentioned briefly here.

The tumor biology of KS is not well understood.<sup>80</sup> Unlike most tumors that have readily identifiable neoplastic cells, KS tumors are histologically complex. The predominant cell and the most likely candidate tumor cell of KS is the spindle cell, but other cells, including infiltrating leukocytes, are present in the tumor. It is unclear how much of the tumor is made up of true neoplastic cells versus hyperplastic, secondary inflammatory, or angiogenic cells. Instead of monoclonality, a polyclonal, multicentric proliferative process seems to occur, which is reflected in the frequently observed waxing and waning clinical course of KS. For example, lesions may disappear in one region, only to be supplanted by new lesions elsewhere. Although evidence supports HHV-8 as the etiologic agent of KS, HIV is clearly an important cofactor in KS development.

In addition to immunodeficiency induced by HIV-1 infection, the viral Tat protein also may be involved in the pathogenesis of KS. Tat increases the level of a variety of cytokines, including interferon- $\gamma$ , tumor necrosis factor- $\alpha$ , IL-1, and IL-6.<sup>81</sup> These factors may promote growth of endothelial cells and production of angiogenic substances, including basic fibroblast growth factor and vascular endothelial growth factor.<sup>82,83</sup> Additionally, Tat protein that is released from HIV-infected cells can be taken up by other cells, thereby widening its potential effects.<sup>84</sup> Thus, a complex interplay between HIV, the cytokines induced by HIV infection, and HHV-8 may provide the microenvironment and stimulus for KS development.<sup>80,85,86</sup>

AIDS patients are also at increased risk for the development of non-Hodgkin's lymphomas.<sup>87,88</sup> and<sup>89</sup> The majority of these lymphomas are of B-cell origin, and many are associated with EBV infection or with rearrangements of *c-myc*. In general, these malignancies carry a poor prognosis. An aggressive form of non-Hodgkin's lymphoma seen in AIDS patients is primary central nervous system lymphoma, a malignancy that is rare in the general population. Unlike the systemic lymphomas, primary central nervous system non-Hodgkin's lymphoma is nearly universally associated with EBV infection. In this respect it is similar to the posttransplant lymphoproliferative disorder seen in organ transplant recipients. Another form of systemic non-Hodgkin's lymphoma, primary effusion lymphoma, has been associated with infection by HHV-8; co-infection of cells with EBV also has been observed.<sup>90,91</sup> Multicentric Castleman's disease also is associated with HHV-8 infection.<sup>92</sup> The role that HIV itself might play in the genesis of the AIDS-associated lymphoproliferative disorders is not clear. In addition to the immunosuppression caused by T-cell depletion, it has been theorized that HIV may contribute to lymphomagenesis by affecting cytokine production and by altering B-cell regulation.

Cervical carcinoma and anal squamous cell carcinoma are two other malignancies seen in AIDS patients; both are associated with human papillomavirus infection. These malignancies may present in a more advanced or invasive form than in non-HIV-infected patients. Immune suppression may support development of and complicates treatment of these tumors, but at this time there is no evidence that HIV plays a more direct role in their genesis.

## HEPATITIS C VIRUS

HCV infection is a well-established risk factor for the development of hepatocellular carcinoma (HCC), although its role in oncogenesis may not be direct.<sup>93,94</sup> HCV belongs to the *Flaviviridae* family of viruses. Virions consist of a single-stranded plus sense RNA molecule surrounded by a nucleocapsid and envelope.<sup>95</sup> The viral genome is approximately 9500 nucleotides long and has a single, large open reading frame encoding viral proteins. The 5' leader sequence of the viral genome contains stem-loop structures, one of which acts as an internal ribosome entry site (IRES). The 5' end of the large open reading frame encodes the capsid (C) protein and envelope (E1,E2) glycoproteins, whereas the enzymatic proteins are encoded by the 3' end. These enzymatic proteins include a metalloprotease, a serine protease and helicase, and the RNA-dependent RNA polymerase responsible for viral nucleic acid replication. The extreme 3' end of the RNA genome contains a short untranslated region.

After entry into cells, the viral genome is replicated by the viral-encoded RNA-dependent RNA polymerase via a minus-strand RNA intermediate; no DNA copy is made. Plus strand viral RNA molecules lack the usual CAP modification at the 5' end of mRNAs and are translated into a single polypeptide, making use of the IRES to initiate translation. The polypeptide produced is processed to yield all HCV enzymatic and structural proteins, including the core and envelope proteins. Genomic RNA and structural proteins associate to form progeny virus particles, which are released from cells, most likely through the endoplasmic reticulum and host cell secretory pathways.

HCV is transmitted by contaminated blood products, by shared needles of intravenous drug users, perinatally, and via sexual routes, but in approximately 10% of cases known risk factors for transmission are not identified. It is estimated that approximately 3 million people in the United States are chronically infected with HCV.<sup>96</sup> HCV infection is strongly associated with the development of cirrhosis and HCC, although the regional prevalence of HCV infection in HCC varies.<sup>96,97</sup> HCV infection is chronic in 75% to 85% of cases, with a subset of people developing chronic hepatitis and cirrhosis. The rate of HCC development in those with cirrhosis is estimated to be 1% to 4% per year. However, an individual patient's risk for progression to HCC development is difficult to assess because many additional factors affect the likelihood of HCC development. For example, alcohol consumption or co-infection with hepatitis B virus greatly increases the relative risk for developing HCC.<sup>98</sup>

The role of HCV in HCC pathogenesis is not entirely clear. There is a 20- to 30-year period after initial HCV infection before development of HCC. It has been postulated that HCC largely develops indirectly as a result of the inflammatory responses that lead to hepatocyte destruction, regeneration, and fibrosis. Nevertheless, the virus may play a more direct role in neoplastic transformation of hepatocytes. For example, growing evidence suggests that the HCV core protein may contribute to tumor development.<sup>99,100</sup> and<sup>101</sup> Infection by different strains of HCV may also pose different levels of risk for HCC development. Many groups have reported that HCV genotype 1b confers an elevated risk for developing HCC. However, the observed effects were variable and not seen in all studies.<sup>102,103</sup> and<sup>104</sup>

For those infected with HCV, interferon- $\alpha$  therapy is effective in a minority of cases in stably reducing viral load and improving histologic hepatic changes.<sup>105,106</sup> In this subgroup of patients, the risk of HCC development appears to be decreased but not eliminated.<sup>107,108,109</sup> and<sup>110</sup> It is still not certain if this treatment can decrease permanently the risk of developing HCV-associated HCC. Treatment with both interferon and ribavirin, a synthetic guanosine analogue, can increase the number of sustained responders to treatment to 30% to 40%.<sup>111</sup> Unfortunately, attempts at early detection of HCV-associated HCC by ultrasound or  $\alpha$ -fetoprotein levels have not proven effective in reducing HCC-related mortality.

In addition to infecting hepatocytes, HCV can infect hematopoietic cells, including lymphocytes and CD34+ precursor cells. Patients infected with HCV are suggested to be at increased risk for the development of B-cell non-Hodgkin's lymphoma.<sup>112,113</sup> This association, however, has not been observed in all studies. Further studies are needed to resolve fully the potential contribution of HCV infection to the development of some subtypes of B-cell lymphoproliferative disorders.

#### INTRODUCTION

Viral oncology has its foundations in scientific observations made at the turn of the twentieth century and defining the transmissibility of avian leukemia (in Denmark in 1908) and an avian sarcoma in chickens (in 1911).<sup>1,2</sup> These important discoveries were not appreciated at the time, and their impact on virology and medicine was not recognized for decades. The importance of the work of Peyton Rous<sup>2</sup> demonstrating that cell-free extracts from a sarcoma in chickens could, within a few weeks, induce tumors in injected chickens, even when the extracts were passed through filters that retained bacteria, finally was recognized by a Nobel prize in 1968. Rous's original work pointed out that this infectious agent not only was capable of inducing tumors but also imprinted the phenotypic characteristics of the original tumor on the recipient cell. At the time, this early work was relegated to the rank of avian curiosities, and its importance remained unrecognized for several decades.

In the 1930s, Richard Shope published a series of articles demonstrating cell-free transmission of tumors in rabbits. The first studies involved fibromatous tumors found in the footpads of wild cottontail rabbits that could be transmitted by injecting cell-free extracts in either wild or domestic rabbits.<sup>3</sup> Subsequent studies have shown that this virus, now referred to as the *Shope fibroma virus*, is a pox virus. Additional studies carried out by Shope demonstrated that cutaneous papillomatosis in wild cottontail rabbits could also be transmitted by cell-free extracts. In a number of cases, these benign papillomas would progress spontaneously into squamous cell carcinomas in infected domestic rabbits or in the infected cottontail rabbits.<sup>4,5</sup> In general, however, the field of viral oncology lay dormant until the early 1950s, with the discovery of the murine leukemia viruses by Ludwig Gross<sup>6</sup> and of the mouse polyomavirus by Gross et al.<sup>7,8</sup> Such findings of tumor viruses in mice led many cancer researchers and virologists to the field of viral oncology. These researchers hoped that these initial observations in mammals could be extended to humans and that a fair proportion of human tumors might also be found to have a viral etiology. The Special Viral Cancer Program at the National Cancer Institute grew from this intense interest in viral oncology and the hope that human tumor viruses would be identified.

Many of the most important developments in modern molecular biology derive from studies in viral oncology from the 1960s and 1970s. The discovery of reverse transcriptase, the development of recombinant DNA technology, the discovery of messenger RNA (mRNA) splicing, and the discovery of oncogenes and, more recently, tumor suppressor genes all are developments that derive directly from studies in viral oncology. Oncogenes were first recognized as cellular genes that had been acquired by retroviruses through recombinational processes to convert them into acute transforming RNA tumor viruses. It is now recognized that oncogenes participate in many different types of tumors and can be involved at different stages of tumorigenesis and viral oncology. This has contributed significantly to the concepts of nonviral carcinogenesis. It is likely that the direct, transforming, oncogene-transducing retroviruses do not play a major causative role in naturally occurring cancers in animals or in humans but rather represent laboratory-generated recombinants. A list of human viruses with oncogenic properties is presented in [Table 10.2-1](#). This list includes such viruses as the transforming adenoviruses, which are capable of transforming normal cells into malignant cells in the laboratory but which have not been associated with any known human tumors. The list also includes viruses such as the papillomaviruses, which have been etiologically associated with specific human cancers and which have been shown to encode transforming viral oncogenes. Finally, it includes such viruses as the hepatitis B and C viruses, which have been closely linked with a specific human tumor, hepatocellular carcinoma (HCC), for which the evidence of a *bona fide* viral oncogene remains unclear.

Virus Family	Type	Human Tumor	Comments
Adenoviridae	Types 1, 2, 12	None	—
Herpesviridae	Herpes B (BHV1)	Hepatosplenic carcinoma	Albino, animal, smoking
Herpesviridae: gamma-herpes	Herpes C (EBV)	Hepatosplenic carcinoma	—
Herpesviridae	Epstein-Barr (EBV)	Burkitt's lymphoma	Salivary
		Nasopharyngeal carcinoma	Non-malignant
		Thyroid carcinoma	Non-malignant, HLA genotype
		Cholangiocarcinoma	—
	KSHV (HHV8)	Spinal sarcoma	EBV infection
		Body cavity fluid carcinomas	EBV infection
		Cardiac fibrosarcoma	EBV infection
Papillomaviridae	HPV 16, 18, 31, 33, 35	Epithelial cancers and some upper airway cancers	Smoking, other factors
	HPV 16, 18, 31	None known	Genetic defects, sunlight exposure, immunosuppression
Polyomaviridae	SV40	Thyroid cancer	—
	JC virus	—	—
	BK virus	—	—
Retroviridae	HTLV-1	Adult T-cell leukemia or lymphoma	Overweight

TABLE 10.2-1. Human Viruses with Oncogenic Properties

This chapter focuses primarily on the DNA viruses that have been associated with specific human cancers and discusses the biology and pertinent molecular biology of these viruses. [Chapter 10.1](#) deals with the RNA viruses, particularly the human retroviruses. The evidence pertaining to the association of each of these viruses with specific types of human neoplasia is presented, and the mechanisms by which these viruses may contribute to malignant transformation are discussed.

#### HEPADNAVIRUSES AND HEPATOCELLULAR CARCINOMA

HCC is one of the world's most common malignancies. Though rare in the West, the disease is highly prevalent in Southeast Asia and sub-Saharan Africa. In the 1970s, this distribution was recognized to mirror the distribution of chronic hepatitis B virus (HBV) infection. This fact, and the long-recognized histopathologic association between HCC and chronic hepatitis in the surrounding nontumorous liver, led to the strong presumption that chronic HBV infection predisposes to hepatic cancer.<sup>9</sup> This presumption has been strikingly validated in large prospective epidemiologic studies in Taiwan, in which chronically infected individuals were followed for deaths due to this tumor.<sup>10</sup> These studies showed that chronic HBV infection is associated with a 100-fold increase in HCC risk over that of controls who are not chronically infected.

HBV is a small DNA virus classified as a member of the hepadnavirus family (for *hepatotropic DNA viruses*); for review, see Ganem and Schneider.<sup>11</sup> HBV is the only human virus in this family, which also includes related viruses of woodchucks [woodchuck hepatitis virus (WHV)], ground squirrels [ground squirrel hepatitis virus, (GSHV)], and ducks [duck hepatitis B virus (DHBV)] ([Table 10.2-2](#)). Primary infection of susceptible hosts with HBV produces either a subclinical infection or acute hepatitis B, depending on the age of the host and many other poorly understood factors. In adult hosts, 95% of such infections resolve, with clearance of virus from liver and blood and the induction of lasting immunity to reinfection. However, 5% of these infections do not resolve but result in persistent hepatic infection and viremia; most of the demonstrated HCC risk falls within this subgroup of infections. Persistent HBV infections usually last for the life of the host and can have a variety of pathologic consequences. In many hosts thus affected, such infections are subclinical and accompanied by little hepatocellular injury. This asymptomatic carrier state provides evidence that the HBV replication cycle is not directly cytopathic for host cells, an inference that has been strongly sustained by studies of viral replication in cultured cells.<sup>11</sup> Nonetheless, 20% to 25% of persistently infected hosts display hepatocellular injury, in the form of either chronic persistent hepatitis

(inflammation limited to the periportal areas, with scant necrosis and no disruption of hepatic architecture) or chronic active hepatitis (necroinflammatory changes extending from portal to central areas). The latter is considered a severe lesion with significant potential to progress to cirrhosis and liver failure.

	HBV	HBV	GHV	DHBV
Genome	3.2 kb	3.3 kb	3.5 kb	3.8 kb
ORF	S, C, P, X	S, C, P, X	S, C, P, X	S, C, P

TABLE 10.2-2. The Hepadnavirus Family

It is thought that in such hosts, the hepatocyte injury is due to host immune responses triggered by recognition of viral antigens presented on the surface of infected cells.<sup>12</sup> Much has been learned recently about the mechanisms of such injury. Cytotoxic T lymphocytes (CTLs) appear to play a key role in this process. In experiments with transgenic mice expressing viral antigens, transfer of CTLs specific for those antigens leads to a hepatitis, the severity of which depends on the dose of transferred T cells.<sup>13</sup> Importantly, however, direct killing of the cells is only a part of the story.<sup>14</sup> Much of the injury produced in such experiments is due to secondary, antigen-nonspecific responses triggered by the initial CTL activation and cytokine release<sup>15</sup>; release of inflammatory molecules that recruit other inflammatory cell types, production of toxic reactive oxygen radicals, and the like. In addition, infected cells displaying deregulated viral gene expression may display enhanced sensitivity to tumor necrosis factor (TNF) and other inflammatory cytokines.<sup>16</sup>

The induction of hepatocellular injury is believed to be important in HCC pathogenesis because it triggers in the liver a stereotypical proliferative response. Two types of regenerative response are known in the liver, which depend to some extent on the nature of the hepatic insult. (The mechanisms by which these responses occur remain obscure.) In classical liver regeneration (as observed, for example, after a partial liver resection), all mature hepatocytes in the liver—which, under normal circumstances, are nondividing—synchronously reenter the cell cycle, resulting in the prompt restoration of normal hepatic mass.<sup>17</sup> A somewhat different proliferative response is observed after treatment with certain toxic or carcinogenic chemicals. In this response, poorly characterized cells in the periductal areas (termed *oval cells*, largely on the basis of their morphology) undergo expansion. These cells are thought to be precursor cells to both bile duct epithelium and hepatocytes.<sup>18</sup> They also share many of the biochemical properties of cells seen in hepatic cancers (e.g.,  $\alpha$ -fetoprotein production) and, for this reason, are thought by some to be the target cell for transformation in hepatic carcinogenesis by a variety of agents. Although it is likely that both forms of proliferative response are operative in chronic hepatitis, considerable debate continues to surround this issue.

However, the fact that major liver cell proliferation is operative throughout the prolonged preneoplastic period is undisputed and is believed to be an important precondition for carcinogenesis. Such proliferation increases opportunities for replicative errors (mutations) that, over time, can contribute to the loss of normal cellular growth control; cells harboring such mutations will have a selective advantage that further perpetuates this cycle. Attesting to the importance of cellular injury and turnover in HCC development is the fact that HCC usually is accompanied by pathologic signs of severe liver injury (chronic active hepatitis and cirrhosis) in the nontumorous liver; it is distinctly uncommon to see hepatoma in hosts whose livers contain minimal evidence of injury.

In the preceding formulation, HBV serves as an agent of oncogenesis chiefly by (indirectly) provoking cellular proliferation in response to immune-mediated injury. In this view, no direct genetic contribution is made by viral sequences acting *in cis* or viral gene products acting *in trans*. If this view is correct, then other agents, which similarly provoke chronic liver cell injury and regeneration, should likewise be associated with hepatic cancer. In this connection, it is of interest that chronic infection with hepatitis C virus, a genetically unrelated hepatotropic RNA virus that similarly produces chronic hepatitis, also confers an increased risk for HCC development.<sup>19</sup>

Despite strong experimental support for the pathogenetic scheme just presented, there is reason to believe that hepadnaviruses may also make a more direct genetic contribution to HCC. Phylogenetic analyses of hepadnaviral genome organization reveal that the structure of the oncogenic mammalian viruses differs from that of the nononcogenic avian viruses in an important way.<sup>11</sup> The mammalian viruses all harbor an additional coding region, termed *ORF X* (for *open reading frame X*; Fig. 10.2-1), that encodes a small regulatory protein.<sup>20</sup> This open reading frame is absent in the avian viruses, which fail to induce HCC in their native hosts despite the regular induction of persistent infection. Interestingly, in several lines of transgenic mice displaying constitutive hepatic expression of *ORF X*, HCC arises with increased frequency.<sup>21,22</sup> Tumors in such mice do not begin until midlife, suggesting that additional genetic changes are necessary for loss of normal growth control.

FIGURE 10.2-1. Genomic and transcriptional organization of the human hepatitis B virus. The inner circle represents the partially double-stranded virion DNA, with dashes specifying the single-stranded genomic region. The locations of the direct repeat (DR1 and DR2) regions are indicated. The boxed arcs specify the viral coding regions, and the arrows indicate the direction of translation. The outermost wavy lines depict the viral RNAs identified in infected cells, with the arrows indicating the direction of transcription and the AAAs indicating the polyadenylated 3' tails. ORF, open reading frame.

The sequence of *ORF X* reveals no homology to known oncogenes or growth regulatory loci, and little is known of its biochemical function. In transient cotransfection assays, *X* expression up-regulates a wide variety of viral and cellular promoters, but the mechanism by which this activation is achieved has remained obscure. In some situations, *X* appears to stimulate cytoplasmic signal transduction pathways (e.g., the ras-raf MAP kinase pathway),<sup>23,24</sup> whereas in other settings, it may function as a nuclear transcriptional activator.<sup>25,26</sup> It has also been suggested that *X* protein might bind to and inactivate the tumor suppressor gene product p53,<sup>27</sup> but such reports require confirmation. The relationship of all of these activities to the putative oncogenic function of *ORF X* is unproven.

Another class of more direct genetic contributions that HBV might make to HCC derives from the existence of integrated copies of viral DNA in the tumor cells. Unlike retroviruses, hepadnaviruses do not specify genetic functions directing genomic integration, and such integration is not essential for HBV replication.<sup>11</sup> (HBV replication actually proceeds from episomal DNA via reverse transcription of an RNA intermediate.) In fact, because every nucleotide of the viral genome is in a coding region, integration of HBV DNA generally disrupts essential genes and is incompatible with replication. Yet most hepatoma cells arising in HBV-infected patients harbor multiple integrated HBV genomes, and in general, active viral replication has been extinguished.<sup>28</sup> The tumors are clonal with respect to these viral insertions: All cells of the tumor bear the same pattern of integrated sequences, indicating that integration preceded or accompanied the final transforming event. However, close inspection of these integrated sequences indicates that they usually are highly rearranged, with multiple deletions, inversions, reduplications, or other mutations typically present.<sup>28</sup> Although individual integrated sequences may retain certain coding functions, no one viral coding region is invariably preserved, as are

E6 and E7 of the human papillomaviruses (HPVs; see the section [Papillomaviruses and Human Cancer](#)).

These facts have led to interest in the model that the viral sequences might be contributing *cis*-acting regulatory signals rather than *trans*-acting proteins to the host cell. Ample precedent for such a model exists in retroviral oncogenesis in animals, wherein insertion of powerful retroviral enhancer sequences into the chromosome can activate the expression of growth-regulatory genes flanking the insert. Strong evidence that hepadnaviruses can mediate such activation events *in cis* has been proffered for WHV. WHV is strikingly oncogenic in its native host: Virtually 100% of animals chronically infected from birth will develop HCC. <sup>29</sup> The oncogenic drive in an infected animal is remarkably strong; many adult animals can be shown to harbor multiple independent HCCs. As in HBV-induced cancer, the tumors display multiple viral insertions, often highly rearranged, and in a clonal pattern. However, here, remarkably, the vast majority of tumors can be shown to harbor at least one viral insertion *in cis* to the protooncogene N-myc.<sup>30,31 and 32</sup> This gene, normally silent in adult liver, is strongly up-regulated by this insertion, and such activation can be seen early in the oncogenic sequence, even in premalignant lesions. <sup>33</sup> Many insertions are within a few kilobases of the N-myc locus, but insertions as far away as 250 kb appear to be activating.<sup>31</sup> Clearly, insertional activation of N-myc plays a major role in WHV oncogenesis.

Similar efforts to identify common integration sites for integrated HBV genomes in human HCC have not met with comparable success. Human hepatomas do not harbor N-myc rearrangements and, although isolated examples of dramatic insertion events have been described (e.g., insertions near loci for retinoid receptors or cyclin A homologues), none of these has been identified in more than one tumor, despite extensive searches. <sup>34,35</sup> The practitioner does well to remember that, despite its many similarities to HBV, WHV differs strikingly in its oncogenic potency; it is possible that insertional activation of N-myc loci is responsible for this difference.

## PAPILLOMAVIRUSES AND HUMAN CANCER

The viral nature of human warts was first demonstrated at the turn of the century by transmission using a cell-free filtrate. <sup>36</sup> This important group of viruses has remained refractory to standard virologic studies, however, because propagating the papillomaviruses in the laboratory in tissue culture under standard conditions is difficult. Although some advances have been made in propagating the virus using organotypic raft cultures of epithelial cells, most knowledge about the molecular biology and genetics of the papillomaviruses has resulted from advances in basic research and the application of reverse genetics using cloned viral DNAs.

The papillomaviruses are found in many higher vertebrate species ranging from birds to humans. Although originally classified as papovaviruses because of their icosahedral shape and circular, double-stranded DNA genome, the papillomaviruses now are recognized to be separate from the other papovaviruses such as polyoma and simian virus 40 (SV40), on the basis of different biologic and genetic characteristics. The papillomaviruses contain a double-stranded circular DNA genome of 8000 base pairs, which is larger than the polyomaviruses (5000 base pairs), and the virion particles have a correspondingly larger capsid diameter (55 nm vs. 40 nm). The papillomaviruses have not yet been propagated in tissue culture under standard conditions.

More than 80 different HPV types have been described in detail to date, <sup>37</sup> and evidence exists that there may be as many as 30 to 40 additional viruses that have not yet been as well characterized. Unlike some human viruses such as adenoviruses, it has not been possible to type the papillomaviruses by serologic methods, as antisera that can distinguish between the different HPV types are currently not available. Through the 1970s and 1980s, the HPVs were typed by DNA hybridization under stringent annealing conditions, but currently the DNA sequence of a portion of the L1 ORF (in the so-called late region of the HPV genome) is used to define new HPV types. A list of many of the HPV types that have now been categorized, and the clinical syndromes with which they are associated or from which they have been isolated, is presented in [Table 10.2-3](#).

**TABLE 10.2-3.** The Human Papillomaviruses

The papillomaviruses are highly species-specific and induce squamous epithelial and fibroepithelial tumors in their natural hosts. These viruses have a specific tropism for squamous epithelial cells, and their full productive cycle is supported only in squamous epithelial cells. The productive infection of cells by papillomaviruses is divided into stages, and these stages are linked to the differentiation state of the epithelial cell. The specific tropism of the papillomaviruses for squamous epithelial cells is evidenced by the restriction of the viral replication functions (vegetative viral DNA synthesis, the production of viral capsid proteins, and the assembly of virions) to the most terminally differentiated keratinocytes.

In a normal squamous epithelium, the basal cell is the only cell normally capable of supporting cellular DNA synthesis and undergoing cellular division. The virus, therefore, must infect the basal cell to establish a persistent lesion. *In situ* hybridization experiments have demonstrated that the papillomavirus DNA is indeed present within the basal cell of a papilloma. <sup>38</sup> In a squamous epithelium, as the cells migrate upward through the stratum spinosum and into the granular layer, they undergo a program of differentiation. The control of papillomavirus late gene expression is tightly linked to the differentiation state of the squamous epithelial cells. <sup>39</sup> Vegetative viral DNA synthesis and expression of the capsid proteins occurs only in the more differentiated squamous epithelial cells.

All HPV types examined to date have a similar genomic organization. The DNA genomes of each of the HPVs sequenced, as well as of the other animal papillomaviruses, are approximately 8000 base pairs in size. All of the ORFs that could serve to encode proteins are located on only one of the two viral DNA strands. RNA studies have indicated that only one strand is transcribed. A more detailed description of the molecular biology of the papillomaviruses can be found in the current edition of *Field's Virology*.<sup>40</sup>

The HPV genome can be divided into two distinct regions: an "early" region, which encodes the viral proteins involved in viral DNA replication, transcriptional regulation, and cellular transformation, and a "late" region, which encodes the viral capsid proteins. This functional division is based largely on genetic studies that were carried out with the bovine papillomavirus. <sup>41</sup> A diagram of the organization of a typical HPV-16 is shown in [Figure 10.2-2](#). The genes located in the early region of the genome are designated as *E1*, *E2*, and so on, and the genes located in the late region are designated as *L1* and *L2*. Studies with the HPVs indicate that it is likely that *E4* encodes a "late" gene, which is expressed only in productively infected keratinocytes. <sup>42</sup> Thus, although this ORF is located with the early ORFs, its function may be important only in the vegetative replication of the virus. A listing of the functions assigned to the HPV-16 ORFs is provided in [Table 10.2-4](#).

**FIGURE 10.2-2.** The genomic map of human papillomavirus-16 (HPV-16) deduced from the DNA sequence. The nucleotide numbers are noted within the circular maps, transcription proceeds clockwise, and the major open reading frames (E1 to E7, L1, and L2) are indicated. The only transcriptional promoter mapped to data for HPV-16 is designated P97. The viral long control region (LCR) containing the putative viral transcriptional and replication regulatory elements is noted. The closed circles on the genome represent the four E2 binding sites, which have been noted in the LCR. (From ref. 16, with permission.)

ORF	Function
L1	L1 protein, major capsid protein
L2	L2 protein, minor capsid protein
E1	Initiation of viral DNA replication, helicase, adenosine triphosphatase
E2	Transcriptional regulatory protein, auxiliary role in viral DNA replication, complexes E1
E4	Late protein; disrupts cytokeratins
E5	Membrane transforming protein may interact with growth factor receptors
E6	Transforming protein of HPV; targets degradation of p53; activates telomerase; other potential targets
E7	Transforming protein of HPV; binds to the retinoblastoma protein and other "pocket proteins"

HPV, human papillomavirus; ORF, open reading frame.

**TABLE 10.2-4.** HPV-16 Gene Functions

In productively infected tissue (i.e., tissue in which viral particles are made, such as a wart), mRNA is transcribed from the early and late regions of the genome.<sup>39</sup> Nonproductive infection of host cells (as seen in the lower cells of the epithelium in a wart) is accompanied by transcription of mRNA from only the early region of the genome. The restricted expression of the genome to only the early region involves regulation of transcription at the levels of the initiation of RNA synthesis, RNA stability, and transcriptional termination.

The molecular biology of the papillomaviruses has been most extensively studied for the bovine papillomavirus (BPV-1), which is capable of transforming a variety of rodent fibroblast cell lines in tissue culture. In these transformed cells, the DNA remains as a stable extrachromosomal plasmid, and this system has served as an excellent model for studying latent infection by papillomavirus (reviewed in Spalholz and Howley<sup>43</sup>). This virus has served as the prototype for unraveling many aspects of the molecular biology of the papillomaviruses over the last 20 years. Two independent transforming activities have been mapped in BPV-1: one to the E5 gene and the other to the E6 and E7 genes. Transformation by the BPV-1 E5 oncoprotein appears to be mediated through activation by binding of the platelet-derived growth factor- $\beta$  (PDGF- $\beta$ ) receptor.<sup>44</sup> The mechanisms by which the E6 and E7 genes of BPV-1 transform have not yet been fully elucidated. BPV-1 E6 has been shown to bind the focal adhesion protein paxillin, and the binding of E6 to paxillin has been implicated in the cellular transformation phenotype through the disruption of the actin cytoskeleton.<sup>45,46</sup>

The papillomavirus E2 proteins are regulatory proteins that have roles in viral DNA replication and in viral transcription. E2 is a DNA-binding protein that was first described as a transcriptional activator<sup>48</sup>; however, subsequent studies have shown that it can also function as a transcriptional repressor depending on the context of the E2 binding sites within the promoter.<sup>49</sup> E2 has several roles in viral DNA replication and plasmid maintenance in infected cells.<sup>50</sup> E2 ensures viral DNA partitioning in persistently infected cells by tethering the viral DNA to the mitotic chromosomes during mitosis.<sup>51,52</sup> E2 also binds to the viral E1 protein and cooperatively promotes origin-dependent viral DNA replication.<sup>53,54</sup> The E1 gene encodes a protein necessary for extrachromosomal replication and has been shown to have DNA-binding, DNA helicase, and adenosine triphosphatase activities.<sup>55,56</sup> No function has yet been found for the E3 or E8 ORFs of BPV-1. The L1 ORF of the papillomaviruses encodes the major capsid protein, and the L2 ORF encodes a minor capsid protein.<sup>57,58</sup> The L1 and L2 ORFs are expressed only in the terminally differentiated keratinocytes.<sup>39</sup>

Although initial papillomavirus transformation studies focused on BPV-1 because it could effectively transform rodent cells in tissue culture, recent studies have focused more on the high-risk HPVs, in particular HPV-16 and HPV-18, which are associated with human cervical cancer. Although the genomic organization of the HPVs is quite similar to that of BPV-1, there appear to be important differences in the mechanisms by which they transform cells. The principal transforming genes for the cancer-associated HPVs have been mapped to E6 and E7, as will be discussed later in this section. E7 alone is sufficient for the transformation of primary rodent cells.<sup>59,60</sup> E7 also is capable of cooperating with an activated *ras* oncogene to transform primary rodent cells.<sup>60</sup> Expression of E6 and E7 together is sufficient for the efficient immortalization of primary human cells, most notably primary human keratinocytes, which are the normal host cell for the HPVs.<sup>62,63</sup> Cellular targets for the HPV E6 and E7 proteins have been identified, as discussed later in this section. HPV E5 may also have transforming activities, but it has not been studied as well as has BPV E5 and does not appear to function through interaction with the PDGF- $\beta$  receptor.

Only a subgroup of the papillomaviruses is associated with lesions that are at risk for progression to cancer. These viruses and their associated malignancies are listed in [Table 10.2-5](#). The papillomavirus that infects cottontail rabbits in nature (CRPV) was first identified by Shope as the etiologic agent of cutaneous papillomatosis in rabbits.<sup>4</sup> CRPV has been extensively studied as a model for papillomavirus-induced carcinogenesis.<sup>5,64</sup> One of the features of carcinogenic progression with the papillomaviruses is the synergy between the virus and carcinogenic external factors (see [Table 10.2-3](#)). In the case of CRPV, carcinomas develop at an increased frequency in virus-induced papillomas that are painted with cool tar or methylcholanthrene.<sup>65,66</sup> These CRPV-associated carcinomas contain copies of the viral DNA that are transcriptionally active, an observation which supports the hypothesis that these viruses play an active role in the cancers that develop. There has been limited study of the molecular mechanisms involved in CRPV-associated carcinogenesis.

Papillomavirus	Cancer	Other Factors
CRPV (Shope)	Skin cancer	Methylcholanthrene
Bovine (BPV-4)	Tongue, esophageal, laryngeal cancers	Bracken fern
Human	Ocular cancer	Chromolipids
Human	Skin cancer	Chromolipids
Human (BPV-4 and others)	Skin cancer (in 23 patients of immunosuppressed patients)	Chromolipids
Human (BPV-16, -18, -31, and other high-risk HPVs)	Cervical cancer, some other sites (including penile cancer)	Smoking, 131C, and contraceptive use

BPV, bovine papillomavirus; CRPV, cottontail rabbit papillomavirus; DL, epidermal dysplasia virus; EBPV, bovine papillomavirus; 131C, 131C-131C-131C.

**TABLE 10.2-5.** Papillomaviruses Associated with Lesions That May Progress to Cancer

In cattle, BPV-4 has been associated with esophageal papillomatosis and also is associated with squamous cell carcinomas of the upper alimentary tract.<sup>67,68</sup> Interestingly, however, only those cattle from the highlands of Scotland that are infected with BPV-4 and that also feed on bracken fern (known to contain a radiomimetic substance) have a high incidence of squamous cell carcinomas of the esophagus and of the foregut.<sup>67</sup> In contrast to the CRPV-associated carcinomas in which the viral DNA can invariably be found, extensive analysis of the squamous cell carcinomas of the upper alimentary tract in these cattle infected with BPV-4 has failed to reveal a consistent pattern of viral DNA sequences within the malignant tumors.<sup>69</sup> In the case of these alimentary tract tumors, possibly the continued presence of BPV-4 DNA sequences is not required for maintenance of the cancer.

The first evidence that HPVs were associated with human cancer came from studies in patients with epidermodysplasia verruciformis (EV), a rare, lifelong disease in humans that usually begins in infancy or childhood (reviewed in Jablonska and Majewski <sup>70</sup>). The disease is characterized by disseminated, polymorphic cutaneous lesions that resemble flat warts and by reddish macules sometimes referred to as *pityriasis-like* lesions.<sup>71</sup> Approximately one-half of the patients with EV develop multiple skin cancers, usually during the third or fourth decade of life. Papillomavirus particles have been detected within the benign lesions and not in the carcinomas. EV is considered an autosomal recessive disorder, and genetic studies of affected families have led to the mapping of a susceptibility gene to 17q, the same region that has been found to contain a dominant locus for the susceptibility to familial psoriasis.<sup>72</sup> It is thus tempting to speculate that distinct defects affecting the same gene may be involved somehow in the pathogenesis of these two hyperproliferative skin conditions. Of interest is that the carcinomas that develop in these patients arise in sun-exposed areas, and it is suspected that ultraviolet radiation plays a cocarcinogenic role with the papillomaviruses in the etiology of these cancers. Although EV is a very rare disease, it has been under intense study by dermatologists and virologists. More than 20 different HPV types have now been demonstrated in individual lesions in patients with this rare disease (see [Table 10.2-3](#)). Furthermore, recent studies have shown that these EV HPVs are widespread and point to psoriasis as a potential reservoir for HPV-5, one of the HPVs commonly found in EV.<sup>73</sup> Whether the EV-associated HPVs also are involved in the pathogenesis of psoriasis remains to be determined.

The cutaneous carcinomas in patients with EV can be bowenoid carcinomas, *in situ* carcinomas, or invasive squamous cell carcinomas. Of the HPV types found in patients with EV, only a subset of them is associated with a risk of malignant progression, most notably HPV-5 and HPV-8, although other types occasionally are found in EV cancers. The role of the HPVs in EV cancers is suggested by the presence of viral DNA of specific HPV types in the EV cancers. Although metastasis is uncommon in the cancers in these patients, the presence of HPV-5 in the two metastatic lymph node lesions examined strengthens the agreement for an etiologic role for HPV in these carcinomas.<sup>74,75</sup> Further studies have established that the viral genomes are transcriptionally active within these carcinomas<sup>76</sup> and that HPV-5 and HPV-8 encode cellular transformation functions.<sup>77</sup> Little work has been done yet to establish the mechanisms by which the EV HPVs contribute to cancer.

The role of HPVs in cutaneous cancers in humans extends beyond EV patients to other patients, both immunosuppressed and immunocompetent. New HPV types have been found in squamous and basal cell carcinomas of immunosuppressed patients and in some of the same tumors in immunocompetent patients.<sup>78,79</sup> However, the cutaneous HPVs are very prevalent in the population, and it has not yet been determined whether the virus has a role in promoting these cancers in immunosuppressed patients or whether it merely persists as a passenger.

The epidemiology of genital warts follows a pattern characteristic of a sexually transmitted disease (STD) with a high prevalence in populations of highly promiscuous women.<sup>80,81</sup> Two general types of genital wart viral infections—condylomata acuminata and squamous intraepithelial lesions (SILs)—are now recognized and can be differentiated by their clinical appearance. Condylomata acuminata can be localized to the penis, the vulva, the perineum, the anus and, rarely, the uterine cervix, and are caused by papillomaviruses. Papillomavirus particles have been demonstrated by the electron microscope.<sup>82,83</sup> HPV-6 and HPV-11 DNAs were directly cloned from condylomata acuminata lesions, and the genomes of these HPV types can be demonstrated in more than 90% of the lesions of condylomata acuminata examined.<sup>84,85</sup> Less frequently, other HPV types can be found in condylomata acuminata. Malignant conversion of condylomata acuminata into squamous cell carcinoma is uncommon. A lesion described by Buschke and Löwenstein and designated as a *giant condyloma* has characteristics similar to a locally invasive squamous cell carcinoma. These tumors are also associated with HPV-6 and HPV-11.<sup>84,85</sup> The majority of cervical carcinomas and other genital tract carcinomas, however, are negative for HPV-6 and HPV-11.

In the mid-1970s, zur Hausen<sup>86</sup> suggested an association between papillomaviruses and genital cancers. Compelling evidence linking an HPV infection with cervical carcinoma came from the recognition that the morphologic changes previously interpreted on Papanicolaou smears and tissue sections of the cervix as cervical dysplasia were due to a papillomavirus infection.<sup>87,88</sup> and <sup>89</sup> The characteristic cell that is diagnostic for a cervical papillomavirus infection is the koilocyte.<sup>90</sup> Electron microscopy demonstrated papillomavirus particles in the koilocytotic cells supporting the papillomavirus etiology.<sup>91,92</sup> Subsequent studies found papillomavirus-specific capsid antigens and HPV DNA within cervical dysplastic lesions, providing confirmation of the viral etiology of cervical dysplasia.

Epidemiologic studies had long implicated an infectious agent in the etiology of human cervical carcinoma.<sup>93,94</sup> Venereal transmission of a carcinogenic factor with a long latency had been suggested by early epidemiologic studies. Sexual promiscuity, an early age of onset of sexual activity, and poor sexual hygiene are known risk factors for cervical carcinoma. There is a correlation between the incidence rates of cervical cancer and penile carcinoma in various geographic areas, although the incidence rates for penile carcinoma are 20-fold lower when compared to those of cervical carcinoma. The similar ratio of incidence between cervical carcinoma and penile carcinoma is maintained, however, in areas of high, medium, or low prevalence, suggesting that the etiologic factors for penile and cervical carcinoma may be the same. The “male factor” also appears to implicate a sexually transmitted agent. Women who are monogamous are at a higher risk for cervical carcinoma if their spouses have multiple sexual partners.

The suggestion that an infectious agent might be involved in the etiology of cervical carcinoma has prompted many studies over the years, evaluating genital pathogens as potential causative agents. Infections by trichomonads, chlamydiae, and bacteria, such as syphilis and gonorrhea, have not been linked to cervical carcinoma. In the late 1960s and early 1970s, genital infection by herpes simplex virus type 2 (HSV-2) was considered as a possible etiologic candidate.<sup>95,96</sup> Support for the notion that HSV might be a cancer-associated virus came from studies demonstrating the ability of HSV to transform certain rodent cells in the laboratory *in vitro* and from some initial serologic studies that suggested a higher frequency of antibodies to HSV-2 in patients with cervical carcinoma. However, subsequent carefully performed molecular studies, attempting to demonstrate HSV RNA or HSV DNA in cervical cancer tissues, could not provide convincing evidence for a role for HSV in cervical cancer.<sup>97</sup> A large prospective epidemiologic study carried out by Vonka et al.<sup>98,99</sup> also failed to support the involvement of HSV-1 or HSV-2 infections in cervical cancer.

The association of an HPV with cervical dysplasia [also referred to as *cervical intraepithelial neoplasia* (CIN) and *SIL*] sparked an examination of cervical cancers for HPV sequences. The natural history linking CIN to carcinoma *in situ* and to invasive squamous cell carcinoma of the cervix had already been well established.<sup>100,101</sup> and <sup>102</sup> Initial experiments from a number of laboratories revealed HPV sequences in occasional cases of cervical carcinoma and anogenital carcinoma, but no consistent pattern of positivity emerged. Using radioactively labeled HPV-11 DNA under conditions of hybridization of low stringency, Durst et al.<sup>103</sup> and Boshart et al.<sup>104</sup> examined human cervical carcinoma DNAs for related HPV DNAs and, in the early 1980s, identified two new papillomavirus DNAs, HPV-16 and HPV-18. Using these HPV DNAs as probes, HPV types 16 and 18 could be demonstrated in approximately 70% of cervical carcinomas.<sup>105</sup> The use of low-stringency hybridization and the polymerase chain reaction with degenerative primers has led to the identification of approximately 20 different HPVs now associated with genital tract lesions (see [Table 10.2-3](#)). HPV-31, -33, -39, -42, and other HPVs are each associated with a small percentage of cervical carcinomas. Specific HPVs can be found regularly in 85% to 90% of human cervical carcinoma tissues and in a lower percentage of other human genital carcinomas such as penile carcinomas, vulvar carcinomas, and perianal carcinomas. The availability of HPV DNA probes has permitted the extensive analysis of specific clinical lesions. Bowenoid papulosis of the penis, also referred to as *penile intraepithelial neoplasia*, is associated with HPV-16 and is the male counterpart of CIN in the female.<sup>106,107</sup> Approximately 20 HPVs are associated with anogenital lesions. These can generally be further classified as either high-risk or low-risk on the basis of whether the genital tract lesions with which these HPVs are associated are at significant risk for malignant progression. Such low-risk viruses as HPV-6 and -11 are associated with venereal warts, whereas such high-risk viruses as HPV-16 and -18 are associated with SILs of the genital tract. The other high-risk viruses include HPV-31, -33, -35, -39, -45, -51, -52, and -56. The 85% to 90% of cervical carcinomas that are HPV-positive contain a high-risk DNA.

Studies of cervical cancers and derived cell lines that are HPV-positive have indicated that the DNA often is integrated, although in some cases the DNA is apparently also extrachromosomal. In those cases in which the DNA is integrated, the pattern of integration is clonal, indicating that the association of the HPV preceded the clonal outgrowth of the tumor. Integration of the viral DNA is not at specific sites in the host chromosome, although in some cell lines the integration event has occurred in the vicinity of known oncogenes. For instance, in the HeLa cell line (which is an HPV-18-positive cervical carcinoma cell line), the integration of the viral genome has occurred within approximately 50 kb of the *c-myc* locus on human chromosome 8.<sup>108</sup> It is not known whether such an integration event provides a selective advantage for the progression of a preneoplastic lesion to a cancer. It does seem plausible that in some individual cancers, the integration of the viral DNA could result in genetic changes such as the activation of a cellular oncogene or the inactivation of a tumor suppressor gene that could contribute to carcinogenic progression.

In HPV-positive cancers, there appears to be a selection for the integrity of the E6–E7 coding region and the upstream regulatory region, which contains the promoter elements that regulate *E6* and *E7* expression. Furthermore, the *E6* and *E7* genes are regularly expressed in HPV-positive cervical cancers.<sup>108,109</sup> and <sup>110</sup> Interestingly, integration of the viral genome into the host chromosome in the cancers often is associated with disruption of the viral *E1* or *E2* genes.<sup>108,109</sup> HPV *E2* is an important viral regulatory factor that can negatively regulate the transcriptional promoter directing the *E6* and *E7* genes.<sup>49,111</sup> The manner of integration observed is such that it results in an increase in the expression of the *E6* and *E7* viral genes. The disruption of the *E2* gene by integration releases the viral promoter of the *E6* and *E7* genes

from the inhibitory activity of *E2*, increasing the expression of these genes. The reexpression of *E2* in HPV-positive cervical cancer cells results in a cell-cycle arrest due to repression of the viral promoter directing expression of the E6 and E7 oncoproteins. <sup>112</sup>

The E6 and E7 proteins encoded by the high-risk HPVs are oncoproteins and contribute to cellular transformation by binding to the cell regulatory proteins p53 and RB, respectively (Fig. 10.2-3). The E7 proteins encoded by the high-risk HPVs share sequence similarity to adenovirus E1A and to SV40 large T antigen, and in all three proteins these regions are critical for the transformation properties of the respective viral oncoproteins. The regions of amino acid sequence similarity between E7 and adenovirus E1A that are shared with SV40 large T antigen are regions that have been shown to participate in the binding of a number of important cellular regulatory proteins, including the product of the retinoblastoma tumor suppressor gene (pRB) and the related “pocket” proteins, p107 and p130. <sup>113,114,115</sup> and <sup>116</sup> The E7 proteins may function in carcinogenic progression, at least in part, through interaction with the product of the retinoblastoma susceptibility gene, *pRB*. One consequence of this interaction is the disruption of a complex between pRB and the E2F-1 transcription factor. <sup>117</sup> The E7-mediated release of E2F from these complexes then activates the expression of genes in cell-cycle progression. Genetic studies indicate, however, that there must be other cellular targets of E7 and that complex formation between E7 and the pocket proteins, including pRB, is not sufficient to account for the immortalization and transforming functions of this viral oncoprotein. <sup>118</sup> Studies in several laboratories have identified additional targets, the physiologic significance of which must still be determined. One intriguing E7 target is the cellular cyclin-dependent kinase inhibitor p21<sup>CIP</sup>, which appears to have a role in skin differentiation. <sup>119</sup>

**FIGURE 10.2-3.** The transforming proteins encoded by three distinct groups of DNA tumor viruses target similar cellular proteins. The binding of human papillomavirus E6 oncoproteins to p53 is mediated by a cellular protein called *E6-associated protein* (E6AP). <sup>124</sup> SV40, simian virus 40.

The immortalization-transformation properties of the E6 protein were first revealed by studies using primary human genital squamous epithelial cell. <sup>62,63</sup> Efficient immortalization of primary human cells by HPV-16 or HPV-18 requires both the E6 and E7 genes. <sup>62,63,120</sup> The ability of the E6 and E7 proteins to cooperate and efficiently immortalize primary human keratinocytes is a characteristic of the high-risk but not the low-risk HPVs. <sup>121,122</sup> Like SV40 large T antigen and the 55-kD protein encoded by adenovirus E1B, the E6 proteins of the high-risk HPVs can enter into a complex with p53. <sup>123</sup> The interaction of E6 with p53 is not direct but is mediated by a cellular protein, called the *E6-associated protein* (E6AP). <sup>124</sup> E6AP is a ubiquitin protein ligase and, in the presence of E6, directly participates in the ubiquitination of p53. <sup>125,126</sup> Multiubiquitinated p53 then is recognized by the 26S proteasome for proteolysis. Consequently, the half-life and level of p53 are low in E6-immortalized cell lines and in HPV-positive cancers. <sup>127,128</sup> Through its ubiquitination of p53, HPV-16 E6 can abrogate the transcriptional activation and repression properties of p53 <sup>129</sup> and disrupt the ability of wild-type p53 to mediate cell-cycle arrest in response to DNA damage. <sup>130</sup> The p53 protein can sense DNA damage and prevent the replication of mutated DNA through its transcriptional activation of the p21 cyclin-dependent kinase inhibitor. Thus, the functional abrogation of p53 by high-risk HPV E6 results in decreased genomic stability and accumulation of DNA abnormalities in high-risk HPV E6-expressing cells. Hence, E6 can be directly implicated in the establishment and propagation of genomic instability, a hallmark in the pathology of malignant progression of cervical lesions. <sup>131</sup>

The high-risk HPV E6 proteins also have other activities that are not linked to their ability to target p53. For instance, it has been shown that expression of the HPV E6 oncoprotein results in the activation of telomerase activity in infected cells. <sup>132</sup> Furthermore, E6 can interact with several additional cellular proteins, including a putative calcium-binding protein referred to as the *E6-binding protein*. <sup>133</sup> and a novel GAP protein, E6TP1. <sup>134</sup> The high-risk HPV E6 proteins as well as the oncogenic BPV E6 protein can complex with paxillin, a cellular focal adhesion protein that may serve as an adapter in transmitting signals from integrin molecules to the actin cytoskeleton. <sup>46,135</sup> The high-risk HPV E6 protein has also been reported to bind p300. <sup>136</sup> HPV-16 E6 can also bind and inhibit the transcription activation function of interferon regulatory factor-3, an interaction that may have more to do with the virus-evading host cell defenses than cellular transformation. <sup>137</sup> It should be noted, however, that the significance of the interaction of E6 with these cellular targets and others described in the literature, other than p53 through E6AP, has yet to be fully established.

It is clear that infection by a specific HPV alone is not sufficient for the development of cervical cancer. Only a small fraction of those individuals who are infected by a specific HPV will eventually develop cancer, and the time interval between infection and invasive cancer can be several decades. Thus, the genetic information carried by the virus *per se* is not sufficient for malignant progression. Other factors must be involved in the progression of virus-associated lesions to these genital tract cancers, and clearly additional genetic mutations in the infected cell are required for a cancer to arise. Epidemiologic studies have suggested that smoking is a risk factor for developing cervical carcinoma. <sup>138,139</sup> and <sup>140</sup> The recognition that other factors are involved in the progression to cervical carcinomas suggests that papillomavirus infections may work synergistically with these other factors. It has been suggested that tobacco condensate in women who smoke could accumulate in the vaginal fluids, bathing the cervix and acting as a cofactor with the papillomavirus infection. <sup>141</sup> Likewise, it has been postulated that herpesvirus infection might act synergistically with specific papillomaviruses to induce human cervical carcinoma. <sup>142</sup>

The use of restriction fragment-length polymorphisms has revealed that a loss of heterozygosity on the short arm of chromosome 3p implicates a potential tumor suppressor gene seen in cervical cancer, <sup>143</sup> which may be the recently described *FHIT* gene. <sup>144</sup> The somatic cell hybrid work of Stanbridge <sup>145</sup> implicates a potential tumor suppressor gene on human chromosome 11. A gene on human chromosome 11 can suppress the tumorigenicity of HPV-positive cervical carcinoma cells. It has been proposed that the loss of this gene on chromosome 11 in HeLa cells results in loss of expression of the cellular interfering factor, which negatively regulates HPV expression in these cells. <sup>146</sup> Further evidence that a negative regulator of HPV transcription is included on chromosome 11 is that fibroblasts with a deletion in the short arm of chromosome 11 can be more efficiently immortalized by HPV-16 than can normal fibroblasts. <sup>147</sup> The identification of genes on human chromosome 11 involved in tumor suppression in cervical cancer cell lines will obviously be a very important advance. Tumor progression, however, is complex and may involve additional loci. It should be noted that late stages of cervical carcinomas are associated with amplification and overexpression of the cellular oncogene *myc*. <sup>148</sup>

The availability of specific HPV DNA probes has provided investigators the opportunity to carry out extensive screenings of a variety of human cancers for HPV sequences. Based on the animal models, it seemed likely that any carcinomas of any squamous epithelium or an epithelium that can undergo squamous metaplasia would be a potential candidate for association with an HPV. Studies examining oral, upper airway, and tonsillar carcinomas have revealed some HPV-positive carcinomas. <sup>149,150</sup> and <sup>151</sup> HPV DNA has been found in benign oral papillomas, <sup>152,153,154</sup> and <sup>155</sup> and oral focal epithelial hyperplasia has been firmly established as having a papillomavirus etiology. <sup>156,157</sup> In addition, papillomavirus DNA sequences have been found associated with some cases of oral leukoplakia. <sup>153,158</sup> Esophageal carcinomas in humans have not yet been convincingly shown to be associated with an HPV. The esophagus is lined by a squamous epithelium, and squamous cell papillomas of the esophagus have been described in humans. <sup>159,160</sup> Additional studies would seem warranted to investigate a possible role of HPV in human esophageal cancers. In addition, sporadic reports in the literature associate occasional human tumors, including colon cancer, ovarian cancer, prostate cancer, and even melanomas, with the presence of HPV DNA. In general, it seems prudent to be skeptical of such reports until systematic and well-performed studies are confirmed in multiple laboratories.

Significant advances have been made recently in the development of vaccines against papillomavirus infections. The expression in yeast and in insect cells of the major capsid protein L1, either alone or together with L2, leads to the assembly of virus-like particles (VLPs) that are morphologically identical to native virion particles. <sup>161,162</sup> Further, these VLPs present the conformational epitopes necessary for the development of a high-titer neutralizing antisera. Such VLPs now are being used in clinical trials in humans. In addition, there is interest in the development of therapeutic vaccines directed against the E6 and E7 proteins expressed in cancers and preneoplastic lesions. A variety of approaches have already been described in the literature, including the use of vaccinia virus vectors, DNA vaccines, and

## EPSTEIN-BARR VIRUS

In 1964, Epstein, Achong, and Barr discovered Epstein-Barr virus (EBV) in electron micrographs of African Burkitt's lymphoma cells growing in culture; raising the expectation that EBV is a human tumor virus.<sup>164</sup> Burkitt's lymphoma cells in culture are mostly latently infected with EBV (for reviews, see Kieff <sup>165</sup> and Rickinson and Kieff<sup>166</sup>). An occasional cell is permissive for virus replication, and large amounts of early and late virus replication-associated proteins are expressed. As with other groups of herpesviruses, most early proteins are involved in viral DNA synthesis, whereas most late proteins are components of the virion. Lytic infection in cell cultures can be increased by activation of protein kinase C with the phorbol ester tumor promoter (12-O-tetradecanoyl-phorbol-13-acetate [TPA]). Viral early proteins can be differentiated from late proteins by exposing TPA-treated cells to inhibitors of viral DNA synthesis, such as acyclovir; the cells then express only early antigens. The staining patterns observed with human sera in microscopical analyses of latently infected Burkitt's lymphoma cells, Burkitt's lymphoma cells treated with TPA and acyclovir, or Burkitt's lymphoma cells treated with TPA alone are the basis for the determination of antibody to latent EBV-encoded nuclear antigen (EBNA), early antigens, and viral capsid antigen, respectively. EBV proteins are serologically distinct from proteins of other human herpesviruses. Early seroepidemiologic studies established that antibody to EBV is prevalent in all human populations and that high titers of antibody correlate with specific malignancies; Burkitt's lymphoma, nasopharyngeal carcinoma, and Hodgkin's disease ( [Fig. 10.2-4](#)),<sup>167,168</sup> and <sup>169</sup>

**FIGURE 10.2-4.** Schematic diagram of the events in Epstein-Barr virus (EBV) infection. Primary EBV infection begins at the oropharyngeal epithelium, where it can produce symptomatic pharyngitis. B lymphocytes are infected as they traffic in close proximity to the oropharyngeal epithelium. EBV BCRF1 is a close homologue of human interleukin-10 and blunts the initial natural killer (NK) CD8 T lymphocyte and gamma interferon responses, enabling EBV better to infect B lymphocytes. In acutely infected B lymphocytes, EBV expresses all EBV-encoded nuclear antigens (EBNAs), latent infection-associated membrane proteins (LMPs), and EBV encoded small RNA (EBERs), causing cell proliferation. In immunosuppressed patients, an acute lymphoproliferative disease may emerge, and the EBNAs, LMPs, and EBERs are expressed in the tumor cells. An EBV-specific CD8+ T-lymphocyte response is demonstrable in normal people shortly after EBV infection and is presumed to account for the fall in peripheral blood EBV-infected B-lymphocyte number from as much as 1 in 10 in acute infection to 1 in 10<sup>5</sup> to 10<sup>6</sup> with convalescence from acute EBV infection. CD8 T lymphocytes recognize determinants from EBNA2, -3A, -3B, -3C or -LP or from LMP1 or LMP2 in the context of specific class 1 major histocompatibility complex (MHC) molecules. B lymphocytes expressing these proteins must continue to be present, as a high level of EBV-immune CD8 T lymphocytes persists for life. EBV persists in some lymphocytes that express only EBNA1. Because CD8 responses to EBNA1 are rare, EBNA1-expressing lymphocytes can escape immune surveillance. Lymphocytes probably carry virus to other organs and to epithelial surfaces, including the oropharynx. LMP2 keeps the virus from reactivating as latently infected B lymphocytes circulate in the peripheral blood and tissues, where they encounter ligands for surface immune globulin or for CD19 or class II MHC. Persistent replication in the oropharynx depends on activation of lytic infection in lymphocytes when they traffic close to oropharyngeal epithelial cells. Years after primary EBV infection, Burkitt's lymphoma, Hodgkin's disease, and nasopharyngeal carcinoma (NPC) tumors occur. These tumors can initiate from a clone of EBV-infected cells. Most African Burkitt's lymphoma, 50% of Hodgkin's disease, and all anaplastic nasopharyngeal carcinomas are composed of EBV-infected cells.

The host range of EBV, *in vitro*, is limited to primate B lymphocytes. B lymphocytes express large amounts of CD21, a surface glycoprotein for which the major EBV envelope glycoprotein has high affinity. Consistent with the notion that EBV is a human tumor virus, infection of normal B lymphocytes confers an ability to proliferate continuously, *in vitro*,<sup>170</sup> in nude mouse brain after intracerebral inoculation or in the mesentery of severe combined immunodeficiency mice after intravenous inoculation.<sup>171</sup> Infection of some new world primates with EBV reproducibly induces an acutely fatal lymphoproliferative disease.<sup>172</sup> A similar lymphoproliferative disease can occur with primary EBV infection in male children with X-linked lymphoproliferative disease<sup>173</sup> or in profoundly immunosuppressed patients with human immunodeficiency virus (HIV) infection or liver, heart, lung, or bone marrow transplantation.<sup>174,175</sup> Although EBV-transformed B lymphocytes have substantial capacity for continuous proliferation, they remain fully differentiated and exhibit phenotypic markers similar to antigen-activated normal B lymphocytes.

In latently infected transformed B lymphocytes growing *in vitro*, in the peripheral blood of patients with primary EBV infection, or in polyclonal lymphoproliferative disease, EBV encodes six EBNAs, two latent infection-associated membrane proteins (LMPs), and two small nonpolyadenylated RNAs (EBV encoded small RNA [EBERs]). Molecular genetic analyses using specifically mutated EBV recombinants indicate that EBNA3B, LMP2, the small RNAs, and most of the viral genome that is expressed in lytic infection can be mutated without a significant effect on the ability of the virus to transform primary B lymphocytes. The other EBNAs and LMP1 are important for lymphocyte transformation. Although not a mediator of cell transformation, LMP2 is important in maintaining latency by preventing lytic infection in response to lymphocyte activation signals.<sup>176</sup>

EBNA1 is an EBV DNA replication origin-binding protein, which is important in latent infection for origin function in episome maintenance and transcriptional activation.<sup>177</sup> The other EBNAs, the functions of which are established, are regulators of transcription of viral or cellular genes. EBNA2 is the best characterized of these virally encoded transactivators and is an acidic type transactivator.<sup>178</sup> EBNA2 lacks DNA sequence-specific binding activity and is dependent on interactions with sequence-specific cell proteins for recognition of enhancer elements. All known EBNA2 response elements have a sequence, which binds the cell protein Jk that, in turn, recruits EBNA2. This interaction is not entirely sufficient for EBNA2 responsiveness; for example, PU.1 is essential for EBNA2 responsiveness of the LMP1 promoter. EBNA3A and EBNA3C also regulate transcription in lymphocyte transformation. Like EBNA2, EBNA3A and EBNA3C achieve specificity in their interaction with viral and cellular promoters by interacting with the cell protein Jk.<sup>179</sup> The interaction of three different EBV proteins with Jk may indicate an importance for Jk-mediated cell gene regulation in B-lymphocyte growth. This is reinforced by the recent findings that *Notch*, a T-cell leukemia gene, activates transcription through Jk.<sup>180,181</sup> From a different perspective, EBNA2 and EBNA3s can be viewed as usurpers of the Notch signaling pathway.

*LMP1* is a key gene in EBV-mediated cell growth transformation. *LMP1* can transform immortalized rodent fibroblasts to loss of contact inhibition, anchorage independence, or nude mouse tumorigenicity. When expressed in normal resting B lymphocytes or in non-EBV-infected Burkitt's lymphoma cells that have a nonactivated phenotype with regard to markers of normal B-lymphocyte activation, LMP1 induces most B-lymphocyte activation and adhesion markers, activates NFκB, and induces Bcl2 and A20, proteins important in preventing apoptosis. In epithelial cells, LMP1 induces epidermal growth factor receptor expression and inhibits differentiation.<sup>176,182</sup> Specific mutations in the *LMP1* gene in EBV recombinants have provided direct evidence that LMP1 is essential for primary B-lymphocyte growth transformation.<sup>183</sup> LMP1 has multiple transmembrane domains that enable it to aggregate in a patch in the plasma membrane, mimicking an activated growth factor receptor. The first 45 amino acids of the LMP1 C-terminal cytoplasmic domain are essential for primary B-lymphocyte growth transformation, whereas the N-terminal cytoplasmic domain and the more distal 155 amino acids of the LMP1 C-terminus are not necessary. The essential C-terminal 45-amino acid domain interacts in the cytoplasm with cellular proteins that ordinarily transduce signals from the TNF receptor (TNFR) family.<sup>184,185</sup> TNF signaling is critical in normal lymphoid development, and the B-lymphocyte TNFR family member, CD40, is remarkably similar to LMP1 in its growth-promoting and NFκB-activating effects ( [Fig. 10.2-5](#)).

**FIGURE 10.2-5.** The first 44 amino acids of latent infection–associated membrane protein type 1 (LMP1) engage tumor necrosis factor receptor–associated factors (TRAF) 1, 2, and 3 and activate NFκB through interaction with TRAF1 and TRAF2. Activation is presumed to proceed by constitutive activation of a TRAF2-associated kinase. It is known that phosphorylation of IκB leads to degradation of IκB and release of NFκB to the nucleus.

Primary EBV infection in most normal people causes clinically apparent or milder forms of acute infectious mononucleosis. Infection initiates in the oropharyngeal epithelium<sup>186</sup> and then spreads to B lymphocytes. As many as 10% of the circulating B lymphocytes may be EBV-infected and express EBNAs and LMPs.<sup>187,188</sup> These infected cells engender a massive natural killer response, followed by a human leukocyte antigen class I and EBV antigen–specific, cytotoxic CD8+ T-cell response.<sup>189,190</sup> The number of responding cells substantially exceeds the number of infected B lymphocytes. As a consequence of the cellular response, the number of infected B lymphocytes falls to 1 in 10<sup>6</sup> and remains at that level. Somewhat higher levels persist in tonsils. The persisting cells may express only EBNA1, EBNA1 and LMPs, or all of the EBNAs and LMPs.<sup>191</sup> The EBNA1-only type latency appears to be undetectable by T-cell surveillance, whereas the other EBNAs are well recognized by CD8+ T cells.<sup>192,193</sup> and <sup>194</sup> In normal people, high-level CD8+ T-cell recognition persists for life, restricting the growth of EBV-infected lymphocytes that progress to expression of all EBNAs and LMPs.<sup>195</sup> The continuous presence of specific CD8+ T cells is unusual and indicates ongoing stimulation of the immune response with EBNA- and LMP-expressing cells. Virus replication also persists in the oropharyngeal epithelium, although this requires reintroduction of virus from the lymphocyte pool. With immunosuppression, latently infected cells in the peripheral blood and persistently infected cells in the oropharynx increase in number.<sup>196</sup>

Long after primary infection, EBV is associated with endemic and nonendemic Burkitt's lymphoma, Hodgkin's disease,<sup>197</sup> neural and peripheral B lymphomas and leiomyomas in immunocompromised patients,<sup>198,199,200</sup> and <sup>201</sup> T-cell malignancies,<sup>202</sup> nasopharyngeal carcinoma,<sup>169,203</sup> squamous tumors of the oropharynx, and gastric epitheliomas.<sup>204,205</sup> In most instances, the association is based on unusually high serologic reactivity to EBV proteins in a substantial number of patients with the malignancy, on the finding that the tumor cells are infected with EBV, and on the finding that the resident EBV genome in tumors is unclonal with regard to EBV infection events.<sup>206</sup> The finding of markers of the same infection event in all the EBV DNA molecules in tumor tissue and in metastases is evidence that the tumor cells are progeny of a single infected cell and that EBV was present in the cell before the cell became malignant.<sup>207</sup> The EBERs are transcribed in high abundance in latent EBV infection of nonepithelial cells, and *in situ* hybridization to EBERs has been useful in demonstrating the specific association of EBV with Hodgkin's disease tumor cells. Hodgkin's cells express EBNA1 and high levels of LMP1; other EBNAs are not expressed.<sup>208</sup> EBNA1, LMP1, and LMP2 are the only EBV proteins expressed in nasopharyngeal carcinoma and in preneoplastic lesions of the nasopharynx, consistent with a role for these proteins in the latent infection and associated cell growth alteration.<sup>203</sup>

The role of EBV in Burkitt's lymphoma and in other late-onset malignancies is complicated. The presence of EBV in all the tumor cells and the unclonality of the tumor cells with regard to EBV infection indicate that the tumors arise in an EBV-infected cell.<sup>207</sup> Thus, EBV infection clearly sets the stage at the cellular level for progression to malignancy. At the cellular level, EBV infection may enable further evolution of the malignancy by increasing *NFκB*, *c-myc*, immune globulin, and *RAG* gene expression and by preventing apoptosis. Increased *c-myc*, Ig, and *RAG* gene expression may increase the frequency of *c-myc/Ig* translocation, which can result in constitutive *c-myc* activation.<sup>209,210</sup> On the basis of transgenic models, constitutive *c-myc* activation can further expand the B-cell pool and predispose to subsequent genetic changes that lead to more malignant phenotypes. EBV genes may initially complement *c-myc* in promoting cell growth but eventually become redundant. In Africa and New Guinea, the very high-level predisposition of EBV to Burkitt's lymphoma appears to be due to holoendemic malaria; malaria infection stimulates B-cell proliferation and depresses cytotoxic T-cell function.<sup>211,212</sup> In this regard, malarial infection has effects in endemic Burkitt's lymphoma that overlap with the effects of HIV infection or high-level immunosuppressive therapy in EBV-associated lymphoproliferative disease.<sup>213</sup> The significance of the failure of T-cell immune surveillance in the evolution of lymphoproliferative disease in immunosuppressed patients<sup>213</sup> has been experimentally confirmed by the beneficial effects of EBV-specific or -nonspecific reconstitutive therapy or prophylaxis.<sup>214</sup> Cytotoxic T-cell failure rarely is complete, and Burkitt's lymphoma or similar unclonal B lymphomas involving EBV-infected cells that emerge in normal or immunocompromised patients frequently are characterized by the absence of cells that express EBV proteins other than EBNA1. Thus, the current model for EBV-associated B-cell malignancy is that EBV causes B-lymphocyte proliferation. The number of EBV-infected cells can increase as a result of CD8+ T-cell disorders. Given sufficient immunosuppression, several clones of EBV-infected B cells or the best-growing clone may emerge as a lymphoproliferative disease. EBV infection also predisposes to *c-myc* translocation, and a more malignant cell clone can eventually emerge as a tumor cell in a host with normal immune function.

EBV also causes oral hairy leukoplakia, a benign proliferation of epithelial cells that occurs in acquired immunodeficiency syndrome (AIDS) patients. The lesions are sites of persistent EBV replication and disappear in response to suppression of EBV replication with acyclovir.<sup>215</sup> As no evidence exists for EBV latency in these lesions, the pathogenesis of oral hairy leukoplakia may involve secretion of a cytokine from lytically infected cells.<sup>216</sup>

## KAPOSI'S SARCOMA–ASSOCIATED HERPESVIRUS (HUMAN HERPESVIRUS-8)

Kaposi's sarcoma (KS) is the most common neoplasm associated with AIDS.<sup>217,218</sup> Initially described as a rare and indolent tumor of elderly Mediterranean men, it was later recognized to occur at a higher frequency in Africa.<sup>219</sup> Still later, KS was documented among immunosuppressed organ transplant recipients.<sup>220</sup> In all cases, the histologic picture of the disease is strikingly similar and highly distinctive. Unlike most tumors, which arise from the clonal outgrowth of a single cell, KS lesions contain many cell types.<sup>217</sup> Advanced lesions contain a predominance of spindle-shaped cells (spindle cells), the histogenesis of which remains uncertain but which are believed to arise from endothelial cells (or a more primitive mesenchymal precursor of such cells). In addition, there are infiltrating mononuclear cells (including plasma cells and monocyte-macrophages) and a highly characteristic profusion of slit-like neovascular spaces. The vascularity of the lesion gives KS its distinctive reddish or violaceous appearance.

This complex histology sets KS apart from most other tumors and raises important questions about its pathogenesis. Based on the properties of spindle cells cultivated from AIDS-related KS specimens, many studies have pointed to a key role for growth factors and cytokines in the evolution of a KS lesion.<sup>217,221,222</sup> and <sup>223</sup> In general, such cells are not fully tumorigenic: Most do not produce stable, transplantable tumors in nude mice or grow in soft agar. In fact, they are dependent on exogenous growth factors for their proliferation<sup>221,224,225</sup> and, in turn, they produce an array of growth factors and angiogenic factors.<sup>226</sup> When transplanted into nude mice,<sup>223,227</sup> they survive only transiently, then involute. However, during their period of viability, they recruit host inflammatory cells and neovascular structures very reminiscent of KS. When the human spindle cells involute, the entire lesion disappears. This suggests a model for KS in which the proliferating spindle cells drive the rest of the lesion via the elaboration of growth and angiogenic factors. The central question then is: What drives the proliferation of the spindle cells?

One early model attempted to relate spindle cell growth to HIV infection.<sup>217</sup> Certainly, HIV infection is an enormous risk factor for KS development: The prevalence of KS in AIDS patients is 20,000 times that in the general population and 300 times that observed in other immunosuppressed populations.<sup>228</sup> However, both *in vivo* and in cell culture, spindle cells do not appear to carry the HIV genome, ruling out direct infection by HIV as the growth-promoting event. Rather, HIV infection is limited to the smaller lymphoid and mononuclear cell components of KS. Such HIV-infected cells can be shown *in vitro* to release factors that promote cultured spindle cell growth, including both cellular cytokines and the HIV *tat* gene product.<sup>229,230</sup> These observations suggest a plausible mechanism by which HIV infection could drive KS lesion formation without directly infecting the spindle cell.

However, doubts soon arose concerning the ability of HIV infection alone to account for the etiology of KS. First, of course, KS can certainly arise in HIV-negative hosts. More important, even within the HIV-infected population, large differences in KS risk are not accounted for by the preceding formulation.<sup>228,229,230</sup> and <sup>231</sup> KS risk is

highest in homosexual men with AIDS: A full 20% to 30% of such individuals will develop KS in the course of their HIV disease. By contrast, fewer than 1% to 2% of AIDS cases related to hemophilia (i.e., blood product administration) will be complicated by KS, and KS is rarer still among pediatric AIDS cases in which HIV infection is acquired vertically from infected mothers. These and other data<sup>231</sup> suggest the possibility of a sexually transmitted cofactor in KS etiology or pathogenesis. In 1994, Chang et al.<sup>232</sup> used a polymerase chain reaction–based method to identify DNA sequences that were present in DNA extracted from an AIDS-KS specimen but absent from normal genomic DNA from the same patient. Two small DNA fragments emerged that were shown to be highly correlated with KS: Virtually all AIDS-KS tumors were positive for these sequences, whereas available tissue specimens from a large number of HIV-negative hosts were negative, as were most non-KS tissues from patients with KS. Interestingly, approximately 10% to 15% of lymphoid tissues from AIDS patients who did not have KS were also positive, indicating that the sequences track with both KS and the risk for KS development. Sequence analysis of these two small DNA fragments reveals homology to two known lymphotropic herpesviruses, human EBV and the simian herpesvirus saimiri (HVS). These seminal findings point to the existence of a novel herpesvirus, termed *KS-associated herpesvirus* (KSHV) or *human herpes virus-8* (HHV-8), and suggest it as a candidate for the exogenous cofactor earlier predicted by epidemiologists.

Subsequent work has confirmed these findings and extended them in important ways, all of which are consistent with a role for this virus in KS development. First, KSHV/HHV-8 sequences are present in virtually all KS specimens from HIV-negative patients with the disease, as well as their HIV-positive counterparts.<sup>233,234,235,236</sup> and<sup>237</sup> Because most HIV-negative KS patients are not grossly immunodeficient, it is unlikely that KSHV/HHV-8 is simply an opportunistic saprophyte that overruns the profoundly immunodeficient host. In KS tumors, KSHV DNA is found primarily in the spindle cells<sup>238</sup>—the key cell type in KS pathogenesis—and active but restricted viral gene expression consistent with latent infection is demonstrable in the vast majority of these cells.<sup>239,240</sup> In addition, a small subset of the spindle cells appears to harbor viral genomes undergoing lytic replication. Second, KSHV/HHV-8 sequences have been identified in the peripheral blood mononuclear cells (PBMCs) of 30% to 50% of KS patients and a much smaller proportion (10% to 15%) of AIDS patients lacking clinical KS.<sup>241</sup> Importantly, in KS-negative AIDS patients, the risk of subsequent KS development is much greater among patients whose initial PBMC sample harbored KSHV than among those whose PBMCs did not.<sup>241</sup> Thus, viral infection precedes the development of KS, and prior infection appears to be predictive of increased KS risk.

These early inferences have been sustained by more recent seroepidemiologic studies, which have yielded the following important conclusions. First, KSHV infection is not ubiquitous; among screened (low-risk) U.S. and European blood donors, only approximately 5% to 7% are seropositive. (This number probably slightly underestimates the true prevalence of infection in the general population.) However, in HIV-positive populations, seroprevalence tracks very strikingly with KS risk: While 30% to 60% of HIV-infected homosexual men are KSHV-seropositive, fewer than 5% of HIV-positive hemophiliacs or women show serologic evidence of KSHV infection, and KSHV seroreactivity is surprisingly rare among U.S. children with AIDS.<sup>242,243,244</sup> and<sup>245</sup> In large prospective studies, KSHV seroreactivity was shown to antedate the onset of the tumor (often by up to 10 years) and strongly predicted an increased risk of KS development.<sup>246,247</sup> and<sup>248</sup> Studies in male homosexuals in the United States produced strong evidence for sexual transmission in this group: KSHV seroprevalence rises sharply with increasing numbers of sexual partners and with histories of other STDs, for example. In a key study, Martin et al.<sup>246</sup> showed that the risk of subsequent KS among KSHV-seropositive individuals was the same even after normalizing for the prevalence of other STDs.<sup>246</sup> This result indicates that it is KSHV infection itself, not some cotransmitted STD, that is responsible for KS risk.

These data clearly indicate that KSHV is the agent predicted by KS epidemiology and strongly implicate KSHV in KS pathogenesis. The epidemiologic case for involvement of KSHV in KS biogenesis now is as compelling as the cases for HBV and hepatoma or HPV and cervical cancer. Given the large number of subjects studied to date, the evidence supports the assertion that KS is virtually never observed in the absence of documented KSHV infection. Accordingly, most experts in the field now accept that KSHV is necessary for KS development. However, there is also strong consensus that it is not sufficient for this process. For example, 5% to 7% of the general population in the United States is infected by KSHV, yet this population has no significant KS risk. Clearly, therefore, one or more cofactors, in addition to KSHV, are required to promote tumorigenesis. In the case of AIDS-KS, of course, that cofactor is HIV, although exactly what HIV contributes to pathogenesis is much debated. Some argue that HIV's link to KS generation is simply the production of an immunodeficient state; others hypothesize that individual HIV proteins released from infected cells (specifically tat or HIV-induced host cytokines) participate directly in spindle cell growth deregulation in a paracrine fashion.<sup>226,249,250</sup> Such notions need not, of course, be mutually exclusive. The nature of the cofactors in the HIV-negative forms of KS remains unknown.

Studies of KSHV seroepidemiology conducted in the developing world have yielded additional new insights. First, the prevalence of KSHV in the general population is remarkably elevated in countries in which classic KS is common. For example, in southern Italy, Sicily, and Sardinia, KSHV antibodies are found in more than 20% of the general population<sup>251,252</sup>; in many populations in sub-Saharan Africa, where classic KS was common even in the pre-AIDS era, 60% to 80% of the population is seropositive.<sup>253,254,255</sup> and<sup>256</sup> Thus, KS seroprevalence tracks with KS risk even outside of HIV-positive cohorts. However, these numbers also reflect major epidemiologic differences between KSHV infection in Africa and the Mediterranean, on the one hand, and KS risk in Western Europe and America, on the other. In the latter countries, homosexual men represent a major reservoir of infection, with much lower rates in women and very little infection in prepubertal children.<sup>257,258</sup> By contrast, in Africa and the Mediterranean, seroconversions begin in childhood, and the seroprevalence rises nearly continuously throughout the first four to five decades of life. Moreover, seroprevalence is equal in both genders, in sharp contrast to the developed world. The basis for this strikingly different epidemiology is not yet understood. The frequent occurrence of infection in young children in the Mediterranean and Africa suggests the existence of nonsexual routes of spread, and the equal infection rates in adult men and women also suggests different routes of spread from those observed in the West.

How does KSHV infection predispose to KS? Understanding of this association at the molecular level is still fragmentary. Because most KS tumor cells are latently infected, efforts to identify and characterize KSHV latency genes have been made, presuming, as in EBV, that these genes will play strong roles in spindle cell growth deregulation. To date, several interesting genes have been identified in this fashion. An important group of latency genes is clustered in one region of the viral genome, where two transcription units have been mapped.<sup>259,260</sup> One expresses a set of three genes, including (1) LANA, an antigen that appears to function in KSHV genomic maintenance in latency,<sup>261</sup> (2) a viral homologue of cellular cyclin D1, and (3) a homologue of cellular inhibitors of caspase activation (Flice-inhibitory protein). The viral cyclin can bind and activate cdk6, indicating that it is a functional cyclin.<sup>262,263</sup> It appears to display reduced sensitivity to the inhibitory effects of certain cdk inhibitors.<sup>264,265</sup> and<sup>266</sup> It is easy to imagine how such a gene might figure in growth deregulation, especially given the known links between deregulation of cellular cyclin D1 and several forms of human cancer.<sup>267</sup> The viral Flice-inhibitory protein presumably functions to block apoptosis—a potentially important activity, as overexpression of viral cyclin sensitizes cells to apoptosis.<sup>268</sup> A second transcription unit encodes a family of related proteins, the kaposins, which are generated by a complex translational strategy.<sup>269</sup> Their transcripts are used widely to identify latently infected cells,<sup>270,271</sup> but the functions of their gene products remain unknown. Remote from these genes, at the right-hand terminus of the genome, is a coding region for a multiply spliced transcript encoding a series of transmembrane proteins called *latency-associated membrane proteins* (LAMPs).<sup>272,273</sup> These proteins contain a variety of motifs suggestive of roles in cellular signal transduction and can bind tumor necrosis factor receptor–associated factors (TRAFs) 1, 2, and 3 *in vitro*, but their *in vivo* roles remain to be defined.<sup>272</sup>

As noted, KS tumors also harbor smaller numbers of lytically infected cells.<sup>270,274</sup> The significance of lytic infection in KS tumorigenesis is unknown, but there are reasons to believe that the lytic cycle may play a more profound role in KS than in other herpesvirus-induced malignancies. First, a recent clinical trial has shown that even in patients with advanced AIDS, treatment with ganciclovir, which is active only against lytic herpesvirus infection, profoundly reduced the subsequent development of KS over the ensuing 6 to 12 months.<sup>275</sup> Although this result might mean simply that lytic reactivation from the lymphoid reservoir is necessary for spread to the endothelium to initiate latent infection there, it is also compatible with a requirement for ongoing KSHV replication in KS pathogenesis. The latter is an attractive notion, because the virus contains numerous genes that are potent signaling molecules expressed principally during lytic growth.<sup>276,277</sup> and<sup>278</sup> Some of these are secreted factors (e.g., homologues of interleukin-6, chemokines, and other factors), whereas others (e.g., the K1 protein and a virus-specific G protein–coupled receptor) are transmembrane proteins that trigger deregulated signal transduction in the host, often leading to secretory products that can influence surrounding cells.<sup>279,280</sup> and<sup>281</sup> For example, virus-specific G protein–coupled receptor expression induces the release of vascular endothelial growth factor,<sup>282</sup> a protein long speculated to play a role in the angiogenic phenotype of KS. Some of the viral chemokines can trigger angiogenesis as well<sup>283</sup>; moreover, these molecules would be expected to contribute to the influx of inflammatory cells in the lesion, another hallmark of KS. Defining the relative contributions of latency and lytic growth to KS pathogenesis will be a major focus of KSHV research in the coming decade.

The homologies to EBV and the simian herpesvirus saimiri place KSHV/HHV-8 within the lymphotropic herpesvirus subfamily, an assignment supported by the finding of viral DNA in the B-cell compartment of the PBMC population.<sup>237</sup> This raises the possibility that the virus might participate in lymphoid neoplasia as well and, in recent years, viral infection has in fact been associated with at least two lymphoproliferative conditions. The first is a rare B-cell lymphoma, termed *body cavity–based lymphoma*, that has thus far been limited to HIV-positive hosts.<sup>284</sup> It presents as ascitic tumors in the pleural and peritoneal cavities, often without clinically evident lymphadenopathy or bone marrow involvement. Body cavity–based lymphoma cells are uniformly latently infected with HHV-8; many (but not all) also bear latent EBV genomes. Cultured B-cells derived from such tumors are latently infected and, in some of these cells, lytic viral replication can be induced *in vitro* with phorbol esters.<sup>285</sup> The other lesion associated with HHV-8 is *multicentric Castleman's disease* (MCD), a complex and poorly understood lymphoproliferative syndrome that can occur in both HIV-positive and HIV-negative individuals. The HIV-positive form appears to be uniformly associated with KSHV/HHV-8, whereas only approximately half

of the HIV-negative forms can be shown to harbor this virus.<sup>286</sup> Although the role of the virus in this condition is unclear, it is interesting that an association of Castleman's disease with KS has long been recognized, though little discussed.

Study of viral gene expression in MCD has revealed some provocative surprises. Within the involved tissue, viral DNA is confined to B cells in the mantle zones surrounding the lymphoid follicles. There, both latently and lytically infected cells can be found, with a rather larger proportion of the infected cell population being in the lytic cycle than there are in KS.<sup>287,288</sup> Interestingly, although MCD-involved nodes contain equal numbers of B cells bearing k and l light chains, all the infected cells appear to bear l chains on their surface. Though this might simply indicate clonality of these cells, it is striking that among more than a dozen analyzed cases, no KSHV-infected cells with surface k chains have yet been described. The meaning of this observation is not yet clear, but it may suggest a particular stage in B-cell ontogeny is targeted by KSHV during MCD pathogenesis. Although the links of KSHV to primary effusion lymphoma and MCD are very strong, it bears noting that formal epidemiologic evidence for causality—of the type that has been so compelling for KS—is lacking for these disorders, owing primarily to their rarity.

### INTRODUCTION

The chemical origin of human malignancies was recognized by observations of unusual cancer incidences in persons in certain occupational groups. The capacity for chemicals to cause cancer was subsequently confirmed in numerous experimental animal studies. The extent to which chemical exposures contribute to cancer incidence was not appreciated fully until population-based studies documented differing organ-specific cancer rates among geographically distinct populations. Changes in cancer frequency among migrating ethnic groups, high cancer rates associated with specific occupations, and the high risk of smoking-associated cancers confirmed that environmental and lifestyle exposures were major determinants of human cancer risk. Current data indicate that changing lifestyles and exposures can modify cancer risk.<sup>1</sup> Individual genetic factors also can influence cancer risk in several ways. In hereditary cancer syndromes, genetic factors dictate a very high cancer risk for a small group of individuals. However, the general population carries hereditary susceptibility genes that increase cancer risk for particular exposures. Thus, most human cancer is not simply a genetically determined sequela of aging but rather the manifestation of personal and cultural behavior superimposed on individually determined hereditary susceptibility.

The experimental induction of tumors in animals, neoplastic transformation of cultured cells by chemicals, and analysis of environmentally induced human tumors have revealed important concepts regarding the pathogenesis of cancer.<sup>2,3,4</sup> and <sup>5</sup> Often, chemical carcinogens are organ-specific, target epithelial cells, and cause genetic damage (i.e., are genotoxic). Chemically related DNA damage can occur either directly from environmental exposures or indirectly by activation of endogenous mutagenic pathways (e.g., nitric oxide and oxy radicals).<sup>6</sup> Most chemically induced tumors are clonal in origin and require an accumulation of genetic changes in a multistage progression from normal to premalignant to carcinoma. The risk of developing a chemically induced tumor may be modified by nongenotoxic exogenous and endogenous exposures and factors and by accumulated exposure to the same or different genotoxic carcinogens. Somatic mutations relevant to cancer pathogenesis have been documented after carcinogen exposures in experimental animals and humans, and pathways for carcinogen metabolism have defined a set of genetic variables that contribute to human cancer risk. Studies with cultured rodent and human cells<sup>7</sup> confirm the remarkable qualitative similarities among mammalian species for responses to carcinogens but also have revealed some important quantitative differences that have enhanced our understanding of chemical carcinogenesis in human populations.

Analysis of the chemical induction of cancer in animal models and human populations has had a major impact on human health. Experimental studies have been instrumental in validating hypotheses generated from human studies. Animal experiments confirmed the carcinogenic and tumor-promoting properties of cigarette smoke and identified the active chemical and gaseous components.<sup>8</sup> The transplacental carcinogenicity of diethylstilbestrol and the hazards of specific occupational carcinogens [e.g., vinyl chloride, benzene, aromatic amines, and bis (chloromethyl) ether] led to the removal of the suspected human carcinogens from the environment and reduction of the cancer rate. Dietary factors that enhance or inhibit cancer development have been identified in models of chemical carcinogenesis,<sup>9</sup> resulting in a reduction of cancer incidence through nutritional alterations. The application of cancer chemoprevention strategies, particularly retinoids, antiestrogens, and inhibitors of the arachidonic acid cascade, are the direct result of studies conducted in models of chemical carcinogenesis<sup>10</sup> and are reducing the tumor incidence in high-risk populations.

### THE NATURE OF CHEMICAL CARCINOGENS: CHEMISTRY AND METABOLISM

A wide variety of chemicals and chemical classes can cause cancer in animals and humans,<sup>11</sup> yet the process is very specific. Most chemicals are not known to be carcinogenic. Within chemical classes, stereoisomers may vary widely in carcinogenicity. Carcinogens can be genotoxic, nongenotoxic, or both. Sometimes, the distinction is arbitrary.<sup>12,13</sup> Genotoxic carcinogens have high chemical reactivity (such as alkylating agents) or can be metabolized to reactive intermediates by the host. They form covalent adducts with macromolecules and target DNA in the nucleus and mitochondria.<sup>5,14</sup> Because a good correlation exists between the ability to form DNA adducts and the potency to induce tumors in laboratory animals, DNA is considered the ultimate target for most carcinogens. Genotoxic carcinogens may transfer simple alkyl or complexed (aryl) alkyl groups to specific sites on DNA bases (Fig. 11-1)<sup>5,14</sup> These alkylating and arylalkylating agents include (but are not limited to) N-nitroso compounds, aliphatic epoxides, aflatoxins, mustards, polycyclic aromatic hydrocarbons, and other combustion products of fossil fuels and vegetable matter. Others transfer arylamine residues to DNA (see Fig. 11-1) as exemplified by aryl aromatic amines, aminoazodyes, and heterocyclic aromatic amines; the latter are produced by overcooking meat, poultry, or fish at high temperatures.<sup>15</sup> For genotoxic carcinogens, the interaction with DNA is not random, and each class of agents reacts selectively with purine and pyrimidine targets (see Fig. 11-1).<sup>14,16</sup> Furthermore, targeting of carcinogens to particular sites in DNA is determined by nucleotide sequence,<sup>17</sup> by host cell,<sup>18</sup> and by selective DNA repair processes, rendering some genetic material at risk over others. As expected from this chemistry, genotoxic carcinogens are potent mutagens, particularly adept at causing base mispairing or small deletions and leading to missense or nonsense mutations.<sup>16</sup> Others may cause macrogenetic damage, such as chromosome breaks and large deletions.<sup>19</sup> In all cases, mutations detected in tumors represent a combination of the effect of the mutagenic change on the function of the protein product and the effect of the functional alteration on the behavior of the specific host cell type.

**FIGURE 11-1. A:** Metabolic activation to yield DNA-reactive alkylating, arylaminating, and aralkylating agents. Ar is an aromatic residue, X is a leaving group, and SG represents a glutathione residue. **B:** Sites of substitution of DNA bases by genotoxic carcinogens. Sites modified by alkylating agents are marked by the numeral I, those modified by arylaminating agents are marked by a II, and those modified by polycyclic aralkylating agents are marked by a III. Because C8-substituted arylamino adducts have been suggested to have arisen from N7-substituted precursors, the arylaminating agents are listed parenthetically at the 7-position of the purines. (Reproduced by permission of the author, Dr. Anthony Dipple, and the publisher, Oxford University Press, from *Carcinogenesis* 1995;16:437.)

A number of chemicals that cause cancers in laboratory rodents are not demonstrably genotoxic.<sup>12,13,20</sup> Synthetic pesticides and herbicides fall within this group, as do a number of natural products that are ingested.<sup>21</sup> In general, these agents are carcinogenic at high doses in laboratory animals and require prolonged exposure. The mechanism of action by nongenotoxic carcinogens is controversial and may be related in some cases to toxic cell death and regenerative hyperplasia.<sup>20,22</sup> Induction of endogenous mutagenic mechanisms, such as DNA oxy radical damage,<sup>23</sup> depurination, and deamination of 5-methylcytosine by exposure to nongenotoxic carcinogens, may contribute to carcinogenicity of these agents. In other cases, nongenotoxic carcinogens may have hormonal effects, influencing hormone-dependent tissues directly.<sup>24,25</sup> Though the contribution of nongenotoxic carcinogens to human cancer causation is not certain, they may serve also as modifiers in concert with genotoxic agents.

A number of metabolic pathways activate or detoxify carcinogens and procarcinogens (chemicals that can be transformed into active carcinogens).<sup>5,26,27</sup> These pathways are complex and interactive (Table 11-1), and genetic polymorphisms in animal models and humans are thought to be major determinants of cancer susceptibility.<sup>28</sup> In general, metabolic activation of carcinogens involves oxidation at carbon-carbon double bonds or saturated carbon atoms, in the latter case often requiring a further esterification (see Fig. 11-1). Oxidation at nitrogen on aromatic amines or reduction at nitrogen of aromatic nitro compounds yields reactive intermediates that transfer an arylamine residue to DNA. An esterified intermediate may be required, as in the case of heterocyclic amine carcinogens.<sup>29</sup> Conjugations are also frequent intermediates of metabolism of many carcinogens and can be both activating and detoxifying pathways (see Fig. 11-1 and Table 11-1).<sup>14,27</sup> The importance of metabolic activation to carcinogenesis and the polymorphic nature of metabolic activity among individuals provides an approach to estimate individual risk profiles for particular exposures.<sup>30</sup> Furthermore, a number of metabolic pathways are inducible (see Table 11-1) and modified by diet, hormones, and additional exposures, adding further complexity to the process of carcinogenesis.

Enzyme	Metabolic Pathway	Major Reaction (Substrate)	Major Activity (Substrate)	Typical Substrate	Inducible	Polymorphic
Cytochrome P450	1	N- or C-oxidation (aromatic)	Aromatic (aromatic amines)	PAH, nitroaromatics, azo dyes, nitroaromatic amines	Yes	Yes

TABLE 11-1. Enzymatic Pathways of Carcinogen Metabolism in Experimental Animals and Humans

## ANIMAL MODEL SYSTEMS AND MULTISTAGE CARCINOGENESIS

Virtually every major form of human cancer can be reproduced in experimental animals by exposure to specific chemical carcinogens. In many cases, the cell of origin, morphogenesis, phenotypic markers, and genetic alterations are qualitatively identical to corresponding human cancers (Table 11-2).<sup>2</sup> Animal models have demonstrated the modifying effect of tumor promoters and hormones or cofactors, such as asbestos or viral infections. Furthermore, animal models have revealed the constancy of carcinogen-host interaction among mammalian species by reproducing organ-specific cancers in animals with chemicals identified as human carcinogens, such as coal tar and squamous cell carcinomas; vinyl chloride and hepatic angiosarcomas; aflatoxin and hepatocarcinoma; and aromatic amines and bladder cancer. These results validate the qualitative value of animal models in carcinogenesis research and support the extrapolation of data from experimental studies to human applications with specific limitations. The introduction of genetically modified mice designed to reproduce specific human cancer syndromes has accelerated both the understanding of the contributions of chemicals to cancer causation and the identification of potential exogenous carcinogens.<sup>31,32</sup>

TABLE 11-2. Animal Models for Chemical Carcinogenesis

From analyses of both human cancer pathogenesis and experimental animal tumor induction by chemical carcinogens, specific stages that have been identified have typical phenotypic, genetic, and biochemical characteristics (Fig. 11-2). However, in reality, these stages are not distinct, and steps to cancer do not follow a straight line. Mutations in single cells frequently “initiate” carcinogenesis. On clonal expansion, initiated cells form a premalignant lesion, often a benign tumor (e.g., an adenoma) but also recognized as hyperplastic or dysplastic foci in some tissue sites. Agents that cause clonal expansion of initiated cells are called *tumor promoters*. Tumor promotion may occur as a consequence of exogenous exposures, such as cigarette smoke or viral infections. Promotion may be an endogenous process, such as hormonal stimulation in breast and prostate cancer or bile salts in colon cancer. Premalignant lesions undergo further phenotypic changes, often in a predictable sequence and commonly multifocal within a single lesion. Some foci progress at a faster rate than others, and these are at highest risk for malignant conversion. Premalignant progression encompasses the majority of the tumor latency period prior to malignant conversion, when the lesion shows invasive properties.

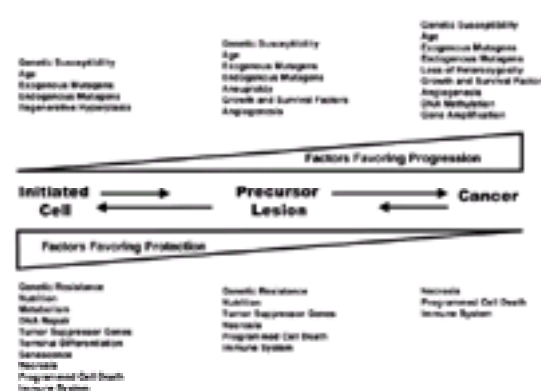

FIGURE 11-2. Factors influencing multistage carcinogenesis from environmental exposures. Early events reflect a balance of protective and initiating factors that determine the long premalignant latency period. As the process proceeds, protective factors are superseded by phenotypic alterations in the emerging neoplasm, whereas genetic instability accelerates selection of more deviant clones, even in the absence of exogenous exposures. The emerging cancerous clones are resistant

to most of the endogenous protective mechanisms.

Usually, initiation is a low-frequency genetic event and is directly dependent on carcinogen dose. The phenotype of initiated cells varies according to tissue site and includes a defect in maturation, resistance to cytotoxicity, escape from senescence, and altered dependence on growth factors and hormones.<sup>2</sup> At the molecular level, initiation involves an alteration in signal transduction pathways that regulate cellular responses to extracellular signals, and these are internally regulated by protooncogenes and tumor suppressor genes.<sup>33,34</sup> and <sup>35</sup> Mutational activation of protooncogenes to oncogenes and inactivation of tumor suppressor genes contribute to initiation in most tissue sites.

Usually, experimental tumor promoters are nongenotoxic and frequently are tissue-specific and have multiple mechanisms of action, generally resulting in a disturbance of tissue homeostasis.<sup>36,37</sup> The mechanisms of tumor promotion include activation of cell-surface receptors; activation or inhibition of cytosolic enzymes and nuclear transcription factors; stimulation of proliferation; inhibition of apoptotic cell death; and direct cytotoxicity.<sup>2,38</sup> Genotoxic carcinogens also can have promoting properties, and repeated exposures to low concentrations of genotoxic carcinogens can induce tumors more effectively than do fewer exposures to the same total dose in experimental carcinogenesis.<sup>39</sup> Exogenous tumor promoters can determine the target site for tumor formation when experimental animals are initiated systemically with widely acting carcinogenic agents.<sup>2,37</sup> Thus, tumor promoters may contribute to target organ specificity when germline mutations produce an initiated state in multiple cell types. In general, initiated cells respond differently than do normal cells to promoters, and this is the basis for a clonal selection of an initiated population.<sup>2,37</sup> The contribution of exogenous tumor promoters to human cancer risk is clear only in a few cases, such as cigarette smoke and asbestos,<sup>40</sup> although other experimental promoting agents are found in the human environment (see [Table 11-2](#)).<sup>37</sup> Any change that causes a selective outgrowth of a preneoplastic cell, including additional genetic changes that selectively enhance growth of initiated cells, can be considered a promoting stimulus.

Premalignant progression in an initiated cell clone can occur spontaneously without further exposures, but this stage is accelerated by additional exposures to genotoxic agents, including some cancer chemotherapeutic drugs.<sup>41</sup> Spontaneous premalignant progression has been attributed to genomic instability that is constitutive in the premalignant phenotype.<sup>42</sup> Premalignant progression in most tumor models and in humans is associated with nonrandom, sequential chromosomal aberrations, including duplications, deletions, and loss of heterozygosity,<sup>43</sup> suggesting repeated episodes of cell selection and producing modally dominant chromosomal aberrations. Thus, at least one function of the relevant genetic events in premalignant progression must result in a growth advantage for the affected cell. In rodent populations, the genetic background of specific strains is determinant for the rate of premalignant progression, suggesting that constitutional factors influence both early and late events in cancer progression.

Frequently, malignant conversion is a multifocal change in premalignant lesions. Experimentally, malignant conversion has been linked to up-regulation of AP-1 transcriptional activity, gene amplification, and alterations in cell-cycle regulatory genes and secreted proteases.<sup>44,45,46</sup> and <sup>47</sup> Other studies have revealed gene splicing changes with expression of modified cell-surface molecules.<sup>48,49</sup> Together, these changes could facilitate migration and invasion that characterize the malignant phenotype. These observations also suggest that malignant conversion can be an epigenetic, high-frequency event during premalignant progression, perhaps related to changes in gene expression. Alterations in methylation of DNA in tumor cells also could contribute to this stage of carcinogenesis.<sup>50,51</sup>

## **PROTECTION AGAINST CHEMICAL CARCINOGENS: DNA REPAIR, TUMOR SUPPRESSOR GENES, AND TRANSFORMING GROWTH FACTOR- $\beta$**

DNA repair defects have been identified in a number of cancer-prone individuals, and repair-deficient mammalian cells are susceptible to transformation by chemical and physical carcinogens.<sup>52,53,54</sup> and <sup>55</sup> Commonly, nucleotide excision repair removes carcinogen-DNA adducts or ultraviolet photoproducts by a complex process involving at least 10 gene products, each potentially associated with mutations leading to human DNA repair defect syndromes and increased cancer rates. Nucleotide excision repair commonly favors adduct removal on the transcribed strand to protect protein synthesis, but damage from some mutagens does not exhibit strand bias.<sup>56</sup> Genetically engineered mice deficient in genes involved in nucleotide excision repair are particularly sensitive to chemical and ultraviolet carcinogenesis at particular organ sites.<sup>54</sup> The highly mutagenic O<sup>6</sup>-methylguanine, a consequence of exposure to certain methylating agents (see [Fig. 11-1](#)), is repaired by O<sup>6</sup>-alkyldeoxyguanine-DNA alkyltransferase. Overexpression of this enzyme in transgenic mice protects the host from thymic lymphomas, colonic preneoplastic lesions, and colonic K-*ras* mutations after exposure to methylating agents.<sup>57</sup> O<sup>6</sup>-alkyldeoxyguanine-DNA alkyltransferase activity varies in different tissues and cell types, and the enzyme can be inhibited by exogenous exposures that may act as cofactors in carcinogenesis.<sup>58,59</sup> Recently, interest has focused on a multigenic nucleotide mismatch repair system designed to repair mismatched bases after replication.<sup>60</sup> Mutations in components of this pathway increase risk for colon cancer in humans, and engineered mice that are null for a gene in this pathway are predisposed to develop tumors.<sup>61</sup>

Tumor suppressor genes represent a growing family of regulators of the cell cycle, genomic stability, cell senescence, cell death, or cell-cell communication that are inactivated during carcinogenesis.<sup>4</sup> Some may be direct targets of carcinogens, such as the *P53* gene in liver and the K-*ras* gene in lung cancer,<sup>8,18</sup> whereas others may become spontaneously altered during premalignant progression or may be suppressed by promoter methylation.<sup>51</sup> Suppressor genes can be inactivated by structural gene changes, but genomic imprinting, reduction in stability of the protein product, or mutations with a dominant-negative effect that suppresses the function of the product of the normal allele variously have been reported.<sup>18,62</sup> Inactivation of a single allele of a tumor suppressor gene (in which mutations at multiple sites may cause inactivation) occurs commonly, because it is a higher-probability event than is activation of an oncogene (in which specific changes at a few selected sites are required). However, a dominant effect of a tumor suppressor gene loss requires inactivation of both alleles (e.g., the combination of a point mutation in one allele and chromosome loss of the second allele). Certain carcinogenic hazards, such as ionizing radiation, metals, carcinogenic hormones, and fibers, frequently cause chromosomal abnormalities and may contribute to carcinogenesis through inactivation of suppressor genes.

A unique role in tumor suppression is developing for the growth inhibitory peptide, transforming growth factor- $\beta$  (TGF- $\beta$ ).<sup>63,64</sup> Frequently, the regulation of this family of homodimeric growth inhibitors is altered in tumors as they undergo premalignant progression. Dysregulation takes the form of loss of expression, inactivation of required posttranslational processing of TGF- $\beta$  precursor, or reduction in responsiveness of tumor cells. Inactivating mutations in the TGF- $\beta$  type II receptor or the intracellular signaling pathway it activates have been documented in human tumors. Transgenic targeting of TGF- $\beta$  to the mammary gland and skin markedly inhibit tumor development in response to carcinogen administration. These studies suggest a role for TGF- $\beta$  in suppression of premalignant progression and offer a novel approach to therapeutic intervention.

## **GENETIC SUSCEPTIBILITY TO CHEMICAL CARCINOGENESIS IN EXPERIMENTAL MODELS**

The identification and characterization of genes that modify risks for cancer development have been facilitated by substantial variation among inbred strains of rodents in their susceptibility to spontaneous and chemically induced carcinogenesis at specific tissue sites.<sup>65</sup> Furthermore, carcinogenesis experiments in spontaneous mutant strains or genetically modified mice created by transgenic or knockout technology have identified specific loci that modify cancer risk. For a variety of tissue sites, including lung, liver, breast, and skin, pairs of inbred mice that differ by 100-fold in risk for tumor development have been characterized. Detailed analyses of these differences using backcross, recombinant inbred, and recombinant congenic breeding protocols have shown specific determinants for initiation, promotion, premalignant progression, and metastatic stages.<sup>66</sup> In most cases, susceptibility or resistance is a property of the target tissue, not the host. Genetically determined differences in the affinity for the aryl hydrocarbon hydroxylase (Ah) receptor or other differences in metabolic processing of carcinogens is one modifier that has a major impact on experimental cancer risk.<sup>28,30</sup> Other loci regulate the growth of premalignant foci, the response to tumor promoters, the immune response to metastatic cells, and the basal proliferation rate of target cells.<sup>65</sup> In mice susceptible to colon cancer due to a constitutive mutation in the *apc* gene,<sup>67</sup> a locus on mouse chromosome 4 confers resistance to colon cancer.<sup>68</sup> Similarly, an autosomal dominant locus in the rat genome protects susceptible rats from chemically induced mammary gland neoplasia.<sup>69</sup> Recent advances in mapping of the mouse and rat genome<sup>70</sup> now promise to provide precise localization and identification of the loci involved in experimental genetic susceptibility, and translation of this information to syntenic loci of the human genome<sup>71</sup> should provide important insights into human susceptibility traits.

## **DETERMINATION OF CHEMICAL CARCINOGENS FOR HUMANS AND POPULATION-BASED RISK ASSESSMENT**

Current understanding of carcinogenesis and risk to human health comes from a variety of models and methods, including mutagenesis assays, mammalian cell-culture experiments, animal studies, and both classic and molecular epidemiology. The goal of these studies is to elucidate cancer etiologies, to define cancer

risks in humans (population and individual), and to identify more rational cancer prevention methods. Physicians are challenged when they attempt to determine what causes a cancer in a particular individual. The determination process requires an accurate history and physical examination and interpretation of research data. Often, the latter are beyond the scope of the practitioner and, in many cases, beyond the current state of knowledge. Nevertheless, methods for cancer risk assessment have been proposed and resources are available.<sup>72</sup> Several types of study models are used to assist in elucidating carcinogenic mechanisms and identifying potential human carcinogens. The usefulness of each method for identifying carcinogenic mechanisms and for identifying cancer risk can be contrasted with its limitations (Table 11-3). A direct relationship of *in vitro* experimental studies (i.e., metabolic activation of chemicals by cytochrome P-450s), *in vitro* mutagenicity tests, experimental animal studies, and human epidemiology has not been proved, but most chemicals that are positive in one method generally are positive with other methods. Nevertheless, 100% concordance does not exist; though sensitivity is high, specificity is low. It may be that consideration of multiple assays yields greater productivity, but this is not yet proved, and the concordance from animal to human experience is variable, although carcinogens that are more potent in one species tend to be more potent in others, including humans.

Method	Example	Advantage	Limitation
<i>In vitro</i> testing	Ames test (bacterial mutagenicity); SCE test; micronucleus test; chromosome aberration; sister chromatid exchange; chromosome break; cell transformation assay	Rapid results; human cells can be used; economical	Correlation is always uncertain; false-positive and false-negative results; requires interpretation to see the use as a carcinogenicity indicator; interlaboratory variation
Animal testing	National Toxicology Program rodent bioassays	More predictive of human response; has shown some toxicologic species differences	Dosage does not higher than dose reported by human; murine animal-to-human extrapolation
Epidemiology	Prospective cohort studies; case-control studies	Direct measurement of human response; can assess potential dose-response; can assess genetic and other host factors	Interference does not prove causation; reliance on confounding variables; biomarker data studies in early stage of development and validation

TABLE 11-3. Testing for Carcinogenicity

Human investigations provide the most relevant data regarding human risk. Classic epidemiology measures the incidence or prevalence of disease in human populations. Epidemiologic studies have identified such previously unknown risks as asbestos-related pleural mesothelioma, benzene-induced leukemia, and bladder cancer in dye workers. Study design and controlling for confounding variables are important determinants of a true association. It must be realized that epidemiologic methods, by themselves, do not demonstrate causation, and specific guidelines for assessing causation are available (Table 11-4).<sup>73</sup> The concordance between different scientific methods for inferring human cancer risk is variable.

Criteria	Explanation
Strength of association	What is magnitude of risk?
Consistency	Are these repeated observations by multiple investigators in different populations?
Specificity	Is the effect specific or are there other known causes?
Temporality	Does exposure precede effect?
Biologic gradient	Is there a dose-response relation?
Biologic plausibility	Is the effect predictable?
Coherence	Is the effect consistent with other scientific data?
Analogy	Do other similar agents act similarly?

TABLE 11-4. Evaluating Cancer Etiology: Bradford-Hill Criteria<sup>73</sup>

Physicians can look to various regulatory, governmental, or review organizations for extensive evaluation of the scientific literature. Some organizations generate documents that report findings of experts who critically review the scientific literature, whereas others simply summarize data from other organizations. Several lists of carcinogens also have been published, but the evaluations of the literature and the definitions can vary greatly among organizations. Physicians should be aware of the purposes and goals of an organization when requesting its information. For example, the National Institute for Occupational Safety and Health and the American Council of Governmental Industrial Hygienists are concerned primarily with occupational exposures. The Environmental Protection Agency is concerned primarily with environmental exposures, quantitative risk assessments, and regulations relating to health hazard prevention for the entire population. The International Agency for Research on Cancer and the National Toxicology Program do not limit themselves to occupational or environmental exposures. The Agency for Toxic Substances and Disease Registry was created to study persons exposed to environmental toxins and to evaluate the adequacy of scientific literature. The known and potential human carcinogens, as reported by various regulatory and research organizations, are listed in Table 11-5.

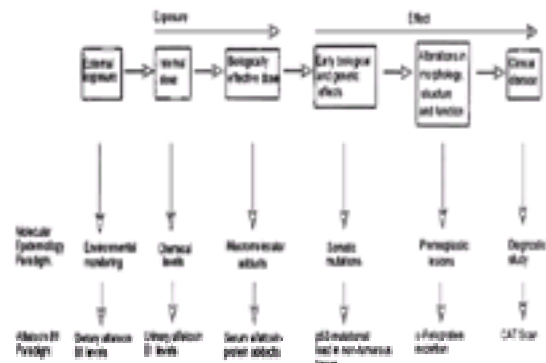

Target Organ	Agents	Substances	Tumor Type
Lung	Polycyclic aromatic hydrocarbons, nitrosamines, aflatoxins, asbestos, radon, diesel engine exhaust, 1,3-butadiene, chromium VI compounds, and for oral and gastric, nickel compounds, nickel and iron	Aluminum production, and purification, and pyrolysis; iron, boron, nitrate, nitrite, pesticides	Squamous, large cell, and small cell cancer and adenocarcinoma
Bladder	Aromatic amines		Squamous cell cancer
Esophagus	Polycyclic aromatic hydrocarbons, nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>	Beer and other products; fertilizer manufacturing; iron pyrite dust; diesel production	Squamous cell cancer
Gastric cancer	Nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>	Rubber industry	Adenocarcinoma
Uterus	Diethylstilbestrol, diethylstilbestrol, diethylstilbestrol, diethylstilbestrol, diethylstilbestrol	Diethylstilbestrol	Epithelial cell carcinoma, leiomyosarcoma, gestational trophoblastic disease
Colon	Polycyclic aromatic hydrocarbons, nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>	Nitrosamine metabolism; acetaminophen metabolism	Adenocarcinoma
Rectum	Polycyclic aromatic hydrocarbons, nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>		Adenocarcinoma
Prostate	Polycyclic aromatic hydrocarbons, nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>		Adenocarcinoma
Testis	Alkylating agents, nitrosamines, aflatoxins, and aflatoxin G <sub>1</sub>	Coal gasification, color production	Squamous cell cancer; germ cell cancer
Brain (meninges)	Diethylstilbestrol, diethylstilbestrol, diethylstilbestrol, diethylstilbestrol, diethylstilbestrol	Rubber workers	Lymphoma, meningioma

TABLE 11-5. Known or Suspected Chemical Carcinogens in Humans

A formal quantitative risk assessment is used by regulatory agencies to estimate the risk to a population exposed to a particular carcinogen at a specific dose. Risk assessments serve public health interests as they attempt to predict the frequency of cancer in a population before epidemiologic investigations can be performed (i.e., before significant exposure and adverse outcomes occur). Risk estimates are formulated for potential dietary, airborne, and workplace carcinogens. Several mathematical models are used by various regulatory bodies to predict risks and to regulate allowable exposures. Risk assessments include four general steps: (1) hazard assessment, which qualitatively reviews scientific literature to decide whether a hazard might exist; (2) dose-response assessment, which evaluates the doses used in scientific studies and relates them to human exposures; (3) exposure assessment, which examines a population thought to be at risk regarding the quantity, duration, and routes of exposure; and (4) risk characterization, which incorporates the foregoing information and evaluates the assumptions used and the uncertainties to estimate risk. The modeling process requires many assumptions that are open to debate, and safety factors are incorporated to compensate for the uncertainties. At the conclusion, an incidence of cancer will be predicted, such as one additional case in 1 million persons. Owing to methodological limitations and uncertainties, wide confidence limits often prevail for the prediction.

## MOLECULAR EPIDEMIOLOGY OF CANCER RISK FROM CHEMICALS

The field of molecular epidemiology seeks to identify cancer risk on the basis of individual exposures and genetically determined susceptibilities to cancer. Cancer epidemiology differs from traditional epidemiology because of its complexity. Traditional epidemiology paradigms implicate single causative agents that cause specific diseases (i.e., demonstrated through Koch's postulates). However, cancer is caused by multiple agents, and different combinations of agents can cause the same cancer. Conversely, the same agents might contribute to the development of different cancers. Molecular approaches to epidemiology use a priori hypotheses and biomarkers, rather than simply seeking associations between an exposure and disease (Fig. 11-3). Two fundamental principles underlie current studies of molecular epidemiology. First, carcinogenesis is a multistage process, and behind each stage are genetic events and complex pathways that may be responsible for these events. Thus, characterizing a specific risk factor against a background of many risk factors is difficult for scientists and can limit statistical power. Second, wide interindividual variation in response to carcinogen exposure and carcinogenic processes indicate that the human response to carcinogens is not homogeneous; hence, other studies (e.g., the use of a single-cell clone to study a gene's effect experimentally or the assumption that the population responds similarly to the mean in epidemiology studies) might not be representative of susceptible and resistant groups within a population.

**FIGURE 11-3.** Schematic model depicting the range (from exposure to effect) and types of biomarkers that might be used for cancer risk assessments. Aflatoxin-B<sub>1</sub> is shown as a paradigm for the range of biomarkers. CAT, computer-aided tomography.

The carcinogenic process is driven by genetic events (mutations or epigenetic changes), and in most people they are triggered by environmental exposures modified by host susceptibility. These are so-called gene-environment interactions.<sup>74</sup> Cancer-causing genes can be categorized into caretaker and gatekeeper genes.<sup>75</sup> Caretaker genes are involved in maintaining genomic integrity, such as those of DNA repair and carcinogen detoxification. Gatekeeper genes are involved in normal cellular function, such as those that are involved in cell-cycle control or apoptosis. Also, given that cancers are caused by multiple exposures causing damage in different genes, now the carcinogenic process is being considered as gene<sup>N</sup>-environment<sup>N</sup> interactions. This new paradigm will lead to different perspectives of cancer genetics and cancer risk factors, wherein some genetic effects will be modeled differently (see Fig. 11-2).

### EXPOSURE ASSESSMENT AND INTERNAL DOSIMETRY

Chemicals cause genetic damage in different ways: formation of carcinogen-DNA adducts leading to base mutations or bringing about gross chromosomal changes. Carcinogen-macromolecular adducts are formed when a mutagen, or part of it, irreversibly binds to DNA so that it can cause a base substitution, insertion, or deletion during DNA replication. Gross chromosomal mutations are chromosome breaks, gaps, or translocations. The level of DNA damage is the biologically effective dose in a target organ,<sup>76</sup> and reflects the net result of carcinogen exposure, activation, lack of detoxification, lack of DNA repair, and lack of programmed cell death or necrosis.

A variety of assays are available to identify carcinogen-macromolecular adducts in human tissues. These assays include the <sup>32</sup>P-postlabeling assay-nucleotide chromatography, immunoassays that include immunohistochemistry, fluorescence spectroscopy, gas chromatography-mass spectroscopy, and electrical chemical detection. Each has its usefulness and limitations, and all are challenged by sensitivity or specificity (or both). The effect of an individual's metabolism on carcinogen-DNA adduct formation might be different at different levels of exposure—where adduct levels formed from lower exposures are relatively higher—and similar to that of persons with decreased metabolic capacity but higher exposures.<sup>77</sup> The relationship of such surrogate markers as carcinogen-DNA adducts in blood to the target organ has been studied partially<sup>78,79</sup> but is not yet well established, and the use of target organs<sup>80,81</sup> can provide specific information about potentially carcinogenic effects.

The detection of gross chromosomal changes in normal-appearing cells is technically difficult. Presumed surrogate measures of chromosomal damage include the estimate of sister chromatid exchanges or baseline gross chromosomal changes. The latter has been associated with increased cancer risk, but these studies have significant limitations.<sup>82,83</sup>

The effect of some potential carcinogens has been studied extensively using molecular epidemiological tools.<sup>84,85</sup> These carcinogens tend to be present in tobacco smoke and, in some cases, diet and workplace.

Commonly, people are exposed to N-nitrosamine and other N-nitroso compounds from dietary<sup>86</sup> and tobacco exposures,<sup>8</sup> which are associated with DNA adduct formation and cancer in laboratory animals.<sup>87</sup> Exposure can occur through endogenous formation of N-nitrosamines from nitrates in food<sup>88</sup> or directly from dietary sources, cosmetics, drugs, household commodities, and tobacco smoke. The greatest source of exposure in the United States is from processed meats and (until recently) beer. Endogenous formation occurs in the stomach from the reaction of nitrosatable amines and nitrate, used as a preservative, which is converted to nitrites by bacteria. Host capacity to form N-nitrosamines is associated with risk of stomach<sup>89</sup> and esophageal cancer.<sup>90,91</sup> It has been shown also that coadministration of vitamin C can reduce the rate of endogenous nitrosation. N-nitrosamines undergo metabolic activation by cytochrome P-450s (CYP2E1, CYP2A6, and CYP2D6) and form DNA-adducts that have been identified in target tissues or have been associated with specific cancers.<sup>92,93</sup> and <sup>94</sup>

Exposures to polycyclic aromatic hydrocarbon (PAH) compounds are associated with an increased risk of lung and skin cancer. Industrial pollution, fossil fuels, and tobacco smoke account for the major environmental sources, although diet is considered the major source.<sup>95</sup> DNA damage in white blood cells has been documented for a variety of exposures.<sup>85</sup> PAH-adducts can be formed from the consumption of charcoal-broiled foods, where adduct levels exceed those from smoking.<sup>96</sup>

Substantial data implicate aromatic amines and amides in human carcinogenesis.<sup>77</sup> Aryl aromatic amines have been implicated in bladder carcinogenesis, especially in occupationally exposed cohorts (e.g., dye workers) and tobacco smokers. Some of the largest carcinogenic occupational exposures occur in the dye industry. Initially, aryl aromatic amines are activated by CYP1A2, which ultimately leads to the formation of nitrenium ion that then forms a DNA adduct. N-acetyltransferase-1 and N-acetyltransferase-2 (NAT-2) play an activating or detoxifying role, depending on the aryl amine. Generally, internal dosimetry for the chemicals has focused on hemoglobin rather than on DNA adducts. Levels are higher in smokers than in nonsmokers, and different types of tobacco can lead to higher adduct levels.<sup>97</sup>

Other mutagenic aromatic amines are heterocyclic amines. They are formed from the cooking of meat, poultry, and fish as a result of the condensation of amino acids and creatine during pyrolysis.<sup>98</sup> Some are present also in cigarette smoke. Levels of exposure typical for humans produce DNA adducts at the C8 position of guanine and are associated with cancers in experimental animals.<sup>99,100</sup> Heterocyclic amines, estimated as consumption of well-done meat, have been associated with breast and colon cancer.<sup>101</sup>

Aflatoxins are suspected human liver carcinogens and are considered to be a major contributor to liver cancer in China and parts of Africa. Aflatoxin remains one of the best examples of the range and use of biomarkers for cancer risk (see Fig. 11-3). The primary adduct formed from aflatoxin exposure is to the N7 position of guanine.<sup>102</sup> The metabolic activation in humans is similar to that of sensitive laboratory animals.<sup>103</sup> Urinary aflatoxin adduct levels vary among regions of the world, depending on dietary exposures.<sup>104</sup> Serum albumin adducts correlate with dietary intake and urinary excretion of the M1 metabolite.<sup>105</sup> Important is that urinary aflatoxin adduct levels correlate with the incidence of hepatocellular carcinomas, and an interaction is seen with hepatitis B infection.<sup>84</sup>

## GENETIC SUSCEPTIBILITY

The cancer risk from genetic variation can range from small to large, depending on its penetrance. Highly penetrant cancer susceptibility genes cause familial cancers and account for fewer than 1% of all cancers.<sup>106</sup> Low-penetrant genes cause common sporadic cancers, which have large public health consequences. [Table 11-6](#) lists several investigated genetic polymorphisms and their association with cancer risk. A genetic polymorphism is defined as a genetic variant present in at least 1% of the population.

**TABLE 11-6.** Selected Examples of Inherited Susceptibilities for Cancer

Lung cancer has been studied most extensively for gene-environment interactions. Among the low-penetrant genes studied most commonly are cytochrome P-450 (CYP)1A1 and glutathione S-transferase M1 (*GSTM1*). The CYP1A1 enzyme is the first step in the metabolic activation of polycyclic aromatic hydrocarbons, which are known human lung and skin carcinogens. Studies of Japanese subjects indicated an interaction between a CYP1A1 polymorphism and smoking for lung cancer risk,<sup>107</sup> wherein the combination of the homozygous minor allele and smoking yielded odds ratios similar to having one of the other genotypes and a greater smoking history.<sup>108</sup> Western studies, however, do not show the same association.<sup>109,110,111</sup> and <sup>112</sup> *GSTM1* is a detoxifying enzyme that catalyzes the conjugation of PAHs to glutathione. Expression of *GSTM1* is inherited as an autosomal dominant trait, and the cause of low *GSTM1* activity is an entire gene deletion of *GSTM1*. Phenotypically and genetically, this polymorphism has been related to lung cancer risk.<sup>113,114</sup> and <sup>115</sup> Gene-gene interactions for CYP1A1 and *GSTM1* have been found in ongoing Japanese studies of lung cancer.<sup>116</sup> Also, the “at-risk” genotype conferred a higher probability for presenting with more extensive cancer, and the combined genotypes yielded a shorter survival time.<sup>117</sup> The lack of *GSTM1* activity has been associated also with increased PAH-DNA adducts in human lung tissue,<sup>81</sup> increased sister chromatid exchange,<sup>118,119</sup> and production of mutagenic intermediates by lung microsomes.<sup>120</sup>

Breast cancer clearly is related to endogenous and exogenous estrogens, but these factors explain less than one-half of the excess risk,<sup>121</sup> and certain reasons implicate nonhormonal chemical etiologies.<sup>122</sup> Thus, the role of exogenous chemicals is being studied actively. For hormonal etiologies, variation in estrogen metabolism by cytochrome P-450s (CYP1A1, CYP1B1, CYP1A2, CYP17) and other genes can be hypothesized to affect hormonal levels, resulting in altered cell proliferation or DNA damage and subsequent cancer risk. One study has implicated cytochrome 17,<sup>123</sup> whereas others have provided conflicting evidence for catechol-methyltransferase that detoxifies estradiol.<sup>124,125</sup> For chemical etiologies, aromatic amines have been implicated as potential human breast carcinogens.<sup>122</sup> These chemicals are detoxified by NAT-2, in which a genetic polymorphism governs the metabolism of isoniazid for tuberculosis treatments.<sup>126</sup> One study indicated that tobacco smoking is associated with breast cancer in white postmenopausal women who have a decreased capacity to detoxify aromatic amines, because they are NAT-2 slow acetylators.<sup>127</sup> Although a prospective study of nurses<sup>128</sup> seemingly provided conflicting data, differences were found in data analysis and study size. Considering a specific role for polycyclic aromatic hydrocarbons in breast cancer, some suggestions posit that one polymorphic variant of CYP1A1 might be a risk factor for breast cancer in subsets of smokers,<sup>129,130</sup> whereas another polymorphism might be a risk factor in African Americans.<sup>131</sup> A nested case-control study from a prospective cohort of women in Maryland found a 2.1-fold increased risk for women who lacked *GSTM1*,<sup>132</sup> although two studies have not found similar results.<sup>129</sup>

The role for genetic determinants of carcinogen metabolism in cancer risk is established for other cancers, although this area of study is newer.<sup>113</sup> Several studies have implicated deficient *GSTM1* and NAT-2 detoxification of smoke-related or occupational carcinogens in bladder cancer.<sup>77,133</sup> For colon cancer, studies have demonstrated that risk increases for NAT-2 rapid acetylators,<sup>134,135</sup> wherein, in contrast to its detoxification role in bladder and breast cancer, evidence suggests that NAT-2 works to activate heterocyclic amines formed from the overcooking of meats.<sup>136</sup>

Genetic polymorphisms for housekeeping genes controlling such cellular functions as cell-cycle control and DNA repair logically may affect cancer risk.<sup>106</sup> In the general population, DNA repair capacity in humans decreases with aging,<sup>137,138</sup> which would make this decrease an acquired risk factor for cancer and might explain a portion of the increased cancer risk in the elderly.<sup>139</sup> However, inherited susceptibilities via specific genetic polymorphisms that affect the efficiency of DNA repair, such as for nucleotide excision repair, are largely unknown. A nonspecific DNA repair assay that measures chromosomal aberrations in human cultured lymphocytes after an *in vitro* challenge with a mutagen has shown initial promise. An increased mutagen-related aberration rate has been observed in persons with primary and secondary upper aerodigestive tract cancers,<sup>140</sup> multiple primary cancers,<sup>141</sup> and lung cancer.<sup>142</sup>

## MUTATIONAL SPECTRUM OF HUMAN CANCERS

The study of mutations in human tumors and experimental models is elucidating important carcinogenic mechanisms.<sup>143</sup> *In vitro* studies using prokaryotic and simple eukaryotic assays, including human cells (e.g., site-specific mutagenesis assays), indicate that human exposure to mutagens might result in a narrow spectrum of mutations that are nonrandom.<sup>18</sup> Some carcinogenic agents produce a “fingerprint” of mutations. In eukaryotic studies, for example, examining the mutational spectra in endogenous genes<sup>144</sup> or exogenous genes transfected into cell systems<sup>145,146</sup> have identified different phenotypes, depending on the exposures. These assays, however, may underestimate the induced mutational frequency due to deletions, chromosomal nondysjunction, and frameshift mutations that cause loss of other genes essential for cell survival and result in cytotoxicity or apoptosis. The data also show that the fingerprint hypothesis is likely the exception rather than the rule, because most mutagens actually can form several types of mutations, depending in part on the conformation of DNA and the type and the location of the adduct.<sup>143</sup> Nonetheless, a comparison of the mutational spectrum at the *aprt* locus in Chinese hamster ovary cells induced by ionizing radiation, ultraviolet radiation, or benzo[a]pyrene-diol-epoxide is consistent with the mutagenesis models for these exposures.<sup>144</sup> Promutagenic cyclobutane and pyrimidine-pyrimidone(6-4) photoproducts are induced by ultraviolet light, whereas ionizing radiation frequently causes deletions, and benzo[a]pyrene-diol-epoxide causes the predicted G:C@T:A transversion.

The study of mutations in the *P53* tumor suppressor gene is suited uniquely for the study of cancer etiology, exposure, and susceptibility, because *P53* is involved in many cellular processes, including maintenance of genomic stability, programmed cell death, DNA repair, and others.<sup>147</sup> The *P53* mutation frequency varies by organ site and histological subtype,<sup>18</sup> indicating that cancers occur through different pathways and different exposures at the cellular level. Several examples of particular carcinogenic exposures are linked to cancers via a *P53* mutational mechanism, especially the demonstration that ultraviolet light exposure and skin cancer are associated with cytosine-cytosine to thymine-thymine tandem transitions.<sup>148</sup> Another example is dietary aflatoxin B1 exposure and a consistent finding of mutations in the third nucleotide pair of codon 249 of liver cancers in regions with endemic exposure to aflatoxin B1.<sup>149,150</sup> Combinations of exposures can lead also to different outcomes in the same organ site. An interactive effect of alcohol drinking and cigarette use in oral cavity cancers yields different types of *P53* mutations.<sup>151</sup>

Showing that the *P53* mutation frequency is modulated by gene-environment interactions has been difficult because of the technical difficulties in determining the mutational spectra in large numbers of cancer patients, but preliminary evidence exists. The mutational spectra of lung<sup>18</sup> and breast cancers<sup>152</sup> are different among whites, African Americans, and Japanese, consistent with the hypothesis that differences exist in both exposure and the frequency of genetically determined carcinogen metabolism and DNA repair. More specific evidence for a relationship of gene-environment interactions and mutations in the *P53* gene can be found from Japanese studies of *CYP1A1*, *GSTM1*, and lung cancer.<sup>153</sup>

Among the most exciting areas in molecular epidemiology is the potential ability to identify mutations and preneoplastic lesions prior to the development of cancer or as a diagnostic test for early cancer. Analyses of stool from cancer patients have found cells with the same K-*ras* mutations present in the cancer.<sup>154</sup> Similar findings have been reported in sputum samples from patients with head and neck cancers.<sup>155</sup> Analysis of codon 12 mutations in the K-*ras* gene of bronchoalveolar cells has shown a 33% rate of detection in cancer patients, with an acceptable specificity; many of the positive samples were cytologically negative for cancer.<sup>156</sup> Archived sputum samples also have revealed, in K-*ras*, mutations that were matched later to a confirmed diagnosis of lung cancer.<sup>157</sup>

## TOBACCO SMOKING AND CANCER RISK

Tobacco smoking is the major cause of cancer and accounts for almost 96% of all male lung cancers in whites. Though the risk of lung cancer decreases after smoking cessation, the risk never returns to that for nonsmokers. According to 1990 estimates, persons who died of smoking-related diseases would have lived an additional 15 years if they had never smoked. Tobacco smoke contains more than 3500 chemicals, of which more than 20 are carcinogens.<sup>8</sup> Specific chemicals in tobacco smoke include PAHs and N-nitrosamines, aromatic amines, ethylene oxide, 1,3-butadiene, and agents that cause oxy radical damage. For example, tobacco-specific nitrosamines (TSN)—that is, 4-(methyl-nitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and N'-nitrosornicotine (NNN), which are potent carcinogens in laboratory animals<sup>158</sup> result in the formation of hemoglobin adducts.<sup>159</sup> PAHs and TSNs are considered to be the most potent carcinogens in tobacco smoke.<sup>8</sup> During the last 40 years, the approximate threefold decrease in tar (containing PAHs) and nicotine content has been accompanied by an increase of other carcinogens, including TSNs.<sup>160</sup>

Convincing laboratory animal and human studies demonstrate a relationship between tobacco smoke constituents, carcinogen-DNA adduct formation, and cancer.<sup>161</sup> In humans, case-control studies find a positive relationship for lung and bladder cancer.<sup>162,163</sup> Also, studies of tobacco smoke exposure have shown increased adduct formation in the lung,<sup>78,164,165</sup> blood,<sup>78,163,166</sup> and larynx.<sup>167,168</sup> and <sup>169</sup> However, wide interindividual variation for adduct levels is common, so several studies have failed to show a direct relationship between smoking and adducts.<sup>81,162,170,171</sup>

The *P53* gene, in particular, has a unique spectrum of mutations in tobacco-associated lung cancers.<sup>172</sup> Also, an increased frequency of *P53* tumor suppressor gene mutations has been reported at non-CpG sites in smokers with head and neck cancers, especially in conjunction with alcohol consumption.<sup>151</sup> The decrease in nicotine content in cigarettes has led to a paradoxical increase in smoking, owing to the drive for maintaining higher blood nicotine levels.

Several determinants of tobacco carcinogen exposure and cancer risk exist, including the number of cigarettes smoked per day, years smoked, cigarette type (e.g., tar content, which is the total dry particulate component of smoke), and smoking topography (e.g., how much smoke entering the lung is measured by puff volume, number of puffs per cigarette, puff duration, and interpuff interval).<sup>173</sup>

Also important is that not all smokers experience the same carcinogenic risks; only 1 in 10 heavy smokers develop lung cancer, and some heavy smokers live to their 90s. Thus, interindividual variation in host susceptibility likely is important for cancer risk (e.g., those related to carcinogen metabolism, DNA repair, or behavior).<sup>174</sup> Overall risk is related to dose, which is directly affected by nicotine addiction; more cigarettes are consumed to maintain nicotine blood levels, and cigarettes with lower nicotine levels result in the need to smoke more, thereby increasing the exposure to tobacco carcinogens.

### INTRODUCTION

This chapter discusses the induction of cancer by three physical agents that are known to cause cancer in humans: radiation, UV light, and asbestos. Exposures to ionizing radiation can come from both natural and man-made sources. We are continually exposed to naturally occurring radioisotopes contained in soil and rocks, and, as a result, in building materials and even in our own bodies. In addition, we are exposed to cosmic rays from the sun and radon. The levels of this naturally occurring environmental radiation, often referred to as *background radiation*, varies with altitude, geology, and types of building materials used to construct homes and other buildings. One of the most important man-made sources of exposure is from imaging and therapy procedures in medicine. It is also one of the largest sources of exposure. On average, the dose to the general population from medical exposures is similar to that received from background radiation.

UV light from the sun is responsible for an increasing number of skin cancers throughout the world. Risks for skin cancer vary with altitude, latitude, and pigmentation, all of which modify exposure to UV light. UV light and certain types of ionizing radiation, such as x-rays and gamma rays, are all part of the electromagnetic spectrum, which also includes static magnetic fields, fields generated by 50 or 60 cycle alternating current, radiowaves, microwaves, infrared light, and visible light. UV light and electromagnetic forms of ionizing radiation have the highest frequencies and energies.

Asbestos is a third physical agent that is a well-known human carcinogen. Asbestos is a naturally occurring mineral silicone that results from fibrous crystallization. Health effects, including lung cancer, arise from its commercial uses that lead to high occupational exposures. Health effects from low-level exposures, such as those to the general population, are more controversial. The concern over the effects from occupational exposures and potential health risks in the general population has markedly reduced the mining and use of asbestos worldwide.

Because their carcinogenic potential is well known, questions about these physical agents focus on the degree of risk to humans as a function of level of exposure and on mechanisms of cancer development. These mechanistic studies can provide insight into potential risks at very low levels of exposure, for which effects cannot be directly measured by epidemiologic studies. These studies also provide information about potential sensitive subpopulations, suggest ways to reduce risks, and provide insight into fundamental mechanisms of cancer development.

### INTERACTIONS OF RADIATION WITH CELLS AND TISSUES

Gamma rays, x-rays, and UV light are all part of the electromagnetic spectrum, which is shown in [Figure 12-1](#).<sup>1</sup> Their interactions with biologic material depend on the frequency or wavelength of the radiation. At the short wavelengths of x-rays, electromagnetic radiation has sufficient energy to produce ionizations as a result of the removal of electrons from atoms. At the longer wavelengths of the other forms of electromagnetic radiation, from UV light to low-level electric and magnetic fields, the energy deposition is insufficient to produce ionizations, and these forms are often generally referred to as *nonionizing radiations*.

FIGURE 12-1. Electromagnetic spectrum.

### IONIZING RADIATION

In addition to the electromagnetic forms of ionizing radiation (such as x-rays and gamma rays), electrons, protons, alpha particles, and neutrons are particulate forms of ionizing radiation. The spatial distribution of the ionizations produced by these different forms of ionizing radiation provide a means of classification based on their interactions in matter, including their interaction with biologic material. This spatial distribution of ionization is measured as the energy transferred per unit track length [linear energy transfer (LET)] in units of keV/mm.<sup>2</sup> On this basis, x-rays, gamma rays, and electrons are classified as *sparsely ionizing*, whereas alpha particles (such as those associated with radon) and neutrons are *densely ionizing*. The density of the ionization tracks can have a substantial impact on the biologic effects of the radiation. These influences can be qualitative as well as quantitative. The quantitative differences in the effectiveness of different ionizing radiations are measured by comparing the dose of the test radiation (e.g., neutrons) to produce a specific level of effect against the dose of x-rays (or sometimes gamma rays) to produce that same level of effect. That ratio is the relative biologic effectiveness (RBE). For cell killing effects, RBEs for neutrons and alpha particles are often approximately 3 to 5; for cancer induction in animals, the RBE values can be 20 or higher (RBEs of 50 or more have been reported).<sup>3</sup> The RBE increases with increasing LET to a maximum at approximately 100 keV/mm. At this LET, the average separation of ionizing events is approximately the diameter of the double helix. This results in a high probability that a single track of radiation of this LET can produce a double-strand break. Qualitative differences between high and low LET radiation are suggested by the fact that, for all effects observed, including cell killing, chromosome aberrations, mutations, and cancer induction, the radiation damage that induces these

effects appears to be less easily repaired by the cell or organism after exposure to high LET radiation. <sup>2</sup>

Energy deposited in biologic material can produce ionizations in target molecules, such as DNA, directly or indirectly by interactions with water molecules that result in the formation of free radicals. These free radicals can then produce damage to DNA. Because ionizing events from low LET radiation exposures are sparsely distributed, damage to DNA and other targets from such radiation is principally a result of indirect mechanisms mediated by free radicals. High LET effects are more generally mediated via direct effects on the target molecules. <sup>2</sup>

Whether the effects are directly or indirectly produced, ionizing radiation results predominantly in base damage, and single- and double-strand breaks in DNA. As already mentioned, for low LET radiations, these effects are mediated via reactive oxygen species much like those produced by normal cellular processes. The reason that ionizing radiations are able to cause the degree of damage that they do is because of the different spatial distribution of energy that results in a markedly different distribution of these reactive oxygen species than occurs during normal cellular processes. Ionizations from the deposition of ionizing radiation are highly clustered, which results in localized areas of sites in DNA molecules with multiple and complex lesions consisting of a combination of base damage and single- and double-strand breaks. <sup>2,4</sup> These more complex lesions are less easily repaired with fidelity than are the more simple forms of DNA damage. <sup>4,5</sup> For high LET radiations, because of the density of the ionization clusters, the molecular damage can be particularly complex and difficult to repair.

## ULTRAVIOLET LIGHT

UV radiation does not have sufficient energy to produce ionizations. Rather, its effects are the result of molecular excitation after absorption of energy by the molecule. UV light can be categorized into three types, based on wavelength: UVC with wavelengths ranging from 240 to 290 nm, UVB ranging from 290 to 320 nm, and UVA ranging from 320 to 400 nm. UVC is not in sunlight that reaches earth because it is readily absorbed by the atmosphere. It has proven to be useful, however, for other reasons. It is produced by low-pressure mercury lamps commonly used for sterilization. In addition, because the peak wavelength of these lamps (254 nm) is very close to the peak for absorption in DNA molecules (260 nm), it has been an important experimental tool for studies of UV light effects on DNA. UVB appears to be primarily responsible for skin cancer induction after sunlight exposure via direct damage to DNA. The amount to which the population is exposed depends on many factors, including the ozone layer. Effects of UVB and UVC appear to be mediated via effects on DNA. Interactions of UVB and UVC with DNA result in a number of molecular changes, the most prevalent of which are dimers between adjacent pyrimidines. <sup>6</sup> The most biologically important of these are the cyclobutane dimer and the 6-4 photoproduct. Other products are less frequent, but these two, especially the cyclobutane dimers, appear to play a major role in the mutagenic and carcinogenic effects of UVB. UVA is not absorbed by the atmosphere and penetrates deeper into the skin than UVB. Because of its wavelength, DNA and proteins only weakly absorb UVA, but it has been shown to be carcinogenic. This carcinogenic effect appears to be due to the production of reactive oxygen species and free radicals through its interactions with target chromophores. As a result, such products induce indirect damage to DNA. <sup>7</sup>

For UVC and UVB, the distribution of specific changes in the genome depends on base sequence and secondary and tertiary genomic structure. For example, cytosine absorbs higher wavelengths of UV radiation than thymine, resulting in dimers containing cytosine being more readily formed after UVB radiation. Data have shown that methylation at specific sequences in the p53 molecule enhance formation of dimers in specific regions, resulting in mutations that are relatively specific for UV damage. <sup>8</sup> These specific mutations have been found quite early in skin tumors. <sup>9,10</sup>

## IONIZING RADIATION AND CANCER

### HISTORY AND SOURCES OF INFORMATION

The benefits of ionizing radiation in the diagnosis and treatment of disease were recognized by the medical community very soon after the discovery of x-rays and radioactivity. <sup>11</sup> Almost as quickly, the risks of exposure began to be recognized as well. The first cancers, detected a few years after the discovery of x-rays, were skin cancers that developed after high skin doses received by early workers who often used their hands to test the output of x-ray tubes. These cases were followed by cases of radiation-induced leukemias among radiologists and radioisotope workers. These early studies established that radiation could cause cancer in humans, but the extent of the risk as a function of dose was not known. This began to change in the 1950s and 1960s with the study of the Japanese survivors of the atomic bombs, the study of patient populations exposed to radiation for therapeutic and diagnostic procedures, and occupationally exposed populations, such as radiologists, uranium miners, and nuclear industry workers. A partial list of the principal sources of information is shown in [Table 12-1](#). These studies, which began in the 1950s and continue today, have provided and continue to provide extensive quantitative information about radiation dose and cancer risk. In addition, such studies provide information on tissue and organ sensitivity and risk-modifying factors, such as age and genetic background.

**TABLE 12-1.** Studies of Radiation-Exposed Populations

The largest population studied and the one that has served as the primary source for risk estimates are the populations in Hiroshima and Nagasaki, Japan, who survived the atomic bombings of these two cities. <sup>12,13,14</sup> and <sup>15</sup> The doses received were single acute exposures of a mixture of gamma rays and neutrons to the entire body. The doses ranged from lethal to very small, depending on the location of the individuals at the time. The average dose received by the survivors was less than 0.3 Sv. The study of this group, which began a few years after the exposures, has provided extensive information on risk as a function of dose and provided insight into variations in tissue and organ sensitivity. Because the age distribution of the population was wide, including the old and the very young (as well as children exposed *in utero*), this study is also an important source of information about the effects of age on risk and on the time between radiation exposure and the appearance of leukemias and solid cancers (latent period). This study is still ongoing, and a large fraction of the population exposed as children, adolescents, and young adults are still living. Because of this fact, we are continuing to learn about the risks from radiation exposure, and this population will continue to provide new information for many years to come.

Another major source of information is patient populations exposed to ionizing radiation as a result of therapeutic or diagnostic procedures. The numbers of patients in each individual study are smaller than in the atomic bomb survivors, but the number of such studies is relatively large. <sup>16</sup> In spite of the large numbers of studies, only a few have been useful for the quantification of risk as a function of dose. Because such populations generally receive localized exposures, these groups generally provide information on cancer risks in specific organs and tissues. Such populations also have provided insight into modifying factors, such as age and genetic background. Studies of second cancers after radiation therapy has become an increasingly important source of information. <sup>17</sup> This group is discussed in more detail later in the section [Second Cancers](#). In the past, radiation was used to treat a number of benign disorders, including enlarged thymus glands and tonsils, tinea capitis, ankylosing spondylitis, and peptic ulcers. <sup>16</sup> Epidemiologic studies of such treated populations have provided information on radiation-induced leukemia, as well as thyroid, breast, and stomach cancers. In general, diagnostic procedures result in very low radiation exposures; however, a few studies have provided evidence for increased cancer risks. One of the most intensively studied of these is a group of tuberculosis patients who were subjected to multiple diagnostic fluoroscopies during their treatment. <sup>18,19</sup> In these studies, female patients have been shown to be at an increased risk for breast cancer. Although individual doses were low, the number of exposures resulted in the accumulation of relatively large doses.

As is the case for other carcinogenic agents, occupational exposures also have been a valuable source of information. Studies of uranium miners and other

underground miners have been a particularly valuable source of information on risks of lung cancer after exposure to radon. <sup>20</sup>

## RADIATION AND CANCER RISKS

### Tissue Sensitivity and Latent Period

Although radiation can induce many different types of cancer, certain organs, tissues, and cell types are more sensitive than others. Chronic myelocytic leukemia and acute leukemia are very sensitive to induction, whereas no evidence indicates that chronic lymphocytic leukemia, Hodgkin's disease, or non-Hodgkin's lymphoma can be induced by radiation exposure. <sup>14</sup> Among solid cancers, cancers of the thyroid gland, female breast, and lung appear to be the most sensitive. <sup>13</sup> Evidence also suggests increased risk for salivary gland tumors; colon cancer; stomach cancer; and cancers of the liver, ovary, bladder, esophagus, skin, and central nervous system; however, these sites are not as sensitive. Most skin cancers are basal cell and squamous cell carcinomas, whereas there is little evidence for the induction of melanomas. In general, bone sarcoma and cancer of connective tissues require relatively high doses before a significant increased risk can be detected. No clear evidence exists for the induction of cancers of the pancreas, prostate, uterine cervix, small intestine, or most childhood cancers (except for acute leukemia).

Radiation-induced leukemias are the first to appear after radiation exposure. <sup>21,22</sup> Depending on dose, these leukemias can begin to appear as early as 2 years after exposure, with peak incidence occurring between 4 and 8 years after irradiation. After this peak, the incidence begins to drop toward baseline levels. In general, solid cancers do not appear until 10 or more years after the radiation exposure, and it is not unusual for the latent period to exceed 20 years. <sup>16</sup> The time between irradiation can depend on the age at exposure, the dose, and a variety of host factors. For example, the appearance of breast cancer is greatly influenced by age at the time of irradiation. The time between radiation exposure and the appearance of breast cancer is quite long for a prepubertal or adolescent girl, whereas for a woman in her late twenties or early thirties, the latent period is generally shorter. A close look at the relationship between age at exposure and time of appearance for breast cancer indicates that these radiation-induced cancers appear at a time when the natural incidence of these cancers is also rising. This is likely a result of host factors that play an important role in breast cancer development and that also appear to strongly influence the expression of radiation-initiated cells. These data have important implications for potential mechanisms of radiation carcinogenesis. These very long latent periods, particularly for younger individuals, are also important to remember when assessing risks associated with specific treatment protocols.

### Dose-Response Relationships

Understanding the relationship between cancer frequency, or risk, and radiation dose is important for providing insight into mechanisms underlying radiation carcinogenesis. It is also important for estimating risks at low doses for which effects cannot be directly determined from experimental or epidemiologic studies. Accurate risk estimates at low doses are essential in regulating environmental and occupational exposures. <sup>21</sup> It is also essential in decisions about medical uses of radiation when weighing the benefits of the procedure versus its risks. <sup>2</sup> One of the most prominent examples of this issue has been the debate over mammography, both with respect to its general use to screen women for breast cancer and with respect to the age at which such screening should be initiated and practiced routinely. The question of whether the benefits of this screening outweigh the risks for inducing new breast cancers depends on many complex issues, but central to these issues is the risk of breast cancer from the doses received. It is virtually impossible to observe an increase in risk in an epidemiologic study at the low doses received as a result of a single mammographic procedure (or for that matter any diagnostic procedure) (Table 12-2), so estimates must be based on models of dose-response relationships that allow estimates to be derived. Mainly because of these low-dose risk issues, a substantial amount of effort in epidemiologic studies and in experimental studies of radiation carcinogenesis has been to define dose-response relationships and test predictions of dose-response models.

Procedure	Dose (mGy)
Chest x-ray (single PA film) (air kerma <sup>a</sup> )	0.16
Dental bitewing (air kerma)	1.0
Mammography (mean glandular dose)	1.6

PA, posterior to anterior beam projection  
<sup>a</sup> Air kerma is dose in air in units of joules/kg of air.

TABLE 12-2. Approximate Doses from Common Diagnostic Procedures

From theoretical models of radiation interactions at the cellular and molecular level, and from experimental and epidemiologic studies, two dose-response models are most prominent: the linear model and the linear-quadratic model. <sup>21,23</sup> As suggested by its name, with the linear model cancer risk (or I, incidence) is linearly related to dose ( $I = aD$ ). With the linear-quadratic model, risk at low doses is linearly related to dose, whereas at higher doses, the risk increases more rapidly as a function of dose. In this region, risk increases as a function of the square of the dose. As a result, the dose response takes the form  $I = aD + bD^2$ . The linear-quadratic model is based on biophysical theories of radiation interactions. The  $bD^2$  component represents effects produced by the interaction of multiple ionization tracks, whereas the  $aD$  component represents effects produced by single ionization tracks. For sparsely ionizing low LET radiation at low doses, the probability is that only a few ionization tracks will traverse a cell (at very low doses perhaps only one such ionization track might traverse a cell). Therefore, any effects observed, such as a double-strand break or a chromosome aberration, must have been a result of effects produced by such single tracks. At higher doses, in which multiple tracks would be traversing a cell, such effects would be expected to be a result of interactions of damage produced by these multiple tracks. Because the probability of inducing a complex type of damage, such as a double-strand break, is greater with multiple events occurring in close proximity, the dose response would be expected to rise more rapidly than at low doses. For densely ionizing radiation, ionization tracks through a cell are few, but the density of the ionization is sufficient to produce complex effects with single tracks with a high probability. As a result, the dose response is expected to be linear over a wide range of doses.

Irrespective of the model, the prediction at low doses is that the dose response is linear. This prediction implies that any dose of radiation received has a probability of inducing damage and, therefore, results in some increased risk for cancer development. Although there is some argument about this assumption at very low doses because of the repair and damage response capabilities of cells, current information about underlying mechanisms of cancer induction by ionizing radiation would tend to support the view that any dose of radiation confers some degree of risk.

At high dose, the linear quadratic and linear models differ not only in form but also in predictions about risks at low dose rates and fractionated exposures. <sup>24</sup> Such predictions impact lifetime risks for those exposed occupationally at low dose rates over many years and also impact estimates of risks from multiple medical procedures, such as mammography, computed tomographic scans, fluoroscopies, or even dental x-rays over a lifetime. The linear model in its most simple form predicts that lowering the dose rate or giving many small fractions confers the same cancer risk as the same dose delivered as a single, high dose-rate exposure. The linear-quadratic model predicts that, at high total doses, reducing the rate at which the total dose is received or giving the dose in multiple small fractions reduces the risk. This makes sense when considering acute effects of radiation. A dose of 4 Gy delivered instantaneously would have the chance of being lethal in a short time, whereas that same dose accumulated over a lifetime would not produce such acutely lethal effects. But whether this same concept holds for the damage that results in increased cancer risk is not certain. Theoretically, because effects are likely to be a result of the interaction of damages produced by independent tracks, lowering the dose rate or fractionating the exposure reduces the probability of the interaction of damage because of cellular repair processes that rapidly respond to such damage. If this theory applies to the damage responsible for radiation-induced cancers, the cancer risk at low dose rates and after low dose fractions would be lower than that predicted from high dose, high dose-rate exposures. At very low dose rates and very low doses per fraction, this results in a predicted dose response that simply is a continuation of the slope of the dose-response curve at low doses [i.e., the dose response would be linear ( $I = aD$ )]. <sup>25</sup> Because most epidemiologic studies involve populations irradiated at high dose rates, the applicability of this model potentially impacts the accuracy of estimates of risk for low dose, low dose-rate, and fractionated exposures derived from such studies. Whether this model is appropriate and the degree of the so-called dose-rate effect is a matter of debate and study. Epidemiologic and experimental data are not adequate to resolve the issue at the present time.

Analyses of results from epidemiologic studies of the atomic bomb survivors suggest a linear quadratic dose response for the induction of all leukemia, although a

simple linear model also fits the data.<sup>21,25</sup> For all solid cancers combined, a linear dose response is suggested based on the data at hand.<sup>21,25</sup> Except for a few tumor types, such as breast cancer, data for individual cancers are insufficient to address the issue of dose response. It must be remembered that the solid tumor data are incomplete at present because of the late onset of these cancers and because a significant fraction of the population who were children and young adults at the time of the bombing are still alive. Studies of radiation-induced breast cancer in the atomic bomb survivors support a linear dose response over a wide range of doses.<sup>13,21</sup> This linear response is supported by studies of other populations as well.<sup>18,21,26</sup>

For breast cancer, limited data on fractionation effects are available from studies of tuberculosis patients who received multiple diagnostic fluoroscopies during their course of treatment. Although the doses from the individual fluoroscopies were small, relatively large total doses were accumulated. Analysis of these data suggest similar risks for radiation-induced breast cancer in this group compared with those derived from the atomic bomb survivors and other groups who received radiation at a high dose rate.<sup>18,19,21,23,26</sup> The lack of an apparent fractionation effect is in contrast to results of analyses of the same tuberculosis patients for lung cancer. Comparing the risk for lung cancer in the groups receiving fractionated exposures from fluoroscopy to the risk in the atomic bomb survivors indicates that fractionation resulted in a markedly decreased risk for radiation-induced lung cancer.<sup>27</sup> Information on dose-response relationships for high LET radiation-induced cancer in human populations is relatively limited but suggest linear dose-response relationships.<sup>20</sup> Some of the most extensive dose-response data are for lung cancer in underground miners exposed to radon (see [Radon](#), later in this chapter).

Experimental studies examining dose-response relationships for leukemia and a variety of solid cancers generally support the linear-quadratic model.<sup>23,24,28,29</sup> and <sup>30</sup> In addition, most of these studies have found that reducing the dose rate or fractionating the dose into small fractions reduces the risk for development of radiation-induced cancer in the manner predicted by the linear-quadratic model. The degree of the dose-rate effect appears to vary with tumor type. Interestingly, in mice the dose-rate effect for the induction of lung cancer is greater than that for breast cancer.<sup>24</sup> Dose-response relationships for cancer induction after exposure to high LET radiation are limited mainly to studies of neutrons and only a few tumor types, but the data available clearly demonstrate linear dose-response relationships.<sup>3,31,32</sup> Fractionating the exposure or delivering the exposure at low dose rates has little effect on the dose response in most instances. However, data for mammary tumors in mice, and for transformation *in vitro*, have shown a so-called inverse dose-rate effect in which doses delivered at low dose rates were seen to be more effective with respect to cancer induction than single acute exposures.<sup>32,33</sup> and <sup>34</sup>

## MODIFIERS OF RISK

### Age

Age has a significant impact on susceptibility to radiation-induced cancer. Increased risks for thyroid cancer are primarily found after exposure of children to radiation, whereas the risk in adults after exposure to radiation is small.<sup>13</sup> For breast cancer, young children and adolescents are at the highest risk.<sup>13,17,21,35,36,37</sup> and <sup>38</sup> Risks, although still increased, are lower for young adults in their twenties and thirties compared with younger individuals. For women older than 45 to 50 years of age, radiation appears to have little influence on breast cancer risk.<sup>17,39,40</sup> Although not as dramatic, risks for acute leukemia, colon cancer, cancer of the central nervous system, and skin cancer are all greater if the exposure occurs early in life.<sup>13,17,22</sup>

Reports in the mid-1950s suggested for the first time an increased risk of childhood leukemia and all childhood solid cancers as a result of *in utero* radiation exposure from diagnostic procedures.<sup>41,42</sup> Initial concerns of a selection bias that might have resulted in more *in utero* exposures because of an underlying medical problem that was the actual risk factor were essentially dispelled by confirmation of these results in a study of twins in which such a selection bias could be minimized.<sup>43,44</sup> Similar studies of effects from *in utero* exposure in atomic bomb survivors have not observed such an increased risk. However, it is generally accepted that an increased risk exists for childhood cancers, including leukemia, from *in utero* exposure, which should be avoided.<sup>45</sup> Studies to date on risks of adult cancers after *in utero* exposure are inconclusive.<sup>46</sup>

### Genetic Susceptibility

It has been recognized for many years that there are individuals within the population who have a higher risk for spontaneous cancer. Studies of these individuals and their families have led to the discovery of several genes involved in heritable susceptibility to specific cancer. A number of these genes have now been cloned. In individuals with such susceptibility, the probability of developing a tumor during their lifetime can exceed 50%, and in some instances the probability is higher.<sup>47,48</sup> and <sup>49</sup> However, such mutations are relatively rare in the population. The prevalence of currently known, high penetrance genes account for approximately 5% of the total cancers in the population, and the prevalence of such genes in the total population is less than 1%. Because of this incidence, it is difficult to obtain adequate data to assess the impact of such genes on susceptibility to radiation-induced cancer.

Most information has come from studies of second cancers after radiation therapy. Studies to date have demonstrated increased risks for radiation-induced osteosarcoma and soft tissue sarcoma in patients with the hereditary form of retinoblastoma.<sup>50</sup> Studies of patients with basal cell nevus carcinoma syndrome have been found to be at an increased risk for basal cell carcinoma and ovarian tumors in the irradiated field.<sup>51</sup> In addition, patients with Li-Fraumeni syndrome appear to be at an increased risk for radiation-induced cancer.<sup>52,53</sup> In each instance, these patients have defects in genes that are known to act as tumor suppressor genes, the retinoblastoma gene (RB), the human homologue of the patched gene PTCH, and the p53 gene, respectively. It has also been proposed that the gene involved in ataxia-telangiectasia (AT) may also influence susceptibility to radiation-induced cancer.<sup>54</sup> AT is a recessive inherited syndrome that results in hypersensitivity to acute radiation effects, such as cell killing, because of mutations in the ATM gene, which is involved in DNA damage signaling and response pathways.<sup>55,56</sup> Patients homozygous for mutated ATM are extremely sensitive to acute radiation effects and are at a high risk for the development of certain forms of cancer. It has been suggested that individuals heterozygous for mutated ATM are also at an increased risk for radiation-induced cancer, in particular breast cancer.<sup>54</sup> The sensitivity of these individuals to acute effects of radiation is generally within the normal range. This hypothesis has been difficult to definitively test, and the question of enhanced susceptibility remains unresolved. Also unknown at the present time is the impact of the breast cancer genes BRCA1 and BRCA2 on susceptibility to radiation-induced cancer.

A major area of uncertainty and increasing interest is the potential impact of low-penetrance mutations that are likely to be relatively common in the population.<sup>48</sup> Such genes are difficult to identify in epidemiologic studies. Experimental studies in animal models and in human cells have provided evidence for such mutations and provided data implicating such mutations in susceptibility to radiation-induced cancer. It is also likely that such low-penetrance mutations could be involved in other delayed effects, such as radiation-induced fibrosis. The identification of such susceptible subpopulations is now a major research activity in radiation oncology.

## SECOND CANCERS

As the treatment of cancer has improved, long-term survivors have begun to develop second cancers as a result of treatment. Studies of such populations can provide information on the nature of potential risks and suggest new approaches to treatment that may reduce risks. Several studies have now been reported on risks of second cancers from radiation therapy. The most extensive data are available from studies of second cancers arising after treatment for childhood cancer, cervical cancer, Hodgkin's disease, and breast cancer. Data also are becoming available regarding risks of second cancers after whole body irradiation for bone marrow transplantations.

Relatively little information has been reported on radiation-induced second cancers in long-term survivors of childhood cancer.<sup>17</sup> Interpretation of results are complicated by the fact that many of these cancers are associated with germinal mutations that can influence susceptibility to the development of second cancers independent of the radiation or perhaps enhance susceptibility to radiation exposure. Another complicating factor is that many of these patients received chemotherapeutic agents as well. Furthermore, in many cases insufficient time has passed for risks for adult solid tumors to be properly assessed. The most common second cancers appear after treatment of childhood cancers appears to be bone and soft tissue sarcomas. By far the largest source of information on these sarcomas come from study of retinoblastoma patients, many of whom have an elevated risk for such cancers independent of the radiation exposure because of heritable mutations in the RB gene.<sup>17,50,57</sup> In these children, risk after radiation therapy can be as high as 50%. Although genetic susceptibility of these children to the familial form of these cancers can complicate interpretation, studies of retinoblastoma patients who do not have the familial form and studies of patients with other forms of childhood cancer also show increased risks for these sarcomas. Not unexpectedly, based on the earlier discussion about age susceptibility (see [Age](#), earlier in this chapter), the risk for thyroid, breast, and skin cancers also are elevated after radiation therapy for a variety of childhood cancers, as are tumors of the central nervous system and leukemias.<sup>17</sup> It appears, however, that the effects of radiation are primarily on the induction of solid cancers. The relative increase in risk for leukemia

development after radiation therapy is lower than that for the development of a subsequent solid cancer.

A series of large studies have examined the development of second cancers in cervical cancer patients treated with high doses of ionizing radiation. <sup>58,59</sup> Increased risks for second cancers have been difficult to detect, although a small (twofold) increased risk of leukemia was detected when the sample size was increased to include several hundred thousand women. The reason for such a small increase in leukemia risk is likely a result of a number of factors. First, the high doses delivered to a small volume likely resulted in cell killing in nearby target cells, and the dose outside the field was relatively low so that the fraction of target cell irradiated may have been small. Second, the doses were protracted (brachytherapy), fractionated, or both. In spite of the small numbers of leukemias, a dose-response curve was constructed that showed a rise in leukemia risk up to approximately 4 Gy, followed by a decline from the peak at higher doses. This decline at higher doses was suggested to be a result of cell killing that could have reduced the number of transformed cells. With respect to time of occurrence, a minimum latent period of approximately 2 years was seen, and the risk remained elevated for approximately 15 years before declining to normal levels. Within the field of irradiation, cancers of the bladder and bone, as well as soft tissue sarcomas, were observed. Outside of this field, cancers of the stomach were seen, probably as a result of scatter radiation of approximately 1 Gy.

In long-term survivors of Hodgkin's disease, the risk of leukemia appears to be mainly associated with the use of alkylating agents. Radiation in combination with chemotherapeutic agents does not seem to markedly enhance the risk of leukemia over that associated with chemotherapy alone. <sup>17,60,61</sup> and <sup>62</sup> Although these data would suggest that radiation is not a particularly effective leukemogenic agent, studies of second solid cancers indicate radiation is capable of increasing the risks of a number of solid cancers, including cancers of the breast, thyroid, stomach, bone, and skin. <sup>35,36,39</sup> Second cancers of the breast are particularly pronounced in women treated at young ages. <sup>35</sup> It has been reported that the relative risk for women treated when they were younger than 15 years is 136. For those treated between the ages of 15 and 24, the relative risk was 19; for ages 25 to 29 years, a relative risk of 7.3 was reported. Women treated at older ages did not appear to be at an increased risk. It is also important to note that the time between radiation exposure and the onset of breast cancer was long. The risk was higher at times beyond 15 years after treatment than before 15 years. Clearly, such patients should be identified as high risk and monitored carefully on a long-term basis.

In addition to breast cancer, an excess of lung cancer has been reported. <sup>63,64</sup> Unlike breast cancer, lung cancer has been reported to appear as early as 5 years after treatment. As might be expected, a strong interaction between smoking and radiation with respect to lung cancer risk has been reported. An increased risk for thyroid cancer has been found in patients treated at very young ages but not in adults, and an increased risk for bone cancer has been reported mainly in patients treated as adolescents. <sup>65,66</sup> Concerns over these second cancer risks, particularly breast cancer, has led to treatment modifications but not to elimination of radiation as an important tool in the treatment of Hodgkin's disease. <sup>17</sup> In spite of the risk, radiation is very effective, and the potential benefits of its continued use (a high probability of long-term survival) is thought to outweigh the risks of a second cancer many years later.

On the basis of epidemiologic studies of breast cancer risks in other populations, the dose to the contralateral breast during radiation therapy for breast cancer is sufficient to result in an increased risk for a second breast cancer. This potential risk has been shown to be the case in several studies. <sup>39,40</sup> An increase in risk has been found in women irradiated before age 45 who survive longer than 10 years. For women older than 45 at the time of treatment, the risk does not appear to be increased. In addition to breast cancer in the contralateral breast, an increased risk of lung cancer also has been reported. <sup>67</sup>

Studies have been reported on patients receiving whole body irradiation for bone marrow transplantations who received radiation doses in the range of 10 to 15 Gy. It was found that, in those patients who survived 10 or more years, the risk was 8.3 times higher than expected. Risks were elevated for cancer of the buccal cavity, liver, brain and central nervous system, thyroid, bone, and connective tissue, as well as for malignant melanoma. Those treated at younger ages were at higher risk than those treated at older ages. <sup>68</sup>

## RADON

Radon is a gas that comes from the naturally occurring uranium in rocks and soil. As a gas, it is able to flow from rocks and soil into the air, and because of this, underground mines, especially uranium mines, often contain high levels of radon. Homes in many areas also contain measurable levels of radon because of the makeup of the rocks and soil in the area. Radon, although radioactive, is chemically inert and uncharged. The spontaneous decay of radon results in radon progeny that are also radioactive but are electrically charged. These charged particles can attach to dust particles and, when inhaled, can deposit in the lung, where decay of these progeny results in irradiation of lung tissue with alpha particles.

Studies of underground miners exposed to high levels of radon have clearly demonstrated that radon and its progeny are responsible for an increased risk of lung cancer. <sup>20</sup> The risk is specific for lung cancer, and an increased risk for leukemia and other cancers is not observed. Based on extensive studies of such miners, an exposure-response relationship has been constructed that indicates a linear relationship between exposure and lung cancer risk, as would be expected for high LET radiations, such as alpha particles. It has been more difficult to detect risks due to radon in homes, but newer analyses have provided evidence of such risks and appear to confirm that the exposure-response relationship derived from the underground miner studies adequately projects risks at low radon levels as well. All of these estimates are complicated because of the overwhelming risk associated with smoking that must be taken into account in many study groups. On the basis of estimates from the uranium miners and studies of risks of radon in homes, it is currently estimated that approximately 10% to 15% of lung cancers in the U.S. population each year could be attributed to radon exposure. <sup>20</sup>

## MECHANISMS

It is clear from the discussion in the previous section that a single dose of ionizing radiation can result in an increased risk of cancer from years to decades later. Although it is generally assumed that these carcinogenic effects are somehow related to its mutagenic and clastogenic potential, the precise mechanisms through which radiation results in this increased frequency of cancer is unknown. The long period between radiation exposure and cancer development and the multistage nature of carcinogenesis make it particularly difficult to sort out radiation-induced changes from other alterations that occur once the process has been initiated. Radiation-induced cancers do not appear to be unique or specifically identifiable. The mutations and the growth characteristics of tumors likely caused by radiation are the same as those spontaneously occurring tumors of the same site. Attempts to identify radiation-specific changes have not been successful, despite fairly extensive investigation. However, there are clues to possible underlying mechanisms that emerge from epidemiologic and experimental investigations.

Based on experimental studies, it is generally thought that the induction of complex forms of double-strand breaks is the most biologically important type of lesion induced by ionizing radiation. That is, this type of double-strand break is likely to be responsible for subsequent molecular and cellular effects. <sup>4</sup> Attempts to repair these complex lesions are likely to be error-prone, and it is thought that this error-prone repair process can lead to gross chromosomal effects and mutagenesis. Molecular analyses of radiation-induced mutations have found a full range of mutations, including base pair substitutions, frameshift mutations, and deletions. Importantly, the most common alterations are deletions rather than point mutations. Because mutations predominate, theories of radiation-induced cancer have focused mainly on effects in oncogenes and tumor suppressor genes that would be expected to occur through this mode of action rather than through the induction of point mutations. Thus, mechanisms involving gene and chromosome rearrangements, loss of heterozygosity, and gene deletion are considered the most likely radiation-induced events to initiate the process of cancer development. Some support for this view comes from the molecular analysis of radiation-induced cancers. In the papillary form of thyroid cancer, rearrangements in the RET protooncogene are a common feature, <sup>69</sup> and it has been demonstrated that such rearrangements can occur in thyroid cells after irradiation. <sup>70,71</sup> and <sup>72</sup> Radiation-induced myeloid leukemia in mice appears to be associated with specific deletions in chromosome 2 that occur very early after irradiation. <sup>73,74</sup> and <sup>75</sup> In a murine model of p53 deficiency containing mice with one normal and one mutant allele of the p53 gene, it has been shown that these mice are highly sensitive to radiation tumorigenesis. <sup>76</sup> Analysis of these tumors has demonstrated loss of the wild-type allele and duplication of the mutant p53 allele. In patients with familial forms of RB, basal cell nevus carcinoma syndrome, and Li-Fraumeni syndrome, the pathogenesis of second cancers after radiation therapy appears to involve a similar mechanism. In each case, the patient has a germline mutation in one allele at birth, and radiation appears to facilitate the loss of the normal allele.

More recently, experimental studies have questioned whether the initiating events produced by radiation are direct effects on specific genes or whether the mutations and chromosomal rearrangements result indirectly as a consequence of genomic instability induced by the radiation exposure. <sup>77,78,79</sup> and <sup>80</sup> The observation of genomic instability is relatively recent. It had been generally believed that all the mutagenic and cytogenetic effects of radiation occurred in the first, or at least the first few, cell divisions. It has now been shown that increased mutation rates and new cytogenetic damage can occur in a large proportion of the progeny of irradiated cells many generations later (Fig. 12-2). This has led to the hypothesis that this radiation-induced instability, which appears to be broadly based, is the initiating event responsible for subsequent mutations and chromosomal rearrangements that ultimately lead to cancer. Interestingly, analyses of mutations arising in genomically unstable cells indicate that they are more frequently point mutations rather than deletions. According to this hypothesis, this instability puts all genes at an increased

risk for mutations, and it is this increased mutation rate that ultimately results in cancer development ( Fig. 12-3).

**FIGURE 12-2.** Comparison of mutations and cytogenetic damage as a result of direct radiation damage or as a result of radiation-induced genomic instability. **A:** Directly induced mutations or chromosome aberrations are passed to all progeny (i.e., the alterations are clonal). **B:** In contrast, mutations or aberrations arising as a result of radiation-induced instability arise in the progeny of irradiated cells that have not been directly irradiated. This leads to a nonclonal, or mosaic, pattern. Because the alterations arise in the progeny of the cells, another characteristic of instability is that the mutational or clastogenic effects are delayed with respect to the radiation exposure.

**FIGURE 12-3.** Proposed role of radiation-induced cytogenetic instability in radiation-induced cancer. Radiation exposure induces instability in a high percentage of the progeny of the irradiated cells ( *striped* cells represent unstable progeny). As a result of this instability, the rate of chromosome aberrations and mutations is increased. Some mutations result in cell death ( *black*) or slow-growing cells ( *gray*), whereas some occur in critical genes involved in the regulation of cell growth and differentiation, or in the maintenance of the stability of the genome. These mutations result in the persistence and amplification of genomic instability or in cells with a growth advantage. As these cells continue to develop into a clonal outgrowth, further mutations result in additional cellular changes, which lead to death or progression toward neoplasia. Cells with other patterns represent cells with specific mutations or sets of mutations that arose subsequent to radiation exposure.

The mechanism for induction of radiation-induced instability is not known, but it does not appear to be a result of the induction of a mutation in a specific gene or set of genes. The argument against a specific gene mutation is based on the high frequency of radiation-induced instability after relatively small doses. The probability of a specific gene mutation after 1 Gy of ionizing radiation ranges from 1 in 10,000 to 1 in 100,000, whereas approximately one in five cells or more will express radiation-induced instability. The strongest evidence to date in support of this hypothesis comes from mouse studies that have found a genetic association between susceptibility to radiation-induced chromosomal instability and susceptibility to breast cancer. <sup>81</sup>

## ULTRAVIOLET LIGHT

Skin cancer is one of the most common forms of cancer, and its incidence is rising. <sup>82,83 and 84</sup> Although it is difficult to estimate overall incidence rates for nonmelanoma skin cancer, it is estimated that the annual incidence in 1996 was on the order of 800,000 new cases. Approximately 80% of all nonmelanoma skin cancers are basal cell carcinomas. Squamous cell carcinoma comprises the other 20%. Mortality rates for these nonmelanoma cancers are low. However, this is not the case for melanoma, which has been increasing at a rate of approximately 3% per year in the United States. In 1998, an estimated 41,600 new cases of melanoma were diagnosed, an estimated 7300 of which ultimately will be fatal. <sup>85</sup> A major cause of all forms of skin cancer is UV light from the sun.

## SUNLIGHT AND SKIN CANCER

The evidence that UV light is responsible for a large proportion of skin cancer is considerable. Skin cancer is more frequent in populations in regions with high ambient solar radiation and in individuals exposed to sunlight as a result of their occupations (e.g., farmers). Nonmelanoma skin cancer is most frequent in sites that are the most exposed to sunlight, such as the head, neck, and arms. Pigmented skin is less susceptible to nonmelanoma skin cancer, and lack of pigmentation increases the risk. A high incidence of skin tumors is seen in young individuals associated with sunlight exposure who have xeroderma pigmentosum, a disease that is caused by a deficiency in the ability to repair UV light–induced DNA damage. In the United States, the incidence of basal cell carcinoma and squamous cell carcinoma increase by approximately 2% to 3% for every 1% increase in ambient UV light, and melanoma incidence increases by approximately 0.5% to 1.0%. <sup>86</sup> On a worldwide level, the incidence of skin cancer is extremely dependent on latitude, which equates with level of exposure to UV light; the closer to the equator, the greater the risk. This is particularly true for countries in which a large proportion of the population is lightly pigmented, such as Australia. <sup>87</sup>

Melanoma is also associated with sunlight exposure but is less dependent on total exposure, and it is not correlated with chronically exposed anatomic sites. Rather, increased risk for melanoma appears to be related more to acute burns rather than accumulated dose. <sup>82</sup> Additional evidence for a role for sunlight in melanoma development comes from the observation that children who move to countries with high ambient sunlight are at an increased risk of melanoma. <sup>87</sup> The same does not appear to be true when individuals move at older ages. These findings suggest that both exposure factors and factors involved in age-dependent susceptibility are involved. A greater risk for nonmelanoma skin cancer is seen in children and adolescents as well.

## GENETICS AND RISK

One of the major discoveries that established a direct link between UV light to DNA damage and skin cancer was that patients with xeroderma pigmentosum are defective in nucleotide excision repair. <sup>88</sup> Nucleotide excision repair is the repair pathway that removes the cyclobutane pyrimidine dimers produced in DNA by UV light, as well as other large adducts, and replaces the damaged site. <sup>90,91</sup> This pathway is complex and involves a number of sequential steps, including recognition of the lesion; assembly of the enzymes that make up the excision complex, which excises a 27- to 29-nucleotide region containing the photoproduct; removal of this oligonucleotide containing the damage; and, finally, replacement and filling of the resulting gap by polymerization and ligation. Another pathway, base excision repair, removes less complex base damage. Both pathways are complex processes that are influenced by many factors, including transcriptional activity, the sequence of nucleotides surrounding the damaged site, and DNA conformation.

In addition to xeroderma pigmentosum, a number of other disorders result in increased acute sensitivity to UVC or UVB. <sup>92</sup> These include Cockayne's syndrome and trichothiodystrophy. Both are related to disorders in genes involved in DNA damage repair, but neither has an increased sensitivity to UV-induced skin cancer. Studies of these disorders are providing additional insights into details of underlying mechanisms of UV-induced skin cancer. For example, it has been found that cells from Cockayne's syndrome patients are able to repair only transcriptionally inactive genes. <sup>93</sup> Perhaps repair of transcriptionally active genes is more important for the

prevention of mutagenesis and carcinogenesis.

## MECHANISMS

### *Squamous Cell Carcinoma and Basal Cell Carcinoma*

The development of squamous cell carcinoma and basal cell carcinoma is associated with chronic exposure to sunlight. In other words, multiple exposures of UV light from the sun are necessary for the induction of these cancers. This finding is consistent with experimental evidence indicating that UV radiation (UVB and UVC) acts both as an initiator and a promoter for squamous cell cancers.<sup>85</sup> UV-induced mutations in p53 appear to be an early event in this process.<sup>94,95</sup> Further exposures may lead to additional mutations in oncogenes and tumor suppressor genes, but, in addition, these further exposures facilitate clonal expansion of initiated cells through killing effects on normal but not p53 mutant cells. Exposure to UV light also has been shown to suppress the immune system's ability to suppress tumor growth.<sup>96,97</sup> High doses of UV radiation apparently affect the ability of Langerhans' cells to efficiently transfer antigenic signals to T cells in local lymph nodes.

Studies of patients with basal cell nevus carcinoma syndrome have provided insight into mechanisms of development of basal cell carcinomas. These patients are highly susceptible to basal cell carcinoma as a result of exposure to both ionizing and UV radiation, but keratinocytes from these patients show no difference in sensitivity to cell killing effects.<sup>98</sup> It has been shown that the gene associated with this syndrome is PTC, which is the human homologue of the *Drosophila* patched gene (ptc).<sup>99</sup> In *Drosophila*, this gene plays a role in cell-cell communication and transforming growth factor- $\beta$  signaling. The most common genetic alteration in nonfamilial basal cell carcinoma is loss of heterozygosity at chromosome 9q22, which contains the PTC locus. This loss of heterozygosity has been observed even in very small tumors, suggesting that alteration of PTC is an early event.<sup>100</sup>

### *Melanoma*

Epidemiologic evidence has established a causal relationship between sunlight exposure and melanoma that appears to be primarily a function of acute sunburn rather than chronic exposure, as is the case for squamous cell and basal cell carcinoma. A history of five or more sunburns as an adolescent has been found to double the risk for melanoma.<sup>88</sup> Experimental studies with a fish model suggest that the majority of melanomas are induced by UVA.<sup>101</sup> If this is the case, DNA damage would be predicted to be a result of damage mediated through reactive oxygen species rather than the cyclobutane dimers and 6-4 photoproducts that are associated with exposure to UVB and UVC. In the familial form of melanoma, susceptibility is associated with chromosome 9p21, which contains CDKN2A, the gene encoding p16 and p19.<sup>102</sup> This gene is involved in cell-cycle regulation. In both sporadic and familial forms of melanoma, loss of heterozygosity is found in several chromosomes, including 9p, 6, 8, and 10.<sup>103,104</sup> As yet, no evidence indicates that these changes are a direct result of damage produced by UV light.

## ASBESTOS

Asbestos use has spanned many centuries. Major industrial use began in the late 1800s and became widespread during World War II. Use peaked in the 1970s, and recognition of its health effects has led to major reductions in mining and use of asbestos, as well as programs aimed at removal of asbestos from existing structures. The carcinogenic effects of asbestos have been clearly demonstrated in studies of individuals exposed in the mining and industrial use of asbestos.<sup>105</sup>

## FIBER QUALITY AND DISEASE

Asbestos is actually a group of fibers, with each type having a unique structure and chemical composition ( [Table 12-3](#)).<sup>106</sup> Each type also appears to differ in its chemical reactivity. Not unexpectedly, each type also appears to have differing biologic properties as well. There are two main subgroups. Chrysotile fibers are long, curly snake-like fibers. Amphibole fibers are shorter and rod-like in structure. The most common amphibole types include crocidolite, amosite, and tremolite. Few malignant mesotheliomas are associated with occupational exposure to chrysotile fibers, probably because they do not tend to persist in lung. The persistence of amphibole fibers, which are more commonly linked with mesothelioma, is significantly greater.

Name	Type	Chemical Composition
Chrysotile	Serpentine (curly)	$Mg_3Si_2O_5(OH)_2$
Crocidolite	Amphibole (rod-like)	$Na_2(Fe^{2+})_2(Fe^{3+})_2Si_8O_{22}(OH)_2$
Amosite	Amphibole (rod-like)	$(Fe,Mg)_7Si_8O_{22}(OH)_2$
Tremolite	Amphibole (rod-like)	$Ca_2Mg_5Si_8O_{22}(OH)_2$
Anthophyllite	Amphibole (rod-like)	$(Mg,Fe)_7Si_8O_{22}(OH)_2$
Actinolite	Amphibole (rod-like)	$Ca_2Mg_5Si_8O_{22}(OH)_2$

TABLE 12-3. Characteristics of Asbestos Fibers

## CANCER RISK AND ASBESTOS EXPOSURE

The most common form of cancer associated with asbestos exposure is malignant mesothelioma, but the risk of bronchogenic cancer is also significantly elevated. Although lung cancer is generally associated with asbestos exposure, other cancers that have been reported to occur at an increased frequency include cancers of the larynx, oropharynx, kidney, esophagus, and gallbladder/bile duct.<sup>107,108</sup>

Because it is very rare, it has been relatively easy to link the risk of mesothelioma to asbestos exposure. Occupational exposure can be linked to 50% to 80% of all patients with malignant mesotheliomas.<sup>107,109</sup> In a study of tile workers exposed to asbestos over a 50-year period, it was found that the incidence of mesothelioma was as high as 2%.<sup>110</sup> A study of a large group of asbestos insulation workers found that mesothelioma was responsible for approximately 8% of all deaths.<sup>111</sup> The latent period between exposure and development of malignant mesothelioma is usually long, typically 30 to 40 years.<sup>107</sup> Approximately one-half of malignant mesotheliomas are epithelioid, and the other half are sarcomatoid or mesenchymal, or mixed.<sup>112</sup>

A link between asbestos and bronchogenic carcinomas was first reported in the 1930s and has been subsequently confirmed in several investigations.<sup>113</sup> Although the vast majority of bronchogenic carcinomas are related to smoking, it has been estimated that from 3% to 17% of such cancers are from occupational exposures, including asbestos.<sup>114</sup> Asbestos and smoking appear to interact in a multiplicative manner, and risk is decreased when exposure to either agent is stopped. Whereas the majority of smoking-related tumors are squamous cell carcinomas originating in the upper lobes of the lung, those associated with asbestos are more often adenocarcinomas located in the lower lobes.<sup>115,116</sup> and <sup>117</sup> The asbestos-related tumors are also often associated with areas of fibrosis.<sup>118</sup>

## MECHANISMS

Asbestos fibers are cytotoxic and genotoxic. They have been shown to induce DNA damage, including double-strand breaks, mutations, and chromosomal damage.<sup>119,120</sup> Evidence also indicates that asbestos fibers can impair mitosis and chromosomal segregation, which can result in aneuploidy. The majority of these effects are believed to be due to oxidoreductive processes that result in the formation of reactive oxygen species.<sup>121,122</sup> Support for this view comes from studies showing that the amount of damage induced is increased if iron is present in the chemical structure of the fibers. Besides the direct induction of reactive oxygen species, these effects may also be induced indirectly as a result of phagocytosis of the asbestos fibers. Fibers also tend to induce inflammatory responses, resulting in the release of cytokines.<sup>106</sup> Such cytokines may facilitate the growth, selection, and expansion of initiated cells.

Loss of one copy of chromosome 22 is one of the most common chromosomal alteration in malignant melanoma. A wide range of other changes also are seen, including deletions in chromosomes 1p, 3p, 6q, 9p, 13q, 15q, and 22q. Analysis of tumors with these chromosomal alterations have found deletions of CDKN2A, located on chromosome 9p, and mutations in NF2 (the neurofibromatosis type 2 gene that is located on chromosome 22q), coupled with the loss of the normal NF2 allele associated with loss of one of an entire chromosome 22, as common features. <sup>123</sup>

#### INTRODUCTION

Hundreds of genetic traits are associated with an increased risk of neoplasia. <sup>1</sup> The extent to which cancer risk is attributable to genetic factors varies among tumor types. For rare childhood cancers up to 30% occur in genetically predisposed individuals, <sup>2</sup> whereas not more than 5% to 10% of common adult cancers arise in an hereditary setting. <sup>3</sup> For those malignant tumors most closely associated with environmental carcinogens, the risk attributable to genetic factors is low; but genetic variation may still influence the effect of environmental agents on the host (e.g., sun exposure is a major risk factor for skin cancer, but dark-skinned individuals are virtually immune). <sup>4</sup>

Many of the genes underlying hereditary cancer predisposition are fundamentally involved in the control of cell growth and differentiation or in DNA repair and maintenance of genomic integrity. Analysis of the molecular basis for cancer predisposition has contributed a great deal to our understanding of the biology of tumor cells.

#### CANCER AS A GENETIC DISEASE

Cancer is a clonal disorder. All cells in a tumor arise from a single cell in which regulatory mechanisms for proliferation have been disrupted. Malignant cells have several qualities that distinguish them from their normal counterparts. They are immortal, often grow more rapidly than normal cells of the same origin, and fail to exhibit normal cell-cell interactions. This latter quality results in their ability to invade and to metastasize and grow in an abnormal cellular environment. <sup>5</sup> The transition from completely normal to frankly malignant occurs through a series of steps or *hits* (e.g., a cell may first acquire one abnormal property, such as immortality, and then become truly malignant when additional abnormal qualities develop) ( [Fig. 13-1](#)). <sup>6</sup>

**FIGURE 13-1.** Carcinogenesis is a multistep process. The transition from completely normal to frankly malignant occurs through a series of mutations in genes that control cell growth and differentiation. Epigenetic phenomena, such as methylation, also play a role. Early hits may have little apparent phenotypic effect, but ultimately growth patterns and cellular morphology are altered.

*Hits* are mutations or other alterations of genes involved in regulation of cell growth and cell interactions. They may occur by random chance during DNA synthesis and cell replication, as the result of exposure to environmental carcinogens (chemical mutagens, ultraviolet or ionizing radiation, oncogenic viruses), or they may be inherited as germline mutations. Regardless of the source of the genetic alterations, a cell must acquire two or more hits before becoming malignant, a process that usually takes years to decades in humans.

Several types of genes are involved in carcinogenesis. <sup>5</sup> Normal cell regulation results from a balance between the function of growth-promoting genes and growth-suppressing genes. When the former type of gene is *activatea* through amplification or mutation to a hyperfunctioning form, it exerts a positive effect of cell growth. Such genes are known as *oncogenes*. The latter type of gene is known as a *tumor suppressor*. Loss of function of both homologous copies of a tumor suppressor gene has a powerful growth-promoting effect. Loss of just one copy typically has little effect. DNA repair genes are another class that may be mutated in cancer cells and do not clearly fit into the categories of oncogene or tumor suppressor gene.

#### MECHANISMS OF CANCER PREDISPOSITION

Molecular analysis of inherited cancer susceptibility has elucidated a number of mechanisms by which germline mutations can lead to cancer predisposition. Several categories can be distinguished based on the functional characteristics of the genes involved, and additional mechanisms may yet be discovered. The examples that follow use rare genetics defects with a very high risk for cancer to illustrate mechanisms of cancer predisposition. Milder and more common defects in genes belonging to any of these categories may account for a significant portion of cancer risk attributable to hereditary factors.

#### GERMLINE TUMOR SUPPRESSOR GENE INACTIVATION

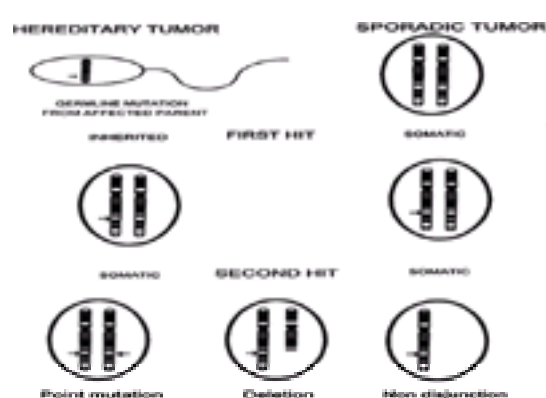

Tumor suppressor genes were identified through their role in familial predisposition to cancer. However, these genes are now known to be critically important in growth control of both sporadic and hereditary tumors. It appears that the majority of hereditary cancer predisposition is attributable to germline mutations in tumor

suppressor genes. The retinoblastoma gene (RB1) was the first of this class to be isolated.

Retinoblastomas are eye tumors occurring in young children. Most are sporadic, occurring in one eye of children between the ages of 2 and 4 years. In 30% of patients, multiple retinoblastomas arise in one or both eyes and occur before the age of 2 years. Such children often come from families in which retinoblastoma is segregating as an autosomal dominant trait. Based on these observations Knudson<sup>7</sup> proposed that children with hereditary retinoblastoma have inherited a *first genetic hit* that affects every cell in their bodies. Tumors arise from retinoblasts in which a somatic *second hit* has occurred. Given the large number of retinoblasts in a child's eye, it is not surprising that retinoblastomas would arise from multiple cells of predisposed children at an early age. In sporadic retinoblastoma, both hits must occur in a single somatic cell. Because of the much lower probability of two somatic hits, sporadic retinoblastomas are uncommon, occur later in childhood, and are solitary. Knudson did not know the nature of the first and second hits. Mapping and cloning of the retinoblastoma gene proved the two-hit hypothesis and elucidated the nature of tumor suppressor genes.

Clues to the location of the retinoblastoma gene came from studies of the constitutional karyotype of a group of patients with multifocal retinoblastoma plus other physical abnormalities. It was hypothesized that such patients might have an abnormality of one copy of the retinoblastoma gene, but had other genetic defects as well. The simplest explanation for this complex phenotype was an underlying deletion involving the retinoblastoma gene and surrounding genes. A variety of deletions of chromosome 13 were found in such patients, the smallest region of overlap being 13q14 (the cytogenetic study of retinoblastoma tumors might have yielded the same information, but as with many types of cancer, retinoblastoma cells show a great variety of chromosomal defects including but not limited to chromosome 13).

This putative location for the retinoblastoma gene was confirmed by linkage studies in heredity retinoblastoma families.<sup>8</sup> A polymorphic marker, esterase D (ESD), on chromosome 13q14 was shown to map very close to the retinoblastoma locus. In a related study, a patient with bilateral retinoblastoma was described who had half the normal levels of ESD in constitutional tissues but no visible deletion.<sup>9</sup> Presumably, a submicroscopic deletion in one copy of chromosome 13 had eliminated the retinoblastoma gene and the ESD gene. Cytogenetic studies of tumor cells from this patient showed that one copy of chromosome 13 was consistently absent. Biochemical studies of tumors found no ESD activity. Therefore, the first hit in this patient was a constitutional deletion involving the retinoblastoma as well as ESD genes. The second hit in tumor cells was loss of the copy of chromosome 13 containing the normal retinoblastoma and ESD homologue. This study indicated that retinoblastomas arise only when both copies of the gene are defective or absent. Several mechanisms for first and second hits have been described.<sup>10</sup> Often the first hit is a point mutation or tiny deletion. The second hit may be loss of the entire homologous chromosome by nondisjunction in mitosis, loss of a portion of the homologous chromosome by deletion, point mutation of the second copy of the gene, or gene conversion through mitotic recombination (Fig. 13-2). An epigenetic mechanism involving methylation of one copy has been shown to play a role in inactivation of other tumor suppressor genes.<sup>11</sup>

**FIGURE 13-2.** Germline mutation in a tumor suppressor gene gives cells a head start in multistep carcinogenesis. Homozygous inactivation of the gene in an individual with an inherited mutation requires a single somatic hit. In a normal individual two hits in the same cell are required. In addition to point mutations, gross chromosomal mechanisms such as deletion or nondisjunction may be involved in somatic hits.

The retinoblastoma gene (RB1) was one of the first to be positionally cloned<sup>12</sup> (i.e., the gene was isolated based on its location with no prior knowledge of its sequence). RB1 extends over more than 100 kb of genomic DNA and encodes a nuclear phosphoprotein (pRb),<sup>13</sup> which is constitutively expressed in a large variety of cell types during all phases of the cell cycle. However, its growth-suppressing activity seems to be modulated through varying levels of phosphorylation. It is relatively dephosphorylated during the G<sub>1</sub> phase and phosphorylated during the remainder of the cell cycle. It appears that pRb normally maintains cells in a resting state but can be overcome by signals from the cell-cycle machinery, particularly phosphorylation by cyclin-dependent kinases. The effect of pRb is probably mediated through its ability to bind and sequester several transcription factors. The oncogene products of several DNA tumor viruses function by binding and inactivating the pRb protein. Notably, reintroduction of wild-type RB1 into tumors lacking a functional copy of the gene results in reversion of the tumor cells to a less malignant phenotype.

Homozygous inactivation of RB1 may be sufficient to transform a cell from completely normal to frankly malignant. However, additional genetic changes may enhance the growth and invasiveness of retinoblastoma cells.<sup>2</sup> There is compelling evidence that homozygous inactivation of other tumor suppressors is not sufficient for tumorigenesis (e.g., germline homozygous mutation of the CDKN2 gene<sup>14</sup> does not produce a more severe phenotype than heterozygous germline mutation). Other alterations must be required for development of tumors or else tumors would be present in every cell of the relevant organs almost from the time of birth.

The RB1 gene is often inactivated in tumors other than retinoblastoma, such as breast cancer, lung cancer, and genitourinary cancer, but it may not play an essential role in regulation of cell growth in many tissue types. Patients with germline mutation of RB1 are prone to osteosarcoma, soft tissue sarcoma, and perhaps melanoma and brain tumors, but not breast, lung, and genitourinary cancers.<sup>15</sup> In the latter group of neoplasms, loss of RB1 may contribute to malignant characteristics, but apparently is not essential to growth control in these tissues.

There is increasing evidence that inactivation of just one homologue of a tumor suppressor gene may have an effect on cell growth and differentiation. In the heterozygous state, mutations in the FAP gene (familial adenomatous polyposis) may promote excessive proliferation of the colon epithelium. A more dramatic effect is seen with heterozygous mutations in the WT1 (Wilms' tumor gene), which lead to congenital anomalies of the genitourinary system.<sup>16,17</sup>

### GERMLINE ONCOGENE ACTIVATION

Expression of protooncogenes in normal cells appears to be carefully regulated.<sup>18</sup> Different oncogenes are turned on and off at different steps of the cell cycle, at different stages of embryologic development, and in different cell types. The biochemistry and molecular biology of oncogene function is a rapidly evolving field. In general, protooncogenes function as messengers in the pathway by which external stimuli received at the cell surface lead to DNA synthesis, cell growth, and division. It follows that activating mutations of such genes could lead to abnormal, unrestrained stimulation of cell proliferation in the absence of appropriate signals.

Although activating mutations of oncogenes have for many years been considered as a possible cause of hereditary cancer predisposition, extensive investigations of a wide variety of disorders have until relatively recently yielded no positive results.

The first evidence for *constitutional* (but not germline) activation of an oncogene came from studies of McCune-Albright syndrome,<sup>19</sup> a sporadic disorder characterized by precocious puberty, adenomas of several endocrine tissues, areas of bone dysplasia, and café au lait spots. Many of the endocrine tumors that can be seen in this syndrome were known to arise with activating mutations of the gene encoding a G protein. G proteins resemble ras very closely and are known to function as oncogenes. Analysis of a variety of normal and neoplastic tissues from patients with the syndrome showed that they are all mosaic for activating mutations in the a subunit of the G(s) gene. These mutations are not inherited, but arise somatically at an early stage in embryogenesis.

The first disorders shown to be caused by true germline activation of an oncogene were multiple endocrine neoplasia (MEN) type 2a and MEN 2b.<sup>20,21,22</sup> and<sup>23</sup> These autosomal dominant syndromes are characterized by medullary thyroid carcinoma and pheochromocytoma. MEN 2b has additional features including mucosal neuromas, blubbery lips, and marfanoid habitus; and MEN 2a can be complicated by hyperparathyroidism. The genes for both syndromes were mapped to the centromeric region of chromosome 10, but the related tumors did not show allelic loss at this site, suggesting that a tumor suppressor mechanism did not underlie the

cancer predisposition. The ret protooncogene had previously been mapped to the same region as the MEN 2 genes, and analysis of RET revealed mutations in both MEN 2a and MEN 2b kindreds. Ret encodes a transmembrane receptor tyrosine kinase. All MEN 2b cases have the same single base alteration in exon 16, a region responsible for the tyrosine kinase activity of the protein product. Most MEN 2a patients have a mutation in codon 634 in exon 11, but mutations in exon 10 have been identified as well.<sup>24</sup> All of the exon 10 and 11 alterations lead to substitution of another amino acid for the normal cysteine residue in an extracellular region immediately adjacent to the transmembrane domain. There is a strong correlation between hyperparathyroidism and a cysteine to arginine change in codon 634.

That the spectrum of ret mutations is extremely limited and none is a stop signal suggests that they have a specific and probably activating effect on the gene product. Transfection studies show that MEN 2a and MEN 2b mutations can indeed induce transformation of NIH3T3 cells.<sup>25,26</sup> Curiously, inactivating mutations of ret have been shown to cause a completely different disorder, Hirschsprung disease.<sup>27</sup> The main clinical feature is pseudo-obstruction of the colon caused by lack of intestinal parasympathetic ganglia. Apparently ret is required for the proper migration of ganglion precursors during embryogenesis.

Other disorders caused by germline activation of growth-promoting genes include hereditary papillary renal carcinoma (met oncogene)<sup>28</sup> and rare cases of familial melanoma (CDK4).<sup>29</sup>

### DNA REPAIR DEFECTS

In the context of cancer as a genetic disease, it is easy to see how disorders involving DNA repair defects would lead to malignancy because failure to repair DNA damage would increase the risk of mutations in cancer-related genes.

A typical disorder of this type is xeroderma pigmentosum, an autosomal recessive disease characterized by extreme photosensitivity, premature aging of skin, and neoplasia of skin and, to a lesser extent, other organs (Fig. 13-3). The molecular basis for this disease is inability to repair the types of DNA damage caused by ultraviolet light. Complementation studies performed by fusing cells from different individuals with xeroderma pigmentosum suggest that there are at least eight different genes for this phenotype (genetic heterogeneity). The genes for several types of xeroderma pigmentosum have been cloned, and their activities include photoproduct binding, helicase, and endonuclease.<sup>30</sup>

**FIGURE 13-3.** DNA repair defects accelerate the process of multistep carcinogenesis because alterations in tumor suppressors and oncogenes are not corrected. This 13-year-old girl with xeroderma pigmentosum and severe actinic changes (lentiginos, atrophy, and ectropion) has had more than 10 epidermal malignancies. Patients with xeroderma pigmentosum are prone to internal malignancies as well as skin cancer. (Courtesy of Drs. J. DiGiovanna and G. Peck.)

Other disorders with faulty DNA repair or replication include ataxia-telangiectasia (x-ray hypersensitivity; defect in a signal transduction protein that mediates multiple responses to DNA damage such as cell-cycle checkpoint control, activation of DNA repair enzymes, and control of programmed cell death),<sup>31,32</sup> Fanconi pancytopenia (sensitivity to DNA cross-linking agents, several genes of unknown function),<sup>1</sup> and Bloom's syndrome (high frequency of spontaneous chromosome breaks, helicase defect).<sup>33</sup> All of these syndromes are rare autosomal recessive disorders associated with an increased risk of cancer.

BRCA1 and BRCA2, which are responsible for approximately 5% of all breast cancers, are important members of this class. Germline mutations in these genes lead to an autosomal dominant syndrome of breast and other cancers. The genes are homozygously inactivated in tumor tissue from patients with germline mutations, but in contrast to typical tumor suppressors they are rarely mutated in sporadic tumors. There is little evidence that introduction of these genes into breast tumor cells causes reversion of the malignant phenotype toward something more benign. Animal models with hypofunctioning versions of these genes exhibit a phenotype reminiscent of ataxia-telangiectasia,<sup>34</sup> and both *in vitro* and *in vivo* studies indicate interactions with the DNA repair genes ATM and RAD51.<sup>35,36</sup> BRCA genes have often been referred to as *tumor suppressors* in the scientific literature, but based on their role in coordinating recombination-based DNA repair,<sup>37</sup> these genes might more properly be called *mutation suppressors* rather than tumor suppressors.

### ECOGENETIC TRAITS

Although DNA repair disorders predispose to malignancies at some rate with or without exposure to aggravating environmental factors, they can be thought of as extreme examples of ecogenetic traits (i.e., hereditary disorders predisposing to cancer through unusual sensitivity to common carcinogens). A more typical example is epidermodysplasia verruciformis, in which papilloma virus and ultraviolet radiation act as cocarcinogens to produce squamous cell carcinoma of the skin in genetically susceptible individuals.<sup>38</sup> This autosomal recessive disorder is characterized by widespread, scaly, red or brown macules that progress over many years to *in situ* and invasive squamous cell carcinomas (Fig. 13-4). The macules are benign lesions containing papilloma virus particles. Decreased cellular immunity has been demonstrated in a high percentage of patients. Malignant lesions occur in sun-exposed areas and are much more frequent in light-skinned individuals with epidermodysplasia verruciformis than in black patients.

**FIGURE 13-4.** Benign skin lesions of epidermodysplasia verruciformis. Papilloma virus and ultraviolet light act as cocarcinogens in producing skin cancer in patients with this ecogenetic trait. In the absence of these environmental agents, affected individuals are not predisposed to cancer. (Courtesy of Dr. D. Lowy.)

Genetic factors influencing host responses to environmental carcinogens may contribute to susceptibility to several common cancer types. Lung cancer has a strong association with cigarette smoking, and the risk attributable to hereditary factors is small. Nevertheless, metabolism of the carcinogens in tobacco smoke may be influenced by genetic variation in detoxifying enzymes. Numerous studies have related polymorphisms in CYP1A1, CYP2D6, and CYP2E1 to lung cancer susceptibility.<sup>39</sup> Likewise aflatoxin B<sub>1</sub> exposure contributes to the risk of hepatocellular carcinoma, and genetic variation in epoxide hydrolase (EPHX) may have an

important influence on susceptibility to this agent. <sup>40</sup>

## ABNORMAL TISSUE ARCHITECTURE

Juvenile polyposis (JPS) is an autosomal dominant disease characterized by hamartomatous polyps and predisposition to colorectal malignancy. JPS can be caused by germline mutations in the PTEN gene on chromosome 10 or the SMAD4 gene on chromosome 18. <sup>41,42</sup> and <sup>43</sup> The polyps in JPS are composed primarily of stromal cells among which nests of epithelial cells become trapped. The growth of these epithelial cells in an abnormal environment is probably responsible for dysplasia and eventual neoplasia. Presumably, the genetic alterations that contribute to malignant transformation of epithelial cells are similar to those that occur in any colon tumor. Allelic loss of PTEN has been seen in the nonmalignant, stromal component of juvenile polyps <sup>44</sup> but not in the epithelial component of malignancies that arise in JPS patients. The best interpretation of these data is that the JPS gene sets the stage for accumulation of other genetic alterations.

Another disorder that may follow this model is epidermolysis bullosa dystrophica, a genetically heterogeneous disease characterized by subdermal blistering that results in chronic inflammation and scarring. <sup>45</sup> Aggressive squamous cell carcinoma of the skin is a well-known complication of this disease <sup>46</sup> and probably arises through increased turnover of epidermal cells leading to a risk of genetic alterations during DNA replication. This mechanism is reminiscent of the carcinogenesis that occurs in chronic, nonhealing burn wounds.

## HUMORAL TUMOR PROMOTERS AND REPRESSORS

Circulating factors, such as hormones and components of the immune system, may play a role in tumor promotion or progression. Genetic disorders causing immune deficiency or an abnormal hormonal milieu can lead to an increased risk of cancer. Polycystic ovary syndrome, for example, is a common disorder characterized by hyperandrogenism and chronic anovulation. Associated malignancies, related to an abnormal balance between estrogen and androgen and possibly excess luteinizing hormone, include endometrial and ovarian cancer. <sup>47</sup> The etiology of polycystic ovary syndrome is heterogeneous, but several studies support a strong hereditary component. <sup>48,49</sup> Genetic alterations in three genes have been implicated in this disorder including luteinizing hormone, CYP11a (involved in the synthesis of androgens), and the 21-hydroxylase gene (involved in synthesis of many steroids). <sup>50,51</sup> and <sup>52</sup>

## GATEKEEPERS, CARETAKERS, AND LANDSCAPERS

The term *gatekeepers* has been proposed to describe genes whose function is essential in control of growth and differentiation. <sup>53</sup> Gatekeepers directly prevent the development of tumors by inhibiting growth or promoting terminal differentiation and cell death. In the original gatekeeper concept, it was proposed that each tissue type had one key gene of this type, and mutation of the gatekeeper gene was necessary for the development of tumors. Hence, both sporadic and hereditary tumors would be expected to bear mutations in gatekeepers. RB1 is a gatekeeper gene with tissue specificity primarily for the developing retina, and this gene is mutated in all or nearly all retinoblastomas. Other genes serve this gatekeeper function in other tissue types. For some tissues, either inactivation of a gatekeeper or activation of another member of the same biochemical pathway can lead to malignant transformation. Melanomas, for example, often arise with inactivating mutations in CDKN2A, a negative regulator of cyclin-dependent kinases. An alternate route to melanoma is mutation of cyclin-dependent kinase 4 to an activated form that is resistant to negative regulation by CDKN2A. Both inactivating mutations in CDKN2A and activating mutations in CDK4 can cause hereditary melanoma. <sup>29,54,55</sup> Other examples of tissues that may arise with mutation in a gatekeeper or another member of the same pathway include colon carcinoma <sup>56</sup> and basal cell carcinoma of the skin. <sup>57</sup> Germline mutation of a gatekeeper leads to a risk of cancer at least 100 times greater than that in the general population.

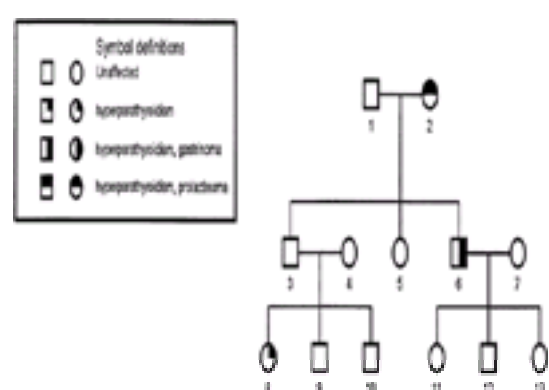

*Caretaker* genes are involved in DNA repair and maintenance of genomic integrity. Inactivation of a caretaker does not directly promote tumor formation, but facilitates the development of mutations in gatekeeper genes and other cancer-related genes. Caretakers, like gatekeepers, may be tissue specific, but mutation in a caretaker is neither necessary nor sufficient for the development of cancer. The risk of cancer is modestly elevated in syndromes caused by germline caretaker mutations, and sporadic tumors rarely have mutations in these genes. BRCA1 is an example of a gene in this class.

*Landscaper* genes, <sup>58</sup> such as the genes for JPS, also act indirectly to cause cancer. Mutations in these genes lead to tissue dysplasia, but are not necessary for the development of cancer and are rarely seen in sporadic tumors.

## CLINICAL CHARACTERISTICS OF CANCER FAMILIES

The hallmarks of hereditary cancer are relatively early age of onset compared with similar sporadic tumors, multiple and bilateral tumors, and a family history of cancer. Some cancer predisposition syndromes also include birth defects or other distinctive physical features. An underlying hereditary disorder should be considered when rare tumor types are encountered because a significant percentage of certain rare cancers are attributable to genetic factors (e.g., retinoblastoma). The same applies to cancers that are common in one gender occurring in the other gender (e.g., male breast cancer). <sup>59</sup>

Because the genes that underlie hereditary cancer predisposition may be important in a variety of tissues, germline mutation may lead to multisystem disease. The production of multiple phenotypic effects by a single mutant gene is called *pleiotropy*. <sup>60</sup> Often different members of a single kindred have different manifestations of the same genetic defect, a phenomenon known as *variable expressivity* (Fig. 13-5). Development of cancer is a multistep process involving two or more independent events. There is always some probability that no cell in a genetically cancer-prone individual will suffer sufficient somatic hits to become neoplastic. In this event a gene carrier could escape all manifestations of disease and be a *nonpenetrant* carrier. Virtually all adult-onset cancer predisposition syndromes have age-dependent penetrance because the probability of accumulating sufficient hits to develop cancer increases with age. Presumably nonpenetrant carriers would develop cancer if they lived long enough.

**FIGURE 13-5.** Multiple endocrine neoplasia type 1 is an autosomal dominant disorder characterized by parathyroid, pancreatic islet, and pituitary tumors. This kindred demonstrates nonpenetrance (individual 3 is an obligate gene carrier because his mother and daughter are affected, yet he has no signs of the disease) and variable expressivity (the three affected individuals have different constellations of neoplasia). Typically, few individuals in the younger generations have signs of the disorder because multistep carcinogenesis may take years to decades even with one inherited hit.

In addition to the effects of random chance, perhaps coupled with environmental exposures, penetrance may be influenced by modifying genes. For example, women who carry a mutation in the BRCA1 gene have a risk of ovarian cancer in the range of 30%. Why do some BRCA1 carriers get ovarian cancer whereas others do not? Common variants in the HRAS gene appear to influence susceptibility to this malignancy. Women with both a BRCA1 mutation and an unfavorable HRAS variant are twice as likely to get ovarian cancer as those without the variant. Susceptibility to breast cancer is not affected by the presence of these unfavorable variants. <sup>61</sup>

## MULTISYSTEM GENETIC SYNDROMES WITH A HIGH RISK OF CANCER

Many disorders involving cancer predisposition are characterized by a distinctive pattern of neoplasia involving several different organs or neoplasia plus unusual

physical features. These genetic *syndromes* often can be definitively diagnosed on the basis of medical and family history plus astute physical examination. Hereditary retinoblastoma/osteosarcoma, MEN 2, and xeroderma pigmentosum fall into this group. Several other syndromes are worth mentioning because they are fairly frequent or are responsible for a significant proportion of certain rare tumors.

## NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder affecting approximately 1 in 3000 individuals. The defining clinical features are café au lait spots of the skin, benign Schwann cell tumors known as *neurofibromas*, and hamartomas of the iris known as *Lisch nodules*. Other manifestations include macrocephaly, segmental hypertrophy, bone dysplasia leading to pseudoarthrosis, learning disability, and seizures. A variety of CNS tumors occur to excess including optic gliomas, astrocytomas, and meningiomas. Malignant tumors such as neurofibrosarcomas, pheochromocytomas, and leukemia are also part of this syndrome.<sup>62</sup>

The gene for this disease was mapped to chromosome 17 in 1987<sup>63,64</sup> and was cloned in 1990.<sup>65,66</sup> Its function involves interaction with the ras oncogene product.<sup>67,68</sup> and<sup>69</sup> Ras proteins have a role in growth regulation through adenylate cyclase activation. They are homologous to G proteins and like G proteins they bind guanosine triphosphate (GTP) in response to signals from cell surface. The GTP-bound form is active in promoting cell growth and slowly inactivates itself by hydrolyzing the bound GTP to guanosine diphosphate. The latter function is influenced by another protein known as the GTPase-activating protein. It follows that homozygous inactivation of the GTPase-activating protein would result in unrestrained stimulation of adenylate cyclase by the activated ras protein. Portions of the NF gene are highly homologous to GTPase-activating protein. Presumably the normal function of this gene is to negatively regulate cell stimulation by the ras gene product or similar growth-promoting proteins. In both benign and malignant tumors related to neurofibromatosis, the NF1 gene is homozygously inactivated.<sup>70,71</sup> Other features of the syndrome could be due to haploinsufficiency (i.e., loss of just one copy of the gene may produce abnormalities in some tissues).

No single clinical feature is sufficient for diagnosis of NF1; in particular, many individuals without NF1 have one or more café au lait spots. Until a valid, gene-based test becomes available, the clinical criteria proposed by the 1988 National Institutes of Health Consensus Development Conference<sup>72</sup> should be used. The life expectancy of patients with NF1 is reduced due to malignant complications,<sup>73</sup> and suggested clinical management includes annual evaluation of blood pressure, skin examination, neurologic evaluation, and ophthalmologic examination.<sup>74</sup> In addition, children should be checked for growth and development, with particular attention to learning disability, sexual maturation, skeletal abnormalities, and speech.

## NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2 (NF2) shares with NF1 several characteristics including café au lait spots, skin neurofibromas, and an autosomal dominant mode of inheritance. The defining feature of this syndrome, however, is bilateral vestibular schwannomas (previously called *acoustic neuromas*). Schwannomas of other cranial nerves and spinal nerve roots, meningiomas, and retinal hamartomas are also seen. Cataracts, particularly the posterior capsular type, are common. NF2 is far less common than NF1, with a prevalence of approximately 1 in 35,000.<sup>75</sup> The gene for NF2 is related to the ezrin family of proteins that link the cell cytoskeleton to cell membrane proteins, and its mode of action is not fully understood.<sup>76</sup>

The diagnosis of NF2 should be considered in patients with bilateral vestibular schwannomas, unilateral schwannoma before the age of 40, or meningioma and any other feature of the syndrome. In the setting of a family history of NF2, DNA-based testing of at-risk individuals is recommended.<sup>77</sup> Recommended follow-up studies in gene carriers include gadolinium-enhanced magnetic resonance imaging to detect early spine and CNS tumors. In the case of vestibular schwannomas, surgical removal of small tumors can preserve some useful hearing.<sup>78</sup>

## HEREDITARY WILMS' TUMOR AND RELATED SYNDROMES

On the order of 1% of Wilms' tumor cases occur in a familial setting, following an autosomal dominant inheritance pattern with incomplete penetrance.<sup>79</sup> Twenty percent of familial cases and 3% of sporadic cases are bilateral, consistent with a two-hit model for development of this neoplasm.<sup>80</sup> Rare cases have, in addition to Wilms' tumor, aniridia, hemihypertrophy, genitourinary anomalies, and mental retardation (WAGR syndrome)<sup>81</sup>; and cytogenetic analysis has revealed deletions of chromosome 11p13 in such patients.<sup>82,83</sup> The WAGR complex qualifies as a *contiguous gene syndrome* (i.e., the multiple features are caused by loss of more than one gene). Denys-Drash syndrome involves Wilms' tumor, genitourinary abnormalities similar to those in WAGR, pseudohermaphroditism, and nephropathy<sup>84,85</sup> without aniridia or mental retardation; and no chromosome abnormality has been identified.

The Wilms' tumor gene on chromosome 11p13 was isolated by positional cloning, and encodes a zinc finger protein<sup>86,87</sup> possibly involved in transcriptional regulation of insulin-like growth factor-2 (IGF-2) and a variety of other growth factors. Additional motifs in the gene may have a role in RNA processing.<sup>88</sup> During development WT1 is expressed specifically in the developing kidney and the genital ridge and fetal gonad, and point mutations in WT1 are capable of causing the genitourinary abnormalities seen in the WAGR syndrome and Denys-Drash syndrome.<sup>16,17</sup> It seems clear that there is not a separate gene for the G part of the WAGR syndrome, although there is a separate gene for aniridia and almost certainly for mental retardation.

WT1 mutations are not the only cause of genetic predisposition to Wilms' tumor.<sup>75</sup> Beckwith-Wiedemann syndrome, which maps to chromosome 11p15, is characterized by a high frequency of Wilms' tumor. Other features of this disorder are large size at birth, disproportionately large tongue, omphalocele, and linear creases in the earlobe. Several families have been described in which the gene causing predisposition to Wilms' tumor maps to neither chromosome 11p13 nor 11p15.

There is no clear consensus on appropriate screening studies in children at risk for Wilms' tumor.<sup>89,90</sup> and<sup>91</sup> Computed tomographic scanning is superior to ultrasound in detecting early tumors. However, the low cost and lack of radiation exposure make ultrasound an attractive option for serial studies. Magnetic resonance imaging may prove useful as a high-quality imaging tool that does not involve radiation exposure. In practice, abdominal ultrasound at 3- to 6-month intervals is the most common screening method. The exact duration of screening is variable, but most tumors in genetically predisposed individuals occur between birth and the age of 5.

## LI-FRAUMENI SYNDROME

In 1968, Miller<sup>92</sup> analyzed 21,659 death certificates of U.S. children who died of cancer and found an excess mortality from sarcomas and brain tumors in siblings. To pursue the observation, Li and Fraumeni<sup>93</sup> reviewed several hundred hospital charts of children with rhabdomyosarcoma. There were four families with multiple childhood sarcomas occurring in association with other childhood cancers and early-onset breast cancer. Subsequent studies established an autosomal dominant pattern of occurrence of at least six tumors: premenopausal breast cancer and childhood soft tissue sarcomas, osteosarcoma, brain tumors, adrenal cortical carcinomas, and acute leukemia.<sup>94</sup> Similar familial aggregates were identified by Strong<sup>95,96</sup> and Birch and colleagues<sup>97</sup> through studies of hospital-based and population-based series of childhood sarcomas, respectively. Segregation analyses suggested that 50% of carriers in affected families would develop cancer by 35 years of age and 90% by age 70.<sup>97</sup> Penetrance appears to be higher in female subjects, who are at risk of breast cancer in adulthood. Patients who survive cancer are prone to develop second primary neoplasms, often within the field of prior radiotherapy.<sup>94</sup>

In 1990, germline mutations in the p53 tumor suppressor gene were identified in five families with Li-Fraumeni syndrome, and the observation was soon confirmed by several groups.<sup>98</sup> In addition, germline p53 mutations have been identified in a small fraction of unselected patients with early-onset multiple primary cancers, multifocal brain tumors, childhood sarcoma, and childhood adrenal cortical carcinoma.<sup>99,100</sup> and<sup>101</sup> However, less than 1% of breast cancer patients have germline p53 mutations. The germline p53 mutational spectrum is similar to that for somatic p53 mutations in sporadic cancers and tends to occur in exons 5 through 9.<sup>102</sup> Germline p53 mutations have not been detected in a substantial minority of Li-Fraumeni families, suggesting that other genes might produce the syndrome.<sup>103</sup> Genetic heterogeneity is also indicated by exclusion of linkage to p53 for at least one affected family.<sup>104</sup>

When germline p53 mutations were identified, the possibility of predictive testing to identify unaffected carriers became feasible. However, the risks and benefits of predictive testing for a syndrome of multiple cancers are unknown. In particular, early detection at a curable stage is problematic for the component cancers of this syndrome.<sup>105</sup> Several small research programs of predictive genetic testing for p53 mutations have been offered to adults in families with a known alteration. Lessons from p53 testing may be useful in developing testing programs for more common inherited susceptibility genes for breast and colon cancer.<sup>106,107</sup>

## NEVOID BASAL CELL CARCINOMA SYNDROME

The nevoid basal cell carcinoma syndrome (NBCC), also known as *Gorlin syndrome* and the *basal cell nevus syndrome*, is an autosomal dominant disorder that predisposes to basal cell carcinomas of the skin, medulloblastomas, and ovarian fibromas.<sup>108</sup> Its prevalence has been estimated at 1 per 56,000, and 1% to 2% of medulloblastomas and 0.5% of basal cell carcinomas are attributable to the syndrome.<sup>109,110</sup> Other neoplasms that probably occur to excess include fibrosarcomas, meningiomas, rhabdomyosarcomas, and cardiac fibromas.

In addition to benign and malignant tumors, malformations are a striking component. The syndrome is associated with pits of the palms and soles, keratocysts of the jaw and other dental malformations, cleft palate, characteristic coarse facies, strabismus, dysgenesis of the corpus callosum, calcification of the falx cerebri, spina bifida occulta and other spine anomalies, bifid ribs and other rib anomalies, ectopic calcification, mesenteric cysts, macrocephaly, and generalized overgrowth.<sup>111,112</sup> and <sup>113</sup>

The NBCC gene was mapped to chromosome 9<sup>114,115</sup> and <sup>116</sup> and the demonstration that the exact same region is deleted in a high percentage of sporadic basal cell carcinomas and other tumors related to the disorder provided strong evidence that the gene functions as a tumor suppressor. Positional cloning identified a human homologue of *Drosophila patched* as the gene for this syndrome,<sup>117</sup> and subsequent studies showed that *patched* is mutated in a high percentage of sporadic basal cell carcinomas.<sup>118</sup> *Patched* is a negative regulator of the hedgehog pathway, several members of which are known to function as oncogenes in skin and brain tumors. Mutation of *patched* may be a necessary if not sufficient step in basal cell carcinoma development. Minute basal cell carcinomas are as likely as large tumors to have *patched* mutations, and all histologic subtypes, whether primary or recurrent, have a high frequency of loss of *patched*. Tumors with allelic loss on chromosome 9 sometimes show additional areas of loss on other chromosomes, but no tumors have loss on other chromosomes without involvement of chromosome 9.<sup>114</sup> *Patched* appears to function as a gatekeeper gene in the epidermal cell type from which basal cell carcinomas arise.<sup>119</sup>

In contrast to many other disorders caused by tumor suppressors congenital anomalies are a prominent feature of NBCC. One hypothesis to explain at least some of these anomalies is a two-hit mechanism in which a single fetal or embryonic cell that has lost the normal copy of the gene gives rise to a developmentally abnormal clone.<sup>120</sup> However, other symmetric generalized features of the syndrome (e.g., overgrowth, corpus callosum defects) suggest that loss of just one copy of the NBCC gene exerts an effect on growth and differentiation.

The diagnosis of NBCC should be considered in anyone below the age of 30 with a single basal cell carcinoma and in older individuals with multiple basal cell carcinomas. Medulloblastoma, keratocysts of the jaw, and typical skeletal anomalies should raise the suspicion of NBCC regardless of the presence or absence of basal cell carcinomas. Palmar and plantar pits are pathognomonic. DNA-based testing is available for individuals at risk with a family history of NBCC and for sporadic patients as well. The most important follow-up study in affected individuals is dermatologic examination for basal cell carcinomas at intervals of 6 months to 1 year. Yearly dental examinations, with particular attention to the possibility of jaw cysts, are also recommended. Because the frequency of medulloblastoma in this syndrome probably does not exceed 5% and may be as low as 1%, screening studies for this tumor type in children are controversial.<sup>111,113</sup>

## TWO MECHANISMS LEADING TO FAMILIAL COLON CANCER

Familial aggregation of carcinomas of the colon and rectum have been reported in multiple studies in the literature.<sup>121</sup> Close relatives of an affected individual have approximately twofold increased risk of the disease.<sup>122</sup> Risk increases with the number of affected members in the kindred. Some families develop colorectal carcinoma in an autosomal dominant pattern, strongly suggesting the influence of highly penetrant gene(s).

Familial adenomatous polyposis (FAP) was the first hereditary colorectal cancer syndrome to be clinically recognized. The inheritance pattern is autosomal dominant, and the disorder accounts for approximately 1% of colorectal carcinoma. Affected individuals develop hundreds to thousands of colonic adenomas by the second decade, and almost all develop colorectal carcinomas by age 45.<sup>123</sup> FAP carries a substantial risk for small intestine and gastric adenomas with a 5% lifetime risk of small bowel or gastric carcinoma.<sup>124</sup> Although most families develop only polyposis and cancer of the colon and rectum, others have associated osteomas of the jaw and skull, fibromas of the skin, and benign and malignant tumors of the ampulla of Vater and stomach (Gardner's syndrome). In addition, polyposis coli has been reported in association with brain tumors, a condition called *Turcot's syndrome*. The association of brain tumors and colon cancer without polyps has also been termed *Turcot's syndrome* but is genetically distinct.<sup>125</sup>

Early efforts to identify the gene for adenomatous polyposis coli (APC) were unrevealing. Eventually, a case report of a patient with mental retardation, multiple congenital anomalies, adenomatous polyposis of the colon, and a chromosome 5 deletion localized the APC gene to the long arm of chromosome 5(5q).<sup>126</sup> In 1991, the APC gene was cloned and shown to have the characteristics of a tumor suppressor gene.<sup>127,128</sup> APC promotes the degradation of the b-catenin, which can function as an oncoprotein in colon carcinoma.<sup>57</sup> Most APC germline mutations yield a truncated protein product, and correlations have been found between size of the APC protein and phenotype.<sup>129</sup> Mutations in the 5'(proximal) end of the gene result in small protein products and attenuated manifestations of polyposis coli. Pigmented lesions in the eye (congenital hypertrophy of retinal pigment epithelium) in polyposis cases are associated with APC mutations clustering around exons 10 through 14.<sup>130</sup> An APC mutational *hot spot* is at codon 1309 (exon 15), and mutations in this region are associated with larger numbers of polyps of early onset.<sup>131</sup> These patients have poor prognoses for survival when compared with those with mutations at other APC sites. I1307K, a common variant among Ashkenazi Jews, causes genetic instability in the APC gene and a tendency toward somatic mutations.<sup>132</sup> This variant is associated with a small increase in the risk of colorectal cancer and possibly an increased risk of other types of cancer as well,<sup>133</sup> but not with large numbers of colon polyps. A role for clinical testing for this mutation is not established.

The other major form of hereditary colorectal cancer is hereditary nonpolyposis colorectal cancer (HNPCC). In this autosomal dominant disorder, the colon is not carpeted with polyps, but the lifetime risk of colon cancer is still very high. Other tumor types that occur in this syndrome include carcinomas of the endometrium, stomach, ovary, small bowel, pancreas, hepatobiliary tract, ureter, and renal pelvis.<sup>134</sup> Muir-Torre syndrome is a variant of HNPCC with sebaceous adenomas, carcinomas, and keratoacanthomas.<sup>135</sup> Because colorectal carcinoma is common in the general population, familial aggregates of two or three cases might be caused by chance association or shared environmental influences. The International Collaborative Group on HNPCC has proposed that the diagnosis be based on the following findings (called the *Amsterdam criteria*): three or more relatives with histologically diagnosed colorectal cancer, of whom one is a first-degree relative to the other two; cancers involve at least two generations; at least one case diagnosed before age 50; and exclusion of FAP.<sup>136</sup>

In 1993, an HNPCC gene was mapped to the short arm of chromosome 2 (2p16).<sup>137</sup> Simultaneously, two studies described widespread genetic instability in short repeated DNA markers (microsatellites) in cancers of the proximal colon, particularly within tumors of familial cases.<sup>138,139</sup> The widespread genetic instability raised the possibility that the inherited defect in HNPCC might involve mutations in mismatch repair genes that had been well characterized in yeast and *Escherichia coli*. Fishel and associates cloned several human homologues of yeast mismatch repair genes, and found that MSH2 is mapped to human chromosome 2p.<sup>140</sup> They then demonstrated inherited MSH2 mutations in several families with HNPCC. Using a second approach, positional cloning, Leach and colleagues independently demonstrated MSH2 as the colon cancer gene on chromosome 2.<sup>141</sup> Within months, a second HNPCC gene, MLH1, was mapped to the short arm of chromosome 3 and cloned.<sup>142,143</sup> MSH2 and MLH1 account for the large percentage of HNPCC families including cases of Muir-Torre syndrome. Other genes that can cause HNPCC include MSH6 and PMS1 and PMS2, which are homologous to *E coli* MUTL and yeast PMS1.<sup>144,145</sup> Mutations in mismatch repair genes are found in a high percentage of families that conform to the Amsterdam criteria, particularly if endometrial cancer is present in the family as well as colon cancer.<sup>136</sup>

Management of hereditary colon cancer involves surveillance and preventive treatment of affected patients for colonic and extracolonic cancers, counseling of patients and their families, and presymptomatic diagnostic testing of at-risk family members.<sup>146,147</sup> and <sup>148</sup> In FAP, prophylactic colectomy is recommended in all affected patients during the second or third decade. Regular endoscopic checkup of the upper gastrointestinal tract is necessary to detect malignant transformation of duodenal and gastric polyps. For HNPCC patients, only preventive measures such as regular colonoscopic and gynecologic examinations are recommended. Prophylactic colectomy or hysterectomy are not considered to be routine procedures at present. On a research basis, trials of chemopreventive agents are under way. Substances being explored in colorectal cancer prevention include (1) the nonsteroidal antiinflammatory drugs, which inhibit the formation and evolution of adenomas in animal models presumably by their inhibition of cyclooxygenase and prostaglandin synthesis; and (2) antioxidants, such as vitamin E or C, which may modulate carcinogenic substances and correlate with lower colon cancer risk in epidemiologic studies. Dietary intervention with decreased fat intake and increased fiber consumption has also been linked to a lower incidence of colon cancer in epidemiologic studies.<sup>149</sup>

## NONSYNDROMIC HEREDITARY CANCER

In the absence of a characteristic pattern of neoplasia or neoplasia plus developmental defects, diagnosis of hereditary cancer predisposition is far more difficult than in the case of a distinctive genetic syndrome. Nevertheless, a family history of cancer, early age of onset, and multiple primaries strongly suggests an underlying genetic disorder, particularly in the absence of known carcinogen exposure. Laboratory testing for mutations in cancer predisposition genes will become increasingly important for diagnosis of site-specific, nonsyndromic cancer. Evaluation of patients with isolated, site-specific cancer predisposition is discussed elsewhere in this book.

#### INTRODUCTION

Cancer epidemiology is the study of cancer patterns in populations and cancer causation. Through epidemiologic studies, we have learned about changing patterns of cancer incidence and mortality worldwide, risk factors for specific cancers, potential prevention strategies, and the role of genetic variation in cancer etiology. Leads from these studies have formed the basis of many laboratory investigations that have revealed biologic mechanisms for the associations first described in epidemiologic studies. It is beyond the scope of this chapter to detail the complex methodology of epidemiologic studies. A number of excellent texts elucidate the nuances of study design and conduct.<sup>1,2,3,4</sup> and <sup>5</sup> The object of this chapter is to provide clinicians with information about epidemiologic approaches and the strengths and shortcomings of various study designs so that they may evaluate the literature more critically.

Similar to clinical trials, epidemiologic studies are of human populations and, therefore, are frequently multiple years in duration and subject to certain limitations. Epidemiologic studies are usually observational and sometimes opportunistic, to learn as much as possible when humans are unexpectedly exposed to potentially harmful substances. An example is the long-term study of the population of Seveso, Italy, after the 1976 explosion that exposed the local population to high levels of 2,3,7,8-tetrachlorodibenzo-para-dioxin.<sup>6</sup> Another example involves the study of long-term toxicities of therapeutic irradiation and chemotherapy for cancer treatment (one of the few instances in which humans are deliberately exposed to well-documented doses of carcinogens; see [Chapter 55.7](#)). These studies have greatly enhanced our understanding of cancer biology and have affected treatment (e.g., less radiation therapy for heritable retinoblastoma).<sup>7,8</sup> The central distinction in epidemiologic studies is between the observational and experimental approaches ([Fig. 14.1-1](#)).<sup>2</sup> The experimental approach controls exposures to some extent and, therefore, presents different issues in design, conduct, and analyses of studies. This chapter focuses predominantly on observational studies, since the experimental approach is covered in other chapters on prevention and clinical trials.

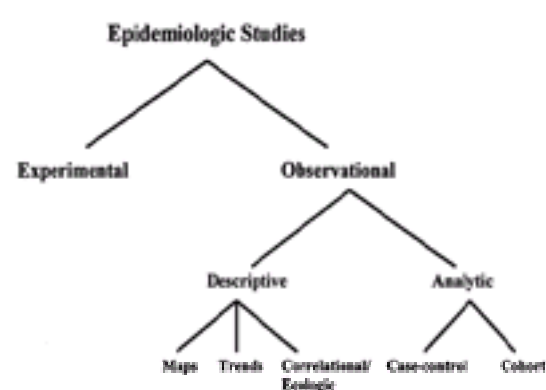

FIGURE 14.1-1. Schematic of types of epidemiologic studies.

#### OBSERVATIONAL STUDIES

Observational epidemiologic studies can be divided into two broad categories: descriptive studies and analytic studies. Descriptive studies are usually large, population-level studies of patterns of disease based on demographic data, such as age, gender, race, geographic residence, calendar year, type of cancer, and possibly other attributes. Descriptive studies provide important information for public health decisions and are often hypothesis-generating. Examples of these studies are the comparison of cancer rates among migrants to a different country, such as the evaluation of breast and colon cancer in Asians after migration to Western countries<sup>9,10</sup> and the evaluation of melanoma among individuals of British origin in Australia.<sup>11</sup> Analytic studies are designed to test hypotheses by obtaining individual information about potential risk factors for specific types of cancer. Examples would be the resultant investigation of the role of Western diet and lifestyle among Asian migrants to the United States<sup>12,13</sup> and the role of sun exposure in the development of melanoma among migrants to Australia.<sup>11</sup>

Certain general concepts are important to the evaluation and interpretation of all epidemiologic studies. The inference of causation from epidemiologic studies is quite complex; there are no fixed and agreed-on criteria to establish causation.<sup>2,3</sup> Most formulations, however, derive from the criteria originally proposed at the time of the controversy about cigarette smoking and lung cancer.<sup>14,15</sup> Descriptive studies in general will not lead to causal inferences. No one analytic study, however large and methodologically robust, is likely to “prove” a causal association. Because epidemiologic studies are largely observational, it is important to replicate findings from one study in other groups or populations to evaluate the consistency of the results. The consistency of results should be interpreted taking into account the relative rigor of both the study designs and the conduct of the investigations and the size and statistical power of the studies. Within appropriately designed and conducted studies, the magnitude of the risks demonstrated and the statistical significance of the risks are important. The greater the magnitude of the risk, the stronger the evidence for causation. Evidence of increasing risk of cancer with increasing exposure to a risk factor strengthens a postulated association. Data from studies must be interpreted within the current body of knowledge of that exposure and that cancer. There needs to be sufficient time between the exposure and the development of cancer as well as biologic plausibility of the exposure. Animal studies demonstrating carcinogenicity of an exposure lend credence to the hypothesis.

In trying to determine whether an association found in an investigation is plausible and valid, it is important to consider the possibility of bias in the data, confounding factors, and chance associations. Bias can result from a flaw in the design of the study or in the collection of the data. For instance, the study could be designed such that individuals with cancer are identified several months after the cancer is diagnosed. For individuals with a cancer for which there is high survival, this may not be a problem. For individuals with a cancer for which the survival is poor and mortality is rapid, only a subset of better-prognosis individuals would be alive to participate. This subset of individuals may fundamentally differ from those with more aggressive disease in host susceptibility or in risk factor exposures, if either is related to more aggressive disease. Another type of problem could be in long-term follow-up of groups under study. If there is differential effort in locating individuals with specific exposures or differential effort in locating individuals who may have become ill, there could be profound effects on the data. If interviewers know who has cancer and who does not, they may be (even unconsciously) more persistent in prompting individuals with cancer for answers to specific questions. This could lead to a systematic bias in data collection. These types of difficulties cannot be accommodated well in the data analyses and affect how one can interpret the results.

*Confounders* are variables associated with disease risk and with an exposure under investigation.<sup>2</sup> If confounder variables are not appropriately recognized and dealt with in analyses, the risks associated with the exposure of interest may be altered, either increased or decreased. Confounder variables must demonstrate three characteristics: (1) The confounder must be related to disease risk in individuals with and without the exposure of interest; (2) the confounder variable must be

associated with the exposure of interest in the group from which the study participants come; and (3) a confounding variable cannot be an intermediate end point in the development of disease.<sup>16</sup> These relationships can be complex to disentangle but can frequently be handled by specific analytic techniques. An example of a confounder would be cigarette smoking in participants in a case-control study that is investigating the role of alcohol consumption in the etiology of oral cancer.<sup>17,18</sup> Cigarette smoking is related to alcohol consumption and is a risk factor for oral cancer. If the level of cigarette smoking is not accounted for in the analysis, the risk shown for alcohol consumption would be altered.

In interpreting results of epidemiologic studies, one must always also consider that a finding occurs by chance alone. These spurious associations are more likely in large, complex analyses with multiple comparisons. Chance associations usually do not show evidence of a dose response and may or may not have biologic plausibility. Evaluating the level of statistical significance of a finding is usually helpful also. Most risk estimates are accompanied either by a test of statistical significance or by confidence intervals. Ninety-five percent confidence intervals that do not include 1.0 indicate significance of at least the 0.05 level. This can be interpreted as a 1 in 20 likelihood of the observation occurring by chance alone. The more comparisons that are done, the more likely it is that a chance association will occur.

In descriptive studies, most demographic data are collected from institutions, not individuals. In those data, the completeness of ascertainment of data and quality of data from the relevant sources are important to evaluate. In analytic studies, response rates indicate the percentage of people approached who actually complete components of an investigation. Especially in analytic studies, epidemiologists are dependent on the generosity of study participants to spend time, provide sensitive or confidential information (or both), and donate biologic specimens. This is becoming an increasing problem. In the late 1970s and early 1980s, response rates in excess of 90% were not uncommon. As individuals have become more concerned about privacy issues and as studies have become more demanding of time, biologic specimens, and other impositions, response rates have dropped substantially. It is now common to have response rates of 50% or lower if biologic specimens are requested. Lower response rates are of concern because it often is not clear that respondents are identical to nonrespondents in terms of risk factor exposures or genetic susceptibility factors. Inferences about the entire group are quite limited if only a minority of individuals provide information. In addition, low response rates affect the statistical power of the study to detect associations.

## DESCRIPTIVE STUDIES

Descriptive studies are important for noting differences in patterns of cancer among different populations or over time.<sup>19</sup> Evaluating changes in cancer incidence has been essential in determining public health priorities. To have equivalent data to compare across populations or time, crude data are adjusted to standard age distributions. Crude incidence is the number of new cancer cases in a selected group that occur over a specified time period, divided by the total number of people in that selected group (usually the number at the midpoint of the specified time period). Similarly, crude mortality is the total number of deaths from cancer in a selected group that occur over a specified time period, divided by the total number of people in that selected group. For international comparisons, these crude rates usually are adjusted to an age-standardized population, as the age structure of populations varies widely and cancer rates are age-dependent. In an equivalent manner, to compare rates in the same population over different calendar periods, the crude rates need to be adjusted to a similar population structure.

Descriptive studies are highly dependent on the quality of data collected. The quality of incidence data varies substantially, depending on the medical care systems, the thoroughness with which a diagnosis of a specific type of cancer is pursued, the completeness of reporting a new diagnosis of cancer to whatever institution is collecting the data, and the accuracy of the population numbers. The percentage of histologic confirmation of new cancer diagnoses also varies widely among health care systems and among tumor registries.<sup>20,21</sup> In some areas, where there is better reporting of causes of death than of new cases of cancer, mortality may be a more reliable estimate of rates, particularly if the type of cancer is associated with poor survival. The ideal population for evaluating cancer rates would be a large, diverse one in which there is little in or out migration, one health care system provides high-quality care from birth to death, and each individual has a unique identifier for life.

Maintaining the infrastructure for these descriptive studies is essential for monitoring trends in cancer incidence and mortality over time, which is necessary for monitoring the health of the population. For instance, through evaluating data from the Surveillance, Epidemiology, and End Results (SEER) program, it is clear that lung cancer incidence has leveled overall for men.<sup>21</sup> For women, however, the rates are still increasing, and lung cancer now is the leading cause of cancer-related deaths in women. The SEER data are now available on the National Cancer Institute (NCI) Web site <http://www-seer.ims.nci.nih.gov/>. These data provide population-based incidence rates, survival, and mortality for the United States, based on information from 11 population-based registries and three supplemental registries. These registries cover approximately 14% of the U.S. population, with measures of poverty and education similar to the U.S. population. The SEER population tends to be more urban, with a higher percentage of foreign-born persons than the general U.S. population.<sup>21</sup> For international comparisons, the World Health Organization's International Agency for Research on Cancer and the International Association of Cancer Registries publishes *Cancer Incidence in Five Continents*.<sup>22</sup> This volume is extremely useful in comparing the wide variation in cancer incidence. The Scandinavian countries have long-standing active cancer registries.<sup>23</sup> Several years ago, the NCI and the Danish Tumor Registry collaborated on analyzing data regarding multiple primary tumors occurring in Connecticut and Denmark over approximately a 50-year period.<sup>24</sup>

The NCI has also published *Atlas of Cancer Mortality in the United States 1950–94*, which is available at Web site <http://www.nci.nih.gov/atlas/>.<sup>25</sup> Two components comprise this atlas: a static version and a dynamic version. These maps were used to show a substantial change in geographic patterns of lung cancer mortality over time that correlates with changes in smoking patterns.<sup>26</sup> The mortality is higher for white male individuals in the Southeast (Fig. 14.1-2), for white female subjects in the West, and for African Americans in the urban North.<sup>25</sup> This is also an example of another variant in descriptive studies, a correlational or ecologic study, in which statistics gathered for another purpose are correlated with cancer incidence. An earlier version of the mortality maps showed an excess of lung cancer in white men along the southern seaboard.<sup>25</sup> A number of analytic studies were undertaken to evaluate potential risk factors that revealed that the excess was largely due to asbestos exposure in shipyards during World War II.<sup>27,28</sup> and <sup>29</sup> In the recent maps, this coastal excess has essentially disappeared for white men (see Fig. 14.1-2). These mortality maps can be used to generate many new hypotheses related to the geographic clustering. Newer technologies, such as satellite mapping that provides data for geographic information systems, will likely become increasingly important in the future for ecologic or correlational studies.

**FIGURE 14.1-2.** Age-adjusted lung cancer mortality rates for white male population by state economic areas for the years 1970 to 1994. Overall, the age-adjusted mortality was 69.4 per 100,000. The areas with the highest 10% of mortality are shown in black; the areas with the lowest 10% are shown in white. The midrange areas are in shades of gray, with the darker areas denoting higher rates. The highest rates are generally in the Southeast.

## ANALYTIC STUDIES

In contrast to descriptive studies, in which only demographic information is available, analytic studies obtain information on specific risk factors from individuals. Each of the two broad categories of analytic studies—cohort studies<sup>30</sup> and case-control studies<sup>31</sup>—has specific advantages and limitations.

### COHORT STUDIES

Cohort studies are frequently prospective and longitudinal. A group is identified and defined and then followed prospectively for outcomes of interest. There are multiple advantages of this type of design. Information on specific risk factors can be obtained before onset of disease. This is particularly important for risk factors

that may be altered in individuals who have become symptomatic from their disease. For example, the diet of a patient who has just had a colectomy for colon cancer or a gastrectomy for stomach cancer will be quite different from that patient's diet before diagnosis. There may be recall bias in remembering previous dietary intakes. Usually, updated information is collected at regular intervals, so that longitudinal patterns of exposure can be obtained (variations in smoking patterns, alcohol consumption, etc.). Because information is collected on a large number of people at regular intervals, information is best collected on relatively common exposures. It is impractical to expect participants to complete extensive questionnaires every year or two. Biologic samples can also be obtained, so that sequential patterns of exposure (micronutrients, viral titers, nicotine metabolites) can be quantified and obtained, again, before alteration by disease status. Usually, as information is collected from participants routinely before being affected with a specific type of cancer, there is much less problem with differential information from affected and unaffected participants. Another advantage of cohort studies is that multiple outcomes (several different types of cancer, mortality from other causes, morbidity if data are collected, etc.) can be evaluated.

In a prospective cohort, when part of the cohort has a specific exposure (e.g., cigarette smoking) and part does not, the relative risk of developing disease is calculated by the ratio of the proportion of exposed individuals who develop cancer to the proportion of unexposed individuals who develop cancer.<sup>2</sup> This is a direct comparison of the rate of cancers (or for mortality rate of death) in the exposed and unexposed groups. A relative risk of 2 means that the exposed group is twice as likely to develop the cancer as the unexposed group; a relative risk of 0.5 means that the exposed group is half as likely to develop the cancer. The terms in these calculations usually include the time interval over which the event occurred, usually person-years of observation. Relative risks are usually reported with 95% confidence intervals. If the 95% confidence intervals do not include 1.0, the relative risk is considered statistically significant. One can also calculate other measures of risk that reflect the percentage of disease attributable to the specific exposure, if it is causal.

Cohorts are sometimes defined by a previous "exposure," which could be an occupational exposure, an occupational group, a specific disease, a type of vaccination, a certain medication, and the like. In these retrospective studies, individuals are followed up from a specific time of exposure in the past to onset of disease, death, or time of study. The rates of cancers (or death, if evaluating mortality) over the time period frequently are compared to the general population rates rather than to an unexposed group (which may not be available). This comparison assumes that the group under study would have the same baseline rate of cancer as the general population, absent the exposure under study.

In both the prospective and retrospective cohort designs, careful definition of study participants and exposition of follow-up procedures are crucial for interpreting data. This includes how potential participants are identified (and contacted), initial and continuing participation rate, loss to follow-up, and refusal rate (which may change over time). In evaluating the relationship of exposure to disease, methods and precision of quantification of exposure are important. Exposure measures can range from industrial hygiene estimations of occupational exposures, to dietary histories (or diaries), smoking history, medication records, and biologic measures, such as DNA adducts or metabolites of specific substances in specimens. The potential error in these measures must be considered in interpreting the data. An advantage of cohort investigations is that when onset of exposures is well documented, one can evaluate latency of the exposure to disease diagnosis and the duration of an effect after exposure. For instance, 20 years after the explosion in Seveso, detectable levels of dioxin persisted in the blood of heavily exposed individuals.<sup>32</sup> As with all epidemiologic studies, confounding variables should be identified when possible.

A relative disadvantage of cohort studies is that they are usually large, long-term, complex, and very expensive endeavors. Outcomes in prospective cohorts may not be apparent for decades, and it is extremely difficult to motivate study participants to continue. With increasing concerns about privacy and confidentiality of data, fewer participants are willing to undertake the commitment. If a substantial part of the proposed cohort does not participate or if there is continuous loss of participants due to refusal or withdrawal from the study, the results may become difficult to interpret. The participant group may no longer reflect the entire group from which they were derived. Even with very large cohorts, it is difficult to study relatively rare diseases or uncommon exposures (unless the cohort was chosen because of the exposure). Because of the limitations of imposition on cohort participants, detailed information on other exposures of interest may be lacking. This lack of focused exposure information can be a problem when specific cancers are evaluated. To overcome these constraints, within larger cohort investigations, additional information on other exposures of interest (including confounders) may be collected from smaller substudies of identified individuals with a specific cancer and a subgroup of the cohort (either matched controls or a selected sample of the cohort).<sup>2</sup> These are called either *nested case-control* or *case-cohort analyses*. These approaches may be cost-effective mechanisms for evaluating specific cancers of interest free of selection bias if the participants with the cancer are still alive to provide the information. Another approach within the cohort design for evaluating rare cancers is to combine data from several cohorts.

## CASE-CONTROL STUDIES

Case-control studies, also called *case-referent studies*, usually obtain data within a limited time frame on previous exposures of interest. They are, therefore, considered retrospective. Cases (individuals with the cancer of interest) and controls (individuals similar to the cases but who do not have the cancer) are identified in a systematic manner, and data are collected. These data are frequently collected using questionnaires, abstracting occupational or medical records, or examining participants. Usually, there is not longitudinal follow-up. Several advantages accompany this design. The studies are much shorter in duration than cohort studies and, therefore, are less costly. The amount of data collected at one time can be greater than in a cohort study because the investigators will not be imposing on the participants repeatedly over many years. Questionnaires can be longer, with detailed information about more risk factors specific to the type of cancer being studied. This may allow evaluation of interaction of risk factors. Because the cancers have already occurred, it is more feasible to identify a larger number of individuals with relatively rarer tumors to include in the study than to wait to accrue a sufficient number in a large cohort. It is, therefore, more efficient and cost-effective to try to study a rare tumor in a case-control study than in a cohort study.

Biologic specimens can also be collected relatively efficiently, often in close temporal proximity to extensive information about recent exposures. In contrast to cohort studies, however, for the cases, this will be after the onset of disease. If the disease process directly or indirectly affects the exposure measure, there will be difficulty in interpreting the results. (Biospecimen collection as part of case-control studies is discussed later in [Molecular Epidemiologic Studies](#).) Other limitations in case-control studies include recall bias, as individuals with cancer may have spent time already pondering the causes of their illness. In contrast to cohort studies, in which multiple types of cancers can be evaluated as outcomes, in case-control studies, usually only one cancer type or a small number of closely related cancer types is evaluated in one study.

The identification of cases and the selection of controls are crucial to the validity of the investigation. Two general approaches are used to identify cases. The first is through population-based registries. Theoretically, this should lead to the least biased ascertainment of cases and should identify cases representative of the group from which they are identified. For cancers associated with high survival, this technique can be highly successful. There is frequently a several-month delay between the time the cancer is diagnosed and the time that the case is identified from the registry, however, which can cause a selection bias for cancers with high mortality. This delay can also cause problems if biologic specimens to measure exposure or host characteristics are to be collected. Many of the bioassays would be profoundly altered by interval treatment with radiation therapy or chemotherapy. In some instances, special efforts are made to identify cases rapidly. Although this is necessary for some types of cancer, it is frequently very costly.

The second general approach is to identify the cases from a hospital or clinic setting. If essentially all cases from a defined area are treated in the hospital from which the cases are identified, the cases may be essentially as representative of the population as the true population-based ascertainment. An advantage of hospital ascertainment is that the cases may be more cooperative, and it is logistically easier to enroll them and to collect the data, including biospecimens. Again, if biologic samples are collected, which could be affected by being in the hospital (dietary factors, smoking, occupational exposures, etc.), the results may be difficult to interpret. For both of these methods of identification, it is important to evaluate closely how scrupulously the cases were identified.

Equally important to the validity of the study is the selection of the controls. The controls should be from the same population group as the cases. Controls are frequently matched to the cases on characteristics that are important in determining risk of disease, such as gender, age, and ethnicity, or on potential confounder variables (e.g., socioeconomic status or, possibly, smoking status). Controls may be population-based (i.e., identified from the same population by use of population registries or lists, random-digit dialing if telephones are common in the population, neighborhood canvassing, or other methods). Although theoretically these methods should yield controls that are most representative of the population from which the cases come, if only a small proportion of individuals approached agree to participate in the study, this may not happen. The participants may differ from the nonparticipants in manners that are difficult to quantify and may not be representative. True population-based controls are becoming increasingly difficult to enroll in studies, at least partially because of privacy concerns.

If the cases are identified from hospitals or clinics, an alternative control selection could be patients from the same hospital or clinic. Care must be taken to select individuals who have the same likelihood of coming to that hospital or clinic if they developed the same disease as the cases (a surrogate may be the same catchment area for the control disease as for the type of cancer the case has). Selecting individuals as possible controls who have a variety of diagnoses that do not include conditions related to the development of the type of cancer of interest is also important to minimize bias. For instance, considering individuals being evaluated for skin conditions in a dermatology clinic as controls for a melanoma case-control study would often be inappropriate, because the reason they were being seen may be related to melanoma risk factors.<sup>33</sup> If there is a clinical component to the study, such as a structured physical examination, this is often best performed in a clinical

setting. Obtaining biologic specimens can also be facilitated in a clinical facility, but similar difficulties in interpreting results can occur as with cases. Cooperation and participation are frequently higher among hospital- or clinic-based controls.

The measure of association in case-control studies is the odds ratio, which is an estimate of the relative risk. Unlike cohort studies, case-control studies cannot directly evaluate the actual rate or risk associated with a specific exposure, because the rates in the unexposed and exposed populations are not known. This estimate is the ratio of the odds of exposure among cases (number of exposed cases divided by number of unexposed cases) to the odds of exposure among controls.<sup>3</sup> The odds ratio is a good approximation of the relative risk when cancer is uncommon in the population. Estimates can also be made for the attributable risk, which also cannot be directly measured as in cohort studies. Similar to cohort studies, the odds ratio shows a positive association between exposure and disease when it is greater than 1.0 and a negative association (or protective effect) when it is less than 1.0. Odds ratios usually are reported with 95% confidence intervals, which are considered statistically significant when they do not include 1.0. In case-control studies, detailed exposure information may have been collected on several exposures and potential confounders identified. The other risk factors and confounders should be considered in the analyses and dealt with appropriately. In large studies, with sufficient numbers of participants exposed to two risk factors, interactions between two exposures, such as asbestos and smoking in lung cancer, can be examined.<sup>26,27</sup> and <sup>28</sup>

In limited situations, a variant of a case-control design or analysis, a case-case design, may be appropriate. This type of analysis can be useful when attributes or risk factors are not available or present in controls or when controls are not available. This design cannot evaluate main effects of specific genes or exposures but can evaluate the interaction between a genotype and an environmental exposure.<sup>34</sup> Case-only or case-case studies are more efficient than case-control studies for detecting interaction. These analyses require that the genotype and the exposure be independent. The inferences from this type of analysis are often difficult to interpret and somewhat limited, because the risks do not reflect comparisons between affected and unaffected individuals but between affected individuals. An example might be comparing cases with a specific genotype to cases without the genotype, when the genotype is rare in the control population. Another example could be a study comparing somatic mutations in tumors to risk factors.

## MOLECULAR EPIDEMIOLOGIC STUDIES

Two other variations of both cohort and case-control studies must be considered: molecular and genetic epidemiologic studies. Molecular epidemiologic studies have been developed over the last decade or so to enhance exposure measurement methods. These have generally ranged in three large categories: (1) studies that directly assay exposure to specific substances; (2) those that evaluate phenotype or genotype information about metabolic pathways that may alter effective dose of an exposure or other host susceptibility factors; and (3) those that use markers of a specific effect to refine disease categories for analyses (of heterogeneity, prognosis, etiology, etc.). The type of specimen collected is determined by the exposure of interest and the methods available to quantify that exposure. Some investigations focus on directly measuring exposure, such as blood levels of substances (e.g., toxins, carcinogens, nutrients, micronutrients, viral titers), DNA adducts, levels of metabolites in urine, and the like. These data are then correlated with measures of exposure from occupation records, questionnaire responses, medical records, and other sources of data. If the metabolic pathways of the exposure of interest are known, often genes with variations (polymorphisms) are evaluated and correlated with either biologic measurements of dose or historic measures or both. Other host susceptibility factors (e.g., immune response determinants) may be related to time to progression, disease severity, or other parameters.<sup>35,36</sup>

Molecular epidemiologic studies have all of the logistic and methodologic characteristics of conventional epidemiologic studies. They also have the added constraints of laboratory components.<sup>37,38</sup> Molecular epidemiologic studies are, by definition, interdisciplinary and require investigators from highly divergent fields to collaborate closely from study design to completion. The complexity of these investigations manifests in both the epidemiologic and the laboratory components.

Many of the early molecular epidemiologic investigations were relatively small, exploratory studies to determine the feasibility of this approach, to validate biologic markers, and to estimate level of risk.<sup>37</sup> Even when assessing polymorphisms present in one-half of the population, these relatively small studies do not have power to evaluate modest risks, especially in subgroup analyses.<sup>39,40</sup> and <sup>41</sup> With the advances in laboratory techniques and the identification of many genetic variations that alter effective dose of exposure, much larger studies now are necessary to test adequately hypotheses involving complex exposures.<sup>42,43</sup> Careful estimates of sample size to detect the level of risk expected, given the frequency of exposure expected and the variation in biologic measures, must be accomplished as part of the early planning. The epidemiologic study design is directly affected by the sample size necessary for molecular studies. These investigations typically need to include hundreds or thousands of study subjects to detect a significant difference in, for instance, the effect of a genetic polymorphism that occurs in one-third of the population or a difference in adduct levels when one-half of the population is exposed. Even larger numbers are necessary to try to evaluate gene-exposure or gene-gene interactions. The appropriate controls for these molecular epidemiologic studies have also been under extensive discussion.<sup>37,44</sup> The type and quantity of biologic specimens to be collected has to be selected with the laboratory investigators. The specimens requested will have an effect not only on the study design and cost but on the response rate of the potential participants.<sup>45</sup> Adequate consent procedures are complex and essential. Because many of the exact laboratory assays may not have been selected (or developed) at the time the participant is enrolled in the study, specifying exactly what will be done with the specimen may be somewhat problematic. Many investigators are now using a consent that allows for different levels of use of the specimen (e.g., for only the specified assays or for other assays related to the disease of interest) or for any future use. Analytic methods to incorporate laboratory information as well as more standard epidemiologic information must be carefully developed.

The additional complexity of the laboratory components begins with establishing appropriate collection, processing, and transportation of biologic specimens with necessary quality control measures. Because many of the specimens must be stored for various lengths of time before being assayed, some type of repository system is needed to locate and track specimens. As laboratory assays are completed for the samples, each sample becomes more valuable because of the laboratory information in combination with the epidemiologic information connected to each sample. Repository functions, including proper identification and tracking of each sample, remain essential. All the routine difficulties of validity and reproducibility of the laboratory techniques being used on the specimens must be resolved before analysis of the samples. Many of the assays of particular interest may be technically challenging or quite complex. The laboratory collaborators often have to develop the methods to conduct the assays or genotyping on large numbers of samples (hundreds or thousands). Despite the risk of these complex studies, they hold the promise of more closely integrating biologic measures of exposure to the more traditional questionnaire and record abstraction of exposure information.

Many investigators conducting cohort studies try to collect biologic specimens for future use. One major advantage of these collections is that specimen collection occurs before disease onset. Because, in large cohorts, a majority of individuals will not develop the diseases of interest, many specimens will not be informative about the diseases the study was designed to investigate. With the sequential information gathered over time, new hypotheses and different outcomes can be evaluated in these cohorts, however. Collection and storage of large numbers of specimens for decades is costly, especially because relatively few of the samples will actually be assayed (in nested case-control or case-cohort analyses). Storage costs are proportional to volume of material and number of specimens collected. For cohort studies with large numbers and continuing contact with the study participants, the type of specimen collected is a trade-off between imposition costs for the participants, the storage needs and costs of the specimen, and the potential uses of those specimens. For low-cost blood storage for DNA, limited quantities of blood (100 to 150  $\mu$ L) can be stored on collection cards.<sup>46</sup> For noninvasive collection of genetic materials, buccal cell collection is a reasonable option with limitations.<sup>47</sup> Because, for most cohort studies, specimen collections will be relatively limited with finite quantities, extremely careful selective use of samples for assays is essential. As new laboratory techniques develop that consume less of the total sample, these invaluable resources can be increasingly informative.

Case-control studies may offer more efficient collection and storage of specimens but, as noted earlier under [Case-Control Studies](#), these samples may be altered by the presence of disease in the cases or by hospital-related exposures or lack of exposures in cases and controls. A relative advantage is that the specimens will be quickly informative. In contrast to cohort studies, there is not a long latency before cases occur and samples are potentially useful for proposed laboratory tests. Greater volumes of specimens (e.g., blood) can possibly be collected and stored, because the participants are not being sequentially contacted and long-term storage (for decades) before use is not anticipated. Storage issues for thousands of samples accrued over a several-year period are not trivial, however. Consent issues may still be problematic, as with cohort studies, because new hypotheses or laboratory tests may be developed that were not originally anticipated when participants were accrued. Case-control studies may be a more efficient design to investigate interactions between host susceptibility factors and exposures (gene-exposure and gene-gene interactions), especially when the type of cancer being studied is relatively rare.<sup>37</sup>

## GENETIC EPIDEMIOLOGIC STUDIES

Genetic epidemiologic studies overlap substantially with molecular epidemiologic studies, particularly when the "molecular" component is evaluating variations in genes. The field of genetic epidemiology has rapidly increased with the advent of gene identification and large-scale genotyping. Genetic epidemiology in its broad context, however, includes family studies, molecular epidemiologic studies with genetic components, and more traditional cohort and case-control studies with family history components. Similar to the molecular epidemiologic studies, genetic epidemiologic studies are multidisciplinary from the outset and involve clinicians, geneticists, epidemiologists, and laboratory investigators. These studies include all the complications of molecular epidemiologic studies, often with the additional

complexity of having to deal with family dynamics.<sup>48</sup>

Family studies have been essential for mapping and identifying the more than 20 major cancer susceptibility genes found in the late 1990s.<sup>49</sup> (The methods for identifying and evaluating these genes are discussed in [Chapter 13](#).) Once the contribution of genetic variation to disease within the families has been established, however, these variations should be evaluated in relation to known exposure factors for the specific cancers of interest (parity, reproductive factors for breast cancer; sun for melanoma, etc.). Complex analytic techniques that incorporate both genotype information and environmental risk factors into a regressive model have been developed.<sup>50</sup> Again, large numbers of families are necessary for these gene-environment and, potentially, gene-gene interactions. Care must be taken in these analyses to account for familial relationships, as the observations within families are not necessarily independent. Families share not only genes but environmental exposures and lifestyles. Within high-risk families, selected because there are many living members, penetrance (risk of developing disease associated with carrying an altered gene) estimates will be high but useful for determining an upper limit on the risk associated with alteration of a specific gene.

Larger population studies are important for estimating the effect of an altered gene outside of high-risk families selected for linkage analyses. Because most cancers are adult-onset, complex diseases, even when a major susceptibility gene is mutated, other factors may be important. Large epidemiologic studies are needed to identify these additional risk factors so that the complex chain of events that results in a cancer development can be interrupted. One approach is to conduct a large case-control study in which usual risk factors are obtained and large genes, such as *BRCA1* or *BRCA2* (each having hundreds of mutations throughout the gene), are analyzed.<sup>51</sup> This is logistically challenging, laboratory time-intensive, and costly. Even though mutations in such genes as *BRCA1* and *BRCA2* account for a percentage of familial breast cancer and are important for understanding the biology of breast cancer development, they account for only a small fraction of breast cancer in the general population.<sup>51</sup> Sample sizes for these studies must, therefore, be large and, even then, the limitation is the number of mutation carriers in the referent (control) population.

Another approach to understanding the role of mutations in the development of cancers is to take advantage of the opportunity afforded by relatively isolated populations with so-called founder mutations, recurrent mutations prevalent in a specific group. Unlike other populations in which an entire gene needs to be sequenced, these founder mutations can be more easily genotyped because the laboratory searches for one or a limited number of specific mutations.<sup>52</sup> It is thus feasible to screen thousands of samples for the specific mutation. Founder mutations have been identified in a number of populations worldwide. For example, breast, ovarian, and prostate cancer risk associated with prevalent mutations in *BRCA1* and *BRCA2* were estimated in volunteers from the Jewish community of Washington, DC.<sup>46</sup> To estimate risk of cancer among mutation carriers, a novel analytic technique was devised, called the *kin-cohort method*.<sup>53</sup> The risk of breast and ovarian cancers could not be directly estimated among the genotyped participants because of the potential survival bias. Information on cancer history of first-degree relatives of genotyped individuals was used to estimate penetrance of breast, ovarian, and prostate cancers. The cumulative risk of each type of cancer in relatives of carriers was compared to that of noncarriers and found to be much lower than that in high-risk families.<sup>46,53,54</sup> Other novel analytic techniques will need to be developed for other types of data sets to maximize the information gleaned from both genetic and environmental risk factors.

Family history data from case-control or cohort studies can be used to evaluate clustering of cancers in families. Information on first-degree relatives is usually accurate among well-educated Americans,<sup>55,56</sup> but this type of information is culture-specific. In cultures where notification of cancer diagnoses is not routine, obviously information on cancer diagnoses in relatives will not be accurate. One approach to identifying families with known ascertainment for clustering studies or linkage analyses is to identify individuals from case-control or cohort studies with a family history of interest, contact the individual to ask for permission to contact other family members, and then evaluate the family members who are willing to participate. Another approach to systematically identifying families at increased risk of specific cancers is through population registries,<sup>48</sup> where genetic findings can be extrapolated to the population from which the cases are derived.<sup>46,57</sup> Individuals with a disease of interest are identified at the time of registration, and family history is obtained. If the family meets the criteria, family members are invited to participate in a family registry study. This approach is being developed to provide resources for the research community.<sup>49</sup>

Genetic epidemiologic studies that investigate other genes not considered among the major susceptibility genes are similar to those described in molecular epidemiology. There are some special issues for genetic epidemiologic studies, however.<sup>48</sup> Informed consent is complex. (The issues of consent in families are discussed in [Chapter 56.4](#).) A growing concern among potential participants in any type of genetic epidemiologic study is the implementation of confidentiality practices to protect the privacy of genetic information. Another concern is notifying participants of results and the approach of this notification. If all identifiers are removed, individual notification becomes impossible. In most large studies, it is not feasible to counsel participants individually about their genotype status, even if it were possible to interpret the meaning of such variation. One approach is to notify participants about aggregate results, so that they can then pursue clinical, rather than research, genetic testing with their physicians.

## INTERVENTION STUDIES

In some senses, intervention studies represent the culmination of descriptive studies that reveal patterns of cancer and analytic studies that discover risk factors for developing the cancers. The ultimate goal of both approaches is to identify individuals at high risk of developing cancer, to establish risk factors for the cancer, and to develop rational approaches to interrupting the causal pathway in cancer development. Intervention studies are designed to test ways of disrupting the chain of events that may lead to cancer causation. As such, some investigations are designed to evaluate intermediates in tumor development. The hypotheses in general are developed from case-control and cohort studies. Intervention studies randomize individuals to a group receiving some type of prevention intervention and those not receiving the intervention. The risk of cancer is compared in the two groups using similar analytic techniques as in the cohort studies. These intervention trials may be dietary (e.g., giving supplementary micronutrients to individuals at risk of esophageal or stomach cancer)<sup>58</sup>; chemopreventive (e.g., the tamoxifen trial for women at increased risk of breast cancer)<sup>59</sup>; vaccine trials (e.g., hepatitis B<sup>60</sup> or the papilloma virus<sup>61</sup> vaccination trials); medical screening (e.g., the NCI's Prostate, Lung, Colon, and Ovary screening trial); or lifestyle-altering (e.g., sun exposure) programs.<sup>62</sup> When individuals are randomized, confounding factors should be equivalently distributed between the groups. The baseline characteristics should also be equivalent among the randomized groups. Most of these trials are conducted with participants who are considered to be at high risk for disease. An important consideration is that because participants are healthy individuals, prevention strategies should not have substantial side effects: That is, toxicity should not outweigh potential benefit.

In the design of these trials, sample size estimates are crucial. Even among selected high-risk participants, cancer outcomes may be relatively rare, and a large number of participants may have to be enrolled and followed up for decades. Oversight committees are not uncommon; they are quite useful in monitoring data and helping with the ethical decision to stop a trial if a substantial benefit is shown in one group.

## FUTURE DIRECTIONS

Epidemiologic studies have pointed to the direction of many fruitful avenues of cancer research in the basic sciences and have established the causes and major risk factors for many cancers. Much needs to be done, however. The major progress in the next few years will likely emerge from large, interdisciplinary, highly collaborative research programs with improved measures of host susceptibility and environmental exposure. A new era of chemopreventive studies, based on identifying high-risk individuals and the biologic mechanisms of tumor progression, hold great promise for altering the natural history of disease. The identification of genetic factors that may influence addiction to tobacco<sup>63,64</sup> and<sup>65</sup> could, in time, reduce the number of individuals who smoke.

### Acknowledgments

I am deeply grateful to my husband, Dr. David Schlafer, for his support and help; to my colleagues, Drs. Neil Caporaso, Alisa Goldstein, and Patricia Hartge, for their insightful comments; and to Dan Grauman for providing the mortality maps.

## INTRODUCTION

The malignant diseases have both a descriptive and an analytic epidemiology. Descriptive epidemiology consists primarily of vital statistics, particularly incidence and mortality rates. These usually relate to large populations divided according to age, gender and race. Differences in these statistics from one place or time to another are part of descriptive epidemiology. Survivorship also is descriptive. The descriptive epidemiology of the malignancies is described in this Section.

Analytic epidemiology consists of the knowledge of suspect and known causes of disease. It is developed from disease-specific or cause-specific investigations. The analytic epidemiology of the malignancies is described in Section 3 of this chapter.

## DESCRIPTIVE EPIDEMIOLOGY

### USA

Most data presented here pertain to the United States of America (USA). This is not limiting in that cancer patterns vary relatively little over the developed world. Further, differences that occur reflect geographic and cultural variations in the distribution of the causes of cancer, not differences in the causes themselves. However, in the developing world cancer patterns vary from that of the developed world and differ from one region to another. In many developing countries there are high frequencies of cancers of the liver, stomach, cervix and, in parts of Asia, cancer of the nasopharynx. Cancer patterns in many newly industrialized societies are changing rapidly towards those of the West. This reflects their recent large-scale adoption of cigarette smoking. <sup>1</sup> Global variations in the descriptive epidemiology of cancer are reviewed in "Global cancer statistics" by Parkin, Pisani and Ferlay. <sup>2</sup>

### CANCER ENTITIES

Depending on the cancers of interest and on their grouping, there could be several dozen groups of malignancies for which statistics are available. This Section describes "all cancer" and 20 specific cancers and groups of cancer that cause the largest numbers of deaths in the USA. These entities accounted for 88% of cancer deaths in 1996. [Table 14.2-1](#) ranks them by number of deaths. The names in the table were chosen for brevity. The cancers included in each group will be specified.

Entity	Site of Cancer	Incidence				Mortality			
		Number	% <sup>a</sup>	Rate, %	Rate, %/10 <sup>4</sup>	Number	% <sup>a</sup>	Rate, %	Rate, %/10 <sup>4</sup>
All cancer		1243200	100	1.1	598000	100	1.1	5.9

a specified time, usually one year. The more commonly used measure, the incidence rate (*I*), relates the incident number to the size of the population and to the interval in which the cases were diagnosed. *I* is expressed as cases per 100,000 persons per year or, usually, as cases per 100,000 person-years (py). An *I* may relate to an entire population (the *I* of lung cancer in the USA is 54 cases per 100,000 py), may be specific, e.g., as to gender (the *I* of lung cancer among males in the USA is 70 per 100,000 py) or may be ever more specific, e.g., as to males of one race and of a narrow age range. Whether or not they are specific, *I*'s that span a broad age range usually are age-adjusted to facilitate comparison with one another. Age-adjustment nearly eliminates age as the explanation for any differences seen among a group of *I*'s. All *I*'s and mortality rates in the remainder of this chapter are adjusted to the age distribution of the total USA population in 1970.

Cancer *I* data in the USA are provided mainly by population-based cancer registries. These vary in size and somewhat in the quality and completeness of their data. Most of the incidence data come from a national system of cancer registries that has existed since 1973. This Surveillance, Epidemiology and End Results (SEER) Program now includes 11 registries. The incidence data reported for 1973 and later are from SEER's nine original registries which include about 10.5% of the USA population.<sup>3</sup>

Data from a cancer registry less than 20 years old are viewed cautiously. As a registry matures its coverage will improve, possibly giving the false impression of a rise in *I*'s. There are other potential sources of distortion in *I*'s, even those from established registries.<sup>4,5</sup> These include a population's increased use of cancer screening services and improvements in access to medical care. Improvements in diagnostic capabilities and, rarely, changes in diagnostic categories also affect *I*'s. All of these advances may convey the false impression of a rise in cancer *I*'s.

## MORTALITY

Cancer mortality or the number of deaths, and the cancer mortality rate (*M*) are analogous to the corresponding measures of incidence. Of course these measures relate to deaths certified as due to cancer not to diagnosed cases of cancer. *M* usually is expressed as deaths per 100,000 py and may be made specific for population subgroups just as is *I*.

*M*'s are of very high quality in the USA,<sup>6</sup> especially for cancer. Nearly 90% of persons considered to have died from cancer, on the basis of autopsy, will have the disease correctly listed on their death certificate.<sup>7</sup> Numbers of deaths and *M*'s are available annually in great detail for the entire country. In this Section we usually present mortality data for 1996. This is the latest year for which detailed information is available and it is the same as the year for most incidence data presented. Preliminary mortality data are available for 1997 and 1998. This recent information extends all of the trends described in this Section. All of the mortality data come from publications of the National Center for Health Statistics.<sup>8,9,10</sup>

## SEX RATIO

Males and females differ in their rates of most cancers. These male:female differences are expressed as the age-adjusted sex ratio, the ratio of the age-adjusted male *I* or *M* to the corresponding female rate. Since this ratio is based on age-adjusted rates it accommodates the fact that the female population is larger and older than the male.

## RACE RATIO

For brevity *I*'s and *M*'s are presented for all races combined. However, we also present the ratio of age-adjusted *I*'s and *M*'s of Blacks to those of Whites. The ratio of Black to White *M*'s is typically higher than the *I* ratios and this discrepancy, for each cancer, may be an index, albeit a crude index, of the access to and use of cancer-related services by the two races.

## SURVIVORSHIP

Survivorship is described by the five-year **relative** survival rate (**RSR-5**). The **RSR-5** is the proportion of persons with a particular form (and usually, stage) of cancer who survive to the fifth anniversary of their diagnosis, divided by the proportion of the general population expected to live that long. The expectation is based on mortality rates from all causes among persons with the same age, gender and race composition as the cancer patients. An **RSR-5** of, say 75%, indicates that five years after diagnosis the cancer group has 25% fewer survivors than does the comparable population. The **RSR-5** is based on all deaths in the cancer group, so it does not describe mortality from the specific cancer in question. Instead, it indicates the incremental mortality imposed by that cancer. Because **RSR-5**'s are available for specific stages of a cancer, they permit evaluation of long-term gains in patient survival.

## AGE PATTERNS, TIME TRENDS

Patterns of *I*'s and *M*'s are described by age for men and women for each of the cancers addressed. For cancers of greatest public health importance and for several others of special interest, the age-patterns are also presented graphically. Time trends are presented graphically for *I*'s and *M*'s for cancers of the greatest public health significance and for those of interest for some other reason. Finally, **RSR**'s are presented for 1950-1959, 1974-1976, 1979-1981 and 1989-1991, for all cancer and the 20 cancers of major interest. The data come from the SEER program<sup>3</sup> and its predecessor, the End Results Group.<sup>11</sup>

## ALL CANCER

(This category includes all malignant neoplasms except non-melanoma cancers of the skin. It is not limited to the 20 cancer groups that follow.) Variation in the causes and the descriptive patterns of malignancies make statistics for "all cancer" difficult to interpret. Moreover, lung cancer accounts for about 15% of all cancer cases and 30% of deaths. As a result descriptive patterns for "all cancer" reflect those of lung cancer. Yet, an overview of the malignancies as a whole gives perspective to national issues such as time trends, improvements in survivorship, the value of cancer screening, etc. Further, the public has an abiding interest in "cancer" as a group.

Table 14.2-1 shows that the *I* of all cancers combined in the USA population in 1996 was 389 cases per 100,000 py. Table 14.2-2 shows that the rate was 455 for males and 342 for females, an age-adjusted incidence sex ratio of 1.3. The Black:White (B/W) incidence ratio of 1.1 indicates that for all cancer combined, Blacks have a slightly higher incidence rate than do Whites. Useful explanations of B/W ratios different from 1.0 are specific to each form of cancer and are beyond our scope.

Cancer Site	Site of Cancer	Incidence				Mortality			
		Number	Rate	Rate	Rate	Number	Rate	Rate	Rate
00	All cancer	1,040,000	389	455	342	167	207	139	167

TABLE 14.2-2. Incidence and Mortality Data for Major Forms of Cancer by Gender. USA, Total Population 1996

The *M* of all cancer for the total population in 1996 was 167 deaths per 100,000 py, 207 for males and 139 for females. The age-adjusted mortality sex ratio is 1.5, slightly higher than the corresponding ratio of 1.3 for incidence. This discrepancy does not indicate that females survive cancer better than do males since males experience relatively more cases of the more fatal malignancies (lung, stomach, liver, esophagus). Actually, women do survive most cancers better than do men. But

this is best inferred from a comparison of the sex-specific **RSR-5's** of each form of cancer.

The B/W mortality ratio for all cancer is 1.3, larger than the 1.1 incidence ratio. The discrepancy between the incidence and the mortality ratio may reflect the fact that Blacks have less access to, and use, medical care less than do Whites.

Figure 14.2-1 shows age patterns of **I's** and **M's** for all cancer for males and females, respectively, averaged for 1992-1996. These five years were combined because age-specific **I's** are not available for any individual recent year. The pattern of **I's** shows an upward inflection during the late 40's for men. The rates start to rise earlier and increase more gradually for women. The earlier rise of **I's** among women reflects the early onset of breast cancer and cervix cancer. For both genders, **I's** then increase nearly linearly to about age 75 and peak in the early 80's. The "late-age decline" appearing in these data is common and is usually an artifact due to underdiagnosis of cancer among the elderly and to overestimation of the size of the elderly population. For both genders the pattern of mortality lags that of incidence by about 10 years and there is no late age decline seen for either gender.

FIGURE 14.2-1. Incidence rates and mortality rates for all cancer and for seven selected cancers. According to age.

Age-specific cancer **I's** were used to estimate the risk of developing cancer over a lifetime and over several age spans of interest. For a newborn in 1996, the overall cancer **I** of 389 equates to a 45% risk of developing cancer through age 85. For persons aged 45 in 1996 the risk of developing cancer in the remaining lifetime is 44% while for persons aged 65 it is 35%. These risk projections pertain only to persons who develop cancer or live to age 85. More realistic, actuarial, estimates of these risks are corrected for mortality from all causes and are about 15% lower, that is the 45% figure becomes 38%, etc. More important, cancer **I's** are declining over time and the risks to be experienced in the future are likely to be lower, perhaps much lower, than even the actuarial projections.

Figure 14.2-2 shows time trends, from 1973 through 1996, of age-adjusted **I's** and **M's** for all cancer for males, females and for the genders combined. For men **I's** rose gradually until 1987 and then sharply for several years before declining. The sharp rise reflects increases in prostate cancer. **I's** for women increased to 1991 and now are declining. For both genders, **M's** rose very gradually to 1990 or 1991 and now are declining. Reports in the literature suggest that the overall cancer **M** peaked in the USA in 1990<sup>12</sup> or in 1991.<sup>13</sup> The distinction reflects different standard populations used for age-adjustment and is of no practical significance.

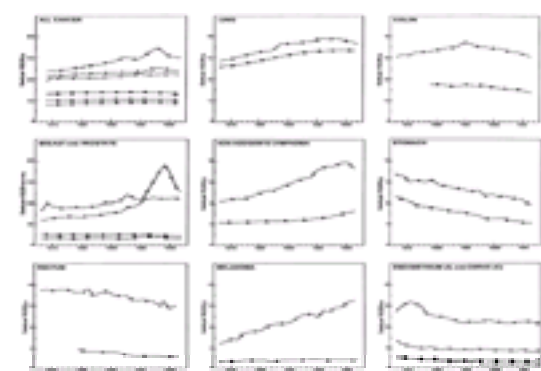

FIGURE 14.2-2. Incidence rates and mortality rates for all cancer and for ten selected cancers. According to time. See Figure 14.2-1 for key.

Finally, discussions of *All Cancer* often reinforce a view that, "cancer is a disease of old people". In two important ways, it is not. First, the leukemias and tumors of the central nervous system (CNS) remain major threats to children. Young adults experience considerable illness due to Hodgkin's disease and testis cancer as well as death from leukemia, non-Hodgkin's lymphoma and CNS tumors. Second, the frequency of each major cause of death rises sharply with age. Among persons who die from the major diseases, cancer decedents have a **below** average age at death. In 1996 the average age of all decedents in the USA was 72.0 years, but it was 70.7 years for those who died of cancer. Among deaths occurring after age 45, the average age of all decedents is 78.1 years but it is 72.5 for cancer decedents. Table 14.2-3 shows for each age group the percentage of deaths within it that are certified as due to cancer. In 1996 the proportional mortality for cancer peaked at 37% for ages 55-64. Further, the average cancer decedent lived with his or her disease for more than eight years. Thus, while cancer's highest proportional mortality is at about age 60 it afflicts many persons during their mid-50's. The below average age at death of cancer decedents and the peak of cancer's proportional mortality in middle age are readily explained. The other major chronic diseases, especially cardiovascular diseases, also exact a considerable mortality in middle age but, thereafter, their mortality rates rise more sharply than do those of cancer.

Age	Cancer Proportional Mortality (%)
0-4	2
5-14	12
15-24	5
25-34	10
35-44	18
45-54	31
55-64	37
65-74	34
75-84	23
85+	12
All ages	23

TABLE 14.2-3. The Proportion of All Deaths Within Each Age Group Attributed To Cancer. USA Total Population, 1996.

Although cancer decedents die relatively young, that age at death will increase gradually because the population's average age is increasing. Also, many recent advances in cancer treatment, while effective are not necessarily curative. Such treatments postpone death and thereby raise the age of cancer decedents.<sup>5</sup>

### CANCER OF THE LUNG AND BRONCHUS

(This category includes cancers of the trachea, lung and bronchus and of the pleura. Less than one percent of cases or deaths in this category are cancers of the

pleura.) Lung cancer had an overall *I* of 54 cases per 100,000 py in 1996, 70 for males and 42 for females. The corresponding *M*'s were 49, 68 and 34. Whether based on *I*'s or *M*'s the condition is a predominantly male disease with sex ratios of 1.7 and 2.0, respectively. However, the sex ratios are declining. For incidence this is occurring because the male rate is declining while that for females is stable. The declining mortality sex ratio reflects the ongoing steep drop in male *M*'s.

The age pattern of *I*'s and *M*'s for lung cancer for males and for females is shown in [Figure 14.2-1](#). For both genders, *I*'s and *M*'s start to rise at about age 40 and then increase to a peak at about age 75. All four curves then show the late age decline which, for this disease occurs because persons, especially women, born before 1930, did not smoke in large numbers.

[Figure 14.2-2](#) describes lung cancer *I*'s and *M*'s for 1973-1996. Both measures increased until 1991-1992 (incidence) or 1990-1994 (mortality). Both rates were level briefly and now are declining. The incidence rate curve declines more steeply than the mortality curve. *I*'s usually change earlier and more abruptly than do *M*'s, as the *M* in any year reflects *I*'s of many prior years. The overall *I* curve for lung cancer should continue to decline even more steeply when *I*'s among women begin to decline. In fact, a leveling began in 1991 and a slight decline occurred in lung cancer *I*'s for women in 1995 and 1996.

Cancer of the lung was for decades the most commonly diagnosed form of cancer in the USA. However, in 1984 the *I* of prostate cancer began to surge and by 1989 or 1990 more prostate cancers were diagnosed than lung cancers in men and women combined. Yet, lung cancer remains the principle cause of cancer deaths. In fact, lung cancer causes nearly as many deaths as do the next four cancers (colon, breast, prostate and pancreas) combined. The singular importance of lung cancer as a cause of death, combined with its strong association with smoking, continue to offer the greatest opportunity for cancer prevention.

Statistics for larynx cancer are not presented because as the cause of 3918 deaths in 1996, it ranks twenty-first among the malignancies. However, larynx cancer is associated with smoking just as strongly as is lung cancer and so is amenable to prevention on that basis.

## CANCER OF THE COLON

(This entity is restricted to cancer of the colon.) It is customary to consider cancers of the colon and rectum together but this is not appropriate from an epidemiologic view. The two diseases eventually may be found to have part of their etiologies in common but they differ in their sex ratios, time trends and survivorship.

Colon cancer ranks fourth in incidence after cancers of the lung, breast and prostate gland with an *I* of 30 cases per 100,000 py, 35 for males and 27 for females. The incidence sex ratio of 1.3 is typical for all cancer. However, in terms of mortality, colon cancer ranks second. The overall *M* of 14.4 deaths per 100,000 py is similar for men and women. The mortality sex ratio of 1.0 is lowest among the major malignancies.

Age patterns for colon cancer are shown in [Figure 14.2-1](#). Both for males and for females *I*'s start to increase at about age 40 and rise sharply to peaks at the oldest ages. *M*'s lag *I*'s by about 10 years and at first rise more gradually than do *I*'s but then accelerate upward. Colon cancer's time trends appear in [Figure 14.2-2](#). *I*'s peaked at about 38 cases per 100,000 py in 1987 and then began declining. Mortality has declined since at least 1979, the first year for which data specific to the colon are available.

## CANCER OF THE BREAST

(This entity is restricted to cancer of the breast in females.) The *I* of breast cancer was 111 cases per 100,000 woman-years (wy) in 1996 making it by far the most frequently diagnosed cancer in women. However, with an *M* of 24 deaths per 100,000 wy, breast cancer kills about 30% fewer women than does lung cancer.

The age patterns of *I*'s and *M*'s for breast cancer for the 1992-1996 interval are given in [Figure 14.2-1](#). *I*'s start to rise in the late 20's and increase more-or-less steadily to about 500 cases per 100,000 wy at age 70. *M*'s rise more gradually with a peak at ages over 85. In data from many Western countries the age pattern shows a notch, with *I*'s declining at ages 45 to 54 before resuming their increase. That pattern does not occur in these data for unknown reasons. The typical bimodal age-incidence pattern of breast cancer, with a trough at age 50, has been offered as evidence that breast cancer is two etiologic entities. In this view, the premenopausal disease is related primarily to reproductive factors and the postmenopausal to body form and menopausal changes.

[Figure 14.2-2](#) shows breast cancer's time trends. The *I* of breast cancer long was stable but began to rise in the early 1980's. The *I* peaked in 1987 at 113 and was stable through 1996 at about that level. It is unclear whether the 1980's rise in breast cancer was due to the ever-greater use of breast cancer screening or to an actual increase in the causes of the disease. An increase in *I* due to screening should be transitory, eventually declining to pre-screening levels even if screening continues. In such a situation the stage distribution of cases detected in the screening era should be favorable relative to that of cases diagnosed in the previous era. It remains to be seen whether the *I* of breast cancer will decline but earlier diagnosis is occurring: in 1965-1969 47% of cases were "local" when diagnosed but in 1989-1995 the figure was 62%.

Breast cancer's *M* shows a time trend different from that of its *I*. *M* was stable from the 1930's, or even earlier, through about 1990. It is now declining at about 3% per year. This steep decline probably is due both to earlier diagnosis and to improved treatment.

## CANCER OF THE PROSTATE GLAND

With an *I* of 136 per 100,000 man-years (my) this cancer is by far the most frequently diagnosed malignancy among men in the USA. With an *M* of 24, it ranks second among men in mortality. [Figure 14.2-1](#) shows the *I*'s and *M*'s of prostate cancer by age. The curves are remarkable for their steepness, with rates increasing almost three-fold with every 10-year age increase.

[Figure 14.2-2](#) shows the time trend in the *I* and *M* of prostate cancer for 1973-1996. A gradual increase in *I* was evident until about 1986 when a sharp increase began. *I* peaked in 1992 and then declined, precipitously at first but then more gradually in recent years. The unique upward spike in *I* reflected the widespread adoption of the prostate-specific-antigen (PSA) test to screen for the disease.<sup>14</sup> The decline in *I* since 1992 may reflect decreased PSA testing or, because of the widespread screening, a reduction in the number of men with preclinical disease. The *M*'s in the Figure show a plateau, at about 26 deaths per 100,000 my from 1990 to 1993 and then a very slow decline. The decline in mortality may result from the more effective treatment of cases diagnosed early by PSA screening, from actual improvements in treatment *per se* or, possibly, from a gradual reduction in the unidentified causes of the disease. Whatever the full explanation of the mortality decline may be, there is evidence of major treatment advances. This is addressed below in the discussion of the *RSR-5*. Beyond this we can indicate only that the causes of prostate cancer are unknown and, while it seems reasonable that screening would lower *M*, it is uncertain that it has done so.

## CANCER OF THE PANCREAS

The descriptive epidemiology of this disease presents a uniformly unfavorable, seemingly unchanging pattern. Pancreas cancer has an *I* of 8.6 per 100,000 py, 10.0 for males and 7.4 for females, an incidence sex ratio of 1.4. The overall *M* is 8.3 deaths per 100,000 py, 9.6 for men and 7.2 for women, a mortality sex ratio of 1.3, similar to that of incidence. Pancreas cancer is the most highly fatal of all the malignancies.

Both among men and women, *I*'s and *M*'s of pancreas cancer begin to rise in the late 40's and reach a peak of about 110 cases or deaths per 100,000 py among men and of about 90 among women in the oldest age group. For both genders, the two curves, *I*'s and *M*'s, are virtually identical, so highly fatal a disease is this.

The *I*'s and *M*'s of pancreas cancer have varied little over time. Perhaps this is changing, however. From 1973 to 1992 the *I* of pancreas cancer declined in no consistent pattern by about seven percent from 10 cases per 100,000 py to 9.3. Over the next four years it dropped another eight percent. Mortality data are less encouraging. Despite the declining *I*'s, *M*'s were essentially unchanged from 1973 to 1996.

## NON-HODGKIN'S LYMPHOMA

The *I* and *M* of this condition, or group of conditions, are higher than is generally recognized even by physicians. This disease is the sixth-ranked cause of death among the malignancies. The overall *I* is 15.5 per 100,000 py, 19.2 in men and 12.2 in women, an incidence sex ratio of 1.6. The overall *M* is 6.9 per 100,000 py, 8.6 in men and 5.6 in women, a similar mortality sex ratio of 1.5.

NHL shows increased *I*'s as early as the mid-20's. *I*'s increase sharply after about age 50 and *M*'s after about age 60 in men. For women the upward inflections occur at ages 60 and 70. [Figure 14.2-2](#) shows the time trends in *I*'s and *M*'s. *I*'s now are rising sharply, increasing by 80%, from 8.6 cases per 100,000 py to 15.5 from 1973 to 1996. It has been suggested that some of this increase is an artifact due to changes in diagnostic classifications, which are bringing new entities into the lymphoma family.<sup>15</sup> However, such changes are unlikely to explain more than one-fourth of the increase seen. *M*'s also are increasing but more slowly and may now be stabilizing. The increase from 1973 (4.7 deaths per 100,000 py) to 1994 (6.9 deaths) was 47%. However, there was no further increase in 1995 or 1996.

## LEUKEMIA

(Leukemia here refers collectively to the four major forms of the disease, acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL) and chronic myelogenous leukemia (CML)). This discussion does not specifically address leukemia in children. Ninety percent of all leukemia cases occur after age 20. The statistics presented are inclusive of all ages but the observations pertain to leukemia in adults.

The leukemias are a category of diseases combined under one label both by historical precedent and by practical considerations of contemporary diagnosis and treatment. Nonetheless, while the leukemias eventually may be found to share some etiologic factors, this has been shown only for ionizing radiation and CLL is exempt even from that.

The *I* of leukemia was 9.7 cases per 100,000 py, 12.3 in males and 7.7 in females, an incidence sex ratio of 1.6. *M*'s were 6.3 deaths per 100,000 py overall and 8.2 and 4.8 for males and females, giving a nearly identical mortality sex ratio of 1.7.

The *I* of leukemia is relatively high at 6.8 cases per 100,000 under age 5. It is then steady at about 2 to 5 until about age 40 when it begins to rise at a constant rate. The *I* of leukemia reaches a peak of 120 cases per 100,000 in men and 71 in women at ages 85 and over.

Leukemia *M*'s are no longer particularly high in childhood; they remain under 1.3 deaths per 100,000 py through age 20 and then begin a steady increase to ages 85 and over.

Age-adjusted *I*'s of leukemia were essentially unchanged at about 10.5 cases per 100,000 py from 1973 to 1995. In 1996 the *I* was 9.7, perhaps signaling the start of a decline. *M*'s have declined from 6.7 deaths per 100,000 in 1973 to 6.3 at present. This 6% decline is identical for males and females and largely reflects treatment advances for the leukemias of childhood.

## CANCER OF THE STOMACH

Although cancer of the stomach long has been declining, it remains the eighth-ranked cause of cancer death. The overall *I* is 6.6 per 100,000 py, 9.8 in men and 4.2 in women, a rather high incidence sex ratio of 2.3. The overall *M* is 4.0, with rates of 5.7 in men and 2.7 in women giving a sex ratio of 2.1.

*I*'s of stomach cancer start to rise at about age 40. They rise progressively to age 85 and over, reaching a maximum of 119 cases per 100,000 py in men and 58 in women. The age pattern of *M*'s closely follows that of *I*'s but is one-third lower.

The *I* of stomach cancer has declined one to two percent per year for as long as data have been available, that is, since the mid-1930's. Mortality data suggest that the disease has been declining, at the same rate, since 1900. Stomach cancer was by far the most common cause of cancer death in men until surpassed by colorectal cancer in the late-1940's. It was also the most common cause of cancer death in women until about 1937 when it declined to fourth place. The "intestinal" type of stomach cancer declined two to three times faster than did the "diffuse" type of disease.<sup>16,17</sup> During the last 25 years or so, the long-term declines in stomach cancer have continued unchanged ([Figure 14.2-2](#)). *I* was 10.2 cases per 100,000 py in 1973 and declined about 1.5% per year to the 1996 level of 6.6, an overall reduction of 35%. The decline was identical in both sexes. *M*'s have declined more, the reduction being 43% from 7.0 deaths per 100,000 py in 1973 to 4.0 in 1996. It was the same in both sexes.

The reason for the declining *I* of the intestinal type of stomach cancer is unknown. However, the decline extends over 90 years indicating that one or more causes of the disease started downward before 1900. The similarity of the decline in both sexes is remarkable and suggests that the declining cause is closely tied to domestic life or to residential, not occupational, settings. The favored hypothesis relates to the introduction of refrigeration and chemical food additives, several of which have anti-oxidant properties.<sup>18</sup> These twentieth-century methods of food preservation gradually displaced older methods such as the smoking, salting and pickling of foods. This hypothesis is supported by the fact that stomach cancer is strongly, and inversely, associated with economic status as the well-to-do adopted the newer methods first. Some other unidentified aspect of improving living standards also may have played a role in the decline of this disease. For example, *Helicobacter pylori*, a bacillus that colonizes the stomach of about 45% of Americans, was recognized as a cause of stomach cancer in 1994.<sup>19</sup> The prevalence of *H.pylori* infection also is strongly and inversely related to economic well being.

## CANCER OF THE OVARY

The *I* of cancer of the ovary is 14.1 cases per 100,000 py while the *M* is 7.4. The *I* has been stable for 40 years. An apparent rise in *I* from 1945 to 1960 probably resulted from improving ability to diagnose the condition. Despite the constancy of the *I*'s, *M*'s have declined recently from 8.4 in 1973 to 7.4 in 1996, about 0.3% per year.

The age pattern of cancer of the ovary is exceptional in that *I*'s start to increase in the late teens. Both *I* and *M* increase slowly until about age 40 or 45 and then rise sharply to peaks at about age 80.

## CANCER OF THE NERVOUS SYSTEM

(This entity includes cancers of the brain, spinal cord, other central nervous system and the peripheral nervous system. However, 97% of deaths due to malignancies in this group are from tumors of the brain. We refer to this group as "CNS" cancer.) In 1996 CNS cancer had an overall *I* of 5.8 per 100,000 py in the USA, 7.2 in males and 4.5 in females. The corresponding *M*'s are 4.2 and 5.0 and 3.4 for men and women respectively. With age-adjusted sex ratios of 1.6 for incidence and 1.5 for mortality this disease has a typical male predilection.

The age patterns for CNS cancer are shown in [Figure 14.2-1](#). They are unusual in the long, gradual rise that extends from about age 20 to age 60 followed by a leveling, and then sharp declines. The leveling and decline in the statistics may result from a progressively greater underdiagnosis of cases and undercertification of deaths due to CNS cancer with increasing age. This would occur because of confusion of the cancer's symptoms with those of the much more common condition, stroke.<sup>20</sup>

The *I*'s of CNS cancer long have been increasing. The rise during the middle of the century was probably due to improving diagnosis. More recently, *I*'s rose from 5.0 cases per 100,000 py in 1973 to a peak of about 6.4 in 1987-1989. There has since been a gradual reduction to the current *I* of 5.8. The pattern of *M*'s closely follows that of *I*'s with a short lag. *M*'s rose from 3.7 deaths per 100,000 py in 1973 to a peak of 4.3 in 1990. *M* is now stable at about 4.1 deaths per 100,000 py.

## LIVER AND BILIARY TRACT

(This entity includes all primary cancers of the liver, bile ducts and gall bladder. We refer to it as liver cancer.) Liver cancer had an *I* of 4.2 cases per 100,000 py in 1996, 6.4 for men and 2.4 for women, a high incidence sex ratio of 2.7. For mortality the corresponding figures are 3.6 deaths per 100,000 py overall, 5.3 and 2.3 for men and women, a mortality sex ratio of 2.3.

Age patterns of liver cancer both among men and women are unremarkable. *I*'s start to rise by the mid-30's among men and by the mid-40's among women and peak at about age 80. *M*'s are virtually identical to *I*'s in every respect.

Since 1973 *I*'s for liver cancer have been increasing steadily from 2.3 cases per 100,000 py to the 1996 figure of 4.2. This 80% increase in just 23 years is worrisome

but has attracted little attention. This is strange, since **M's** show a similar pattern, a 50% increase from 2.4 deaths per 100,000 py in 1973 to 3.6 in 1996. Moreover, the increases are occurring both among men and women.

Liver cancer is caused by the carrier state of the hepatitis-B and -C virus and these agents are the overwhelming cause of the disease in much of the developing world. Together, they probably account for about 50% of the disease in the USA.<sup>21</sup> In the USA there is also a clear association between abuse of alcoholic beverages and liver cancer.

## URINARY BLADDER

(This entity includes cancer of the urinary bladder and "other urinary organs", essentially the ureter and urethra. Cancers of the kidney and renal pelvis are in a separate category. Ninety-seven percent of cancers in this group are bladder cancers and we refer to the disease that way.) Bladder cancer is the number 12-ranked cancer killer, responsible for 11,452 deaths in the USA in 1996. The overall **I** is 16.2 cases per 100,000 py. With **I's** of 27.7 for men and 7.4 for women, the incidence sex ratio is a striking 3.7. This reflects men's higher prevalence of smoking and greater exposure to occupational carcinogens. The overall **M** is 3.2 deaths per 100,000 py. With **M's** of 5.5 and 1.7 for men and women, respectively, the sex ratio is also a remarkably high 3.2.

Bladder cancer **I's** begin rising at about age 40 in men and 45 in women. A peak of 297 cases per 100,000 py is reached in men at ages 85 and over. A much lower peak of 75 appears at the same age in women. **M's** lag **I's** by about 10 years and peak at 139 and 42 deaths per 100,000 py for men and women, respectively.

**I's** for bladder cancer rose from 14.6 cases per 100,000 py in 1973 to a peak of 17.5 in 1987. A slow decline is now occurring with a rate of 16.2 in 1996. **M's** for bladder cancer declined 25%, about 1% per year, from 4.2 deaths per 100,000 py in 1973 to 3.2 in 1996. The decline has been slightly greater for men than for women.

## CANCER OF THE ESOPHAGUS

This disease has an overall **I** of 4.0 per 100,000 py but for men the **I** is 6.8 while for women it is 1.7. The corresponding **M's** are 3.6 overall and 6.3 and 1.5 for men and women respectively. With age-adjusted sex ratios of 4.0 for incidence and 4.2 for mortality, this disease is the most strongly male-associated malignancy.

**I's** start to rise at about age 35 in men and 45 in women. There is then a sharp rise to an **I** of 41 cases per 100,000 py in men, 15 in women, at ages over 80. **M's** are virtually identical to **I's**. The **I** of esophagus cancer increased gradually from 3.4 cases per 100,000 py in 1973 to 4.0 in 1996. However, there was almost no change in **I's** among women while rates among men increased about one percent per year from 5.5 in 1973 to 6.8 in 1996. The patterns of **M's** are virtually the same.

Cancer of the esophagus results from smoking, alcoholic beverage abuse and the combination of the two. Poor nutrition, particularly micronutrient deficiency may also be involved in causing this disease, especially in regions of the world where rates are very high.<sup>22</sup> If there is some good news in this it is that the now ongoing long term decline in smoking should bring reductions in **I's** of esophagus cancer in developed countries both directly and also by reducing the impact of alcohol abuse. In developing countries the correction of micronutrient deficiencies, which is relatively practical, may produce reductions in the disease.

## CANCER OF THE KIDNEY AND RENAL PELVIS

(This group includes cancers of the kidney and of the renal pelvis, an unfortunate combination with a historical basis. Kidney cancer nearly always is a renal cell adenocarcinoma while renal pelvis cancer is a tumor of transitional or squamous cells. The renal pelvis is better seen as an extension of the bladder than of the kidney and both the histology and epidemiology of its cancer reflect that. Ninety-eight percent of tumors in this group are kidney cancers and we will refer to it as such.) The **I** of kidney cancer is 9.4 cases per 100,000 py, 12.9 among men and 6.5 among women. The corresponding **M's** are 3.5, 5.1 and 2.3. The respective sex ratios are relatively high at 2.0 and 2.2.

Both for men and women the age patterns of cancer of the kidney are unremarkable. **I's** start to increase in the 30's and peak at about age 80. **M's** show a similar pattern but lag **I's** by 5 to 10 years. The **I** of kidney cancer has undergone a 40% increase from 6.7 cases per 100,000 py in 1973 to 9.4 in 1996, nearly 1.7% per year. The increase is somewhat higher for women (48%) than for men (38%). The time trend in **M's** is similar but less striking. For both genders there was about a 20% increase from 2.9 deaths per 100,000 py in 1973 to 3.5 in 1996.

Kidney cancer and renal pelvis cancer are clearly though not strongly associated with smoking. This may explain why **I's** have been rising more sharply among women than among men. The fact that **I's** of kidney cancer reached a peak among men of 13.3 cases per 100,000 py in 1994 and may now be declining also supports the idea that long-term smoking patterns influence the disease's descriptive statistics. That is, the gender-specific time trends of **I's** for kidney cancer may duplicate, later in time and at a lower level, those of lung cancer.

## MULTIPLE MYELOMA

The **I** of multiple myeloma was 4.2 cases per 100,000 py in 1996, 5.3 in men and 3.4 in women, an incidence sex ratio of 1.6. The corresponding **M's** were 3.1 deaths per 100,000 py, 3.8 for men and 2.6 for women, a mortality sex ratio of 1.5.

The age patterns, both of **I's** and **M's** for multiple myeloma are unexceptional. **I's** begin to rise in the early 40's and increase to a peak in the late 70's. **M's** lag **I's** by about 5 years and both **I's** and **M's** rise more sharply among men than among women.

**I's** of multiple myeloma have changed on a long term basis moving from 3.8 cases per 100,000 py in 1973 to a peak of 4.8 in 1987. There has been some decline since 1987 but the current **I** remains at 4.2. In contrast, **M's** have been increasing steadily. Both for men and for women the increase was about 35% from 1973 to 1996.

## CANCER OF THE RECTUM

(This condition includes cancers of the rectum, rectosigmoid junction and anal canal.) Cancer of the rectum had an **I** of 12.5 cases per 100,000 py in 1996, 16.1 for men and 9.6 for women, an incidence sex ratio of 1.7. In the same year, **M's** were 2.4 deaths per 100,000 py overall, 2.6 for men and 2.2 for women, a lower mortality sex ratio of 1.2. These statistics are quite different from those of colon cancer which has lower sex ratios of 1.3 and 1.0.

Both for men and women **I's** rise in the 30's and rise sharply after age 45 to peaks at ages 75-79. For both genders, **M's** lag **I's** considerably and peak at 44 deaths per 100,000 py among men and at 34 among women. The time trend for rectum cancer is shown in [Figure 14.2-2](#). The **I** of cancer of the rectum peaked at 15.2 cases per 100,000 py in 1981 and then declined slowly to 12.5 in 1996, a reduction of 18% in 15 years. This pattern was similar for males and females. **M's** have shown a similar pattern.

## CANCER OF THE ORAL CAVITY AND PHARYNX

(This entity includes cancers of the entire oral cavity and of the pharynx. We refer to it as OCC, oral cavity cancer.) In 1996 the **I** of OCC was 10.0 cases per 100,000 py, 14.8 for males and 5.9 for females. The corresponding **M's** were 2.6, 3.9 and 1.4. The respective sex ratios were 2.5 and 2.8.

**I's** of OCC rise sharply among men from about 2 cases per 100,000 py at age 30 to a near peak of 65 at ages 60-64 and then rise slowly to a peak of 77 at ages 80-84. The pattern for women is similar although more gradual with a peak **I** of 34 at ages 85 and over. For each gender the age pattern of mortality closely follows that of incidence but **M's** typically are only about one-fourth of the corresponding **I's**. **I's** of OCC declined over the period 1973-1996, about 15% for men and 10% for women. **M's** declined much more, about 30% both for men and women.

OCC shares much of its etiology with cancer of the esophagus, the lower sex ratio notwithstanding. It is not known whether the considerable decline in **M's** of OCC is due to increased screening for the disease, especially by dentists, or to treatment advances. However, stage-specific increases in survival have been relatively small,

suggesting major benefits from earlier detection.

## MALIGNANT MELANOMA OF THE SKIN

In 1996 melanoma had an *I* of 13.8 cases per 100,000 py, 17.0 for men and 11.4 for women, an incidence sex ratio of 1.5. For mortality, the corresponding rates were 2.3 deaths per 100,000 py, 3.2 and 1.5 for men and women, a mortality sex ratio of 2.1, much higher than that of incidence. The relatively poor survival of males occurs because a high proportion of their lesions are on the trunk and carry a poorer prognosis than do those on the extremities. <sup>23</sup>

*I*'s of malignant melanoma begin to rise early in life, at about age 15 in both genders. There is a steep increase among men to a plateau of about 45 cases per 100,000 py at ages 70 and over. Among women the increase is more gradual to a lower plateau of about 30 cases per 100,000 py at ages 70 and over. For both genders, *M*'s lag *I*'s considerably in age and reach peaks of 27 and 12 deaths per 100,000 py among men and women, respectively, at ages 85 and over. The *I*'s of melanoma have increased greatly, particularly over the last 25 years. This is shown in [Figure 14.2-2](#). The increase from 1973 to 1996 was 140% overall, 178% and 110% for men and women respectively. However, *M*'s have increased much less, 44% among men and only 15% among women. The increase in *I*'s is due in part to an increased awareness of the disease and efforts to find it by physical examination of the skin. Part of the increase is also real and possibly due to increases in leisure time and sun exposure.

## CANCER OF THE ENDOMETRIUM

(This entity includes cancer of the endometrium and cancer "of the uterus, not otherwise specified". At least 78% of cancers of the uterus, not otherwise specified, are cancers of the endometrium<sup>24</sup> and we refer to the entity that way.)

As shown in [Figure 14.2-1](#) *I*'s of endometrial cancer begin to rise at about age 30 and increase sharply to about 84 cases per 100,000 wy at age 64. They then increase more gradually to a peak of 109 at ages 75-79 and then decline slowly. *M*'s start to increase at age 45 and rise gradually to a peak of 36 deaths per 100,000 wy at ages 85 and over. The *I* of cancer of the endometrium is 21.1 cases per 100,000 while the *M* is 3.3.

As shown in [Figure 14.2-2](#) the *I* of endometrial cancer peaked at 32 cases per 100,000 wy in 1975. This reflected the gradually increasing use of estrogens, particularly conjugated equine estrogens, to manage symptoms of menopause. When that causal relation was recognized, <sup>25</sup> and this use of estrogens diminished, the *I* began to drop sharply reaching 21 in 1986 and changing little since. *M*'s for this condition declined from 4.6 deaths per 100,000 wy in 1973 to 3.4 in 1989 and are now stable.

## CANCER OF THE UTERINE CERVIX

This disease has an *I* of 7.7 cases per 100,000 wy and an *M* of 2.7 deaths per 100,000 wy. The exceptional age pattern of *I*'s for cervix cancer is shown in [Figure 14.2-1](#). The disease occurs among the young and *I*'s rise sharply to age 35 and are then more-or-less steady for the remainder of the life span. This pattern strongly suggests that the rate of exposure to the causal agent is constant after about age 30 or that the agent's carcinogenic potency is reduced after that age. The age pattern of *M*'s is unexceptional. The continued rise, long after *I*'s have stabilized does, however, indicate that death can occur long after diagnosis.

*I*'s of cervical cancer have declined since at least the 1940's. And, as shown in [Figure 14.2-2](#), the recent decline was from 14.2 in 1973 to 7.9 in 1996, about 2% per year. *M*'s are also in a long-term downtrend from 5.2 deaths per 100,000 wy in 1973 to 2.8 in 1996, also 2% per year. Some of the decline, both in *I* and *M*, reflects the gradually increasing proportion of women in the population who have had a hysterectomy. Also, this disease is strongly and inversely related to economic well-being and so some general aspect of improving standards of living may play a protective role.

Screening for cervical cancer with the pap smear probably is responsible for some of the decline in *I*'s and *M*'s. However, the relationship is not straightforward. The use of the pap smear increased greatly during the 1960's, 1970's and 1980's and, while this test is intended to detect dysplasia and *in situ* carcinoma, it also detects invasive disease. Thus, the early effect of the gradually increasing use of the pap smear should have been to **increase** the apparent *I*. Eventually, the identification of large numbers of *in situ* cases presumably would lower the *I* of invasive cases and *M*. Nonetheless, *I*'s and *M*'s of cervical cancer were declining long before pap smear programs could have had any major effect. This is not to deny the value of these programs, especially among high-risk women. Whatever may be the full explanation for the long-term declines of cervical cancer it seems likely that causes of the disease have been diminishing since at least the 1930's.

## RELATIVE SURVIVAL RATES

[Table 14.2-4](#) shows **RSR-5's** for all cancer and for the 20 major forms of cancer. The diagnosis intervals presented are 1950-1959, 1974-1976, 1979-1981 and 1989-1991; hereafter, 1955, 1975, 1980 and 1990. For most of these cancers, information is available for three stages of the disease: local, regional and all. These categories allow reasonably valid comparisons of survival statistics from as long ago as 1975. The 1955 data are of good quality but are not fully comparable with the subsequent data. They are provided for interest but are not discussed.

**TABLE 14.2-4.** Five-Year Relative Survival Rate, as Percent, for All Cancer and for Twenty Major Forms of Cancer, by Stage, According to Time Period of Diagnosis

For all cancer, no improvement is seen in survival for any stage from 1975 to 1980, possibly because of the short interval between the two periods. Substantial gains occurred in each of the three stage groups from 1980 to 1990, a 15% increase (from 78% to 90%) for local disease and 25% for regional. The 16% improvement, from an **RSR-5** of 50% to 58% for all stages of all cancer is remarkable. It suggests a reduction in deaths of about 1.5% per year and conveys the **magnitude** of the gain that occurred during this 10 to 15 year period.

The data for all 20 forms of cancer allow 104 stage-specific comparisons to be made from one time period to another, e.g., for colon cancer, regional, from 1975 to 1980. Of these 104 comparisons, 82 (79%) show an increase in the **RSR-5**, 10 show a decline and 12 were unchanged. This indicates the **breadth** of the gains that have occurred. This breadth makes it unlikely that the gains over the last 20 years in the all cancer **RSR-5's** would be explained by any gradual increase in the proportion of cancers that are inherently more benign.

In 1986 Bailar and Smith<sup>26</sup> indicated that cancer *M*'s were still increasing and that gains in **RSR-5's** probably reflected earlier diagnosis or a "lead time" bias, not a true increase in cures or delay of death. The statement regarding mortality rates was accurate but, if lung cancer had been excluded, *M*'s for all other cancers combined would have been seen to be declining as early as the mid 1950's. <sup>27</sup> It is more difficult to exclude lead time as the explanation of the small gains in **RSR-5's** through 1980 or even of the larger gains thereafter. However, data for breast cancer and prostate cancer may be useful for addressing this. From 1975 to 1990 these cancers became special targets for earlier diagnosis by screening and public education. Most of the lead time bias from screening, in terms of a seeming lengthening of survival, results from advancing the time of diagnosis of local disease and little results from earlier diagnosis of regional disease. Therefore, we may infer that survival gains for regional disease largely reflect actual treatment effects. Both for breast cancer and, especially for prostate cancer, for 1975 to 1990, large gains are

seen in the **RSR-5's** for regional disease in [Table 14.2-4](#). These gains suggest that there has been real improvement from medical care advances above and beyond any lead time effect. In another approach to this question, Cole and Rodu evaluated survival data for patients diagnosed from 1950-1991 and focussed on particular stages of specific cancers for which lead time gains presumably would be minimal or absent. Even for these conditions they found gains of about 0.5% per year in survival. They suggested that about one-half of the ongoing 1.0% per year decline in the overall cancer **M** that they reported for 1990-1995 was due to real advances in medical care.<sup>12</sup> A gain of 0.5% per year due to improvements in all aspects of medical care may seem disappointing. But we should bear in mind that for gains to occur each advance must favorably alter the course of ever more difficult cases, those that were resistant to prevailing diagnosis and treatment.

## PERSPECTIVES

The descriptive epidemiology of the malignancies during the last quarter of the twentieth century provides five important observations:

First, the **I's** of the four major cancers (lung, colon, breast, prostate), and of all cancer combined are declining.<sup>28</sup> In fact, the **I's** of many forms of cancer, including cancers of the stomach, cervix, endometrium, rectum and oral cavity, were declining during the 1980's or before.

Second, **RSR-5** is increasing for most stages of many forms of cancer. It is unlikely that lead-time bias explains this because the improvements are occurring even for conditions for which diagnostic advances probably have been minimal.<sup>12</sup> Further, practicing oncologists now report seeing survival gains on a regular basis among patients with all stages of disease. These clinical observations can not be dismissed as anecdotal because they are nearly universal and because they are supported by improved survival figures and by declining cancer **M's**.

Third, **M's** are declining for all cancer combined and for most forms of cancer and this has been true since 1991.<sup>12</sup> We must conclude that by 1996, there had been a decline in mortality for many forms of cancer extending over a period of at least 35 years that was due at least in part to advances in medical care.

In 1997, Bailar and Gornick<sup>29</sup> repeated the suggestion that declining **M's** were unlikely to be due to advances in diagnosis and treatment. This was based primarily on the view that the declines were minimal and that **M's** for most cancers were continuing upward. However, the decline in cancer mortality is accelerating downward (from 1996 to 1998 alone, the decline amounted to four percent<sup>8,10</sup>) and most forms of cancer are, in fact, declining.<sup>14</sup>

Fourth, a national pattern of the breadth and depth of the ongoing cancer mortality reductions can neither start nor stop abruptly. The length of cancer induction periods and the likely reduced exposure to carcinogens over the last 25 years make it reasonable to expect **M's** to continue down until at least 2010.

Fifth, we are winning but have not won the war on cancer. Bailar and Gornick<sup>29</sup> are correct in their view that more emphasis should be placed on prevention and prevention-related research. Several of the malignancies, notably non-Hodgkin's lymphoma and malignant melanoma, continue to increase in incidence and others, notably cancer of the esophagus and pancreas, remain resistant to diagnostic and treatment advances. Yet, to achieve the greatest overall reduction in cancer deaths, the target remains clear and unchanging; anti-smoking efforts must be reinvigorated and, most especially, heavy smokers must be provided with alternative ways to quit.<sup>30</sup>

Finally, the largest perspective. During the twentieth century cancer emerged from a minor position and became a major public health problem in the developed world. Over the next 30 to 50 years it will resume a minor position.<sup>31</sup> This waxing and waning occurred for virtually all the great scourges of mankind and it will occur for cancer. The descriptive epidemiology tells us that cancer's decline is now well established.

#### INTRODUCTION

Most known causes of cancer of human beings became suspect because of observations made by physicians and surgeons treating cancer patients. These “alert practitioners” noted unusual characteristics among several patients with the same disease. Investigations by themselves or others then identified a cause of the cancer. An early example is the observation in 1895 by the German urologist, Rehn, that three men with bladder cancer had worked at a particular chemical facility, a dyestuffs manufacturer.<sup>1</sup>

Cancer causation also is studied in experimental settings. Such studies can be complex and difficult to perform but may permit a straightforward judgement of causation to be made. When several investigators reproduce an experimental finding it is usually accepted as demonstrating causation.

Evaluating causality with epidemiologic research is more problematic. Epidemiology is not an experimental science. The epidemiologist observes heterogeneous, free-living human beings and has no control over their exposures or any other aspect of their lives. Further, the observations may be distorted by the retrospective nature of most epidemiologic research. That is, studies are made of exposures and of illnesses or deaths that occurred in the past, often in the distant past. For these reasons and others epidemiologic studies of cancer causation may produce highly variable results. History shows that studies of true and moderately strong causal associations will be reasonably consistently positive. However, a series of studies of a non-existent association will produce positive findings as well as the correct negative ones.

In 1965 Hill advanced guidelines for evaluating causality in epidemiologic studies of diseases with a long induction period.<sup>2</sup> The “Hill criteria”, especially the major ones, the strength, consistency and plausibility/coherence of associations remain useful. A recently-developed set of guidelines<sup>3</sup> are more detailed than Hill's and are specific to the different circumstances in which causality is assessed. Several of these guidelines apply to the results of an individual study while others apply to a general causal hypothesis. Yet others address causality in the exposure-illness experience of a specific person.

#### EVALUATING CARCINOGENICITY

Many considerations underlie the judgement that a suspect agent is or is not a carcinogen for human beings. An important factor is whether the determination is to serve scientific or public health and regulatory purposes. The scientific focus addresses the question, “Is this agent, virtually certainly, a cause of cancer in man?” An affirmative response could be based on strong, consistent evidence from epidemiologic studies or on overwhelming evidence of carcinogenicity in animals and the absence of meaningful negative findings in human beings. In practice, a positive judgement usually rests on both consistent human and animal evidence.

When public health and regulatory purposes are the focus the question will be, “Is the probability that this agent is a human carcinogen sufficiently high that exposure to it should be eliminated or restricted?” The evidence needed for a positive response is less than that needed for the scientific question. The use of a lower standard means that a positive judgement does not imply that the agent is considered a carcinogen but only that society should act *as if* it is.

These different purposes partly explain why available lists of carcinogens are rather different. For example, the National Toxicology Program (NTP) of the USA lists 33 agents as “known to be human carcinogens” and an additional 274 as “reasonably anticipated to be” human carcinogens,<sup>4</sup> the “NTP-A” and “NTP-B” lists, respectively. It is clear that the NTP, in compiling both lists, is addressing the scientific question. At the other extreme, the EPA of California attempts to serve a regulatory purpose. It lists 456 “known” carcinogens, but there is no representation that the agents are known to cause cancer in human beings.<sup>5</sup>

Agencies also produce differing lists of carcinogens because they evaluate different agents or group them differently. For example, while the NTP-A list includes 33 entries the International Agency for Research on Cancer (IARC) has a “Group 1” list of 75 items for which there is “sufficient evidence” of human carcinogenicity.<sup>6</sup> This discrepancy seems surprising, since both agencies have a scientific mission. However, the IARC uses three categories: “agents”, “mixtures” and “exposure circumstances”. The category “agents” includes 25 items and, considering variations in the way agents are grouped, is virtually identical to the NTP-A list. The NTP recently has begun to evaluate “mixtures” and “exposure circumstances”. When we turn from “known” to “suspect” carcinogens, we find that the NTP-B list includes 274 agents while the IARC has a Group 2A (“probably carcinogenic to humans”) and a Group 2B (“possibly carcinogenic”) which include 59 and 227 listings respectively, a total of 286. While the two lists are not directly comparable their similar lengths suggest correctly that their contents are very much alike.

There are important lessons in the 25-year experience of various agencies in classifying carcinogens. First, once suspicion falls on a true human carcinogen it usually soon is recognized as such. In contrast, despite decades of research on them, hundreds of items languish on lists of suspect carcinogens, especially on those of regulatory agencies. For example, the NTP-B list has included at least 274 agents since 1980. Only two of these ever were “promoted” to the NTP-A list, both in 1998. During the same 18-year interval 12 compounds were added directly to the NTP-A list without appearing on the “B” list. Evidently, the probability that a suspect item will come to be recognized as a human carcinogen is small. Second, the identification of “known” causes of human cancer has slowed. During the 1990's, the NTP added only four agents to its “A” list of known carcinogens, including the two from the “B” list. Ten had been added during the 1980's. This slowdown occurred despite ever more intensive searches for causes of cancer. The public health implication of this slowdown is that the extension of declines in cancer *1's* will require more effort against the known causes of cancer. The clinical implication is that improved access to medical care and improved methods for the detection, diagnosis and treatment of cancer will be needed to extend the ongoing increases in patient survival.

#### CAUSES OF CANCER

The causes of the malignancies are as diverse as the causes of disease in general. They include genetic defects, environmental and lifestyle factors, and chemical, physical and biologic agents. We address primarily the known human carcinogens but will mention a few suspect agents in context. Our list of 72 causes, or groups of causes [Table 14.3-1](#) is adapted from the IARC's Group 1 list of 75 agents, mixtures and exposure circumstances for which there was judged to be sufficient evidence of carcinogenicity for human beings. We organized related agents into groups and combined them into five major categories. We added a few lifestyle factors of the type that the IARC does not consider. IARC does not list genetic causes of cancer and this Section does not address them. Finally, we indicate the NTP classification for each agent.

**TABLE 14.3-1.** Known Causes of Cancer of Human Beings and the Major Cancers that They Cause

Many items in the table could be listed in more than one of the five categories. For example, solar radiation is an *environmental* factor but excessive sun exposure could be a *lifestyle* choice. It also poses an *occupational* hazard for outdoor workers, especially farmers. We placed each agent in the category where it seemed that most adverse exposure occurs. For each of the five categories, we estimated the attributable risk percent (**AR%**) for the general population. This is the proportion of cancer cases that would be prevented if the agents in the category were virtually entirely controlled. **AR%**'s were determined from estimates of the proportion of the USA population exposed to each agent in a category and the relative risks of cancer for such persons. We also considered the related efforts of Doll and Peto,<sup>7</sup> Trichopoulos *et al*.<sup>8</sup> and of others. Collectively, a series of **AR%**'s provides an overview of the profile of cancer causation in a large population. But **AR%**'s are highly variable from one population or time period to another.

Table 14.3-1 includes the major malignancies resulting from each of the causes listed. For cancers for which reasonably reliable data are available, we provide an estimate of the relative risk (**RR**). This is the *I* of the cancer among persons with a typical exposure to the listed cause divided by the *I* among non-exposed.

We do not review the evidence relating to these established causal relationships but provide one or two references in support of each. In some instances we referenced the IARC discussion itself. We describe some of the causal relationships that are of greatest public health significance and a few others because of some biologic or epidemiologic feature that they exhibit. Reviews of known and suspected cause-effect relationships are available in two widely-used textbooks of cancer epidemiology.<sup>9,10</sup>

## ENVIRONMENTAL FACTORS

For decades the mass media represented to the American public that the general environment was becoming polluted and that as a result cancer was increasing. Little attention was given to the underlying issue: Are the carcinogens in the environment or our exposure to them increasing?

From an epidemiologist's view the "environment" includes both the general or shared environment and individual behaviors and lifestyles. Only in this inclusive sense of the word is it correct that more than 90% of cancer is due to environmental, that is to all non-genetic, factors. On the other hand, in lay usage, the word "environment" designates only the shared environment, i.e., the air, water, ground and food supplies. We have adopted this usual meaning of the word, but point out that insofar as is known, individual behaviors are much more important causes of cancer than is the general environment.

All aspects of the long-term environmental deterioration in this country differ from place to place. There is no accurate way to summarize what the major contaminants were, when their inappropriate discharge occurred or when there was human exposure to them. Nevertheless, in much of the country the accumulated contamination had become consequential by about 1940. Most solid tumors of adults have an average induction period of about 20 years so it would be expected that cancers caused by environmental contaminants would have started to occur in about the mid-1950's.

Public awareness of the large scale of America's environmental problems began in 1962 with the publication of *Silent Spring*.<sup>11</sup> When Lake Erie and the Cuyahoga River caught fire in 1969 there was a public outrage that led to the environmental regulations and the broad-based cleanup that continue to this day. But, despite the cleanup the exposure of human beings to environmental contaminants probably continued to increase in much of the country until at least the mid-1970's and more likely until about 1980. Thus, environmental cancers would have increased in frequency until about 2000 or later.

In reality, **M**'s from all cancer were increasing in this country by the early 1900's. **I**'s would have begun to increase even earlier. That is, the overall cancer *I* probably had been increasing for fifty years before environmental pollution could have had any discernible effect. The overall *I* of cancer began declining in 1991<sup>12</sup> and many forms of cancer began declining in the 1970's. This implies that many causes of cancer had begun to decline by 1970, that is, 30 or more years before an environmental cleanup could have had a beneficial effect.

While our concern with environmental causes of cancer is focused on **I**'s, there is reason to review **M**'s as well. The principle reason is the superior quality and representativeness of **M**'s over **I**'s when evaluating long-term, large-scale patterns of a relatively fatal disease. Excluding lung cancer, **M**'s for "all other cancer" have been declining continuously since 1950.<sup>13</sup> Mortality from all cancer, even including lung cancer, has been declining since 1991<sup>14</sup> and is now accelerating downward.<sup>15,16</sup> This overall decline reflects reductions in the **M**'s of many specific forms of cancer, including the four major cancers.<sup>17</sup> In fact, the American cancer experience, never static, is now changing favorably and profoundly: there was no meaningful increase in the **number** of cancer deaths from 1996 through 1998.<sup>16</sup> This is impressive because the USA's population is increasing in size and age—two demographic changes that would increase the annual number of cancer deaths substantially even if age-specific **M**'s were constant.

We can not exclude agents in the environment as causes of some cancer. However, the study of general environments has led to the identification of only one cause of cancer in human beings. In that instance, endemic pleural mesothelioma in three villages in Turkey was found to be due to erionite, a naturally-occurring mineral which shares physical properties, including fiber size and shape, with asbestos.<sup>18,19</sup> Moreover, if an environmental agent were to cause cancer, cases probably would first appear as a "cancer cluster" in a residential or social (e.g., school or house-of-worship) setting. Erionite came to attention in this way. However, none of the other investigations of hundreds of cancer clusters by the Centers for Disease Control and Prevention<sup>20</sup> or by a state health department<sup>21</sup> identified a culpable agent, old or new. There is no way to know how many such investigations have gone unpublished because they provided no useful clue to the identity of a carcinogen. These considerations do not reduce the need to seek environmental carcinogens when their presence is suspected. And, they do not justify the environmental contamination that occurred. But they do indicate that there are more fruitful arenas in which to seek human carcinogens.

Table 14.3-1 lists the four natural environmental agents that are on IARC's list of known carcinogens. Arsenic also could be listed here. Except for the inclusion of radon gas, and occupations involving exposure to radon, IARC makes no mention of ionizing radiation and its sources, natural or man-made. Aflatoxins and erionite cause little or no cancer in this country but aflatoxins are discussed because of scientific interest. Solar radiation is addressed elsewhere in this text. Man-made environmental contaminants are addressed below.

### Aflatoxins

Aflatoxins are a group of toxins formed by the fungus *Aspergillus sps.* which lives on peanuts, maize and animal fodder. The aflatoxins kill bacteria which compete with the fungus for the vegetable material as food. Aflatoxin B1, produced by *Aspergillus flavus*, is a potent cause of several forms of cancer in many species. It is considered a cause of hepatocellular carcinoma (HCC) in man on the basis of animal and epidemiologic studies.<sup>22</sup> HCC caused by aflatoxin is a major public health problem in Africa, in China and elsewhere in Asia.<sup>23</sup> In these regions it also may interact with hepatitis viruses to cause a large amount of HCC, probably the most common cancer in the world, among men. The frequency of HCC caused by aflatoxin in developed countries probably is very low.<sup>24</sup>

Concern over environmental carcinogens usually is focussed on agents discharged in large amounts into the air or water supplies or dumped inappropriately. Rarely is there concern about naturally occurring geophysical factors or agents, even though the cancer burden imposed by natural agents is likely to exceed greatly that imposed by artificial ones.<sup>25</sup> Only three agents on IARC's Group 1 list of known carcinogens were widely distributed in the environment by man. These are arsenic,

asbestos and benzene. These agents were distributed primarily through the application of pesticides (arsenic), use of insulation and automotive brake materials (asbestos) and motor vehicle exhausts (benzene). Other Group 1 agents (e.g., the metals) also were dumped in large amounts but in limited areas.

How much cancer is caused by the three man-made, or man-distributed, agents in IARC's Group 1? That question can not be answered with precision. However, several groups<sup>7,8</sup> have suggested that less than four percent of cancer deaths in America are caused by known carcinogens that pollute the environment. Perhaps the issue of greatest interest is that of general air pollution and lung cancer. Although this is not an established causal relationship, estimates of the **AR%** abound. For example, in 1990 the EPA estimated that less than one percent of lung cancer in the USA was caused by all of the "toxic pollutants" in air.<sup>26</sup> However, the estimate related to known, or suspect, carcinogens. Thus, the actual amount of lung cancer caused may be somewhat higher because of the possible additional effects of unidentified agents. On the other hand, the actual percentage may be or soon may become lower if the environmental cleanup of the last 25 years produces benefits.

Benzene can be used to illustrate the effort to estimate the **AR%** of a widely-dispersed environmental carcinogen. In this example, we focus on benzene as a cause only of leukemia and not of lymphomas as has been suggested by some persons. Several benzene-leukemia risk assessments<sup>27,28</sup> suggest that a benzene exposure of 50 to 100 part-per-million years is needed to double a person's risk of leukemia. The higher estimate, implying that benzene is weaker, is probably superior but we will use 50 ppm-years as the "first doubling dose" for leukemia. The "years" in the assessments refer to a year's work, that is 240 days at eight hours per day or about 22% of a full year. In highly contaminated public areas, e.g., a congested intersection in a major city, benzene levels in air rarely exceed 0.005 ppm. A person who spent a 75 year lifespan (about 350 work years) in this highly contaminated environment would accumulate a benzene exposure of 1.8 ppm-years (350 years x 0.005 ppm). This is about four percent of the first doubling dose of leukemia. Members of a population living under this condition would have a lifetime probability of death from leukemia of 1.04% instead of the usual 1.0%. This estimate may be too high as there is evidence that the benzene-leukemia relationship is a threshold phenomenon in animals<sup>29</sup> and that benzene does not produce leukemia in human beings at cumulative doses below 50 ppm-yrs.<sup>30</sup>

Benzene was used to illustrate the basis for the existing low estimates of the carcinogenic effects of environmental pollutants. Estimates for arsenic and asbestos are even lower because of their limited dispersal. Thus, the suggestion that environmental pollutants cause an appreciable amount of cancer in the USA usually rests upon conjectures: Unrecognized environmental pollutants are the culprits. Risk assessments such as that described are too general; concern should focus on local areas where exposures are uniquely high. The risk assessments do not consider possible synergistic effects of combinations of carcinogens. Or, finally, the population includes highly susceptible persons who will develop cancer at doses much lower than those experienced by the workers whose experience provides the basis for most risk assessments. It is correct that IARC's Group 2A and 2B together include about two dozen agents and mixtures that are suspected to cause cancer in human beings and are widespread. Trichloroethylene, polychlorinated biphenyls and diesel exhausts are relevant examples. But, whether these agents, alone or combined, do cause cancer is unknown.

## LIFESTYLE FACTORS

There are five "mixtures" on IARC's Group 1 list that are included as lifestyle factors in [Table 14.3-1](#). Each except the third, betel quid with tobacco, is discussed. We added reproductive factors. The NTP includes no lifestyle factor on its lists. We consider that about 45% of cancer in the USA is attributable to lifestyle factors but two-thirds of this 45% results from smoking.

### Smoking

Smoking was not the first cause of cancer identified in human beings but it is premiere in almost every other way. It was the first lifestyle factor shown to cause cancer and probably the first established by epidemiologic means. Most important, **smoking causes more cancer in the USA than do all other known causes combined**. A typical 50 year old smoker has a risk of dying from cancer that is three times as great as that of a nonsmoker. Smoking leads to at least 25% and perhaps 35% of cancer deaths. Finally, smoking is preventable and its elimination would lower cancer mortality more than would the optimization of all other known preventive and treatment strategies combined.

**CANCER OF THE LUNG.** Cigarette smoking began in about 1900 and increased among men during World War I and the "roaring" twenties. It continued upward through the 1950's. Large numbers of women began to smoke during World War II and their smoking increased until the mid-1960's.<sup>31</sup> By the 1930's many physicians suspected that the increase in lung cancer seen in their practices resulted from cigarette smoking. But this was contentious because many persons thought that the undoubted rise was due to urban air pollution. The importance of smoking was established in 1950 when the earliest case-control studies<sup>32,33</sup> showed the strength of its association with lung cancer. The association was widely accepted as causal by the public health and medical communities by the mid-1950's.

When the first Surgeon General's Report on Smoking and Health appeared in 1964,<sup>34</sup> smoking was a well-established cause of lung cancer. Interest had shifted to estimating benefits from smoking cessation and from switching to filter-tipped and to "low tar" cigarettes. It is now known that the **RR** of lung cancer declines 60% within 10 years of quitting smoking, and more thereafter.<sup>35</sup> However, a switch to filter-tipped and low tar cigarettes only minimally lowers risks.<sup>36</sup> Low tar cigarettes also have a low nicotine level and so "switchers" practice compensatory smoking, largely negating potential benefits.<sup>37</sup> Recent concerns relate to the effects of environmental tobacco smoke or "passive smoking". Although lung cancer remains uncommon among nonsmokers, nonsmoking spouses and associates of smokers have a 25% increased risk of the disease from environmental tobacco smoke.<sup>38</sup>

The persistence of smoking-induced lung cancer requires that conventional public health approaches to smoking control be reconsidered. These 40 year old programs have produced some beneficial effects. For example, the proportion of adults who smoke declined from about 50% in 1960 to 30% in 1990. However, it has not declined further. Moreover, there is something of a puzzle: Anti-smoking campaigns reduced the prevalence of smokers substantially in the mid-1960's. Why, then, did not lung cancer stabilize and begin to decline by the mid- to late 1970's? In fact, lung cancer stabilized (in men) only in the late 1980's and, so far, has declined only about nine percent. The explanation is that it was almost exclusively light smokers who quit first. Yes, light smokers do experience elevated lung cancer risks. However, it is the heavy or "inveterate" smokers, persons who are unable to quit, who suffer the greatest lung cancer mortality.<sup>39</sup> The prevalence of heavy smokers has declined relatively little and only recently.<sup>40</sup> Moreover, this decline is occurring not because the heavy smokers are quitting, but because they are dying. It still may be possible to save many of these heavy smokers, more than one-half of whom otherwise will die of a smoking-related illness,<sup>41</sup> by a harm reduction strategy which switches them *permanently* from cigarettes to an alternative nicotine source. This strategy is distinct from the usual one in which alternative sources (nicotine patch, gum) are employed only temporarily to assist conventional smokers to quit. No nicotine source is ideal for permanent use but, esthetic considerations aside, smokeless tobacco packets come closest.<sup>39</sup>

**CANCER OF THE LARYNX.** Smoking's association with larynx cancer is as strong as that with lung cancer. However, the risk of the disease among nonsmokers is so low that even the high **RR** among smokers produces rather few cases among them. The increased risk of larynx cancer from smoking is magnified by abuse of alcoholic beverages. A similar interaction or synergy is seen for cancer of the oral cavity and of the esophagus.

**CANCER OF THE ORAL CAVITY (OCC).** This condition, including cancer of the pharynx, is caused by smoking with a **RR** of about 5.

**CANCER OF THE ESOPHAGUS.** The risk of this disease is increased in smokers with a **RR** of about 4. It is a strikingly male disease, uncommon even among women who smoke.

**URINARY TRACT CANCER.** Renal cell cancer has a weak association with cigarette smoking with **RR**'s rarely exceeding 2. However, the association is consistent and widely accepted as causal. The disease presumably is caused by a urogenous agent(s), possibly the same as that, or those, which cause squamous and transitional cell carcinomas of the lower urinary tract.

Smoking was causally linked to cancer of the bladder by the mid-1950's.<sup>42</sup> Smoking also is a likely cause of carcinomas of the other urinary passages, the renal pelvis, ureter and urethra.<sup>43</sup> These associations are moderate, with **RR**'s of 2-4 and are consistent. There is some evidence that aromatic amines, especially 4-aminobiphenyl,<sup>44</sup> created from tobacco proteins by the pyrolysis of smoking, explain these causal relationships. One of the largest studies found that persons who quit smoking lowered their **RR** of bladder cancer by 20 to 30% within about four years.<sup>45</sup> This suggests that the urogenous carcinogen in cigarette smoke acts as a late-stage carcinogen in producing bladder cancer, whether or not it also acts as an early-stage carcinogen.

**OTHER CANCERS.** IARC considers smoking a cause of pancreas cancer. Smoking is moderately to strongly suspect as a cause of cancer of the cervix and liver and of leukemia.

## Smokeless Tobacco

Use of smokeless tobacco imposes a moderate **RR** of 2 for OCC. However, this risk may be declining because the suspect carcinogens in smokeless tobacco, naturally-occurring tobacco-specific nitrosamines (TSNAs), have been reduced over the past two decades. In Sweden, where *per capita* consumption of smokeless tobacco is very high, TSNAs levels are undetectable and recent studies report no OCC attributable to the use of Swedish products.<sup>46</sup>

## Alcoholic Beverages

Four forms of cancer are caused by abuse of alcoholic beverages (AB), OCC and cancers of the larynx, esophagus and liver. **RR's** averaged over different levels of AB abuse and from different studies are about 4 for these cancers. Thus, 75% of these cancers that occur among AB abusers is attributable to their drinking. In a general population with a six percent prevalence of AB abusers, a typical figure for men and women combined,<sup>31</sup> about 20% of these cancers, and about 3% of all cancers, is attributable to AB abuse. Similar estimates have been made by others.<sup>7,8</sup> However, none of these estimates includes the synergistic effects of smoking with AB in causing OCC and larynx and esophagus cancer.

Smoking and alcohol show a strong synergy in causing OCC and cancers of the larynx and esophagus. For example, among men, the **RR** of OCC is 5 for smokers and 5 for AB abusers. However, it is about 25 for men who have both exposures.<sup>47</sup> Each of these three cancers has a distinctly high incidence sex ratio: 4.1, 4.0 and 2.5 for cancers of the larynx, esophagus and OCC, respectively. These high sex ratios probably occur because the combination of heavy smoking and AB abuse is four times as common among men as among women.<sup>47</sup> A practical reality is that all three of the cancers would decline by 40% or so if AB abuse were to cease.

Despite its acceptance as a cause of four forms of cancer, the carcinogenic effect of AB abuse is unexplained. Ethanol is not carcinogenic in animals or *in vitro*.<sup>48</sup> It has been suggested that AB abuse is associated with cancer because of the poor diet, including micronutrient and vegetable deficiencies, that characterize AB abusers. Another suggestion is that alcohol acts as a topical solvent on epithelial tissues and increases the amount of carcinogens in food or cigarette smoke or in the AB themselves that penetrate cells. Both suggestions have existed for decades without becoming established or disproven.

## Dietary Factors

Diet is widely seen as a cause of a high proportion of cancer in human beings. This perception has three major bases, the 1981 report by Doll and Peto,<sup>7</sup> a wealth of seemingly incriminating research and an intuitive appeal. Doll and Peto estimated that 35% of cancer deaths in the USA **might be** attributable to diet (with a range of 10-70%). They wrote, "It must be emphasized that the figure chosen is highly speculative and chiefly refers to dietary factors which are not yet reliably identified." This qualification of the 35% estimate is as valid today as it was 20 years ago.

If the estimate is restricted to known and strongly suspect dietary causes of cancer it is much lower than 35%. IARC includes only one dietary item, Chinese style salted fish, on its list of known carcinogens. It causes nasopharynx cancer where heavily salted fish is eaten in large amounts by persons of all ages, including children. This item presumably causes almost no cancer in America.

Although not a dietary factor in the usual sense, caloric excess and the resultant obesity may be seen as a cause of cancer. This is virtually certain for cancer of the endometrium<sup>49</sup> and likely for breast cancer.

The items in the American diet often linked to cancer are red meat especially when charred,<sup>50</sup> animal fats<sup>51</sup> and "pesticide residues" ingested on over-treated and under-washed fruits and vegetables. The cancers related to these items are those of the stomach, colon, breast and prostate. None of these associations is established as causal. Similarly, many dietary agents have been suggested as protective against one or another form of cancer. These include, as examples, zinc and cancer of the larynx and esophagus,<sup>52</sup> fruits and vegetables and cancers of the gastrointestinal tract, lung and endometrium.<sup>53</sup> None of these associations is established.

## Reproductive Factors

Virtually every aspect of a woman's reproductive life is associated with alterations in her breast cancer risk. These include age at menarche (earlier, increased risk), age at first delivery (later, including nulliparity, increased risk), parity (more children, lowered risk), lactation (longer, lowered risk), age at menopause (earlier, lowered risk) and the use of exogenous estrogens (increased risk). Prolonged use of oral contraceptives (OCs) by younger women may increase breast cancer risk but this relationship remains poorly understood. The observations seem consistent in suggesting that the duration of a woman's reproductive life is the primary risk determinant.<sup>54</sup> But, there also is evidence that much of a woman's breast cancer risk is determined in her youth and young adulthood.<sup>54,55</sup> And yet, there is no accepted mechanism that links these reproductive features to a causal agent or to a means of preventing breast cancer.

Cancer of the endometrium and ovary share descriptive epidemiologic features with breast cancer and their risk is increased by nulliparity. But they share few of the other reproductive correlates of risk. Endometrial cancer is caused by use of sequential but not of combined OCs. This is presumably due to the regimen of sequential agents which involves two weeks per month of exposure to estrogens unmodified by a progestogen. Endometrial cancer also is caused by exogenous estrogens, primarily estrone, that until 1975 were prescribed frequently and in relatively high doses for the control of menopausal symptoms. These observations suggest that endogenous estrone is also a cause of the disease. In any event, some aberration of endogenous hormone production or metabolism is likely to cause endometrial cancer. This is consistent with the correlation of endometrial cancer risk with male pattern (upper body) obesity in which hormonal aberrations commonly are seen.<sup>56</sup> Finally, endometrial cancer is caused by tamoxifen, anti-estrogenic for the breast but estrogenic for the endometrium.<sup>56</sup>

There is no established cause of ovarian cancer except ionizing radiation, although several agents are suspect. These include asbestos, talc and hair dyes. Parity is moderately protective with **RR's** declining gradually from 1.0 for nulliparas to about 0.4 for women with four or more children. Lactation may be moderately protective with perhaps a 30% risk reduction from prolonged lactation. Five or more years of use of combined OCs may lower risk by 40%. Weiss et al<sup>57</sup> indicated that major progress will require a massive study which evaluates demographic features and possible causes separately for each of the major types of ovarian tumor (germ cell, sex cord and stromal and epithelial).

## OCCUPATIONAL FACTORS

No area of epidemiologic research has identified as many human carcinogens as has occupational epidemiology. One-half of the 75 agents on the IARC Group 1 list of known carcinogens were identified, or confirmed, by occupational investigations. Yet, only about four percent of cancer in the USA is due to occupational factors.

The discovery of new carcinogens in occupational settings has slowed but this research setting remains important for four reasons: 1) There are several strong suspect occupational carcinogens. 2) For many agents thousands of workers are exposed in the USA and several hundred thousand worldwide. Thus, the hazard to workers alone from an occupational carcinogen could pose a major public health problem. 3) Workers typically are exposed to high concentrations of the agents with which they work and so serve as sentinels for the general population. 4) Almost all occupational studies are of the retrospective follow-up (also termed retrospective cohort) type. This design permits all causes of death, or all major illnesses, to be identified. Thus, these studies may identify not only carcinogens but causes of other diseases as well.

Only one occupational carcinogen, creosote, has been added to the NTP "A" list since 1981. More generally, the health of employed groups now is remarkably high and is likely only to improve as advances in industrial hygiene and manufacturing efficiency make the workplace cleaner.

## PHARMACOLOGIC/IATROGENIC FACTORS

The use of a carcinogen as a therapeutic agent is justified for treating a life-threatening condition and even for treating severe non-fatal conditions. At least one known carcinogen, tamoxifen, is also a cancer preventative in women at high risk of breast cancer.<sup>58</sup> The need to evaluate carefully the risks from the therapeutic use of a carcinogen in each patient is obvious. This is especially so for children since a child cured of a malignancy has a life expectancy much longer than the induction period of any cancer. It is not so well recognized that the same issue applies to adults. Even a 60 year old person in the USA has a life expectancy of 20 years or

more, an adequate induction period for many forms of cancer and especially for the leukemias induced by oncolytic therapy.

IARC's Group 1 list of known carcinogens includes 18 agents and mixtures that are, or were, used in medical practice. There are nine alkylating agents (including as one, MOPP and other combinations that include an alkylating agent), four hormone groups, 1 hormone antagonist, two immunosuppressants, and two additional mixtures. They are listed in [Table 14.3-1](#). Most of the agents are used to treat cancer and a few are used to treat other life-threatening conditions, e.g., transplanted organ rejection. Several, such as the estrogen mixtures are, or were, used to treat relatively benign conditions and OCs are used without a therapeutic indication.

The carcinogenic effects of therapeutic agents can be difficult to recognize and to quantify. The reasons are best described if we consider first the agents used for non-malignant conditions. The carcinogenic effect of these agents is difficult to evaluate because, although they are available only on prescription, the actual amounts prescribed and consumed are uncertain as any patient (or member of the general public) may obtain the drugs. A patient, or another physician may change the drug prescribed to another which has a similar biologic effect but which has a different carcinogenic potential, e.g., substitution of non-steroidal for steroidal estrogens. Finally, if the patient is not under long-term observation at a single medical center a cancer that occurs will not be noted, much less be related to drug use.

Perhaps because of the difficulties just mentioned, as well as the low risk of cancer posed by agents that are not anti-neoplastic, [Table 14.3-1](#) lists few such agents. This dearth does **not** reflect a lack of suspicion or of searches for carcinogenic effects of pharmacologic agents. Many agents have been evaluated and not found to be carcinogenic. For example, the IARC's Group 3 ("Unclassifiable as to carcinogenicity to humans") includes, among other medications, chloral, acetaminophen (the major metabolite of phenacetin), reserpine and spironolactone.

The causal relationship between DES exposure *in utero* and clear cell adenocarcinoma (CCA) of the vagina in young women warrants mention. DES is the only non-oncolytic pharmacologic agent that imposes a massive **RR** of cancer on exposed persons. Although the association is strong with an **RR** >100 the disease is nonetheless rare among exposed women; their lifetime risk of developing CCA is only 1 in 1000.<sup>58</sup>

When we turn to the anti-neoplastic agents, most of the investigative problems mentioned above are reduced. The identity and dosage of the agents prescribed are documented. Outpatient compliance with treatment is presumed to be good. The agents are not used by the general public and so the baseline number of cancers of a particular type to be expected among treated patients can be estimated. However, there are three problems that complicate the study of the carcinogenicity of anti-neoplastic agents: 1) The agents often are used in combinations both simultaneous and sequential or with radiation therapy. This makes it difficult to identify the effect of any one agent and also introduces the possibility of synergistic effects. There is particular concern about synergy between pharmacologic agents and radiation therapy. However, there is as yet no evidence of this synergy.<sup>59</sup> 2) Many cancer patients survive relatively few years after receiving chemotherapy. This makes it difficult to accumulate a substantial number of person-years at risk after the passage of a reasonable minimum induction period for a second cancer. 3) Cancer patients are at increased risk of developing a second primary cancer for reasons unrelated to their treatment. These include the high risk of a second primary of the same type as the first. The causes of one type of cancer also cause others, e.g., patients with lung cancer have an increased risk of bladder cancer, and vice versa, because smoking causes both. Also, causes of cancer often cluster in an individual, e.g., smoking, AB abuse and poor diet. Finally, there is the possibility of a "cancer diathesis", the prospect that, for some constitutional reason, e.g., genetic makeup, a person who developed one cancer has an inherently increased risk of developing another.

The many reasons why a cancer patient might develop a second primary tumor cause us to be skeptical of reports of an excess of second primaries following anti-neoplastic treatment. This is especially so if the excess is minimal or is restricted to cancers of the same type or etiology as the first. However, as [Table 14.3-1](#) indicates, a characteristic of the risk of second primaries following cancer treatment is that almost all of the **RR's** are 5 or greater. And, the second cancer commonly is AML, irrespective of the cancer for which treatment was given. The associations in the table are virtually certainly attributable to the agents listed and not to any of the other reasons why a cancer patient might develop a second tumor.

## BIOLOGIC FACTORS

Oncogenic biologic agents long have challenged laboratory investigators and epidemiologists. For nearly a century one microbe after another that appeared to cause cancer in man was identified but soon discarded. Few contemporary researchers will remember the "*Bacillus hodgkini*" – the "cause" of Hodgkin's disease discovered in 1915.<sup>60</sup> More memorable, if only because of their recency, are the various "B" and "C" particles that were considered fragments of a virus which was thought to cause breast cancer in women. *Herpesvirus hominis, type 2*, was virtually established in the mid-1970's as the cause of cervix cancer. But, by 1981, in their review of known and suspect causes of cancer, Doll and Peto<sup>7</sup> indicated only that the EBV-Burkitt's lymphoma relationship seemed likely to be causal and they appeared to accept the hepatitis-B virus and HCC association as causal. They suggested as, "a very uncertain best estimate" that 10% of cancer deaths in the USA might prove to be due to infectious agents.

Now, the discovery of causes of cancer has slowed in virtually every area except that of biologic agents. Almost certainly as a direct result of advances in molecular biology, there are nine biologic agents known to cause cancer in human beings ([Table 14.3-1](#)). All nine agents are of considerable scientific and clinical interest but only the hepatitis viruses, the human papilloma viruses (HPV) and *H. pylori* cause enough cancer to be considered public health problems in the USA. The hepatitis-B and -C viruses together cause about 50% of the cases of HCC that occur<sup>61</sup> and so cause about 6000 deaths per year. HPV causes about 90% of cervical cancer or 4000 deaths per year.<sup>62</sup> Both categories of agents produce much more disease in the developing world, as does EBV. *H. pylori* is estimated to cause 60% of stomach cancer or about 7000 deaths per year in the USA. The other known infectious agents combined probably cause less than 500 cancer deaths per year. The total for infectious agents is about 18,000 deaths per year or about four percent of cancer deaths. Doll and Peto's "best estimate" of 10% still seems reasonable as a virus etiology may yet be found for several forms of cancer, especially in the leukemia-lymphoma group.

Cervical cancer is the most common cancer in the world, among women. It has a long and rich epidemiologic history. Its long-term declining **I** and **M** in developed countries, its striking association with poverty, with "reproductive" factors, and the large-scale use of the pap smear all have caused this disease to receive considerable attention from the cancer research community. Cancer of the cervix is the "epidemiologic opposite" of the other major cancers of women. It is associated with early childbearing, high parity and poverty. However, the representation that cervix cancer is associated with "reproductive" factors is a euphemism. The disease actually is associated largely with sexual practices. The more sexual partners a woman has had, especially before age 20, the higher her risk of cervical cancer.<sup>63</sup> We now recognize that this association reflected a woman's probability of becoming infected with HPV. There may be small, independent associations of cervical cancer risk with factors beyond those that are indices of exposure to HPV. These factors are use of OCs and micronutrient, especially vitamin, deficiencies.

A notable feature of the epidemiology of cervical cancer is the recent increase of adenocarcinomas. This condition has an epidemiology like that of cancer of the endometrium and unlike that of the usual squamous cell carcinoma of the cervix.<sup>64</sup>

## PERSPECTIVES

The year 2001 is the thirtieth anniversary of the National Cancer Act and of the USA's "War on Cancer". These three decades brought major achievements. Since at least 1972 **M's** of most forms of cancer have been declining; in 1991 the overall cancer **M** started to decline and is now accelerating downward. This favorable trend probably will continue for many years. Thus, progress may now be described as, at the very least, substantial.

Cancer **M's** started to decline earlier and still decline more sharply than do **I's**. This is *prima facie* evidence of major improvements in medical care. And yet **I's** finally are also declining indicating that prevention efforts are bringing results. This is what we address here. Do we now know, and protect against, the causes of more cancers than we did 20 or 30 years ago?

## ARE MORE CANCERS NOW OF KNOWN ETIOLOGY?

At the beginning of this Section we compared the 1998 NTP-A list of known carcinogens with its 1980 counterpart. The list increased from about 20 agents to about 33. However, the added items are almost all pharmacologic agents that, combined, cause less than three percent of cancer deaths.

In 1981 Doll and Peto estimated the percentage of cancer deaths in the USA attributable to each of 11 major causes or groups of causes of cancer.<sup>7</sup> The left column of [Table 14.3-2](#) is an adaptation of their summary estimates of **AR%'s**. (We made minor alterations in their format, described below.) The 97% figure of Doll and Peto does not imply that they thought they were explaining nearly all cancer. The **AR%'s** listed are not mutually exclusive and the totals presented are only general indicators of how much disease might be prevented if the causes listed were controlled. The right column in [Table 14.3-2](#) shows our present estimates of the

all-cancer **AR%'s** for the same categories of agents. A comparison of the two sets of estimates seems to imply that there has been little progress. The total in the second column is actually moderately **lower** than that in the first! Do we know the causes of fewer cancers than we did 20 years ago? No. The explanation of the decline in the **AR%'s** lies in the different bases of the two sets of estimates. Doll and Peto addressed what reasonably might be true; we describe what is known or highly probable. To clarify this we address several categories in the table.

Category	%	
	1981*	2000**
1. Pollution	2%	2%
2. Geophysical	3	3
3. Smoking	30	30
4. Alcohol	3	3
5. Diet	35	5
6. Food additives	1	0
7. Reproductive/Sexual	7	7
8. Occupation	4	4
9. Industrial products	1	1
10. Medicines/Procedures	1	2
11. Biologic	10	4
Total	99%	61%

\*\*Present authors.

**TABLE 14.3-2.** Percentage of Cancer Deaths Attributable to Agents in Eleven Categories

We labeled the third category “smoking” but Doll and Peto termed it “tobacco”. The distinction is important. During the last 20 years in the USA many anti-smoking campaigns shifted their focus from preventing deaths caused by smoking to preventing tobacco use. If we refocus attention on deaths from smoking we can learn a valuable lesson from Sweden, the only country which has met the World Health Organization's goal of a less than 20% prevalence of smokers. It also has Europe's lowest rates of lung cancer, larynx cancer, OCC and bladder cancer.<sup>65</sup> How were these benchmarks attained? There may be several explanations, but it is certainly relevant that Sweden has the highest *per capita* use in Europe of smokeless tobacco.<sup>66</sup>

Whether we refer to “tobacco” or “smoking”, the situation has not changed in 20 years: smoking causes about 30% of cancer deaths. It will now change. Lung cancer and other smoking-related cancers will decline sharply over the next decade. The impending decline in lung cancer deaths will occur because the number occurring among inveterate, that is heavy, smokers at last has started down. These persons are literally a dying breed whose numbers, finally, are not being replaced fully by equally heavy smokers. The misfortune is that the decline in smoking-related morbidity and mortality that is now beginning might have occurred 20 or more years ago if our initial efforts against smoking had focussed on the heavy smokers.

Doll and Peto thought that dietary factors might cause about 35% of cancer. Yet, the evidence that dietary factors are carcinogens is as elusive today as it was 20 years ago. Our present estimate even of just five percent is defensible only as “strongly suspect”. Despite limitations and controversy the information on diet and cancer is useful. Virtually all of the dietary alterations recommended today to reduce cancer risk are, at the least, prudent. The specific reason why people choose a healthful diet and whether it is the “prudent” diet,<sup>67</sup> the Asian diet, or the Mediterranean diet<sup>68</sup> may matter little. Each of the diets, adopted not as a temporary regimen, but as a part of one's lifestyle will contribute to weight control, reduce intake of animal fats and increase the intake of fruits and vegetables. This should lower the risks of cardiovascular diseases and, perhaps, of cancer.

Doll and Peto considered only two of the virus-cancer relationships in [Table 14.3-1](#) as “likely”. Today, none of the relationships in the table is controversial. However, there is uncertainty over the **RR's** and **AR%'s** of cancer associated with infectious agents. Our summary estimate of four percent, developed above, is a reasonably firm estimate of the minimum amount of cancer caused by infectious agents.

We consider Doll and Peto's estimate of one percent of cancer due to “medicines, procedures” and our analogous estimate of two percent as identical if only because both are imprecise. The amount of cancer caused by these agents is unlikely to be increasing. In fact, in a carefully developed opinion in 1977 Jick and Smith suggested two percent.<sup>69</sup> Cancer due to pharmacologic and iatrogenic agents probably is declining because of their more guarded use.

No, we do not know the causes of fewer cancers today than we did 20 years ago. But, if we focus on what we know, as distinct from what may be true, we do not know the causes of many more, either.

## HAVE WE REDUCED EXPOSURE TO RECOGNIZED CAUSES OF CANCER?

Yes. The population's smoking, both active and passive, is diminishing, albeit slowly. Exposure to workplace carcinogens probably is declining and occupational cancers are in decline.<sup>8</sup> *H. pylori* is treated widely, sunblockers are in common use and carcinogenic agents in medical practice are used carefully. Although obesity unfortunately is increasing,<sup>70</sup> animal fat in the American diet is declining while the amount of fruit and vegetables is increasing.<sup>71</sup> Also, contaminants in the general environment, possibly including carcinogens, are in decline. It is impractical to estimate the cancer reductions that these changes will bring. But, the reductions already are evident and appear certain to increase.

### INTRODUCTION

Surgery is the oldest treatment for cancer and, until recently, was the only treatment that could cure patients with cancer. The surgical treatment of cancer has changed dramatically over the last several decades. Advances in surgical techniques and a better understanding of the patterns of spread of individual cancers have allowed surgeons to perform successful resections for an increased number of patients. The development of alternate treatment strategies that can control microscopic disease has prompted surgeons to reassess the magnitude of surgery necessary.

The surgeon who treats cancer must be familiar with the natural history of individual cancers and with the principles and potentialities of surgery, radiation therapy, chemotherapy, immunotherapy, and other new treatment modalities. The surgeon has a central role in the prevention, diagnosis, and definitive treatment of the disease and in palliation and rehabilitation of the cancer patient. The principles underlying each of these roles of the surgical oncologist are discussed in this chapter.

### HISTORICAL PERSPECTIVE

Although the earliest discussions of the surgical treatment of tumors are found in the Edwin Smith papyrus from the Egyptian Middle Kingdom (circa 1600 BC), the modern era of elective surgery for visceral tumors began in frontier America in 1809.<sup>1,2</sup> Ephraim MacDowell removed a 22-pound ovarian tumor from a patient, Mrs. Jane Todd Crawford, who survived for 30 years after the operation. This procedure, the first of 13 ovarian resections performed by MacDowell, was the first elective abdominal operation and provided a great stimulus to the development of elective surgery.

The treatment of most tumors depended on two subsequent developments in surgery. The first of these was the introduction of general anesthesia by two dentists, Dr. William Morton and Dr. Crawford Long. The first major operation using general ether anesthesia was an excision of the submaxillary gland and part of the tongue, performed by Dr. John Collins Warren on October 16, 1846, at the Massachusetts General Hospital. The second major development stimulating the widespread application of surgery resulted from the introduction of the principles of antisepsis by Joseph Lister in 1867. Based on the concepts of Pasteur, Lister introduced carbolic acid in 1867 and described the principles of antisepsis in an article in the *Lancet* in that same year.

These developments freed surgery from pain and sepsis and greatly increased its use for the treatment of tumors. In the decade before the introduction of ether, only 385 operations were performed at the Massachusetts General Hospital. By the last decade of the nineteenth century, more than 20,000 operations per year were performed at that same hospital.<sup>3</sup>

[Table 15-1](#) lists selected milestones in the history of surgical oncology. Although this list does not include all the important developments, it does provide the tempo of the application of surgery to cancer treatment.<sup>4</sup> Major figures in the evolution of surgical oncology included Albert Theodore Billroth who, in addition to developing meticulous surgical techniques, performed the first gastrectomy, laryngectomy, and esophagectomy. In the 1890s, William Stewart Halsted elucidated the principles of *en bloc* resections for cancer, as exemplified by the radical mastectomy. Examples of radical resections for cancers of individual organs include the radical prostatectomy by Hugh Young in 1904, the radical hysterectomy by Ernest Wertheim in 1906, the abdominoperineal resection for cancer of the rectum by W. Ernest Miles in 1908, and the first successful pneumonectomy performed for cancer by Everts Graham in 1933. Modern technical innovations continue to extend the surgeon's capabilities. Recent examples include the development of microsurgical techniques that enable the performance of free grafts for reconstruction, automatic stapling devices, sophisticated endoscopic equipment that allows for a wide variety of "incisionless" surgery, and major improvements in postoperative management and critical care of patients that have extended the safety of major surgical therapy.

Year	Surgeon	Event
1809	Ephraim MacDowell	Elective abdominal surgery (ovarian tumor)
1846	John Collins Warren	Use of ether anesthesia (excised submaxillary gland)
1867	Joseph Lister	Introduction of antisepsis
1868-1880	Albert Theodor Billroth	First gastrectomy, laryngectomy, and esophagectomy
1879	Richard von Volkmann	Excision of carcinoma rectum
1886	Theodore Kocher	Development of thyroid surgery
1896	William Stewart Halsted	Radical mastectomy
1904	Hugh H. Young	Radical prostatectomy
1906	Ernest Wertheim	Radical hysterectomy
1908	W. Ernest Miles	Abdominoperineal resection for rectal cancer
1912	E. Martin	Excision for the treatment of pain
1916-1930	Harveyushing	Development of surgery for brain tumors
1917	Ernst Starck	Successful resection of cancer of the thoracic esophagus
1927	G. Dole	Successful resection of pulmonary carcinoma
1933	Everts Graham	Pneumonectomy
1935	A. O. Whipple	Pancreaticoduodenectomy
1941	Charles B. Thigpen	Adjuvant therapy for gastric cancer
1948	Bernard Fisher	Organization of NSABP as random prospective evaluation trials

TABLE 15-1. Selected Historical Milestones in Surgical Oncology

Critics who believe that the application of surgery has reached a plateau beyond which it will not progress should remember the words of a famous British surgeon, Sir John Erichsen, who, in his introductory address to the medical institutions at University College, said,

There must be a final limit to the development of manipulative surgery, the knife cannot always have fresh fields for conquest and although methods of practice may be modified and varied and even improved to some extent, it must be within a certain limit. That this limit has nearly, if not quite, been reached will appear evident if we reflect on the great achievements of modern operative surgery. Very little remains for the boldest to devise or the most dextrous to perform.

These comments, published in the *Lancet* in 1873, preceded most important developments in modern surgical oncology.

### ANESTHESIA FOR ONCOLOGIC SURGERY

Modern anesthetic techniques have greatly increased the safety of major oncologic surgery. Regional and general anesthesia play important roles in a wide variety of diagnostic techniques, in local therapeutic maneuvers, and in major surgery. These techniques should be understood by all oncologists.

Anesthetic techniques may be divided into those for regional and general anesthesia. Regional anesthesia involves a reversible blockade of pain perception by the application of local anesthetic drugs. These agents generally work by preventing the activation of pain receptors or by blocking nerve conduction. Agents commonly

used for local and topical anesthesia for biopsies in cancer patients are shown in [Table 15-2](#) and [Table 15-3](#).<sup>5</sup> Topical anesthesia refers to the application of local anesthetics to the skin or mucous membranes. Good surface anesthesia of the conjunctiva and cornea, oropharynx and nasopharynx, esophagus, larynx, trachea, urethra, and anus can result from the application of these agents.

Drug	Concentration (%)	Pain Relief		EpiDural-Caudal Block	
		Maximum Dose (mg)	Duration (min)	Maximum Dose (mg)	Duration (min)
<b>Short duration</b>					
<b>Procaine</b>					
Chlorprocaine	1.5-2.0	800	15-30	1000	50-90
<b>Moderate duration</b>					
Lidocaine	0.5-1.0	300	30-60	500	120-180
Prilocaine	0.5-1.0	300	45-90	500	120-180
<b>Long duration</b>					
Bupivacaine	0.25-0.5	175	120-240	225	180-420
Tetracaine	0.5-1.0	300	120-180	400	180-420

(From ref. 5, with permission.)

**TABLE 15-2. Infiltration Anesthesia**

Anesthetic Agent/Preparation	Concentration (%)	Pharmacological Application Form	Approved Area of Use
Procaine	1-2	Crystalline	Skin, mucous membranes
	0.5	Solution	Skin, mucous membranes
Lidocaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Prilocaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Bupivacaine	0.25-0.5	Crystalline	Skin, mucous membranes
	0.25-0.5	Solution	Skin, mucous membranes
Tetracaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Articaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Chlorbutol	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Etidocaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Mepivacaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Ropivacaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Succinylcholine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Cocaine	0.5-1	Crystalline	Skin, mucous membranes
	0.5-1	Solution	Skin, mucous membranes
Benzocaine	0.5-1	Crystalline	Skin, mucous membranes

**TABLE 15-3. Various Preparations Intended for Topical Anesthesia**

Local anesthesia involves injecting anesthetic agents directly into the operative field. *Field block* refers to injection of local anesthetic by circumscribing the operative field with a continuous wall of anesthetic agent. Lidocaine (Xylocaine) in concentrations from 0.5% to 1% is the most common anesthetic agent used for this purpose. Peripheral nerve block results from the deposition of a local anesthetic surrounding major nerve trunks. It can provide local anesthesia to entire anatomic areas.

Major surgical procedures in the lower portion of the body can be performed using epidural or spinal anesthesia. Epidural anesthesia results from the deposition of a local anesthetic agent into the extradural space within the vertebral canal. Catheters can be left in place in the epidural space, allowing the intermittent injection of local anesthetics for prolonged operations. The major advantage of epidural over spinal anesthesia is that it does not involve puncturing the dura, and the injection of foreign substances directly into the cerebrospinal fluid is avoided.

Spinal anesthesia involves the direct injection of a local anesthetic into the cerebrospinal fluid. Puncture of the dural sac generally is performed between the L-2 and L-4 vertebrae. Spinal anesthesia provides excellent anesthesia for intraabdominal operations, operations on the pelvis, or procedures involving the lower extremities. Because the patient is awake during spinal anesthesia and is breathing spontaneously, it often has been thought that spinal anesthesia is safer than general anesthesia. There is no difference in the incidence of intraoperative hypotension with spinal anesthesia compared with general anesthesia, and there is no clear benefit in using spinal anesthesia for patients with ischemic heart disease.<sup>6</sup> Because patients are awake during spinal anesthesia and can become agitated during the surgical procedure, spinal anesthesia actually can cause more myocardial stress than general anesthesia. The health status of patients with preoperative evidence of congestive heart failure is more likely to be worsened by general anesthesia than by spinal anesthesia. In one series, heart failure developed *de novo* in 4% of adults older than age 40 who were undergoing major surgery and worsened in 22% of patients who had a history of heart failure.<sup>6</sup> Spinal anesthesia was not associated with any new or worsened heart failure. Because of local irritating effects of general anesthesia on the lung, it has been suggested that spinal anesthesia may be safer for patients with severe pulmonary disease.

*General anesthesia* refers to the reversible state of loss of consciousness produced by chemical agents that act directly on the brain. Most major oncologic procedures are performed using general anesthesia, which can be induced using intravenous or inhalational agents. The advantages of intravenous anesthesia are the extremely rapid onset of unconsciousness and improved patient comfort and acceptance. Ultra-short-acting barbiturates, such as sodium thiopental, or tranquilizers, such as the benzodiazepines or droperidol, are the most frequently used intravenous agents for general anesthesia or for sedation during regional anesthesia.

A variety of inhalational anesthetic agents are in clinical use. Nitrous oxide is popular, usually in combination with narcotics and muscle relaxants. This technique provides a safe form of general anesthesia with the use of nonexplosive agents. Two other agents in widespread use are the fluorinated hydrocarbons, halothane (Fluothane) and enflurane (Ethrane). Although they are used frequently, the fluorinated hydrocarbons have a variety of side effects. Halothane depresses myocardial function, reduces cardiac output, causes significant vasodilation, and sensitizes the myocardium to endogenous and administered catecholamines that can lead to life-threatening cardiac arrhythmias. In rare instances, halothane can cause severe hepatotoxicity, which begins 2 to 5 days after surgery. Enflurane also depresses myocardial function but does not appear to sensitize the myocardium to catecholamines and has not been associated with hepatic toxicity. The newest of the halogenated hydrocarbons is isoflurane, which was introduced in 1980. Isoflurane depresses the myocardium less than halothane or enflurane, but it has more potent vasodilatory properties.

Virtually all general anesthetics affect biochemical mechanisms, including depression of bone marrow, alteration of the phagocytic activity of macrophages, and exhibition of immunosuppressive properties. General anesthetic agents, such as cyclopropane and diethyl ether, rarely are used because of their explosive potential.

Intravenous neuromuscular blocking agents, called *muscle relaxants*, are commonly used during general anesthesia. These agents are nondepolarizing (e.g., curare), preventing access of acetylcholine to the receptor site of the myoneural junction, or are depolarizing (e.g., succinylcholine), acting in a manner similar to that of acetylcholine by depolarizing the motor end plate. These agents induce profound muscle relaxation during surgical procedures but have the disadvantage of inhibiting spontaneous respiration because of paralysis of respiratory muscles. Succinylcholine is short-acting (3 to 5 minutes), with a rapid recovery phase. Curare-induced paralysis lasts for 30 to 40 minutes after usual clinical doses of 0.3 to 0.5 mg/kg. Pancuronium has fewer side effects than curare but can induce tachycardia by means of sympathetic stimulation.

## DETERMINATION OF OPERATIVE RISK

As with any treatment, the potential benefits of surgical intervention in cancer patients must be weighed against the risks of surgery. The incidence of operative mortality is of major importance in formulating therapeutic decisions and varies greatly in different patient situations ([Table 15-4](#)). The incidence of operative mortality is a complex function of the basic disease process that involves surgery, anesthetic technique, operative complications and, most important, the general health status of patients and their ability to withstand operative trauma.

General health status  
 Severity of underlying illness  
 Degree to which surgery disrupts normal physiologic functions  
 Technical complexity of the procedure (related to incidence of complications)  
 Type of anesthesia required  
 Experience of personnel

**TABLE 15-4.** Determinants of Operative Risk

In an attempt to classify the physical status of patients and their surgical risks, the American Society of Anesthesiologists (ASA) has formulated a general classification of physical status that appears to correlate well with operative mortality.<sup>7</sup> Patients are classified into five groups depending on their general health status (as shown in [Table 15-5](#)).

<b>CLASS I</b> A healthy patient with no organ, physiologic, biochemical, or psychiatric disturbance. The physical status for which operation is performed is localized and does not affect respiratory, circulatory, or other vital functions.	<b>CLASS IV</b> A patient with an incapacitating systemic disease that is a constant threat to life and that does not render the patient capable of undergoing an operation or anesthesia (i.e., the patient has obtained consent with full knowledge of the nature, extent, and risks of the operation and the consequences of refusal to undergo it).
<b>CLASS II</b> A patient with mild to moderate systemic disturbance caused either by the condition to be treated surgically or by other pathophysiologic processes (i.e., myocardial or valvular disease, hypertension, diabetes, mild asthma, controlled hypothyroidism, or similar). There might be the presence of the organ system of the disease to be treated. Systemic disease and chronic conditions may be included in this category.	<b>CLASS V</b> A moribund patient who is not expected to survive 24 hours without operation or who has little chance of survival had a successful operation or anesthesia (i.e., the patient has obtained consent with full knowledge of the nature, extent, and risks of the operation and the consequences of refusal to undergo it).
<b>CLASS III</b> A patient with severe systemic disease that limits activity but is not incapacitating, even though it may not be possible to define the degree of disability with health (i.e., severely limiting organ system disease, severe asthma with variable expiratory dysfunction, or severe degrees of pulmonary hypertension and/or peripheral vascular disease).	<b>EMERGENCY</b> In the event of emergency operation, provide the patient with as high a physical status as the clinical condition permits when operation is an emergency or considered to be in the patient's best interest. The best physical status possible under the circumstances. Thus, the patient with a chronic condition that is not incapacitating and associated with stress and tension is classified as II. In both cases, class I does not constitute an emergency.

(From ref. 7, with permission.)

**TABLE 15-5.** American Society of Anesthesiologists Classification of Physical Status

Operative mortality usually is defined as mortality that occurs within 30 days of a major operative procedure. In oncologic patients, the basic disease process is a major determinant of operative mortality. Patients undergoing palliative surgery for widely metastatic disease have a high operative mortality rate even if the surgical procedure can alleviate the symptomatic problem. Examples of these situations include surgery for intestinal obstruction in patients with widespread ovarian cancer and surgery for gastric outlet obstruction in patients with cancer of the head of the pancreas. These simple palliative procedures are associated with mortality rates of approximately 20% in most series because of the debilitated state of the patient and the rapid progression of the basic disease.

Mortality caused by anesthetic administration alone is related directly to the physical status of the patient. In a review of 32,223 operations, Dripps et al.<sup>8</sup> determined the mortality thought to be related to anesthetic administration alone ([Table 15-6](#)). It is extremely difficult to differentiate the mortality caused by anesthesia from that resulting from other contributors to operative mortality. However, this analysis indicates that operative mortality due to anesthesia in physical status class 1 patients is extremely low, fewer than 1 in every 16,000 operations. The anesthetic mortality increased with worsened physical status.

Physical Status Grade	Spinal Anesthesia (Frequency)	General Anesthesia and Risks (Frequency)
<b>Definitely related to anesthesia</b>		
1	1:100,000*	1:25,000*
2	1:5500	1:1000
3	1:400	1:550
4	1:85	1:45
5	1:16	1:24
<b>Possibly related to anesthesia</b>		
1	0:10,164	0:6028
2	1:2250	1:600
3	1:228	1:150
4	1:19	1:23
5	1:16	1:10

\*Estimated.

**TABLE 15-6.** Mortality Related to Physical Status

There is considerable evidence that anesthesia-related mortality has decreased in the last two decades, largely because of the development of rigid practice standards and improved intraoperative monitoring techniques.<sup>9,10 and 11</sup> A summary of the specific intraoperative monitoring methods used to achieve improved anesthetic safety is presented in [Table 15-7](#).<sup>12</sup> A study of 485,850 anesthetics administered in 1986 in the United Kingdom revealed the risk of death from anesthesia alone in patients from all ASA classes to be approximately 1 in 185,000.<sup>9</sup> In a retrospective review encompassing cases from 1976 through 1988, Eichorn<sup>10</sup> estimated anesthetic mortality in ASA class I and II patients to be 1 in 200,200. These are probably underestimates, since underreporting of anesthetic-related deaths is a problem in all studies. Most cancer patients undergoing elective surgery fall between physical status I and II; thus, an anesthetic mortality rate of 0.01% to 0.001% is a realistic estimate for this group.

Variable	Monitoring Method
Inspired gas	Oxygen analyzer with a low oxygen concentration alarm
Blood oxygenation	A quantitative method, such as pulse oximetry, adequate elimination and exposure to areas color
Endotracheal tube position	Correct positioning in the trachea must be verified by clinical assessment and identification of CO <sub>2</sub> in the expired gas
Ventilation	Clinical assessment, monitoring of CO <sub>2</sub> content and volume of expired gas (rebreager)
Ventilator function	A device with audible alarm, capable of detecting disconnection of components of the breathing system when a mechanical ventilator is used
Circulation	Continuous electrocardiography; blood pressure and heart rate determined every 5 min, continued evaluation of circulation by pulse palpation, heart auscultation, noninvasive pressure tracing, ultrasonic Doppler pulse monitor, pulse photoplethysmography, or telemetry
Temperature	Measurement when changes in temperature are intended, anticipated, or suspected

(From ref. 12, with permission.)

**TABLE 15-7.** Summary of Specific Intraoperative Monitoring Methods

Anesthesia-related mortality is rare, and factors related to the patient's preexisting general health status and disease are far more important indicators of surgical outcome. A study of the factors contributing to the risk of 7-day operative mortality after 100,000 surgical procedures is shown in [Table 15-8](#).<sup>13</sup> The 7-day perioperative mortality in this study was 71.4 deaths per 10,000 cases, and the major determinants of death were the physical status of the patient, the emergent nature of the procedure, and the magnitude of the operation.

Variable	Description	Relative Odds of Dying
<b>Patient Factors</b>		
Age	<60 y versus >60 y	3.70
Gender	Female versus male	0.77
Physical status	ASA III-V versus ASA I-II	10.63
<b>Surgical Factors</b>		
Operation type	Major versus minor	3.82
Urgency	Emergency versus elective	4.44
<b>Anesthesia factors</b>		
Technique	Inhalation + narcotic versus inhalation alone	0.76
	Narcotic alone versus inhalation alone	1.41
	Narcotic + inhalation versus inhalation alone	0.70
	Spinal versus inhalation alone	0.33
	Number of anesthetic drugs: 1-2 versus ≥3	2.84
Experience of anesthesiologist	<500 procedures/y for 0-4 y versus >500 procedures/y for ≥5 y	1.06

ASA, American Society of Anesthesiologists. (From ref. 13, with permission.)

**TABLE 15-8.** Risk Factors Associated with 7-Day Operative Mortality

Several specific health factors can increase the risks of the operative procedure. Using discriminant analysis, Goldman et al.<sup>6</sup> identified nine independent variables that correlated with life-threatening and fatal cardiac complications in patients undergoing noncardiac surgical procedures. By assigning a point value to each variable, a cardiac risk index could be computed ([Table 15-9](#)) that separated patients into four categories of risk ([Table 15-10](#)). The two risk factors most predictive of life-threatening complications were the presence of a third heart sound (S<sub>3</sub>) or jugular vein distention (11 points) or a myocardial infarction in the previous 6 months (10 points).

Characteristic	APACHE II Score	Points
<b>Demographics</b>		
Age older than 70 y	0.100	0
Major cardiac disease on preoperative exam	0.200	2
<b>Physical Examination</b>		
3rd heart sound present on auscultation	0.100	1
Respiratory distress on preoperative exam	0.100	1
<b>Medical History</b>		
Myocardial infarction within 6 months preoperative	0.200	2
Myocardial infarction 6-12 months preoperative	0.100	1
Myocardial infarction >12 months preoperative	0.050	0.5
Myocardial infarction on preoperative exam	0.100	1
<b>Operative Factors</b>		
Emergency operation	0.100	1
Major operation	0.100	1
Emergency major operation	0.100	1

APACHE II, Acute Physiology and Chronic Health Evaluation II. (From ref. 6, with permission.)

**TABLE 15-9.** Computation of the Cardiac Risk Index

Class	No. of Patients	Post-Op Complications (n=93)	Life-Threatening Complications (n=29)	Cardiac Death (n=7)
I	27	4 (15%)	1 (4%)	1 (4%)
II	33	20 (61%)	16 (48%)	3 (9%)
III	38	32 (84%)	25 (66%)	3 (8%)
IV	3	1 (33%)	1 (33%)	0 (0%)

Detected intraoperative or postoperative myocardial infarction, pulmonary edema, or ventricular arrhythmia without preoperative cardiac risk. (Adapted from ref. 6.)

**TABLE 15-10.** Cardiac Risk Index

A recent myocardial infarction significantly increases the incidence of reinfarction and cardiac death associated with surgery ([Table 15-11](#)). Significant improvements have occurred as new techniques of anesthetic monitoring and hemodynamic support have been developed.<sup>14,15 and 16</sup>

Time from MI to Operation (mo)	Incidence of Reinfarction*		
	Topkins and Aronoff <sup>14</sup> (1959-1963)	Tarhan et al. <sup>15</sup> (1975-1976)	Rao et al. <sup>16</sup> (1976-1982)
0-3	12/22 (55%)	3/8 (37%)	3/52 (6%)
4-6		3/19 (16%)	2/36 (2%)
7-12	9/36 (25%)	2/24 (5%)	1/104 (1%)
>12	—	(5%)	(1%)

MI, myocardial infarction. \*The incidence of MI in patients with no previous evidence of an MI is approximately 0.5%.

**TABLE 15-11.** Incidence of Perioperative Myocardial Infarction in Patients with a Previous Myocardial Infarction

The impact of general health status on operative mortality is seen when operative mortality as a function of age is analyzed. Palmberg Hirsjarvi<sup>17</sup> studied the postoperative mortality of 17,199 patients undergoing general surgical procedures. The overall mortality rate of patients younger than age 70 was 0.25%, as compared with 9.2% for patients older than 70. In these elderly patients, the operative mortality rate for emergency operations was 36.8%, as compared with 7.8% for elective surgical procedures. The four leading causes of operative mortality that accounted for approximately 75% of all postoperative deaths in this age group were pulmonary embolism, pneumonia, cardiovascular collapse, and the primary illness itself.

More recently, Hoskings et al.<sup>18</sup> reviewed the outcome of surgery performed on 795 patients aged 90 or older. Surgery was generally well tolerated. As with younger

patients, the ASA classification was an important predictor of outcome.

Cancer is often a disease of the elderly, and there is sometimes a tendency to avoid even curative major surgery for cancer in patients of advanced age. In the United States and in most Western countries, life expectancies for the elderly have increased substantially. The average life expectancies for 80-year-old men and women in the United States are 7 and 9.1 years, respectively.<sup>19</sup> The 5-year expected survival rates of 90-year-old men and women are 30% and 39.8%, respectively; for 95-year-olds, the rates are 16.5% and 23.2%, respectively. Thus, even in the very old cancer patient, aggressive curative surgery can be warranted.

Reports of most surgical series include an account of operative mortality and operative complications. These results, combined with a consideration of the general health status of the patient, allow a reasonable estimate of the operative mortality for any given surgical intervention in the treatment of cancer.

## ROLES FOR SURGERY

### PREVENTION OF CANCER

Because surgeons are often the primary providers of medical care, they are responsible for educating patients about carcinogenic hazards and about direct surgical intervention for the prevention of cancer. All surgical oncologists should be aware of the high-risk situations that require surgery to prevent subsequent malignant disease.

Underlying conditions or congenital or genetic traits are associated with an extremely high incidence of subsequent cancer. When these cancers are likely to occur in nonvital organs, it is necessary to remove the offending organ to prevent subsequent malignancy.<sup>20</sup> Examples of diseases associated with a high incidence of cancer that can be prevented by prophylactic surgery are presented in [Table 15-12](#). An excellent example is presented by patients with the genetic trait for multiple polyposis of the colon. If colectomy is not performed in these patients, approximately one-half will develop colon cancer by the age of 40. By age 70, virtually all patients with multiple polyposis will develop colon cancer.<sup>20</sup> It is, therefore, advisable for all patients containing the mutant gene for multiple polyposis to undergo prophylactic colectomy before age 20 to prevent these cancers.

Underlying Condition	Associated Cancer	Prophylactic Surgery
Cryptorchidism	Testicular	Orchiopexy
Polyposis coli	Colon	Colectomy
Familial colon cancer	Colon	Colectomy
Ulcerative colitis	Colon	Colectomy
Multiple endocrine neoplasia types 2 and 3	Medullary cancer of the thyroid	Thyroidectomy
Familial breast cancer	Breast	Mastectomy
Familial ovarian cancer	Ovary	Oophorectomy

**TABLE 15-12.** Conditions in Which Prophylactic Surgery Can Prevent Cancer

In this situation, as for many of the other familial conditions associated with a high incidence of cancer, the surgeon has a responsibility for alerting the family to the hereditary nature of the disorder and its possible occurrence in other family members. Another disease associated with a high incidence of cancer of the colon is ulcerative colitis. Approximately 40% of patients with total colonic involvement ultimately die of colon cancer if they survive the ulcerative colitis.<sup>21</sup> Three percent of children with ulcerative colitis develop cancer of the colon by the age of 10, and 20% develop cancer during each ensuing decade.<sup>22</sup> Colectomy is indicated for patients with ulcerative colitis if the chronicity of this disease is well established.

Other disorders that require early treatment to prevent subsequent cancers include cryptorchidism and multiple endocrine neoplasia. Cryptorchidism is associated with a high incidence of testicular cancer that probably can be prevented by early prophylactic surgery.

In the past, patients with multiple endocrine neoplasia type 2a (MEN 2a) were screened for the presence of C-cell hyperplasia and calcitonin secretion using pentagastrin stimulation tests to determine the possible need for prophylactic surgery to prevent the occurrence of medullary thyroid cancer. Recent studies using polymerase chain reaction–based direct DNA testing for mutations in the *RET* protooncogene have shown it to be the preferred method for screening MEN 2a kindreds to identify individuals in whom total thyroidectomy is indicated, regardless of the plasma calcitonin levels.<sup>23</sup>

A more complex example of the role of surgery in cancer prevention involves women at high risk for breast cancer. Because the risk of cancer in some women is increased substantially over the normal risk (but does not approach 100%), counseling is required. Women in this situation must carefully balance the benefits and risks of prophylactic mastectomy. A careful understanding of the factors involved in increased breast cancer incidence is essential for the surgical oncologist to provide sound advice in this area. Statistical techniques can provide approximations of the risk for patients, depending on the frequency of disease in the family history, the age at the first pregnancy, and the presence of fibrocystic disease. For example, a woman who has a family history of breast cancer in a sister or mother, has fibrocystic disease, and is nulliparous or had a first pregnancy at a late age has an 18% probability of developing breast cancer over a 5-year period.<sup>20</sup> These estimates can be of value in advising women about prophylactic mastectomy.

### DIAGNOSIS OF CANCER

The major role of surgery in the diagnosis of cancer lies in the acquisition of tissue for exact histologic diagnosis. The principles underlying the biopsy of malignant lesions vary, depending on the natural history of the tumor under consideration. Various techniques exist for obtaining tissues suspected of malignancy, including aspiration biopsy, needle biopsy, incisional biopsy, and excisional biopsy.

*Aspiration biopsy* involves the aspiration of cells and tissue fragments through a needle that has been guided into the suspect tissue. Cytologic analysis of this material can provide a tentative diagnosis of the presence of malignant tissue. However, major surgical resections should not be undertaken solely on the basis of the evidence of aspiration biopsy. Even the most experienced cytologist can mistake inflammatory or benign reparative changes for malignant cells. This error is inherent in the uncertainties of an individual cell analysis and, even in the best of hands, provides an error rate substantially higher than that of standard histologic diagnosis.

*Needle biopsy* refers to obtaining a core of tissue through a specially designed needle introduced into the suspect tissue. The core of tissue provided by needle biopsies is sufficient for the diagnosis of most tumor types. Soft tissue and bony sarcomas often present major difficulties in differentiating benign and reparative lesions from malignancies and often cannot be diagnosed accurately. If these latter lesions are considered in the diagnosis, attempts should be made to obtain larger amounts of tissue than are possible from a needle biopsy.

*Incisional biopsy* refers to removal of a small wedge of tissue from a larger tumor mass. Incisional biopsies often are necessary for diagnosing large masses that require major surgical procedures for even local excision. Incisional biopsies are the preferred method of diagnosing soft tissue and bony sarcomas because of the magnitude of the surgical procedures necessary to extirpate these lesions definitively. The treatment of many visceral cancers cannot be undertaken without an incisional biopsy, but be aware of opening new tissue planes contaminated with tumor by performing excisional biopsies for large lesions. An inappropriately performed excisional biopsy can compromise subsequent surgical excision. When this is a possibility, incisional biopsies should be performed.

In excisional biopsy, an excision of the entire suspected tumor tissue with little or no margin of surrounding normal tissue is done. Excisional biopsies are the procedure of choice for most tumors if they can be performed without contaminating new tissue planes or further compromising the ultimate surgical procedure.

The following principles guide the performance of all surgical biopsies:

1. Needle tracks or scars should be placed carefully so that they can be conveniently removed as part of the subsequent definitive surgical procedure. Placement of biopsy incisions is extremely important, and misplacement often can compromise subsequent care. Incisions on the extremity generally should be placed longitudinally so as to make the removal of underlying tissue and subsequent closure easier.
2. Care should be taken not to contaminate new tissue planes during the biopsy. Large hematomas after biopsy can lead to tumor spread and must be scrupulously avoided by securing excellent hemostasis during the biopsy. For biopsies on extremities, the use of a tourniquet may help in controlling bleeding. Instruments used in a biopsy procedure are another potential source of contamination of new tissue planes. It is not uncommon to take biopsy samples from several suspected lesions at one time. Care should be taken not to use instruments that may have come in contact with tumor when obtaining tissue from a potentially uncontaminated area.
3. Choice of biopsy technique should be made carefully to obtain an adequate tissue sample for the needs of the pathologist. For the diagnosis of selected tumors, electron microscopy, tissue culture, or other techniques may be necessary. Sufficient tissue must be obtained for these purposes if diagnostic difficulties are anticipated.
4. Handling of the biopsy tissue by the pathologist is also important. When the orientation of the biopsy specimen is important for subsequent treatment, the surgeon should mark distinctive areas of the tumor carefully to facilitate subsequent orientation of the specimen by the pathologist. Certain fixatives are best suited to specific types or sizes of tissue. If all biopsy specimens are placed in formalin immediately, the opportunity to perform valuable diagnostic tests may be lost. The handling of excised tissue is the surgeon's responsibility. Biopsy tissue obtained from breast cancer lesions, for example, should be saved for estrogen receptor studies and placed in cold storage until ready for processing.

Surgery also has a role in diagnosing pathologic states in cancer patients that do not directly involve the diagnosis of cancer. Cancer patients often are immunosuppressed by their disease or their treatment and are subject to opportunistic infections not commonly seen in most general surgical patients. Open lung or liver biopsies are often important in diagnosing these lesions adequately and in planning suitable therapy.

Oncologists are becoming increasingly aware of the need for precise staging of patients when planning treatment. Lack of proper staging information can lead to poor treatment planning and compromise the ability to cure patients. Staging laparotomy can be important in determining the exact extent of spread of lymphomas.

In performing accurate surgical staging, the surgeon must be familiar with the natural history of the disease under consideration. The development of ovarian cancer treatment is an excellent example. The tendency of ovarian cancer to metastasize to the undersurface of the diaphragm is a good example of the need to obtain a biopsy of an anatomic site that would not normally be subjected to biopsy by most surgeons. Extensive surgical staging may be required before undertaking other major surgical procedures with curative intent. For example, biopsy of the celiac and paraaortic lymph nodes in patients with cancer of the esophagus is often important so that unnecessary esophageal resections can be avoided.

Placement of radioopaque clips during biopsy and staging procedures is important to delineate areas of known tumor and as a guide to the subsequent delivery of radiation therapy to these areas.

## TREATMENT OF CANCER

Surgery can be a simple, safe method to cure patients with solid tumors when the tumor is confined to the anatomic site of origin. When patients with solid tumors present to the physician for the first time, approximately 70% already have micrometastases beyond the primary site. The extension of the surgical resection to include areas of regional spread can cure some of these patients, although regional spread often is an indication of undetectable distant micrometastases.

The emergence of effective nonsurgical therapies has had a profound impact on the treatment of cancer patients and on the role and responsibilities of the surgeon treating the cancer patient. John Hunter, a brilliant eighteenth-century surgeon, characterized surgery as being "like an armed savage who attempts to get that by force which a civilized man would get by strategem."

Although surgery continues to be the most important aspect of the treatment of most patients presenting with solid tumors, modern clinical research in oncology has been devoted to applying other adjuvant "strategems" to improve the cure rates of those 70% in whom surgical therapy alone ultimately fails. The role of surgery in the treatment of cancer patients can be divided into six separate areas: (1) definitive surgical treatment for primary cancer, selection of appropriate local therapy, and integration of surgery with other adjuvant modalities; (2) surgery to reduce the bulk of residual disease (e.g., Burkitt's lymphoma, ovarian cancer); (3) surgical resection of metastatic disease with curative intent (e.g., pulmonary metastases in sarcoma patients, hepatic metastases from colorectal cancer); (4) surgery for the treatment of oncologic emergencies; (5) surgery for palliation; and (6) surgery for reconstruction and rehabilitation. In each area, interactions with other treatment modalities can be essential for a successful outcome.

### Primary Cancer

There are three major challenges confronting the surgical oncologist in the definitive treatment of solid tumors: accurate identification of patients who can be cured by local treatment alone; development and selection of local treatments that provide the best balance between local cure and the impact of treatment morbidity on the quality of life; and development and application of adjuvant treatments that can improve the control of local and distant invasive and metastatic disease. The selection of the appropriate local therapy to be used in cancer treatment varies with the individual cancer type and the site of involvement. In many instances, definitive surgical therapy that encompasses a sufficient margin of normal tissue is sufficient local therapy. The treatment of many solid tumors falls into this category, including the wide excision of primary melanomas in the skin that can be cured locally by surgery alone in approximately 90% of cases. The resection of colon cancers with a 5-cm margin from the tumor results in anastomotic recurrences in fewer than 5% of cases.

In other instances, surgery is used to obtain histologic confirmation of diagnosis, but primary local therapy is achieved through the use of a nonsurgical modality, such as radiation therapy. Examples include the treatment of Ewing's sarcoma in long bones and the treatment of selected primary malignancies in the head and neck. In each instance, selection of the definitive local treatment involves careful consideration of the likelihood of cure balanced against the morbidity of the treatment modality.

The magnitude of surgical resection is modified in the treatment of many cancers by the use of adjuvant treatment modalities. Rationally integrating surgery with other treatments requires a careful consideration of all effective treatment options. The surgical oncologist must be thoroughly familiar with adjuncts and alternatives to surgical treatment. It is a knowledge of this rapidly changing field that separates the surgical oncologist from the general surgeon most distinctly.

In some instances, effective adjuvant modalities have led to a decrease in the magnitude of surgery. The evolution of childhood rhabdomyosarcoma treatment is a striking example of the successful integration of adjuvant therapies with surgery in the treatment of cancer.<sup>24,25</sup> Childhood rhabdomyosarcoma is the most common soft tissue sarcoma in infants and children. Before 1970, surgery alone was used almost exclusively, and 5-year survival rates of 10% to 20% were commonly reported. Local surgery alone failed in patients with rhabdomyosarcomas of the prostate and extremities because of extensive invasion of surrounding tissues and the early development of metastatic disease. The failure of surgery alone to control local disease in patients with childhood rhabdomyosarcoma led to the introduction of adjuvant radiation therapy. This resulted in a marked improvement in local control rates that was further improved dramatically by the introduction of combination chemotherapy with vincristine, dactinomycin, and cyclophosphamide. Long-term cure rates are in the range of 80%. Many other examples of the integration of surgery with other treatment modalities appear throughout this book.

### Residual Disease

The concept of cytoreductive surgery has received much attention in recent years.<sup>26,27</sup> In some instances, the extensive local spread of cancer precludes the removal of all gross disease by surgery. The surgical resection of bulk disease in the treatment of selected cancers may well lead to improvements in the ability to control residual gross disease that has not been resected. Studies that suggest the merit of this approach are discussed in [Chapter 45](#) and [Chapter 36](#) (Burkitt's lymphoma and ovarian cancer, respectively).

Enthusiasm for cytoreductive surgery has led to the inappropriate use of surgery for reducing the bulk of tumor in some cases. Clearly, cytoreductive surgery is of benefit only when other effective treatments are available to control the residual disease that is unresectable. Except in rare palliative settings, there is no role for

cytoreductive surgery in patients for whom little other effective therapy exists.

### **Metastatic Disease**

The value of surgery in the cure of patients with metastatic disease tends to be overlooked. As a general principle, patients with a single site of metastatic disease that can be resected without major morbidity should undergo resection of that metastatic cancer. Many patients with few metastases to lung or liver or brain can be cured by surgical resection. This approach is especially true for cancers that do not respond well to systemic chemotherapy. The resection of pulmonary metastases of soft tissue and bony sarcomas can cure disease in as many as 30% of patients. As effective systemic therapy is developed for the treatment of these diseases, cure rates may increase. Studies have shown that similar cure rates occur in patients with adenocarcinomas when resected metastatic disease to the lung is the sole clinical site of metastases. Small numbers of pulmonary metastases often are the only clinically apparent metastatic disease in patients with sarcomas. However, this is rare in the natural history of most adenocarcinomas. If solitary metastases to the lung do occur in patients with carcinoma of the colon or other adenocarcinomas, surgical resection is indicated.

Similarly, there is increasing enthusiasm for the resection of hepatic metastases, especially from colorectal cancer, in patients in whom the liver is the only site of known metastatic disease. In patients with solitary hepatic metastases from colorectal cancer, resection can lead to long-term cure in approximately 25%. This far exceeds the cure rates of any other available treatment.

The resection for cure of solitary brain metastases should also be considered when the brain is the only site of known metastatic disease. The exact location and functional sequelae of resection should be considered when making this treatment decision.

### **Oncologic Emergencies**

As in the treatment of all patients, emergencies arise for oncologic patients that require surgical intervention. These generally involve the treatment of exsanguinating hemorrhage, perforation, drainage of abscesses, or impending destruction of vital organs. Each category of surgical emergency is unique and requires an individual approach.

The oncologic patient often is neutropenic and thrombocytopenic and has a high risk of hemorrhage or sepsis. Perforations of an abdominal viscus can result from direct tumor invasion or from tumor lysis resulting from effective systemic treatments. Perforation of the gastrointestinal tract after effective treatment for lymphoma involving the intestine is not uncommon. The ability to identify patients at high risk for perforation may lead to the use of surgery to prevent this problem. Surgery to decompress cancer invading the central nervous system represents another surgical emergency that can lead to preservation of function.

### **Palliation**

Surgical resection often is required for the relief of pain or functional abnormalities. The appropriate use of surgery in these settings can improve the quality of life for cancer patients. Palliative surgery may include the relief of mechanical problems, such as intestinal obstruction, or the removal of masses that are causing severe pain or disfigurement.

### **Reconstruction and Rehabilitation**

Surgical techniques are being refined that aid in the reconstruction and rehabilitation of cancer patients after definitive therapy. The ability to reconstruct anatomic defects can substantially improve function and cosmetic appearance. The development of free flaps using microvascular anastomotic techniques is having a profound impact on the ability to bring fresh tissue to resected or heavily irradiated areas. Lost function (especially of extremities) often can be rehabilitated by surgical approaches. This includes lysis of contractures or muscle transposition to restore muscular function that has been damaged by previous surgery or radiation therapy.

## **THE SURGICAL ONCOLOGIST**

Several factors have led to a recent increase in the development of surgical oncology and to the organization of separate sections of surgical oncology in large hospitals and departments of surgery within universities. This enthusiasm derives from the recognition that modern oncologic management requires levels of expertise in cancer surgery, chemotherapy, and radiation therapy that are not common to most general surgeons and from a desire to use effectively the resources being committed to cancer care and research by hospitals, private foundations, and the federal government. A sense of urgency has existed because some surgical leaders believe that the surgeon is experiencing a declining intellectual role in modern cancer treatment and research and that steps must be taken to reassert the surgeon's role in modern oncology.

Many surgeons have resisted the development of surgical oncology as a specialty area because of the fear of fragmenting the field of general surgery. A survey of 124 university surgery departments in the United States between January and July of 1985 revealed that 38% had formal divisions of surgical oncology, compared with the divisions of medical oncology present in 95%, radiation oncology in 94%, pediatric oncology in 76%, and gynecologic oncology in 79%.<sup>28</sup> Of the 47 divisions of surgical oncology that did exist, only 13 (28%) had formal clinical training programs in surgical oncology.<sup>28</sup> This lack of emphasis on surgical oncology at universities may be a factor in the decreasing success of surgeons in obtaining grant support from the National Cancer Institute. From 1980 to 1985, an analysis of 6407 applications submitted from clinical departments of medical schools for peer-reviewed grants revealed that 44% were submitted from departments of medicine and only 16% from departments of surgery.<sup>29</sup> Thirty-four percent of applications submitted from departments of medicine were awarded, compared with 25% from departments of surgery.<sup>29</sup> The publication of research in major surgical journals appears to be decreasing.<sup>30</sup>

The development of surgical oncology as a specialty area of surgery depends on a clear delineation of its role. There are six major areas in which the modern surgical oncologist can play a valuable role in the care of cancer patients at major treatment centers<sup>31</sup>:

- Organizing surgical oncology teaching programs for staff, residents, and students
- Providing expert consultation for unusual or difficult oncologic patient problems
- Providing unique surgical expertise in surgical cases unfamiliar to general surgeons (e.g., major soft tissue resections, exenterations, head and neck resections, isolation perfusions)
- Organizing clinical research protocols for surgical oncology patients
- Coordinating surgical oncology efforts with medical and radiation oncologists
- Conducting experimental research programs in oncology where possible

The rapid development of new information in surgery, chemotherapy, and medical oncology and of newer disciplines of immunotherapy, hyperthermia, and phototherapy requires the continuing education of all surgical staff. Surgical oncologists maintain close contact with all these areas and should be responsible for teaching programs for general surgical staff, residents, and students.

Because of the unique training and exposure to oncologic problems, the surgical oncologist has expertise in dealing with unusual or difficult oncologic patient problems and can provide expert consultation in these areas. The surgical oncologist is trained to perform many types of surgical procedures not commonly performed by general surgeons. Although most surgeons are able to perform many of the standard cancer resections, some operations are not performed frequently by general surgeons and can be performed better by a specialist in surgical oncology.

In most hospital settings, general surgeons operate on cancer patients. It is often essential, however, that patients receiving care for various cancers enter clinical protocols that help to answer important questions related to the treatment of that cancer. The surgical oncologists can help to organize clinical research protocols for surgical oncology patients treated by all surgeons at that institution. A large surgical group should have a surgical specialist capable of coordinating efforts with medical and radiation oncologists. Successful coordination with these nonsurgical specialists requires expertise in medical oncology and radiation therapy that is not common among most general surgeons.

The surgical oncologist can also be involved in administering and defining the need for adjuvant treatments. Adjuvant chemotherapy commonly is administered by surgeons when the chemotherapy regimens use well-known single or combination agents. The future development of immunotherapies and other new adjuvant

treatments can be logically administered by surgical oncologists to their patients after recovery from the surgical procedure.

The surgical oncologist, when the situation allows, is in a position to perform experimental research in oncology that can lead to the introduction of new diagnostic and treatment regimens in clinical care. Laboratory research programs that contribute to basic knowledge of cancer biology also provide an important source of stimulation to residents and students.

The emergence of a subspecialty of surgical oncology within general surgery requires that special attention be given to the training of surgeons interested in pursuing this area of clinical care. Although it is generally agreed that all surgical oncologists should be well-trained general surgeons, attempts have been made to define additional areas of expertise that must be studied. In 1978, a group of surgical oncologists met under the sponsorship of the Society of Surgical Oncology and the Division of Cancer Research, Resources, and Centers of the National Cancer Institute to develop guidelines for the training of surgical oncologists. The guidelines adopted by this meeting include suggestions for such training<sup>32,33</sup>:

- Two-year training program on a surgical oncology service after completion of eligibility for general surgical certification by the American Board of Surgery or other surgical specialty board
- Training at an institution with a cancer program approved by the Commission on Cancer of the American College of Surgeons and whose clinical resources provide a sufficient variety and volume of clinical material to ensure exposure to a broad variety of clinical cancer problems
- Training at a center with sufficient basic science resources to provide education in these areas, with exposure to basic and clinical research
- Training at an institution that provides adequate operative experience, including standard curative and palliative procedures, with broad exposure to surgical procedures unique to the oncologic patient
- A full-time assignment during the training period to radiation oncology and chemotherapy services to allow the trainee to gain confidence and knowledge in these nonsurgical disciplines

These training recommendations are designed to provide general surgeons with the expertise in oncology and nonsurgical disciplines necessary to bring the best aspects of all disciplines of modern oncology to the care of the cancer patient.

### INTRODUCTION

To understand the practice of radiation therapy, one must seek its roots in principles derived from three separate areas. The first is practical radiation physics, which must be understood much as the surgeon understands the use of the equipment available in the operating room and as the internist understands the pharmacologic basis of therapeutics. The basic concepts of physics necessary to consider radiation therapy in the disease-related chapters of this textbook are introduced in this chapter.

The second important discipline to be understood is cell, tissue, and tumor biology. This chapter describes the fundamental principles of radiation biology and cell kinetics. These two discussions provide the rudiments of cell biology necessary to understand the uses of radiation.

A large clinical experience in radiation use has resulted in certain principles of treatment. These are discussed separately and are related to the physical and biologic concepts that may underlie their success.

### PHYSICAL CONSIDERATIONS

Only the most important concepts of the physics of ionizing radiation can be discussed in this chapter. If more detailed information is needed, a standard textbook of radiation physics is a more appropriate source of information.<sup>1</sup>

Ionizing radiation is energy that, during absorption, causes the ejection of an orbital electron. A large amount of energy is associated with ionization. Ionizing radiation can be considered as a wave and as a packet of energy (a photon). The packet of energy is large enough to cause ionizations, and these are distributed unevenly through tissue. Examples of particulate radiation are the subatomic particles: electrons, protons,  $\alpha$  particles, neutrons, negative pi mesons, and atomic nuclei. All of these have been experimentally considered or are being used in radiation therapy.

### ELECTROMAGNETIC RADIATION

Electromagnetic radiation consists of roentgen and gamma radiation. They differ only in the way in which they are produced: Gamma rays are produced intranuclearly, and roentgen rays are produced extranuclearly. In practice, this means that gamma rays used in radiation therapy are produced by the decay of radioactive isotopes and that almost all of the roentgen rays used in radiation therapy are made by electrical machines. Exceptions are roentgen rays produced by orbital electron rearrangements, as in the decay of iodine 125 ( $^{125}\text{I}$ ), which is a radioactive isotope but produces photons by extranuclear processes.  $^{125}\text{I}$  also emits a small number of gamma rays from the nucleus.

The intensity of electromagnetic radiation dissipates as the inverse square of the distance from the source. The dose of radiation 2 cm from a point source is 25% of the dose at 1 cm.

The relative prevalence of the three dominant absorption mechanisms of electromagnetic radiation depends on the energy of the radiation. The first is photoelectric absorption, which predominates at lower energies. In this circumstance, the photon interaction results in the ejection of a tightly bound orbital electron. The vacancy left in the atomic shell is then filled by another electron falling from an outer shell of the same atom or from outside the atom. All or most of the photon energy of the transition is lost in this process. Photoelectric absorption varies with the cube of the atomic number ( $Z^3$ ). This fact has significant practical implications because it explains why materials with high atomic numbers, such as lead, are such effective shielding materials. It also means that bones absorb significantly more radiation than soft tissues at lower photon energies, the basis for conventional diagnostic radiology.

The second type of radiation absorption is the Compton type. In this process, the photon interaction is with a distant orbital electron that has a low binding energy. In this absorptive process, the photon does not give up all its energy to a single electron; an appreciable portion reappears as a secondary photon, which is created in the interaction. In contrast to the photoelectric effect, the probability of Compton absorption does not depend much on atomic number, but rather on electron density. This explains why films made at supervoltage energy do not show much difference between bone and soft tissue, but air cavities are clearly distinguished.

The third type of absorption is the pair production process. This type of absorption requires an incident photon energy greater than 1.02 MeV. In this process, positive and negative electrons are produced at the same time.

The fundamental quantity necessary to describe the interaction of radiation with matter is the amount of energy absorbed per unit mass. This quantity is called *absorbed dose*, and the rad was the most commonly used unit. Absorbed dose is measured in joules per kilogram; another name for 1 J/kg is the gray (1 Gy = 100 rad), which is now the recommended unit. The roentgen (R) is a unit of roentgen rays, or gamma rays, based on the ability of radiation to ionize air. At the energies used in radiation therapy, 1 R of roentgen rays, or gamma rays, results in a dose of somewhat less than 1 rad (0.01 Gy) in soft tissue.

The different ranges of electromagnetic radiations used in clinical practice are superficial radiation, or roentgen rays from approximately 10 to 125 keV; orthovoltage

radiation, or electromagnetic radiation between 125 and 400 keV; and supervoltage, or megavoltage, radiation for energies of more than 400 keV. There are important differences between these classes. As energy increases, the penetration of the roentgen rays increases ( Fig. 16-1), and at supervoltage energies, absorption in bone is not higher than that in surrounding soft tissues, as is the case with lower energies. This is because at supervoltage energies, Compton absorption predominates. Compared with orthovoltage, supervoltage radiation is skin sparing, meaning that the maximum dose is not reached in the skin, but instead occurs below the surface. The electrons created in the interaction travel some distance and do not attain full intensity until they reach some depth, resulting in a reduced dose to the skin. With orthovoltage radiation, the skin frequently is the dose-limiting normal tissue.

**FIGURE 16-1.** Relative dose at different depths for various types of ionizing radiation.

## RADIATION TECHNIQUES

Two general types of radiation techniques are used clinically: brachytherapy and teletherapy. In brachytherapy, the radiation device is placed within or close to the target volume. Examples of this are interstitial and intracavitary radiation used in the treatment of many gynecologic and oral tumors. Teletherapy uses a device located at a distance from the patient, as is the case with supervoltage machines.

Because the radiation source is close to or within the target volume with brachytherapy, the dose is determined largely by inverse-square considerations. This means that the geometry of the implant is important. Spatial arrangements have been determined for different types of applications based on the particular anatomic considerations of the tumor and important normal tissues. An example of isodose distribution around an intracavitary application for carcinoma of the cervix is shown in Figure 16-2. The dose decreases rapidly as the distance from the applicator increases. This emphasizes the importance of proper placement. The applicator pictured is used to treat the cervix, uterus, and important paracervical tissues while limiting excessive irradiation of the bladder and rectum in front of and behind the tumor.

**FIGURE 16-2.** Isodose distribution around an intrauterine radium (Ra) applicator. **A:** Anteroposterior view. **B:** Lateral view.

Historically, the removable interstitial and intracavitary sources used were radium and radon, the latter primarily for permanent implants. Marie Curie, the discoverer of radium, recognized its importance early and championed the medical use of these isotopes. They were important tools in early cancer therapy but now have been largely replaced by man-made isotopes, which overcome most of the disadvantages of the naturally occurring ones.

Initially, even removable isotopes were used by directly applying the isotope, thereby exposing the operator to significant radiation doses. This problem has largely been circumvented through the use of cesium 137, iridium 192, and cobalt 60. The iridium and cesium have a lower energy and are much easier to shield. Afterloading techniques are used for removable implants as often as possible. Receptacles for the radioactive material are placed in the patient in the form of needles, tubes, or intracavitary applicators. When they have been satisfactorily placed, they are afterloaded with the radiation sources. Remote afterloading using high-intensity sources whose dwell time is determined for a particular dose distribution is now a common treatment method. Permanent implants are primarily done today with gold 198 and  $^{125}\text{I}$  and palladium 109.

Typical teletherapy isodose distributions are shown in Figure 16-3. The dose depends on inverse-square considerations and tissue absorption. The distribution of radiation depends on characteristics of the machine and the patient. The isodose curve depends on the energy of radiation, the distance from the source of radiation, and the density and atomic number of the absorbing material. The beam of radiation produced in typical radiation treatment may be modified to make isodose distributions conform to the specific target volume, and individually designed shields are used to protect vital normal tissues.

**FIGURE 16-3.** Isodose distributions for 4 MeV without **(A)** and with **(B)** a wedge filter.

Figure 16-4 shows some radiation treatment plans in which the target volumes are depicted. This volume contains the tumor and the normal tissues intimately involved with the tumor. The diagram also contains the transited normal tissues, or transit volume. The purpose of the treatment plan is to maximize the dose to the target volume and minimize the dose to the transit volume. It is important that the tumor dose is relatively homogenous, because the maximum dose in the target volume is often the cause of complications, and the minimum dose in the target volume determines the likelihood of tumor recurrence. The volumes of interest in the

patient have been specified as the: gross tumor volume (GTV), clinical tumor volume, and planning target volume. The GTV is the clinically evidenced tumor volume, taking into account all diagnostic procedures. The clinical tumor volume is the GTV plus the volume considered at risk for microscopic extensions. The planning target volume includes the GTV and a margin for physiologic organ motion.

**FIGURE 16-4.** Typical supervoltage treatment plans for opposing fields (A), rotation (B), three fields (C), and wedge rotation (D).

## BEAM-MODIFYING DEVICES

In modern radiation therapy, teletherapy is given almost exclusively with supervoltage equipment. These radiations are produced by the decay of radioactive cobalt or with the production of roentgen rays in the range of 2 to 35 MeV (the most common are 4 to 8 MeV). High-energy photons and electrons are made by linear accelerators.

Regardless of the radiation source, the beam must be modified for clinical use. With electrical machines, the beam tends to have a much greater intensity in the center than on the sides. Modification to give a uniform dose of radiation across the beam is done with a flattening filter (unnecessary in cobalt units). For the beam to be limited to the designated size, collimators are placed in the head of the machine. These usually are made of materials that have a high  $Z$  value and can be varied to conform to the exact rectangular beam dimensions desired.

It is sometimes desirable for the beam to be more intense on one side than the other. This is especially important when fields at angles to each other are to be used. To modify the beam in this fashion, wedge filters are used (see [Fig. 16-3B](#)). These wedge-shaped pieces of metal absorb the beam differentially, depending on the thickness that produces the desired angled isodose curves.

The primary radiation beam is rectangular. This rectangle may be varied for individual patients using the secondary collimators in the head of the machine. These can then be further modified by individually constructed blocks shaped to the contour of the normal tissue ([Fig. 16-5](#)). The newest equipment has multileaf collimators, which permit the collimator to follow closely the desired portal contour, rather than being restricted to a rectangular shape. This type of collimator can be moved while the radiation beam is on, allowing the physicist to shape the dose distribution within each radiation field in a desired fashion. The result of multiple fields treated in such a fashion can greatly improve the dose distribution so that the transited normal tissue dose is greatly reduced. This is described in [Chapter 29.4](#).

**FIGURE 16-5.** A: A film made on a therapy simulator on which outlines for shielding blocks are drawn. B: Supervoltage portal film with blocks in place. C: Technique for checking accuracy of the blocks with simulator films.

## RADIATION TREATMENT

Once the decision has been made to treat a patient with radiation, pretreatment procedures must be performed. First, the target volume must be accurately localized and the dose-limiting, transited normal tissues must be determined. This localization requires physical examination, radiography, ultrasonography, computed tomography (CT), and other diagnostic procedures. Before this step, the clinician must understand the natural history of the disease and its patterns of spread.

Once localization has been completed, the treatment planning process begins, in which alternative techniques of treatment are considered. The selection of the appropriate treatment plan is made by the clinician in consultation with the radiologic physicist and dosimetrist. This team effort must consider the best beam distribution, homogeneity within the target volume, and appropriate minimizing of dose in the transit volume.

Once the appropriate treatment plan has been accepted, the technique is tested using a radiation simulator. This device mimics the treatment machine but produces superficial radiation that can be used for direct imaging with an image intensifier and for producing radiographs that delineate exactly the beam location. Treatment simulation often causes modifications to be made in the treatment plan, allowing further sparing of normal tissues. Simulator films must be compared with the check, or portal, films made with the supervoltage machine, which confirm the treatment plan (see [Fig. 16-5](#)). Image quality is poor because these films do not distinguish bone from soft tissue. This is because supervoltage radiation is absorbed primarily by the Compton process, which does not depend on  $Z$ . In contrast, the simulator films are made with radiations of 80 to 110 keV, which are in the photoelectric range and therefore dependent on  $Z^3$ . Treatment planning and simulation are now greatly facilitated using a CT simulator. This single device combines CT image acquisition with treatment planning in the treatment position.

**FIGURE 16-6.** Electron and superficial roentgen ray depth–dose curves.

For the treatment to be applied as designed on the radiation simulator, proper immobilization and marking techniques must be used. These also ensure that daily treatments are given to the same volume. Markings on the patient's skin may be temporary or permanent. Usually, temporary marks are used to supplement the permanent small dots, or “tattoos,” ensuring that the treatment is given to the same volume each day. Should the patient require further therapy at a later date, these markings accurately indicate the location of previous treatment portals. Within the treatment room, light localizers describe the outline of the field, and small laser dots are used to check whether the patient is in the correct position. Immobilization of the patient usually is achieved by devices made of foam, plastic, plaster, and other materials that can be made to conform to each patient's anatomy. It is most important that the patient be put in a position that is comfortable and easily reproduced from day to day.

## ELECTRON THERAPY

Electrons differ greatly in their characteristic depth-dose distributions ( [Fig. 16-6](#)). The maximum dose is reached and followed by a prompt fall. Little skin sparing is possible with electron beam therapy. It is the most useful radiation in the treatment of superficial tumors because the deeper tissue is spared by the prompt fall in the radiation dose. With higher electron energy, the penetration is greater and the fall in depth dose not as steep. A major problem with electrons is that absorption can be modified greatly by bone or air-containing tissues. Bone greatly reduces the depth dose because it absorbs much more of the radiation; the contrary is true for air-containing spaces.

Currently there is a great deal of interest in proton therapy, which is discussed in more detail in [Chapter 65](#).

## BIOLOGIC CONSIDERATIONS

### RADIATION INTERACTION WITH BIOLOGIC MATERIALS

Because mammalian cells may be considered dilute aqueous solutions, there are two possible mechanisms of interaction with biologically important molecules—the direct effect of radiation on the important target molecule, and the indirect effect produced by intermediary radiation products. For most events, the important target molecule is thought to be the DNA, and when considering the maintenance of reproductive integrity, it is useful to assume that DNA is the target. Whatever the critical target, it can be affected directly by ionizing radiation that causes a change in the molecular structure of the biologically important molecule. This direct effect is most common for high linear energy transfer (LET) radiation. Alternatively, the photon may interact with water, the predominant molecule in these dilute solutions, to produce free radicals. All of these forms of radiation are short-lived; they can interact with biologically important material, causing a detrimental effect, or they can react innocently and revert to their former state. The likelihood of interaction or reversion can be modified by reaction with molecular oxygen, which favors prolonging the life of a reactive species, or by reaction with sulfhydryl compounds, which reduces the lifespan of the free radicals by combining with them to return to innocuous substances.

### CELL SURVIVAL CONSIDERATIONS

Radiation effects, whether direct or indirect, are random, an important principle in the general nature of cell killing. The biologically important effects of radiation therapy are those concerned with reproductive integrity. It usually is assumed that DNA is the critical target for this radiation effect, although it has not been proved with certainty. Other biologically important effects of radiation (e.g., edema) are far more likely to be caused by its action on membranes.

At least four possible consequences of radiation interaction with cells can affect long-term reproductive viability of the cell or its progeny: necrosis, apoptosis, accelerated senescence, and terminal differentiation. Current research is focused on these different effects of radiation on cells.

A cell that is damaged by radiation and loses its reproductive integrity may divide once or more often before all the progeny are rendered reproductively sterile. Possible consequences to the cell include the following:

1. Rapid death by apoptosis.
2. It may die while trying to divide.
3. It may produce unusual forms as a result of aberrant attempts at division.
4. It may stay as it is, unable to divide, but physiologically functional for a long period. Such functional but sterile cells do not appear different from fertile cells. Some of these may be terminally differentiated cells.
5. It may divide, giving rise to one or more generations of daughter cells before some or all of the progeny become sterile. Those colonies in which some reproductively viable progeny emerge may then regrow.<sup>2</sup>
6. The cell may undergo no alterations in the divisional process or only minor ones.

Except for those cells undergoing apoptosis, some delay in division is usually produced, even in cells that are not damaged lethally.

### Survival Curves

Survival curves plot the fraction of cells surviving radiation against the dose given. Survival is determined by the ability to form a macroscopic colony. The simplest relation can be seen for bacteria in which survival is a constant exponential function of dose. The importance of this exponential relation is that, for a given dose increment, a constant proportion (rather than a constant number) of cells is killed. Because of the randomness of radiation damage, if there is, on average, one lethal lesion per cell, some cells have one lesion, some more than one, and some fewer than one. Under such circumstances, the proportion of cells that have fewer than one (i.e., no lethal events) is  $e^{-1}$ , or a survival fraction of 0.37. The dose required to reduce the survival fraction to 37% on the exponential curve is known as the  $D_{0.37}$ . This term is related to the slope of the exponential survival curve. If a smaller dose is required to reduce the survival fraction to 37%, the cells are more sensitive to radiation.

Survival curves of most mammalian cells differ from those of bacterial cells by having a “shoulder” in the low-dose region and the exponential relation at higher doses. This shoulder indicates a reduced efficiency of cell killing. Such an idealized curve is shown in [Figure 16-7](#), with the shorthand terminology used to describe survival curves. The terminal exponential portion is described by the  $D_{0.37}$ , whereas the initial shoulder region can be described by the extrapolation number  $n$  or the  $D_{0.37}$ , the quasi-threshold dose. The former is the number on the ordinate found when the exponential portion is extrapolated to 0 dose, whereas  $D_{0.37}$  is the dose at which the straight portion of the survival curve extrapolated backward intersects the line where the survival fraction is unity. If any two of these are known, the third can be calculated. The survival curve is described as follows:  $\log e^{-n} = D_q/D_{0.37}$ . This curve is best described by a linear quadratic model with the following formula<sup>3</sup>:

$$S = e^{-(\alpha D + \beta D^2)}$$

**FIGURE 16-7.** Idealized radiation survival curve.  $D_0$ , dose required to reduce the survival fraction to 37% on the exponential curve,  $D_q$ , the quasi-threshold dose,  $1/e$ , dose energy divided by dose loss.

The  $a$  and  $b$  terms in this equation and their ratio are used to describe survival curve characteristics and to classify cellular response to radiation. Survival curves have been determined for benign or neoplastic mammalian cells in culture. No general characteristics of tumor cells make them different from normal cells in culture. The survival curves for various human tumors thought to be sensitive and resistant to radiation were studied by Weichselbaum and colleagues,<sup>4</sup> who did not show any survival-curve characteristics that allow these two to be separated. Therefore, the differences in clinical response cannot be explained by simple acute differences in survival curves, although recurrent tumors have the radiobiologic characteristics of the more resistant subclones of the primary tumor.

Normal tissues also have been studied using clonogenic survival as an end point, with survival curves determined analogously to those for cells in tissue culture. The simplest clonal system, as originally described by Till and McCulloch,<sup>5</sup> is that used for murine bone marrow stem cells. When bone marrow cells are injected into lethally irradiated recipient animals, colonies are formed in the animals' spleens. These can be used to assess the reproductive integrity of the injected cells. The viability of the small intestinal clonogenic mucosal cells can be assessed by looking at sections of the small intestine at various times after irradiation and determining the appearance of colonies derived from cells surviving this radiation.<sup>6</sup> Using these and other techniques, the general properties of survival curves of normal and tumor cells are shown in Table 16-1. There are no characteristic differences in survival curves between normal tissues and tumors. Tumors generally resemble their normal tissue of origin in this respect.

Cell Type	How Determined	$D_0$ (Rad)	$n$	$D_q$ (Rad)
Hamster V-79 fibroblast	In vitro	150	7	250-300
Chang liver	In vitro	150	2	150
HeLa	In vitro	150	4	180
P80 leukemia	In vitro	150	8.5	280
Mouse bone marrow	In vivo	90-100	1.5-2.1	40
Mouse small intestine	In vivo	100	50	200
Mouse chondroblast	In vivo	160	9	350
Rat endothelium	In vivo	170	7	340

**TABLE 16-1.** Survival Curve Parameters for Some Mammalian Cells

### Repair of Radiation Damage

When cells are irradiated, lethal damage can occur, or the damage may be modified and not lead irrevocably to cell death. Such amelioration of radiation damage is called *repair*. Repair can be divided into potentially lethal damage repair and sublethal damage repair.

Potentially lethal damage, under certain circumstances, leads to cell death. If postirradiation conditions are modified to allow repair, cells that would have died can be salvaged. In general, postirradiation conditions that suppress cell division are the ones most favorable to repair of potentially lethal damage. The simplest example of this was shown first in bacteria for UV and x-radiation.<sup>7</sup> A similar effect was seen in mammalian cells and persists into the first few postirradiation generations.<sup>8,9</sup> and <sup>10</sup> Potentially lethal damage repair may be most important in relating the cell culture studies of human tumors to their clinical response. Weichselbaum and colleagues<sup>11</sup> have shown that osteogenic sarcoma, a tumor characteristically thought to be resistant to radiation, has a great capacity for potentially lethal damage repair compared with tumors that may be much more responsive to radiation. After irradiation in the clinical circumstance, the tumor cell may not be faced with the necessity of rapid cell division, and it may have the opportunity for potentially lethal damage repair.

One explanation for the shoulder of the radiation survival curve is that the cell can repair some of the radiation damage, including a great proportion of the damage incurred with low doses of radiation. This is called *sublethal damage*. Elkind and Sutton<sup>12</sup> have studied the shoulder and its return by using divided doses of radiation. They have shown that if the dose of radiation is divided into two fractions and a few hours elapse between radiation doses, the shoulder will return. Therefore, two doses of radiation separated in time are less effective than the same total dose given as a single dose. Both  $D_q$  and the  $a/b$  ratio measure similar characteristics of the survival curve. With the exception of the bone marrow stem cells, acutely responding normal tissues have a large  $D_q$  and a large  $a/b$  ratio. This suggests that multiple small fractions of radiation can preserve these tissues, but not bone marrow.

Varying the dose rate of radiation may be considered a form of radiation fractionation. When the dose rate is low, such as during interstitial or intracavitary irradiation, it can be considered as a large number of small doses on the shoulder of the survival curve.<sup>13</sup> Therefore, differences between the dose-limiting normal tissues and the tumor in their shoulder characteristics and differences in the break point between shoulder and steep exponential have great clinical implications for such continuous radiation.

Apoptosis is an important response to radiation in many cells.<sup>14</sup> The relative proportion of cells undergoing apoptosis rather than pausing in the cell cycle to repair radiation damage may be a very important determinant of the likelihood of the radiation curability of a tumor. Certain normal cells, such as lymphocytes and germ cells, show apoptosis with very small doses of radiation. The reciprocal nature of radiation repair and apoptosis may explain the correlation between potentially lethal damage repair and radiocurability; cells with a great capacity for potentially lethal damage repair have little apoptotic response to radiation. It may be the latter that is the determining characteristic. The loss of the apoptotic response seems to be correlated to tumor progression. A number of genes associated with oncogenesis affect the likelihood of a cell demonstrating programmed cell death after DNA damage, including Bcl-2, Bcl-x, and P53.<sup>15,16</sup> A variety of factors can induce or stimulate apoptosis,<sup>16</sup> including those stimulated by radiation.<sup>17</sup>

### Importance of Oxygen

The most important modifier of the biologic effect of ionizing irradiation is molecular oxygen. First noted in the 1920s, its importance was not realized until Mottram studied it systematically.<sup>18</sup> The general scientific community became aware of this phenomenon with the publications by Read<sup>19</sup> and Gray et al.<sup>20</sup> in the early 1950s. Figure 16-8 shows a survival curve for cells under aerobic and hypoxic conditions.<sup>21</sup> For equivalent cell killing at every level of survival, greater doses are required under hypoxic conditions compared with oxic conditions. There is some disagreement in the literature as to whether the dose ratio is the same throughout the survival curve. Most data suggest a smaller difference when low doses are used. A shorthand term, the *oxygen enhancement ratio* (OER), often is used. OER is the ratio of dose required for equivalent cell killing in the absence of oxygen compared with the dose required in the presence of oxygen. This term has most relevance on the exponential portion of the curve, because there appears to be a reduced shoulder on the survival curve of cells under hypoxic conditions.<sup>21</sup> Tumor cells allowed to

grow into physiologic hypoxia have reduced capacity to repair sublethal damage ( Fig. 16-9).

FIGURE 16-8. *In vivo* survival curves for oxalic and hypoxic tumor cells. (From ref. 21, with permission.)

FIGURE 16-9. *In vivo* curves comparing two-dose survival to single-dose survival for oxalic and hypoxic tumor cells. (From ref. 21, with permission.)

The OER range for different cells that have been studied varies from approximately 2.5 to 3.5. This means that, for reduction to a given survival level, three times as much radiation is required under hypoxic conditions as under oxalic conditions. Because the curves are exponential, the ratio of survival fractions increases with dose. For example, in Figure 16-8, at 1000 rad the ratio of survival is 30.

Study of the phenomenon reveals that oxygen must be present during irradiation. Figure 16-10 shows the relative radiosensitivity of cells as a function of the oxygen tension at the time of irradiation. A low oxygen tension must be reached before there is a protective effect of hypoxia. The exact mechanism of the oxygen effect has not been determined definitively. It is believed that oxygen affects the initial chemical products of the interaction of radiation with biologic material. The important free radicals have short half-lives. A useful way to think about them is that they may return to an innocuous state or remain highly reactive molecules. Oxygen appears to favor the latter, whereas the presence of high levels of sulfhydryl compounds favors the former.

FIGURE 16-10. Radiation sensitivity as a function of ambient oxygen pressure. (Modified from Deschner EE, Gray LH. Influence of oxygen tension of x-ray induced chromosomal damage in Ehrlich ascites tumor cells irradiated *in vitro* and *in vivo*. *Radiat Res* 1959;11:115, with permission.)

Thomlinson and Gray<sup>22</sup> recognized the importance of the oxygen effect in a classic paper in which they showed that tumors from humans frequently had anoxic regions. Calculations of oxygen diffusion from capillaries and metabolism predicted that the oxygen tension would decrease to zero at approximately 150  $\mu\text{m}$ . They measured the width of tumor cords and showed that tumors can be modeled as shown in Figure 16-11. Those cells within approximately 100  $\mu\text{m}$  of the capillary are well oxygenated, those beyond 150  $\mu\text{m}$  are anoxic and necrotic, and those between 100 and 150  $\mu\text{m}$  are hypoxic at an oxygen tension that might protect cells from radiation. This model has had a profound influence on radiobiologic and radiotherapeutic thinking. If all tumors look this way and such hypoxic regions contain cells that ultimately could cause tumor regrowth, then no clinically apparent tumor would be cured by radiation therapy. Because this is not the case, this paradox must be explained.

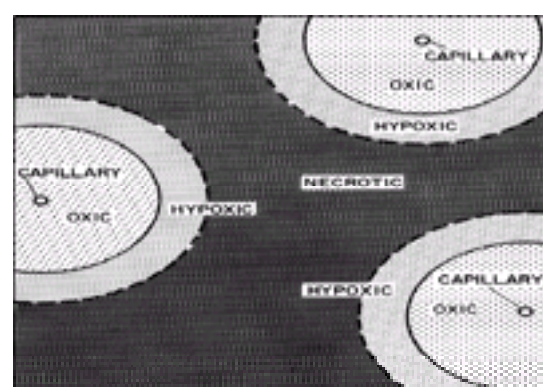

FIGURE 16-11. Diagrammatic representation of a tumor.

Laboratory experiments have indicated that immediately after a single dose of radiation, the surviving tumor cells are mainly the original hypoxic cells. After a period, the proportion of hypoxic cells returns to the preradiation level. This process has been called *reoxygenation*.<sup>23</sup> The term can be confusing because these are indirect experiments and do not record the fate of individual cells. The results of these experiments can be explained by suggesting that tumor cells do reoxygenate for

several reasons: (1) reduced total tumor cell population relative to the surface area of tumor blood vessels; (2) reduced separation of hypoxic cells from the blood vessels, resulting from preferential cell kill of oxygenated cells; (3) increased oxygen diffusion; and (4) decreased intratumoral pressure, which opens blood vessels.

Alternatively, a large number of these hypoxic cells might in fact be doomed because, with proliferation in the oxic regions, they are pushed outward, ultimately forced to reside in the anoxic regions, and therefore die. Hypoxic cells, rather than being determinant in tumors surviving irradiation, may be on the way to anoxia and death, thus having limited clinical importance. It is likely that different mechanisms pertain under different circumstances in the laboratory and in the clinic.

The clinical importance of the oxygen effect has led to clinical and laboratory experiments, including the use of high-pressure oxygen with radiation therapy to improve results. These studies have indicated that, with a small number of radiation fractions, hyperbaric oxygen increases curability. If normal fractionation schemes are used, hyperbaric oxygen often does not show an advantage. However, some reports of tumors of the head, neck, and uterine cervix indicate that hyperbaric oxygen with 10 fractions of radiation results in greater cure than conventional daily fractionation. <sup>24,25</sup> and <sup>26</sup> Table 16-2 depicts the results with head and neck cancers. Despite these promising studies, the hyperbaric oxygen technique is cumbersome, difficult for the patient, and prohibits the use of the careful beam definition and beam modification so important in radiation therapy. The technique has been abandoned in most radiotherapy centers.

	Local Control (%)	Survival Rate (%)
Hyperbaric oxygen	61	56
Conventional treatment	40	27

(From ref. 24, with permission.)

**TABLE 16-2.** Results of a Randomized Prospective Trial of Hyperbaric Oxygen in the Radiation Treatment of Head and Neck Cancer

A more attractive alternative has been the development of hypoxic cell sensitizers. In the 1960s, Adams and colleagues <sup>27,28</sup> began searching for compounds that would mimic oxygen in its effect. They sought agents that would be metabolized slowly and reach all portions of the tumor. This is an important distinction, because high-pressure oxygen increases diffusion only slightly, whereas slowly metabolized sensitizers can reach all areas of the tumor. Although newer methods were based on replacing molecular oxygen, other effects of the nitroimidazoles, the most well-studied class of these agents, have been described. They appear to be cytotoxic to hypoxic cells and may sensitize cells to chemotherapeutic agents. <sup>29,30</sup> How important these last two points are in their use remains to be seen. However, this general class of agents offers a whole new approach to the chemical treatment of tumors based on a known tumor-normal tissue difference (i.e., the presence of hypoxic cells in tumors).

A practical clinical concern is whether the presence of anemia affects tumor response to radiation. Historic review and a prospective study from the Princess Margaret Hospital (Table 16-3) appear to indicate that anemia results in an adverse effect on tumor curability by radiation, presumably because it increases the hypoxic component of tumor cells. <sup>31</sup>

	Control		Transfused
Hemoglobin	<12 g/dL	>12 g/dL	>12 g/dL
Pelvic recurrence	10/20 (50%)	11/48 (23%)	11/67 (16%)

(Adapted from ref. 31, with permission.)

**TABLE 16-3.** Effects of Anemia on Pelvic Recurrence in Stage IIB or III Cervical Cancer

A review of intercapillary distance and tissue oxygen tension correlates local recurrence with evidence of hypoxia using these parameters in studying carcinoma of the cervix. <sup>32</sup> These studies emphasize the promise of techniques that improve tissue oxygenation in the treatment of epithelial cancers. *In vitro* measurement of hypoxia using radioactively labeled hypoxic sensitizers may alter selection of appropriate tumors for such therapeutic manipulation. <sup>33,34</sup>

#### Variable Radiation Response during the Division Cycle

The cell cycle can be divided into four phases: G<sub>1</sub>, S, G<sub>2</sub>, and M. Terasima and Tolmach <sup>35</sup> and Sinclair and Morton <sup>36</sup> studied synchronized populations to determine whether there is a difference in response to radiation as a function of the cell's position in the division cycle. They found that, generally, the mitotic phase (M) is most sensitive and G<sub>2</sub> almost as sensitive. G<sub>1</sub> is relatively sensitive in cells with a short G<sub>1</sub> phase. Cells gradually increase in resistance as they proceed through the late G<sub>1</sub> and S phases, reaching a maximum of resistance in the late S phase. In cells with a long G<sub>1</sub> phase, a peak of resistance is seen early in G<sub>1</sub>. These findings *in vitro* also seem to be true *in vivo* for normal and tumor cells. <sup>37,38</sup>

The changes in radiation response are reflected in changes in the shoulder of the survival curve and in the terminal slope. These differences can be large. The difference between the most resistant and the most sensitive can show slope ratios equal to that of the oxygen effect.

The clinical consequences of different fractional survival after 2 Gy can be seen in Table 16-4. Small differences in fractional survival when repeated have profound consequences in the level of cell killing.

Survival Fraction	X <sup>20</sup> X =	X <sup>32</sup> X =
10 <sup>-11</sup>	0.45	0.28
10 <sup>-10</sup>	0.49	0.32
10 <sup>-9</sup>	0.52	0.35
10 <sup>-8</sup>	0.56	0.40
10 <sup>-7</sup>	0.60	0.45
10 <sup>-6</sup>	0.65	0.50
10 <sup>-5</sup>	0.70	0.56

\*Calculated cumulative survival fraction for either 32 or 20 equal fractions when the fractional survival is varied.  
(From ref. 39, with permission.)

**TABLE 16-4.** Calculated Cumulative Survival Fraction <sup>a</sup>

A second consequence of differential cell killing and the mitotic delay induced by radiation is a tendency to partially synchronize the cells. The timing of the second dose of a fractionated scheme may be critical. This synchronization is short-lived because cells desynchronize rapidly and redistribute themselves according to the original cell age distribution. This phenomenon, which could pose a clinical problem or a clinical advantage, does not seem to be important unless an incomplete redistribution between fractions exists.

### Cell Proliferation

During a course of fractionated radiation, the ultimate response of the tumor and normal tissue depends on whether cell proliferation has taken place between the fractions, thereby increasing the number of cells exposed to radiation. This cell increase may be caused by cell proliferation within the irradiated volume (i.e., within the tumor or normal cell renewal tissue) or by cells that immigrate from unirradiated adjacent areas. The latter situation is seen in the skin, oral gastrointestinal mucosa, or from great distances, as found with bone marrow and lymph node repopulation. The balance between radiation-induced cell killing and repopulation is responsible for most of the clinical findings seen during fractionated radiotherapy treatment.

In addition to spontaneous repopulation, an induced cell proliferation, or recruitment of cells, may take place. <sup>40,41</sup> Physiologically, many tissues of the body respond to trauma by being recruited into rapid proliferation (e.g., after a wound in the skin, a break in bone, or a partial hepatectomy). The reparative process requires proliferation of the undamaged cells. Similarly, when the oral mucosa is irradiated, strong evidence indicates that the cell-cycle time is decreased and that net cell proliferation increases. This also may occur in some tumors but appears to be of less magnitude than that in normal tissues. <sup>42</sup> If cell proliferation is greater in the tumor, then fewer fractions will be desired. Part of the differential effect of fractionated radiation may lie in differential recruitment of normal versus tumor cells.

### TRANSCRIPTIONAL ACTIVATION, GENE INDUCTION, AND REGULATION AFTER IONIZING RADIATION

A new class of actions of ionizing radiation may explain a number of perplexing effects. Immediately after exposure to ionizing radiation, expression of genes such as FOS, JUN, and EGR1 appear to take place. <sup>43,44</sup> This seems to occur in the presence of protein synthesis and is thought to be due to transcriptional activation and inhibition of protein degradation. Radiation also induces tumor necrosis factor- $\alpha$ , <sup>45,46</sup> and <sup>47</sup> which may produce additive, synergistic, and distant cytotoxic effects of radiation. Platelet-derived growth factor- $\alpha$  and fibroblast growth factor are induced and released from vascular endothelium. <sup>48</sup> It is suggested that this release stimulates proliferation of smooth muscle cells in the smaller arterioles and contributes to the undesirable long-term vascular events associated with radiation exposure. <sup>49</sup>

### PHARMACOLOGIC MODIFICATION OF RADIATION EFFECTS

Pharmacologic agents can modify the basic parameters of radiation response. [Figure 16-12](#) shows a radiation survival curve for cells that have semiconservatively incorporated the halogenated pyrimidine bromodeoxyuridine into their DNA. Under such circumstances, these cells are more sensitive to radiation, their survival curve having the slope and the shoulder modified. <sup>50</sup> This occurs only when the halogenated pyrimidines bromodeoxyuridine or iododeoxyuridine are incorporated into the DNA; their presence at the time of radiation is not sufficient. Sublethal damage repair also is markedly inhibited under these circumstances.

**FIGURE 16-12.** Radiation survival curve for cells incorporating halogenated pyrimidines. (From ref. 50, with permission.)

A second class of agents includes those that primarily affect the shoulder and only slightly affect the slope. The two most important of these agents are dactinomycin and doxorubicin. Sublethal damage apparently is inhibited by dactinomycin but not by doxorubicin. <sup>51,52,53,54,55,56</sup> and <sup>57</sup> Strong evidence suggests that these drugs can and do modify radiation effects when given simultaneously. Furthermore, when given after radiation therapy, they can recall the irradiated volumes by erythema on the skin or by producing pulmonary reactions. <sup>52,55,58,59</sup> Chemicals may also interact with radiation by preferentially killing cells that are more resistant to radiation. For example, agents that, along with radiation, preferentially destroy cells in the most resistant phase of the cell cycle (S) increase the cell kill; an example of this is hydroxyurea. <sup>60</sup> Radioprotective agents, such as sulfhydryl-containing compounds, act in the reverse fashion and tend to make cells more resistant. <sup>61</sup> They also reduce the chromosome abnormalities associated with radiation.

Agents with dose-limiting normal tissue toxicities different from radiation may be used effectively with radiation. This is one of the basic principles of multiple-drug chemotherapy—add agents with nonoverlapping toxicities. This strategy also works well with radiation.

The combined effects of drugs and radiation, or of two drugs, can be divided into the following types:

1. Independent. The agents act independently, their mechanisms of action are independent, and their damage is independent.
2. Additivity. The agents act on the same loci, and therefore their sublethal damage and their lethal damage are additive. Because of additive sublethal damage, the lethality of the two together may be greater than the lethality of each alone added together.
3. Synergism. The two agents have a result that is more effective than pure additivity.
4. Antagonism. The cell killing is less than independent action.

The most important parameter for the clinician is the therapeutic index. The sigmoid curve of tumor cure and that of dose-limiting toxicity are portrayed in [Figure 16-13](#). If both curves are moved but their relative place (one to the other) is not changed, then the proportion cured for a given level of toxicity is unchanged. Drug-roentgen ray interaction is useful only when the curves are separated and not merely displaced.

**FIGURE 16-13.** Sigmoid curves of tumor control and complications. Dose for tumor control with minimum complications (A). Maximum tumor dose with significant complications (B).

### HIGH LINEAR ENERGY TRANSFER RADIATION

Most of the discussion so far has been concerned with sparsely ionizing radiation, such as that produced by photons or high-energy electrons. More densely ionizing radiation is produced by larger atomic particles. The biologic actions of these two types of radiation are different and relate to the density of ionization. LET is the rate of energy loss along the path of the particle ( $de/dl$ ). High LET radiations are densely ionizing, with  $de/dl$  being high. In general, the density of ionization depends on  $Z^2/v$ , where  $Z$  is the atomic number and  $v$  is the particle velocity. Photons and electrons are characterized by high energy and low mass. Therefore, the density of ionization is low until the secondary electrons come to rest at the end of their path. Particulate radiation ionizes directly. Gamma particles and stripped nuclei have a high LET; neutrons have an intermediate LET because of recoil protons. The  $Z^2$  is large for large particles, intermediate for protons, and low for photons. High LET radiations have little or no shoulder on the survival curve ( [Fig. 16-14](#)).

**FIGURE 16-14.** Survival fractions for high and low linear energy transfer (LET) radiations. RBE, relative biologic effectiveness.

### RELATIVE BIOLOGIC EFFECTIVENESS

Relative biologic effectiveness (RBE) is a commonly used parameter in radiation biology. It is the dose ratio of different average LET beams required to produce the same biologic effect. If the biologic end point of interest is associated with a high survival fraction, then the RBE is large because it considers shoulder differences and those of the terminal slope. If the biologic end point involves a low survival fraction, the RBE is less because it primarily considers slope differences. In general, RBE increases as the dose decreases. Not only is the shoulder reduced, but other measures of sublethal damage repair or potentially lethal damage repair are markedly reduced with high LET radiation.

A general explanation is that the ionization is so dense that, when a cell is hit, the damage is so great it cannot be repaired. It is also true that the oxygen effect decreases as the LET increases. With very high LET radiation, no oxygen effect is seen. <sup>62</sup>

Although this advantage in RBE and OER suggests the possible therapeutic use of these radiations, a cautionary note must be made. Increasing RBE in itself does not afford a therapeutic advantage. It is the therapeutic gain factor that is important—the RBE of the tumor compared with the RBE of the normal tissue. This factor is complicated and greatly depends on the specific tumor and the dose-limiting normal tissue being considered.

### TUMOR RADIOBIOLOGY

Many experiments have been done using animal tumors. In general, these tumors are spontaneous tumors occurring with reasonably high frequency in certain strains of mice (e.g., mammary carcinoma in C3H mice) or tumors induced by carcinogens. Such primary tumors of animals are difficult to use experimentally because their production is time consuming, and numbers of tumors of the same size and location are limited, restricting some experimental designs. A much more common technique is the use of transplanted tumors. These are tumors that may have occurred spontaneously or from the application of a carcinogen but have now been transplanted from animal to animal. They grow with predictable and known kinetics. Although this is a great advantage in experimental work, it does increase the likelihood that the application of the results may be somewhat limited. Because these tumors are selected for rapid growth and for the ability to transplant serially, they may not represent tumors that occur spontaneously in the host animal. Currently, many laboratories study human tumors transplanted into “nude” mice. These genetically immunosuppressed mice permit the growth of these xenografts, but interpretation of these experiments is limited by the artificiality of the experimental circumstance.

Tumors can be used in radiobiologic experiments and assayed in a number of ways. The simplest is to study the likelihood for cure. A researcher implants a tumor into animals, allows it to grow to palpable size, treats it with a specific regimen, and then determines how many tumors of this type in various host animals are cured. If the dose of radiation is plotted against the likelihood for cure, a sigmoid curve is generated ( [Fig. 16-15](#)).<sup>64</sup> There is insufficient cell kill to cause tumor cure at very low doses. As the dose is raised (to approximately one lethal event per cell), the statistics of random cell kill become important. Occasionally, tumors have zero viable cells and are cured. The likelihood of cure rises rapidly with dose at this portion of the curve; it starts to plateau when the maximum effect of the particular technique is reached. The dose required to increase a 10% likelihood of tumor control to 90% is approximately three times the  $D_{10}$  dose. This sigmoid relation is important, because it is true not only for tumors in experimental animals but also for clinical situations. The steepness of the curve in the effective range emphasizes the importance of small increases in dose.

**FIGURE 16-15.** Sigmoid curve of tumor control.

The shape and steepness of the sigmoid dose-response relation for tumors can be affected by many factors. If the  $D_0$  is large, then the dose-response curve is also shallow. It also is affected by host defense mechanisms. This curve is steep with nonimmunogenic tumors or in hosts with an abrogated immune response, but it is significantly shallower in immunogenic tumors.<sup>65</sup> The shallowness means that occasional cures are found at low doses and occasional failures are noted at very high doses.

A similar sigmoid relation is seen when plotting the likelihood for complications against tumor control. [Figure 16-13](#) shows the two sigmoid curves, one for cure and one for complications. This is presented optimistically—the important complication curve is placed to the right of the tumor cure curve. The difference between these curves is a measure of therapeutic gain. Much of clinical medicine and research in cancer treatment is concerned with separating these curves.<sup>63</sup> After the curves are separated, for a given level of complications, the likelihood of cure can be increased. Or, for a high likelihood of cure, the likelihood of complications can be decreased. Some methods for separating these curves include better restriction of the radiation dose by using techniques such as intensity-modulated radiation therapy (see [Chapter 29.4](#)). Combining agents with nonoverlapping toxicity, such as certain chemotherapeutic agents, antiangiogenic agents, or even gene therapy, offer the promise of improved cure without increasing the radiation toxicity. It may also be possible to modify radiation toxicity without decreasing effectiveness.

Tumors, like normal tissues, have certain physiologic characteristics. We associate some of these with the definition of malignancy: continued growth and extension into surrounding tissues, and the ability to metastasize. In addition, growing tumors must induce a blood supply to meet their increasing metabolic needs. The production of these blood vessels appears to result from the release of substances described by Folkman and colleagues<sup>66,67</sup> and<sup>68</sup> as “tumor angiogenesis factors” and may have important clinical implications. If tumors can be prevented from producing such substances, they cannot grow beyond a size supported by diffusion alone.<sup>66,67</sup> and<sup>68</sup> From the radiobiologic point of view, it means that, when irradiating a tumor, the radiobiology of the tumor and the vascular endothelial cells are important. Complete destruction of the ability of tumor blood vessels to proliferate effectively limits tumor growth.

As tumors grow, they often exceed their blood supply and develop areas of necrosis and hypoxia (see [Fig. 16-11](#)). The proportion of hypoxic cells in a tumor can be determined by studying the radiation survival curves. In [Figure 16-16](#), curve A represents a well-oxygenated cell population, curve B describes hypoxic cells, and curve C represents a mixture of oxic and hypoxic cells (as in a tumor). Extrapolation of the curves to the ordinate gives the proportion of hypoxic cells within a tumor, first described by Powers and Tolmach.<sup>69</sup> In most experimental tumors studied, the percentage of hypoxic cells is 10% to 20%.

**FIGURE 16-16.** Idealized survival curves for oxic tumor cells (A), hypoxic tumor cells (B), and a tumor containing both oxic and hypoxic tumor cells (C). Prop, proportion.

There has been great interest in trying to determine whether appropriate laboratory correlates exist for clinical radiation treatment.<sup>70,71</sup> [Table 16-5](#) shows important parameters found by *in vitro* survival determinations for six histologic groups of human tumor cells.<sup>72</sup> The first four parameters have already been described.  $S_2$  and  $S_8$  are the survival fractions found with 2 Gy and 8 Gy, respectively.  $\bar{D}$  is the mean inactivation dose, a mathematically determined characteristic of the initial portion of the survival curve. It appears that  $S_2$  and  $\bar{D}$  correlate directly with clinical radiocurability, whereas  $\alpha$  is inversely related. All of these are measures of the initial portion of the radiation survival curve;  $S_2$  is the most closely correlated with clinical practice, because doses between 1.5 and 2.5 Gy are used most often in patient care.

Histologic Group	$\alpha$	$\beta$	$n$	$D_0$ (Gy)	$S_2$ (%)	$S_8$ (%)	$\bar{D}$ (Gy)
Glioblastoma (1)	0.20 (8%)	0.02 (7%)	12	1.61 (2%)	38 (3%)	4.86 (17%)	3.8 (2%)
Melanoma (2)	0.20 (8%)	0.02 (8%)	75	1.94 (2%)	38 (3%)	1.11 (3%)	2.0 (2%)
Spindle cell carcinoma (3)	0.27 (9%)	0.02 (2%)	5	1.28 (1%)	6 (3%)	4.86 (8%)	2.0 (2%)
Mesothelioma (4)	0.52 (17%)	0.02 (2%)	15	1.94 (2%)	6 (3%)	4.59 (10%)	2.0 (2%)
Lung carcinoma (5)	0.40 (12%)	0.02 (2%)	14	1.68 (2%)	34 (3%)	4.07 (12%)	1.7 (1%)
Oesophageal carcinoma (6)	0.68 (21%)	0.01 (1%)	14	1.31 (1%)	22 (2%)	3.18 (8%)	1.0 (1%)

(Stabilized from ref. 72, with permission.)

**TABLE 16-5.** Mean Values and Coefficients of Variation (in Parentheses) of the Survival Curve Parameters and of the Surviving Fractions at 2 Gy ( $S_2$ ) and 8 Gy ( $S_8$ ) for Human Tumor Cell Lines

Because in radiation therapy the dose is divided into many fractions, small differences in  $S_2$  can have significant consequences. [Table 16-4](#) shows that, in a typical 32-fraction radiation treatment, the difference between survival fractions of 0.45 and 0.60 results in an ultimate survival fraction of  $10^{-11}$  compared with  $10^{-7}$ , respectively. Also, certain tumors that are known to be difficult to cure by radiation have been shown to have great capacity to repair radiation damage, as measured by allowing the cells time for repair before plating them for *in vitro* growth.<sup>73</sup> That these two simple laboratory determinations correlate with clinical results gives hope that *in vitro* techniques can be used to determine mechanisms of modifying clinical parameters. This does not mean that the other biologic parameters, such as oxygenation, position in the cell cycle, and cell proliferation, are not important; no doubt, all of these factors add to the complexity of correlating the clinical response with *in vitro* determinations.

### NORMAL TISSUE RADIATION BIOLOGY

To understand normal tissue radiation biology, an appreciation of the cell kinetics of cell renewal tissues is vital. The effects on organ function depend on the reproductive requirements of the irradiated cells. Tissues whose functional activity does not require cell renewal (e.g., muscle and neurologic tissue) are considered resistant to radiation. Both muscle and neurologic tissue also have important vasculoconnective tissue stroma that support them.<sup>74</sup> These stromal cells may be required to divide and, therefore, determine the organ response to radiation. The radiation response of endothelial cells demonstrates a  $D_0 = 340$  rad,  $n = 7$ , and a  $D_q = 170$  rad, values similar to those of epithelial cells.<sup>75</sup>

Many tissues of the body require continued cellular proliferation for their function, and they promptly demonstrate the effects of radiation. These cell renewal tissues include the skin and its appendages, the gastrointestinal mucosa, bone marrow, reproductive tissues, and many exocrine glands. Clonogenic survival curves for bone marrow stem cells, gastrointestinal epithelial cells, and skin are all available.

Tissues such as the liver and bone require little or no proliferation during the steady state, and normal function can be maintained despite large doses of radiation. However, both of these respond to injury with rapid cell renewal. If trauma (fracture or partial hepatectomy) occurs, then the cells die when they attempt repair. Irradiation of the liver has few consequences in moderate doses, but if this is followed by a partial hepatectomy, hepatic failure can occur. This finding has been of clinical importance in the preoperative irradiation of right-sided Wilms' tumors attached to the liver, in which a significant amount of liver must be removed. <sup>74</sup> Under such circumstances, it is far better to operate, allow the liver to regenerate, and then irradiate.

Patients who have received large amounts of radiation to the bone do perfectly well unless the bone is fractured. The damaged bones fail to be reconstituted or heal slowly, causing a significant deformity and disability to the patient. These examples are included to stress that it is not the different cells that have such great differences in radiation response, but rather that the proliferative requirements of different tissues largely determine the radiation effects. If the proliferative requirements are low, the organ is considered resistant to radiation. If the proliferative requirements are high, it is considered radiosensitive. Some common limitations on all systems may apply, based on the radiosensitivity of the stromal support cells, such as connective tissue and endothelial cells. <sup>74</sup> Stem cells of the cell renewal tissues may have a limited proliferative capacity, and stem cell exhaustion appears to be a cause of late organ failure after irradiation. <sup>77</sup>

Many other effects of radiation that do not depend on reproductive viability may have clear clinical relevance. For example, radiation is damaging to the cell membrane and changes membrane transport. Subsequent radiation-induced edema is seen with moderate doses of radiation. Damage to certain membrane lipids can cause apoptosis without nuclear damage. These nonreproductive effects of radiation are far less well understood but may be important in understanding the effects of radiation on nondividing tissue, especially on the central nervous system.

Large doses of whole body irradiation have obvious clinical consequences, which generally are not relevant to conventional radiation therapy. However, because whole body irradiation has been used in low doses in treating the lymphomas and in high doses in treating metastatic carcinoma, this topic is discussed briefly.

After large doses of radiation, the prodromal syndrome of nausea, vomiting, diarrhea, cramps, fatigue, sweating, fever, and headache occurs. Three distinct modes of death may occur. The first, with very high doses of radiation (more than 10,000 rad), is seen within hours and appears to result from neurologic and cardiovascular damage. Because this occurs so quickly, it probably is not caused by failure of cell proliferation but rather by extranuclear events within these organs. At intermediate doses of radiation (500 to 1000 rad), death occurs within days. It is associated with extensive gastrointestinal mucosal damage, resulting in prolonged, severe, bloody diarrhea; dehydration; and secondary infection occurring as the gastrointestinal mucosa is denuded. At lower doses of radiation (near the LD<sub>50</sub>), death is caused by hematopoietic failure. This complication has a latency period because the formed blood elements are nondividing, and bone marrow failure does not occur until the progeny of the proliferating cells are required to maintain the patient. The lymphocyte level falls promptly as some of these cells die by apoptosis. The granulocyte level falls on approximately day 5 or 6, and thrombocytopenia occurs later. Anemia does not occur as a direct result of a failure of red blood cell production, because of the long life of the red blood cell, but it may be caused by hemorrhage.

Whole body irradiation appears to have significant antitumor activity exceeding that seen when the same dose is given to the tumor alone. <sup>78,79</sup> Very low doses of whole body radiation in humans (10 to 15 rad, two to three times per week for 6 to 10 fractions) may be effective treatment for lymphomas and may cause marked depression of the formed blood elements. The mechanism of action of this type of treatment is not understood. The effects on tumor and normal tissue are greater than can be explained by the typical survival curve. One possible explanation is the release of TNF- $\alpha$  after radiation. <sup>45,46,48</sup> Perhaps the release of this and other factors may contribute to the general effects of low-dose whole body radiation and the abscopal (distant) effects of regional irradiation. Many of the effects of radiation on both tumors and normal tissues may be mediated or modified by the release of cytokines. Their effect may be tissue specific; for example, basic fibroblast growth factor protects against the apoptotic microvascular component of radiation pneumonitis but has no effect on other mediastinal organs. <sup>49</sup>

## ADVERSE EFFECTS OF RADIATION

Some biologic considerations of localized radiation may decrease the likelihood for tumor control. The first and most commonly discussed is the effect of radiation on the immune response. High-dose, whole body irradiation has a well-known and profound effect on the immune response. This generalized treatment rarely is used in clinical therapy, however, except as preparation for bone marrow transplantation.

Shortly after the discovery of roentgen rays, whole body irradiation before the administration of antigens was found to suppress the production of antibodies. After whole body irradiation, a prompt fall in the lymphocyte count is seen. The lymphocytes appear to have two types of radiation response: Approximately 80% apoptose, but some lymphocytes survive the radiation. When assayed on the basis of reproductive capacity by exposure to mitogens after irradiation or other functional end points, their radiation survival curves looked similar to that of hematopoietic cells with a D<sub>0</sub> of approximately 70 to 80 rad and an n of approximately 1. <sup>80</sup> Response depends on the classes of lymphocytes involved, the extent of cell proliferation required, cell traffic, and the balance between suppressor and helper systems. The following conclusions concerning the effect of radiation on the immune response can be made <sup>81</sup>:

1. B lymphocytes are radiosensitive and undergo interphase (apoptosis) and mitotic death after irradiation.
2. All functional T-cell subpopulations have sensitive precursor cells. Suppressor T-cell precursors may undergo interphase death.
3. The homing potential of cells is affected by radiation.
4. Resting cells are more sensitive to interphase death than are the same cells when stimulated to divide before irradiation. (In the latter case, they have an n and D<sub>0</sub> similar to those of hematopoietic stem cells.)
5. The effects of whole body irradiation are qualitatively and quantitatively different from those caused by localized or regional irradiation.

Whole body irradiation is more effective in preventing response to new antigens than in modifying response to a previously encountered antigen. Survival of second-set skin grafts are affected much less than are initial grafts. Localized radiation, as used in radiation therapy, affects the immune response by decreasing the number of circulating lymphocytes, presumably by irradiating and destroying them as they pass through the irradiated volume and by the release of certain cytokines.

Other adverse effects of radiation on the patient may be seen in addition to those affecting host-defense mechanisms. Radiation-induced mutagenesis is of concern for germline and somatic cells. If the gonads are irradiated, there is an increased likelihood of mutation with increasing doses, without any evidence of a threshold dose or of an ameliorating effect of fractionation. At higher doses, significant cell killing takes place, and the dose-response curve is no longer linear, presumably because the cells that mutated received sufficient radiation to become sterile. Abnormal live births are uncommon after gonadal irradiation because most radiation-induced mutations are recessive. Furthermore, dominant mutations, when they occur, usually are lethal. In the mouse, some evidence indicates that the risk of mutation decreases with time after ovarian irradiation. Whether this is true in humans and how the mechanism occurs in animals are not known. It does not appear to be true for irradiation of the testes.

The mutagenic effects of radiation depend on the type of irradiation. The RBE for high LET radiation can be extremely high for mutations. It is difficult to quantify the risk because experiments with mice indicate a large difference in the mutation rate for different loci, with as much as a 1000-fold variation in the mutation rate. <sup>81</sup> In general, the prudent figure used is that the mutation rate doubles with approximately every 50 rad.

Perhaps of even greater concern are somatic mutations, especially those that may lead to tumors. A great deal of evidence indicates that low doses of radiation increase the incidence of tumors after significant latent periods. This information comes largely from whole body exposures to the atomic bomb and experience with patients irradiated for benign diseases. <sup>82,83</sup> and <sup>84</sup> In general, there appears to be a linear increase in tumor incidence with dose until high doses are reached, at which point the incidence reaches a plateau or even falls. <sup>85,86</sup> Presumably, this is true, again, because of cell killing. [Figure 16-17](#) is an example of this biphasic dose-response curve. Such tumor induction is associated with a latent period of 3 to 5 years for leukemia but is much longer for solid tumors. There are different ages at which tumor induction is most likely. For example, the induction of breast cancer by radiation appears primarily with exposure in the first and second decades of life and decreases with radiation later in life.

## CLINICAL CONSIDERATIONS

It is often suggested that the goal of treatment is the greatest probability of uncomplicated cure. Although this goal is desirable, circumstances actually may dictate a different policy. Consider Figure 16-13, in which the curve for complications is to the right of the sigmoid curve for tumor control. If tumor failure can be salvaged by subsequent surgery but complications are severe, long-lived, and difficult to manage, then line A is the optimal line.<sup>63</sup> An example of this would be the treatment of T2 and T3 glottic cancer. On the other hand, if complications are not severe or are remediable but cancer failure is fatal, then line B would be appropriate. This is the case in stage II and III carcinoma of the uterine cervix. There is no simple answer. Often, the worst complication of treatment is tumor recurrence.

Many clinical examples of sigmoid dose-response curves have been reported. An example for tumors of the head and neck is shown in Figure 16-18 and for Hodgkin's disease in Figure 16-19.<sup>87,88</sup> In Figure 16-18, the ordinate is arranged to convert a sigmoid curve to a straight line. An instructive clinical experience is described by Stewart and Jackson<sup>90</sup> in which a consistent ~10% change in dose was used. Figure 16-20 shows the results in tumor control and complications. The small increase in dose markedly improved the curability of the larger tumors, presumably because this dose is on the steep portion of the sigmoid dose-response curve. It did not change the cure rate for small tumors very much because, presumably, the dose already was large enough to be on the plateau of the dose-response curve, where changes in dose do not affect the cure appreciably. Similarly, complications were not increased significantly. The point indicating complications is to the right, still on the shallow portion of the curve. This is a good example of separation of response between tumor and normal tissues. It also shows displacement of the curve for cure as a function of tumor size.

FIGURE 16-18. Tumor control versus dose for supraglottic carcinoma. (From ref. 87, with permission.)

FIGURE 16-19. Tumor control versus dose for Hodgkin's disease. (From ref. 88, with permission.)

FIGURE 16-20. Tumor control versus dose for cancer of the larynx (4 MeV given over 3 weeks for a treatment period of 5 years). (From ref. 89, with permission.)

Even though tumors have a very steep dose-response relationship, significant intertumor heterogeneity may cause great flattening in the radiation dose-control curves.<sup>90</sup> Considerable heterogeneity exists between tumors of the same histologic type and location, and this consideration explains the shallower nature of the clinical dose-response curves compared with those for experimental animals. These analyses further indicate that, when the tumor control probability is low, the major reason is a high  $S_2$ . This fact emphasizes the importance of identifying prospectively tumors that have a high  $S_2$ . Changes in the likelihood of apoptosis after radiation may have an important effect on  $S_2$ .

## FRACTIONATION

Early in the twentieth century, as the practice of radiation therapy evolved, the virtues of dividing the radiation into small fractions were noticed. The reasons given were often incorrect, but the clear observation was that fractionation of the dose allowed more effective tumor cure without excessive complications.

Fractionation considers the size and number of radiation increments. Protraction considers the overall time during which the course of radiation therapy is given. Both factors affect all radiation therapy plans. The fashioning of a plan for fractionated radiation therapy for carcinoma of the larynx by Coutard,<sup>91</sup> whose work was based on the principles of Regaud,<sup>92</sup> laid the foundation for the development of radiation therapy. The principles of such treatment were as follows:

1. Fractionation is important.
2. A relation exists between the acute reaction of the skin and oropharyngeal mucosa to cure and to late effects.

The association between acute and late effects has sometimes led radiotherapists astray. This relation depends on the fractionation scheme, the energy of radiation used, and other factors. In general, acute effects are much more dependent on time than late effects. Late effects are influenced primarily by the total dose and fraction size.

## CONTINUOUS RADIATION

Another important technique of radiation therapy that evolved in the early part of the twentieth century was the application of continuous radiation by interstitial or intracavitary application.<sup>93</sup> If the dose rate was too high or the volume too large, unacceptable complications occurred. Rules for treatment were developed that resulted in the cure of certain tumors without unacceptable complications. These rules required that the dose rate be kept moderate (less than 100 rad/hour) and an attempt at a good implant geometry be made to avoid unnecessary hot and cold spots.

The whole question of homogeneity of dose is much more difficult with intracavitary and interstitial irradiation than with external-beam techniques. To a great extent, the clinical use of radioactive isotopes, especially by implantation techniques, developed separately from external-beam radiation therapy. Some physicians only practiced one or the other of these techniques. More recently, external-beam and interstitial treatment have been used together to take advantage of the virtues of both modalities. Good examples of this combined treatment are described in the chapters dealing with tumors of the head and neck and uterine cervix (see [Chapter 30.2](#) and [Chapter 36.2](#)). The increase in the use of high-dose-rate afterloading techniques, although having the practical and logistical advantages, eliminate the dose-rate advantage of brachytherapy. It remains to be determined whether this will have significant clinical consequences (see [Chapter 36.2](#)).

## ACUTE AND LATE NORMAL TISSUE EFFECTS

Acute radiation effects occur largely in renewing tissues, such as skin, oropharyngeal mucosa, small intestine, rectum, bladder mucosa, and vaginal mucosa. These cell-renewing tissues are rapidly proliferating, and as they are confronted with fractionated radiation, the processes of repair, repopulation, and recruitment all obtain. Because the response of rapidly renewing tissues depends on the balance between cell birth and cell death, acute tissue reaction is crucially affected by the time allowed for repopulation and, therefore, is dependent on protraction. It also depends on the cell kill per fraction, so fraction size is important. The radiotherapist observing an excessive reaction by the oral mucosa knows that a small decrease in fraction size or a small treatment break allows rapid resolution of the problem, because these changes permit reconstitution of the normal tissue.

Late effects are really the dose-limiting factor in radiation therapy. These include necrosis, fibrosis, fistula formation, nonhealing ulceration, and damage to specific organs, such as spinal cord transection and blindness. Although the mechanisms of these phenomena are not clear, they do not appear to depend primarily on the rapid proliferation of cells. Clinically late effects appear to depend much more on the total dose of radiation and the size of the radiation fraction than on protraction. Only if the same fractionation scheme is used with the same normal tissue end point, the same irradiated volume, and the same treatment technique, can acute and late effects be correlated. If any of these parameters are varied, the acute reactions to radiation may be dissociated from eventual late effects and are misleading.

Two hypotheses for late effects are worth discussion. One theory holds that all late effects result from damage to vasculoconnective stroma. Because this tissue is common throughout the body, it would suggest a common mechanism for the late effects in any organ.<sup>74</sup> A variation on this hypothesis is that it is damage to the endothelial cells, ubiquitous throughout the body, that determines late effects.<sup>75</sup> An alternative hypothesis suggests that the acute and the late effects of radiation and cytotoxic chemotherapy are caused by cell depletion of the targeted cell-renewal tissues. Acute effects depend on the balance between cell killing and compensatory replication of the stem and proliferative cells. The development of late effects requires that stem cells have only a limited proliferative capacity.<sup>94,95</sup> Compensation for extensive or repeated cell killing may exhaust this capacity, resulting in eventual tissue failure.<sup>73,96</sup>

## ALTERING THE THERAPEUTIC INDEX

Goodman and Gilman<sup>98</sup> define the therapeutic index as the relation between desired and undesired effects of therapy. For the oncologist, separation of the sigmoid curve of complications from that of local control (see [Fig. 16-13](#)) is the graphic representation of manipulation of the therapeutic index. Some techniques of time-dose relations used by the radiation oncologist to take advantage of this are fractionation, protraction, split-course technique, interstitial treatment, and manipulation of the target volume. Although fractionation has been discussed, the use of multiple small fractions two, three, or more times a day (hyperfractionation), is being explored, with some good results.<sup>98,99 and 100</sup>

Another technique to reduce complications is the use of normal-size fractions given more than once a day. This is referred to as *multifraction*, *multiple daily fractions*, or *accelerated fractionation*.<sup>101</sup>

When tumor cells are proliferating rapidly, accelerated fractionation makes sense. Waiting 24 hours between each fraction may allow significant proliferation. Perhaps the best example of the changing therapeutic index obtained with accelerated fractionation is the enhanced success in treating Burkitt's lymphoma.<sup>102</sup>

In general, most radiotherapists administer conventional radiation in fractions between 180 and 250 rad each day. This allows tumor control without excessive acute or late effects. The fraction size that is tolerated in terms of acute effects depends on the volume irradiated (the larger the volume, the smaller the fraction size), the amount and type of dose-limiting normal tissue, the age of the patient, and other clinical factors.

Small changes in fraction size make a big difference in tolerance. Patients often are given small breaks during the treatment. These rest periods usually are caused by weekend interruptions of daily fractionation. This protraction of the treatment allows for repopulation and recruitment. The days of rest also allow amelioration of many acute effects, and they may allow time for tumor regression, resulting in reoxygenation.

An attempt to formalize and extend treatment breaks is the so-called split course technique.<sup>103,104 and 105</sup> Two to 3 weeks are allowed in the middle of treatment for recovery from the acute effects and to permit tumor regression. When the dose of radiation is not increased, accumulating evidence indicates that this treatment (although better tolerated) may be associated with less tumor control.<sup>106</sup> When the split course is administered with an increase in total dose, the results seem to be comparable to conventional fractionation but perhaps with greater late effects.

Interstitial irradiation is administered by permanently or temporarily placing radioactive material into tissues. It requires biologic and physical considerations. Great inhomogeneity is found, even in the most geometrically perfect implant. There is large inhomogeneity of dose and a similar variation in dose rate; the dose rate of radiation is greater in areas of high dose. The half-life of <sup>125</sup>I is long (60 days), resulting in a significant amount of the dose being given so slowly that significant cell division may occur in the tumor and some normal cells. Therefore, the important dose may not be the total dose, but rather the dose per cell cycle, which is different for each cell type and different as the isotope decays. Also, <sup>125</sup>I irradiates primarily by the emission of very low-energy photons, some of which are absorbed by the seeds themselves, leading to further inhomogeneity.<sup>107</sup>

When implants can be used alone or in combination with external irradiation, the results are often better in terms of the therapeutic index than with external-beam techniques alone. The high local dose, continuous radiation, and even inhomogeneity allowing normal tissue regrowth all contribute to better cosmetic and functional results and cure of the tumor. Examples are breast cancer and tumors of the tongue and other head and neck sites.<sup>108,109</sup> Tumor volume also is important in clinical radiotherapy. Although the gross tumor extent can be determined, most clinicians recognize that a characteristic of tumors is to extend beyond those macroscopically

identifiable borders. Determination of the target volume must include this consideration, but if a larger volume must be irradiated, then a smaller dose is tolerated. Conversely, if the volume of the tumor is larger, then a larger dose is required. This dilemma limited the success of early radiotherapy of certain tumors by reducing the target volume, resulting in recurrences at the treatment margins, or by causing significant complications in the treatment of large target volumes. Today, distinctions are made between gross tumor and the subclinical extensions into apparently normal tissues. Subclinical disease means small numbers of cells, perhaps favorable to irradiation (well oxygenated), which can be controlled with modest doses of radiation ( [Table 16-6](#)). The large number of cells present in the clinically evidenced tumor requires higher doses (see curves in [Fig. 16-20](#) and [Fig. 16-21](#)). This difference has led to the development of techniques for administering different doses to microscopic tumor extensions and to the gross tumor. These include shrinking-field techniques, boost treatments, and certain strategies of combined surgery and radiotherapy.

Dose (Gy)	Control Rate (%)	
	Adenocarcinoma of the Breast	Carcinoma of Upper Aerodigestive Tract
30-35	60-70	60-70
40	80-90	>90
50	>90	>90

(From Fletcher GH. Clinical dose-response curves of human malignant epithelial tumors. *Br J Radiol* 1973;46:1, with permission.)

**TABLE 16-6.** Control of Subclinical Disease

Shrinking-field technique means giving the largest potential tumor bed a moderate dose of radiation, then reducing the target volume to the tumor and its immediate confines and raising the dose. This can be done by reducing the fields; changing the treatment technique and target volume; or using a treatment technique such as intensity-modulated radiation therapy, which gives the desired moderate dose to the larger volume and a higher dose to the smaller volume. Attempts have been made to consider fractionation, protraction, and even implantation used with external beam in some form of mathematical formulae, all of which tend to oversimplify complex clinical circumstances and can be misleading.

The dose-limiting normal tissues are of two kinds: those transited by the radiation as a consequence of irradiating the target volume, and those normal tissues within the target volume (e.g., the urethra in a prostatic target volume). Radiotherapy with detailed treatment planning, CT scanning, and computer-controlled radiation therapy may reduce the dose to the transited volume, possibly changing the therapeutic index.<sup>110</sup> However, it is unlikely that significant physical techniques will be available for reducing the dose to normal tissues in the target volume. This can be done only by some biologic mechanism that distinguishes tumor from normal tissues.

## RADIOSENSITIVITY

The term *radiosensitivity* is used in different ways in the literature and can mean what is defined as radiosensitivity, radioresponsiveness, or radiocurability. Each is a somewhat different concept. To the radiation biologist, radiosensitivity means the innate sensitivity of the cells to radiation. For cells that die a reproductive death, this is related to the slope of the survival curve, or the  $D_{0.1}$ .

Radioresponsiveness means the clinical appearance of tumor regression promptly after moderate doses of radiation. This may be a function of the cell's radiosensitivity, but it also may be a function of the active cell kinetics of a tumor. Bergonie and Tribondeau<sup>114</sup> first established an association between the rate of proliferation and the response of normal tissues, although they considered this to be radiosensitivity. A similar relation was presumed to apply to tumors. Because cells do not undergo a reproductive death until they face mitosis, some tumors that proliferate rapidly regress rapidly, but they also may regrow rapidly. This is often confused with radiosensitivity.

Radiocurability means that the tumor-normal tissue relations are such that curative doses of radiation can be applied regularly without excessive damage to normal tissues. Examples of such radiocurable tumors are carcinomas of the cervix, larynx, breast, and prostate, in addition to Hodgkin's disease and seminomas. Some of these are radioresponsive, some are radiosensitive, and some are neither.

## RADIATION AND SURGERY

Radiation and surgery can be combined in many different ways. The general rationale for combining surgery and radiation is that the mechanism of failure for the two techniques is different. Radiation rarely fails at the periphery of tumors, where cells are small in number and well vascularized. When radiation fails, it usually does so in the center of the tumor where there are large volumes of tumor cells, often under hypoxic conditions. Surgery, in contrast, is limited by the required preservation of vital normal tissues adjacent to the tumor. In resectable cancers, the gross tumor can be removed, but it is these vital normal tissues that limit the anatomic extent of the dissection. When surgery fails under these circumstances, it is usually because of microscopic tumor cells left behind. It seems logical, therefore, to consider combining the two techniques.

Radiation can be given before or after surgery. Preoperative radiation has the advantages of sterilizing cells at the edges of the resection, sterilizing cells that perhaps would be dislodged and seeded at the time of surgery and, in the special circumstance of unresectable tumors, reducing the tumor volume sufficiently to allow resection. It is not clear how often this results in a cure, because it may only change gross tumor to microscopic tumor and still result in tumor recurrence. It does seem to benefit selected cases of large unresectable cancers.<sup>112</sup>

There are disadvantages in the use of preoperative irradiation. The pathology reports are not valuable because, if sufficient time is allowed between the radiation and the surgery, the destruction of tumor caused by preoperative radiation prevents ascertainment of the tumor's initial anatomic extent. In contrast, if the tumor is slow-growing or if the surgery is done shortly after the radiation, the consequences of the radiation will not be represented in the pathologic evaluation of the material because sufficient time was not allowed for tumor destruction and regression.

Another disadvantage is that the patient is irradiated before the careful staging available at surgical exploration, and some patients who would not benefit from preoperative radiation are given this treatment (e.g., preoperative radiation to a colorectal carcinoma in a patient with occult liver metastases). Metastases may be found only at the time of surgery.

A disadvantage often mentioned is the delay before surgical resection. This may not be a disadvantage, because as long as the patient's tumor is being treated, the order of treatments should make no difference. The radiation dose usually is moderate (40 to 50 Gy) and given in conventional 2-Gy fractions 5 days a week or in smaller total doses given more quickly in larger fractions. If the total dose of radiation is kept small (less than or equal to 20 Gy), then the delay between radiation and surgery is small. When the dose reaches approximately 40 Gy, it is valuable to delay the surgery (usually 4 to 6 weeks) to allow the tissues to recover from the radiation. If the total dose is greater than 50 Gy, then the surgery often will be more difficult. However, with moderate doses of radiation and some time allowed between radiation and surgery, the resection can proceed without difficulty.

Postoperative radiation has a number of advantages as well. The subgroup of patients who may be helped by radiation can be defined accurately as a consequence of the surgical exploration and pathologic review. Unnecessary irradiation to patients who are not likely to benefit can be avoided, and the target volumes are tailored to meet what is found at surgery. Time can be allowed for wound healing so that the radiation does not interfere with this process. A disadvantage of such treatment is that it has no effect on seeding at the time of surgery. Surgery also may alter the physiology of the tumor left behind because of reduction of the vascular supply. Cells that were well oxygenated may be rendered physiologically hypoxic and more resistant to radiation. Another disadvantage in the peritoneal cavity is that the surgery causes loops of bowel to be fixed in specific positions and increases the likelihood of small intestinal damage by radiation.

Some uncertainty exists as to which technique is better for particular clinical circumstances. Both preoperative and postoperative radiation appear to be valuable, and the choice of the method, the dose of radiation, and time between radiation and surgery should be considered in terms of the goals planned.

An additional technique for combining surgery with radiation is limited surgical removal of the gross tumor. Because the gross tumor limits the radiotherapeutic treatment, new interest has been raised in using surgery as the boost technique. Full courses of radiation combined with tumorectomy are given. This surgery can be done before or after the irradiation. An example of this strategy is the "lumpectomy" used in the treatment of breast masses before definitive radiation (see [Chapter 37.2](#)).<sup>113,114</sup> In the latter there appears to be evidence to suggest that the removal of gross tumor displaces the sigmoid curve of cure to lower radiation doses and makes it change more steeply with dose (see [Fig. 16-21](#)).

**FIGURE 16-21.** Tumor control versus dose for stage II and III breast cancer. (From Hellman S. Improving the therapeutic index in breast cancer treatment. *Cancer Res* 1980;40:4335, with permission.)

## RADIATION AND CHEMOTHERAPY

The purpose of combined radiation and chemotherapy treatment is not to decrease the dose of radiation to gain the same effect, but rather to increase the therapeutic index. This may be achieved using techniques that take advantage of the different mechanisms of action of systemic chemotherapy and regional irradiation. Chemotherapeutic agents that directly modify the radiation survival curve may be used. A good example of this is the use of dactinomycin in the treatment of childhood rhabdomyosarcoma or Wilms' tumor. A second way to increase the therapeutic index is to use drugs that specifically affect tumor response to radiation; the most exciting of these are the hypoxic sensitizers, because they affect hypoxic cells that usually are restricted to tumors.

A third mechanism is the combination of drugs and roentgen rays with independent action or additivity. This strategy is just beginning to be explored but appears to be of value in increased local control achieved in head and neck cancer. Because the major advantage of chemotherapy is its wide distribution throughout the body, the combination of radiation and chemotherapy may improve the therapeutic index because, like the combination of surgery and irradiation, the target volumes are different. Adjuvant chemotherapy with radiation for breast cancer, or with surgery and radiation for colon cancer, may improve survival because the chemotherapy is effective against occult micrometastases outside the radiation field. Similarly, radiation may be of value in the treatment of leukemia by chemotherapy because the radiation can be applied to specific sanctuary sites, such as the central nervous system.

### INTRODUCTION

The introduction of chemotherapy in the fifth and sixth decades of the twentieth century has resulted in the development of curative therapeutic interventions for patients with several types of advanced solid tumors and hematologic neoplasms. These advances provided important proof of the principle that anticancer drugs could cure cancer and subsequently resulted in their integration into treatment programs with surgery and radiation therapy in early stages of disease, with excellent results. The important obstacles encountered in the use of chemotherapy have been toxicity to the normal tissues of the body and the development of cellular resistance to these chemotherapeutic agents. During the 1990s, the application of molecular techniques for analysis of the DNA of normal and neoplastic cells began to identify some of the critical mechanisms through which chemotherapy induces cell death. This modern-day technology has also provided insight into the changes within these cells that can confer either sensitivity or resistance to drug treatment. This new level of understanding of the molecular pathways through which chemotherapy works and by which genetic change can result in resistance to drug therapy has opened the door for novel therapeutic strategies in which molecular, genetic, and biologic therapies can be used in combination to attack directly new and specific targets to increase the chemosensitivity of malignant cells to treatment and to protect the normal tissues of the body from therapy-induced side effects. The implementation of such novel therapeutic approaches may provide an important paradigm shift in the manner in which therapy is delivered as we move into the next millennium. Clearly, the long-term goal is to improve the outcome of cancer patients undergoing treatment, especially in those with neoplasms that currently are resistant to conventional-dose therapy.

### HISTORY

The systemic treatment of cancer has its roots in the work of Paul Ehrlich, who coined the word *chemotherapy*. Erlich's use of *in vivo* rodent model systems to develop antibiotics for treatment of infectious diseases led George Clowes, at Roswell Park Memorial Institute in Buffalo, New York, in the early 1900s, to develop inbred rodent lines bearing transplanted tumors that could be used to screen potential anticancer drugs. This *in vivo* system provided the foundation for mass screening of novel compounds.<sup>1</sup> Alkylating agents represent the first class of chemotherapeutic drugs to be used in the clinical setting. Of note, they were a product of the secret gas program of the United States in both world wars. The exposure of military seamen to mustard gas in World War II led to the observation that alkylating agents caused marrow and lymphoid hypoplasia.<sup>2,3</sup> This observation then led to the direct application of such agents in humans with hematologic neoplasms, including Hodgkin's disease and lymphocytic lymphomas, at the Yale Cancer Center in 1943. However, given the secret nature of the gas warfare program, this work was not published until 1946.<sup>1,4</sup> The demonstration of dramatic regressions in advanced lymphomas with chemotherapy generated much excitement. At approximately this same time, Sidney Farber reported that folic acid had a significant proliferative effect on leukemic cell growth in children with lymphoblastic leukemia. These observations led to the development of folic acid analogs as cancer drugs to inhibit folate metabolism; thus, the era of cancer chemotherapy began in earnest.

The cure of childhood leukemias and Hodgkin's disease with combination chemotherapy in the 1960s proved the much-disputed point that a fraction of human cancers, even in their advanced stages, could be cured by drugs. This seminal work laid the foundation for the application of chemotherapy in the treatment of solid tumors. The most disappointing aspect of the work with solid tumors was the failure to cure more patients once it was shown that cancer cells might be more sensitive to cytotoxic drugs than normal cells. This is an especially relevant issue in the adjuvant setting where, because of low tumor burden, cancer cells were thought to be more sensitive to eradication by drug therapy.<sup>5</sup> In addition, a curious and perplexing distribution of responses to chemotherapy has been noted, in that nearly 90% of all drug cures occur in only 10% of cancer types.<sup>6</sup>

Chemotherapy failure was, at first, thought to be due to variations in tumor growth characteristics. Attention then shifted to the role of specific and permanent mechanisms of resistance to individual chemotherapeutic agents that were either acquired after exposure to cancer drugs or were already present as a consequence of intrinsic genetic mutations within the tumor.<sup>7</sup> During the 1980s, a new form of multidrug resistance (mdr gene) to a host of natural-product antitumor agents, including the anthracyclines, the taxanes, the vinca alkaloids, and a few antifolate analogs, was identified. This resistance mechanism was believed to play a significant role in the failure of cancer chemotherapy *in vitro*. The mdr gene encodes a 170-kD membrane glycoprotein that acts to extrude these various anticancer agents from the cell, resulting in decreased intracellular drug accumulation. Recently, the mrp gene, a related family member, has been characterized in pleiotropic drug-resistant cancer cells. This gene encodes a 190-kD protein that functions in a fashion similar to that of the p170 glycoprotein to mediate the rapid efflux of drug from the cell.<sup>8,9</sup> Although mdr and mrp appear to play a key role in the development of drug resistance *in vitro* and *in vivo*, their actual relevance to clinical drug resistance remains unclear.

The therapeutic emphasis in the design of early studies was on maximizing the interaction of the active component of cancer drugs with the cycling cancer cell. The availability of tritiated thymidine, a DNA precursor taken up during the S phase of the cell cycle, made possible the study of the kinetics of cell proliferation. It was quickly determined that cancer cells did not divide faster than normal cells; rather, a larger fraction of the population was dividing.<sup>10</sup> This capacity to enter the cell cycle more frequently was referred to as the *tumor growth fraction*, and it is widely appreciated that cancers, in general, have a significantly higher growth fraction than their normal cell of origin.<sup>11</sup> Though the molecular technology at the time was limited, it was clear even then that the essence of a malignant cell was a critical defect in the ability to control its own growth.

Much of the early clinical work in cancer chemotherapy was based on the kinetic modeling of the drug therapy of the murine leukemia L1210 cell line. Cell kinetic studies revealed this system to be an exponentially growing malignancy with a growth fraction approaching 100%.<sup>12</sup> Except for the rare Burkitt's lymphoma, however, a growth fraction this high has no parallel in human solid tumors. For this reason, the mathematics of cell kill based on the L1210 murine leukemic model could never properly account for the ability to cure some human cancers with a relatively small fraction of cycling cells.<sup>5</sup>

The work with the L1210 model also was the basis for the long-held dogma that rapidity of growth and frequency of cycling in responsive tumors determined sensitivity to chemotherapy. Thus, slowly growing tumors are not kinetically vulnerable, whereas faster-growing tumors are both responsive and curable. Largely because of their good response to treatment, leukemias and lymphomas were considered to be rapidly growing. This observation led to the odd conclusion that solid tumors, such as lung cancer, colon cancer, and other "resistant tumors," were slow-growing, even though there was insufficient evidence for this. It also ran counter to another important clinical observation: Certain human cancers that display a spectrum of growth patterns from indolent to aggressive become significantly more treatable as well as potentially curable as the cell of origin becomes less differentiated and the growth rate, as measured by thymidine-labeling index, increases. When this same

tumor transforms, however, to a highly aggressive phenotype, paradoxically it often becomes almost totally incurable.

Non-Hodgkin's lymphoma is an ideal example of this treatment paradox. Diffuse large cell lymphoma (DHL) is a more rapidly growing form of non-Hodgkin's lymphoma that is curable by combination chemotherapy in its advanced stages. Indolent, low-grade lymphomas are more slowly growing tumors than DHL and, while they are highly responsive to treatment, they are generally incurable in their advanced form with conventional-dose chemotherapy. Thus, despite a similar cell of origin, the more rapidly proliferating cells are subject to complete eradication by chemotherapy. However, further increases in growth rates within populations of patients with diffuse aggressive lymphomas, as predicted by the degree of expression of the Ki-67 antigen, a nuclear antigen that closely parallels the labeling index, negatively predict for both response to treatment and curability.<sup>13</sup> This finding suggests that, beyond a certain point, the emergence of drug resistance in some way accompanies an increase in the growth rate of the tumor.

Another important and curious clinical observation not easily explained by the dogma on acquired drug resistance was that normal renewing tissue, such as the bone marrow and gastrointestinal (GI) mucosa, never develop resistance to these drugs. These are the two host tissues that are most commonly affected by most anticancer agents used in the clinic. It is a consistent and disconcerting clinical experience to have a patient's tumor respond to treatment with associated marrow suppression, only to have the tumor grow back in the face of continued treatment while the sensitivity of the marrow to chemotherapy-induced toxicity remains invariant. The same can be said for toxicity to GI mucosa.<sup>6</sup> It is now well-appreciated that the genetic machinery involved in the cell-cycle checkpoint and apoptosis is preserved in normal host tissues. This fact most likely explains why normal host cells are constantly sensitized to the toxic effect of cytotoxic agents.

## CHEMOTHERAPY AS PART OF THE INITIAL TREATMENT OF CANCER

Currently, chemotherapy has a role in four different clinical settings<sup>14</sup>: (1) as induction treatment for advanced disease, (2) as an adjunct to local methods of treatment, (3) as the primary treatment for some patients who present with localized disease, in whom local forms of therapy by themselves are inadequate, and (4) by direct instillation into sanctuary sites or by site-directed perfusion of specific regions of the body directly affected by the cancer.

The term *induction chemotherapy* has been used to describe drug therapy given as the primary treatment for patients who present with advanced cancer for which no alternative treatment exists.<sup>15</sup> Adjuvant chemotherapy denotes the use of systemic treatment after the primary tumor has been controlled by an alternative modality, such as surgery and radiation therapy. The selection of an adjuvant treatment program for a particular patient usually is based on response rates in separate groups of patients with advanced cancers of the same histologic type. The determination of a population of patients as suitable for adjuvant treatment is based on available data about their average risk of recurrence after local treatment alone. Currently, adjuvant chemotherapy is considered standard treatment for early-stage breast and colorectal cancer.<sup>16,17</sup> There is also evidence to support the use of chemotherapy after surgical resection of anaplastic astrocytomas.<sup>18</sup>

*Primary (neoadjuvant) chemotherapy* denotes the use of chemotherapy as the initial treatment for patients who present with localized cancer for which there is an alternative but less than completely effective local treatment.<sup>19,20</sup> For chemotherapy to be used as the initial (primary) treatment of a cancer partially curable by either surgery or radiation therapy, there must be considerable evidence for the effectiveness of the drug program in question against advanced disease of the same type. At this time, neoadjuvant therapy has been effectively used in the treatment of anal cancer, bladder cancer, breast cancer, esophageal cancer, laryngeal cancer, locally advanced non-small cell lung cancer, and osteogenic sarcoma. For some of these tumors, it has now been determined that chemotherapy, when given concurrently with radiation therapy, is superior to sequencing chemotherapy before radiation therapy.

## CLINICAL END POINTS IN EVALUATING RESPONSE TO CHEMOTHERAPY

### INDUCTION CHEMOTHERAPY

In induction chemotherapy for patients with advanced cancer and measurable disease, it is possible to assess response to drugs on a case-by-case basis. Partial response is usually defined as the fraction of patients who demonstrate at least a 50% reduction in measurable tumor mass. There is growing evidence to suggest that quality-of-life indices are better in patients who show either a response to therapy or a minimal response as compared to supportive care, even if overall survival is not improved. However, partial responses are also useful in the evaluation of new drugs or new drug regimens, to determine whether the particular experimental approach is worthy of further clinical development.

It is clear, however, that the most important indicator of the effectiveness of chemotherapy is the complete response rate. No patient with advanced cancer has ever been cured without first achieving a complete remission. When new programs consistently produce more than an occasional complete remission, they have invariably been proven to be of significant practical value in medical practice. Thus, in clinical trials, complete and partial responses should always be reported separately. The most important indicator of the quality of a complete remission is the relapse-free survival from the time treatment is discontinued. This criterion is the only clinical counterpart of the quantifiable cytoreductive effect of drugs in the *in vivo* rodent system. The use of freedom from progression in patients who have attained a mixture of complete and partial responses can be misleading when evaluating a new treatment.<sup>20</sup> This method of analyzing clinical outcomes is a relatively simple indicator of the practical potential of a new treatment but, for experimental treatments, it obscures the value of a relapse-free survival of complete responders as the major determinant of the quality of remission and the potential for cure. Other end points, such as median response duration and median survival, are also of little practical value until treatment results have been refined so that the complete response rate is higher than 50%.

### ADJUVANT CHEMOTHERAPY

There was initially great excitement with the concept of using chemotherapy as an adjunct to local treatment. The rationale for adjuvant chemotherapy was to treat micrometastatic disease at a time when tumor bulk would be at a minimum, thereby enhancing the potential efficacy of drug treatment. It was assumed that drug therapy, at this stage, would result in a much higher cure rate.<sup>21,22</sup>

The major indicator of effectiveness of a chemotherapy program—the complete remission rate—is lost in the adjuvant setting because the primary tumor has already been removed. In the clinic, treatment is selected for individual patients based on response rates in an entirely different population of patients with advanced disease of the same histologic type. In adjuvant programs, relapse-free survival remains the major end point but, in each patient, micrometastases consist of a mixture of tumor cells, some of which could have been expected to be sensitive to chemotherapy and others of which could have been expected to be resistant to chemotherapy. The relapse-free survival in the adjuvant setting, therefore, measures time to regrowth to clinically detectable levels of cells unresponsive, partially responsive, or very sensitive to chemotherapy and is the equivalent of the duration of remission of a combined group of complete responders, partial responders, and nonresponders. In this sense, it is similar to the use of freedom from progression in patients with advanced disease.

### PRIMARY (NEOADJUVANT) CHEMOTHERAPY

The unique feature of using chemotherapy in patients with localized tumor before or in place of purely local treatments, such as surgical excision or radiation therapy (or both), is the preservation of the presenting tumor mass as a biologic marker of responsiveness to the drugs. Moreover, this approach has allowed the sparing of vital normal organs, such as the larynx, the anal sphincter, and the bladder, as the primary tumor is reduced in size and rendered easier to deal with by traditional local measures. As with induction chemotherapy for patients with advanced cancer, it is possible to determine, on an individual basis, the potential efficacy of a new treatment program. A good response to chemotherapy identifies a patient who may benefit from further treatment. A poor response of the primary tumor to chemotherapy identifies a patient for whom alternative methods of treatment should be seriously considered. Another feature of primary chemotherapy is the ability to differentiate partial responders with varying degrees of prognosis. Removal of residual tumor masses and histologic examination of the tissue allow determination of the viability and character of the remaining tumor cells. The response duration of complete and partial responders must be catalogued separately. Such an approach could result in briefer, less morbid, and more effective treatment programs.<sup>14</sup> When chemotherapy is administered concurrently with radiation therapy, the determinants of sensitivity to drugs are obviated unless compared to radiation alone in a control arm.

The use of chemotherapy as primary treatment is reviewed in each of the appropriate disease-oriented chapters. [Table 17-1](#) lists the specific malignancies in which primary chemotherapy for localized forms of the cancer in question already have been incorporated into clinical usage (first and second categories) and in which current clinical trials show considerable promise (third category).<sup>23,24,25,26,27,28,29,30,31 and 32</sup>

Principle	Explanation
1. Drugs should be used in their optimal dose and schedule, and drug combinations should be given at consistent intervals.	Because long intervals between cycles negatively affect dose intensity (discussed in further detail later in <a href="#">Concept of Dose Intensity</a> ), the treatment-free interval between cycles should be the shortest possible time necessary for recovery of the most sensitive normal target tissue, which is usually the bone marrow. Finally, there should be a clear understanding of the biochemical, molecular, and pharmacokinetic mechanisms of interaction between the individual drugs in a given combination, to allow for maximal effect.
2. Omission of a drug from a combination may allow overgrowth by a cell line sensitive to that drug alone and resistant to other drugs in the combination.	In addition, arbitrary reduction in the dose of an effective drug to add other less effective drugs may dramatically reduce the dose of the most effective agent below the threshold of effectiveness and destroy the capacity of the combination to cure disease in a given patient.
3. Most standard treatment programs were designed around the kinetics of recovery of the bone marrow in response to exposure to a cytotoxic agent.	The introduction of the colony-stimulating factors (CSFs) has been a significant advance for cancer therapy, as they help to accelerate bone marrow recovery and prevent the occurrence of severe myelosuppression. <sup>38</sup> They play an instrumental role in decreasing the incidence of infections and the need for hospitalizations and allow for maintenance of optimal dose intensity of chemotherapy. Clearly, these cytokine growth factors have revolutionized the next generation of chemotherapy treatment.
4. Bone marrow has a storage compartment that supplies mature cells to the peripheral blood for 8 to 10 days after the stem cell pool has been damaged by cytotoxic drugs.	Events in the peripheral blood are usually a week behind events occurring in the bone marrow. In previously untreated patients not primed by CSFs, leukopenia and thrombocytopenia are observed on the ninth or tenth day after initial dosing. Nadir blood counts are noted between days 14 and 18, with the onset of recovery beginning by day 21 and usually completed by day 28 in patients who have not had prior treatment with drugs or x-irradiation. This sequence may be altered in patients with previous therapy by depletion of the stem cell pool, shortening the time to the appearance of leukopenia and thrombocytopenia and prolonging the recovery time. The interval of greatest importance in the clinic is the duration of the nadir level of leukocytes and platelets. The highest risk of infection or bleeding occurs with granulocyte counts lower than 500/dL and platelet counts lower than 10,000/dL. If this nadir lasts only 4 to 7 days, it is tolerated by most patients without the need for supplemental support. Increasing doses of most anticancer drugs within the range of the maximally tolerated standard dose does not usually ablate the marrow or even prolong the time to recovery; however, it does usually influence the nadir count levels. Repeated dosing during the phase of early recovery of the marrow (days 16 to 21) may result in more severe toxicity in the second treatment cycle in patients whose marrow is not the source of, or involved with, the tumor.
5. These clinical observations, coupled with the kinetic studies of bone marrow recovery in mice and humans, led to the now-familiar 2-week interval between cycles of the most effective drug combinations, using standard doses without CSFs (new cycles begin on days 21 or 28 after the first dose) to accommodate the recovery time of human bone marrow.	Although this treatment schedule is suitable for some tumors, the rapid regrowth of others, such as DHLs, Burkitt's lymphoma, and leukemia, often permit the tumor volume to return to pretreatment levels in the interval required for bone marrow recovery, and other approaches to cycling drug combinations are being explored.
6. No rigid schedule can accommodate all the variables assumed to be important for maximum effectiveness of combination chemotherapy and the requirements of the patients in the practice of medical oncology.	Physicians must often adjust doses at intervals to allow for the safe administration of drugs. The certainty that the therapeutic effect of a drug or drug combination can be lost if the dose or schedule is altered should temper these judgments. Reductions in dose rates also often result in only minimal decreases in toxicity but major reduction in the capacity to attain a complete remission in patients with drug-responsive tumors. <sup>6</sup> Adherence to the standard sliding scale for dose adjustments, usually published with most new treatments, or the prompt initiation of CSF adjunct therapy is the most appropriate way to optimize the delivery of chemotherapy without compromising long-term outcome. The application of appropriate guidelines for dose reductions preserves the intervals between treatment cycles, preserves the integrity of each drug combination and, finally, provides consistency between patients and various clinical studies. <sup>39</sup>
7. For many years, clinical trial design has been dominated by the use of alternating cycles of combination chemotherapy.	The basis for this study design came from the translation of preclinical experimental data into a model for clinical treatment. In 1943, Luria and Delbruck <sup>40</sup> observed that the bacterium <i>Escherichia coli</i> developed resistance to bacterial viruses (bacteriophage) not by surviving exposure but by expanding clones of bacteria that had spontaneously mutated to a type inherently resistant to phage infection. This was a seminal principle in bacterial genetics that laid the framework for the understanding of the development of spontaneous resistance to cancer chemotherapy. <sup>40</sup> In 1979, Goldie and Coldman <sup>41</sup> applied this principle to the development of resistance to anticancer drugs by cancer cells without prior exposure to these drugs. They proposed that the nonrandom cytogenetic changes now known to be associated with most human cancers probably were tightly associated with the development of the capacity to resist the action of certain types of anticancer drugs. They developed a mathematical model that predicted that tumor cells mutate to drug resistance at a rate intrinsic to the genetic instability of a particular tumor. Their model predicted that such events would begin to occur at population sizes between 10 <sup>3</sup> and 10 <sup>6</sup> tumor cells (1000 to 1 million cells), much lower than the mass of cells considered to be clinically detectable (10 <sup>9</sup> , or 1 billion cells). The probability that a given tumor will contain resistant clones when a patient's disease is newly diagnosed would be a function of both tumor size and the inherent mutation rate. If the mutation rate is as infrequent as 10 <sup>-6</sup> , a tumor composed of 10 <sup>9</sup> cells (a 1-cm mass) would be predicted to have at least one drug-resistant clone; however, the absolute number of resistant cells in a tumor composed of 10 <sup>9</sup> cells would be relatively small. Therefore, in the clinic, such tumors should initially respond to treatment with a partial or complete remission but would recur as the resistance clone expands to repopulate the tumor mass. Such a pattern is commonly seen in the clinical setting with the use of chemotherapy in many drug-responsive tumors.
8. The Goldie-Coldman hypothesis, therefore, predicts that cellular drug resistance should be present even with small tumors and that the maximal chance for cure	

TABLE 17-1. Primary Chemotherapy

## PRINCIPLES GOVERNING THE USE OF COMBINATION CHEMOTHERAPY

With rare exceptions (e.g., choriocarcinoma and Burkitt's lymphoma), standard single drugs at clinically tolerable doses have been unable to cure cancer. In the early years of cancer chemotherapy, drug combinations were developed based on known biochemical actions of available anticancer drugs rather than on their clinical efficacy. These regimens were largely ineffective.<sup>33,34,35,36</sup> and <sup>37</sup> The era of effective combination chemotherapy began when an array of active drugs from different classes became available for use in combination in the treatment of leukemias and lymphomas. Combination chemotherapy has now been extended to the treatment of most solid tumors, as described throughout this book.

Combination chemotherapy using conventional cytotoxic agents accomplishes several important objectives not possible with single-agent treatment. First, it provides maximal cell kill within the range of toxicity tolerated by the host for each drug as long as dosing is not compromised. Second, it provides a broader range of interaction between drugs and tumor cells with different genetic abnormalities in a heterogeneous tumor population. Finally, it may prevent or slow the subsequent development of drug resistance.

Certain principles have been useful in the selection of drugs in the most effective drug combinations, and they guide the development of new drug therapeutic programs. First, only drugs known to be partially effective against the same tumor when used alone should be selected for use in combination. If available, drugs that produce some fraction of complete remission are preferred to those that produce only partial responses. Second, when several drugs of a class are available and are equally effective, a drug should be selected on the basis of toxicity that does not overlap with the toxicity of other drugs to be used in the combination. Although such selection leads to a wider range of side effects, it minimizes the risk of a lethal effect caused by multiple insults to the same organ system by different drugs and allows dose intensity to be maximized.

Additionally, drugs should be used in their optimal dose and schedule, and drug combinations should be given at consistent intervals. Because long intervals between cycles negatively affect dose intensity (discussed in further detail later in [Concept of Dose Intensity](#)), the treatment-free interval between cycles should be the shortest possible time necessary for recovery of the most sensitive normal target tissue, which is usually the bone marrow. Finally, there should be a clear understanding of the biochemical, molecular, and pharmacokinetic mechanisms of interaction between the individual drugs in a given combination, to allow for maximal effect.

Omission of a drug from a combination may allow overgrowth by a cell line sensitive to that drug alone and resistant to other drugs in the combination. In addition, arbitrary reduction in the dose of an effective drug to add other less effective drugs may dramatically reduce the dose of the most effective agent below the threshold of effectiveness and destroy the capacity of the combination to cure disease in a given patient.

Most standard treatment programs were designed around the kinetics of recovery of the bone marrow in response to exposure to a cytotoxic agent. The introduction of the colony-stimulating factors (CSFs) has been a significant advance for cancer therapy, as they help to accelerate bone marrow recovery and prevent the occurrence of severe myelosuppression.<sup>38</sup> They play an instrumental role in decreasing the incidence of infections and the need for hospitalizations and allow for maintenance of optimal dose intensity of chemotherapy. Clearly, these cytokine growth factors have revolutionized the next generation of chemotherapy treatment.

Bone marrow has a storage compartment that supplies mature cells to the peripheral blood for 8 to 10 days after the stem cell pool has been damaged by cytotoxic drugs. Events in the peripheral blood are usually a week behind events occurring in the bone marrow. In previously untreated patients not primed by CSFs, leukopenia and thrombocytopenia are observed on the ninth or tenth day after initial dosing. Nadir blood counts are noted between days 14 and 18, with the onset of recovery beginning by day 21 and usually completed by day 28 in patients who have not had prior treatment with drugs or x-irradiation. This sequence may be altered in patients with previous therapy by depletion of the stem cell pool, shortening the time to the appearance of leukopenia and thrombocytopenia and prolonging the recovery time. The interval of greatest importance in the clinic is the duration of the nadir level of leukocytes and platelets. The highest risk of infection or bleeding occurs with granulocyte counts lower than 500/dL and platelet counts lower than 10,000/dL. If this nadir lasts only 4 to 7 days, it is tolerated by most patients without the need for supplemental support. Increasing doses of most anticancer drugs within the range of the maximally tolerated standard dose does not usually ablate the marrow or even prolong the time to recovery; however, it does usually influence the nadir count levels. Repeated dosing during the phase of early recovery of the marrow (days 16 to 21) may result in more severe toxicity in the second treatment cycle in patients whose marrow is not the source of, or involved with, the tumor.

These clinical observations, coupled with the kinetic studies of bone marrow recovery in mice and humans, led to the now-familiar 2-week interval between cycles of the most effective drug combinations, using standard doses without CSFs (new cycles begin on days 21 or 28 after the first dose) to accommodate the recovery time of human bone marrow. Although this treatment schedule is suitable for some tumors, the rapid regrowth of others, such as DHLs, Burkitt's lymphoma, and leukemia, often permit the tumor volume to return to pretreatment levels in the interval required for bone marrow recovery, and other approaches to cycling drug combinations are being explored.

No rigid schedule can accommodate all the variables assumed to be important for maximum effectiveness of combination chemotherapy and the requirements of the patients in the practice of medical oncology. Physicians must often adjust doses at intervals to allow for the safe administration of drugs. The certainty that the therapeutic effect of a drug or drug combination can be lost if the dose or schedule is altered should temper these judgments. Reductions in dose rates also often result in only minimal decreases in toxicity but major reduction in the capacity to attain a complete remission in patients with drug-responsive tumors.<sup>6</sup> Adherence to the standard sliding scale for dose adjustments, usually published with most new treatments, or the prompt initiation of CSF adjunct therapy is the most appropriate way to optimize the delivery of chemotherapy without compromising long-term outcome. The application of appropriate guidelines for dose reductions preserves the intervals between treatment cycles, preserves the integrity of each drug combination and, finally, provides consistency between patients and various clinical studies.<sup>39</sup>

For many years, clinical trial design has been dominated by the use of alternating cycles of combination chemotherapy. The basis for this study design came from the translation of preclinical experimental data into a model for clinical treatment. In 1943, Luria and Delbruck<sup>40</sup> observed that the bacterium *Escherichia coli* developed resistance to bacterial viruses (bacteriophage) not by surviving exposure but by expanding clones of bacteria that had spontaneously mutated to a type inherently resistant to phage infection. This was a seminal principle in bacterial genetics that laid the framework for the understanding of the development of spontaneous resistance to cancer chemotherapy.<sup>40</sup> In 1979, Goldie and Coldman<sup>41</sup> applied this principle to the development of resistance to anticancer drugs by cancer cells without prior exposure to these drugs. They proposed that the nonrandom cytogenetic changes now known to be associated with most human cancers probably were tightly associated with the development of the capacity to resist the action of certain types of anticancer drugs. They developed a mathematical model that predicted that tumor cells mutate to drug resistance at a rate intrinsic to the genetic instability of a particular tumor. Their model predicted that such events would begin to occur at population sizes between 10<sup>3</sup> and 10<sup>6</sup> tumor cells (1000 to 1 million cells), much lower than the mass of cells considered to be clinically detectable (10<sup>9</sup>, or 1 billion cells). The probability that a given tumor will contain resistant clones when a patient's disease is newly diagnosed would be a function of both tumor size and the inherent mutation rate. If the mutation rate is as infrequent as 10<sup>-6</sup>, a tumor composed of 10<sup>9</sup> cells (a 1-cm mass) would be predicted to have at least one drug-resistant clone; however, the absolute number of resistant cells in a tumor composed of 10<sup>9</sup> cells would be relatively small. Therefore, in the clinic, such tumors should initially respond to treatment with a partial or complete remission but would recur as the resistance clone expands to repopulate the tumor mass. Such a pattern is commonly seen in the clinical setting with the use of chemotherapy in many drug-responsive tumors.

The Goldie-Coldman hypothesis, therefore, predicts that cellular drug resistance should be present even with small tumors and that the maximal chance for cure

occurs when all available effective drugs are given simultaneously.<sup>41</sup> Because this would involve using eight to 12 drugs simultaneously, this approach has not generally been tested in the clinic for fear that the use of more than five cytotoxic drugs, at full doses, would not be possible. An alternative approach, using two programs of equally effective, non-cross-resistant drug combinations in alternating cycles, has been under evaluation since the mid-1980s. However, many studies purporting to test the Goldie-Coldman hypothesis have not been properly designed. First, in many instances, inadequate testing has been carried out to determine whether the alternate combination is truly non-cross-resistant and is as effective as the primary treatment. In most instances, these requirements are not met. Second, except in rare instances, dosing is usually not controlled properly. Doses of essential drugs are modified downward, *a priori*, without testing the potential impact of such dose reductions on outcome. Finally, the requirement for symmetry in biologic characteristics of tumors in different patients is unrealistic. The use of alternating cycles of combination chemotherapy has not yet proven to be more effective than full doses of a single effective combination program.

In 1986, Day<sup>42</sup> and Norton and Day<sup>43</sup> reanalyzed the Goldie-Coldman hypothesis and relaxed the requirement for symmetry in the model. Although it verified the basic tenets of the Goldie-Coldman hypothesis, their model suggested a different approach to sequencing combinations: In many instances, the sequential use of combinations should outperform alternating cycles, because no two combinations are likely to be strictly non-cross-resistant or have equal cell-killing capacity, the symmetry assumed by Goldie and Coldman. Day formulated “the worst-drug rule,” which refers to any strategy using more or earlier doses of a treatment that is the least effective of two or more available options.<sup>6</sup> The worst-drug rule has interesting implications. First, it is a nonintuitive approach. If two treatments—treatments A and B—are available and B is known to be better, a physician is more likely to use B first. Cells that are resistant to the best treatment, B, must be eliminated by the weaker program, A; however, because it is the weaker program, one cannot wait too long to use it or the overgrowth of the population resistant to B will place the physician and patient in a situation that is difficult to overcome. The model predicts that if six cycles of A and B are planned, use of the weaker program, A, first offers a better outcome. There have been clinical examples in which sequential therapies have outperformed alternating cyclic use of the same programs if the dose intensity of the two regimens is carefully controlled.<sup>44,45</sup>

## EFFECT OF THE BIOLOGY OF TUMOR GROWTH ON RESPONSE TO CHEMOTHERAPY

Applying the principles of chemotherapy developed by Skipper et al.<sup>12,46,47</sup> in leukemia L1210 to the drug treatment of human cancers requires a clear understanding of the differences between the growth characteristics of this rodent leukemia and of human cancers as well as an understanding of the differences in growth rates of normal target tissues between mice and humans. For example, L1210 is a rapidly growing leukemia with a high percentage of cells synthesizing DNA, as measured by the uptake of tritiated thymidine (the labeling index). Because L1210 leukemia has a growth fraction of 100% (i.e., all its cells are actively progressing through the cell cycle), its life cycle is consistent and predictable.<sup>48</sup>

The time to death of animals bearing L1210 leukemia is the interval required to achieve a population size of approximately  $10^9$  (1 billion) cells. With a growth fraction of 100% and a doubling time of 12 hours,  $10^9$  cells accumulate by 19 days after the injection of a single cell, by 10 days after the injection of  $10^5$  cells, and by 5 days after the administration of  $10^8$  cells. Skipper et al.<sup>46,47</sup> postulated that the increase in host life span after cytotoxic chemotherapy of L1210 leukemia was largely due to the cytotoxic effect of treatment on the tumor cell population. In these early elegant mouse experiments, they calculated the residual number of cells after treatment by extrapolating back from the duration of prolongation of life after a single treatment. An increase of 2 days in life would be equivalent to a 90% destruction of tumor cells (a 1-log kill), or a reduction in the cell number from  $10^6$  to  $10^5$ . A 99.999% destruction of tumor cells, a number that seems enormous to most clinicians, represents only a 5-log kill and does not cure disease in animals unless the initial inoculum is small, perhaps  $10^4$  cells or fewer. If multiple treatments are given, the net tumor cell kill per treatment is the sum of the surviving cells plus the regrowth of the tumor cell population before the next treatment.

The cytotoxic effects of cancer drugs in this tumor model follow log cell-kill kinetics. Thus, if a particular dose of an individual drug kills 3 logs of tumor cells and reduces tumor burden from  $10^{10}$  to  $10^7$  cells, the same dose used at a tumor burden of  $10^5$  cells reduces the tumor mass to  $10^2$ . Cell kill, therefore, is proportional, regardless of tumor burden. This model fits the response of L1210 murine leukemia to chemotherapy. When treatment failed in sensitive cell lines, it was because the initial tumor burden was too high to allow the delivery of curative doses of chemotherapy to eradicate the last leukemia cell. The cardinal rule of chemotherapy—the invariable inverse relation between cell number and curability—was established in this model and applies to other model systems. Skipper et al.<sup>12</sup> proceeded to show that this rodent leukemia could be cured by specifically designing doses and schedules of administration that were based on tumor volume and growth characteristics.

Although growth of murine leukemias closely follows exponential cell kinetics, available data suggest that most human solid tumors do not grow in an exponential fashion. For example, the concept of log kill would have predicted that some large tumors in the clinic should have been more sensitive to treatment than has been experienced. *In toto*, the experimental data in human solid cancers support a Gompertzian model of tumor growth and regression. The critical distinction between Gompertzian and exponential growth is that in Gompertzian kinetics, the growth fraction of the tumor is not constant but decreases exponentially with time (exponential growth is matched by exponential retardation of growth). The growth fraction peaks when the tumor is approximately 37% of its maximum size. In a Gompertzian model, when a patient with advanced cancer is treated, the tumor mass is larger, its growth fraction is low, and the fraction of cells killed is, therefore, small. An important feature of Gompertzian growth is that response to chemotherapy in drug-sensitive tumors depends, in large measure, on where the tumor is in its particular growth curve. Sensitive Gompertzian-growing tumors respond to cytotoxic drugs in a Gompertzian fashion.

Therefore, predictions can be made about the behavior of small tumors, such as the microscopic tumor burdens that might be present after primary surgical therapy. When the tumor is clinically undetectable, its growth fraction would be at its largest and, although the numerical reduction in cell number is small, the fractional cell kill from a known-to-be-effective therapeutic dose of chemotherapy would be higher than later in the tumor course. This observation was initially used to justify dose reductions at lower tumor volumes. However, such an unnecessary dose reduction may account for some of the disappointment in the outcome of adjuvant studies in breast cancer. The Gompertzian model for tumor growth is important for another reason: It affects the patterns of regrowth of residual tumor cells. In breast cancer, Norton<sup>43,49</sup> has analyzed the clinical data from multiple adjuvant studies and from available studies of untreated patients with localized disease.<sup>6,50</sup> In each clinical study, the Gompertzian model precisely fit the growth curves of these tumors. In the adjuvant setting, the model showed that relapse-free survival and survival curves are unable to discriminate between residual cell populations of only one cell and a residual population of 1 million cells, because the regrowth of residual cell populations will be faster at smaller volumes than it will be at larger volumes, producing identical results sometimes at 5 years after diagnosis and treatment. These findings suggest that short of total eradication of micrometastases (cure), varying residual volumes produce similar 5-year relapse-free survival and obscure the major differences in tumor reduction by different programs. This information has been especially useful in the design of new adjuvant treatment protocols for early-stage breast cancer.

## APOPTOSIS, CELL-CYCLE CONTROL, AND RESISTANCE TO CHEMOTHERAPY

The kinetic models described are realistic only in the context of a tumor that is sensitive to chemotherapy. Only recently have we arrived at a new understanding of the critical determinants of drug sensitivity and resistance. For more than 30 years, the classic view of anticancer drug action has involved the specific interaction between a given drug and its respective target. Cell death arises as a direct consequence of this drug-receptor interaction. However, the critical molecular mechanisms involved in facilitating the initial coupling of the stimulus to the final response of the cell were never clearly elucidated. With an enhanced understanding of the molecular mechanisms underlying the control of the cell cycle and the process of programmed cell death (apoptosis), it is now clear that this very simplistic model must be reevaluated. In contrast to the drug-target interaction directly leading to cell death as was viewed in the classic model, it is now well appreciated that such an interaction acts as a stimulus to initiate a cascade of events eventually resulting in apoptosis. It is doubtful that cell death induced by chemotherapy occurs by any other mechanism. This pathway involves some type of sensor that detects a death-inducing signal, a signal transduction network, and an execution machinery that facilitates the process of cell death. Moreover, this entire process is exceedingly complex as it is highly dependent on the specific cell type under study, the specific anticancer agent being tested, and the cellular context and environment in which the drug-target interaction is being considered.

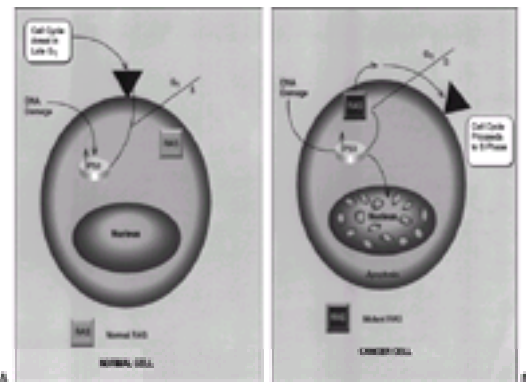

In addition, it now appears that the capacity of certain cancers to resist the cytotoxic effects of cancer chemotherapy may be more closely connected to either abnormalities in the genetic machinery of cancer cells or to alterations in the critical pathways of cell-cycle checkpoint control and apoptosis than to the specific mechanisms of resistance unique to each agent. This observation is underscored by the general failure to overcome resistance to chemotherapy in the clinic with approaches that attack only the classic biochemical or molecular mechanisms of resistance (or both). Although this section briefly reviews the complex interrelationship between products of cell-cycle checkpoint genes, oncogenic viruses, transcription factors, apoptosis, and chemotherapy as they relate to drug resistance, more detailed discussion of these topics are reviewed elsewhere.<sup>51,52,53,54,55,56,57,58</sup> and <sup>59</sup>

As noted earlier in the [History](#) section of this chapter, normal tissues never develop resistance to chemotherapy. However, one of the most remarkable features of both radiation therapy and chemotherapy, when used to treat sensitive tumors, is that their cytotoxic effects may be initially greater in neoplastic cells than in normal host tissues, including the bone marrow and the GI tract. Doses that eradicate some sensitive tumors will not ablate the bone marrow or destroy the capacity of the GI mucosa to regenerate. No molecular basis for this therapeutic selectivity was available until just recently. However, this difference in cytotoxic action between normal

and malignant cells appears to relate to mechanisms that allow normal renewing cell populations, such as bone marrow and GI precursor cells, to monitor and repair damaged DNA or destroy cells with irreparable DNA, rather than allowing damaged cells to proceed through the cell cycle and potentially replicate their damaged DNA. Because they express an intact genetic machinery, normal cells can almost always recover from exposure to DNA-damaging anticancer agents, except in the case of high-dose chemotherapy, as used in transplantation programs. In this particular setting, the high doses of chemotherapy are able to overwhelm these protective mechanisms or to destroy the DNA of exposed cells by direct necrosis (or both). Initially, sensitive cancer cells can be destroyed by effective chemotherapy but, if not, they develop resistance to further treatment, perhaps in part because of drug-induced mutations in their DNA. This resistance may be linked to the dysregulation of the same genetic and signaling pathways that control entry into the cell cycle and the process of programmed cell death.

p53

p53 (Fig. 17-1) is a tumor suppressor protein and critical transcriptional activator that causes both G<sub>1</sub> and G<sub>2</sub> arrest of the cell cycle when cells are exposed to DNA-damaging agents.<sup>51,52,53</sup> and <sup>54,57,60,61</sup> and <sup>62</sup> This function is thought to be critical in preserving the integrity of the cellular genome in response to treatment with a cytotoxic agent. In addition to its role in the cell-cycle checkpoint, p53 is a potent inducer of programmed cell death (apoptosis) within a cell in which DNA damage has occurred.<sup>50</sup> The basis for the cell's decision either to undergo growth arrest and repair DNA damage or to induce apoptosis remains unknown. Significant research efforts are focused on elucidating the critical factors that determine the eventual cellular function of p53. This is undoubtedly a complex issue, however, that must take into account the extent of DNA damage, the stage of the cell cycle at which the DNA damage occurs, the presence of other genetic abnormalities in either the cell-cycle regulatory apparatus or the signaling machinery, or the specific cellular context. It is now clear that some cell types, such as lymphocytes and the tumors derived from them, have a more rapid access to apoptotic mechanisms than the large majority of epithelial cancers.

**FIGURE 17-1.** Role of p53 in chemotherapy sensitivity in normal and neoplastic cells. Exposure of normal cells (A) to DNA-damaging agents results in increased levels of p53, which induces an arrest of progression from the G<sub>1</sub> or quiescent phase to the S or DNA synthetic phase of the cell cycle. Exposure of cancer cells (B) to DNA-damaging agents increases p53 but does not stop cell-cycle progression to S phase, owing to mutant Ras. This results in apoptosis. (From AB Deisseroth, VT DeVita. The cell cycle: probing new molecular determinants of resistance and sensitivity to cytotoxic agents. *Cancer J Sci Am* 1995;1:15, with permission.)

Mutations in the p53 gene are among the most common genetic alterations observed in human tumor samples and have been estimated to occur in at least 50% of all human tumors.<sup>63</sup> The initial studies showing that loss of p53 function was associated with resistance to radiation therapy as well as chemotherapy came from *in vivo* model systems using p53 knockout mice.<sup>64,65,66</sup> and <sup>67</sup> Subsequent studies have confirmed that various malignant cell lines and tumors expressing mutant or deleted p53 are chemoresistant to a wide range of anticancer agents.<sup>68</sup> However, loss of p53 function is not always associated with chemoresistance. Some studies suggest that cells with impaired p53 function can become sensitized to various anticancer agents.<sup>69</sup> Thus, the relationship between p53 status and chemosensitivity is complex and is presumably dependent on a number of factors, including the specific cytotoxic stimuli, tissue-specific differences, and the specific cellular context that incorporates the overall genetic machinery and the various intracellular signaling pathways.

The specific cytotoxic treatment, the conditions of treatment, p53 status, and other cell-cycle regulatory elements may all contribute to the outcome of an exposure of a cell to DNA-damaging agents. If the dose of the treatment is very high, nonapoptotic cell death (e.g., necrotic cell death due to DNA or other damage) may occur. At an intermediate level of dose intensity, p53-dependent or p53-independent apoptotic cell death can occur. When p53 function is intact, the level of inhibitors of p53 is not high, and the regulatory environment of the cell is such that the cell circumvents the interruption of the cell-cycle progression that occurs after DNA damage, the cell will undergo p53-dependent apoptosis. However, in the setting of abnormal p53 function, whether through the acquisition of point mutations in the p53 gene, posttranslational inactivation of p53 through binding to other protein partners (e.g., MDM2) or enhancement of the degradation (e.g., the E6 protein of the human papilloma virus), or decreased translation of wild-type p53 messenger RNA by the folate-dependent enzyme thymidylate synthase, the cell is unable to undergo cell-cycle arrest or apoptosis in response to DNA damage. In a tumor population, the functional inactivation of p53 through any of these regulatory mechanisms facilitates genomic instability and contributes to the development of cellular resistance. Normal hematopoietic cells tend to be more genetically stable during chemotherapy as a result of an intact p53 mechanism that provides an opportunity to repair DNA damage. In contrast, the malignant cell with functional p53 may be more sensitive to chemotherapy than normal cells because of the fact that common transforming mutations in other proteins, such as ras, which tend to drive cells into S phase, overcome the p53-dependent mechanisms that allow for repair. Because the p53-dependent apoptotic mechanisms, triggered by DNA damage, may remain intact, the tumor cell dies after chemotherapy, whereas the normal cell survives. When the function of p53 is finally lost, the stability of the genome of the tumor cells decreases, and the disease progresses rapidly to higher and higher levels of resistance to therapy and to a more advanced pattern of dysregulated growth and metastasis.

Although it was initially thought that drug-curable tumors, in general, were less often found to have p53 mutations, this is not always the case. In addition to p53-dependent mechanisms, it is well appreciated that p53-independent mechanisms also exist. In general, the presence of p53 mutations has been correlated with a poor prognosis, even in such treatable tumors as lymphomas.<sup>70</sup> However, the issue of whether mutations determine cure or no cure will be addressed only by reexamination of the tissue specimens of patients cured many years ago, to separate easily the impact of a damaged cell-cycle checkpoint control system on early response to treatment rather than cure.

This is an important question. If drugs can kill only cells with an intact apoptotic mechanism, as expressed by a functioning p53 gene, the chemotherapy of cancer may have gone as far as it can go in its present form, except for the increment of additional cures that may be attained by using high-dose regimens that overwhelm these mechanisms. If cures are possible in tumors with mutant p53, responsiveness to treatment may relate more to the degree of dysregulation of the checkpoint control system, which is downstream from p53 in the growth regulatory pathway, something that possibly can be manipulated as an approach to treatment.

How might dysregulation of this pathway increase drug resistance beyond the failure to induce apoptosis? p53 affects events within the cell by binding to p53 recognition sites located in the transcriptional regulatory regions of genes.<sup>71,72,73,74,75</sup> and <sup>76</sup> The acquisition of point mutations in the p53 gene can affect the DNA-binding function and the transcriptional activation functions of p53 at these regulatory sites.<sup>59</sup>

Some of the genes that are transcriptionally activated by p53 belong to a class of proteins known to inhibit the cyclin-dependent kinases (Fig. 17-2). One of these proteins, known as p21 (Waf-1, Cip-1), can form a complex with proliferating cell nuclear antigen or inhibit the full activation of the cyclin-dependent kinase.<sup>76</sup> When the cyclin kinase is fully active, it acts on another tumor suppressor, the retinoblastoma (RB) gene, to phosphorylate it.<sup>77</sup> This causes the release of the E2F family of transcription factors, which then bind to the regulatory regions of a number of genes that participate in the synthesis of DNA. These genes are shown in Figure 17-2 and include ribonucleotide reductase, dihydrofolate reductase, DNA-dependent RNA polymerase, thymidylate synthase, c-myc, c-fos, and c-myb.

**FIGURE 17-2.** Once its level is high within the cell, p53 can induce p21 expression to such an extent that the cyclin-dependent kinase activation complex does not occur. The absence of this kinase activity permits the retinoblastoma protein to remain in its unphosphorylated form, in which it binds to the transcription factor E2F. This, in turn, prevents the release of E2F and its binding to the transcriptional enhancers of the genes necessary for DNA synthesis to occur. DHFR, dihydrofolate reductase; PCNA, proliferating cell nuclear antigen. (From AB Deisseroth, VT DeVita. The cell cycle: probing new molecular determinants of resistance and sensitivity to cytotoxic agents. *Cancer J Sci Am* 1995;1:15, with permission.)

Activation of this family of proteins promotes and supports the entry of the cell into S phase. The activation of cyclin-dependent kinases and the consequent turning on of the DNA synthetic machinery by release of E2F from RB occur in normal cells after growth factor stimulation, which probably provides the signal for the initiation of the cyclin clock.<sup>78</sup> When normal p53 is activated after DNA damage, the levels of the p21, p27, and other gene products, such as MDM-2, an apparent feedback regulator of p53, and GADD 45, a gene involved in DNA repair, may become very high.<sup>79</sup> When the expression of p21 is induced to high levels, it exerts an inhibitory effect on the formation of the fully active cyclin kinase complex. This critical checkpoint function of p53, which restricts the procession of the cell into the DNA synthetic phase of the cell cycle, also prevents the E2F-dependent expression of gene products related to rapid cell growth.

The *mdr-1* gene has been added to the list of those potentially influenced by p53 because it has been shown that wild-type p53 suppresses the promoter of the *mdr-1* gene, whereas the mutant protein can actually stimulate the promoter.<sup>80,81</sup> The biologic basis for this action is not readily apparent but, when the foregoing effects are considered *in toto*, dysregulation of the p53 pathway, which would be expected to be associated with more rapid growth, might well be a prominent mechanism of drug resistance due to the overproduction of gene products responsible for entry into S phase and rapid cell growth. The activation of these genes could theoretically increase the resistance of cells to the following chemotherapeutic agents: methotrexate, 2-chlorodeoxyadenosine, hydroxyurea, fludarabine, cytosine arabinoside, and 5-fluorouracil. Furthermore, the action of an entire array of the most effective natural product antitumor agents could be suppressed through stimulation of the *mdr-1* promoter directly by a mutant form of p53.

Thus, an active p53 in the setting of such DNA-damaging agents as chemotherapy or irradiation increases the levels of key gene products to levels that are sufficient to inhibit the phosphorylation of the RB gene by cyclin-dependent kinase (Fig. 17-3). This, in turn, prevents the expression of the gene products necessary for DNA synthesis to occur.

**FIGURE 17-3.** DNA damage induced by anticancer drugs and irradiation and oncogene expression initiate pathways involved in apoptosis or cell-cycle arrest (or both). CDKs, cyclin-dependent kinases; UV, ultraviolet. (From ref. 56, with permission.)

It is conceivable that increasing growth rates may be associated with increasing levels of drug resistance through the increased transcription of genes involved in rapid cell growth and entry into the cell cycle. The high degree of resistance in more advanced tumors, including the spontaneous development of resistance, which was the basis of the Goldie-Coldman hypothesis, and the development of multidrug resistance, appear more likely to be related to mutations in key genes in the cell-cycle regulatory system than to drug-specific spontaneous mutations, as has been proposed in the past. Cell death in response to exposure to DNA-damaging agents may require an intact p53-dependent apoptotic mechanism under some experimental circumstances. On the other hand, it also may depend on the activation of alternative pathways of apoptosis or some degree of reregulation of the system which would ultimately lead to the reduced release of transcription factors from genes such as RB, or a homologous gene, p107, and the production of lower levels of growth-related gene products, thereby sensitizing cells to chemotherapeutic agents. An enhanced understanding of the complexities surrounding chemotherapy-induced cell death may shed light on critical insights with profound implications for the design of future approaches to therapy that might couple standard cytotoxic agents to new biologic agents that attack specific molecular targets to reregulate the cell-cycle checkpoint.

### ROLE OF BCL-2 FAMILY IN APOPTOSIS

Because apoptosis is a genetically programmed event, inactivation of genes that induce the apoptotic program or activation of antiapoptotic genes can result in the development of cellular drug resistance. Bcl-2 is a potent suppressor of apoptotic cell death, and a number of studies have shown that it is able to repress cell death triggered by either  $\gamma$ -irradiation or a variety of anticancer agents (see Fig. 17-3).<sup>54,56,82</sup> In further support of the role of Bcl-2 as an inhibitor of cell death are studies that show that treatment of certain human leukemia or lymphoma cells with an antisense strategy directed against *bcl-2* leads to the reversal of chemoresistance. Lymphoma cells treated with either antisense oligonucleotides or with plasmid constructs that overexpress antisense *bcl-2* messenger RNA are sensitized to the cytotoxic effects of methotrexate and cytosine arabinoside.<sup>83</sup> In addition, the phosphorylation status of *bcl-2* may play an important role as a determinant of chemosensitivity. It has been suggested that phosphorylated *bcl-2* may interact less efficiently with its heterodimer protein partner *bax*, resulting in cell death. Some work suggests that Bcl-x<sub>1</sub>, a functional and structural homologue of Bcl-2, is also able to confer protection against radiation-induced apoptosis as well as against a wide number of anticancer agents, including bleomycin, cisplatin, etoposide, and vincristine. Recently, the antiapoptotic effects of Bcl-2 and Bcl-x<sub>1</sub> were compared. Using FL5.12 lymphoid cells, it was shown that these two proteins have a differential ability to protect against chemotherapy-induced cell death.<sup>84</sup> This differential effect depends more on the molecular mechanism targeted as opposed to the cell-cycle specificity of an individual drug. In contrast to Bcl-2 and Bcl-x<sub>1</sub>, other family members, including Bax, Bcl-x<sub>s</sub>, and Bak, have been shown to promote apoptosis in response to either radiation or various anticancer drugs (or both). The underlying mechanisms through which these Bcl-2 family members control apoptosis remains unknown at this time. However, the mitochondrial pathway with altered release of cytochrome C presumably plays a critical role in this process.

### ROLE OF STRESS-ACTIVATED PROTEIN KINASE IN APOPTOSIS

The mitogen-activated protein kinase family of proteins is highly conserved among all eukaryotic species.<sup>85</sup> These kinases play a critical role in mediating signal transduction pathways that are sensitive to extracellular stimuli. Stress-activated protein kinase (SAPK), also known as *c-Jun N-terminal protein kinases*, represents one of the key mitogen-activated protein kinase–signaling pathways. It is now well appreciated that SAPK activation is necessary for cell death in response to

exposure to certain forms of cell stress and that defects in SAPK signaling promote cell survival. With regard to chemotherapy, SAPK functions are an important mediator of apoptosis.<sup>86,87 and 88</sup> Inhibition of SAPK activation has a protective effect against cancer cells treated with various anticancer agents, including the anthracyclines and etoposide. In addition, SAPK is required for ceramide-induced apoptosis, a key mediator of cytotoxicity induced by various cancer drugs.<sup>89</sup> Thus, the SAPK-signaling pathway plays an essential role in facilitating chemotherapy-induced apoptosis. The precise mechanism by which the SAPK pathway is actually activated remains the focus of much research. However, one potential clue rests with the observation that DNA damage induced by genotoxic stress is sensed by kinases, including the DNA-dependent protein kinase or the ataxia-telangiectasia-mutated gene product (or both).<sup>90,91</sup> These proteins can then phosphorylate p53, resulting in its activation. In addition, DNA-dependent protein kinase can stimulate c-Abl tyrosine kinase, which in turn leads to direct activation of SEK-1, an upstream signal in the SAPK cascade.<sup>92</sup>

## DEATH EXECUTIONER PATHWAY

The molecular mechanisms and signal transduction pathways initiated by a given cellular stress may differ significantly. However, the final stage of these various death pathways occurs through the activation and function of the caspases (see Fig. 17-3).<sup>59</sup> The caspases represent a conserved family of cysteine proteases with specificity for aspartic acid residues in their substrates. The cleavage of certain essential substrates then results in cell death. Exogenous inhibition of caspase proteases by CrmA promotes the development of resistance of human leukemia cells to a broad array of anticancer agents.<sup>93</sup> In addition, some knockout mouse models with germline disruptions of Apaf1, caspase-3, or caspase-9 have shown these genetically engineered mice to be resistant to g-irradiation and a wide number of chemotherapeutic drugs.<sup>59,94,95</sup>

## CELL SURVIVAL PATHWAYS

It has been shown that a number of external stimuli, including various cytokines, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), chemotherapy, and radiation, lead to activation of the transcription factor NF- $\kappa$ B.<sup>96</sup> Paradoxically, activation of NF- $\kappa$ B results in potent suppression of the apoptotic potential of these stimuli.<sup>97</sup> Several studies have demonstrated that inhibition of NF- $\kappa$ B *in vitro* leads to enhanced apoptosis in response to different stimuli.<sup>98</sup> Some *in vivo* work shows that the adenoviral delivery of a modified form of I $\kappa$ B $\alpha$ , an inhibitor of NF- $\kappa$ B, results in inhibition of NF- $\kappa$ B expression. Moreover, the chemoresistant fibrosarcoma tumors derived from HT1080 cells become sensitized to the apoptotic potential of TNF- $\alpha$  and the topoisomerase I compound, CPT-11, leading to significant tumor regression.<sup>99</sup> These findings suggest that activation of NF- $\kappa$ B expression in response to chemotherapy may represent an important mechanism of inducible tumor chemoresistance. Moreover, they suggest that strategies to inhibit NF- $\kappa$ B may lead to enhanced antitumor therapy through increased apoptosis.

## DEVELOPMENT OF NOVEL THERAPEUTIC STRATEGIES

Significant efforts continue to be placed on elucidating the critical intracellular signal transduction pathways required for cell-cycle control and the induction of apoptosis and cell death. However, based on current knowledge, attempts are already being made to manipulate these intracellular programs so as to design and develop novel therapeutic approaches to improve the efficacy of chemotherapy. Tumor suppressor genes were originally identified because of the ability of transforming viruses to bind to the protein product of the tumor suppressor gene and induce the growth required for the virus lytic growth cycle. It has been shown that some viral gene products, such as the adenovirus E1A protein, which by itself is nontransforming, can actually sensitize cells to agents that induce apoptosis. E1A is involved in the release of E2F from the RB protein, which could be expected to facilitate entry of cells into S phase. It has been hypothesized that the transmission of conflicting signals, which act both to slow and to stimulate growth simultaneously, may lead to E1A-induced apoptosis.<sup>100</sup> Thus, the identification of analogs of E1A to be used in this setting is an attractive concept.

Clearly, it will be important to identify novel strategies that are selective in their targeting of malignant cells while preserving normal function of host tissues. Along these lines, viral vectors expressing apoptotic genes can now be directly introduced into the tumor. Adenoviral vectors that express p53 have been injected into human tumors, resulting in suppression of tumor growth.<sup>101,102</sup> Moreover, this gene therapy approach shows a synergistic interaction with various cytotoxic agents to produce enhanced antitumor activity with minimal host toxicity. This strategy has been taken into the clinic where a phase I study was performed in patients with non-small cell lung cancer.<sup>103</sup>

TNF-related apoptosis-inducing ligand, or TRAIL, is a type II transmembrane protein that was initially identified based on the homology of its extracellular domain with CD95L. Like TNF and Fas, TRAIL induces apoptosis in a wide range of tumor cells.<sup>104</sup> Walczak et al.<sup>105</sup> evaluated the ability of TRAIL as a therapeutic agent. They created leucine zipper (LZ) forms of human (hu) and murine (mu) TRAIL to promote trimerization and found that these trimers of LZ-TRAIL effectively killed cultured mammary adenocarcinoma cells but not normal, nontransformed mammary epithelial cells, fibroblasts, renal tubule cells, skeletal muscle cells, pulmonary epithelial cells, and melanocytes. Administration of either the hu or mu TRAIL was nontoxic to the normal tissues of mice *in vivo*. Finally, repeated administration of LZ-huTRAIL showed impressive antitumor activity against human mammary adenocarcinoma MDA-231 cells implanted in severe combined immunodeficient mice, and histologic examination of tumors revealed clear areas of apoptosis within 9 to 12 hours of injection. These findings show that TRAIL exerts potent antitumor activity *in vivo* by selectively and directly activating tumor cell death without affecting normal tissues. Studies are ongoing to determine whether TRAIL-based therapy may be used either alone or in combination with other cytotoxic agents and whether these promising results can be effectively translated into the clinic.

It has been suggested that initiation of the cyclic production of cyclins in the cell is due, in part, to the effect of growth factors. Some cyclin classes, such as the D cyclins, may indeed be the essential sensors for multiple growth factor signals.<sup>60</sup> In some experimental systems, a determining factor in the decision of a cell either to undergo cell-cycle arrest and repair damaged DNA or to undergo apoptosis may be the presence of key growth factors within the cellular environment.<sup>106,107</sup> Thus, in the absence of a growth signal, with growth factors serving as a survival factor, the cell becomes committed to the apoptotic pathway. It is presumed that apoptosis is taking place within the context of an intact p53 mechanism. However, one issue is whether, even in the presence of mutations of p53 or other checkpoint genes (or both), deprivation of critical growth factor signals would still result in enhanced sensitivity to chemotherapy.

Experiments using *in vivo* mouse models bearing human tumor xenografts suggest that this may be so. An antiepidermal growth factor receptor, monoclonal antibody C225 targeted to the epidermal growth factor receptor, was used in combination with the anticancer agent doxorubicin against human A431 squamous carcinomas and human MDA468 breast carcinomas. The effects of either the antibody or the drug alone are modest, with no long-term survivors. However, when the antibody is administered before doxorubicin, the effects of the combination are dramatic, often leading to complete tumor regression and long-term survival.<sup>108</sup> Similar results were observed in mice bearing human GEO colon cancer xenografts. Complete tumor regression was noted only in mice treated with the topoisomerase I inhibitor topotecan and the C225 monoclonal antibody.<sup>109</sup> These effects at first seem paradoxical, as the cytotoxic effects of an anticancer drug are being enhanced by a biologic agent that presumably is slowing down growth. However, an alternative explanation is that treatment with the antibody sensitizes the tumor to chemotherapy by depriving it of a vital growth factor signal, thereby facilitating the process of apoptosis. The results are provocative enough that other monoclonal antibodies that block key growth factor receptors have been coupled with chemotherapy and are being tested in the clinic. A similar approach is being taken with the use of the anti-HER2 (Herceptin) antibody for the treatment of advanced breast cancer, in combination with either paclitaxel (Taxol) or with the combination of cyclophosphamide (Cytoxan) and doxorubicin (Adriamycin).<sup>110,111</sup> Based on the promising clinical results, these combination regimens have been approved by the U.S. Food and Drug Administration for women with advanced breast cancer.

## CONCEPT OF DOSE INTENSITY

Irrespective of the molecular mechanisms underlying the development of human cancers, a principal factor limiting the capacity to cure is proper dosing. The dose-response curve in biologic systems is usually sigmoidal in shape, with a threshold, a lag phase, a linear phase, and a plateau phase. For radiation therapy and chemotherapy, therapeutic selectivity is dependent on the difference between the dose-response curves of normal and tumor tissue that must be exploited during treatment. In experimental models, the dose-response curve is usually steep in the linear phase. Almost without exception in rodents bearing transplantable tumors, a reduction of dose in the linear phase of the dose-response curve usually results in a loss of the capacity to cure the tumor effectively before a diminution in the response rate is seen. Thus, although complete remissions continue to be observed with a dose reduction as small as 20%, the residual tumor cells may not be eliminated, allowing for eventual relapse to occur. There is an extremely important lesson in these animal data for clinicians who, in their daily practice, judge the adequacy of their therapy by measuring the response rate of visible or palpable tumor masses and only much later are able to evaluate the treatment by survival results. This point is nicely illustrated in Table 17-2, which summarizes data from numerous experiments conducted by Skipper<sup>112</sup> at the Southern Research Institute using the transplantable and palpable Ridgway osteosarcoma tumor model. Reduction in the average dose intensity of the two-drug combination of L-phenylalanine mustard and cyclophosphamide causes a marked decrease in the cure rate before a significant reduction in the complete remission rate occurs. On average, a dose reduction of approximately 20% leads to a loss of 50% of the cure rate. The converse is also true. In tumors with a high growth fraction, a twofold increase in dose often leads to a tenfold increase (1-log) in tumor cell kill. Although *in vivo* systems are not the perfect model for human malignancies, the invariable nature of these

data indicates that the general principle may be applied to the clinic. Because anticancer drugs are toxic, it is often appealing to avoid acute but not life-threatening toxicity by either reducing the dose or increasing the time interval between each cycle of treatment. This kind of empiric dose adjustment is a major reason for treatment failure in patients with drug-sensitive tumors who are undergoing induction chemotherapy.

Relative Dose Intensity			Complete Response Rate (%)	Cure Rate (%)
CPA	L-PAM	Average		
0.58	0.82	0.50	100	60
0.75	0.18	0.47	100	44
0.25	0.55	0.44	100	0
0.50	0.12	0.31	10	0
0.17	0.36	0.27	0	0

CPA, cyclophosphamide; L-PAM, l-phenylalanine mustard.

**TABLE 17-2.** Ridgway Osteogenic Sarcoma: Response to Different Dose Intensity of Two-Drug Combination of Cyclophosphamide and L-PAM

One problem facing clinicians is the difficulty in adequately comparing the impact of different dosing practices on the clinical efficacy of chemotherapy. To approach this issue, Hryniuk et al.<sup>113,114,115,116,117</sup> and <sup>118</sup> analyzed treatment outcomes in various tumor types as a function of dose intensity. Dose intensity is defined as the amount of drug delivered per unit of time, expressed as milligrams per square meter per week, regardless of the schedule or route of administration. Relative dose intensity (RDI) is the amount of drug delivered per unit of time relative to an arbitrarily chosen standard single drug or, for a combination regimen, the decimal fraction of the ratio of the average dose intensity of all drugs of the test regimen compared with the standard regimen. A sample calculation of the RDI for a commonly used regimen, the cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) combination for breast cancer, is provided in [Table 17-3](#).<sup>73</sup> To calculate the average RDI for a regimen containing fewer drugs than the standard regimen, a dose intensity of zero is assigned to the missing drug, and the average RDI of the test regimen is divided by the total number of drugs in the standard.<sup>114</sup> The dose intensity of each drug regimen is then determined based on the time period in which the treatment program is administered. Specific calculations can be made of the intended dose intensity, the dose intensity as described in the treatment protocol, or the actually received dose intensity. However, determination of the received dose intensity would seem to be the most clinically relevant as it reflects the direct impact of dose reductions and treatment delays imposed in actual practice.<sup>118</sup> A positive relation between dose intensity and response rate has, in fact, been demonstrated in several solid tumors, including advanced ovarian, breast, lung, and colon cancers, and in the lymphomas.<sup>113,114,116,117</sup> and <sup>118</sup>

CALCULATION OF RELATIVE DOSE INTENSITY (RDI)	
Standard:	Cyclophosphamide, 800 mg/m <sup>2</sup> /d (continuous), 5600 mg/m <sup>2</sup> /wk
Test regimen:	Cyclophosphamide, 100 mg/m <sup>2</sup> /d (days 1-3), q3w 300 mg/m <sup>2</sup> /wk
RDI =	300/5600 = 0.05
CALCULATION OF AVERAGE RDI	
Standard:	Cyclophosphamide, 2 mg/kg/d, 5600 mg/m <sup>2</sup> /wk Methotrexate, 0.7 mg/kg/wk, 28 mg/m <sup>2</sup> /wk 5-Fluorouracil, 12 mg/kg/wk, 480 mg/m <sup>2</sup> /wk
Test regimen:	Cyclophosphamide, 100 mg/m <sup>2</sup> /d (days 1-3), 300 mg/m <sup>2</sup> /wk; RDI = 300/5600 = 0.05 Methotrexate, 40 mg/m <sup>2</sup> on days 1 and 8, 80 mg/m <sup>2</sup> /wk; RDI = 80/28 = 0.71 5-Fluorouracil, 600 mg/m <sup>2</sup> on days 1 and 8, 3000 mg/m <sup>2</sup> /wk; RDI = 3000/480 = 0.62 Repeat cycles q3w Average RDI = (0.05 + 0.71 + 0.62)/3 = 0.46

\*Assume standard regimen to be cyclophosphamide, methotrexate, and 5-fluorouracil. To convert milligrams per kilogram (mg/kg) to milligrams per square meter (mg/m<sup>2</sup>), multiply by 40.<sup>113</sup>

**TABLE 17-3.** Sample Calculations: Dose Intensity, Relative Dose Intensity, and Average Relative Dose Intensity

Because dose intensity is determined based on the amount of drug given per week, regardless of schedule, treatment delays are given equal weight with dose reductions. Calculations of the dose intensity, therefore, assume that differences in scheduling do not influence treatment outcome. Although this concept may at first appear to be contradictory, close scrutiny of all available data in humans and rodents reveals that the schedule of administration influences outcome mainly by affecting toxicity. In this way, higher doses of drug can be administered over the same time frame. As one example, daily administration of low doses of methotrexate is extremely toxic and severely limits the dose and duration of therapy with this drug. However, a twice-weekly schedule, which is much more effective in rodents and humans, allows much higher doses to be delivered over a longer period. Of note, this particular schedule is associated with significantly less host toxicity. As calculated, the dose intensity of the twice-weekly schedule is much greater than that of the daily oral schedule. In practice, the impact of scheduling on the calculation of dose intensity can be neutralized by comparing programs in which drugs with toxicities affected by scheduling, such as the antimetabolites, are given on similar schedules.

One of the potential limitations of the dose-intensity concept is that calculations of an average RDI of a drug combination assume that each drug has equal efficacy against the tumor being treated. In most clinical settings, this is usually not the case. However, the impact of a single drug or combinations of two or three drugs in a multidrug combination can be assessed separately. Such an analysis has been performed to show the greater impact of cisplatin in a drug combination for ovarian cancer<sup>113,114,115</sup> and <sup>116</sup> and to show the importance of adequate doses of alkylating agents and vinca alkaloids in lymphoma treatment. The most active drug in a combination regimen can be identified, and this information is important because such data can help to avoid dose adjustments that may radically alter the clinical outcome. Moreover, by identifying the most essential drugs in a given regimen, protocols can focus on administering the optimal dose intensity of those specific agents.

To judge adequately the dosing of a particular protocol, data on total dose of each drug used and cumulative doses of each drug are necessary. However, the collection of such information is not part of the routine practice in medical oncology, and reports are not generally available in the literature. Therefore, for proper assessment of the impact of dosing schedules in clinical trials, it is critical that such data be provided.

Calculations of the impact of dose intensity on outcome are particularly important in estimating the value and exploring some of the pitfalls of adjuvant chemotherapy. The steep dose-response curve for anticancer drugs indicates that dose reductions in adjuvant drug treatment programs are likely to be associated with significantly less therapeutic effect. Dose reduction, however, has been the norm in the design of adjuvant trials. One example is the standard CMF regimen for breast cancer referred to in [Table 17-3](#). The initial reports of this regimen revealed an impressive complete remission rate of approximately 30%, albeit at the expense of considerable host toxicity.<sup>119</sup> When this regimen was advanced for use in the cooperative group setting, initially for advanced disease and later for adjuvant trials by Bonadonna et al.,<sup>120</sup> its doses were arbitrarily reduced without pretesting the potential impact of such reductions on clinical outcome. In addition, further reduction was empirically made for patients older than 60 years, with the assumption that such a dose reduction would be required for age. When the effect of these reductions is correlated with outcome, there is a strong suggestion of a negative impact.<sup>120,121</sup> In premenopausal women, the differences in relapse-free survival at both low and high doses of CMF are statistically significant. The importance of dose effect was further confirmed by a large study in which a survival benefit was observed as a result of increasing dose intensity in the adjuvant chemotherapy for women with stage II, node-positive breast cancer.<sup>122</sup>

An increase in the dose intensity represents one approach to improve on the effect of specific drugs or drug combination, but it may not be useful in all clinical circumstances. In the setting of large tumor burdens, the dose-response curve tends to shift to the right. At the low end of the curability curve (i.e., in the presence of the highest tumor burdens), an increase in dose intensity may not improve treatment outcome, as the dose-response curve is flat, but most often leads to unacceptable host toxicity. In addition, increasing the dose intensity of drug regimens that are already associated with curing nearly 100% of a subset of patients would not be expected to be of clinical benefit. Such a scenario would hold for the treatment of germ cell cancer using the cisplatin, etoposide, bleomycin combination and for Hodgkin's disease, using either the mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone regimen; the doxorubicin, bleomycin, vinblastine, and dacarbazine regimen; or regimens derived from them, such as BEACOPP (see [Chapter 45.3](#)). However, for most drugs, there appears to be a threshold dose that

produces clinical response. The success of high-dose chemotherapy programs with stem cell support in refractory lymphomas, breast cancer, childhood sarcomas, and neuroblastomas suggests that maximizing dose intensity can improve response rates or cure in drug-responsive tumors.

Frei et al.<sup>123</sup> and Hryniuk et al.<sup>124</sup> have proposed the term *summation dose intensity* to reflect the relationship between dose and combination chemotherapy. As part of this concept, they suggested that the final outcome of either a high-dose or combination treatment must be related in some manner to the sum of the dose intensities of all the agents used in that treatment. The intrinsic chemosensitivity of a given tumor is critical for treatment success. An active agent is defined as one that, when used alone, is associated with at least a 30% response rate for a given tumor. It is now well appreciated that for almost all malignancies, a combination regimen incorporating at least three active drugs is necessary for cure. In the case of childhood leukemia, the cure rate increases linearly when the number of active drugs increases from three to seven. The critical issue for this concept is that all active agents must be used at their full therapeutic doses. However, until the advent of the various cytokine growth factors and autologous or peripheral stem cell transplantation (or both), the effective administration of maximal doses of chemotherapy has not been possible. Although the concept of summation dose intensity is not new, it does offer a unified approach for the careful design and interpretation of clinical trials.

## IN VITRO DRUG-RESPONSE ASSAYS

Several methods have been developed since the 1950s to determine the *in vitro* drug sensitivities of human tumor cells to various anticancer agents.<sup>125,126,127,128,129,130,131,132,133,134,135,136,137,138</sup> and 139 The advent of reliable *in vitro* drug-response assays has raised the possibility of selecting effective anticancer agents to be used either alone or in combination to treat a patient's individual tumor. In this setting, identification of agents with an extremely low probability of response makes it possible to eliminate the use of such agents and thus their potential for adverse events. A number of methods have been used to investigate the sensitivity of tumors and tumor cell lines, including clonogenic, differential staining cytotoxicity assay; colorimetric, rapid <sup>3</sup>H-thymidine incorporation assay; and chemotherapeutic treatment of athymic nude mice with human tumor xenografts. Fruehauf and Bosanquet<sup>140</sup> reviewed the correlation between the results of *in vitro* sensitivity testing and a patient's tumor response to chemotherapy and, in general, they found an overall sensitivity of 85% and an overall specificity of 80%.

In the mid-1950s, Black and Spear<sup>134,135</sup> were the first to report the use of an *in vitro* assay to predict patient response. Their studies compared the *in vitro* activity of aminopterin with its clinical response. Their assay technology was based on the colorimetric detection of viable cells using a substrate for mitochondrial succinate dehydrogenase. Although the predictive accuracy of their results was not particularly strong, the development of the clonogenic stem cell assay in the 1970s brought *in vitro* testing of solid tumors into the mainstream.<sup>137</sup> However, the results of these studies indicated that there were significant technical issues to overcome.<sup>138,139</sup> As illustrated in [Table 17-4](#), further work to improve on the technology led to a variety of techniques and approaches with a pronounced ability to identify drug resistance accurately. The major distinction among the differing assay methods is the end point used to measure cell viability. Assay end points include colony growth from single stem cells, incorporation of tritiated thymidine, microscopic examination of cells with vital dyes, mitochondrial enzyme activity, cytosolic esterase activity, and adenosine triphosphate content. Given the variety of assay types, it is remarkable that the predictive accuracy for the identification of chemosensitivity for most of these approaches appears to be at least 90%. Several issues should be considered when evaluating an assay technology ([Table 17-5](#)).<sup>125,127,140</sup>

Assay Type	Patients	Patient Response					Sensitivity (%)	Specificity (%)
		CR	PR	SD	PD	NR		
Clonogenic	780	102	147	228	115	49	78	86
Microscopic	464	123	162	119	20	18	88	88

**TABLE 17-4.** Correlations of *In Vitro* Test Results with Patient Response

Tumor heterogeneity: Is the assay end point selective for malignant cells versus stromal cells?
Is the assessability rate greater than 80%?
Have the assays been correlated with clinical response and survival?
Can the tests evaluate all histologic types, or are they restricted to only certain types of tumors?
Are clinically appropriate drugs evaluated in the test?
Does the turnaround time meet clinical requirements?
Is the test information easily interpreted and applied?
Is the test cost-effective?

**TABLE 17-5.** Factors Influencing the Utility of the *In Vitro* Assay

The clonogenic assay evaluates the ability of chemotherapeutic agents to inhibit tumor stem cell proliferation in agarose, a medium that precludes proliferation of nontransformed cells.<sup>133,134</sup> Most of the *in vitro* drug-response techniques use similar methods for tumor preparation. Solid tumors are disaggregated into suspensions of multicellular clumps with scissors and by passing the fragments through mesh or by stirring tissue fragments with collagenase. Single-cell suspensions then are generated by passing the cellular aggregates through high-gauge needles.<sup>133,138</sup> Cell suspensions are incubated with drug for 1 hour, rinsed, and plated on an agar base with growth media. After a period of 14 to 28 days, the number of colonies that have grown from the treated cells is compared with the number of colonies from untreated control cells. The fraction of control growth provides an index of drug activity. Studies by the National Cancer Institute and the Southwest Oncology Group indicate that the assay is reproducible among multiple laboratories.<sup>138</sup> Problems with assay interpretation arising from the initial plating of small cell clumps were overcome with the use of chromomycin A3.<sup>138,139</sup>

The conventional clonogenic stem cell assay has suffered from a relatively low success rate (<50%) of specimens yielding results, rendering it difficult to accrue adequate numbers of patients into clinical trials.<sup>133</sup> Although this factor initially dampened enthusiasm for this approach, a significant number of clonogenic assays (>2500 cases) have now been performed by various groups, with an overall positive predictive value of 69% and a negative predictive value of 91% (see [Table 17-4](#)).<sup>120</sup>

Tritiated thymidine incorporation, as an assay end point, was introduced in part to eliminate the problem of discriminating between true colony growth from a single cell and from a clump of cells plated at the outset. This technique also decreased the assay time from more than 14 days to less than 1 week and was associated with an improved success rate of diagnostic yield to 85%.<sup>125,126</sup> and [127,141,142](#)

Processing and plating of the tumor for the thymidine assay is similar to that for the clonogenic assay. However, in the thymidine assay, small clumps rather than single cells are preferred to maintain cell-cell interactions. In addition, cells are grown in an agar suspension, which allows tumor growth *in vitro* to recapitulate the three-dimensional *in vivo* morphology. Cell-cell interactions resulting from three-dimensional growth may be critical for the detection of acquired drug resistance, which can be missed in monolayer cultures.<sup>143</sup>

In contrast to the clonogenic assay, prolonged drug exposures are utilized in the thymidine-based system. Tumor suspensions are continuously exposed to drug for 5 days, and tritiated thymidine is added during the final 48 hours of the assay to label proliferating cells. Determination of drug action is based on a comparison of the incorporation of labeled thymidine by untreated controls with incorporation by the groups treated with different drugs. Clinical correlations obtained using this assay technique demonstrate a reasonable overall predictive accuracy (72%) and indicate that it is an accurate predictor of drug resistance (99%).<sup>126</sup> The prolonged drug exposure in the thymidine assay results in a five- to 20-fold higher concentration  $\times$  time factor than that used in the clonogenic assay, biasing assay accuracy toward detection of drug resistance. Tumor growth after drug exposure in the thymidine assay is associated with multifold drug resistance, which led the authors of one article to describe it as the "extreme drug resistance assay."<sup>126</sup> Some paclitaxel-resistant tumors identified with this technique have been found to overexpress P170 glycoprotein, suggesting that this assay can be used to identify the activity of specific mechanisms of drug resistance in different tumor histologies.<sup>144</sup>

Another promising assay is the differential staining cytotoxicity (DiSC) assay.<sup>140,145</sup> The DiSC assay relies on the structural integrity of cells. In the DiSC assay, cells are incubated with drugs for 4 days. Dead cells are stained in suspension with fast green dye in the absence or presence of nigrosin, and duck red blood cells are added as an internal standard for counting. The specimen is cytocentrifuged to deliver discs of cells onto microscope slides. Live cells then are stained with either hematoxylin-eosin or Romanowsky stain. The end point of this test is the morphologic identification of tumor cell cytotoxicity as compared with the internal control of fixed duck erythrocytes. The DiSC assay requires more than 10% tumor cells and measures cell kill in both dividing and nondividing tumor cell populations. Microscopic identification of the cell population renders it possible to determine the differential kill of normal and tumor cells, and this is the therapeutic index for new agents undergoing *in vitro* screening for activity. The DiSC assay (see Table 17-4) offers an overall predictive accuracy of 83%, with a sensitivity of 94% and a specificity of 71%.<sup>125,132,145</sup>

The potential efficacy of individualized chemotherapy selected by *in vitro* drug sensitivity testing for patients with cancer has been reviewed.<sup>146,147</sup> A number of issues seriously limit the widespread use of this approach in the clinic. First, *in vitro* drug sensitivity testing is relatively expensive and time-consuming. Second, the efficient procurement of tumor tissue remains a serious problem. In fact, only two studies, both from the National Cancer Institute, have evaluated the ability to obtain tumor tissue from patients with limited- and extensive-stage small cell lung cancer.<sup>147,148</sup> Tumor tissue was obtained from 30% of patients with limited-stage disease, in contrast to nearly 70% of patients with extensive-stage disease. Third, even with successful procurement of tumor tissue, a host of technical issues limits the ability for efficient and successful drug testing. In fact, of 12 different trials reviewed, only slightly more than one-half of all tumor samples had sufficient cell numbers for drug testing. Finally, only one-third of all patients entered in prospective trials of *in vitro* drug testing were actually treated with an *in vitro* best regimen. In those patients, the response rates appear to be as good as, and perhaps even slightly better than, those achieved with empiric therapy. It is not surprising, then, that when all the clinical studies are taken together, no potential benefit in survival is observed for this approach. Of note, however, is a survival advantage that has been reported, in a small select series of studies, in patients treated with an individualized *in vitro* best regimen.<sup>148</sup>

The reliability of newer *in vitro* assay technologies to identify drug sensitivity suggests that such assays can help the clinician to avoid exposure of patients to the toxicity of drugs with little clinical benefit. Although the promise of an *in vitro* sensitivity assay has not yet been met, there remains value in identifying inactive agents before their administration and eliminating them from drug combinations. These tests render it possible to tailor drug combinations for the individual cancer patient. They also offer a rational stopping point for both the patient and clinician in situations in which the patient's tumor demonstrates extreme resistance to all conventional anticancer agents. An understanding of when to terminate therapy in hopeless situations is as important as any management issue facing the clinician.<sup>149</sup> Although only a few hundred patients have been enrolled to date to evaluate the impact of *in vitro* assay-directed therapy on survival, it is intuitively obvious that there should be a therapeutic advantage in the activity of agents to which a tumor is highly responsive *in vitro* as compared with agents that demonstrate significant *in vitro* drug resistance.<sup>125</sup> Further prospective, randomized studies are needed to define more properly the true role of *in vitro* drug testing in the selection of chemotherapy for cancer patients in the adjuvant, induction, or salvage setting.

Although *in vitro* tissue culture studies serve as an important guide for selecting chemotherapy, they are inadequate at addressing the issues of tumor cell heterogeneity, drug distribution, drug bioactivation, and host toxicity. *In vivo* model systems overcome some of these obstacles, and several have been developed, including the subrenal capsule assay, a semipermeable membrane in the Millipore diffusion chamber as vessels for tumor implantation into mice, and the tumor xenograft model, which is perhaps the most widely used method for drug testing.<sup>140,150,151</sup> and <sup>152</sup> However, each of these experimental systems has its unique drawbacks. Recently, a novel system was developed using a semipermeable polysulfone fiber with a molecular weight cutoff of 30 kD. Human cancer cells derived from tissue culture or from patient tumor specimens are injected directly into semipermeable fibers that are then implanted into immunocompetent rats.<sup>153,154</sup> Animals are treated with the given drug and, after a defined period, they are sacrificed, the fibers are recovered, and the remaining viable cells are counted using the trypan dye exclusion method. There are several advantages to this polysulfone fiber model. First, the entire process of tumor recovery, injection, and implantation of fibers, drug treatment, fiber recovery, and cell analysis can be completed in less than 1 week. This short period minimizes the potential waiting time for selection of the optimal drug, thereby rendering this model feasible for application in the clinical setting in treating a patient. Second, the results from this model system are consistent, reliable, and highly reproducible. As many as six to seven fibers can be implanted into an individual rat; thus, each fiber can be injected with the same cell type and the individual rat treated with the same drug. In addition, this reduces the unnecessary expense of using multiple animals for drug *in vivo* testing. Third, because up to six to seven fibers can be implanted into an individual rat, cancer cells derived from different primary tumors can be tested simultaneously for drug sensitivity, a process that can result in greater cost and time efficiency. Further testing and validation are required to determine whether such a novel *in vivo* system can help to individualize and optimize the clinical therapy of cancer patients.

Finally, studies by Waldman et al.<sup>155</sup> have raised concerns regarding the validity of the *in vitro* colony formation assay as a measure of the cytotoxicity of DNA-damaging agents in tumor cells with altered checkpoint response. Using the human colon cancer HCT116 cell line that expresses wild-type p53 and p21 (p21+/+) and a subline that was rendered p21-deficient (p21-/-) by homologous recombination, these researchers tested the effects of g-irradiation using the *in vitro* colony formation assay and an *in vivo* xenograft model. Of note, they observed no differences in sensitivity to ionizing radiation, as determined by the *in vitro* colony formation assay. However, using the nude mouse xenograft model, they found that tumors derived from the parent p21+/+ cell line were able to survive exposure to ionizing radiation. In contrast, a significant fraction of the tumors deficient in p21 underwent apoptosis and were thus completely cured. Clearly, the *in vitro* assay was unable to detect this significant difference in sensitivity, as both the processes of cell arrest and apoptosis preclude the outgrowth of colonies. Given the critical role of checkpoint status as a determinant of chemosensitivity, these findings are important as they suggest that *in vivo* assays may represent a more relevant model system to compare the effects of anticancer agents.<sup>156</sup> Moreover, such an *in vivo* model may be ideal for testing novel agents that specifically target cell-cycle control and the pathways associated with the process of apoptosis.

### INTRODUCTION

Biologic therapy is cancer treatment that produces antitumor effects primarily through the action of natural host defense mechanisms or the administration of natural mammalian substances. Biologic therapy has emerged as an important fourth modality for the treatment of cancer. Its increased application is the result of a better understanding of the basic aspects of host defense mechanisms against cancer and rapid biotechnologic developments that made molecules available in quantities large enough for use in manipulating biologic processes *in vivo*. Although this field is still in its infancy, there are many examples of the successful application of biologic therapy to the treatment of human cancers.

### BASIC PRINCIPLES OF TUMOR IMMUNOLOGY

Most applications of biologic therapy for cancer have attempted to stimulate immune defense mechanisms. The immune system evolved as a means to detect and eliminate molecules or pathogens that are recognized as “nonself” but not to react to host (self) tissues. Many immunotherapies attempted to cause the tumor to appear more “foreign” compared with normal tissues or tried to magnify relatively weak host immune reactions to growing tumors.

The immune system differs from most other organ systems because its cells are not in constant contact with each other. They circulate freely throughout the body in and out of the circulatory and lymphatic systems. Immune reactivity involves the integrated action of lymphocytes, monocytes, macrophages, basophils, eosinophils, dendritic cells, endothelial cells, and many other cells throughout the body. Although separate functions have been assigned to these cell types, it is now clear that they interact in many ways and can regulate one another's activities.

Immune cells secrete two major classes of soluble protein. The first of these lymphocyte products to be recognized was the antibody. Antibodies are a group of proteins composed of one or several units, each of which is composed of two pairs of different polypeptide chains (i.e., heavy and light chains). Each unit possesses two recognition sites, which are capable of combining with the immunizing antigen. The unique bond between antigen and antibody is part of the basis for the exquisite specificity that is the hallmark of immunologic reactivity. The existence of circulating antibodies was first demonstrated in 1890, and until recently, scientific studies of antibodies monopolized the study of immune reactions.

Since the 1970s, it has become clear that selected subpopulations of lymphoid cells can secrete a second (nonantibody) class of protein molecules. These molecules are not biochemically similar to antibodies, are produced in tiny amounts, and are not normally detectable in the circulation. Collectively called *cytokines*, they represent a new class of hormones with actions on many different target cells within and outside the immune system. Increasing knowledge of a wide variety of cytokines has dramatically altered the understanding of the functions of the immune system and created new possibilities for cancer immunotherapy.

### CELLS OF THE IMMUNE SYSTEM

The central cell in immune function is the lymphocyte. Lymphocytes constitute approximately 20% of blood leukocytes and fall into three major classes—B cells, T cells, and null cells—on the basis of ontogeny and function. Basic aspects of modern cellular immunology are presented in [Chapter 4](#). Analysis of cell surface molecules, usually using monoclonal antibodies, revealed substantial heterogeneity in human leukocytes and lymphocytes. In 1982, the First International Workshop on Human Leukocyte Differentiation Antigens was held in Paris to attempt to codify the proliferating number of cell surface determinants detected on leukocytes and the antibodies used to detect them. As a result of the testing of large numbers of antibodies on target cells of many different leukocyte types, cluster analysis permitted the definition of groups of antigens that are similar and those that are clearly different on each type of target cell. This workshop defined the clusters of differentiation (CD), now used to describe cell surface components on leukocytes. A summary of selected CD classifications, the cells on which they are found, and the principal antibodies that are used to detect them as assigned by the Fourth International Workshop in 1989 are shown in [Table 18-1](#).

**TABLE 18-1.** Workshop Antigen Designation by the Nomenclature Committee of the Fourth International Workshop on Human Leukocyte Differentiation Antigens <sup>a</sup>

The results of the Fifth International Workshop on Human Leukocyte Differentiation Antigens were presented in November 1993 and represented the efforts of more than 500 laboratories that analyzed 1450 antibodies. Based on these findings, 48 new CD clusters and subclusters were adopted and 14 previously established clusters were redefined. These additions and changes are shown in [Table 18-2](#). An updated source of detailed information concerning all CD molecules can be found on the internet at <http://www.ncbi.nlm.nih.gov/prow/guide/45277084.htm>.

**TABLE 18-2.** Modifications and Additions to CD Nomenclature by the Fifth International Workshop on Human Leukocyte Differentiation Antigens

## IMMUNE EFFECTOR MECHANISMS RESULTING IN CELL DESTRUCTION

A variety of immune effector mechanisms can cause destruction of vascularized tissue or of circulating tumor cells (see [Chapter 4](#)).

Antibodies can mediate cell destruction by the binding of complement or by action as an opsonin to facilitate phagocytosis by macrophages or by other phagocytic cells bearing Fc receptors.

The direct interaction of an immune cell with a target cell can also result in lysis, and a variety of immune cytotoxic cells have been described. The best-characterized lytic immune cell is the cytotoxic T lymphocyte (CTL). These T cells can interact with specific cell surface antigens by an interaction with the T-cell receptor and a class I or II major histocompatibility complex (MHC) molecule. This lysis appears to involve direct cell contact and can occur quickly, with the initial lytic events initiated within minutes of the adhesion of the target cell to the lymphocyte. Although binding of the CTL to the tumor target occurs by means of the T-cell receptor, other means for binding lytic cells to targets also produce lysis. One such mechanism is antibody-dependent cellular cytotoxicity. In this lysis, antibody bound to immune cells serves as a cross-link to a cytolytic cell bearing an Fc receptor. The Fc receptor on the immune effector binds to the free Fc portion of the antibody on the target cell; after this cross-linkage, lysis of the target cell occurs. Similarly, the phenomenon of lectin-dependent cellular cytotoxicity involves the association of a lytic cell with a target using a lectin such as concanavalin A or phytohemagglutinin as the cross-linking agent.

Natural killer (NK) cells can lyse selected cultured target cells without a prior sensitizing stimulus. The most common target for NK cells is the K562 leukemia cell line. NK lymphocytes have little or no ability to kill fresh tumor cells, and their physiologic role as an antitumor effector mechanism is unclear.

Lymphokine-activated killer (LAK) cells are lymphocytes that acquire the ability to lyse a broad array of tumor cells after incubation in interleukin (IL)-2. The precursor of LAK cells is a null lymphocyte, and most mature LAK cells do not bear T- or B-cell markers. However, one subpopulation of LAK cells has been shown to be CD3+, and precursor and effector LAK cells appear to bear the Leu-19 cell surface marker. LAK cells can lyse a broad array of malignant, but not normal, fresh target cells in 4-hour chromium-release assays. LAK cells also can lyse normal and malignant cultured lines. LAK cells are capable of lysing most cells that have their membranes perturbed by malignant transformation, culture, or other activation processes.

Activated macrophages also recognize and lyse tumor cells. Although most lymphocyte-mediated lysis can easily be detected in 4 hours, the measurement of significant macrophage-mediated lysis often requires 48 to 72 hours.

Many of the cytokines secreted by immune cells can mediate toxicity of tissue directly or by the recruitment of other inflammatory processes. For example, tumor necrosis factor (TNF) can interfere with the blood supply of tumors. Interferon (IFN)- $\gamma$  has an antiproliferative effect on some tumor cells. Many chemotactic and vascular permeability factors that are involved in inflammatory responses also can indirectly mediate tumor destruction and may play a role in tumor immune phenomena.

## CYTOKINES

Cytokines are soluble proteins produced by mononuclear cells of the immune system (usually lymphocytes or monocytes) that have regulatory actions on other cells of the immune system or target cells involved in immune reactions. Cytokines produced by lymphocytes are referred to as *lymphokines*, and cytokines produced by monocytes are referred to as *monokines*. Cytokines are true hormones, acting on other cells at a distance from the secreting cells.

It has been known for more than two decades that the soluble substances produced by immune cells are involved in immune function and regulation. These cytokines were first identified by the function they exhibit in *in vitro* assays. Lymphokines that inhibited the migration of macrophages were known as *migration-inhibition factors*, and other factors that activated macrophages were known as *macrophage-activation factors*. This identification of cytokines on the basis of function led to a confusing situation in which the same molecules were often described by various investigators using different assays for their detection.

Substantial progress in this field resulted from the use of molecular biologic techniques to clone the genes for these cytokines, express them in bacteria, purify them to homogeneity, and produce large amounts of homogeneous cytokines for detailed study. A new nomenclature referring to cytokines as *ILs* (meaning "between leukocytes") has been introduced that supplants the acronyms based on functional properties. In 1979, a meeting of the Second International Lymphokine Workshop in Ermatingen, Switzerland, reached a consensus that a variety of lymphokines that had been referred to as *T-cell growth factor*, *thymocyte-stimulating factor*, *thymocyte mitogenic factor*, *killer cell helper factor costimulator*, and *secondary CTL-inducing factor* were all the same molecule and should be referred to as *IL-2*. The term *IL-1* was adopted to refer to a monocyte product previously called *lymphocyte-activating factor*. Since that time, many cytokines have been described. This list is rapidly expanding as new hormones produced by cells of the immune system are described.

Cytokines are proteins or glycoproteins, mostly with molecular weights in the range of 15,000 to 40,000, and many are glycosylated, although it appears that the glycosylation is often not essential for function. In many cases, the cytokines described in mouse and human are structurally related. For example, IL-1a shows a 61% to 65% amino acid homology among human, rabbit, and mouse. Some lymphokines exhibit species specificity; for example, IL-1, IL-2, IL-5, and IL-6 derived from human are active on cells from mouse and human, but IL-3, IL-4, and IFN-g derived from humans are active only on human cells and not on mouse cells.

Most research on cytokines has involved *in vitro* studies or animal studies. Many cytokines, such as IFN-a, IFN-b, IFN-g, IL-2, TNF, and the colony-stimulating factors, have reached clinical application in patients with cancer.

A summary of the major characteristics of IL-1 through IL-18 follows and is taken from S. K. Durum in *Principles and Practice of Biologic Therapy of Cancer*, S. A. Rosenberg, ed. The characteristics of the IFN and colony-stimulating factors are shown in [Table 18-3](#) and are further discussed in [Chapter 20.1](#) and [Chapter 53.4](#).

Cytokine	Major Effect	Biologic Activity
IFN-α	Antiviral	Induces antiviral state in cells, activates natural killer cells, and stimulates interferon-γ production.
IFN-β	Antiviral	Induces antiviral state in cells, activates natural killer cells, and stimulates interferon-γ production.
IFN-γ	Antitumor	Activates macrophages, natural killer cells, and T lymphocytes; induces expression of major histocompatibility complex class II molecules.
IL-1	Proinflammatory	Induces fever, acute-phase response, and shock; stimulates production of other cytokines.
IL-2	Immunomodulatory	Stimulates proliferation and activity of T lymphocytes; induces expression of cell surface receptors.
IL-3	Stimulatory	Stimulates proliferation and survival of hematopoietic cells.
IL-4	Immunomodulatory	Stimulates B cell proliferation and differentiation into antibody-secreting cells.
IL-5	Stimulatory	Stimulates eosinophil production and activation.
IL-6	Proinflammatory	Induces acute-phase response, fever, and shock; stimulates production of other cytokines.
IL-7	Stimulatory	Stimulates T cell proliferation and survival.
IL-8	Chemotactic	Attracts neutrophils to sites of inflammation.
IL-9	Stimulatory	Stimulates B cell proliferation and differentiation.
IL-10	Immunosuppressive	Inhibits T cell activation and interferon-γ production.
IL-11	Stimulatory	Stimulates hematopoiesis and bone marrow stromal cell growth.
IL-12	Proinflammatory	Induces interferon-γ production and Th1 cell differentiation.
IL-13	Immunomodulatory	Stimulates B cell proliferation and differentiation.
IL-14	Stimulatory	Stimulates B cell proliferation and differentiation.
IL-15	Stimulatory	Stimulates natural killer cell proliferation and activity.
IL-16	Chemotactic	Attracts T lymphocytes to sites of inflammation.
IL-17	Proinflammatory	Induces production of other cytokines and chemokines.
IL-18	Proinflammatory	Induces interferon-γ production and Th1 cell differentiation.
IL-19	Stimulatory	Stimulates B cell proliferation and differentiation.
IL-20	Stimulatory	Stimulates keratinocyte proliferation and differentiation.
IL-21	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-22	Stimulatory	Stimulates keratinocyte proliferation and differentiation.
IL-23	Proinflammatory	Induces production of other cytokines and chemokines.
IL-24	Stimulatory	Stimulates keratinocyte proliferation and differentiation.
IL-25	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-26	Stimulatory	Stimulates keratinocyte proliferation and differentiation.
IL-27	Immunomodulatory	Inhibits T cell activation and interferon-γ production.
IL-28	Antiviral	Induces antiviral state in cells, activates natural killer cells, and stimulates interferon-γ production.
IL-29	Antiviral	Induces antiviral state in cells, activates natural killer cells, and stimulates interferon-γ production.
IL-30	Antiviral	Induces antiviral state in cells, activates natural killer cells, and stimulates interferon-γ production.
IL-31	Chemotactic	Attracts T lymphocytes to sites of inflammation.
IL-32	Chemotactic	Attracts T lymphocytes to sites of inflammation.
IL-33	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-34	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-35	Immunosuppressive	Inhibits T cell activation and interferon-γ production.
IL-36	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-37	Immunosuppressive	Inhibits T cell activation and interferon-γ production.
IL-38	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-39	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-40	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-41	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-42	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-43	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-44	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-45	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-46	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-47	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-48	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-49	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-50	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-51	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-52	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-53	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-54	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-55	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-56	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-57	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-58	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-59	Stimulatory	Stimulates T cell proliferation and differentiation.
IL-60	Stimulatory	Stimulates T cell proliferation and differentiation.

**TABLE 18-3.** Interferons, Colony-Stimulating Factors, and Tumor Necrosis Factor, with Their Biologic Activities

## INTERLEUKIN-1

IL-1<sup>1,2</sup> was among the earliest cytokines identified because it has so many potent activities. Many features of the IL-1 system, however, are not particularly representative of cytokines. IL-1 has an unusual mechanism of release from the cells that produce it. The two family members, a and b, are only distantly related but act on the same receptor. It has two dedicated inhibitors that block ligand-receptor interaction. IL-1 is a powerful inducer of inflammatory processes, both local and global, although knockout of the IL-1 system only modestly reduces these processes. Clinically, the main goals have been to block the IL-1 system in inflammatory states, such as rheumatoid arthritis (RA) and septic shock.

### Proteins

Three members of the IL-1 family exist: a, b, and the receptor antagonist, encoded by a cluster of genes. IL-1a<sup>3</sup> and -b<sup>4</sup> have little homology to one another, but it is accurate to term them both *IL-1* because they act on the same receptor. Neither a nor b has a typical signal sequence, and both are released from the producing cell by an unusual mechanism. Mature 17-kD IL-1a is produced from a biologically inactive 31-kD precursor by cleavage<sup>5</sup> with caspase 1. Mature 17-kD IL-1a is also produced by cleavage from a different 31-kD precursor, which is biologically active. The receptor antagonist<sup>6</sup> is produced in two forms by alternative message splicing: one secreted form with a signal peptide and a second intracellular form lacking a signal peptide.

### Producers

The most prolific IL-1-producing cells are macrophages following stimulation with a variety of microbial products or other agents, including cytokines. Many other cell types, such as keratinocytes, also produce IL-1. The IL-1 promoters are complex, perhaps accounting for the ability of these genes to respond to so many different stimuli in different cell types. In macrophages, the mechanism of IL-1 induction is partly based on the PU-1 transcription factor in cooperation with other nuclear factors.<sup>7,8</sup> IL-1 production is also regulated by message stability, message translation, and the release mechanism. The receptor antagonist is produced concurrently with IL-1a and -b in many cell types, acting as a natural buffer to the action of IL-1.

### Receptors and Cellular Response

Two IL-1 binding proteins exist: IL-1RI, which serves all known receptor function,<sup>9</sup> and IL-1RII, which serves as a “decoy” receptor.<sup>10</sup> These genes are also linked to the IL-1 gene cluster in humans, but not in mice. IL-1RI is a member of the “toll” family of receptors. After IL-1 binding, IL-1 receptor accessory proteins,<sup>11</sup> a kinase [IL-2 receptor–associated kinase (IRAK)]<sup>12</sup> and TRAF6,<sup>13</sup> are recruited to the complex. IL-18 receptor forms a similar complex (see [Interleukin-18](#), later in this chapter). MyD88 serves as an adaptor protein, linking IRAK to the receptor complex.<sup>14</sup> Intracellular cascades lead to activation of several types of transcription factors, including nuclear factor κB<sup>15</sup> and AP-1.<sup>16</sup> This results in the induction of many genes, including a number of other inflammatory cytokines, such as IL-6. A wide variety of cell types respond to IL-1. IL-18 signaling has many parallels with that of IL-1.

### Activities

IL-1 is considered a key mediator of inflammation.<sup>2</sup> It has a broad spectrum of inflammatory activities, including local effects, such as induction of prostaglandins, chemokines, and adhesion molecules. IL-1 also has global effects, such as fever, the acute-phase response, and hypotension. Knockout mice show deficiency in local inflammation and delayed-type hypersensitivity and are resistant to collagen-induced arthritis.<sup>17</sup> The fact that IL-1 deficiency does not eliminate inflammation has been interpreted to mean that other cytokines with overlapping activities, such as TNF and IL-6, are equally important.

### Clinical Use

Trials were performed in cancer patients<sup>18</sup> with some benefit in preventing thrombocytopenia induced by chemotherapy, but significant toxic side effects, such as hypotension, arrhythmia, and pulmonary-capillary leakage, occurred. Intratumoral injection in mouse cancers has shown promising responses. Blocking IL-1 activity via receptor antagonist, soluble receptors, or newly tailored drugs shows promise in controlling inflammatory diseases, such as RA and septic shock, probably most effectively if combined with blockade of other inflammatory cytokines, such as TNF and IL-6.

## INTERLEUKIN-2

IL-2 was originally discovered as a growth factor for T cells *in vitro* and is one of the most extensively studied cytokines. Knockout of IL-2 in mice suggests complex regulatory roles, perhaps in programming T cells for death. The IL-2 receptor complex shares components with receptors for IL-4, -7, -9, and -15. IL-2 has been used clinically for acquired immunodeficiency syndrome, cancer, and for *ex vivo* expansion of T cells directed against tumors and viruses.

### Protein

IL-2<sup>19,20</sup> is a 15-kD protein, contains one internal disulfide bond, and is a member of a family of cytokines (IL-4, -7, -9, and -15) containing a helix.

### Producers

IL-2 is produced by T lymphocytes after activation by antigen-MHCs and costimulators on the surface of antigen-presenting cells. The T helper 1 (Th1) subset of

memory T cells retains the capacity to produce IL-2, whereas the Th2 subset loses this capacity, producing IL-4 instead. <sup>21</sup>

### **Receptor and Cellular Response**

The IL-2 receptor comprises three chains:  $\alpha$ , <sup>22</sup>  $\beta$ , <sup>23</sup> and  $\gamma_c$ . <sup>24</sup> The  $\beta$  and  $\gamma_c$  chains are members of a cytokine receptor superfamily, whereas the  $\alpha$  chain is related to IL-15Ra. The  $\beta$  and  $\gamma_c$  chains are essential for signaling, whereas the  $\alpha$  chain increases affinity of the complex for IL-2 but is not required. After binding of IL-2, the Janus kinase Jak3, <sup>25,26</sup> associated with the  $\gamma_c$  chain, phosphorylates tyrosines on the  $\beta$  chain, which serve as docking sites for signal transducers and activators of transcription protein (STAT)3 and -5. The STATs <sup>22,27</sup> are then phosphorylated and translocate to the nucleus, where they serve as transcription factors. Many other intracellular second messenger pathways are also triggered by IL-2 <sup>28</sup> and involve Ick, syk, ras, phosphoinositide 3 kinase (PI3-kinase), protein kinase C, and Akt. The  $\gamma_c$  chain of the IL-2 receptor is shared by the receptors for IL-4, -7, -9, and -15. Jak3 is also a component of the signaling complex in these receptors.

### **Activities**

The property that led to the discovery of IL-2 was its induction of activated T-cell proliferation. <sup>19</sup> Thus, IL-2 is widely used for propagating T-cell lines. Knockout of IL-2 in mice, <sup>29</sup> however, resulted in excessive, uncontrolled T-cell proliferation, leading to the concept that IL-2 is not essential for growth *in vivo*, but is essential for programming T cells to die. Other activities of IL-2 include stimulation of cytotoxicity in NK and T cells and acting as a cofactor in activating macrophages and B cells.

### **Clinical Use**

IL-2 has been used clinically in several ways (see [Chapter 20.2](#)). Treatment of malignant melanoma renal cell carcinoma has shown efficacy. <sup>30,31</sup> A significant side effect of IL-2 is the vascular leak syndrome. <sup>32</sup> IL-2 has been used for *ex vivo* expansion of LAK cells, tumor-infiltrating T cells, <sup>33</sup> and antiviral T cells, <sup>34,35</sup> and <sup>36</sup> which are then returned to the patient. Anti-IL-2 receptor shows promise in blocking rejection of organ transplantations. <sup>37</sup>

## **INTERLEUKIN-3**

IL-3 is produced by activated T cells and induces hematopoiesis. Its receptor shares components with IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF). It is used clinically to sustain explanted hematopoietic stem cells before reinfusion.

### **Proteins**

IL-3 <sup>38,39</sup> is linked to IL-4, -5, -9, and -13 in humans.

### **Producers**

Activated T cells are the major producers of IL-3. <sup>40</sup> Activated mast cells are also producers.

### **Receptors**

Two chains that compose the IL-3 receptor exist in humans: IL-3Ra <sup>41</sup> and IL-3Rbc, <sup>42</sup> which are shared by the receptors for GM-CSF and IL-5. In the mouse, two different  $\beta$  chains exist. Both  $\alpha$  and  $\beta$  are members of the cytokine receptor superfamily. Cross-linking of the  $\alpha$  to the  $\beta$  chain triggers receptor activation. <sup>43</sup> The nature of this cross-linking process is thought to resemble that of the IL-2 and IL-4 receptors, in that the ligand directly binds one chain with intermediate affinity. The second receptor chain, which cannot bind ligand on its own, then recognizes some features of the complex formed by the ligand and the other receptor component. Jak2 is associated with the  $\beta$  chain <sup>44</sup> and activates STAT5. <sup>45</sup> A number of other second messenger pathways are also activated. <sup>46</sup> The cellular response includes survival, such as the pathway leading to disposal of BAD, the proapoptotic protein. <sup>46,47</sup>

### **Activities**

IL-3 stimulates production of macrophages, granulocytes, erythrocytes, and megakaryocytes from primitive pluripotential stem cells. Knockouts indicate that IL-3 is not required during normal hematopoiesis, indicating its importance probably lies in the hematopoietic stimulation during immune responses. Mature myelomonocytic-lineage cells also react to IL-3.

### **Clinical Use**

IL-3 has been tested extensively for a variety of potential clinical uses. <sup>48</sup> In individuals with normal hematopoiesis, IL-3 treatment increased platelets, reticulocytes, and leukocytes and showed only mild side effects. <sup>49</sup> To increase hematopoiesis, IL-3 has been tested in myelodysplastic syndrome, aplastic anemia, Diamond-Blackfan anemia, chemotherapy, bone marrow transplantation, and stem cell mobilization. Although responses were observed, it has not been adopted as a therapeutic agent. IL-3 is widely used, however, as part of a cytokine cocktail to sustain hematopoietic stem cells *ex vivo* for treatment after radiation or chemotherapy (i.e., promoting introduction of recombinant constructs for gene therapy). <sup>50,51</sup>

## **INTERLEUKIN-4**

IL-4 is an important cofactor in B-lymphocyte activation, particularly for production of immunoglobulin E (IgE). One type of IL-4 receptor incorporates  $\gamma_c$ , as do IL-2, -7, -9, and -15. IL-4 is closely related to IL-13 and can share some receptor components and signaling pathways. IL-4 is critical in directing activated T cells into the Th2 pathway. Overproduction is implicated in atopy.

### **Proteins**

IL-4 <sup>52,53</sup> and <sup>54</sup> is 20 kD, with six cysteines involved in intrachain disulfide bonds, and forms four  $\alpha$  helices. The human IL-4 gene is found in a cluster together with genes for IL-3, -5, -9, and -13.

### **Producers**

Several types of T cells produce IL-4 after activation by antigen-MHC complexes and costimulators on the surface of antigen-presenting cells. <sup>21</sup> IL-4 is a key member of the spectrum of cytokines produced by Th2 T cells. In mice, CD4 T cells that express NK1 are also producers, as are a subset of CD8 T cells. Mast cells and basophils also produce IL-4. <sup>55</sup> The induction of Th2 cell development is dependent on IL-4 produced by T cells themselves. <sup>56</sup> Production of IL-4 requires the transcription factor GATA3 <sup>57</sup> and, possibly, c-maf. <sup>58</sup>

### **Receptors**

The primary binding chain, IL-4Ra, <sup>59</sup> forms two types of receptor complexes: IL-4Ra +  $\gamma_c$  and IL-4Ra + IL-13Ra. <sup>60</sup> These receptor chains are members of the cytokine receptor superfamily. IL-4 first binds to IL-4Ra;  $\gamma_c$  is then recruited to the complex. The Janus kinase Jak3, bound to the intracellular domain of  $\gamma_c$ , is required for many, but not all, IL-4 effects. <sup>61</sup> STAT6 is required for IL-4 signaling. <sup>62</sup> IRS-1 is an important adaptor molecule, coupling the receptor to second messenger pathways other than the Jak-STAT pathway. <sup>60,63</sup>

### **Activities**

IL-4 was discovered as a growth factor for preactivated B cells and induces class II MHC expression on B cells. In macrophages, it suppresses production of inflammatory cytokines and it has effects on endothelial cells and fibroblasts. Knockout mice show major defects in Th2 cell generation and in IgE production, <sup>64</sup> suggesting that the selective value of IL-4 may be immunity against parasitic infections.

#### **Clinical Use**

An overactive IL-4 pathway appears to be one component of atopy. <sup>65,66</sup> and <sup>67</sup> Therefore, IL-4 presents a therapeutic target for allergy. IL-4 itself could be used to divert immunity away from autoimmune or inflammatory directions.

#### **INTERLEUKIN-5**

IL-5 induces production of eosinophils during immune responses, which probably contributes to protection against some kinds of parasites. It shares a receptor component with IL-3 and GM-CSF.

#### **Proteins**

IL-5<sup>68,69</sup> is a disulfide-linked homodimer, which is unusual among the ILs, and is heavily glycosylated. Its crystal structure resembles that of two IL-4 molecules with two bundles, each with four  $\alpha$  helices. <sup>70</sup> It is genetically linked to IL-3, -4, -9, and -13 in humans. <sup>68</sup>

#### **Producers**

IL-5 is produced by activated Th2 cells, <sup>21</sup> as well as mast cells and eosinophils.

#### **Receptors**

The receptors for IL-5 consist of two chains: IL-5Ra <sup>71</sup> and IL-5Rb<sub>c</sub>, <sup>42</sup> which is shared by the receptors for GM-CSF and IL-3. Both chains are members of the cytokine receptor superfamily. Cross-linking principles are similar to IL-3, as are the ensuing Jak2-STAT5 pathways and other second-messenger pathways. <sup>46</sup>

#### **Activities**

IL-5 was initially identified as a T-cell factor that induced production of eosinophils. <sup>72</sup> Knockout of IL-5 eliminated the eosinophilia induced by helminth infection, <sup>73</sup> whereas baseline production of eosinophils was normal. IL-5 also promotes local accumulation <sup>74</sup> and sustains the life span and function of eosinophils in tissues, such as the lung and bowel. Evidence exists that IL-5, presumably via its eosinophil activities, contributes to protection from helminth infections. <sup>75,76</sup>

#### **Clinical Use**

IL-5 has long been implicated in allergic asthma. <sup>77</sup> Efforts are therefore being made to develop IL-5 antagonists. <sup>78</sup>

#### **INTERLEUKIN-6**

IL-6 is a key inflammatory mediator produced by many cell types. It is the major inducer of the acute-phase response and fever. IL-6 receptor shares the gp130 chain with several other cytokine receptors.

#### **Proteins**

IL-6 is a glycoprotein of 21 to 28 kD.

#### **Producers**

IL-6 is produced after stimulation by many cell types, including T and B lymphocytes, macrophages, fibroblasts, and endothelial cells.

#### **Receptors**

Two components of the IL-6 receptor exist: a ligand-specific  $\alpha$  chain <sup>79</sup> and a signal-transducing gp130 chain, <sup>80</sup> which is shared by receptors for leukocyte inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), IL-11, and CT-1. The  $\alpha$  chain binds IL-6. This complex then cross-links multiple gp130 chains, initiating signal transduction. Unlike many cytokine receptors, the  $\alpha$  chain has no intracellular signaling function in this class of receptors. The Janus kinases Jak1, Jak2, and Tyk2 are activated, as are the transcription factors STAT1, -3, and -5, as well as other signal transduction pathways, such as the ras–mitogen-activated protein kinase pathway. <sup>81</sup>

#### **Activities**

IL-6<sup>82,83</sup> was originally characterized based on its activity in inducing Ig synthesis by activating B cells. Knockout of IL-6 <sup>84,85</sup> showed defects in a number of inflammatory processes, including production of acute-phase reactants and bone loss after estrogen depletion. Fever responses depend on IL-6. <sup>86</sup> Hematopoietic defects were also found in IL-6 knockouts. <sup>87</sup>

#### **Clinical Use**

Blocking IL-6 may alleviate RA and may also be effective in other autoimmune, inflammatory, and bone-erosive diseases. In mice, IL-6 is required for development of oil-induced plasmacytomas<sup>88</sup> and is involved in tumor cachexia. <sup>89</sup> In humans, IL-6 is a growth factor for myelomas,<sup>90</sup> suggesting further applications of IL-6 blockers.

#### **INTERLEUKIN-7**

IL-7 is produced by stromal cells and is essential for T lymphopoiesis, partly because of a survival or “trophic” effect, a partial role in VDJ recombination. This is the pathway deficient in X-linked, severe combined immunodeficiency in humans. IL-7 also has trophic effects on mature T and B lymphocytes and is therefore potentially useful in the clinic as an adjuvant.

#### **Proteins**

IL-7 is a 25-kD protein predicted to contain four  $\alpha$  helices and an internal disulfide bond. <sup>91</sup> After secretion, it binds to extracellular matrix via a glycosaminoglycan-binding site, <sup>92</sup> which could be the form encountered by developing thymocytes.

#### **Producers**

Unlike most ILs, IL-7 is produced constitutively by nonhematopoietic cells. In the thymus, the IL-7 producer resembles the cortical epithelial cell. <sup>93</sup> In bone marrow, the producer is a reticular stromal cell. <sup>94</sup> Other sources include the intestine, <sup>95</sup> skin, <sup>96</sup> and follicular dendritic cells. <sup>94</sup>

## Receptors

The primary binding chain for IL-7 is IL-7Ra.<sup>97</sup> The IL-7–IL-7Ra complex then recruits  $g_c$ ,<sup>98,99</sup> bearing Jak3 to the complex. TSLP, a homologue of IL-7, also binds the IL-7Ra chain but does not recruit  $g_c$  and Jak3.<sup>100</sup> Jak1 and a number of other kinases are induced,<sup>101</sup> including PI3-kinase. STAT3 and -5 partly mediate the nuclear effects. Because  $g_c$  is also a component of the receptors for IL-2, -4, -9, and -15, some similarities appear to exist in the signal transduction pathways.

## Activities

IL-7 was discovered based on its activity in inducing proliferation of murine pro-B cells.<sup>91</sup> B-cell development depends on IL-7 in mice, but not in humans.<sup>102</sup> Normal T-cell development requires IL-7 based on the knockout phenotypes for IL-7<sup>103</sup> and its receptor,<sup>104</sup> which show a severe block at an early stage in T-cell development. A related block is seen in X-linked, severe combined immunodeficiency in humans, which is in  $g_c$ , a component of the IL-7 receptor. This requirement for IL-7 is partly attributed to its trophic activity on lymphoid progenitors<sup>105</sup> and its promotion of VDJ recombination.<sup>106</sup> In mice, the  $g_s$  lineage is particularly dependent on IL-7, perhaps not only during thymic generation, but also for survival in the intestine and skin. Pharmacologic activity of IL-7 has been observed in mice, inducing increases in B and T cells.<sup>107,108</sup> Overexpression of IL-7 in mice can induce lymphomagenesis.<sup>109</sup> In human skin, IL-7 may provide trophic support for the survival of lymphoma cells.<sup>110</sup>

## Clinical Use

IL-7 has not been tested clinically. Potential clinical uses of IL-7 include boosting immunity to infectious diseases or prolonging the life of lymphocytes, as in acquired immunodeficiency syndrome. Antagonists to IL-7 might be effective in treating autoimmune diseases, blocking rejection of allografted organs, or treating lymphoma.

## INTERLEUKIN-8

IL-8 induces chemotaxis and activation of neutrophils. It is one of the chemokines, a large group of chemotactic cytokines. IL-8 signals through seven transmembrane G protein–coupled receptors that are related to other chemokine receptors.

## Proteins

IL-8<sup>111,112,113</sup> and <sup>114</sup> is a 6- to 8-kD glycoprotein containing two intrachain disulfide bonds. At high concentrations, IL-8 homodimerizes via hydrogen bonding. It is presented to neutrophils on endothelial cell surfaces.<sup>115</sup> IL-8 was the first to be discovered of the family of cytokines known as *chemokines*.<sup>116</sup> More than 50 members have been identified; only IL-8 has the IL terminology. IL-8 is one of a subgroup termed *CXC chemokines* and is linked to a group of these genes. Mice lack a close homologue to human IL-8. It is thought that IL-8's inflammatory roles are fulfilled in mice by other chemokines using the same receptor.

## Producers

Many cell types produce IL-8 after stimulation with lipopolysaccharide, IL-1, or TNF,<sup>117</sup> including macrophages, endothelial cells, and keratinocytes.

## Receptors

Two functional IL-8 receptors exist: CXCR1<sup>118</sup> and CXCR2.<sup>119,120</sup> They are both members of the seven-transmembrane family of receptors that includes rhodopsin. These receptors also respond to other chemokines. The two receptors induce some overlapping and distinct responses.<sup>121</sup> Receptors are coupled to G proteins, including Gi2a,<sup>122</sup> which trigger downstream events involving phospholipase C, diacylglycerol, inositol triphosphate, release of calcium from intracellular stores, RhoA, and the ras pathway.

## Activities

IL-8 induces neutrophil chemotaxis, respiratory burst, and degranulation. In rabbits, blocking IL-8 with antibodies has potent inhibitory effects on some inflammatory processes, particularly of the lung.<sup>123,124</sup> and <sup>125</sup> Knockouts in mice cannot directly address IL-8 function because no close IL-8 homologue exists in mice. Mice lack CXCR1. Knockout of the receptor CXCR2, however, greatly affects neutrophil attraction to inflamed peritoneum,<sup>126</sup> which establishes that chemokines are involved in neutrophil accumulation *in vivo*. IL-8 also induces angiogenesis.<sup>127</sup>

## Clinical Use

Increased IL-8 is detected in a variety of human clinical conditions, ranging from myocardial infarction to RA,<sup>128</sup> and suggests potential applications for IL-8 blockers. In rabbits, a number of studies have shown that anti–IL-8 inhibits inflammation of various tissues. Despite the numerous chemokines that exist, blocking IL-8 alone can be sufficient.

## INTERLEUKIN-9

IL-9 is related to IL-2, -4, -7, and -15 and has some overlapping activities based most likely on sharing some receptor components. It is produced by T cells and acts on lymphocytes and mast cells. It may be involved in Hodgkin's disease and lymphoma.

## Proteins

IL-9<sup>129,130</sup> is predicted to have an  $\alpha$ -helical topology like IL-2, -4, -7, and -15. The human IL-9 gene is found in a cluster together with genes for IL-3, -4, -5, -9, and -13. This does not apply to mice. Ten cysteines exist, implying extensive intrachain disulfide bonding, heavy N-linked glycosylation, and a high isoelectric point (approximately ten).

## Producers

Memory helper T cells produce IL-9 after activation.<sup>131</sup> This induction involves a cascade of cytokines, including IL-2, -4, and -10, eventually leading to IL-9 production.<sup>132</sup> Murine Th2 clones are producers.<sup>133</sup>

## Receptors

The IL-9 receptor  $\alpha$  chain<sup>134</sup> is a member of the hematopoietin superfamily. In humans, the IL-9 receptor  $\alpha$  chain is unusual because it is encoded on chromosomes X and Y.<sup>135</sup> Four IL-9Ra pseudogenes also exist. The receptor complex shares the  $g_c$  chain<sup>136</sup> with receptors for IL-2, -4, -7, and -15. After receptor ligation, Jak3 ( $g_c$ -associated) and Jak1 (IL-9Ra-associated) increase their tyrosine kinase activity, phosphorylating the IL-9Ra chain, adaptor protein IRS-1,<sup>137</sup> and transcription factors STAT1, -3, and -5.<sup>138,139</sup>

## Activities

IL-9 was discovered as a growth factor for T-cell clones<sup>129</sup> and independently as a growth factor for mast cell lines.<sup>130,140</sup> It is not clear, however, whether a normal T-cell growth role should be ascribed to IL-9, because normal T cells have not been found to proliferate in response to it until after 10 days or so of prior *in vitro* stimulation. Some transformed T cells, however, can respond to IL-9, and human T-cell leukemia–transformed T cells produce it<sup>141</sup>; overexpression of IL-9 as a transgene induced T-cell transformation,<sup>142</sup> suggesting possible autocrine function. This was also suggested for Hodgkin's disease.<sup>143</sup> Mast cells and eosinophils, B

lymphocytes,<sup>144</sup> and hematopoietic stem cells<sup>145</sup> also respond to IL-9. Because its receptor is a member of the  $g_c$  family, overlapping activities are expected to be present with other cytokines in this group.

### **Clinical Use**

No extensive preclinical data on IL-9 are available. The possibility that it has autocrine activity in Hodgkin's disease and T lymphomas suggests potential uses for IL-9 antagonists.

## **INTERLEUKIN-10**

IL-10 is a powerful inhibitor of inflammatory and immune responses, partly via its inhibition of some macrophage functions. It is produced by Th2 cells. Its receptor is related to IFN receptors.

### **Proteins**

Human IL-10 is an 18-kD monomer with little glycosylation and two presumed intrachain disulfide bonds.

### **Producers**

Activated Th2 cells were the originally described IL-10 producers. Other cell types, including macrophages and keratinocytes, however, also produce IL-10. Epstein-Barr virus encodes an active IL-10 homologue.<sup>146</sup>

### **Receptors and Cellular Response**

The first identified component of IL-10 receptor<sup>147,148</sup> is related to the IFN receptors. It is expressed by many types of hematopoietic cells. In mice, a second receptor component, CRF2-4, has been identified,<sup>149</sup> which is related and linked to the IFN receptors. Jak1 and Tyk2 are activated by IL-10.<sup>150</sup> STAT3 mediates some downstream effects in macrophages.<sup>151</sup>

### **Activities**

IL-10 was originally discovered and cloned<sup>152</sup> as an inhibitor of the ability of Th1 cells to synthesize IFN. This inhibition occurs largely via effects on antigen-presenting cells, such as macrophages, especially by inhibiting their IL-12 production. Other macrophage functions also are inhibited, such as synthesis of inflammatory cytokines (i.e., IL-1, IL-6, IL-8, and TNF) and phagocytosis. IL-10 knockout mice show extensive pathology, particularly in the gut, which is thought to arise from unattenuated immune responses to gut flora.<sup>153</sup> Receptor knockout mice have similar pathology.<sup>149</sup>

### **Clinical Use**

IL-10 has been shown to inhibit some lipopolysaccharide-induced inflammatory responses in humans.<sup>154</sup> Clinical trials are under way in inflammatory bowel disease, RA, thoracic-abdominal aortic surgery, acute lung injury, multiple sclerosis, psoriasis, and human immunodeficiency virus infection.<sup>155</sup> Evidence exists that the Epstein-Barr virus IL-10 homologue acts as an autocrine in B lymphomas, suggesting benefit in blocking IL-10.<sup>156,157</sup>

## **INTERLEUKIN-11**

IL-11 is a mesenchymal cell product with activity on hematopoietic cells. IL-11 has been used to promote hematopoiesis in patients. IL-11 receptor shares the gp130 component with IL-6, LIF, OSM, CNTF, and CT-1. IL-11 is required for embryonic implantation in the uterus.

### **Proteins**

IL-11<sup>158</sup> is a 19-kD protein with no intrachain disulfide bonds. IL-11 is slightly homologous to IL-6, OSM, and LIF.

### **Producers**

IL-11 is produced by a variety of mesenchymal cells, including keratinocytes, chondrocytes, osteoblasts, fibroblasts, and bone marrow stromal cells.<sup>159</sup>

### **Receptors and Cellular Response**

The IL-11 receptor includes a ligand-specific  $\alpha$  chain and gp130, which is common to IL-6, LIF, OSM, CNTF, and CT-1. Two alternative  $\alpha$  chains exist in the mouse. The ligand-binding chains of this family do not contribute to signaling, which is wholly performed by gp130. Thus, the intracellular cascades should be the same for all members (gp130 signaling is discussed in [Interleukin-6](#), earlier in this chapter). As in the IL-6 system, soluble IL-11 receptor can capture its ligand and then associate with cell-bound gp130 and signal.<sup>160</sup>

### **Activities**

IL-11 was identified based on promoting growth of a plasmacytoma line.<sup>158,159</sup> It stimulates multilineage hematopoiesis when administered to mice and humans and is particularly effective in stimulating thrombopoiesis by inducing production of megakaryocytes. Knockout of the major receptor did not show a requirement in hematopoiesis<sup>161</sup> but revealed an IL-11 requirement in the uterine response to implantation.<sup>162</sup>

### **Clinical Use**

Trials performed in breast cancer patients show that IL-11 can significantly restore suppressed hematopoiesis and alleviate thrombocytopenia induced by chemotherapy.<sup>163</sup> In mice, IL-11 also protects intestinal cells from damage induced by chemotherapy and radiotherapy.<sup>164</sup>

## **INTERLEUKIN-12**

IL-12 is produced by antigen-presenting cells. IL-12 promotes Th1 cell development and IFN production. It is required for development of some types of autoimmunity in mice.

### **Proteins**

IL-12<sup>165,166</sup> and<sup>167</sup> is a heterodimer consisting of disulfide-linked 35-kD and 40-kD subunits encoded by distinct genes. Both subunits are glycosylated and have intrachain disulfide bonds. Homodimers of p40 also are observed<sup>168</sup> and, in mice, have receptor-antagonist activity. This does not apply to humans.

### **Producers**

Macrophages, B lymphocytes, and dendritic cells are major producers of IL-12. In macrophages, this synthesis is stimulated by microbial products and during contact with T cells via CD40L-CD40 interaction.<sup>169</sup> The two IL-12 chains associate intracellularly before secretion. The p35 subunit is expressed by a much wider range of

cell types than the p40 subunit. [166,170](#)

### **Receptors and Cellular Response**

Two components comprise the IL-12 receptor, the b1 and b2 chains. [171,172](#) Th2 cells fail to respond to IL-12 because they lack the b2 chain. [173](#) Many protein kinases are triggered by the IL-12 receptor, including the Janus kinases tyk2 and Jak2, [174](#) which are associated with the b1 and b2 chains, respectively. [175](#) STAT3, STAT4, and IRF-1 are implicated in gene induction by IL-12. [176,177](#)

### **Activities**

IL-12 was discovered as one factor promoting CTLs and as an independent factor for promoting NK cells. These activities include proliferation, differentiation, and cytokine secretion, especially of IFN. The IFN- $\gamma$ -inducing activity of IL-12 is as a cofactor, such as with IL-18 (see [Interleukin-18](#), later in this chapter). IL-12 knockout mice [178](#) showed greatly suppressed IFN production and revealed a requirement for IL-12 in development of Th1 cells in some settings but not in others. [179](#)

### **Clinical Use**

IL-12 has been tested in cancer patients in phase 1 trials with no major toxicity other than a decrease in circulating lymphocytes, which, nevertheless, showed increased activity. [180](#) In preclinical studies, antitumor activity of IL-12 was detected, [181](#) and increased effects were seen in combination with a pulse of IL-2. [182](#) In mice, IL-12 is a required component of some types of autoimmunity in tissues, including the bowel, joint, eye, pancreas, and central nervous system. [183](#)

## **INTERLEUKIN-13**

IL-13 is a T-cell product closely related to IL-4 and shares a receptor component. It elicits a subset of IL-4 responses and is implicated in Th2 cell generation and IgE synthesis. IL-13 is antiinflammatory.

### **Proteins**

IL-13 [184](#) is a 12-kD protein, and it is structurally related to IL-4, although the homology is low. [185,186](#) The gene is clustered together with IL-3, -4, -5, and -9.

### **Producers**

IL-13 is expressed in Th2 cells after activation by antigen-MHC complexes and costimulators on the surface of antigen-presenting cells. Unlike IL-4, IL-13 expression is not strictly repressed in Th1 cells. IL-13 also is produced by dendritic cells.

### **Receptors and Cellular Response**

The IL-13 receptor is comprised of IL-13Ra together with IL-4Ra. The same receptor complex also responds to IL-4. Two homologous IL-13Ra chains exist with different affinities for IL-13 in the absence of IL-4Ra: a high-affinity  $\alpha 2$  chain [187](#) and a low-affinity  $\alpha 1$  chain. [188](#) Receptors are expressed on monocytes, macrophages, eosinophils, basophils, mast cells, keratinocytes, and endothelial cells. Human B cells express the receptor, whereas mouse B cells do not. T cells have not been found to express receptors or respond to IL-13. Jak1 and Tyk2 are activated by receptor ligation. Unlike IL-4, Jak3 is not activated, [189](#) because it is associated with  $\gamma_c$ , which is not part of this receptor complex. STAT6 is phosphorylated and accounts for one set of responses, whereas IRS-2 is phosphorylated and initiates other second-messenger pathways.

### **Activities**

Knockout of IL-13 [190](#) revealed a requirement in Th2 development, which is perhaps indirect given the lack of receptors on T cells. IL-13 induces a subset of IL-4 effects, including effects on human B cells and macrophages, but not T cells. No apparently unique IL-13 effects have been noted. IL-13 activities include inducing IgE synthesis in human B cells. Whereas an IL-4 requirement for B cells to produce IgE was verified by IL-4 knockout, the same logic cannot be applied to IL-13 because mouse B cells do not express IL-13 receptors and do not respond to IL-13. Although IL-13 knockout did reduce IgE production, this may have occurred indirectly via decreased Th2 and IL-4 production. IL-13 [184](#) is a potent inhibitor of inflammatory product synthesis by macrophages *in vitro* and an effective antiinflammatory *in vivo*; it can also induce monocytes to differentiate into dendritic cells.

### **Clinical Use**

The induction of IgE synthesis implicates blocking the IL-13 pathway as a potential target in atopy. Other applications are suggested by IL-13 inhibiting inflammatory processes in mice.

## **INTERLEUKIN-14**

Difficulties have occurred in reproducing the original observations regarding IL-14 and are therefore not discussed.

## **INTERLEUKIN-15**

IL-15 resembles IL-2 in its activities on T cells and shares some receptor components with IL-2. It is essential for NK cell development. Unlike IL-2, the IL-15 gene is expressed by many cell types, but little protein is produced.

### **Proteins**

IL-15 [191,192](#) and [193](#) is a 15-kD glycoprotein with two internal disulfide bonds. IL-15 is predicted to fold into a four-part  $\alpha$  helix structure like IL-2 and IL-4. It is genetically linked to IL-4, -5, and -9.

### **Producers**

Unlike most of the ILs, many cell types constitutively transcribe the IL-15 gene. However, considerable constraints on translation imposed by the 5' and signal peptide region of the message exist. [194](#)

### **Receptors and Cellular Response**

The IL-15 receptor shares the b and  $\gamma_c$  chains with the IL-2 receptor [195](#) but uses its own unique  $\alpha$  chain that is expressed on more cell types than the IL-2Ra chain. [196](#) Mast cells appear to have a different receptor. [197](#) Jak1 and -3, and STAT3 and -5 are activated by the receptor in T cells, whereas Jak2 and STAT5 are activated in mast cells.

### **Activities**

IL-15 was discovered as a T-lymphocyte growth factor activity. NK cell development can be induced by IL-15. [198](#) The knockout of IL-15Ra verified its requirement for NK development. [199](#) Mast cells also respond to IL-15, as do mature T and B lymphocytes, which are also deficient in knockouts.

### **Clinical Use**

IL-15 has not been tested clinically. It may find use in boosting innate or T-cell immunity, or in *ex vivo* expansion of NK and T cells before reinfusion. Antagonists could be immunosuppressive.

### **INTERLEUKIN-16**

IL-16 is a product of CD8 T cells that has activities on CD4 cells, including chemotaxis. It is implicated in airway inflammation in asthma.

#### **Proteins**

IL-16<sup>200,201</sup> and<sup>203</sup> is the C-terminal 17-kD peptide cleaved from a larger nonglycosylated precursor by caspase 3.<sup>203</sup> IL-16 lacks a typical signal peptide and is therefore released from cells by an atypical process. It is not homologous or linked to other cytokines, has an unusual protein structure with a PDZ domain otherwise found in intracellular proteins, and aggregates in solution.<sup>204</sup>

#### **Producers**

IL-16 is constitutively transcribed and translated by CD8 T cells. Release of the active form is then induced by stimuli, such as T-cell antigen cross-linking, histamine, and serotonin.<sup>205</sup> Other producers include eosinophils<sup>206</sup> and airway epithelial cells.<sup>207</sup>

#### **Receptors and Cellular Response**

IL-16 binds to CD4, which it appears to cross-link, inducing signaling.<sup>208</sup> The second messenger pathway does not require *Ick*, which is associated with CD4. Implications of PI3-kinase and protein kinase C involvement exist.

#### **Activities**

IL-16 was discovered based on chemotactic activity for CD4 T cells.<sup>200,201</sup> and<sup>203</sup> It is also chemotactic for monocytes and eosinophils. IL-16 induces G<sub>0</sub> to G<sub>1</sub> transition in CD4 T cells, but not entry into S phase, which can be induced by IL-2. IL-16 inhibits the activation of T cells induced by the T-cell receptor, perhaps by sterically inhibiting CD4 interaction with class II MHC.<sup>209</sup> It inhibits human immunodeficiency virus replication, not through competing with entry via CD4, but through the human immunodeficiency virus promoter.<sup>210</sup>

### **Clinical Use**

IL-16 has been implicated as the attractant for CD4 T cells in asthmatic inflammation of airways in humans,<sup>202</sup> suggesting uses for antagonists. It could possibly be used to induce T-cell blast transformation.

### **INTERLEUKIN-17**

IL-17 is a product of memory T cells, with inflammatory, immunologic, and hematopoietic activities. IL-17 and its receptor bear little resemblance to other genes, although they do bear resemblance to the IL-17 homologue in a herpesvirus.

#### **Proteins**

IL-17<sup>211,212</sup> and<sup>213</sup> is a 17-kD peptide that can dimerize via disulfide bridges.<sup>214</sup>

#### **Producers**

IL-17 is produced by activated T cells, particularly the memory CD4 subset.<sup>214</sup> The gene was captured by *Herpesvirus saimiri*, whose product is biologically active.

#### **Receptors and Cellular Response**

One IL-17 receptor chain has been identified that bears remarkably little resemblance to other receptor types and results in nuclear factor  $\kappa$ B activation.<sup>215</sup> This receptor chain is expressed on many different cell types.

#### **Activities**

IL-17 was discovered as a complementary DNA (cDNA) of unknown function, homologous to a sequence in a herpesvirus also of unknown function.<sup>211</sup> It has been shown to trigger several types of responses in cells, including IL-6 and IL-8 induction in fibroblasts.<sup>214,215</sup> It also has induced production of hemopoietic cytokines and neutrophils in bone marrow cultures and *in vivo*.<sup>214</sup> Blocking IL-17 suppresses T-cell proliferative responses.<sup>215</sup> This result may partly be because IL-17 promotes dendritic cell differentiation. This, in turn, may explain how blocking IL-17 prolonged allografts in mice.<sup>216</sup> Preliminary IL-17 receptor knockout data have not shown gross abnormalities.<sup>217</sup>

### **Clinical Use**

IL-17 appears to promote immune and inflammatory responses. Thus, blocking its activity in humans could be immunosuppressive, as it is in mice.

### **INTERLEUKIN-18**

IL-18 was discovered based on its induction of IFN- $\gamma$  synthesis. Its own structure and that of its receptor system resemble IL-1. It promotes Th1 activities, inhibits Th2 activities, and induces macrophages to produce inflammatory cytokines.

#### **Protein**

IL-18<sup>218,219</sup> is a member of the IL-1 family. Like IL-1b, IL-18 is synthesized as a biologically inactive proform, which is cleaved by caspase 1, generating the active mature form.<sup>220,221</sup>

#### **Producers**

Kupffer cells were the source that led to the cloning of murine IL-18. Blood and tissue macrophages are avid producers, but unlike most cytokines, IL-18 production and release do not require stimulation of the macrophage.<sup>222</sup> Keratinocytes also produce IL-18 constitutively.

#### **Receptors and Cellular Response**

The organization of the cellular receptors for IL-18 is remarkably similar to that of IL-1. IL-18 initially associates with a binding chain,<sup>223,224</sup> which is encoded near IL-1

receptor<sup>225</sup>; this recruits a second signaling chain.<sup>226</sup> As with IL-1, a “decoy” receptor exists.<sup>227</sup> The active IL-18 receptor complex recruits the same kinase (IRAK) and initiates the TRAF6 pathway, as does IL-1.<sup>228</sup> MyD88 serves as an adaptor that links IRAK to the IL-18 and IL-1 receptor complex.<sup>14</sup> The IL-18 receptor is expressed on Th1 cells, but not on Th2 cells. Receptor expression is induced by IL-12 on both T and B cells.<sup>229</sup>

### Activities

IL-18 was discovered based on its activity in inducing IFN-g production. It has been verified in IL-18 knockout mice<sup>230</sup> that IFN-g production is greatly reduced after inflammatory stimuli, although polyclonal T-cell activation induces IFN-g normally. This is probably explained by the observations that IL-18 primarily participates in IFN-g induction as a cofactor together with IL-12; this synergy is partly based on IL-12 inducing expression of the IL-18 receptor. IL-18 promotes Th1 activities and inhibits Th2 activities via IFN-g, such as IgE induction. IL-18 induces macrophages to synthesize secondary inflammatory cytokines, such as IL-1, IL-6, and chemokines.

### Clinical Use

Possible clinical uses based on animal studies include giving IL-18 to promote IFN-g production during viral or mycobacterial infections. IL-18 may combat allergy or asthma. Antagonizing IL-18 (i.e., by using the decoy receptor) could have antiinflammatory uses.

## TUMOR ANTIGENS

### IMMUNE RESPONSE TO TUMORS IN RODENTS

Early attempts to identify tumor antigens in mouse models by immunizing mice with spontaneous or carcinogen-induced tumors were confused by the immune reactions that arose to normal transplantation antigens present on tumors. The development of inbred mouse strains made it possible to differentiate tumor antigens from normal histocompatibility antigens and led to the first demonstrations that tumors did contain unique tumor-associated antigens on their surface.

In 1943, Gross<sup>231</sup> demonstrated that the intradermal immunization of inbred mice against a methylcholanthrene-induced sarcoma could result in immunization of that mouse against subsequent tumor challenge. These findings encouraged studies of the nature of the immune response to transplantable tumors in inbred mice, which demonstrated that tumor-specific antigens did exist in a variety of murine tumors.<sup>232,233,234,235,236</sup> and <sup>237</sup> These tumor antigens could not be detected in the normal tissues of mice, as demonstrated by studies showing that immunization with tumor cells did not immunize mice against normal tissue grafts from the mouse donating the tumor.<sup>234</sup> Immunity to tumor antigens existed in the same mice in which the tumors had originated, demonstrating that the tumor antigens were not the result of minor allogeneic differences between the transplantable tumor and the host.<sup>235</sup> Tumor antigens were found on a variety of tumors induced with chemical or physical carcinogens and on spontaneous tumors.<sup>238,239,240,241,242,243,244,245,246,247,248</sup> and <sup>249</sup>

Tumors induced by chemical carcinogens appear to have limited cross-reactivity, as evidenced by immunization-challenge experiments: Even two sarcomas induced in the same mouse do not cross-react.<sup>233,243,244</sup> and <sup>245,276</sup> The uniqueness of tumor antigens on chemically induced tumors contrasts with the shared antigens that are often found on virally induced tumors.<sup>246,247</sup> and <sup>248</sup> The sharing of antigens on tumors induced by RNA and DNA viruses has facilitated the study of the biologic and molecular nature of these antigens. For example, studies performed with simian virus 40–induced tumors identified the large T antigen, which is expressed primarily in the nucleus and is necessary to maintain the malignant phenotype of these tumor cells.<sup>249,250</sup> Similarly, the polyomavirus has a middle T antigen and small T antigen localized in the nucleus that can be detected by serologic tests. Boon and coworkers<sup>251</sup> isolated the genes that code for murine tumor-associated antigens induced by chemical mutagenesis. The isolated genes from several murine tumors bear little homology with one another or with other known genes.

In most animal studies of tumor immunity, tumor antigens are detected in experiments in which animals are immunized and then challenged with the same transplantable tumor. Lack of growth of a tumor challenge after immunization is taken as evidence for the existence of tumor antigens. *In vitro* assays involving reactivity of the tumor cell with antibodies or immune cells can also provide evidence for the existence of tumor antigens. Although tumors induced by high doses of chemical carcinogens or by viruses often exhibit high levels of immunogenicity in mice, it has been thought that spontaneous murine cancers are far less immunogenic.<sup>252,253</sup> The ability to detect tumor-associated antigens depends on the method used, and as more sensitive methods for detecting tumor antigens are developed, unsuspected antigens are likely to be observed.

A significant difference exists in the nature of the antigens recognized by humoral and cellular detection systems. Humoral antibodies detect specific epitopes on antigenic molecules, and it is the interaction of these molecules with the variable region of the antibody that produces recognition. In contrast, antigens recognized by T-cell receptors recognize processed peptides on the surface of the tumor cell or on an antigen-presenting cell in conjunction with MHC molecules. CD4+ lymphocytes recognize small peptides bound to MHC class II molecules, and CD8+ cells recognize peptides attached to class I molecules. Monoclonal antibodies are not capable of detecting the small processed peptides on MHC molecules on the cell surface, and the nature of the antigens recognized by humoral and cellular immune responses are therefore very different.

Tumor-infiltrating lymphocytes (TILs) provide a valuable reagent for detecting cellular immune responses to tumor antigens, revealing unique tumor antigens on a variety of methylcholanthrene-induced sarcomas in inbred mice.<sup>254,255,256,257</sup> and <sup>258</sup> TILs can recognize tumor antigens based on direct lysis of tumor cells or by the specific release of cytokines such as IFN-g, GM-CSF, or TNF-a when the TILs are cocultured with the specific tumor. These TILs are derived from animals bearing established tumors and may differ from the cellular immune responses that are detected in animals that are highly immunized against the tumor as a result of artificial manipulations.

The detection of tumor antigens on human cancers presents unique problems because of the inability to use the immunization-challenge experiments, which have so effectively demonstrated tumor antigens on animal tumors. Attempts to detect human tumor antigens have relied almost exclusively on the availability of *in vitro* assays that could detect humoral or cellular immune responses.

### IDENTIFICATION OF HUMAN CANCER ANTIGENS RESTRICTED BY CLASS I MAJOR HISTOCOMPATIBILITY COMPLEX AND RECOGNIZED BY CD8+ T CELLS

Attempts to apply the insights gained from increasing knowledge of cellular immunology to the development of effective immunotherapies for patients with cancer fall into three main areas: (1) The identification of antigens on human cancers that are capable of mediating immune responses, (2) the development of techniques for effective immunization of humans using tumor antigens, (3) and overcoming obstacles that enable the tumor to escape antitumor immune reactions. Significant progress has been made in the identification of human tumor antigens, and extensive efforts to develop effective means of immunizing patients have begun. Although substantial progress has been made, the clinical impact of these advances is still limited.

Much experimental evidence points to the importance of cellular immune reactions in mediating the regression of established tumors. Thus, considerable effort has been devoted to identifying human cancer antigens that elicit cellular immune responses. Both class I and class II restricted antigens, mediated by CD8+ and CD4+ lymphocytes, respectively, appear to be important in mediating immune destruction.

Several techniques for cloning tumor antigens recognized by CD8+ cells and presented on MHC class I have been developed and are presented in [Table 18-4](#). Most class I–restricted antigens have been identified by screening cDNA libraries from tumor using MHC class I–restricted T cells to identify the relevant transfectants.<sup>259,260</sup> and <sup>261</sup> Alternatively, peptides have been eluted from tumor cells, pulsed onto target cells bearing the appropriate MHC class I antigen, and then tested by using the MHC class I–restricted T cells to identify the appropriate peptide fractions.<sup>262</sup> By obtaining partial sequences from cDNA libraries or from eluted peptides, it has been possible to identify a variety of class I–restricted tumor antigens.

Screen complementary DNA libraries from tumor using MHC class I-restricted T cells to identify the appropriate transfectants.

Identify peptides eluted from tumor cells, pulsed onto target cells bearing the appropriate MHC class I, and recognized by MHC class I-restricted T cells.

Raise MHC class I-restricted T cells against candidate antigens by *in vitro* sensitization techniques and then test the ability of these T cells to recognize tumor cells ("reverse immunology").

**TABLE 18-4.** Techniques for Cloning Tumor Antigens Recognized by CD8+ Cells and Presented on Major Histocompatibility Complex (MHC) Class I

Both of these approaches, however, depend on the ability to generate T cells capable of recognizing antigens presented on the surface of tumor cells. It is often difficult to generate these T cells *in vitro*, and thus a third approach, commonly referred to as *reverse immunology*, has been used. This approach attempts to determine whether candidate antigens, presumed to have a high likelihood of being tumor antigens based on their biologic characteristics, are actually presented on tumor cells. Class I-restricted T cells that work against these candidate antigens are raised by *in vitro* sensitization techniques. A variety of techniques have been developed, including the use of protein-pulsed or transfected antigen-presenting cells, or *in vitro* sensitization against synthetic peptides from the candidate antigen. If MHC class I-restricted T cells can be raised by these *in vitro* sensitization techniques, then the T cells are tested for the ability to recognize tumor cells and thus confirm the ability of these putative antigens to act as immunotherapeutic targets.

By making use of these approaches, a variety of cancer antigens restricted by MHC class I and recognized by CD8+ T cells have been derived ( [Table 18-5](#)). The first cancer antigens to be described were shared cancer-testes antigens.<sup>263</sup> These antigens are present on a subset of patients with a variety of tumor types and appear to be expressed on cells in the testis but not on other normal cells. Several families of these cancer-testes antigens have been described and are presented in [Table 18-6](#).<sup>264</sup>

**TABLE 18-6.** Cancer-Testis Antigens

Another major class of tumor antigens are the shared melanocyte-differentiation antigens (see [Table 18-5](#)). These antigens are present on melanomas as well as on normal melanocytes, the cells of origin of melanomas. At least six different shared melanocyte differentiation antigens have been described, including MART-1,<sup>265,266</sup> gp100,<sup>267</sup> tyrosinase,<sup>268,269</sup> TRP1,<sup>270</sup> TRP2,<sup>271</sup> and MC1R.<sup>272</sup> The identification of these differentiation antigens on melanomas has led to the conjecture that differentiation antigens unique to other tissues might also be expressed on tumors arising from those tissues and thus serve as immunotherapeutic targets. Thus, differentiation antigens present on the epithelial cells of a variety of organs not essential for life, such as testis, ovary, prostate, breast, and thyroid, might also serve as tumor antigens.

Several tumor antigens such as beta-catenin,<sup>273</sup> CDK4,<sup>274</sup> MUM1,<sup>275</sup> caspase 8,<sup>276</sup> and KIA,<sup>277</sup> have been described and result from individual base mutations that give rise to amino acid differences. These mutated proteins thus represent antigens expressed only on cancer cells and not normal cells. Because each of these antigens is unique to the individual patient bearing the mutation, its use in the development of generally applicable cancer vaccines is limited.

Several unusual antigens with selective expression on cancer cells have been identified. Messenger RNA–encoding antigens, such as p15,<sup>278</sup> PRAME,<sup>279</sup> and SART-1,<sup>280</sup> are presented as antigens in a variety of tissues, but the encoded proteins do not appear to be present on cells other than cancers.

Several viral epitopes are known to be expressed on tumors caused by these viruses. Examples in this category include antigens from the Epstein-Barr virus,<sup>281,282</sup> human T-cell leukemia virus type I,<sup>283</sup> the hepatitis B virus,<sup>284</sup> and the E6 and E7 proteins from human papillomavirus-16. Several other normal or mutant proteins that are overexpressed in epithelial cells or represent mutated oncoproteins or fusion proteins have been hypothesized to be capable of acting as tumor antigens, although convincing evidence to support this hypothesis is lacking.

### CANCER ANTIGENS RESTRICTED BY CLASS II MAJOR HISTOCOMPATIBILITY COMPLEX AND RECOGNIZED BY CD4+ T CELLS

Three general techniques for identifying MHC class II-restricted antigens recognized by CD4+ T cells are presented in [Table 18-7](#). The testing of known class I-restricted antigens for the presence of class II-presented epitopes resulted in the identification of class II-restricted epitopes on tyrosinase<sup>285</sup> and gp100<sup>286</sup> (Touloukian et al., unpublished data). CD4+ T cells can recognize antigen-presenting cells pulsed with tumor lysates or proteins. It has thus been possible to purify proteins from tumor cell lysates that can elicit CD4 reactivity; the triosephosphate isomerase antigen was identified using this technique.<sup>287</sup> A general technique for the identification of class II antigens present on cancers as well as on cells from a variety of other diseases has been described.<sup>288</sup> This technique involves the screening of cDNA libraries transfected into antigen-presenting cells engineered to express the appropriate class II a and b molecules, the DMA and DMB molecules required for antigen processing as well as invariant chain. This technique was based on the unique aspects of the presentation of class II antigens and the inability of normal

cytoplasmic proteins to be presented in the class II pathway. Using this genetic approach, several antigens, such as the CDC27 protein <sup>30</sup> and a mutated fusion protein, were identified <sup>289</sup> (Table 18-8).

Test known class I-restricted antigens
Purification of proteins from tumor cell lysates that elicit CD4 reactivity when incubated with APC
Screening of complementary DNA library transfected into an "engineered" APC containing
DR $\alpha$ and $\beta$
DMA and DMB
Invariant chain
APC, antigen-presenting cell.

**TABLE 18-8.** Cancer Antigens Restricted by Class II Major Histocompatibility Complex and Recognized by CD4+ Tumor-Infiltrating Lymphocytes

### HUMAN CANCER ANTIGENS: GENERAL PRINCIPLES

Tumor antigens can be derived from a variety of sources, including normal differentiation antigens, normal nonmutated antigens expressed on tumors and germ cells, intronic sequences, single base mutations, chromosomal rearrangements, aberrant processing, or alternative open reading frames of normal genes (Table 18-9). Because of the large number of mutations and chromosomal abnormalities present in cancer cells, it appears likely that many, if not all, cancers contain unique sequences capable of being recognized by human immune reactions. In support of this hypothesis are the examples that exist of individual patients who develop immune reactions against multiple different antigens present on their tumor. Two examples of this are shown in Table 18-10. TIL 586 from patient B.C. developed HLA-A31-restricted reactivity against four different epitopes, including one from an alternative open reading frame of TRP1, from the normal open reading frame of TRP2, and from both the normal and alternative open reading frames of the NY-ESO-1 antigen. <sup>271,290,291</sup> Similarly, patient M.G., whose tumors gave rise to TIL 888 and 1290, developed HLA-A24-restricted epitopes from four completely different proteins, including tyrosinase, p15, b-catenin, and gp100. <sup>269,273,278,292</sup>

Normal differentiation antigens

	gp100	A24	VYFLFDHL (intron)

MCH, major histocompatibility complex.

**TABLE 18-10.** A Single Patient Can Develop Reactivity against Multiple Epitopes on Different Antigens

Of importance for the general application of tumor antigens in human immunization is the ability of individual tumor antigens to present immune epitopes on a variety of HLA antigens (Table 18-11). Thus, the gp100 molecule has peptide epitopes that are presented on HLA A2, A3, A24, CDW8, and DR4. <sup>286,292,293,294</sup> and <sup>295</sup> Similarly, tyrosinase has known epitopes presented on HLA A1, A2, A24, <sup>285,296,297</sup> and <sup>298</sup> DRB1\*0401, DRB1\*1501, and B\*4402. Thus, individual antigens can potentially be applicable to the immunization of a majority of patients with different HLA types.

### ANTIBODIES FOR DETECTING TUMOR ANTIGENS

IgG in all species have the same basic structure and consist of two polypeptide chains: the light chain, with a molecular weight of approximately 23,000, and the heavy chain, with a molecular weight of 55,000 to 70,000 (reviewed in [Chapter 4](#)).

Five different classes of Igs have been identified based on structural differences within the heavy-chain constant regions: IgM, IgG, IgA, IgD, and IgE. IgG constitutes the predominant Ig fraction in sera, and most antibody activity is associated with IgG antibodies. IgM constitutes approximately 5% to 10% of serum Igs and is the largest of the Ig molecules. IgA is the predominant Ig in exocrine secretions, and IgE Igs are involved in allergic reactions. The exact function of IgD Igs is unknown.

Kohler and Milstein<sup>299</sup> were the first to demonstrate that somatic cells could be fused with murine myelomas and that monoclonal antibodies with unique specificities could be produced. A vast array of monoclonal antibodies have now been produced against a wide variety of human tumor-associated antigens (reviewed in [Chapter 20.5](#)). Most hybridoma cell lines can produce between 1 and 10 µg of Ig per 1 mL in culture, and ascites fluids can produce between 1 and 10 mg of Ig per 1 mL. In the generation of most monoclonal antibodies, mice are immunized against a specific antigen, and their cells are fused with the mouse myeloma cell. It is possible, however, to use human lymph node or peripheral blood cells for fusion with human myelomas. These human monoclonal antibodies may be able to identify antigens that are not immunogenic in the mouse and are less immunogenic in humans than murine monoclonal antibodies. It is possible to make recombinant chimeric monoclonal antibodies that contain the variable region of murine origin and the constant region of human origin.

Virtually all monoclonal antibodies have at least some reactivity with normal tissues, although the degree of cross-reactivity can be minimal. The potential clinical applications of monoclonal antibodies are summarized in [Table 18-12](#) and [Chapter 20.5](#).

Application	Examples
Diagnosis of tumor	Immunohistochemistry (IHC) for the detection of carcinoma, melanoma, and lymphoma
Diagnosis of infection	Immunofluorescence (IF) for the detection of hepatitis virus, cytomegalovirus, and toxoplasma
Diagnosis of autoimmune disease	Immunofluorescence (IF) for the detection of rheumatoid factor, antinuclear antibody, and anti-SSA/SSB
Diagnosis of organ transplant rejection	Immunofluorescence (IF) for the detection of donor-specific antibody
Diagnosis of drug toxicity	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug allergy	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced lupus	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced thrombocytopenia	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced neutropenia	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced hemolytic anemia	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced hepatitis	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced nephritis	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced vasculitis	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced myocarditis	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced myopathy	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced neuropathy	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced encephalopathy	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced psychosis	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced schizophrenia	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced depression	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced anxiety disorder	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced personality disorder	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced dementia	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced delirium	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced coma	Immunofluorescence (IF) for the detection of drug-antibody complexes
Diagnosis of drug-induced death	Immunofluorescence (IF) for the detection of drug-antibody complexes

**TABLE 18-12.** Clinical Applications of Monoclonal Antibodies (MoAbs)

### IMMUNOTHERAPY

Strategies for the immunotherapy of cancer can be divided into active and passive approaches ([Table 18-13](#)). *Active immunotherapy* refers to the immunization of the tumor-bearing host with materials designed to elicit an immune reaction capable of eliminating or retarding tumor growth. Active immunotherapy can be subdivided into nonspecific or specific immunization. Most early attempts at the immunotherapy of cancer used nonspecific active approaches to immune stimulation with adjuvants such as bacillus Calmette-Guérin, *Corynebacterium parvum*, and levamisole. These early approaches were almost uniformly unsuccessful in humans and have largely been abandoned.

Classification	Examples	
Active immunotherapy	Nonspecific	Immune adjuvants such as bacillus Calmette-Guérin, <i>Corynebacterium parvum</i> , levamisole
		Interferon
		Interleukin-2
Specific	Immunization with tumor antigen vaccines	
Passive immunotherapy	Antibodies	Monoclonal or polyclonal antibodies alone or conjugated with toxins or radiolabels
	Cells	Tumor-infiltrating lymphocytes
Indirect	Removal or blocking factors; inhibition of growth factors or angiogenic factors	

**TABLE 18-13.** Classification of Cancer Immunotherapies

The advent of recombinant cytokines provided a more selective means for stimulating the immune system. Treatment with the IFNs or with IL-2 is a form of nonspecific active immunotherapy, although the selective action of these purified lymphokines provides a greater ability to manipulate immune responses than was previously possible.

### INTERLEUKIN-2

Major progress in immunotherapy has resulted from the identification of the cytokine IL-2 that enabled the *ex vivo* growth of human T lymphocytes.<sup>19</sup> The identification of the gene encoding IL-2,<sup>20</sup> the biologic characterization of recombinant IL-2,<sup>300</sup> increasing information about the dominant role of IL-2 in regulating immune reactions, and extensive studies of IL-2 administration to tumor-bearing mice<sup>301</sup> led to studies of the clinical use of this molecule in patients with advanced cancer (see [Chapter 20.2](#)). IL-2 is now in common use for the treatment of patients with metastatic melanoma and renal cancer and has been instrumental for the conduct of *in vitro* studies identifying human cancer antigens. IL-2 also has been used as an adjuvant for *in vivo* immunization protocols.

The best evidence that manipulation of the human immune system can result in the regression of advanced cancer in patients resulted from clinical studies in which high-dose bolus IL-2 was administered to patients with metastatic melanoma and metastatic renal cancer.<sup>5</sup> IL-2 has no direct impact on cancer cells, and all of its effects result from its ability to stimulate *in vivo* immune reactions. In the National Cancer Institute's Surgery Branch, 409 consecutive patients with either advanced melanoma (n = 182) or renal cancer (n = 227) were treated with high-dose bolus IL-2 alone at a dose of 720,000 IU/kg every 8 hours.<sup>30</sup> The results of the treatment are shown in [Table 18-14](#) and [Table 18-15](#). Seven percent of patients with melanoma underwent a complete response, and 9% underwent a partial response. In patients with renal cancer the complete and partial response rates were 9% and 10%, respectively. Complete responses were most often durable. Of 12 patients with metastatic melanoma who achieved a complete response, only two have recurred, with the remainder having ongoing complete responses of between 95 and 173 months. Of 21 patients with metastatic renal cell cancer who achieved a complete regression, four have recurred and 17 have ongoing responses between 46 and 159 months. The lack of recurrences after 5 years and the follow-up of several patients beyond 10 years indicate that these patients have probably been cured by the administration of high-dose IL-2 ([Fig. 18-1](#)).

Diagnosis	Total	Number of Patients (%)		
		CR	PR	CR + PR
Melanoma	182	12 (7%)	16 (9%)	28 (15%)
Renal cell cancer	227	21 (9%)	22 (10%)	43 (19%)
Total	409	33 (8%)	38 (9%)	71 (17%)

CR, complete response; PR, partial response.  
Patients accrued between September 1985 and November 1996.  
Follow-up as of April 1, 2000 (median follow-up, 5.2 y).

**TABLE 18-14.** Response of Patients with Metastatic Cancer Treated with High-Dose Bolus Interleukin-2

Diagnosis	CR (mo)	PR (mo)
Melanoma	173+, 122+, 120+, 118+, 116+, 109+, 105+, 96+, 96+, 95+, 16, 12	35, 31, 19, 10, 10, 8, 8, 7, 7, 6, 5, 5, 5, 4, 4, 2
Renal cell cancer	159+, 148+, 140+, 119+, 119+, 115+, 111+, 111+, 104+, 95+, 89+, 88+, 87+, 85+, 74+, 64+, 46+, 35, 23, 19, 19	52, 30, 30, 22, 20, 17, 16, 15, 14, 14, 13, 11, 9, 8, 8, 7, 7, 6, 4, 4, 4, 4

+, ongoing response as of April 1, 2000; CR, complete response; PR, partial response.  
Note: Of 53 patients with CR, 27 remain in CR at 46 to 173 mo.

**TABLE 18-15.** Duration of Response in Patients with Metastatic Cancer Treated with High-Dose Bolus Interleukin-2

**FIGURE 18-1.** Complete response to treatment with high-dose interleukin-2, with deaths due to other causes censored.

As experience with the use of IL-2 increased, improved methods for managing the side effects of its administration were developed, and the safety of IL-2 administration has improved dramatically.<sup>302</sup> A consecutive series of 1241 metastatic cancer patients who received 720,000 IU/kg IL-2 every 8 hours by intravenous bolus infusion, either alone or in conjunction with other treatments, were evaluated for the incidence of treatment-related toxicities.<sup>303</sup> Significant decreases in the incidence of grade III and IV toxicities were found as experience with the use of IL-2 increased over the 12 years of this study. Although a 1% to 3% treatment-related mortality was seen in the first 4 years of the administration of IL-2, no treatment-related deaths were reported in this series between May 1989 and January 1997, including the treatment of 809 consecutive patients. These trends suggested that high-dose IL-2 could be safely administered to metastatic cancer patients when appropriate treatment guidelines were used and that the administration of IL-2 could result in durable responses in a small subset of patients with metastatic melanoma and metastatic kidney cancer.

## INTERFERONS

The IFNs are a family of proteins that are produced by cells in response to viral infection or stimulation with double-stranded RNA, antigens, or mitogens. The IFNs can interfere with subsequent viral challenge, and they have many immunomodulatory and antiproliferative effects (see [Chapter 20.1](#)).

More than 20 closely related genes coding for IFN- $\alpha$  exist, and they have approximately 80% to 85% amino acid homology with one another. IFN- $\beta$  is quite similar in many of its properties to IFN- $\alpha$ . The gene for IFN- $\gamma$  has three introns, and there are no introns in the genes that code for IFN- $\alpha$  and IFN- $\beta$ . IFN- $\alpha$  and IFN- $\beta$  are stable to pH 2, although IFN- $\gamma$  is labile at this pH. IFN- $\beta$  and IFN- $\gamma$  are glycosylated, but most IFN- $\alpha$  species are not.

IFN- $\alpha$  can be produced by a variety of cells, including macrophages and lymphocytes. IFN- $\beta$  is produced mainly by fibroblasts and epithelial cells. IFN- $\gamma$  can be produced by a variety of lymphocyte subtypes, such as CD4+ or CD8+ cells, NK cells, and LAK cells. Secretion of IFN- $\gamma$  occurs after stimulation by mitogens or antigens. IFNs have a variety of biologic properties, including immunomodulatory activities, antiviral activities, the ability to interfere with cell proliferation, inhibition of angiogenesis, regulation of differentiation, and enhancement of the expression of a variety of cell surface antigens. Although the direct antiproliferative activity of the IFNs is thought to play a major role in the antitumor effects of these compounds, other actions of the IFNs may also be important.

The IFNs have antitumor activity against a variety of tumor types, including hairy cell leukemia, chronic myelogenous leukemia, cutaneous T-cell lymphoma, and Kaposi's sarcoma.

The response rates of various solid tumors and hematologic malignancies to treatment with IFN- $\alpha$  are summarized in [Table 18-16](#). IFN- $\alpha$  and IFN- $\beta$ , but not IFN- $\gamma$ , demonstrate direct antitumor activity. The side effects associated with IFN therapy include flu-like symptoms, rashes, gastrointestinal complaints, hepatic dysfunction,

neurologic complaints, and chronic fatigue, and they are highly dose and schedule dependent.

Tumor Type	Response Rate (%)
Colorectal adenocarcinoma	100-100
Bladder cell carcinoma	100
Esophageal adenocarcinoma	100-100
Adenocarcinoma of the stomach	100-100
Adenocarcinoma of the esophagus	100-100
Cervical carcinoma	
- Intracavitary	100-100
- Intraperitoneal	100
- Intravaginal	100
Bladder cell carcinoma	100-100
Esophageal adenocarcinoma	100
Adenocarcinoma of the stomach	100-100
Adenocarcinoma of the esophagus	100-100
Bladder cell carcinoma	100
Esophageal adenocarcinoma	100-100
Adenocarcinoma of the stomach	100-100
Adenocarcinoma of the esophagus	100-100
Cervical carcinoma	100-100
- Intracavitary	100-100

**DEVELOPMENT OF APPROACHES TO THE IMMUNIZATION OF HUMANS AGAINST CANCER ANTIGENS**

Although many human cancer antigens have now been identified, relatively little is known about the best methods for successful immunization of patients against these antigens. The number of variables involved in determining optimal methods of immunization of humans presents a daunting challenge and are shown in [Table 18-17](#).

Choice of antigens
- Self
- Allogeneic
- Heterologous
- Synthetic
- Recombinant
- Natural
- Purified
- Crude
- Soluble
- Insoluble
- Adjuvanted
- Non-adjuvanted
- Incomplete
- Complete
- Freund's
- Others
Choice of adjuvants
- Peptides
- Proteins
- DNA
- Recombinant viruses
- Adenovirus
- Fowlpox virus
- Vaccinia virus
Choice of vehicle
- Saline
- Adjuvants (IFA, QS21, etc)
- Antigen-presenting cells
Route of administration
- Intradermal
- Subcutaneous
- Intramuscular
- Intravenous
Immune adjuvants
- Interleukin-2
- Interleukin-7
- Interleukin-12

**TABLE 18-17.** Variables Involved in the Immunization of Humans against Cancer Antigens
